Extraction and Fractionation—One gram of plant material, finely manicured by passing through a 1-mm. sieve to remove seeds and stems and to reduce leaves, flowers, and bracts to small particles, was extracted by shaking overnight with 10 ml. of 95% ethanol. The ethanol was removed *in vacuo* at room temperature. The residue was dissolved in 20 ml. of a 1:1 mixture of petroleum ether and an aqueous solution of 2% sodium hydroxide and 2% sodium bisulfite. Cannabinoid acids dissolve in sodium hydroxide but not in sodium bicarbonate or sodium carbonate solutions. The sodium hydroxide solution does not extract the nonacid cannabinoids under these conditions, and they remain in the petroleum ether. Other workers (2, 10) reported similar results and attributed these observations to steric hinderance or to chelation between the carboxyl and neighboring oxygen functional groups. The very low water solubility of phenolic salts of the cannabinoids probably contributes to these observations. Sodium bisulfite was added to minimize oxidation. The petroleum ether layer was separated, washed with water, dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo* to obtain the nonacidic cannabinoids. The sodium hydroxide extract was acidified with cold 10% sulfuric acid, extracted with ether, washed with water, dried over anhydrous sodium sulfate, and evaporated *in vacuo* at room temperature to obtain the cannabinoid acids.

Table I—Δ^9-Tetrahydrocannabinol and Its Acids in Mexican Strain Marijuana

Percent of Dry Weight[a]	Immature 1969	Female 1969	Female 1968	Male 1969	Male 1968
I	0.22	0.16	0.57	0.45	0.50
II and III	1.00	1.00	0.43	0.71	0.10

[a] Each figure represents the average of two determinations that were within 10% variance.

Table II—Cannabinoids and Cannabinoid Acids in Foreign Strains of Fiber-Type Marijuana

Percent of Dry Weight[a]	Turkish Male	Turkish Female	Swedish	Carmagnola (Italian)	Fibriman (French)	Fibranova (Italian)
I	0.01	0.04	Trace	0.06	Trace	Trace
II and III	0.06	0.02	Trace	0.15	0.05	0.13
IV	0.52	0.44	0.03	0.08	0.08	0.21
V	0.60	0.80	0.04	0.10	0.12	0.45

[a] Each figure represents the average of two determinations that were within 10% variance.

GLC—Both acidic and nonacidic fractions were analyzed using an instrument[1] equipped with flame-ionization detectors and a 0.31-cm. × 3.1-m.(0.125- in. × 10-ft.) stainless steel column packed with 2% OV-17 on 100–120-mesh Gas Chrom Q. Helium was used as carrier gas at 40 ml./min. The oven temperature was kept at 210°, while the inlet and detector temperatures were 250 and 280°, respectively. A steroid internal standard (4-androstene-3,17-dione) was added to each extract. The instruments were calibrated with reference samples of I and IV. The areas under the peaks were directly correlated with the concentration of the compounds (11). The retention time of I was used for the analysis of I and its two respective acids. Similarly, the retention time of IV was used in the analysis of IV and V.

TLC—Each sample was examined by TLC to determine if the separation of acids and nonacids was complete.

Plates—Silica gel GF was coated[2] at a thickness of 0.25 mm. and was activated by warming at 105° for 1 hr.

Solvent Systems—Both acidic and nonacidic fractions were chromatographed in two solvent systems: System A, benzene; and System B, hexane–ether–acetic acid (87:12:1). In System A, the cannabinoids migrated and separated but the cannabinoid acids remained at the starting point. In System B, the acids migrated and separated. Thus, it was possible to tell the presence or absence of the acids as well as the number of acids in the acid fractions. Authentic reference samples of I or IV were always used on each plate.

Detection of Spots—All plates were viewed under a short wavelength UV lamp. All of the cannabinoid acids, as well as IV, quenched the fluorescent background of the plate and were easily detected. After locations of these spots were outlined, the plates were sprayed with freshly prepared diazotized benzedine reagent (12). This reagent yielded a characteristic yellow-orange color with IV, a red-orange color with I, and a brown color with the cannabinoid acids. The R_f values of I in Solvent Systems A and B averaged as follows: A = 0.42 and B = 0.36. The R_x values (x = I) of the other compounds in both systems were: II, A = 0.00 and B = 0.91; III, A = 0.00 and B = 0.86; IV, A = 1.19 and B = 1.11; and V, A = 0.00 and B = 0.64.

RESULTS AND DISCUSSION

Only one strain of the marijuana utilized for this study, the Mexican strain, is of the drug type (high in Δ^9-tetrahydrocannabinol and its acids). Data obtained from the analysis of five samples of this strain are presented in Table I.

The 1969 samples were 6 months old and the 1968 samples were approximately 18 months old at the time of analysis. The lower proportion of acid content in the 1968 samples compared with the 1969 samples suggests that the acids undergo decarboxylation upon storage.

The acidic fraction in System B showed two spots, indicating the presence of both II and III. This was further confirmed by the IR spectra of the acidic fraction and the methyl ester derivative prepared by reaction with diazomethane (2).

Table III—Cannabinoids and Cannabinoid Acids in Domestic[a] Marijuana

Percent of Dry Weight	Iowa I	Iowa II	Des Moines	Minnesota I	Minnesota II	Minnesota III
I	0.34	Trace	Trace	0.04	0.03	0.08
II and III	0.20	Trace	Trace	Trace	Trace	0.04
IV	0.14	0.38	0.60	0.11	0.07	0.63
V	0.25	0.33	0.33	0.27	0.33	0.11

[a] These samples, with the exception of Minnesota III, were collected in the wild in September 1968.

The other foreign strains of marijuana produced in the drug plant garden in 1969 were of the fiber type (low in Δ^9-tetrahydrocannabinol and high in cannabidiol). The results of the analyses of plants produced in 1969 from these strains are illustrated in Table II.

The cannabinoid acid content of each of these samples was higher than the corresponding cannabinoids. Although each of these marijuana samples was prepared from plants at about the same stage of maturity (flowering stage), the cannabinoid content varied considerably, the lowest being the Swedish strain which is almost devoid of cannabinoids.

Three samples of marijuana collected in Iowa and two samples collected in Minnesota (near Minneapolis) were compared with a sample of marijuana grown on campus in 1969 from seed found in the Minnesota I marijuana (Table III). With the exception of the Iowa I sample, which contained a moderately high quantity of the active I, II, and III, all other domestic varieties investigated contained mainly IV and V and were almost void of the active entities. The change of growing conditions provided to the Minnesota III sample did not change this pattern, *i.e.*, did not trigger the plant to produce active entities in any significant quantities.

SUMMARY AND CONCLUSIONS

A procedure was developed for the assay of the acidic and nonacidic cannabinoids, qualitatively and quantitatively, by chemical fractionation prior to GLC and TLC analyses. Various samples of foreign and domestic, wild and cultivated marijuana were analyzed. From the data obtained, the following were demonstrated.

1. Cannabinoids occur in nature as acids or nonacids with comparable abundance.
2. Tetrahydrocannabinoic acids undergo decarboxylation upon storage or exposure to heat.
3. Plants vary significantly in their cannabinoid composition due to heredity.
4. Change in environment does not change the cannabinoid pattern in plants.

Mississippi-Grown *Cannabis sativa* L. IV: Effects of Gibberellic Acid and Indoleacetic Acid

ASAAD N. MASOUD[▲], NORMAN J. DOORENBOS*, and MAYNARD W. QUIMBY*

Abstract □ Four-week-old *Cannabis sativa* L. plants were treated with 1 ml. of gibberellic acid or indoleacetic acid at concentrations up to 250 p.p.m. The treatment was repeated at weekly intervals for 3 weeks. These plants were harvested 1 week after the last treatment. Gibberellic acid caused a significant increase in height and a decrease in the weight of leaves and Δ^9-tetrahydrocannabinol content. Indoleacetic acid produced no significant changes.

Keyphrases □ *Cannabis sativa* L.—effects of gibberellic and indoleacetic acids on plant growth and Δ^9-tetrahydrocannabinol content □ Δ^9-Tetrahydrocannabinol content in *Cannabis sativa* L.—effects of gibberellic and indoleacetic acids □ Gibberellic acid—effect on plant growth and Δ^9-tetrahydrocannabinol content of *Cannabis sativa* L. □ Indoleacetic acid—effect on plant growth and Δ^9-tetrahydrocannabinol content of *Cannabis sativa* L. □ Plant growth regulators—effects of gibberellic and indoleacetic acids on *Cannabis sativa* L.

Many interesting effects upon plants have been demonstrated in recent years with the gibberellins and other plant hormones. The general effects on growth are increased internodal elongation, resulting in taller and spindlier plants. Apical dominance, a growth feature attributed to auxins, is strongly enhanced by the gibberellins (1–3). Gibberellins are reported to decrease alkaloid concentrations in some species (4–6) and increase the concentration of sugars and glycosides in *Digitalis lanata* (7).

Few studies on the cultivation of *Cannabis sativa* L., especially of the drug type, have been reported. At the time this investigation was initiated, there were no reports of the effects of plant hormones on this species. During this study, a group reported (8) that gibberellic acid increased stem length, the percentage of male plants, and the length of the growing season and that a combination of gibberellic acid and colchicine delayed flowering about 20 days. No data on the effects upon yield or concentration of Δ^9-tetrahydrocannabinol (III) were presented, and data on the quantities of gibberellic acid (I) and colchicine used were not included in the abstract.

The objective of this investigation was to determine the effects of gibberellic acid (I) upon the growth and Δ^9-tetrahydrocannabinol (III) content of *C. sativa* L. Since it has been postulated that gibberellins act by increasing the diffusible auxin in plants (9), indoleacetic acid (II) was included in the study.

EXPERIMENTAL

Procedure—Plants employed in this study were of a Mexican strain[1] which is high in III and hence of the drug type (10). Seeds were cultivated in rows 1 m. in width. When the plants were 4 weeks old, they were thinned, allowing 50 cm. between plants.

The plants were divided into nine groups at random. Each group contained 20 plants. These groups included one control group, four kinds of treatments with I[2], and four kinds of treatments with II[2]. The four treatments with each growth substance were 25 p.p.m., 25 p.p.m. × *F*, 250 p.p.m., and 250 p.p.m. × *F*, in which *F* is a factor correlating the height of the plant at the time of application and its height at the time of the first application. One milliliter of the designated concentration of growth substance was applied by a pipet on the uppermost leaves of the treated plants. In the case of the *F* treatments, *F* equaled the number of milliliters applied. Height measurements were taken prior to the application of growth substances and then at weekly intervals. Plants were harvested 1 week after the third application (fourth measurement) which occurred before flowering.

At harvesttime, each plant was uprooted and the roots were thoroughly washed. Plants were divided into leaf, stem, and root portions. Fresh weights were determined immediately in the field. The respective plant parts were then wrapped separately in cheesecloth, marked, and placed in a warm air (50°) circulating dryer. Dry weights were determined. The dried leaves were pooled according to treatment, manicured through a 1-mm. sieve, and thoroughly mixed to a homogeneous mixture.

Analysis—Samples of the pooled manicured leaf samples were assayed for III. One gram of the leaf material was extracted by shaking overnight with 95% ethanol. The ethanolic extract was evaporated under reduced pressure and redissolved in 1 ml. of 95% ethanol containing 10 mg. of the internal standard, 4-androstene-3,17-dione. GLC analysis was carried out using an instrument[3] equipped with a flame-ionization detector and a stainless steel column 0.31 cm. × 3.1 m. (0.125 in. × 10 ft.) packed with 2% OV-17 on 100–200-mesh Gas Chrom Q. Helium was used as a carrier gas at 40 ml./min. The oven temperature was kept at 210°, while the inlet and detector temperatures were 250 and 280°, respectively. The areas under the peaks were directly correlated with the concentration of the compound using a calculated correction factor (11).

The samples were then spotted on silica gel GF plates, developed in two solvent systems [benzene and benzene–hexane–diethylamine (25:10:1)], and then sprayed with diazotized benzedine spray reagent for qualitative comparison of the cannabinoids present (12).

RESULTS

Remarkable changes in branching habit and height were observed in the plants treated with I (Fig. 1). In general, the branching characteristics of the Mexican strain, which is usually bushy with two or more main branches close to the base, demonstrated apical dominance. The plants acquired one main stem with longer internodes and fewer leaves. At the 25-p.p.m. concentration, the plants were healthy and the stems were strong enough for adequate support. At the higher concentrations of 25*F*, 250, and 250*F*, the plants were tall and spindly and had poor support. Furthermore, necroses occurred in the leaves of many of these latter plants.

Treatment with II did not produce any noticeable changes in growth pattern. *T* tests on uncorrelated data were carried out on the height measurements (Table I) and indicated that there was no difference between the groups before treatment, no difference after

[1] Second generation seed harvested in one of the marijuana gardens of the University of Mississippi were used. Original seed was collected near Acapulco, Mexico, and furnished by Dr. John Scigliano, National Institute of Mental Health.

[2] Gibberellic acid (10% potassium salt) and indoleacetic acid (highest purity) were purchased from LaPine Scientific Co., Chicago, Ill., Irwington, N. Y., and Berkeley, Calif.

Figure 1—*Effect of indoleacetic acid and gibberellic acid on the height and branching habit of marijuana plants.*

treatment with various concentrations of II, and a significant increase in treatments with I utilizing the 0.05 significance level.

Weight data of all plant parts were analyzed statistically using the same test (Table II). There was no effect due to the treatments with II. Treatments with I showed a significant decrease in the fresh and dry weights of the leaves at the 0.05 significance level.

It was unexpected not to find an increase in the stem weights. This indicated that there was no actual increase in the stem growth, but that rather the habit of growth was changed from bushy to tall nonbranched.

The concentration of 1.04% of dry weight of III in the control was considered as the population mean (Table III). The standard deviation of this population was found to be 0.1% of dry weight, since this represented the limitations of the sensitivity of the procedure and sampling techniques. Utilizing the above parameters and the significance level of 0.05, the concentration of III of the treated plants was tested for significance. There was a significant decrease in the two factorial treatments of I. These data agree also with the dry weight and height data. The *F* treatments caused a more pronounced effect than expected. This could be interpreted as due to the larger volume of applied solution which is more evenly distributed and better absorbed in the plant and, consequently, acts on more sites producing more pronounced effects.

TLC revealed no qualitative changes in the cannabinoids present in the plants.

DISCUSSION AND CONCLUSIONS

A typical gibberellin effect characterized by increased internodal elongation, apical dominance, and taller plants was noted. Compound I also caused a decrease in the fresh and dry weights of the

Kinetics of Hydrolysis of Hypoglycemic 1-Acyl 3,5-Dimethylpyrazoles

ARLINGTON A. FORIST▲ and DENNIS J. WEBER

Abstract □ Other investigators suggested that various 1-acyl 3,5-dimethylpyrazoles might owe their hypoglycemic activity to a nonenzymatic hydrolysis *in vivo* to the potent compound 3,5-dimethylpyrazole. As a test of this hypothesis, relative rates of hydrolysis at pH 2.0 and 6.7 (37.6°) were determined for a representative series of compounds covering a wide range of hypoglycemic potencies. No correlation between hydrolysis rate and activity was observed. 3,5-Dimethylpyrazole-1-carboxamide and 3,5-dimethylpyrazole-1-*N*,*N*-dimethylcarboxamide possess equivalent biological activity; the former was rapidly hydrolyzed (half-life about 1 hr. at pH 2.0 and 6.7), whereas the latter was totally stable. Differences in biological activity reflect intrinsic potencies of the various compounds or differences in their absorption and/or metabolism.

Keyphrases □ 3,5-Dimethylpyrazoles, 1-acyl series—kinetics of hydrolysis, hydrolysis rate–hypoglycemic activity correlation □ Hypoglycemic activity–hydrolysis rate correlation—1-acyl 3,5-dimethylpyrazoles, kinetics of hydrolysis □ Hydrolysis rates—1-acyl 3,5-dimethylpyrazole series, correlated with hypoglycemic activity, kinetics

Wright *et al.* (1) reported the hypoglycemic activities of a large number of pyrazoles in the intact, fasted, glucose-primed rat. The most active compounds were 3,5-dimethylpyrazole (I) (2) and various 1-acyl derivatives. Preliminary experiments showed that 3,5-dimethylpyrazole-1-carboxamide (II) was readily hydrolyzed to I at pH's encountered *in vivo* in the GI tract and the blood. As a consequence, it was suggested that the various 1-acyl derivatives of I might owe their activities either to nonenzymatic hydrolysis *in vivo* or to metabolic transformation to I (1). To test the hypothesis of nonenzymatic conversion, relative rates of

Kinetics of Hydrolysis of Hypoglycemic 1-Acyl 3,5-Dimethylpyrazoles

ARLINGTON A. FORIST▲ and DENNIS J. WEBER

Abstract □ Other investigators suggested that various 1-acyl 3,5-dimethylpyrazoles might owe their hypoglycemic activity to a nonenzymatic hydrolysis *in vivo* to the potent compound 3,5-dimethylpyrazole. As a test of this hypothesis, relative rates of hydrolysis at pH 2.0 and 6.7 (37.6°) were determined for a representative series of compounds covering a wide range of hypoglycemic potencies. No correlation between hydrolysis rate and activity was observed. 3,5-Dimethylpyrazole-1-carboxamide and 3,5-dimethylpyrazole-1-*N*,*N*-dimethylcarboxamide possess equivalent biological activity; the former was rapidly hydrolyzed (half-life about 1 hr. at pH 2.0 and 6.7), whereas the latter was totally stable. Differences in biological activity reflect intrinsic potencies of the various compounds or differences in their absorption and/or metabolism.

Keyphrases □ 3,5-Dimethylpyrazoles, 1-acyl series—kinetics of hydrolysis, hydrolysis rate–hypoglycemic activity correlation □ Hypoglycemic activity–hydrolysis rate correlation—1-acyl 3,5-dimethylpyrazoles, kinetics of hydrolysis □ Hydrolysis rates—1-acyl 3,5-dimethylpyrazole series, correlated with hypoglycemic activity, kinetics

Wright *et al.* (1) reported the hypoglycemic activities of a large number of pyrazoles in the intact, fasted, glucose-primed rat. The most active compounds were 3,5-dimethylpyrazole (I) (2) and various 1-acyl derivatives. Preliminary experiments showed that 3,5-dimethylpyrazole-1-carboxamide (II) was readily hydrolyzed to I at pH's encountered *in vivo* in the GI tract and the blood. As a consequence, it was suggested that the various 1-acyl derivatives of I might owe their activities either to nonenzymatic hydrolysis *in vivo* or to metabolic transformation to I (1). To test the hypothesis of nonenzymatic conversion, relative rates of

Table I—Reaction Conditions and Kinetic Constants for the Hydrolysis of 1-Acyl 3,5-Dimethylpyrazoles at 37.6°

Compound	pH 2.0 Concentration, $M \times 10^5$	λ, nm.	k', min.$^{-1}$	$t_{1/2}$	pH 6.7 Concentration, $M \times 10^5$	λ, nm.	k', min.$^{-1}$	$t_{1/2}$	Hypoglycemic Activity[a]
II	7.83	235	1.09×10^{-2}	63 min.	7.23	235	1.12×10^{-2}	62 min.	25

[a] *Reference 1*, tolbutamide = 1. [b] No reaction.

hydrolysis were determined (pH 2.0 and 6.7, 37.6°) for a series of representative compounds (II–VI) covering a wide range of hypoglycemic potencies (Table I).

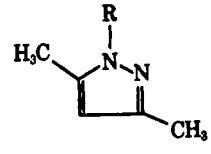
EXPERIMENTAL

Samples of II–VI were dissolved in aqueous ethanol and diluted with 0.01 *N* HCl or 0.08 *M* phosphate buffer, preequilibrated at 37.6°, to yield the final concentrations and pH values shown in Table I. The final ethanol concentration was 0.4% (v/v). Each solution was placed in a UV spectrophotometer equipped with a constant-temperature cell compartment maintained at 37.6°. For the rapidly hydrolyzed compounds (II, V, and VI), absorbances (A_t) were determined at appropriate times at the characteristic absorption maxima (Table I) until no further absorbance decreases occurred (A_∞). Pseudo-first-order reaction rate constants, k', were obtained from the slopes of plots of log $(A_t - A_\infty)$ *versus* time. For the slowly hydrolyzed III, k' was estimated from the initial slope of log A_t *versus* time.

RESULTS AND DISCUSSION

The method utilized for the determination of the kinetics of hydrolysis of Compounds II–VI is based on the differences in their UV spectra from the spectrum of the product, I (λ_{max}: 218 nm. at pH 2.0, 214 nm. at pH 6.7). In each case, first-order kinetics were observed and permitted calculation of the pseudo-first-order reaction rate constants, k', and corresponding half-lives, $t_{1/2}$, shown in Table I.

Examination of the data in Table I shows no correlation between rates of nonenzymatic hydrolysis and hypoglycemic activity. Compounds II and IV possess the same hypoglycemic activity; nevertheless, II was rapidly hydrolyzed in both acid and neutral solutions



I: R = —H

II: R = —C(=O)—NH$_2$

III: R = —C(=O)—NHC$_4$H$_9$

IV: R = —C(=O)—N(CH$_3$)$_2$

V: R = —C(=O)—NH—NH$_2$

VI: R = —C(=O)—C$_6$H$_5$

while IV was totally stable under the conditions studied. Thus, differences in biological activities of these compounds appear to reflect differences in their intrinsic potencies, in their absorption, or in their metabolism. The last is considered the most likely. Metabolism to I *via* *N*-dealkylation and/or hydrolysis and the oxidation of the 3-methyl group to a 3-carboxylic acid are possible. 5-Methylpyrazole-3-carboxylic acid, a metabolite of I in the rat (3, 4), is also a potent hypoglycemic agent (5). Efficient absorption of these compounds from the GI tract would be expected based on the complete absorption after oral administration found for I in the rat (4) and for the highly polar 5-methylpyrazole-3-carboxylic acid in the rat, dog, and man (6).

Scott (7) reported the kinetics of ethanolysis of a number of 1-acyl 3,5-dimethylpyrazoles, including II; Staab (8) and Hüttel and Kratzer (9) determined the kinetics of neutral hydrolysis and of aminolysis of 1-acetyl-3,5-dimethylpyrazole. However, the nature of the catalysis involved in the hydrolysis reaction has not been elucidated. Data in Table I for Compounds III, V, and VI indicate that hydronium-ion catalysis is involved. In addition, the magnitude of the pseudo-first-order reaction rate constants at pH 6.7 relative to those at pH 2.0 implicates hydroxide-ion and/or direct water catalysis. Results for Compounds II–IV indicate a correlation with the degree of steric hindrance by substituents on the carboxamide nitrogen. A similar relationship was observed by Scott (7) in the ethanolysis reaction and is consistent with the mechanism involving attack on the acyl group proposed by Meloche and Laidler for the hydrolysis of aromatic amides (10).

Compound II was unique in that its hydrolysis rates at the pH's studied were essentially identical. The kinetics and mechanism of the facile hydrolysis of II will be the subject of a separate report.

Chemical Synthesis of 1-^{14}C-Octadecyldihydroxyacetone Phosphate and 1-^{14}C-Octadecyldihydroxyacetone

CLAUDE PIANTADOSI*▲, KUN CHAE*, KHALID S. ISHAQ*, and FRED SNYDER†

Abstract □ The synthesis of 1-^{14}C-octadecyldihydroxyacetone phosphate of high specific activity was accomplished *via* the cyclohexylammonium salt of 1-*O*-(1-^{14}C-octadecyl)-2,2-dimethoxypropane-3-phosphate.

Keyphrases □ 1-^{14}C-Octadecyldihydroxyacetone and phosphate—synthesis □ 1-*O*-(1-^{14}C-Octadecyl)-2,2-dimethoxypropane-3-phosphate, cyclohexylammonium salt—used in synthesis of high specific activity 1-^{14}C-octadecyldihydroxyacetone and phosphate

Piantadosi *et al.* (1, 2) previously reported the total chemical synthesis of unlabeled *O*-alkyl dihydroxyacetone phosphate, *O*-alkyl dihydroxyacetone, and the derivatives. However, to study the metabolism of these compounds, it became necessary to synthesize them with radioactive labels. In biological systems, the *O*-alkyl dihydroxyacetone phosphate is a key intermediate in the biosynthesis of complex ether-linked lipids (3–11). This report describes the preparation of 1-^{14}C-octadecyldihydroxyacetone and its phosphate derivative having high radiopurities and high specific activities.

The sequence of reactions used to synthesize the labeled compounds was based on the previous procedure for the synthesis of unlabeled *O*-alkyl dihydroxyacetone phosphate and derivatives (2). In the present synthetic procedure (Scheme I), 3-*O*-benzylglycerol (I) was esterified with *p*-nitrobenzoyl chloride in the presence of pyridine, resulting in a crude mixture of mono- and diesters (II); this mixture contained over 70% of the monoester derivative as determined by TLC. The Compound II mixture was oxidized to III with dimethyl sulfoxide and dicyclohexylcarbodiimide in the presence of trifluoroacetic acid. Compound III was ketalized to IV, which was hydrolyzed to V with sodium hydroxide. Compound V was then reacted with 1-^{14}C-octadecyl bromide in the presence of powdered potassium hydroxide in benzene, resulting in VI. After purification by silica gel column chromatography, Compound VI was debenzylated with palladium black to VII, which was phosphorylated to VIII. Compound VIII was hydrogenated with platinum oxide to remove the phenyl groups, and finally the cyclohexylammonium salt (X) was isolated. Compounds X and VII were treated with dilute hydrochloric acid to release XI and XII, respectively.

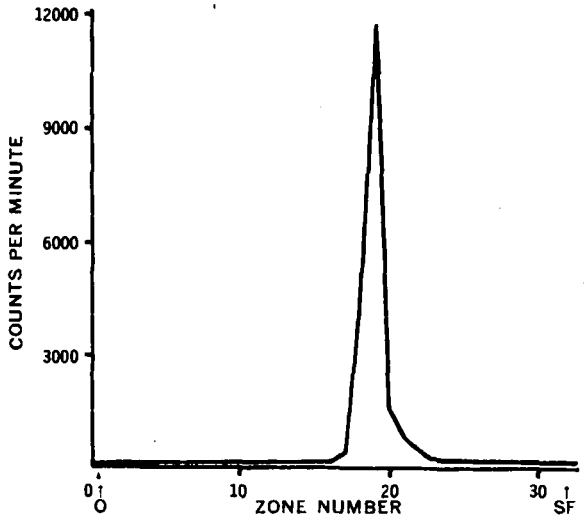

Figure 1—*TLC ^{14}C-zonal profile scans of 1-^{14}C-octadecyldihydroxyacetone phosphate. The solvent system used was chloroform–methanol–acetic acid–water (50:25:8:4 v/v). O = origin, and SF = solvent front.*

EXPERIMENTAL[1]

3-*O*-Benzylglycerol (I)—3-*O*-Benzylglycerol was prepared according to the procedures of Sowden and Fischer (13) and Howe and Malkin (14).

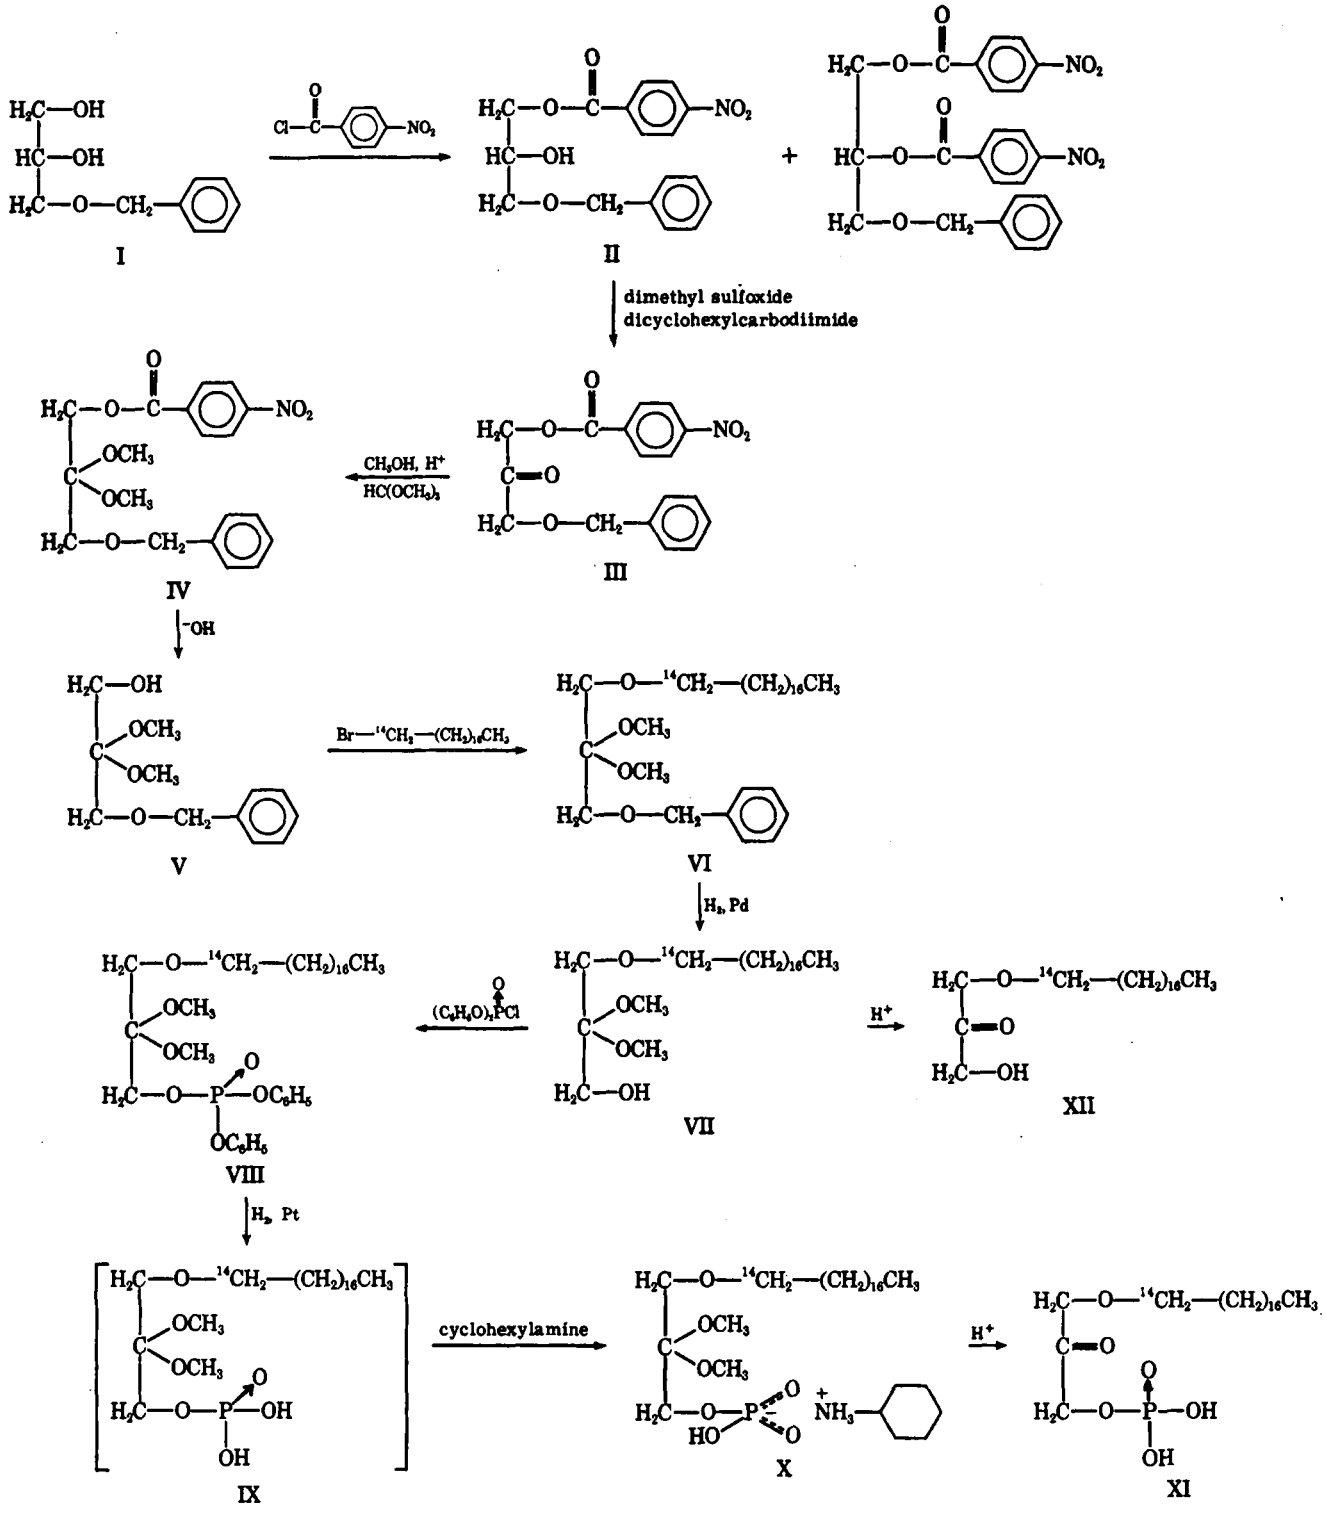
1-*O*-(*p*-Nitrobenzoyl)-3-*O*-benzyl-2-propanone (III)—Compound I was esterified with *p*-nitrobenzoyl chloride in the usual manner to give Compound II. TLC, using a solvent system of chloroform–diethyl ether (60:40 v/v), revealed a 70% yield of the mono-*p*-nitrobenzoyl derivative. Compound II was subjected to the Pfitzner–Moffatt oxidation for a period of 5 hr. (15, 16). The filtrate was extracted three times with 200-ml. portions of an ice-cold saturated sodium bicarbonate solution, two 200-ml. portions of water, and finally dried over anhydrous sodium sulfate. The ether was removed under reduced pressure, and the residue was taken up in 300 ml. of warm ether and left overnight at 5°. The resulting 25 g. of product was recrystallized from 200 ml. of ether at 5° and yielded 21 g. (32% based on the reacted 3-*O*-benzylglycerol ether), m.p. 92–93°. TLC in chloroform–ether (60:40 v/v) revealed one spot having R_f 0.68.

Anal.—Calc. for $C_{17}H_{15}NO_6$: C, 62.00; H, 4.59; N, 4.25. Found: C, 62.01; H, 4.68; N, 4.28.

1-*O*-(*p*-Nitrobenzoyl)-2,2-dimethoxy-3-*O*-benzylpropane (IV)—Compound III was ketalized in the usual manner in the presence of absolute methanol, trimethylorthoformate, and a catalytic amount of concentrated sulfuric acid. TLC in *n*-hexane–ether (80:20 v/v) revealed a single component with R_f 0.51, indicating that complete ketalization of Compound III had occurred to give Compound IV.

1-Hydroxy-2,2-dimethoxy-3-*O*-benzylpropane (V)—Seven grams of Compound IV was dissolved in 100 ml. of methanol containing 10 ml. of 4 *N* sodium hydroxide solution, and the mixture was stirred at room temperature for 24 hr. The methanol was evaporated and the remaining aqueous mixture was extracted three times with 150-ml. portions of ether. The combined ethereal extracts were washed once with 100 ml. of water and dried over anhydrous sodium sulfate. After removing the ether under reduced pressure, 3.2 g. (80% yield) of the syrupy product was obtained. TLC in *n*-hexane–ether (50:50 v/v) revealed one spot with R_f 0.25.

[1] The 1-^{14}C-octadecyl bromide (2.5 mc./mmole), which was purchased from International Chemical and Nuclear Corp., Irvine, Calif., had a radiopurity >99%. Radioactive intermediates were purified on columns (1.9 × 12 cm.) containing 15–20 g. silica gel (70–325 mesh, Brinkmann). Melting points were taken with a Mel-Temp melting-point apparatus and are corrected. Elemental analyses were performed by Atlantic Microlab, Inc., Atlanta, Ga. The specific radioactivities were determined with a Packard Tri-Carb scintillation spectrometer (model 3320) which had a ^{14}C counting efficiency of 79%. The radiopurity of the labeled compounds was determined by a zonal profile scanning method (12).



Scheme I

Anal.—Calc. for $C_{12}H_{18}O_4$: C, 63.69; H, 8.01. Found: C, 63.60; H, 7.98.

1-*O*-(1-^{14}C-Octadecyl)-2,2-dimethoxy-3-*O*-benzylpropane (VI)—In a 30-ml. reaction filter flask, equipped with a magnetic stirrer, Dean-Stark receiver, reflux condenser, and anhydrous calcium sulfate[2] drying tube, were placed 200 mg. of powdered potassium hydroxide and 340 mg. (1.5 mmoles) of Compound V dissolved in 10 ml. of dry benzene. Then 333 mg. of 1-^{14}C-octadecyl bromide (1.0 mmole) in 15 ml. benzene was added, and the mixture was refluxed in a sand bath at 83–87° for 24 hr. The cooled mixture was filtered under nitrogen to remove the potassium bromide, and the filtrate was collected in a 100-ml. round-bottom flask. After the precipitate was thoroughly washed with chloroform, the combined filtrate was evaporated under reduced pressure. The oily product (750 mg.) was dissolved in 5 ml. of warm *n*-hexane and was applied on a column (1.9 × 12 cm.) containing 15 g. of silica gel. The column was eluted with the following sequence of solvents: Solvent I, 100 ml. *n*-hexane; Solvent II, 100 ml. *n*-hexane–ether (7:3 v/v); and Solvent III, 100 ml. *n*-hexane–ether (1:1 v/v); 20-ml. fractions were collected.

[2] Drierite.

Fractions 1–5 contained the alkyl halide and hydrocarbon breakdown products. The desired product, Compound VI, appeared in fractions 7 and 8 (425 mg., 89% yield).

Anal.—Calc. for $C_{30}H_{54}O_4$: C, 75.26; H, 11.37. Found: C, 75.23; H, 11.53.

1-*O*-(1-^{14}C-Octadecyl)-2,2-dimethoxy-3-hydroxypropane (VII)—Compound VI (425 mg.) in 50 ml. of *n*-hexane was debenzylated with 250 mg. of palladium black in a Parr hydrogenator at 20 p.s.i. at room temperature for 5 hr. The catalyst was filtered and washed thoroughly with chloroform. The combined filtrate was evaporated under reduced pressure. Then the white solid product (350 mg.) was dissolved in about 5 ml. of warm *n*-hexane and applied on a column (1.9 × 12 cm.) containing 20 g. of silica gel. The column was eluted with the following solvents: fraction 1, 150 ml. *n*-hexane; fraction 2, 100 ml. *n*-hexane–ether (9:1 v/v); fraction 3, 100 ml. *n*-hexane–ether (8:2 v/v); and fraction 4, 100 ml. *n*-hexane–ether (7:3 v/v). Fractions 1–3 contained some of the hydrocarbon breakdown products, and fraction 4 contained Compound VII (230 mg., 66% yield).

Anal.—Calc. for $C_{23}H_{48}O_4$: C, 71.08; H, 12.44. Found: C, 71.21, H, 12.30.

Cyclohexylammonium Salt of 1-*O*-(1-^{14}C-Octadecyl)-2,2-dimethoxypropane-3-phosphate (X)—A solution of 200 mg. of Compound VII (0.51 mmole) in 10 ml. of dry pyridine was placed in a 30-ml. reaction filter flask and cooled to 0° in an ice bath. Over 5 min., 250 mg. of diphenyl chlorophosphate was added with stirring. The flask was stoppered and allowed to stand at 5° for 24 hr. The precipitated pyridine hydrochloride was removed by filtration under nitrogen pressure and the filtrate was collected. After the precipitate was thoroughly washed with benzene, the combined filtrate was evaporated to dryness under reduced pressure. The oily product (320 mg.) was dissolved in 5 ml. of benzene and was applied to a column (1.9 × 12 cm.) containing 15 g. of silica gel. The column was eluted with 150-ml. portions of benzene, benzene–chloroform (3:1 v/v), and benzene–chloroform (1:1 v/v); 50-ml. fractions were collected. Fractions 5–8 contained 255 mg. (80%) of the phosphorylated intermediate, VIII. Compound VIII was dissolved in 50 ml. of absolute ethanol containing 150 mg. of platinum oxide and hydrogenated at 15 p.s.i. at room temperature for 3 hr. to remove the phenyl groups. The catalyst was removed by filtration and washed with absolute ethanol. Subsequently, 100 mg. of cyclohexylamine was added to the filtrate, and the mixture was left overnight at room temperature. After the solvent was removed under reduced pressure, a white solid product (325 mg.) appeared which was dissolved in 15 ml. of chloroform and stored at −15°.

1-*O*-(1-^{14}C-Octadecyl)dihydroxyacetone Phosphate (XI)—1-*O*-(1-^{14}C-Octadecyl)dihydroxyacetone phosphate was prepared from Compound X by the method described previously (2). About 10 mg. of Compound X was dissolved in 5 ml. of 0.1*N* HCl and shaken at 37° for 2 hr. The mixture was immediately extracted by a modification of the Bligh and Dyer (17) procedure, the solvent was removed under reduced pressure, and the product was dissolved in chloroform. TLC in chloroform–methanol–acetic acid–water (50:25:8:4 v/v) showed the product to be over 99% pure; the specific radioactivity was 2.46 mc./mmole. Figure 1 shows the ^{14}C-zonal profile scan of 1-*O*-(1-^{14}C-octadecyl)dihydroxyacetone phosphate after treatment of the cyclohexylammonium salt with dilute hydrochloric acid.

1-*O*-(1-^{14}C-Octadecyl)dihydroxyacetone (XII)—1-*O*-(1-^{14}C-Octadecyl)dihydroxyacetone was prepared from Compound VII by the same method used to prepare Compound XI. The radiopurity was 98–99%, as determined by TLC using a solvent system of hexane–ether–methanol–acetic acid (70:30:5:1 v/v).

Structure and Activity in Molluscicides IV: New Substituted Tetralins with Potential Molluscicidal Effect

I. NABIH▲ and J. METRI

Abstract □ Upon a rational biochemical and biological basis, a series of new compounds related to the tetralin system was synthesized. Biological testing showed their molluscicidal activity at very high dilutions.

Keyphrases □ Tetralins, substituted—synthesized and tested as potential molluscicides, structure–activity relationships □ Molluscicides, potential—synthesis and biological testing of new substituted tetralins, structure–activity relationships □ Structure–activity relationships—substituted tetralins and molluscicidal effect

In a previous article (1), the structure–activity relationship in molluscicides of the phenolic type was discussed. In this group of compounds, certain specific structural features regarding the nature of substituents on the aromatic ring govern the biological activity of the candidate compound. The presence of an enzyme system of the peroxidase type within the snail body was identified through specific systemic reactions and assay measurements for activity in some species of economic importance (2). The biological transformation of the active phenols to the corresponding quinones through this enzymatic system could explain the molluscicidal effectiveness of the former. The latter are highly toxic (3).

DISCUSSION

The main source of energy in snails, required for the metabolism of living cells, is liberated due to oxidation of many compounds. The most important energy-yielding reactions are those of the oxidation–reduction type. Snails, schistosomiasis intermediate hosts, appear to respire aerobically. In typical aerobic respiration, the hydrogen and electrons of substrate are transferred to molecular oxygen through enzymatic protein catalysts (4, 5). Quinones uncouple phosphorylation by diverting electrons from the enzyme to molecular oxygen; *e.g.*, 2,4-dichloronaphthoquinone reacts by binding the enzyme to the quinone molecule through substitution or addition at the double bond, an oxidative effect on sulfhydryl enzymes, or changing the redox potential in some systems.

Pentachlorophenol, a widely used molluscicidal agent, could undergo biological transformation through enzymatic peroxidase catalysis to furnish 2,2′,3,3′,5,5′,6,6′-octachlorobiphenylquinone, a polysubstituted quinone of potential molluscicidal activity (6).

Generally, the molluscicides of the phenolic and salicylanilide types that are now in common use are still unsatisfactory. The phenolics are toxic during applications, not easily handled, and unstable during storage. The salicylanilides exhibit a water-insolubility problem (a major one in molluscicides), and they are immiscible with water during application. Thus, the rate of distribution is not satisfactory.

Because of these considerations, new synthetic work is necessary to obtain efficient molluscicides of higher activity and fewer disadvantages. In this work the synthesis of new compounds that may undergo biological transformations to quinoidal systems is emphasized. Substituted compounds related to tetralin were chosen to be common structural moieties in these agents. These types of compounds could be oxidized to give products related to naphthoquinones, which are known to possess potent molluscicidal activity (3). In addition, it was of concern to include the salicylanilide type of structure, since these compounds exert their molluscicidal activity through a different mechanism. They act through chelation with the important metals (*e.g.*, iron and magnesium) present and necessary for the biological functions within the snail body[1].

Compounds of Structures I–V were desired.

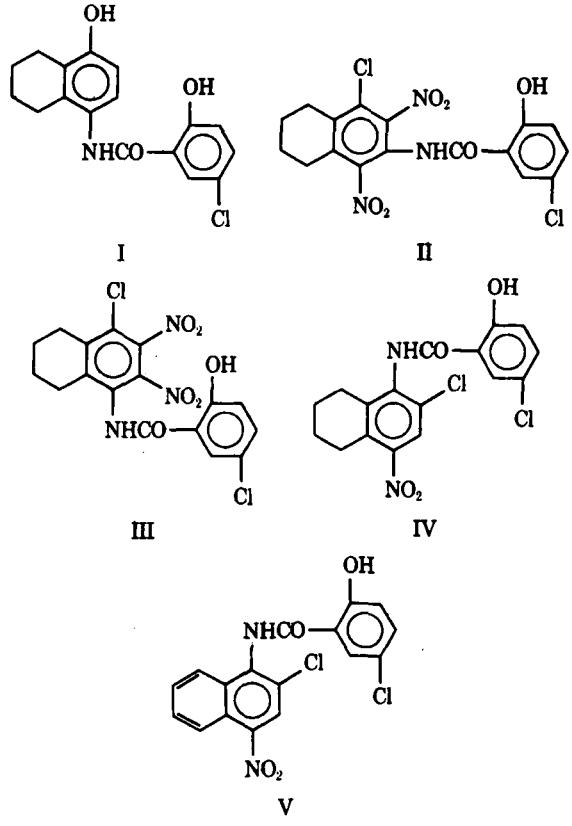
Through the condensation of 5-hydroxy-8-aminotetralin (VI) with 5-chlorosalicylic acid (VII) in the presence of phosphorus pentachloride, 5-hydroxy-8-*N*-(5′-chlorosalicylanilido)tetralin (I) was obtained.

Diazotization of 5-amino-7-nitrotetralin (VIII), followed by subsequent halogenation at the 5-position, reductive acetylation at the 7-position, and nitration at both the 6- and 8-positions, gave 5-chloro-7-amino-6,8-dinitrotetralin (IX). Condensation of VII with IX gave 5-chloro-6,8-dinitro-7-*N*-(5′-chlorosalicylanilido)-tetralin (II).

Chlorination of 8-acetaminotetralin in chloroform gave the 5-chloro derivative (7). Upon nitration (sulfuric acid–nitric acid at −10°), this gave 5-chloro-6,7-dinitro-8-acetaminotetralin (X). Hydrolysis and condensation with VII gave 5-chloro-6,7-dinitro-8-*N*-(5′-chlorosalicylanilido)tetralin (III).

Chlorination of 5-acetamino-8-nitrotetralin (8), followed by hydrolysis, gave 5-amino-6-chloro-8-nitrotetralin (XI). Upon condensation with VII, this gave 5-*N*-(5′-chlorosalicylanilido)-6-chloro-8-nitrotetralin (IV).

Amination of α-nitronaphthalene with hydroxylamine hydrochloride and methanolic potassium hydroxide at 50° gave 4-nitro-1-



[1] This laboratory, to be published.

naphthylamine. Upon acetylation, chlorination, and hydrolysis, this gave 1-amino-2-chloro-4-nitronaphthalene (9). Upon condensation of this amine with VII, the product 1-*N*-(5'-chlorosalicylanilido)-2-chloro-5-nitronaphthalene (V) was obtained.

BIOLOGICAL TESTING

In all tests, the fresh water snails, *Biomphalaria alexandrina*, vector of *Schistosoma mansoni*, were the test animals. Young adult snails (8–11-mm. diameter) were used. Water, freshly boiled to avoid any interference by contaminated chlorine present in tap water (pH 6–6.5), was used as the test medium. Each aquarium was fitted with a glass cover to prevent the accidental dropping of foreign material into test medium. Compounds I–V were tested; they were diluted in volumetric flasks with water to the desired parts per million (p.p.m.). In each test, five snails were used in 200 ml. of the test chemical at each concentration (10, 5, 3, and 1 p.p.m.) and five snails were used as the control in the same volume of water. The exposure period was 24 hr. At the end of each contact period, the snails were removed from the chemically treated water, washed thoroughly, and transferred to fresh water. Food (lettuce) was made available to the snails. On the following day, the mortality rate was determined. Snails that were not fully recovered at the time of the examination were held for future daily observations until death or recovery occurred. Determination of recovery was based on the ability of the snails to move about or cling to the bottom and sides of the glass container.

The concentration effects of different compounds upon *B. alexandrina* (within the 24-hr. exposure period at 25°) are recorded in Table I.

Table I—Effects of Compounds I–V upon Snails of *B. alexandrina* Type

Compound	Concentration, p.p.m. 10	5	3	2	1
I	++[a]	++	++	++	++
II	++	++	++	++	++
III	++	++	++	++	++
IV	++	++	++	++	++
V	++	++	++	++	+

[a] + + = average mortality of 100% and + = average mortality of 80%.

EXPERIMENTAL[1]

5-Hydroxy-8-*N*-(5'-chlorosalicylanilido)tetralin (I)—A mixture of 5-chlorosalicylic acid (VII) (1.06 g.) and 5-hydroxy-8-aminotetralin (VI) (1 g.) (10) in 10 ml. of dry chlorobenzene was refluxed for 10 min. at 160°; then 0.2 g. of phosphorus pentachloride was added to the reaction mixture. Reflux continued for 3 hr., and then the chlorobenzene was steam distilled. The product formed upon cooling was filtered, washed with hot diluted hydrochloric acid (to remove traces of unreacted amine), and then washed with water to give 1.5 g. (79% yield) of I. This compound was purified by dissolving in dilute sodium hydroxide solution and filtering; it was then neutralized with dilute hydrochloric acid, and a dark-brown product formed. Upon recrystallization from ethanol, it melted at 230–232°; IR: 1390 (—OH), 1650 (—CONH—), and 720 (Ar—Cl) cm.$^{-1}$.

Anal.—Calc. for $C_{17}H_{16}ClNO_3$: Cl, 11.16; N, 4.40. Found: Cl, 11.28; N, 4.32.

5-Chloro-7-amino-6,8-dinitrotetralin (IX)—To 8 ml. concentrated sulfuric acid was added 8 g. of 5-chloro-7-acetaminotetralin (11). The mixture was cooled to 0° and nitrated, dropwise, with a nitrating mixture of nitric acid (4 ml.) and concentrated sulfuric acid (12 ml.). The mixture was allowed to stand overnight at room temperature; it was then poured over ice water and the crude dinitro product precipitated. This product was filtered and washed thoroughly with cold water. After drying, it gave 5.2 g. (72% yield) of IX. Upon recrystallization from alcohol, it gave white flakes, m.p. 300°; IR: 1540 (—NO_2), 1680 (—NHCOCH$_3$), and 725 (Ar—Cl) cm.$^{-1}$.

Anal.—Calc. for $C_{12}H_{12}ClN_3O_5$: C, 45.94; H, 3.83; Cl, 11.32; N, 13.39. Found: C, 45.94; H, 4.05; Cl, 11.41; N, 13.41.

The acetamino product was then submitted to acid hydrolysis (hydrochloric acid–ethanol) to give the free amine IX. Due to difficulties encountered in the preparation of an analytical sample, the crude amine, m.p. 162–165°, was used for the condensation reaction in the following step.

5-Chloro-6,8-dinitro-7-*N*-(5'-chlorosalicylanilido)tetralin (II)—A mixture of VII (1.27 g.) and the amine IX (2 g.) was dissolved in 20 ml. of chlorobenzene and heated to 160°. Then 0.4 g. of phosphorus pentachloride was added during reflux, which continued for 2 hr. The solvent was removed through steam distillation. The product was filtered, washed with sodium carbonate solution and then with water, and dried to give 2.2 g. of II (yield 70%). After recrystallization from alcohol, it melted at 194–196°.

Anal.—Calc. for $C_{17}H_{13}Cl_2N_3O_6$: C, 48.00; H, 3.06; Cl, 16.47; N, 9.88. Found: C, 48.46; H, 3.13; Cl, 16.67; N, 9.50.

5-Chloro-6,7-dinitro-8-acetaminotetralin (X)—A mixture of 5-chloro-8-acetaminotetralin (8) (2.36 g.) and 4 ml. of concentrated sulfuric acid was cooled to −10° and then nitrated by the addition of a cold mixture of nitric acid (2 ml.) and concentrated sulfuric acid (6 ml.). The mixture was allowed to stand overnight at room temperature and was then poured over ice. The formed yellow precipitate was filtered and washed with water. After drying, it gave 2.68 g. (82% yield) of X. Upon recrystallization from ethanol, it gave yellow needles, m.p. 250–251°; IR: 1550 (—NO_2), 1685 (—NHCOCH$_3$), and 725 (Ar—Cl) cm.$^{-1}$.

Anal.—Calc. for $C_{12}H_{12}ClN_3O_5$: C, 45.93; H, 3.83; Cl, 11.32; N, 13.39. Found: C, 45.97; H, 3.92; Cl, 11.18; N, 13.19.

5-Chloro-6,7-dinitro-8-aminotetralin—A mixture of X (1.5 g)., ethanol (30 ml.), and concentrated hydrochloric acid (8 ml.) was refluxed for 5 hr., cooled, and poured over ice water. The precipitate was collected, washed with water, and dried to give 1.06 g. of the free amine. After recrystallization from dilute ethanol, it melted at 140–142°.

Anal.—Calc. for $C_{10}H_{10}ClN_3O_4$: C, 44.28; H, 3.69; Cl, 13.10; N, 15.44. Found: C, 44.38; H, 3.73; Cl, 13.20; N, 15.23.

5-Chloro-6,7-dinitro-8-*N*-(5'-chlorosalicylanilido)tetralin (III)—The condensation between the above-mentioned free amine (1 g.) and the acid VII (0.64 g.) was carried out as described for II. The yield (75%) was 1.2 g. After recrystallization from benzene–*n*-hexane, it melted at 187–190°.

Anal.—Calc. for $C_{17}H_{13}Cl_2N_3O_6$: C, 48.00; H, 3.06; N, 9.88. Found: C, 48.26; H, 3.13; N, 9.86.

5-Amino-6-chloro-8-nitrotetralin (XI)—In glacial acetic acid (35 ml.) was chlorinated 9 g. of 5-acetamino-8-nitrotetralin (8) at 100° with a dry stream of chlorine gas for about 15 min. After cooling, the formed yellow precipitate was collected, washed with water, and dried. It weighed 6 g. (90% yield). Recrystallization from ethanol gave white needles, m.p. 181–183°.

Anal.—Calc. for $C_{12}H_{13}ClN_2O_2$: C, 53.53; H, 4.84; Cl, 13.22; N, 10.43. Found: C, 52.97; H, 4.83; Cl, 13.27; N, 10.44.

The free amine XI was obtained through acid hydrolysis of this product. It was recrystallized as yellow crystals (from ethanol), m.p. 110–112°.

Anal.—Calc. for $C_{10}H_{11}ClN_2O_5$: C, 52.98; H, 4.86; Cl, 15.67; N, 12.36. Found: C, 53.11; H, 4.92; Cl, 16.05; N, 12.22.

5-*N*-5'-(Chlorosalicylanilido)-6-chloro-8-nitrotetralin (IV)—The same method of condensation between the free amine (XI) (1 g.) and the acid VII (0.76 g.) was followed as described for II. The product IV, 1.2 g. (70% yield), was recrystallized from benzene–petroleum ether, m.p. 156–158°.

Anal.—Calc. for $C_{17}H_{14}Cl_2N_2O_4$: Cl, 18.42; N, 7.37. Found: Cl, 18.43; N, 7.43.

1-*N*-(5'-Chlorosalicylanilido)-2-chloro-5-nitronaphthalene (V)—The condensation described for II was followed for the acid VII (0.78 g.) and 1-amino-2-chloro-4-nitronaphthalene (1 g.) (9). The product V, 1.3 g. (75% yield), was recrystallized from benzene–petroleum ether, m.p. 210–212°.

Anal.—Calc. for $C_{17}H_{10}Cl_2N_2O_4$: C, 54.26; H, 2.66; Cl, 18.62; N, 7.45. Found: C, 53.98; H, 2.68; Cl, 18.51; N, 7.41.

[1] Melting points were taken in open capillary tubes with a Gallenkamp melting-point apparatus and are uncorrected. The IR spectra were recorded with a Carl-Zeiss Infracord spectrophotometer, model UR 10. Microanalyses were performed by the Spang Microanalytical Laboratory, Ann Arbor, Mich., and the Microanalytical Laboratory, National Research Center, Cairo, Egypt.

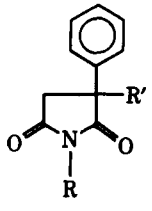
Anticonvulsant Properties of Mannich Base Derivatives of 2-Phenylsuccinimide III

EDWARD O. MAGARIAN▲, GERALD W. BECKER, and LOUIS DIAMOND

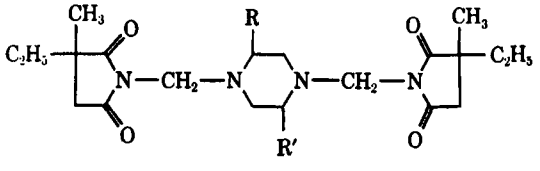
Abstract □ Several Mannich base derivatives of 2-phenylsuccinimide were synthesized and screened for anticonvulsant activity. All products were evaluated by maximal electroshock seizure and pentylenetetrazol seizure threshold tests.

Keyphrases □ 2-Phenylsuccinimide, Mannich base derivatives—synthesis, screened for anticonvulsant properties □ Anticonvulsants, potential—synthesis and screening of Mannich base derivatives of 2-phenylsuccinimide

The preceding papers (1, 2) of this series reported the preparation and anticonvulsant properties of several derivatives of phensuximide[1], *N*-methyl-2-phenylsuccinimide (I). One series of compounds (II), consisting of C-Mannich base derivatives of I, proved interesting since several members were more effective than the parent molecule in eliminating the tonic extensor component of electroshock seizures.



I: R = CH_3, R′ = H
II: R = CH_3, R′ = *tert*-aminomethyl
III: R = *tert*-aminomethyl, R′ = H



IV: R = CH_3, R′ = H
V: R = CH_3, R′ = CH_3

Some researchers (3, 4) reported the preparation of mono- and bis-Mannich bases of succinimides (III–V). These compounds were shown to possess significant anticonvulsant properties.

In view of the foregoing, it was of interest to prepare for evaluation the *N*,2-bis-Mannich bases of 2-phenylsuccinimide (Compounds 1–6 in Table I). The corresponding mono bases (Compounds 7–12 in Table I) were also prepared for comparison purposes. All products were subjected to preliminary pharmacological screening, and the results are presented in Tables II and III.

EXPERIMENTAL[2]

2-Phenylsuccinimide—The title compound was prepared from 2-phenylsuccinic acid and concentrated ammonium hydroxide according to Miller and Long's (5) procedure. It was obtained as a white solid in a yield of 78%, m.p. 79–81° [lit. (6) m.p. 90°].

Preparation of Bis-Mannich Bases (Table I)—To 0.05 mole of the appropriate amine, 5.0 ml. of 40% formalin (2.0 g., 0.067 mole formaldehyde) was added slowly with cooling. This mixture was added immediately to 4.4 g. (0.025 mole) of 2-phenylsuccinimide in 50 ml. of 95% ethanol, after which it was heated at reflux for various periods of time (Table I). The solvent was removed *in vacuo*, leaving either a solid or an oil, which usually solidified upon standing. Occasionally, extraction of the oil with petroleum ether and evaporation of the solvent *in vacuo* yielded solid material. If this procedure failed, an ethereal solution of the oil was washed with 10% NaOH and then with water until the washings were neutral to litmus. The solution was dried (magnesium sulfate), and the ether was removed *in vacuo* to give a solid product.

[1] Milontin, Parke, Davis and Co., Detroit, MI 48232

[2] All melting points were determined on a Thomas-Hoover melting-point apparatus and are corrected. IR spectra were obtained on a Beckman IR-8 spectrophotometer using KBr pellets. The two carbonyl stretching bands, which are characteristic of imides, were present in all products. NMR spectra were obtained on a Varian Associates A-60A spectrometer and are consistent with the assigned structures. Elemental analyses were performed by Micro-Analysis, Inc., Wilmington, Del. Intermediates used in this work are available commercially unless specified otherwise.

[a] Lit. (3) m.p. = 111–112°. [b] Lit. (3) m.p. = 107–108°.

Preparation of Mono-Mannich Bases (Table I)—To 0.05 mole of the appropriate amine, 5.0 ml. of 40% formalin (2.0 g., 0.067 mole formaldehyde) was added slowly with cooling. This mixture was added immediately to a solution of 8.8 g. (0.05 mole) of 2-phenylsuccinimide in 20 ml. of 95% ethanol. The reaction mixture was stirred at room temperature for 15–30 min. and cooled in an ice bath, and the product was removed by filtration.

PHARMACOLOGY

The anticonvulsant activity of each compound was evaluated by maximal electroshock seizure and pentylenetetrazol seizure threshold tests (7). A group of five male albino mice[3] was used for each test, and the results were compared with vehicle-treated control groups.

For the maximal electroshock seizure tests, animals were stimulated with 60-cycle alternating current for 200 msec. *via* a pair of earclip electrodes. A variable transformer was used to regulate the applied voltage. The desired duration of stimulus was obtained by the inclusion of a relay in the circuit, which was operated by a square-wave stimulator[4]. A cathode ray oscilloscope was used to monitor the voltage drop across a 10-ohm resistor coupled in series with the animal. This enabled the calculation of the corresponding current. The sweep on the cathode ray oscilloscope screen was triggered by the stimulator, so accurate readings could be obtained with each shock. Preliminary studies showed that 12–16 ma. was required to produce a convulsive seizure pattern having a tonic flexor phase, a tonic extensor phase, and a clonic phase.

After adequate control data were obtained, each group of animals received 10–600 mg./kg. i.p. of the drug under study. The maximal electroshock seizure tests were repeated 1, 2, and 3 hr. after drug administration. All drugs were administered as suspensions in 0.5% methylcellulose (4000 cps.).

An animal was considered to be protected if the tonic extensor phase of the seizure pattern was absent.

[3] Swiss-Webster mice obtained from the Laboratory Supply Co., Inc., Indianapolis, IN 46241. Food and water were allowed *ad libitum*.

[a] Animals not surviving are excluded from the ratios. [b] Drug was 100% lethal at this dosage level. [c] See *Reference 3*.

A similar experimental design was used for conducting the pentylenetetrazol seizure threshold tests. Animals received pentylenetetrazol, 85 mg./kg. s.c., 1 or 2 hr. after the administration of a test compound. Animals that showed no convulsive activity of any kind during a 30-min. observation period were considered protected.

The ability of the selected experimental testing procedures to detect anticonvulsant activity was assessed by including three agents known to provide significant protection against either electrically or chemically induced seizures—*viz.*, diphenylhydantoin, phenobarbital, and phensuximide.

The neurological status of each animal was evaluated prior to each test for anticonvulsant activity. Toxicity was considered present if the animal failed to exhibit a righting reflex or a hind-limb placing reaction or if the animal's equilibrium, gait, or stance deviated from normal.

It appears from the data in Tables II and III that the mono-Mannich bases were generally more active than the corresponding bis-substituted analogs. The products were less effective in preventing seizures with the maximal electroshock seizure test (Table II) than with the pentylenetetrazol seizure threshold test (Table III). As a rule, protection was obtained in the maximal electroshock seizure test only for dosage levels at which toxic effects were observed. In the pentylenetetrazol seizure threshold test, Compound 9 (Table III) displayed an activity pattern equivalent to that of the standard compound phensuximide. Compounds 8 and 11 (Table III) compared favorably with phensuximide in that they also provided full protection at a dosage level of 300 mg./kg.

Calculating Rate Constants in Forward Drug Transfer Reactions

WILLIAM O. THOMPSON[▲] and SAMUEL T. CHRISTIAN*

Abstract □ A simple method for obtaining and processing drug transfer data derived from *in vitro* model cells such as the Schulman cell is presented. Simplified calculation procedures are developed for determining the rate constants that describe the transfer of the drug through the compartments. Transfer of the acidic drug salicylic acid from a pH 2.0 compartment through a lipid phase to a pH 7.4 compartment was utilized as the test system and example for the method. Theoretical *versus* experimental transfer curves are presented, along with statistical considerations for data of this type.

Keyphrases □ Rate constants—calculations and equations for forward drug transfer reactions, Schulman cell, salicylic acid □ Drug transfer (forward) reactions—calculations and equations for rate constants, Schulman cell, salicylic acid □ Schulman cell—calculations and equations for rate constants in forward drug transfer reactions, salicylic acid

In the area of pharmacokinetics and in the study of drug absorption, the use of *in vitro* or idealized model systems has become increasingly popular for simulation of *in vivo* transport, even with the deficiencies and cautions pointed out by Higuchi *et al.* (1) in extrapolating this type of data to *in vivo* situations. There are many situations arising in which an understanding of the factors influencing solute transport rates is of great importance in the design of new drugs with improved therapeutic properties. These studies appear to have particularly useful implications when one is dealing with a diffusion-limited, weakly acidic or weakly basic drug in which the transport can be regarded as two consecutive first-order reactions.

An investigator using these techniques would find useful a simplified and rapid method of calculation, particularly when measurement output is a continuous graph of concentration *versus* time such as is produced by continuous monitoring by means of flow cells in a recording spectrophotometer. In approaching this problem, we were surprised to find a general lack of statistical evaluation of the various kinetic parameters associated with the diffusion-limited transport investigated using the so-called Schulman cell (2, 3) or similar device (4). The general absence of these data very likely reflects the long periods of time required for a single experiment to be completed, the wide variability of constants derived from a given set of experiments, and the difficulty of obtaining the constants. The purposes of this study were: (*a*) to develop a simple method of calculation for the rate parameters from a plot of concentration *versus* time generated from a continuous monitoring system, and (*b*) to demonstrate the method with an example.

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

95% Confidence interval	$0.8659 < k_1 < 0.9929$	$0.5177 < k_2 < 0.6447$

THEORETICAL

A drug transfer process that can be regarded as two consecutive first-order reactions may be described as shown in Scheme I, where A, B, and C are used for $A(t)$, $B(t)$, and $C(t)$, the concentrations of salicylic acid in compartments A, B, and C, respectively, at time t, as shown in Scheme II. Let V_A, V_B, and V_C equal the fluid volume in each of the three compartments. The three differential equations governing these first-order reactions are:

$$\frac{dA}{dt} = -k_1A \qquad \text{(Eq. 1)}$$

$$V_B\frac{dB}{dt} = k_1AV_A - k_2BV_B \qquad \text{(Eq. 2)}$$

$$V_C\frac{dC}{dt} = k_2BV_B \qquad \text{(Eq. 3)}$$

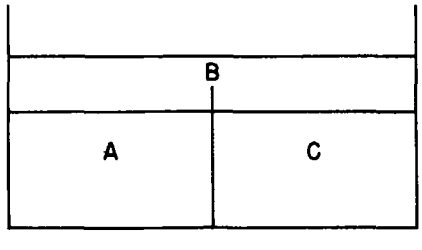
Initial conditions are set so that salicylic acid is only found in compartment A; thus, at time $t = 0$, $A(0) = A_0$ and $B(0) = C(0) = 0$. The solutions to Eqs. 1–3 as a function of time are as follows:

$$A(t) = A_0e^{-k_1t} \qquad \text{(Eq. 4)}$$

$$B(t) = \frac{V_AA_0k_1}{V_B(k_2 - k_1)}(e^{-k_1t} - e^{-k_2t}) \qquad \text{(Eq. 5)}$$

$$C(t) = \frac{V_AA_0}{V_C(k_2 - k_1)}(k_2 - k_1 - k_2e^{-k_1t} + k_1e^{-k_2t}) \qquad \text{(Eq. 6)}$$

Since the data output from the system consists of a continuous plot of the drug concentration in the A and C chambers as a function of time, as for example in Fig. 1, a convenient point for cal-



Scheme II—Sketch of Schulman-type in vitro *model cell*

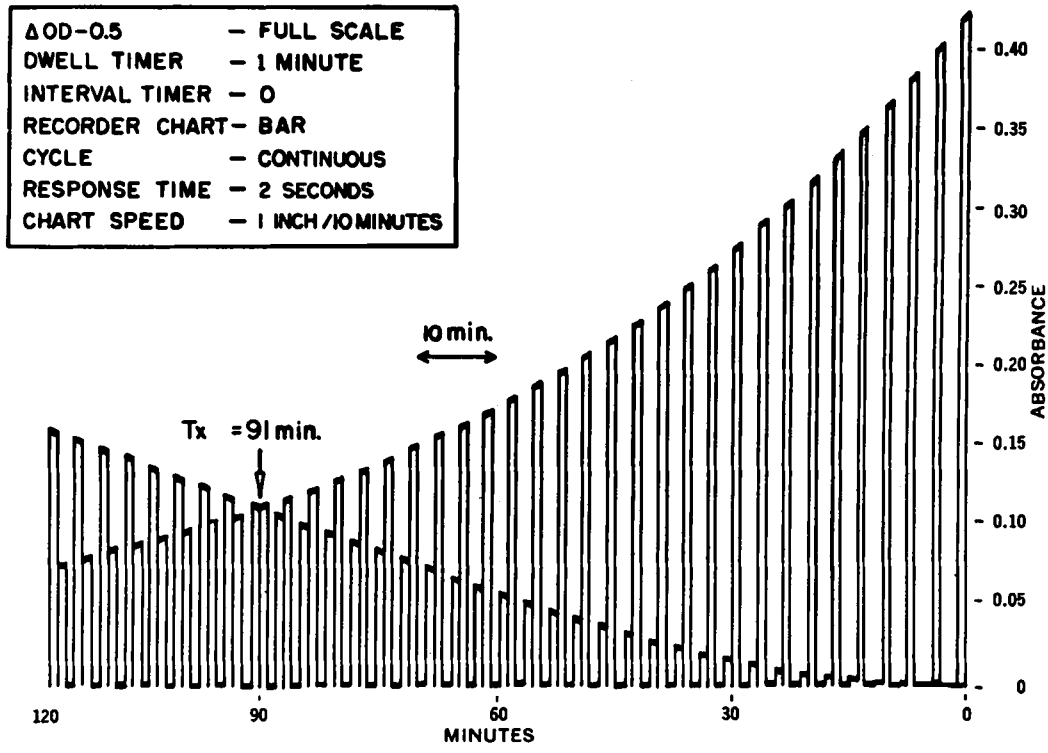


Figure 1—*Actual recorded data for a typical transfer run. Conditions are indicated in the figure insert.* T_x *indicates the time at which the salicylic acid concentrations in the* A *and* C *chambers are equal. The heavy line segment on the time axis represents the blank flow cell containing pH 2.0 buffer only. The starting salicylic acid concentration was 18.3 mcg./ml. in the* A *chamber.*

culation purposes is the point at which the concentration of drug in the A and C chambers is equal. If one designates the time at which this equilibrium occurs as the crossing time (t_x), then at t_x, $A(t_x) = C(t_x) = a$, where a is a constant. It then follows from Eq. 4 that:

$$k_1 = \frac{\ln A_0 - \ln a}{t_x} \qquad \text{(Eq. 7)}$$

where $\ln A_0$ is the natural (base e) logarithm function.

Also, since $A(t_x) = C(t_x)$, equating Eqs. 4 and 6 at time t_x yields:

$$e^{-k_1 t_x} = \frac{V_A}{V_C(k_2 - k_1)}(k_2 - k_1 - k_2 e^{-k_1 t_x} + k_1 e^{-k_2 t_x}) \qquad \text{(Eq. 8)}$$

Substituting for k_1 the solution from Eq. 7 into Eq. 8 and solving in terms of k_2, one has:

$$\alpha k_2 + \beta e^{-k_2 t_x} + \gamma = 0 \qquad \text{(Eq. 9)}$$

where:

$$\alpha = \frac{a(V_A + V_C)}{A_0} - V_A \qquad \text{(Eq. 10)}$$

$$\beta = \frac{V_A(\ln a - \ln A_0)}{t_x} = -k_1 V_A \qquad \text{(Eq. 11)}$$

and:

$$\gamma = V_A k_1 - [V_C k_1 a / A_0] \qquad \text{(Eq. 12)}$$

Equation 9 may be easily solved iteratively since the left-hand side, when considered as a function of k_2, *i.e.*, $f(k_2)$, is strictly monotonically increasing for all $k_2 \geq 0$. Furthermore, at $k_2 = 0$:

$$f(0) = \beta + \gamma = -V_C k_1 a / A_0 < 0 \qquad \text{(Eq. 13)}$$

Therefore, the function $f(k_2)$ is always negative at zero. Thus, if a particular trial value k_2^* produces $f(k_2^*) < 0$, k_2^* must be increased; if $f(k_2^*) > 0$, k_2^* must be decreased. For programming on a digital computer, the initial k_2 can be taken to be zero and then successively increased until $f(k_2)$ changes sign.

DISCUSSION

The solutions to Eqs. 7 and 13 for k_1 and k_2 were programmed on a laboratory-type digital computer[1]. Output from the computer was obtained both as a printout of k_1 and k_2 and as a plot of drug concentration in chambers A, B, and C *versus* time. This allows a direct comparison of the calculated (or theoretical) concentrations in A and C as a function of time and the concentration in A and C determined experimentally. This method has the added advantage of allowing the investigator to see quickly how close the experimental system approximates simple first-order kinetics.

As an example of the method, salicylic acid was transported from the A chamber (pH 2.0) through a layer of 20% decanol in cyclohexane (v/v) saturated with pH 2.0 buffer to the C chamber (pH 7.4). A continuous recording of the concentration in the A and C chambers was done with flow cells read by a recording spectrophotometer. A photograph of the data appears in Fig. 1. Points taken from the graph in Fig. 1 were plotted on Fig. 2, and the smooth lines were generated by a computer using the constants derived from the data of Fig. 1. As is evident from Fig. 2, transport seems to follow the model of two consecutive first-order reactions very well.

The concentration of salicylic acid in the B layer as a function of time is included in the figure, although this layer was not monitored.

After establishing the validity and convenience of the method, six independent runs were made on six different days to evaluate the statistical day by day variability of the rate constants. The results of these runs are shown in Table I. On each individual run, theoretical and empirical curves matched at least as well as those in Fig. 2, so the variabilty is between day to day determinations. Since errors are eliminated on a particular day once this system is in progress, it must be concluded that the between run variability is caused by random errors which are other than the more usual measurement variations. Variability in such systems becomes critical when one is comparing the transport properties of a closely related homologous series of compounds; for this reason, these data are presented. It is evident that comparisons from single determinations on different compounds with closely related rate constants must be made with extreme caution, especially if measurement variability is also introduced. The estimates of variability in these data can be used to provide future experimenters with a means of establishing appropriate sample sizes to detect specified differences with statistical confidence. The correlation coefficient $r = 0.6124$ between k_1 and k_2 is significant with 80% confidence on only six runs, which suggests a future area of research.

[1] Digital Equipment PDP-12.

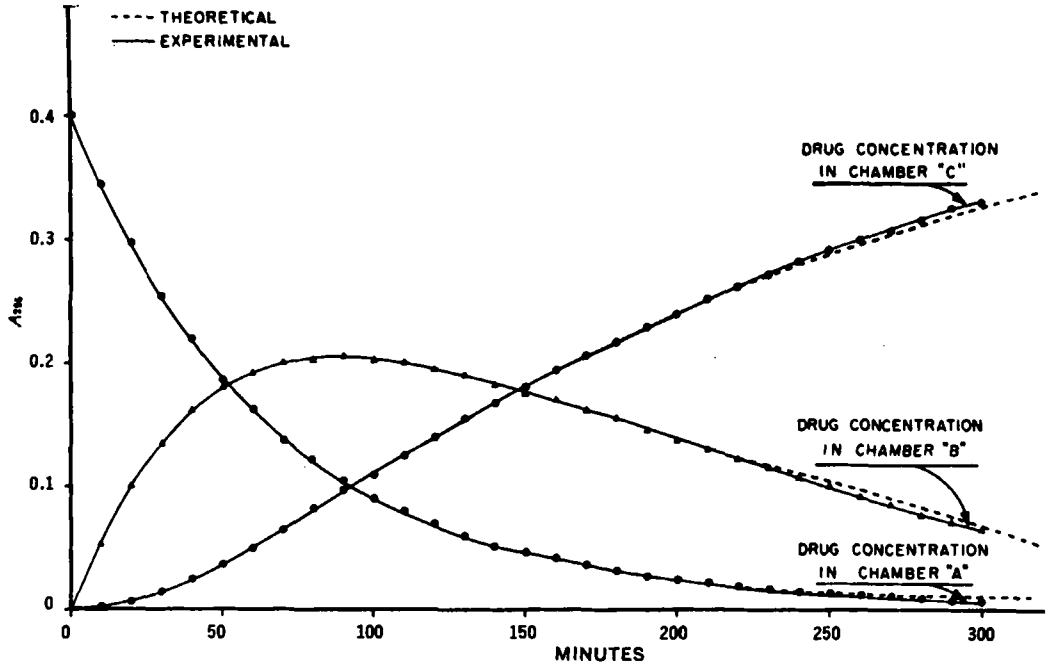

Figure 2—*Theoretical* (- - -) versus *experimental* (——) *salicylic acid transfer curves. Even though the organic layer was not monitored, the concentration–time curve was calculated from input data for comparison* (▲). *Theoretical curves were generated from Eqs. 1–3. The starting salicylic acid concentration for this experiment was 18 mcg./ml.*

The original intention was to utilize methods of calculation already present in the literature (5). However, by using the integrated rate equations which were reported as describing the forward transfer of an acidic drug, it was found that these equations did not describe the actual transfer process. It was then determined that the equations (5) do not satisfy the differential equations for the transfer process and hence are invalid.

Synthesis and Pharmacology of a Pargyline Analog, *N*-3-(1-Butynyl)-benzylamine

JEROME F. SIUDA*▲, CAROLE CIHONSKI*, R. DUANE SOFIA†‡, and JOSEPH P. BUCKLEY†

Abstract □ The synthesis of a structural isomer of pargyline was undertaken to test certain structure–activity relationships. *In vivo*, the new compound, *N*-3-(1-butynyl)-benzylamine, exhibited slight central stimulant effects but showed no MAO inhibitory activity *in vitro*.

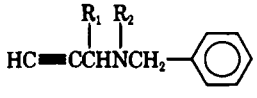
Keyphrases □ *N*-3-(1-Butynyl)-benzylamine (pargyline analog)—synthesis and pharmacology, structure–activity relationships □ Pargyline analog—synthesis and pharmacology of *N*-3-(1-butynyl)-benzylamine, structure–activity relationships □ MAO inhibitors—synthesis and pharmacology of pargyline analog, *N*-3-(1-butynyl)-benzylamine, structure–activity relationships

Pargyline (I*a*) is an MAO inhibitor which demonstrates antidepressant action and also serves as a clinically effective antihypertensive agent. Structure–activity relationships for the propynylamine series (I) indicate that when the R groups are larger than methyl, a decrease in both MAO inhibition and antidepressant activity is observed (1). The synthesis of *N*-3-(1-butynyl)-benzylamine (I*b*), a structural isomer of pargyline, was undertaken to determine whether the shift of the methyl group from the nitrogen to the adjacent carbon in the propynyl chain would greatly affect pharmacological activity. Compound I*b* was synthesized in two steps, beginning with the conversion of 1-butyn-3-ol to 3-chloro-1-butyne (in low yield) followed by condensation of the latter with benzylamine.

DISCUSSION

As an *in vivo* testing procedure, a method similar to that described by Everett and Wiegand (2) was employed. This procedure involves injection of the potential drug into mice followed by injection of dopa. The degree of increase in central activity is considered related to the effectiveness of MAO inhibition. The method has been utilized to determine indirectly MAO inhibition. Since both I*a* and I*b* have identical molecular weights, comparisons were made at equal weight dose levels. Although I*b* produced a slight increase in central activity, this increase was much less than that caused by pargyline. Even at higher toxic dose levels, this effect on the central activity was much less intense than that of pargyline. The overall results indicate that I*b* is at best a weak MAO inhibitor compared to pargyline.

Because I*b* was questionable as an MAO inhibitor, it was tested *in vitro*. Pargyline exhibited a straight-line log dose–response relationship with an ID_{50} (50% inhibition) of MAO at approximately 0.7 mcg./ml. Compound I*b* at concentrations up to 20 times the ID_{50} of pargyline demonstrated no MAO inhibitory activity. It is possible that the slight increase in central activity exhibited by I*b* was not due to MAO inhibition but rather some other unknown factor. However, the antidepressant encyprate was shown to be inactive *in vitro* but active *in vivo*, probably due to its metabolism to an active metabolite *in vivo* (3). Nevertheless, based on these results, it was concluded, in agreement with Swett *et al.* (1), that optimum activity is apparently associated with a small atom or groups of atoms, *i.e.*, hydrogen or methyl connected to the nitrogen atom, and that further *N*-alkylation or further substitution on the aliphatic chain tends to decrease activity.



I*a*: $R_1 = H$, $R_2 = CH_3$
I*b*: $R_1 = CH_3$, $R_2 = H$

EXPERIMENTAL

Pharmacology—The hydrochloride salts of both I*a* and I*b* were dissolved in distilled water. For testing *in vivo*, 152 male, albino mice (Swiss-Webster strain), weighing 20–32 g., were initially divided into groups of eight animals each. Each group was further separated into two subgroups of four mice each from which data were collected and pooled. According to a preset dosing schedule, all four mice in each group were administered various doses of the test drug intraperitoneally and placed in Plexiglas boxes, 12.7 × 12.7 × 12.7 cm. (5 × 5 × 5 in.) with adequate ventilation. At time intervals ranging from 15 min. to 4 hr. following drug administration, mice were injected with 200 mg./kg. i.p. of DL-dopa suspended in 0.25% agar-agar. Immediately following dopa administration and for the ensuing 30 min., the mice were observed as a group and behavioral changes were observed and rated similar to a procedure described by Everett and Wiegand (2). Each parameter received a numerical score: Straub tail = 1, salivation = 2, jumping = 3, and fighting = 4. The maximum total score for any group would be 10 (4 + 3 + 2 + 1), which would be related to a very high level of MAO inhibition.

Pretreatment of mice with I*b* at 40–160 mg./kg. 1 hr. prior to DL-dopa did not produce symptoms suggesting significant MAO inhibitory activity. A dose of 320 mg./kg. of I*b* resulted in a 100% mortality within 5 min.; I*a* resulted in a dose-dependent relationship, with the maximal effect occurring at the 80-mg./kg. dose. When administered by themselves, neither drug caused any of the behavioral characteristics being measured.

When DL-dopa was administered at various time intervals following intraperitoneal injection of 240 mg./kg. of I*b*, pronounced effects were observed. At the 15-min. time interval, when the increase in central activity was maximal, I*b* appeared to be one-third to one-sixth as potent as pargyline. However, the lethal effects of I*b* were evident within 30 min. and all of the animals were dead within the 4-hr. period.

For *in vitro* testing, the procedure of Lovenberg *et al.* (4) was employed, using tryptamine as a substrate. The MAO enzyme was obtained fresh from rat liver. Pargyline was tested at concentrations from 0.1 to 1.6 mcg./ml., and I*b* was tested at concentrations of 0.1 to 13 mcg./ml.

Chemistry[1]—*3-Chloro-1-butyne*—A procedure similar to that described by Hennion and coworkers (5, 6) was employed. A mixture of 1-butyn-3-ol (14.0 g., 0.20 mole), pyridine (0.3 g.), and freshly distilled thionyl chloride (23.8 g., 0.20 mole) was gently refluxed for 30 min., cooled, and poured onto 60 g. of ice water. The mixture was extracted with 30 ml. of ether, and the organic phase was washed successively with water (2 × 5 ml.), 5% aqueous sodium bicarbonate (2 × 5 ml.), and finally again with water (2 × 5 ml.). After drying the ether solution for 2 days over calcium chloride, it was distilled through a 10 × 200-mm. Vigreaux column and 3.15 g. of the frac-

[1] Melting points were taken on a Thomas-Hoover apparatus and are uncorrected. IR spectra were recorded on a Perkin-Elmer Infracord spectrophotometer. NMR spectra were recorded on a Varian Associates A-60 spectrometer using spectroquality carbon tetrachloride as a solvent; chemical shifts are reported in parts per million (δ) relative to tetramethylsilane as an internal standard. Elemental analyses were performed by Spang Microanalytical Laboratories, Ann Arbor, Mich.

tion distilling at 60–61.5° was collected. Longer or shorter reaction times and higher or lower temperatures failed to produce a yield in excess of 18%. Vapor phase chromatographic analysis of the products from various experiments indicated a purity of 70–90%. Redistillation of the 60–61.5° fraction afforded little additional purity. This material was used in the reaction with benzylamine. The purest sample was employed in spectral studies; IR (neat): 2150 (—C≡CH) cm.$^{-1}$; NMR (CCl_4): 1.65 (d, 3, C—CH_3), 2.43 (d, 1, —C≡CH), and 4.50 (quartet of doublets, 1, Cl—CH).

N-3-(1-Butynyl)-benzylamine Hydrochloride—Similar to a procedure described by Hennion and Nelson (7), a mixture of the above chloro compound (2.5 g.), benzylamine (13.1 g.), and water (3.2 ml.) was stirred at room temperature for 60 hr. At the end of this time, an equal volume of water (15 ml.) was added and two phases formed. The upper layer (organic phase) was separated, and the bottom layer (aqueous phase) was diluted again with an equal volume of water. Again two phases formed and the upper layer was combined with the first. Ether (25 ml.) was added, this solution was washed with water (2 × 5 ml.) and dried over potassium hydroxide, and the ether was removed *in vacuo*. The residue was distilled through a Vigreaux column, and the fraction distilling at 168–172°/17 mm. Hg was collected; IR (neat): 3400 (>NH) and 2150 (—C≡CH) cm.$^{-1}$; NMR (CCl_4): 1.31 (d, 3, C—CH_3), 2.16 (d, 1, —C≡CH), 3.38 (quartet of doublets, 1, N—CH), 3.88 (d, 2, $ArCH_2$), and 7.22 (s, 5, ArH). This fraction was dissolved in 50 ml. of anhydrous ether, and hydrogen chloride gas was passed through the solution, giving 1.2 g. of a white solid (22% yield based on pure 3-chloro-1-butyne). Several crystallizations from benzene afforded an analytically pure sample, m.p. 210.5–211.5°.

Anal.—Calc. for $C_{11}H_{11}ClN$: C, 67.52; H, 7.16; N, 7.16. Found: C, 67.37; H, 6.97; N, 7.00.

Synthesis and Antifungal Activity of Polyhalophenyl Esters of Pyridyl- and 4-Quinolylcarbamic Acids IV

I. LALEZARI▲, H. GOLGOLAB, A. SHAFIEE, and M. WOSSOUGHI

Abstract □ Polyhalophenyl esters of 2-, 3-, and 4-pyridyl- and 2-phenyl-4-quinolylcarbamic acids were synthesized. All prepared compounds inhibited the growth of *Candida albicans* at 50-mcg./ml. concentration.

Keyphrases □ Pyridylcarbamic acid, polyhalophenyl esters—synthesis, antifungal activity □ 2-Phenyl-4-quinolylcarbamic acid, polyhalophenyl esters—synthesis, antifungal activity □ Carbamic acid esters—synthesis, antifungal activity □ Antifungal agents, potential—polyhalophenyl esters of pyridyl- and 2-phenyl-4-quinolylcarbamic acids

In a continuation of the studies on the chemistry and antifungal activity of substituted carbamic acid esters (1–3), polyhalophenyl esters of 2-, 3-, and 4-pyridyl- and 2-phenyl-4-quinolylcarbamic acids were synthesized by interaction of the appropriate azide and polyhalophenol (Scheme I).

$$RCOCl \rightarrow RCON_3 \rightarrow RNHCO_2Ar$$

R = 2-, 3-, or 4-pyridyl or 2-phenyl-4-quinolyl
Ar = 2,4,6-tribromophenyl, 2,4,6-trichlorophenyl, 2,4,6-triiodophenyl, or pentachlorophenyl

Scheme I

EXPERIMENTAL[1]

Picolinyl azide was prepared according to Meyer and Mally (4). Nicotinyl azide was prepared by the method of Curtius and Mohr (5). Isonicotinyl azide was synthesized according to Yoshikowa (6). 2-Phenyl-4-quinolylcarboxazide was obtained by the method of John *et al.* (7).

2-Pyridylcarbamic Acid Pentachlorophenyl Ester—2-Pyridyl azide, 0.74 g. (5 mmoles), and 1.33 g. (5 mmoles) of pentachlorophenol in 30 ml. of dry toluene were gently refluxed for 30 min. After evaporation of the solvent under reduced pressure, the residue was recrystallized from 80% ethanol to give 1.16 g. (60%), m.p. 135°; *m/e* 384, 386, 388, and 390; ν_{max}: 2900, 1710, 1620, 1540, 1470, 1440, 1410, 1360, 1320, 1250, 1150, 995, 980, 880, 778, and 715 cm.$^{-1}$.

3-Pyridylcarbamic Acid 2,4,6-Triiodophenyl Ester—This compound was prepared in a similar manner to its pentachlorophenyl analog; *m/e* 592; ν_{max}: 3300, 1750, 1580, 1550, 1480, 1420, 1200, 1060, 1020, 850, 810, 780, 740, and 703 cm.$^{-1}$.

4-Pyridylcarbamic Acid 2,4,6-Triiodophenyl Ester—This compound was prepared in a similar manner to its pentachlorophenyl analog; *m/e* 592; NMR (dimethyl sulfoxide): τ 7.9–8.1 (d, 2H,

[1] Melting points were taken on a Kofler hot-stage microscope and are uncorrected. The IR spectra were determined with a Leitz model III spectrograph. NMR spectra were obtained on a Varian A60A instrument. Mass spectra were determined with a Varian Mat 111 instrument.

tion distilling at 60–61.5° was collected. Longer or shorter reaction times and higher or lower temperatures failed to produce a yield in excess of 18%. Vapor phase chromatographic analysis of the products from various experiments indicated a purity of 70–90%. Redistillation of the 60–61.5° fraction afforded little additional purity. This material was used in the reaction with benzylamine. The purest sample was employed in spectral studies; IR (neat): 2150 (—C≡CH) cm.$^{-1}$; NMR (CCl_4): 1.65 (d, 3, C—CH_3), 2.43 (d, 1, —C≡CH), and 4.50 (quartet of doublets, 1, Cl—CH).

N-3-(1-Butynyl)-benzylamine Hydrochloride—Similar to a procedure described by Hennion and Nelson (7), a mixture of the above chloro compound (2.5 g.), benzylamine (13.1 g.), and water (3.2 ml.) was stirred at room temperature for 60 hr. At the end of this time, an equal volume of water (15 ml.) was added and two phases formed. The upper layer (organic phase) was separated, and the bottom layer (aqueous phase) was diluted again with an equal volume of water. Again two phases formed and the upper layer was combined with the first. Ether (25 ml.) was added, this solution was washed with water (2 × 5 ml.) and dried over potassium hydroxide, and the ether was removed *in vacuo*. The residue was distilled through a Vigreaux column, and the fraction distilling at 168–172°/17 mm. Hg was collected; IR (neat): 3400 (>NH) and 2150 (—C≡CH) cm.$^{-1}$; NMR (CCl_4): 1.31 (d, 3, C—CH_3), 2.16 (d, 1, —C≡CH), 3.38 (quartet of doublets, 1, N—CH), 3.88 (d, 2, $ArCH_2$), and 7.22 (s, 5, ArH). This fraction was dissolved in 50 ml. of anhydrous ether, and hydrogen chloride gas was passed through the solution, giving 1.2 g. of a white solid (22% yield based on pure 3-chloro-1-butyne). Several crystallizations from benzene afforded an analytically pure sample, m.p. 210.5–211.5°.

Anal.—Calc. for $C_{11}H_{11}ClN$: C, 67.52; H, 7.16; N, 7.16. Found: C, 67.37; H, 6.97; N, 7.00.

Synthesis and Antifungal Activity of Polyhalophenyl Esters of Pyridyl- and 4-Quinolylcarbamic Acids IV

I. LALEZARI▲, H. GOLGOLAB, A. SHAFIEE, and M. WOSSOUGHI

Abstract □ Polyhalophenyl esters of 2-, 3-, and 4-pyridyl- and 2-phenyl-4-quinolylcarbamic acids were synthesized. All prepared compounds inhibited the growth of *Candida albicans* at 50-mcg./ml. concentration.

Keyphrases □ Pyridylcarbamic acid, polyhalophenyl esters—synthesis, antifungal activity □ 2-Phenyl-4-quinolylcarbamic acid, polyhalophenyl esters—synthesis, antifungal activity □ Carbamic acid esters—synthesis, antifungal activity □ Antifungal agents, potential—polyhalophenyl esters of pyridyl- and 2-phenyl-4-quinolylcarbamic acids

In a continuation of the studies on the chemistry and antifungal activity of substituted carbamic acid esters (1–3), polyhalophenyl esters of 2-, 3-, and 4-pyridyl- and 2-phenyl-4-quinolylcarbamic acids were synthesized by interaction of the appropriate azide and polyhalophenol (Scheme I).

$$RCOCl \rightarrow RCON_3 \rightarrow RNHCO_2Ar$$

R = 2-, 3-, or 4-pyridyl or 2-phenyl-4-quinolyl
Ar = 2,4,6-tribromophenyl, 2,4,6-trichlorophenyl, 2,4,6-triiodophenyl, or pentachlorophenyl

Scheme I

EXPERIMENTAL[1]

Picolinyl azide was prepared according to Meyer and Mally (4). Nicotinyl azide was prepared by the method of Curtius and Mohr (5). Isonicotinyl azide was synthesized according to Yoshikowa (6). 2-Phenyl-4-quinolylcarboxazide was obtained by the method of John *et al.* (7).

2-Pyridylcarbamic Acid Pentachlorophenyl Ester—2-Pyridyl azide, 0.74 g. (5 mmoles), and 1.33 g. (5 mmoles) of pentachlorophenol in 30 ml. of dry toluene were gently refluxed for 30 min. After evaporation of the solvent under reduced pressure, the residue was recrystallized from 80% ethanol to give 1.16 g. (60%), m.p. 135°; *m/e* 384, 386, 388, and 390; ν_{max}: 2900, 1710, 1620, 1540, 1470, 1440, 1410, 1360, 1320, 1250, 1150, 995, 980, 880, 778, and 715 cm.$^{-1}$.

3-Pyridylcarbamic Acid 2,4,6-Triiodophenyl Ester—This compound was prepared in a similar manner to its pentachlorophenyl analog; *m/e* 592; ν_{max}: 3300, 1750, 1580, 1550, 1480, 1420, 1200, 1060, 1020, 850, 810, 780, 740, and 703 cm.$^{-1}$.

4-Pyridylcarbamic Acid 2,4,6-Triiodophenyl Ester—This compound was prepared in a similar manner to its pentachlorophenyl analog; *m/e* 592; NMR (dimethyl sulfoxide): τ 7.9–8.1 (d, 2H,

[a] IR, NMR, and mass spectra of all compounds were as expected.

α-hydrogens), 7.69 (s, 2H, aromatic H), 7.35 (s, 1H, NH), and 6.65–6.85 (d, 2H, β-hydrogens).

2-Phenyl-4-quinolylcarbamic Acid 2,4,6-Tribromophenyl Ester—This compound was prepared in a similar manner to the pyridyl analog; ν_{max}: 3330, 3050, 1755, 1615, 1560, 1538, 1445, 1380, 1280, 1200, 995, 860, 810, 775, 765, 745, and 690 cm.$^{-1}$.

All other compounds were prepared similarly. The physical data of prepared compounds are listed in Table I.

All prepared compounds were tested against *Candida albicans*[1] *in vitro* using BBL Sabouraud dextrose agar medium. Concentrations of 10 and 50 mcg./ml. of each compound were used. Compounds were dissolved in acetone, diluted with hot culture medium to the desired concentration, and autoclaved at 120° for 1 hr.

Pentachlorophenyl esters of 2-pyridyl- and 2-phenyl-4-quinolylcarbamic acids inhibited the growth at 10 mcg./ml. concentrations against the blank. Slight growth inhibition was observed with other compounds at the same concentrations.

After 5 days at 28°, the growth was entirely inhibited with 50-mcg./ml. concentrations of all compounds prepared.

[1] This microorganism was obtained from the Department of Parasitology, Public Health Institute, Tehran, Iran.

Labile Triazinoindole Hydrates

H. C. CALDWELL

Abstract □ Aqueous topical suspensions of two triazinoindoles in fine particle form produced crystals even when the protective colloid methylcellulose was added. These crystals were found to be monohydrates that readily lost water of hydration under mild heat, but they could be air milled with no water loss. One hydrate was formulated in suspension and found to be free of crystal growth for 2 years.

Keyphrases □ Triazinoindole hydrates, labile—formation, isolation from topical suspensions, effects of air milling and methylcellulose on crystal growth □ Hydrates, labile—formation, isolation from topical triazinoindole suspensions, effects of air milling and methylcellulose on crystal growth □ Suspensions of labile triazinoindole hydrates—formation, isolation, effects of air milling and methylcellulose on crystal growth

Over 90 hydrates are included in USP XVIII and NF XIII. Four of these that readily lose water of hydration in warm dry air are atropine sulfate monohydrate, morphine sulfate pentahydrate, scopolamine hydrobromide trihydrate, and sodium acetate trihydrate. These, like other official hydrates, are usually stored in tight, light-resistant containers.

According to the USP and NF, a tight container protects the contents from contamination by extraneous liquids, solids, or vapors; from loss of the drug; and from efflorescence, deliquescence, or evaporation under ordinary or customary conditions of handling, shipment, storage, and distribution. It is also capable of tight reclosure. Thus, official hydrates properly packaged and stored should not lose moisture. Further, it is reasonable to assume that these hydrates exist as such in formulations.

It is important to recognize that many official compounds form hydrates that readily lose water when dried under mild conditions. The review (1) on hydrates of alcohols and glycols is illustrative. These labile hydrates become particularly important when aqueous suspensions of slightly soluble, anhydrous chemicals are formulated, because these hydrates can produce large particles as they form (2). These large particles would have less surface area for a given dose, and the rate and extent of absorption could be markedly decreased (3). Protective colloids might be expected to retard but not stop this transformation (2, 4).

This report presents a case history of suspension work on two triazinoindoles (I[1] and II[2]) and their labile hydrates. Ravin *et al.* (4) recently described the physical-chemical evaluation of I. They reported that it is practically insoluble (0.008 mg./ml.), that it exists as two polymorphs, and that it forms a hydrate.

The present tasks were to prepare and to evaluate formulations for oral and nasal use. The most stable polymorph of I was used, but it was not known then that I or II formed hydrates.

EXPERIMENTAL

Particle-Size Reduction—The purified compounds were passed through a fluid energy mill[3]. The products were sized with the Coulter counter[4].

Suspensions—The milled chemicals were suspended in buffered vehicles containing a preservative and a protective colloid.

Hydrate Preparation—Small batches of I-hydrate and II-hydrate were made by suspending 5 g. of air-milled I and II in 750 ml. of distilled water and heating the suspensions overnight on the steam bath. The small anhydrous crystals were converted to long hydrate needles. Larger batches of I-hydrate were made by dissolving I in dilute hydrochloric acid and precipitating it with dilute sodium hydroxide solution. The suspension was stirred overnight at room temperature. Samples were collected and air dried at room temperature.

X-Ray Diffraction Procedure—The procedure employed was described (4) previously but was modified so that intensities were not measured by recording the time necessary to count a fixed number of particles.

Thermal Work—A differential thermal analyzer[5] and a thermogravimetric analyzer[6] were used. Heat rates were 20 and 5°/min., respectively. A thermobalance[7] was used to follow weight loss as a function of temperature.

Isolation of Hydrates from Topical Suspensions—Suspensions made with I and II were followed for chemical and physical changes at various storage conditions. Samples that appeared, by microscopic examination, to have completely changed from small to large particles were diluted with water, filtered, washed, and dried at room temperature.

RESULTS AND DISCUSSION

Suspensions of air-milled anhydrous I and II were found to produce large crystals even in the presence of classical crystal growth inhibitors such as methylcellulose. To determine if hydrate formation was responsible, it was necessary to isolate large crystals from I and II suspensions and compare them to crystals of authentic hydrates of I and II.

These data are reported in Tables I and II. Both hydrates of I and both hydrates of II (Table II) analyze as monohydrates. In the thermal gravimetric analysis, all hydrates start to lose weight at relatively low temperature and each loses weight equivalent to 1 mole of water. As expected, the anhydrous forms do not lose weight. In the differential thermal analysis, the hydrate of I shows transitions at about 108–117°, which are not seen with the anhy-

[a] 5.95% theoretical for monohydrate. [b] Exotherm—others are endotherms. [c] 6.54% theoretical for monohydrate.

drous form, and the hydrate of II shows transitions at about 105 and 125°, which are not seen with the anhydrous form. Thus, these data show that suspensions of I and II form hydrates even in the presence of protective colloids. X-ray diffraction patterns for II and II-hydrate are distinctly different, as Fig. 1 shows. X-ray diffraction patterns for I and I-hydrate were reported (4) to be different previously. Weight loss as a function of temperature was determined. Samples were placed in the thermobalance, and percent weight loss was recorded after 15 min. at various temperatures. I-hydrate (air milled) lost no weight at 45°, 1% at 50°, 4% at 55°, and all (5.95%) at 60°. II-hydrate lost no weight at 25°, 0.8% at 28°, 1.5% at 33°, 6.2% at 45°, and all (6.54%) at 60°. Hydrous lactose USP lost no weight at 45° and 1% at 60°, while hydrous sodium citrate lost no weight at 60°.

These data show that the hydrates of I and II are heat labile, and they explain why hydrate samples dried at 60° would be rapidly converted to anhydrous forms.

Because the anhydrous forms of I and II were converted to hydrates in suspension, it was reasonable to think that suspensions of hydrates would be stable with respect to crystal growth. But one other problem had to be solved before suspension work could begin. It had to be established that the hydrates of I and II could be air milled with no water of hydration loss. Three batches of I-hydrate were passed through the air mill with no water loss, as determined by Karl Fischer titration and weight loss on drying. Two batches of II-hydrate treated in the same manner also did not lose water.

Once it had been established that the large crystals formed in suspensions of I and II were the respective hydrates and that the

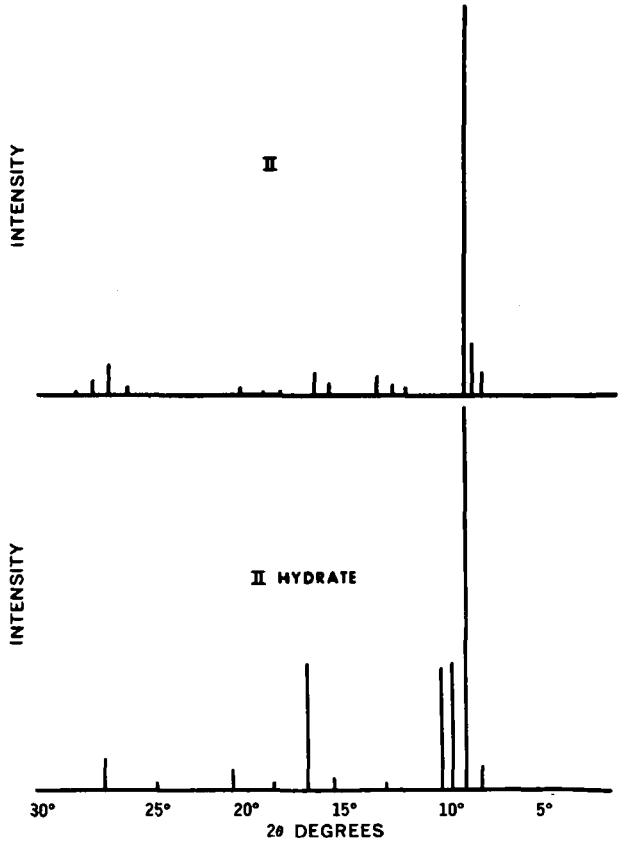

Figure 1—*X-ray diffraction patterns for anhydrous and hydrate forms of II.*

hydrates could be air milled, the author proceeded to prepare suspensions with air-milled hydrate to see if crystal growth still occurred. Work was done with I-hydrate, because at that time development work on II had been discontinued. A 2.5% suspension of air-milled I-hydrate was made (Table III) and observed for 2 years by microscopic examination and particle-size analysis. No evidence for crystal growth was observed.

This case history shows that suspensions are dynamic systems and that it is important to establish which forms are present at equilibrium. It shows that careful work is needed to identify these forms and prove that they can be processed to specifications prior to suspension formulation work. In addition, this report shows that satisfactory suspensions can be made with these equilibrium forms.

ACKNOWLEDGMENTS AND ADDRESSES

Received March 10, 1972, from the *Research and Development Division, Smith Kline & French Laboratories, Philadelphia, PA 19101*

Accepted for publication August 11, 1972.

The author thanks Miss Margaret Carroll and her staff for the microanalysis; Mr. R. Warren for the X-ray analysis; Mr. Bharat Shah, Mr. Fred Ryan, and Mr. Karl Kraus for technical assistance; Mr. Elvin Anderson for the large batch of I-hydrate; and Dr. Takeru Higuchi for helpful discussions.

Bicyclic Thiadiazoles I: 2-(2-Thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole

MAN M. KOCHHAR[▲], MOHAMMAD SALAHI-ASBAHI, and BYRON B. WILLIAMS

Abstract □ 2-(2-Thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole was synthesized and evaluated for its diuretic action. The effect of 2-substitution on the ease of cyclization to a bicyclic system was studied. The carboxylic acid hydrazides were converted to dithiocarbazates which, on cyclization, gave 2-substituted 5-thio-1,3,4-thiadiazoles. Thiothiadiazoles were converted to the bicyclic system by the action of phenacyl bromide.

Keyphrases □ Thiadiazoles, bicyclic—synthesis of 2-(2-thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole, evaluated as a potential diuretic □ 2-(2-Thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole—synthesis, screened as potential diuretic □ Diuretics, potential—synthesis and screening of 2-(2-thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole

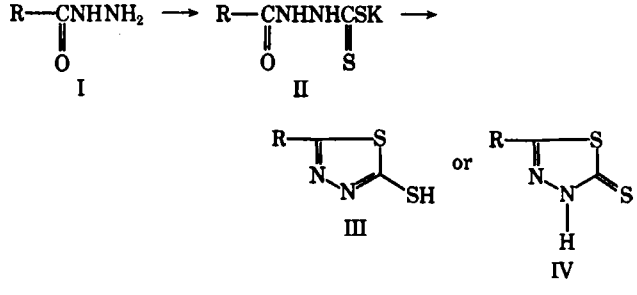
Thiazole and thiadiazole derivatives have been used successfully as diuretics (1–4). Synthesis of 2-acetylamino-1,3,4-thiadiazole-5-sulfonamide (acetazolamide) by Roblin and Clapp (1) led to many acetazolamide derivatives as potential diuretics (5, 6). Heterocyclic mono- and disulfonamides, particularly thiophene and benzothiophene analogs, thiazole and benzothiazole analogs, and thiazides have proved useful as diuretics (7).

These facts prompted us to synthesize a bicyclic thiadiazole to see the effect of the condensed thiadiazole and thiazole nucleus on diuretic activity. The compound synthesized exhibited significant diuretic activity.

DISCUSSION

Treatment of 2-thiophenecarboxylic acid hydrazide (I*a*) and phenylacetic acid hydrazide (I*b*) with carbon disulfide and potassium hydroxide gave the desired unstable potassium dithiocarbazates II*a* and II*b* (8). Without further purification, these salts were cyclized with boron trifluoride etherate (8) to give 2-(2-thienyl)-5-thio-1,3,4-thiadiazole (III*a*) and 2-benzyl-5-thio-1,3,4-thiadiazole (III*b*). The IR of Compounds III*a* and III*b* showed the presence of the (C=S) band at 7.55 μ, the (C—NH) band at 7.05 μ, and (NH) vibration at 3.5 μ, which is only compatible with thione Structures IV*a* and/or IV*b* (Scheme I).

Reaction of 1,3,4-thiadiazole-5-thiol with 2-halogeno ketones was found to be an effective route for the synthesis of a bicyclic system (V). 2-Substitution of the 1,3,4-thiadiazole nucleus had a pronounced effect on the ease of ring closure. Compound III*a* with phenacyl bromide gave 2-(2-thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole (V) using a 6-hr. reaction period (Scheme II). Under the same conditions, 2-benzyl-5-thio-1,3,4-thiadiazole (III*b*) gave an intermediate 2-benzyl-5-(phenacylthio)-1,3,4-thiadiazole (VI) (Scheme III). Increasing the reaction time to 24, 36, and 48 hr. resulted in the same product (VI). This observation can also be substantiated by the reaction of 2-furyl-5-thiol-1,3,4-thiadiazole with phenacyl bromide, which is not reported in this paper but was observed in this laboratory. This reaction also resulted in a compound



I*a*, II*a*, III*a*, and IV*a*: R = 
I*b*, II*b*, III*b*, and IV*b*: R = 
Scheme I

hydrates could be air milled, the author proceeded to prepare suspensions with air-milled hydrate to see if crystal growth still occurred. Work was done with I-hydrate, because at that time development work on II had been discontinued. A 2.5% suspension of air-milled I-hydrate was made (Table III) and observed for 2 years by microscopic examination and particle-size analysis. No evidence for crystal growth was observed.

This case history shows that suspensions are dynamic systems and that it is important to establish which forms are present at equilibrium. It shows that careful work is needed to identify these forms and prove that they can be processed to specifications prior to suspension formulation work. In addition, this report shows that satisfactory suspensions can be made with these equilibrium forms.

Bicyclic Thiadiazoles I: 2-(2-Thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole

MAN M. KOCHHAR[▲], MOHAMMAD SALAHI-ASBAHI, and BYRON B. WILLIAMS

Abstract □ 2-(2-Thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole was synthesized and evaluated for its diuretic action. The effect of 2-substitution on the ease of cyclization to a bicyclic system was studied. The carboxylic acid hydrazides were converted to dithiocarbazates which, on cyclization, gave 2-substituted 5-thio-1,3,4-thiadiazoles. Thiothiadiazoles were converted to the bicyclic system by the action of phenacyl bromide.

having a phenacylthio side chain. Attempts to cyclize VI with phosphoryl chloride in xylene were unsuccessful in this system (*9*, *10*). The identity of Compound V was established by NMR. The chemical shifts of C_6 and C_5 protons are δ 7.10 (s) and 2.50 (s), respectively.

PHARMACOLOGICAL EVALUATION

The diuretic activity of 2-(2-thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole (V) was studied in male Sprague-Dawley rats (165–190 g.) by measurement of the effect on the volume of urine and the urinary output of sodium and potassium. The test compound was suspended in 5% acacia and administered intramuscularly to five rats at a dose of 10 mg./kg. in a volume not exceeding 0.2 ml. Animal subjects were fasted for 18 hr. prior to use and were given a 5-ml. injection of 0.9% saline intraperitoneally immediately before the drug injection. They were housed individually in metabolism cages, and urine was collected in volumetric vessels. Levels were recorded at 60-min. intervals, and at the end of 6 hr. the final urine volumes were recorded and the sodium and potassium concentrations were determined by flame photometer. Control levels of urine volume and electrolyte output were recorded for each experimental rat prior to use in the evaluation of the experimental compound. Table I presents data from the studies described above.

Interval measurements of urine volume indicated that diuretic action began at approximately 4 hr. All mean values (volume, sodium, and potassium) were above control levels at 6 hr. Paired *t* tests, however, did not indicate statistical significance in the sodium output change.

EXPERIMENTAL[1]

2-(2-Thienyl)-5-thio-1,3,4-thiadiazole (IIIa)—To a solution of 2-thiophenecarboxylic acid hydrazide (*Ia*) (11.4 g., 0.08 mole) and potassium hydroxide (9.8 g.) in methanol (160 ml.) was added carbon disulfide (10 ml.). The solution was stirred at room temperature for 5 hr., diluted with cold ether (800 ml.), and cooled in the refrigerator for 2 hr. It was then filtered. The precipitate was washed with cold ether and dried. Without further purification, the potassium dithiocarbazate (*IIa*) [yield 15.2 g. (75%), m.p. 284–285°] was suspended in methylene chloride (750 ml.) under a nitrogen atmosphere. After 80 ml. of boron fluoride ethyl ether was added, the mixture was stirred for 18 hr., poured onto a mixture of ice and water, and extracted with ether. The ether layers were combined and extracted with potassium hydroxide (10%). The alkaline solution was acidified with cold hydrochloric acid (10%). A white precipitate formed which was filtered, washed with water, and dried. The crude product, on recrystallization from benzene, yielded 2.1 g. (17%) of analytical sample, m.p. 193–194°. The IR spectrum (KBr) showed absorptions at 6.50 and 6.70 (typical of thiadiazole), 7.55 (C=S), 7.05 (C—NH), and 3.50 (NH) μ.

Anal.—Calc. for $C_6H_4N_2S_2$: C, 35.97; H, 2.01; N, 13.98. Found: C, 36.02; H, 2.12; N, 13.83.

Similarly, 2-benzyl-5-thio-1,3,4-thiadiazole (*IIIb*) was obtained in 30% yield. Recrystallization from benzene afforded needles, m.p. 118–119°; IR (KBr): 6.40, 6.60, 7.60, and 7.00 μ.

Anal.—Calc. for $C_9H_8N_2S_2$: C, 51.89; H, 3.87; N, 13.45. Found: C, 51.80; H, 3.87; N, 13.62.

2-(2-Thienyl)-5-phenylthiazolo[2,3-*b*]-1,3,4-thiadiazole (V)—A solution of *IIIa* (1.0 g., 0.005 mole) and phenacyl bromide (1.0 g., 0.005 mole) in absolute ethanol (40 ml.) was refluxed for 6 hr. and left at room temperature for 3 days. Light-pink needles separated. Recrystallization from benzene afforded an analytical sample, m.p. 134–135°, yield 0.5 g. (32%); IR (KBr): 6.00, 6.30, 6.80, and 6.95 μ.

Anal.—Calc. for $C_{14}H_{10}N_2S_2$: C, 55.59; H, 3.33; N, 9.26. Found: C, 55.30; H, 3.23; N, 9.01.

2-Benzyl-5-(phenacylthio)-1,3,4-thiadiazole (VI)—A procedure similar to the one used for Compound V was followed. The reaction time was increased to 36 hr. The crude material, on recrystallization from benzene, gave a pure sample, m.p. 105–106°, yield 80%; IR (KBr): 5.80 (C=O), 6.30 (C=N), 6.40, and 6.75 μ.

Anal.—Calc. for $C_{17}H_{14}N_2OS_2$: C, 62.54; H, 4.32; N, 8.58. Found: C, 62.48; H, 4.10; N, 8.56.

Influence of Dosage Form on Antipyretic Activity of Acetaminophen Administered Intraperitoneally in the Rat

MICHAEL H. STOLAR▲, FREDERICK SIEGEL, and RALPH W. MORRIS

Abstract □ The relatively insoluble drug, acetaminophen, administered as a solution and injected intraperitoneally in rats, has been shown to produce an antipyretic response approximately twice that of the same dose administered as a suspension. This experiment indicates that ED_{50}, LD_{50}, and relative potency calculations may be inaccurately determined if dosage form influences on biological availability of insoluble drugs are not considered in the design and evaluation of animal drug testing procedures.

Keyphrases □ Acetaminophen—influence of dosage form on antipyretic activity, bioavailability, and potency calculations, intraperitoneal administration, rat □ Dosage forms—influence on antipyretic activity, bioavailability, and potency calculations, intraperitoneal acetaminophen administration, rat □ Antipyretic activity, acetaminophen—influence of dosage form, related potency calculations and bioavailability considerations, intraperitoneal administration, rat

Failure to maximize absorption of insoluble drugs by proper dosage form design may result in inaccurate determinations of drug potency and activity. The influence of dosage form design on drug activity has been extensively investigated in animals and man (1). The time course of a drug response has been shown to be influenced by factors other than the magnitude of the dose administered. Particle size, for example, has been demonstrated to have a striking effect on biological activity. Tablets prepared from micronized particles of spironolactone are approximately four times as potent as tablets made from coarser drug powders, illustrating that biological activity is generally inversely related to particle size (2).

Thus, it is apparent that improper dosage form design may produce significant alterations in the amount of drug available for transport to the site of action, *i.e.*, the bioavailability of the drug is altered. Drugs can only diffuse through membrane systems as single molecules[1]. A drug suspension consisting of an insoluble powder dispersed in a liquid vehicle (usually aqueous) represents not single molecular units but comparatively large aggregates of drug molecules held together by surface forces or crystalline bridges forming a particle. These particles are too large to diffuse through body membrane systems and must dissolve before absorption can occur. At a given time, the amount of drug in solution below the concentration at saturation is a function of the surface area of the particles, surface area being inversely related to particle size (3).

Such considerations are of importance primarily for drugs of limited aqueous solubility. Ingestion of a sugar cube would probably result in about the same blood level profile as a comparable dose of sugar syrup simply because the cube rapidly and completely dissolves in the GI fluids. With insoluble drugs, however, a significant amount of time is required for the particles to dissolve. The rate at which the primary drug particles dissolve, dissolution rate, is often the rate-limiting step for insoluble drugs in the absorption process. It is well established that the dissolution rate and, hence, the rate of absorption are directly related to particle surface area, which in turn is inversely related to particle size.

Administration of an insoluble drug as a solution rather than as a suspension increases, in effect, the surface area toward infinity and should theoretically produce faster absorption and higher blood levels of drug even though the total amount of drug ultimately absorbed may be the same for both dosage forms[2].

Investigations of the influence of dosage form in dose–response data have centered upon the oral and, to a lesser extent, the intramuscular and subcutaneous routes of administration. This is to be expected because these are the most common methods, along with the intravenous route, of administering drugs to humans. However, in many drug testing procedures involving animals, the preferred route of administration is the intraperitoneal route.

Inspection of the literature pertaining to drug screening procedures and bioassay shows that dosage form considerations are generally neglected. Typically, the testing of a group of drugs entails dissolving those drugs

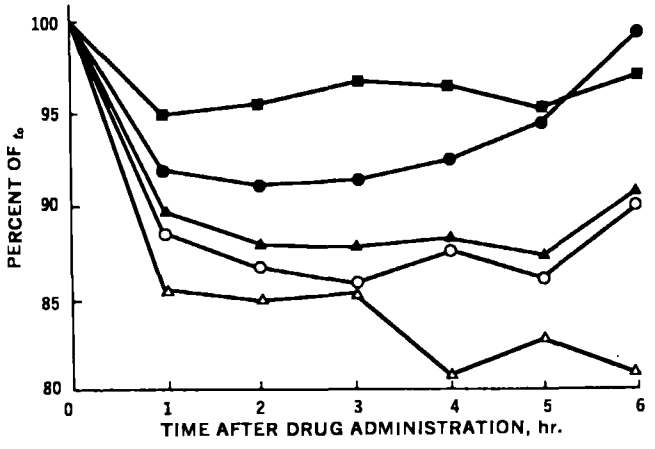

Figure 1—*Mean rectal temperature of rats expressed as percent of* t_0. *Key:* ○, *200 mg./kg. of solution;* △, *400 mg./kg. of solution;* ●, *200 mg./kg. of suspension;* ▲, *400 mg./kg. of suspension; and* ■, *control vehicle.*

[1] With the exception of special situations such as oral polio vaccine which is probably absorbed through the gut wall by a phagocytic process.

[2] Blood levels of drug are determined by a complex interrelationship between absorption, biotransformation, and excretion mechanisms; the level of drug in the body increases when the latter two are exceeded by the rate of absorption.

Table I—Analysis of Variance Table

Variation	*df*	*SS*	*MS*	*F*	*p*
Between formulations	4	0.05605	0.01401	55.4	<0.001
Group A *versus* Group C	1	0.00775	0.00775	30.6	<0.001
Group B *versus* Group D	1	0.00634	0.00634	25.1	<0.001
Between times	5	0.00265	0.000530	2.10	0.10
Interaction (formulation × time)	20	0.00586	0.000293	1.15	—
Between rats (error)	90	0.02276	0.000253	—	—
Total	119	0.08732	—	—	—

that are soluble and preparing simple tragacanth or methylcellulose suspensions of the insoluble drugs. Thus, the possibility exists that intraperitoneal injection of slightly soluble drugs as suspensions rather than solutions will result in reduced pharmacological activity by virtue of the fact that the rate of absorption and, therefore, the amount of drug absorbed during the test period is quite low, even though the peritoneal membranes present a large absorbing surface. This is a result of the particle-size considerations already discussed. It is conceivable then that a drug might be discarded as inactive due to the dosage form used in its evaluation rather than because of any inherent lack of biological activity. At the very least, the determination of parameters such as LD_{50} and ED_{50} will be in error. In this report, data are presented demonstrating the misleading results that may be obtained from a bioassay procedure if precautions to ensure optimum drug absorption are not observed.

EXPERIMENTAL

Acetaminophen[3] was used as a test drug since it is of limited aqueous solubility and possesses good antipyretic activity, a convenient response to measure. Twenty female, albino rats (approximately 300 g.) were marked and randomly divided (*via* a table of random numbers) into five groups of four animals each. Fever was produced in the rats by the subcutaneous injection of 15% brewer's yeast suspension at a dose of 1 ml./100 g. body weight (4). Three test formulations were prepared: a solution of acetaminophen in 75% propylene glycol, a 0.5% tragacanth suspension of acetaminophen in saline, and a control formulation containing the solution vehicle plus tragacanth but without acetaminophen.

Ten hours after the yeast injection, intraperitoneal injections were given to the rats as follows: Group A, acetaminophen solution, 200 mg./kg.; Group B, acetaminophen solution, 400 mg./kg.; Group C, acetaminophen suspension, 200 mg./kg.; Group D, acetaminophen suspension, 400 mg./kg.; and Group E, control vehicle at dosage volume equivalent to that of the 400-mg./kg. groups on a body weight basis.

Rectal temperatures of the animals were recorded[4] at 1-hr. intervals for 6 hr. Room temperature during the experiment was 24 ± 0.5°.

RESULTS AND DISCUSSION

Analysis of variance was used to analyze the results. The experimental differences tested were: (*a*) differences in response between all drug formulations and between Groups A and C and Groups B and D specifically (the primary objective of the experiment was to determine whether a dose of an insoluble drug administered intraperitoneally as a suspension would produce the same response when administered intraperitoneally as a solution), (*b*) differences in response between times after administration, *i.e.*, the change in antipyretic effect with time, and (*c*) interaction of formulation and time, *i.e.*, to determine if the differences in response between formulations would remain constant over the test period. If the interaction term was found to be significant, the specific interaction for formulations A *versus* C and B *versus* D would be tested.

Analysis of variance methods assume that the data are normally distributed and that the variances are homogeneous. Since dose–response data generally follow a log–normal curve, the dosage data were transformed to $\log_{10}$ values. Bartlett's test was used to test the data for homogeneity of variances. Chi-square was calculated to be 0.0718, a value that is not statistically significant ($\chi^2_{0.99(4)} = 0.297$). The variances are thus assumed to be equally distributed.

The temperature measurements were converted to percent of t_0, where t_0 = mean temperature of the rats at the time of drug injection. This transformation was corrected for the variation in fevers produced by the yeast. Figure 1 shows that injection of acetaminophen as a solution produces a much larger percent reduction in temperature than the corresponding dose administered as a suspension. A dose of 200 mg./kg. of solution produced approximately the same response as 400 mg./kg. given as a suspension.

The analysis of variance data are shown in Table I. The interaction term, although suggestive, is not statistically significant. Therefore, the variation between rats was used as the error term to test the other differences. Differences in antipyretic response between times after administration were found to be significant at the 0.10 level. This was to be expected, although the differences were somewhat less than anticipated. Formulation differences (the primary interest of this study) were highly significant at less than the 0.001 level.

The results demonstrate that an insoluble drug, upon intraperitoneal injection, will produce a greater biological response if administered as a solution rather than as a simple aqueous suspension. One may speculate that this is due to the large particle size of the suspended drug powder acting to decrease the amount of drug available for absorption during the test period. Calculation of ED_{50}, LD_{50}, and relative potency values may be adversely affected by neglect of dosage form design. Drug testing procedures involving the intraperitoneal injection of insoluble or slightly soluble drugs may thus be significantly improved by the simple procedure of altering the formulation vehicle.

New Compounds: Synthesis of 1-Aryl Substituted Hydantoins

JAY NEMATOLLAHI[▲], ZARINE MEHTA, and JOHN LANGSTON

Abstract □ A series of 1-aryl substituted hydantoins was synthesized by condensation of monosubstituted ureas and glyoxal. The method is facile and applicable for the preparation of 1-alkyl substituted hydantoins as well as analogs of the compounds.

Keyphrases □ Hydantoins, 1-aryl substituted—synthesis, condensation of monosubstituted ureas and glyoxal □ 1-Aryl-substituted hydantoins—synthesis, condensation of monosubstituted ureas and glyoxal

Because hydantoins manifest a variety of biological activities and function as intermediates in the preparation of some important organic compounds, their chemistry has been investigated extensively. Few reports of the chemistry of 1-aryl substituted hydantoins[1] (1), however, are available. This fact may be ascribed to the difficulty in synthesizing these compounds by the usual procedure involving reaction of an *N*-substituted glycine and an isocyanate.

This report describes a synthetic method for the synthesis of a few representative 1-aryl substituted hydantoins. The method is facile, unequivocal, and applicable to the synthesis of alkyl or aryl analogs of the compounds listed in Table I. It consists of an acid-catalyzed condensation of a substituted urea with glyoxal in relatively polar medium. Some small quantities (less than 5%) of a 1,3-disubstituted tetrahydroimidazo[4,5-*d*]imidazole-2,5-dione (2) and a 3-substituted hydantoin which were formed along with the 1-substituted isomer, were separated simply by fractional crystallization.

The structures of the compounds were elucidated by elemental analysis and spectral data. The NMR spectra were particularly useful both for determining the relative quantity of 1- and 3-substituted isomers present in the product of the reaction and for determining their structures. The peak positions at δ 4.6 and 4.4 (using trifluoroacetic acid as a solvent and sodium 2,2-dimethyl-2-silapentane-5-sulfonate as a reference) for CH_2 were assigned to 1- and 3-substituted hydantoins, respectively, based on comparison with the spectra of authentic samples of 3-substituted hydantoins (3).

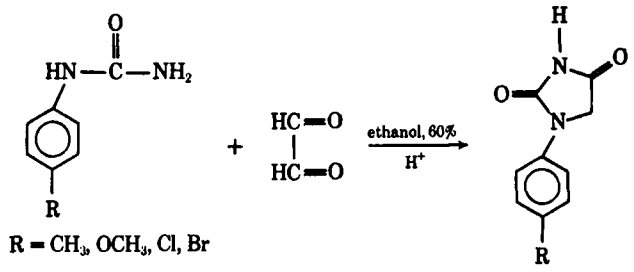
Four *para*-substituted 1-phenylureas, varying in electronic and steric properties, were prepared as representatives for the synthesis of 1-substituted hydantoins. The substituents are CH_3, OCH_3, Br, and Cl (Scheme I). The Hammett σ values for the first two groups are about the same; for Cl and Br, they are identical. The van der Waals' radii for CH_3 and Br are about the same. An analysis of the experimental results using reactants containing such electronic and steric factors is envisaged to contribute both to the synthetic and mechanistic aspects of the urea–glyoxal condensation reaction. So far, the data obtained from this particular series of reactions seem to indicate that

[1] The report by A. Hill *et al.*, *J. Amer. Chem. Soc.*, **44**, 2357(1922), of the synthesis of 3-substituted hydantoins, erroneously designated them as 1-substituted hydantoins.



Scheme I

the nature or the yield of the reaction products is not influenced significantly by either factor.

EXPERIMENTAL[3]

The preparation of compounds listed in Table I is exemplified by the following method described for 1-*p*-methylphenylhydantoin (I).

To a hot solution of 3.0 g. (0.02 mole) of *p*-tolylurea in 50 ml. of 50% ethanol was added 1.56 g. (0.02 mole) of 80% glyoxal, followed by 10 ml. of a 10% solution of hydrochloric acid in ethanol. The solution was heated under reflux for 6–10 hr. A solid that formed was separated from the hot reaction medium to give 1.05 g. of first crop, whose NMR spectrum indicated that it was a mixture of I containing less than 5% 1,4-di-*p*-tolyltetrahydroimidazo[4,5-*d*]imidazole-2,5-dione. Crystallization of this crop from methanol gave 0.9 g. of pure I. The filtrate from the reaction mixture was allowed to remain at room temperature for about 2 hr., at which time an additional 0.4 g. of solid was separated. This crop was identified to be I. A third crop, 0.5 g., obtained after complete evaporation of filtrate, contained about 10% of the 3-substituted isomer of I. Crystallization of this crop from methanol gave 0.3 g. of pure I. The combined yield of I was 1.6 g. (43%), m.p. 212–214°. Microanalysis is recorded in Table I.

[3] Melting points were determined on a Thomas-Hoover apparatus and are uncorrected. The NMR spectra were determined on a Perkin-Elmer R-12. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate was used as a reference; trifluoroacetic acid was used as a solvent except for Compound II for which dimethyl sulfoxide was used. The IR spectra were determined in KBr disk with a Beckman IR-8 instrument.

Effect of Chain Length in Homologous Series of Anionic Surfactants on Irritant Action and Toxicity

Keyphrases □ Chain length effect—irritant action and toxicity of homologous series of anionic surfactants □ Surfactants, anionic—effect of chain length in homologous series on irritant action and toxicity □ Toxicity, anionic surfactants—effect of chain length in homologous series □ Irritant action, anionic surfactants—effect of chain length in homologous series □ Skin—effect of chain length of anionic surfactants on swelling and irritant action

Sir:

Among the investigations into the irritant action and toxicity of homologous series of anionic surfactants containing a single normal alkyl chain are the following. Choman investigated the swelling of human skin in solutions of sodium alkyl sulfates (1) and the swelling of dermal collagen of calf in sodium soaps (2). Edwards (3) studied the effect of sodium soaps on the lysis of red blood cells and on segments of earthworms, while Emery and Edwards (4) studied their irritant action on human skin. Gale and Scott (5) investigated the intraperitoneal and oral toxicity of sodium alkyl sulfates as well as their effects on various types of muscles. In these and other investigations, the greatest effects among the sodium alkyl sulfates ranging from octyl to octadecyl were shown by the dodecyl sulfate. In the series of soaps ranging from sodium octanoate to stearate, sodium laurate displayed the highest activity. Representative curves are shown in Figs. 1 and 2. Figure 1 refers to the net swelling, *i.e.*, swelling in the surfactant solutions minus swelling in pure water, measured as increase in thickness. The surfactant solutions were at or slightly above the CMC.

The purpose of this communication is to present a hypothesis to explain the maximum effectiveness observed for intermediate members of the homologous series. Maxima or minima in the relationship between two variables often arise from the effect of two opposing factors on these variables, one of which tends to enhance the relationship while the other tends to diminish it. In the present case, one of the two factors affecting the relationship between the length of the alkyl chain of

anionic surfactants and their interaction with proteins is the oil–water partition coefficient P. The other factor is the upper limit of the concentration of nonassociated surfactant molecules attainable in the aqueous phase, given by the surfactant solubility below the Krafft point and by the CMC above it.

Oil–Water Partition Coefficients—Partition coefficients of ionic surfactants between octanol and water increase monotonically within a given homologous series. Augmenting the chain length by an ethylene group increased log P by about 0.8 (6). According to:

$$\Delta G = -RT \ln P \qquad \text{(Eq. 1)}$$

the free energy of transfer of an ethylene group from water to octanol at room temperature is −1090 cal./mole. This estimate assumes that the ionic surfactants are equally ionized in water and in octanol. Despite the fact that the water concentration in octanol saturated with water is 2.3 M (more than 25 mole-%) (6), which should lead to considerable ionization of the surfactant molecules in the oil phase, the true P values are probably lower than the apparent partition coefficients obtained from analytical data. Nevertheless, the ΔG value is in reasonable agreement with the value of −1280 cal./mole corresponding to the transfer of an ethylene group from water to the hydrocarbon interior of a micelle (7). Part of the difference is probably due to the fact that the transition from water to octanol saturated with water is less abrupt than that from water to a liquid paraffinic hydrocarbon. Similarly, it is seen from Table I that the CMC decreases approximately by a factor of 4 in a homologous series for each increase in the chain length by an ethylene group; log 4 = 0.6 is reasonably close to the corresponding increase of 0.8 in log P.

According to the hypothesis of this communication, the increase in the oil–water partition coefficient with increasing chain length n is responsible for the ascending branches of the curves in Figs. 1 and 2. In the physiological situations, the oil phase in contact with the aqueous surfactant solutions consists of collagen, skin, muscle tissue, erythrocyte membrane, *etc.*

Limiting Monomer Activity—In all likelihood, only monomeric or nonmicellar surfactant molecules enter the "oil" (collagen, skin, or muscle tissue) phase or interact with erythrocyte membranes. The upper limit

for the concentration of nonassociated surfactant molecules is the solubility limit at temperatures below the Krafft point and the CMC above it. The solubility at the Krafft point is equal to the CMC (7). The monomer activity of aqueous surfactant solutions increases only slightly after the overall concentration has been raised above the CMC because the bulk of the surfactant added in excess of the CMC forms micelles. CMC values and Krafft points for two homologous series of anionic surfactants are assembled in Table I.

As the alkyl chain length increases on ascending a homologous series, there is a monotonic decrease in the maximum concentration of single or nonmicellar surfactant species owing to a decrease in solubility or in the CMC. This effect is responsible for the downturn in the curves of Figs. 1 and 2. This reasoning is only valid if, at temperatures above the Krafft point, the surfactant concentrations in the aqueous phase are equal to or exceed the CMC values.

Conclusion—With the oil–water partition coefficient increasing and the limiting monomer concentration decreasing on ascending a homologous series, a maximum surfactant concentration in the "oil" (collagen, skin, muscle tissue, or erythrocyte membrane) phase is found at an intermediate chain length. As a result, a surfactant of intermediate chain length has the greatest irritant, toxic, or hemolytic effectiveness.

It is to be expected that the chain length for maximum effectiveness within each homologous series depends on the hydrophilicity of the polar headgroup, being greater for the more hydrophilic groups. The $—O—SO_3^-\ Na^+$ group is more hydrophilic than the $—COO^-\ Na^+$ group. The most active alkyl sulfate was found to be the dodecyl ester ($m = n = 12$), whereas sodium laurate ($m = 12$ but $n = 11$) was the most active soap. Unfortunately, only surfactants with even numbers m of carbon atoms were investigated in the two homologous series, making the most effective member among the alkyl sulfates the one with $n = 12 \pm 1$ and among the soaps the one with $n = 11 \pm 1$; n is the number of carbon atoms in the alkyl chain.

Since the increase in P and the decrease in the CMC as a function of n are of comparable magnitude, the ascending and descending branches of curves like the ones of Figs. 1 and 2 should have slopes of comparable absolute values though of opposite signs, as long as the experimental temperatures exceed the Krafft points.

Trichloroacetate	—	97

[a] Mean of five rats ± one standard deviation.

unlabeled, was verified by high-voltage electrophoresis. All other chemicals were reagent or scintillation grade. Tritium-labeled I and sufficient unlabeled drug were dissolved in isotonic buffer to give a concentration of 0.4 mg./ml. The buffer (pH 7.4) contained sodium bicarbonate (26 m*M*), potassium chloride (5 m*M*), potassium acid phosphate (1 m*M*), and either sodium chloride, sodium salicylate, or sodium trichloroacetate (122 m*M*). Trichloroacetate solutions were prepared by dissolving equimolar quantities of sodium hydroxide and trichloroacetic acid in water. The molar ratio of anion (*i.e.*, salicylate or trichloroacetate) to drug was about 90:1.

Male Sprague–Dawley rats, weighing about 300 g. and fasted for 24 hr., were anesthetized with ethyl carbamate (1.3 g./kg. i.p.) and prepared as described by Doluisio *et al.* (8) for studying drug absorption from the *in situ* small intestine. Seven milliliters of drug solution was placed in the intestine, and 0.1-ml. samples were removed at 5-min. intervals for 15 min. The volume of the luminal solution was maintained constant by adding buffer immediately prior to sample removal. In a second series of experiments, the renal pedicles as well as the bile duct were ligated, and loss of drug from the intestinal lumen was followed for 30 min. At the end of the absorption period, blood was collected by cardiac puncture and centrifuged for 10 min. at 575 × *g* to obtain the plasma.

Tritium levels were determined by liquid scintillation spectrometry[3]. Scintillation fluid was prepared by dissolving 0.28 g. 1,4-bis[2-(5-phenyloxazolyl)]benzene, 9.46 g. 2,5-diphenyloxazole, and 142 g. naphthalene in 946 ml. dioxane and 50 ml. water. Two-tenths-milliliter samples of plasma were added to 15 ml. scintillation fluid and counted for 100 min.; raw counts were 500–2000 above background. Half-milliliter samples of diluted intestinal perfusate were counted in 15 ml. of scintillation fluid to 10^5 counts. Tritiated water was used as an internal standard; the efficiency of the system was 32% for tritium in buffer, plasma, and intestinal solution.

The results of the absorption studies are summarized in Table I. Both salicylate and trichloroacetate significantly enhance the disappearance of I from the intestinal lumen. Both anionic agents exert their greatest influence on the initial absorption rate of the drug and, thereafter, the effect tends to decline with time. Throughout the experiment, trichloroacetate was slightly more effective than salicylate in enhancing the absorption of I. Determination of tritium levels in the plasma immediately after the 30-min. absorption studies (Table II) clearly showed that the enhanced loss of I from the intestinal perfusate containing salicylate results in substantially higher apparent drug levels in the body. Salicylate concentration in the plasma at the same time averaged about 1.1 mg./ml. Since most of the apparent drug in whole blood is associated with the nonserum fraction, there was some concern that the elevated levels of I in plasma containing salicylate might be due to displacement of the quaternary ammonium compound from the formed elements of the blood. This possibility was ruled out by demonstrating equal concentrations of I in the plasma of whole blood spiked with drug and of whole blood spiked with both drug and salicylate.

The absorption and plasma level data are in general agreement with equilibrium partitioning data (Table II). Both salicylate and trichloroacetate significantly increase the apparent butanol–water partition coefficient of I, with trichloroacetate being somewhat more effective. The results of our investigations are quite encouraging and offer the possibility of substantially improving the bioavailability of quaternary ammonium compounds and other highly ionized drugs.

Tumor Inhibitory Agent from *Magnolia grandiflora* (Magnoliaceae) I: Parthenolide

Keyphrases ☐ *Magnolia grandiflora* L.—isolation, identification of parthenolide, antitumor activity ☐ Parthenolide—isolation, identification from *Magnolia grandiflora*, antitumor activity ☐ Antitumor activity—evaluation of parthenolide, isolated and identified from *Magnolia grandiflora*

Sir:

As a result of the continuing search for plants having tumor-inhibiting constituents, it was found that the petroleum ether extract of the leaves and stems of *Magnolia grandiflora* L.[1] showed inhibitory activity toward the human epidermoid carcinoma of the nasopharynx test system (9KB cell culture)[2].

A preliminary examination of the petroleum ether extract revealed one major component. This component was isolated and shown to be the active constituent. The isolation was effected by solvent extraction followed by silica gel G, dry column chromatography. The compound was identified as parthenolide by means of its melting point; mixed melting point; IR, mass spectrometry, NMR, and elemental analyses; and comparison with an authentic sample[3]. The compound demonstrated activity at a dilution level of 2.3×10^1 mcg./ml. Activity in the 9KB cell culture is defined as ED_{50} less than or equal to a dilution of 20 mcg./ml. for plant extracts. The results are expressed as a dose that inhibits growth to 50% of the control growth 3 days after drug addition (1).

The dried leaves and stems (7 kg.) were ground, placed in a Lloyd-type extractor, and exhaustively extracted with petroleum ether (b.p. 40–60°). After removal of the solvent, the residue (160 g.) was treated several times with petroleum ether (b.p. 40–60°). The material obtained from the solution was inactive and, therefore, was discarded. The crystalline insoluble portion (30 g.) was further purified by use of silica gel G, dry column chromatography. Seven grams of the crystalline petroleum ether-insoluble material was placed on a silica gel G column and eluted with dichloromethane–benzene–ethyl acetate (12:24:3). Forty 10-ml. fractions were collected. On the basis of TLC (silica gel G, dichloromethane–benzene–ethyl acetate, 12:24:3), fractions 20–39, which showed a single spot, were combined. The solvent was removed, the residue was dissolved in chloroform and treated with activated charcoal[4], and excess ether was added after evaporation of most of the solvent. A crystalline precipitate (2.9 g.) occurred which was identified as parthenolide (2).

[1] The plant was collected on the campus of the University of Arizona, Tucson, Ariz., in January 1969. Identification was confirmed by Robert J. Barr, College of Pharmacy, and Dr. Charles Mason, Botany Department, University of Arizona. A reference specimen was also deposited in the University of Arizona Herbarium.

Simple Method for Portal Vein Infusion in the Rat

Keyphrases ☐ Portal vein infusion method—used to study first-pass effect in rats ☐ First-pass effect—studied using simple method for portal vein infusion, rats ☐ Absorption, first-pass effect—studied using simple method for portal vein infusion, rats

Sir:

The rate and extent of drug absorption into the systemic circulation have been estimated by pharmacokinetic analysis of plasma concentration–time data or urinary excretion data (1, 2). The percent of absorption can be assessed by comparison of the relative areas under the plasma concentration–time curves after oral and intravenous administration. This method is based on the presumptions that the distribution and elimination of a drug may be expressed in terms of first-order kinetics within the dose range studied and that the parameters of the distribution and elimination remain constant after administering the same quantity of drug by different routes. Thus, the resultant areas are independent of the route of administration and proportional to the dose even when given by different routes. However, it was recently shown that the areas under the blood level–time curves for aspirin (3) and lidocaine (4) after infusion into a peripheral vein were considerably greater as compared with results observed after infusion of an equal dose into the portal vein in dogs. The reduction in area under the blood level–time curves after portal vein infusion has been attributed to a significant degree of metabolism of the drugs during the first passage through the liver.

In this communication, we report a simple method for portal vein infusion in the rat to study the first-pass

Simple Method for Portal Vein Infusion in the Rat

Keyphrases ☐ Portal vein infusion method—used to study first-pass effect in rats ☐ First-pass effect—studied using simple method for portal vein infusion, rats ☐ Absorption, first-pass effect—studied using simple method for portal vein infusion, rats

Sir:

The rate and extent of drug absorption into the systemic circulation have been estimated by pharmacokinetic analysis of plasma concentration–time data or urinary excretion data (1, 2). The percent of absorption can be assessed by comparison of the relative areas under the plasma concentration–time curves after oral and intravenous administration. This method is based on the presumptions that the distribution and elimination of a drug may be expressed in terms of first-order kinetics within the dose range studied and that the parameters of the distribution and elimination remain constant after administering the same quantity of drug by different routes. Thus, the resultant areas are independent of the route of administration and proportional to the dose even when given by different routes. However, it was recently shown that the areas under the blood level–time curves for aspirin (3) and lidocaine (4) after infusion into a peripheral vein were considerably greater as compared with results observed after infusion of an equal dose into the portal vein in dogs. The reduction in area under the blood level–time curves after portal vein infusion has been attributed to a significant degree of metabolism of the drugs during the first passage through the liver.

In this communication, we report a simple method for portal vein infusion in the rat to study the first-pass

effect, using propranolol as a test compound. The method consists of cannulation into the pyloric vein. A rat weighing 200–240 g. was anesthetized lightly with ether at suitable intervals, and the abdomen was opened through a midline incision. The pyloric vein was exposed by pushing aside the duodenum of the intestine, and a minimal amount of connective tissue was removed from the pyloric vein to facilitate ligation. The pyloric vein was then ligated approximately 0.7 cm. distal to the junction of the pyloric vein and hepatic portal vein. A cannula (polyethylene tubing, 0.04-cm. i.d., 0.06-cm. o.d., 7-cm. length), filled with heparin solution (200 units/ml.) and closed with an arterial clamp at the other end, was inserted into the pyloric vein, approximately 0.2 cm. proximal to the ligature, after careful venous puncture using a needle point. The cannula was gently guided upward into the portal vein so that its tip projected several millimeters into the vein (Fig. 1). The cannula was secured by ligation with nylon suture. A syringe was attached to the end of the cannula, and it was then confirmed that the portal blood could be detected in the cannula with a slight suction. The abdominal incision was closed, and the syringe was replaced by another syringe containing infused solution. After the end of the infusion experiment, it is desirable to inject methylene blue solution at an appropriate concentration into the cannula and to observe the liver stained with the dye in order to check for lack of leakage during infusion.

Propranolol was administered to rats by rapid infusion into the femoral vein or by constant infusion into the hepatic portal vein during 50 min. using an infusion pump. Blood samples (0.1–0.2 ml.) were taken at various intervals through a cannula inserted into the femoral artery and were diluted with 1.0 ml. of water prior to extraction. The propranolol concentrations in whole blood were determined spectrophotofluorometrically by a minor modification of the method of Shand *et al.* (5). The fluorescence of propranolol in 0.1 *N* HCl was measured in a spectrophotofluorometer[1] (maximum excitation 295 nm., maximum emission 360 nm.). An equal volume of blood to sampled blood was transfused each time by an intravenous infusion. The blood for transfusion was taken from another rat of the same strain.

The blood concentration–time curve after intravenous administration was described in all rats by a biexponential equation of the form $C = Ae^{-\alpha t} + Be^{-\beta t}$. Table I lists the mean areas under the blood concentration–time curves after intravenous and portal vein infusion. The data show that the mean areas under the blood concentration–time curves after portal vein infusion were found to be 7.8 (2.5 mg./kg.) and 90.9% (12.5 mg./kg.) of the mean areas of the corresponding intravenous infusion curves. Although the area under the blood concentration–time curve after intravenous administration was directly proportional to the dose, the mean area obtained after portal vein infusion at a dose of 2.5 mg./kg. was less than 10% of the mean area of intravenous infusion at an equal dose. Shand *et al.* (5) reported that, in the same human subjects, propranolol reaching the systemic circulation was estimated to be 16–60% of an oral dose from the ratio of the areas under the plasma concentration curves after oral and intravenous administration. After oral administration of doses less than 30 mg., only trace amounts of propranolol were detected in the systemic circulation in six human subjects, while the area under the blood concentration–time curve was linearly related to dose with oral doses exceeding 40 mg. (6). The results in rats show that the clearance of propranolol from the portal circulation during its first passage through the liver can explain the significant reduction of the area under the curve at the lower dose.

Table I—Mean Areas under Blood Concentration–Time Curves after Rapid Intravenous and Constant Portal Vein Infusion of Propranolol

Administration Route[a]	Dose, mg./kg.	Number of Rats	Area Mean ± *SE*, ng. min./ml.	Relative Area
Intravenous	2.5	3	52746 ± 3937[b]	1.0
	12.5	3	260546 ± 19245[b]	4.9[c]
Intraportal	2.5	5	4129 ± 750[d]	0.078[e]
	12.5	5	236837 ± 21946[d]	0.909[e]

[a] Intravenous doses were given within 30 sec. into the femoral vein, and intraportal doses were given at a constant rate during 50 min. into the hepatic portal vein. [b] Calculated as $(A/\alpha + B/\beta)$. [c] Compared with the area for an intravenous dose of 2.5 mg./kg. [d] Calculated using the trapezoidal rule. The area for the tail end after the last sampling at a dose of 12.5 mg./kg. was calculated by C_t/β, where C_t is the blood concentration at time t, and the rate constant β was estimated from the terminal slope of a semilogarithmic plot of the blood concentrations of propranolol after the end of infusion. [e] Compared with the areas for the corresponding intravenous doses. Significantly different at a dose of 2.5 mg./kg. ($p < 0.001$) and not significantly different at a dose of 12.5 mg./kg. ($p < 0.4$).

Administration of a drug into the portal vein blood has been attempted only in the dog to study differences in areas under blood level–time curves as a function of route of administration (3, 4). In these reports, a cannula was introduced into the hepatic portal vein through a branch of the splenic vein (3) or a tributary of the superior mesenteric vein (4). The method for sampling portal vein blood presented by Pelzmann and Havemeyer (7) could be used for administering a drug into

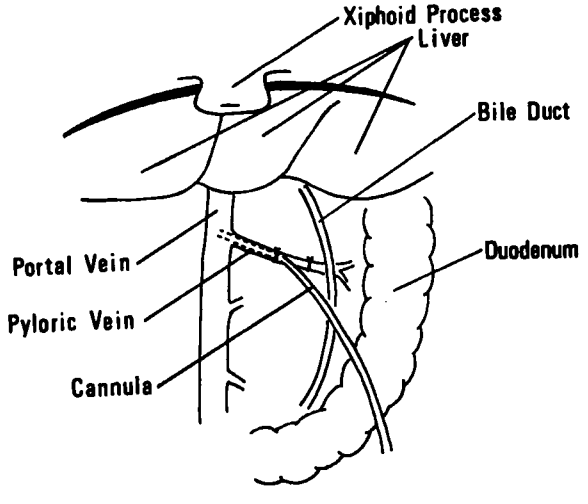

Figure 1—*Representation of pyloric vein cannulation. Mesenteries were retracted to show the cannulation.*

[1] Hitachi model 203.

the portal vein of the rat. However, the portal vein infusion using the pyloric vein cannulation overcomes several disadvantages inherent in the use of direct cannulation into the portal vein, since the latter surgery is delicate, requiring speed and accuracy to prevent excessive engorgement of the intestinal veins and acute loss of blood in the liver. The pyloric vein was selected because of its accessibility and a suitable branch of the hepatic portal vein to facilitate cannulation. The method for portal vein infusion in this communication is simple and practical as compared with that in the dog. This procedure in the rat has proven useful in drug absorption and metabolism studies. Details of these studies will be reported elsewhere.

BOOKS

REVIEWS

Amino-Acids, Peptides, and Proteins. A Specialist Periodical Report. Volume 3. G. T. YOUNG, Senior Reporter. The Chemical Society, London, WIV OBN, England, 1971. xiv + 379 pp. 14.5 × 22 cm. Price $6.00.

This third volume continues the annual review of the literature in the field of amino acids, peptides, and proteins, covering about 2300 papers published mostly in 1970. Under the editorship of G. T. Young from Oxford (who is called "senior reporter" in the Chemical Society's terminology), a group of 15 "reporters" summarize the developments during 1970 in 5 chapters, giving brief abstracts of the papers or mere one line notations, depending on the significance ascribed to the publication. Chapter 1 by B. W. Bycroft covers amino acids (30 pages) in a rather readable fashion. Chapter 2, "Structural Investigation of Peptides and Proteins," takes up most of the space (188 pages). It involves a number of contributors and includes extensive coverage of the work on sequencing and X-ray crystallography of proteins. Chapter 3, "Peptide Synthesis" (57 pages), by J. H. Jones opens with some statistics to document the reporter's contention that essentially all the important news on this topic can be covered by monitoring 25 primary journals. The last two chapters discuss "Peptides with Structural Features not Typical of Proteins" (47 pages) and "Metal Derivatives of Amino-acids, Peptides, and Protein" (36 pages), the latter covering the two-year period of 1969–1970.

The volume is in keeping with the high standards which one has come to expect of the "Specialist Periodical Reports." The reviewer is not expert enough to judge whether the coverage is complete but at least did not notice any major omissions. As is almost unavoidable in a compilation of a huge amount of material like this, occasional errors do creep in, although the number seems to be quite small. One picky little example (as the customary documentation that the reviewer has read the book): A table on page 13 lists among α-amino acids which have been synthesized for the first time, 5-fluorotryptophan with a 1969 reference, a compound which this reviewer has bought as a catalog item from a commercial supplier as far back as 1963. This leads me to what I consider the main shortcoming of this type of publication. The information in the literature is strictly "reported" including many of the claims of the original authors, leaving essentially all the evaluation of the work to the reader. Since many claims take on a stronger flair of truth if they are repeated by third parties, this means that unless the reader goes back to the original literature, he may be left with some conclusions which are not as soundly based as he may think. While this referee would prefer a more critical review of the literature, the contributors usually stick to their assigned role as impartial reporters, with a few notable exceptions (*e.g.*, Jones on pages 247 and 248).

This difference in taste notwithstanding, the reviewer feels that this volume belongs on the bookshelf of every chemist and medicinal chemist who has anything to do with amino acids or their polymers since it is one of the most comprehensive sources of information in this field.

The information in the literature is strictly "reported" including many of the claims of the original authors, leaving essentially all the evaluation of the work to the reader. Since many claims take on a stronger flair of truth if they are repeated by third parties, this means that unless the reader goes back to the original literature, he may be left with some conclusions which are not as soundly based as he may think. While this referee would prefer a more critical review of the literature, the contributors usually stick to their assigned role as impartial reporters, with a few notable exceptions (*e.g.*, Jones on pages 247 and 248).

This difference in taste notwithstanding, the reviewer feels that this volume belongs on the bookshelf of every chemist and medicinal chemist who has anything to do with amino acids or their polymers since it is one of the most comprehensive sources of information in this field.

Food Chemicals Codex, Second Edition. Prepared by the Committee on Specifications, Food Chemicals Codex, of the Committee on Food Protection, National Research Council, National Academy of Sciences, 2101 Constitution Ave., N.W., Washington, DC 20418, 1972. 1039 pp. 15 × 23 cm. Price $20.00.

This edition, slightly larger than the first, contains 639 monographs. Monographs are provided for chemicals added directly to food to perform some desired function as well as substances

not added directly to food but which come into contact with food, such as food processing aids. Also, monographs for a number of substances that are not considered "chemical additives" in the conventional sense have been included, such as masticatory substances.

Specifications set forth in this publication were developed with the cooperation of individual suppliers of food-grade chemicals and with industrial trade organizations.

The Food Chemicals Codex was given official recognition by the U. S. Food and Drug Administration when the "Definitions and Procedural and Interpretative Regulations," relating to the eligibility of substances for classification as generally recognized as safe (GRAS), were revised and published in the *Federal Register* on June 25, 1971.

Supplements to the Codex are issued annually and sent to all holders of the book at no charge.

WHO Expert Committee on Specifications for Pharmaceutical Preparations, Twenty-fourth Report. World Health Organization Technical Report Series. World Health Organization, Geneva, Switzerland (available from American Public Health Association, Inc., 1015 18th St., N.W., Washington, DC 20036), 1972. 60 pp. 16 × 24 cm. Price $1.50.

This report provides a review of the work necessary relative to a general revision of the "International Pharmacopoeia," international reference standards, and new monographs. Three annexes cover 33 new monographs, amendments to manufacturing practices, and a modified method for the determination of morphine in opium, respectively.

Carbon–Fluorine Compounds: Chemistry, Biochemistry & Biological Activities. A Ciba Foundation Symposium. Associated Scientific Publishers, 52 Vanderbilt Ave., New York, NY 10017, 1972. 417 pp. 16 × 24 cm.

The proceedings of this symposium, held in September 1971, represent an interdisciplinary approach to carbon–fluorine chemistry. Topics covered in this volume include a review of the reactivity of the carbon–fluorine bond and its physical characteristics, the toxic effects of carbon–fluorine compounds (particularly the fluoroacetates and fluorocitrates), and the role of fluoro analogs in protein biosynthesis or inhibition.

The synthesis of fluorocarbohydrates and their physiochemical properties are discussed. Of possible particular interest to the pharmaceutical scientist are the discussions of the metabolism, transport, and increasing use of NMR properties of fluoroanalogs for binding studies and structural identification of macromolecules. The involvement of fluoronucleotides in modifying nucleic acid synthesis and its relevance to virus replication are also covered.

Oral Contraceptives: Therapeutics *versus* Adverse Reactions, with an Outlook for the Future II*

A. S. BINGEL▲ and P. S. BENOIT

ADVERSE REACTIONS: OTHER EFFECTS

Cancer and Hyperplasia—The historical developments that led to the theory that steroid hormones might play a role in the etiology and pathogenesis of cancer were reviewed in 1967 by Hertz (163). He discussed the pertinent animal and human studies prior to that time. It was evident from this review that the steroid hormones were able to induce cancer in various tissues of some nonhuman species. However, at that time, data from clinical observations were inadequate to determine whether or not similar effects were produced in humans. The inadequacy of the data resulted from several factors: (*a*) most of the studies had been uncontrolled, (*b*) the populations involved were lacking in sufficient numbers to provide statistically adequate samples, and (*c*) the periods of observation had been too short to allow for the usually long latent period for carcinogenesis in humans. Subsequent studies (*vide infra*), including those reviewed by Goldzieher (80) in 1970, have served to demonstrate further that no simple relationship exists between estrogens, with or without a progestagen, and breast or genital cancer in the human.

Hyperplasia of the uterine cervix was reported in a total of 35 oral contraceptive users (164–166) and in five pregnant patients (166). The distinctive lesion, characterized by atypical polypoid endocervical hyperplasia, had not been recognized previously (164). Of importance was the fact that this lesion resembled adenocarcinoma (164), and an erroneous diagnosis of the latter had been made initially in some instances (165).

The incidence of general atypical cytology of the genital tract has been reported. Kline *et al.* (167) compared cytological smears from the genital tracts of 2296 oral contraceptive users with smears from the genital tracts of a comparable group of 17,724 nonusers. The duration of oral contraceptive use ranged from 2 months to 7 years. A 2.0% incidence of atypical cells was found in the oral contraceptive group and a 1.0% incidence was found in the controls. A significant difference ($p < 0.01$) between the two groups was found for patients less than 30 years of age. The possibility that these atypical manifestations might be precancerous was discussed; observations that their course is unpredictable argues in favor of continuous followup of patients exhibiting them.

Dougherty (168) reported the results of a study of 1983 women who had used sequential oral contraceptives for 0–92 menstrual cycles. He found that the occurrence of atypical cytology in treated patients was twice as high as expected but that the length of time of exposure to the oral contraceptives did not affect the incidence rate of atypical cytology. No patients developed adenocarcinoma during the study.

* *Editor's note:* Part I of this article appeared in the February 1973 issue of the *Journal of Pharmaceutical Sciences.*

Melamed *et al.* (169) compared the prevalence rate of carcinoma *in situ* between two groups of patients: 27,508 women using oral contraceptives and 6809 using the diaphragm. A small difference was found between the two groups, which suggested a higher rate in oral contraceptive users. This difference, however, could have been due to a decreased prevalence rate for women using the diaphragm (a possible protective barrier effect) and/or to an increased rate in oral contraceptive users. The initial observations had shown this apparent difference also, but prior contraceptive use was not reported.

Interestingly, Stern *et al.* (170) found a significant association of cervical dysplasia with contraceptive choice. The prevalence of dysplasia among women from an apparently homogeneous population, who chose oral contraceptives, was 82/1000; among choosers of intrauterine devices, it was 51/1000; and among choosers of other methods, it was 36/1000. These observations emphasize the importance of making genital tract examinations prior to starting women on oral contraceptives, particularly if an association between the latter and cervical cancer is to be proven or disproven.

The data from a 5-year family planning clinic study of cervical epithelial changes during oral contraceptive use were reported by Chai *et al.* (171). Smears from 14 of 4164 women who had been using various oral contraceptives for 0–3 years were found to be positive, *i.e.*, suggestive of severe dysplasia or carcinoma *in situ*. Of the 14, followup was lacking in four. Of the other 10, there were six cases of carcinoma *in situ*, one of moderate dysplasia, one of severe dysplasia, and two of chronic cervicitis. The incidence rate in the oral contraceptive users was compared with that in a group of 30,834 women who were attending other clinics in the same medical center. The incidence rates of positive findings per 1000 were calculated to be 3.36 for the oral contraceptive users and 6.32 for the other group; the corresponding rates for carcinoma *in situ* were 0.96/1000 and 1.68/1000, respectively. No information was given concerning the health status or drug usage of the women attending the other clinics, but at least cervical abnormalities did not appear to be greater in the family planning clinic oral contraceptive users.

Nichols and Fidler (172) examined 128 consecutive cone biopsies that had been taken from patients because of suspicious or positive cytologic findings. Microglandular hyperplasia was found in 24% of the entire series, and the greater proportion of the patients with this condition had been oral contraceptive users. On the other hand, there was no significant difference between users and nonusers with respect to the degree or duration of cytologic squamous dyskaryosis or malignant change.

In 1972 the results were reported of an 8-year prospective study (173) involving the largest group of oral contraceptive users observed thus far for abnormal cervical cytology. The 9634 women were assigned either to an oral group (4846) or a nonoral group (4788) according to a predetermined random procedure. Those in the oral group took norethynodrel with mestranol; those in the nonoral group used other contraceptive methods, excluding intrauterine devices. Requirements for admission into the study included the following: (*a*) age between 21 and 39 years, (*b*) at least one normal pregnancy prior to admission, and (*c*) no previous use of oral contraceptives or intrauterine devices. Excluded were individuals who had a history of serious illness including neoplastic disease, those who were bedridden, and those who had a life expectancy of less than 5 years. At the initial interview the women were given a general physical and a gynecological examination; thereafter, the women returned every 2 months for interviews and annually for a physical examination.

Changes in cervical cytology, *i.e.*, progression to a higher Papanicolaou classification or regression to a lower Papanicolaou classification, were recorded. During the 8-year period, 43.9% of the oral group and 44.3% of the nonoral experienced one or more changes. The data given for the first three changes suggested that there was no difference between the two groups either with respect to the numbers of women undergoing progressive changes or with respect to the numbers undergoing regressive changes.

Various hormones, particularly estrogens, are known to influence the physiology of the breasts, producing cyclic engorgement, for example. Such changes, which can be accentuated by exogenous estrogens, may appear pathologic in some women, but upon scrutiny they often are found merely to be the result of aberrations in breast physiology (174).

Wiegenstein *et al.* (175), however, reported observing multiple fibroadenomas in 12 patients between 1967 and 1971; 11 of the patients were known to be oral contraceptive users. The condition had not been observed during the prior 7 years in that laboratory and was believed to be relatively uncommon. Unfortunately, no figure was given for the normal incidence of this condition.

Arthes *et al.* (176) described three studies involving a total of 283 cases of breast cancer and 585 controls. The results offered no evidence to indicate that administration of female hormones might be associated with the development of breast cancer; no significant excess of estrogen or oral contraceptive users was found among the cancer patients. In one of the studies, however, the number of oral contraceptive users was small, most of the diagnoses having been made prior to 1963 and the majority of women having been over 45 years of age at the time. In the second study, only 30 cases of breast cancer in patients under 35 years of age were found in a diagnostic index of hospitals in four of five study areas. The third study, however, involved 119 patients with breast carcinoma who had been treated at the Johns Hopkins Hospital from June 1969 to December 1970; these cases were matched with an equal number of controls. Analysis of data concerning prior hormone treatment indicated that neither in the total series nor in only those patients under 50 years of age was there any evidence of greater use of estrogens or oral contraceptives in the cases as opposed to the controls.

Vessey *et al.* (177) similarly reported that in a case-control study of 220 women and 216 matched controls, no evidence was found to associate oral contraceptives with either an increased risk of breast neoplasia or an increased development of benign breast lesions.

Leis (178) reviewed a number of studies involving various estrogens and estrogen–progestagen combinations. He concluded that there was no statistically significant evidence to indicate an increased incidence of breast cancer since the advent of widespread use of such compounds. He pointed out studies that had shown no difference between the degree of papillomatosis, hyperplasia, or other types of fibrocystic disease in the breasts of users and in those of nonusers of oral contraceptives. Other studies had shown no difference between the incidence of fibroadenomas, fibrocystic disease, or breast cancer in otherwise comparable groups of users and nonusers.

Taylor (179) reviewed several studies that had shown: (*a*) no histological differences between normal mammary tissue from oral contraceptive users and that taken from nonusers, and (*b*) no histological differences between fibroadenomas, other fibrocystic diseased mammary tissue, and breast carcinomas taken from users as opposed to nonusers.

Leis (178) further commented on the fallacy of drawing generalizations from isolated reports of abnormal breast findings in patients using oral contraceptives. He added, however, that it would be reasonable to stop use of such medication were abnormal breast lesions to develop while using it; altering the hormonal milieu in which breast cancers develop, for example, can lead to retardation of the cancer growth. Finally, in 1971, Lewison (180) observed that the data available were still insufficient for one to draw definite conclusions concerning the association, or lack thereof, between estrogens and/or contraceptives and breast malignancies. Nevertheless, he recommended caution in prescribing such preparations for high-risk patients. He included in this group patients with: (*a*) a strong family history of cancer, (*b*) a history of cancer of one breast (especially lobular cancer), (*c*) recurrent chronic cystic mastitis, (*d*) lobular carcinoma *in situ* of the breast, and (*e*) abnormal mammograms. He concluded, moreover, that prolonged use of these hormones was contraindicated in these predisposed patients.

Hypertension—In their 1970 review, Russell and Sullivan (181) pointed out that prior to 1967 only two isolated case reports concerning the development of hypertension in oral contraceptive users had appeared in the literature; hypertension, furthermore, was reported to be strikingly similar to that which occurred in toxemia of pregnancy. In 1967, reports began to appear of studies of small groups of women in whom the development or enhancement of hypertension was thought to be related to the use of oral contraceptives. In addition, it was suggested that the hypertensive action might be mediated through the renin–angiotensin–aldosterone system (*vide infra*).

The authors quoted three subsequent studies of oral contraceptive users in which it was reported that seven of 45, 51 of 129, and 40 of 141 women, respectively, had shown an elevation in blood pressure. The degree of elevation and definition of hypertension varied among the studies, however, as did the type of drug administered and the population of women receiving treatment. Moreover, in the one study that employed a control group of intrauterine device users, no significant difference was found between the latter group's blood pressure changes and those of the oral contraceptive users. A large-scale study, however, involving 1575 women did indicate a higher and statistically significant adjusted mean systolic and diastolic blood pressure in users as opposed to nonusers of oral contraceptives. The investigator reported that a blood pressure elevation does occur in oral contraceptive users but that it is not marked and requires sophisticated analysis, such as covariance analysis, to reveal statistically significant differences.

Russell and Sullivan (181) also reported data concerning 411 women who had had their blood pressure measured either prior to or during contraceptive therapy. Twenty-three percent of 34 patients and 22% of 26 were classified as hypertensive (b.p. $\geq$ 140/90 mm. Hg) prior to and during, respectively, their use of an intrauterine device or diaphragm. Nine percent of 225 patients and 16% of 126 were classified as hypertensive prior to and during, respectively, their use of various oral contraceptives. These observations might be of interest if it were known that the "before" and "during" users of the nonoral and oral contraceptives, respectively, had been comparable prior to treatment.

During 1970 and 1971, a number of other reports appeared that also associated the use of oral contraceptives with induced or aggravated hypertension. Lansing (182), for example, presented four case reports of oral contraceptive users with hypertension (b.p. $\geq$ 160/100 mm. Hg). In each instance the pressure returned to normal levels ($\leq$ 130/70) when the medication was discontinued.

Within a 10-month period, Clezy (183) observed 11 patients who had developed hypertension while taking oral contraceptives. Guanethidine appeared to produce an unsatisfactory response in the presence of oral contraceptives while blood pressure appeared to decrease when the oral contraceptives were withdrawn. An accurate evaluation is difficult, however, since other drugs, including amobarbital, bendroflumethiazide, chlorothiazide, phenobarbital, and/or methyldopa, had been used concurrently in some patients.

Spellacy and Birk (184) reported a study of 57 women whose blood pressure was measured during pregnancy (45 women only), during labor, at 4 weeks or more postpartum (prior to contraceptive treatment), and during the sixth cycle of oral contraceptive therapy. The women randomly were given a combined (100 mcg. mestranol plus 1 mg. ethynodiol diacetate, 24 women) or sequential (100 mcg. mestranol, 100 mcg. mestranol plus 1.5 mg. chlormadinone acetate, 33 women) preparation. Eight of the combined preparation users demonstrated hypertension (systolic pressure $\geq$ 140 mm. Hg and/or diastolic pressure $\geq$ 90 mm. Hg) while only one of the sequential preparation users did. However, four of the eight in the former group previously had had high blood pressure reading(s) during pregnancy; a prenatal value for the sequential product user was not given.

Chidell (185) reported the results of a study in which 99 of 9000 oral contraceptive users were found to be hypertensive (b.p. > 140°/90 mm. Hg). Approximately one-third previously had been normotensive. One-third

previously had had a higher than average starting blood pressure; 50% of the latter patients showed a further rise while using oral contraceptives. The remaining third already were taking oral contraceptives when their first blood pressure measurements showed them to be hypertensive. Withdrawal of the medication was followed by a reduction in pressure in 27 of 32 women, by no change in four, and by a rise in one. Continuing the medication in 34 other women was accompanied by a continued elevation of pressure in 29, a fall in three, and a further rise in two.

Similar observations were made by Saruta *et al.* (186). Fifty-six of 62 postpartum patients were classified initially as normotensive, and the remaining six were classified as hypertensive; the dividing line was a blood pressure of 140/90 mm. Hg. The initially normotensive patients were classified as becoming hypertensive if their diastolic pressure increased by at least 10 mm. Hg to a level of 90 or more. For those initially hypertensive, a rise of the diastolic pressure by at least 10 mm. Hg was interpreted as their having developed increased hypertension. During the use of 50 mcg. mestranol plus 1 mg. norethindrone, 10 of the 56 became hypertensive under these criteria while of the other six, blood pressure became normal in one, remained unchanged in four, and increased further in the sixth. Among those who became hypertensive, there had been a higher incidence of hypertension during pregnancy.

These workers also found that blood pressure returned to normal in three women in whom oral contraceptive therapy had been discontinued for 6 weeks. Finally, they commented on 18 additional patients, four of whom also became hypertensive during oral contraceptive treatment. The total incidence of hypertension development or enhancement in their series, therefore, became 19%.

Wallace (187) observed retrospectively that 15 of 26 (58%) 20–45-year-old women who had been admitted to one hospital over a 22-month period had been using oral contraceptives for an average of 5.5 years (range 18 months–9 years) at the time of being diagnosed hypertensive (mean diastolic blood pressure for the group: 133 mm. Hg, range 120–170 mm. Hg). He compared this figure (58%) with that of an estimated 32% usage of oral contraceptives in the general population. However, it cannot be assumed that these 26 patients necessarily were a representative sample of New Zealand women. Furthermore, precontraceptive blood pressure values were not known for eight of the 15 and were known to have been high in two others.

A much smaller proportion (17%) of a much larger group (325) of hypertensive women referred to a California medical center was reported by Crane *et al.* (188) to have been taking oral contraceptives or conjugated estrogen. For their study, these workers defined hypertension as a persistent blood pressure $\geq$ 160 mm. Hg systolic or $\geq$ 100 mm. Hg diastolic, and they defined normotensive as a blood pressure $\leq$ 145/95 mm. Hg. Twenty-two of the 36 oral contraceptive users observed by them and five of 20 users of conjugated estrogen had been normotensive prior to therapy. Withdrawal of the medication resulted in a return of the blood pressure in most of the women to normotensive levels.

Weir *et al.* (189), in their 1-year prospective study, found a significant increase in mean systolic pressure in 50 of 66 oral contraceptive users, but in no case did the blood pressure rise as high as 140/90. No change in mean systolic pressure occurred in a control group of 21 women using diaphragms or intrauterine devices; neither did mean diastolic pressure change in either group. Of the two women who had a history of hypertension during pregnancy (preeclampsia), systolic pressure rose in one and decreased in the other after 1 year of oral contraceptive use.

Investigations also have been carried out in an effort to determine the mechanism by which blood pressure may be increased in some women during the use of oral contraceptives. Walters and Lim (190), for example, studied a number of hemodynamic parameters including cardiac output, stroke volume, blood pressure, and heart rate in a group of 30 healthy young women using oral contraceptives of the combined type. Although the absolute numerical value of the mean obtained for the group showed a slight increase for most variables and a slight decrease for a few during therapy, in contrast to before or following therapy, the values of the standard deviations overlapped to a large extent.

Most investigations, however, have been concerned with changes in the renin–angiotensin–aldosterone system. As a result of such studies, it has been postulated that the pressor effects of estrogen and/or progestagen preparations may be mediated by derangements in this system and by associated induced changes in sodium and water balance (191, 192). Indeed, a significant correlation between diastolic pressure and blood angiotensin-II concentration has been found in three forms of hypertension (severe essential, renal, and malignant) while prominent increases in blood levels of this substance have been observed also during oral contraceptive therapy (193, 194).

Actually, a number of parameters have been studied including: (*a*) aldosterone excretion rate (188), (*b*) renin activity (the ability of the plasma to form angiotensin on incubation) (181, 186, 188), (*c*) blood angiotensin concentration (determined by radioimmunoassay) (193, 194), (*d*) renin concentration (renin activity at a constant substrate concentration) (181, 186, 194), and (*e*) renin substrate (angiotensin released by excess renin) (181, 186, 188, 194). A review of the works cited reveals some inconsistencies among the results. Increases usually were reported for blood levels of angiotensin-II, plasma renin activity, renin substrate, and aldosterone excretion, while reports concerning plasma renin concentration tend to be conflicting. Russell and Sullivan (181), for example, quoted a study which had shown that renin concentration tended to fall while renin substrate increased, resulting in no change in the rate of angiotensin formation. Cain *et al.* (194) also found a decrease in renin concentration. However, this decrease was inversely correlated with a marked rise in blood angiotensin-II. Saruta *et al.* (186), on the other hand, found essentially no change in renin concentration in their oral contraceptive users whose blood pressure had remained unchanged; they did find a slight increase in the former parameter in those whose blood pressure had increased. The latter workers suggested that such data

support the hypothesis that hypertension induced by oral contraceptives may be related to a diminished suppression of renin release.

Further complicating an attempt to explain these observations, however, is the fact that derangements in the renin–angiotensin–aldosterone system were found by other workers in oral contraceptive users who had not developed hypertension (181, 191). Nevertheless, it does appear that the oral contraceptives may aggravate preexisting hypertension or precipitate its onset in some patients and that the effect may be mediated by changes in the renin–angiotensin–aldosterone system. However, as Stokes (191) pointed out, it is necessary to postulate the possible presence of other determinants of hypertension, such as an hereditary predisposition, or a previous history of toxemia of pregnancy or renal disease in those patients in whom the blood pressure rises. In conclusion, caution in prescribing oral contraceptives to patients suspected of being at risk is certainly warranted (191), and regular blood pressure determinations in all oral contraceptive users obviously are advisable (181, 186).

Effects on Carbohydrate Metabolism—In 1969, Spellacy (195) reviewed the literature concerning the effects of oral contraceptives on carbohydrate metabolism. Abnormalities that had appeared in some women using these preparations included: (*a*) abnormal response to the oral or cortisone-stimulated oral glucose tolerance test; (*b*) abnormal response to the intravenous glucose tolerance test; (*c*) elevated levels of growth hormone; and (*d*) elevated levels of circulating insulin. Greater numbers of abnormal responses had been associated with oral glucose tolerance tests than with intravenous tests. Greater numbers of abnormal responses also had been associated with the use of combination-type preparations than with the sequential type. Fewer reports were available concerning the sequential type, however, and the duration of use of the latter tended to be shorter. Spellacy suggested a number of factors that might be related to the production of such abnormalities in women using oral contraceptives: (*a*) type(s) of steroid in the preparations, (*b*) duration of treatment, (*c*) age, (*d*) family history of diabetes mellitus, and (*e*) body weight, weight gain while taking the medication, and birth weight of previous infants. He also speculated on the possible mechanisms by which the oral contraceptives might alter carbohydrate metabolism by: (*a*) production of excess cortisol and/or excess growth hormone, (*b*) alteration of liver function, (*c*) alteration of the GI tract (absorption and/or gut-insulin release factors), and/or (*d*) alteration of peripheral tissue glucose utilization. Finally, Spellacy concluded that the presence of diabetes mellitus need not be considered a contraindication to the use of oral contraceptives, but that close supervision of such patients using these drugs was advisable. Subsequent studies (*vide infra*) have provided additional information concerning many of the above points.

A number of studies (196–200), in which a variety of oral contraceptives were employed for varying periods of time, have shown no difference between fasting blood glucose levels in normal women prior to and during therapy with these drugs. In contrast, fasting blood glucose was increased during oral contraceptive use in women with subclinical diabetes (201). Furthermore, 33 of 37 women using an injectable contraceptive, medroxyprogesterone acetate, developed increased fasting blood glucose levels after 1 year of use. Although the remaining four showed a decrease in fasting levels, the increase for the group as a whole was statistically significant (202). Fasting insulin levels, on the other hand, usually have been reported as increased during steroid contraceptive therapy (197, 199, 200, 202), although evidence to the contrary has been reported (196, 198). In general, it would appear that normal glucose levels may be maintained in oral contraceptive users at the expense of increased insulin levels (197). Such observations suggest an increased peripheral resistance to the actions of insulin during oral contraceptive therapy (196).

Oral (196, 199, 200, 202, 203), prednisone-stimulated oral (204), and intravenous (196, 197, 205–207) glucose tolerance tests, as well as intravenous arginine-stimulation tests (198) have been performed in steroid contraceptive users prior to and during therapy. The arginine-stimulation test in 26 women revealed no abnormalities in blood glucose and insulin responses after 3 months of therapy with daily doses of 0.35 mg. ethynodiol diacetate.

The different types of glucose tolerance tests have shown some variation in the results produced, apparently at least partly due to the different contraceptive preparations used as well as to variations in duration of use. Also, more insulin has been reported to be released in the oral test than in the intravenous, probably because gut factors may be stimulated to act at the β-cells, in addition to the glucose (200), in the oral test.

Wynn and Doar (196) reported a deterioration of oral glucose tolerance, as measured by the area under the plasma glucose curve, in 78% of 91 women after they had been treated for 6 months (range 3–42) with a variety of combination and sequential oral contraceptives. Intravenous glucose tolerance similarly was impaired in 70% of these women. Plasma insulin levels also rose significantly. Thirty-nine other women were tested after oral contraceptive therapy was discontinued; 90% of these showed improved oral glucose tolerance and 85% showed improved intravenous glucose tolerance.

One study (197) employed intravenous glucose tolerance tests in users of combined (50 mcg. ethinyl estradiol plus 4.0 mg. megestrol acetate), sequential (100 mcg. mestranol, 100 mcg. mestranol plus 2.0 mg. anagestone acetate), and progestagen-only (0.5 mg. chlormadinone acetate) oral contraceptives. Insulin levels increased during the test after 12–16 months of therapy, but no changes from pretreatment values were observed in the glucose tolerance curves. In a second study (207), no absolute glucose values were given. However, the investigator concluded that one of the three oral contraceptives tested (100 mcg. mestranol plus 1.0 mg. ethynodiol diacetate, but not 50 mcg. ethinyl estradiol plus 4.0 mg. norethindrone acetate or 50 mcg. ethinyl estradiol plus 4.0 mg. megestrol acetate) had a transient diabetogenic effect, as indicated by a slower rate of glucose disappearance from the blood following intra-

venous administration. The effect was statistically significant after 6 months of therapy with this oral contraceptive but almost negligible after 1 year. The results of a study (204) in which patients were given prednisone-stimulated oral glucose tolerance tests also suggested that mestranol (80 mcg.) might have a transient diabetogenic effect; the percentage of abnormal tests increased during the 1st and 3rd months of therapy but had decreased by the 9th month. These investigators had concluded previously that progestagens had no effect on glucose tolerance. Consequently, they presented combined data for women using preparations containing two different progestagens: 2.0 mg. chlormadinone acetate in a sequential preparation and 5.0 mg. norethindrone acetate in a combination product. Moreover, not all women were tested at each time period.

Clinch *et al.* (205) suggested that there might be an improved intravenous glucose tolerance in patients using 50 mcg. mestranol with 1.0 mg. norethindrone, as indicated by a faster decrease in blood glucose levels. The absolute mean values attained during testing were higher, however, after 4 months of therapy in comparison with pretreatment levels.

Spellacy (206) compared the results of intravenous glucose tolerance tests in patients using a combined oral contraceptive (80 mcg. mestranol plus 5.0 mg. norethynodrel) or a sequential product (80 mcg. mestranol, 80 mcg. mestranol plus 2.0 mg. chlormadinone acetate). All women were tested prior to therapy, but only some were tested after 6 months and others after 12 months. During the 6-month test, plasma insulin values, but not glucose values, were elevated significantly in both groups; at the 12-month test, both insulin and glucose values increased above pretreatment test levels in the combination drug-treated group but not in the other. Since the mestranol doses were the same, an influence of the progestagens was suggested. However, the group results tended to return to normal after 2–3 years of oral contraceptive therapy, although some individuals developed abnormal glucose tolerance curves.

Somewhat different responses to oral glucose tolerance tests were reported (199, 200) for patients using a sequential preparation containing 100 mcg. mestranol followed by 100 mcg. mestranol plus 1.5 mg. chlormadinone acetate. In these studies, blood glucose levels during testing were significantly elevated after 6 months of treatment, while plasma insulin levels were increased above pretreatment test values at both 6 and 12 months. Oral glucose tolerance tests in patients using injectable medroxyprogesterone acetate for 12 months produced higher mean blood glucose levels and higher mean plasma insulin levels as compared with pretreatment values of these substances (202).

In the studies just described, levels of blood constituents were measured before and following a period of oral contraceptive use (usually 1 year or less). In other studies (208, 209), these same constituents were measured in women following long-term (5 or more years) use of oral contraceptives. These studies have the disadvantage that no information prior to drug use is available. Abnormal glucose curves were obtained in response to standard oral glucose tolerance tests in 36.8% of 19 women who had used a combination-type (100 mcg. mestranol plus 1.0 mg. ethynodiol diacetate) oral contraceptive for 72–85 cycles. Abnormal responses occurred in 24.5% of 45 women who had used a sequential preparation (80 mcg. mestranol, 80 mcg. mestranol plus 2.0 mg. chlormadinone acetate) for 65–97 cycles. The difference between the two groups was not significant (208). However, a significant difference between the incidence of abnormal oral glucose tolerance curves was observed in the other study (209); the incidence of abnormal responses in this case was 77.4 and 25.8% among 59 combination product users and 43 sequential-type users, respectively. The sequential preparation used in both studies was the same and the duration of use was similar. The parameters differed, however, for the combination product users. The latter in this study (209) had used a preparation containing 60 mcg. mestranol and 10.0 mg. norethindrone for 6 years (approximately 72 cycles), followed by a preparation containing 100 mcg. mestranol and 2.0 mg. norethindrone, which provided this group with a total minimum of 100 cycles of oral contraceptive use. In both studies (208, 209), women who exhibited abnormal glucose curves also had delayed insulin peaks. Moreover, the insulin levels reached at the peaks were higher than normal.

No significant relationship was found in one of these retrospective studies (208) between the occurrence of an abnormal glucose tolerance test and: (*a*) family history of diabetes mellitus; (*b*) the delivery of an excessively large, anomalous, or stillborn infant; or (*c*) the subject's age, parity, or weight. A similar lack of correlation between abnormal glucose tolerance and the patient's: (*a*) age, (*b*) degree of obesity or change of weight during therapy, (*c*) parity, or (*d*) family history of diabetes also was found by Wynn and Doar (196). On the other hand, Spellacy (206) and Spellacy *et al.* (200), in reporting their short-term prospective-type studies, suggested that glucose and insulin changes might be related to age, parity, weight changes, delivery of excessively large infants, and family history of diabetes. Duration of treatment, if sufficiently long, may obscure any influence these other factors might have had initially.

Some patients indeed may be at risk (203). Fifteen patients showed abnormal oral glucose tolerance in their third trimester but normal tolerance following delivery. Five of five who subsequently received a combination-type oral contraceptive (50 mcg. mestranol plus 1.0 mg. norethindrone) had a recurrence of abnormal glucose tolerance during therapy. The other 10 practiced other methods of birth control, and three of them showed a deterioration of glucose tolerance. Although tolbutamide has been shown to correct oral contraceptive-induced glucose tolerance disturbances (201), some investigators have advised against the use of hormonal contraception in women exhibiting definite carbohydrate metabolic derangement (201, 204) or in those with latent diabetes (203, 204) or a family history of diabetes (204). On the other hand, one investigator (207) suggested that such women merely should receive special study. The available evidence, at the very least, seems to argue for close monitoring of carbohydrate metabolism in oral contraceptive users (206, 209).

The mechanism(s) by which oral contraceptives may alter carbohydrate metabolism in some women is(are) still unclear. Growth hormone has been reported to be diabetogenic (195, 204, 208). However, most recent studies of this hormone during contraceptive therapy have not provided evidence to support its having an etiologic effect. For example, growth hormone levels have remained normal in spite of the development of impaired glucose tolerance (196, 202). Furthermore, the normal suppressibility of growth hormone by increased glucose levels has been reported to be intact in oral contraceptive users (208, 209). A second suggested mechanism, involving impaired liver function, still seems tenable (*vide infra*). That the effect may be mediated at least partly by cortisol also seems plausible. Indeed, plasma cortisol levels have been shown to increase in some patients during oral contraceptive therapy with ethinyl estradiol and dimethisterone (210). More importantly perhaps, it has been pointed out (196) that several metabolic patterns are shared by nonobese women using oral contraceptives, nonobese women receiving glucocorticoid therapy, and obese, nondiabetic women. For example, fasting blood pyruvate levels, as well as the increment of the latter following a glucose load, have been reported to be elevated in these three conditions. It has been suggested that these changes might result from glucocorticoid excess in all three classes of women. Finally, although Seng *et al.* (211) did find significant elevations of plasma levels of a number of metabolites, including pyruvate, in women using 75 mcg. mestranol with 2.5 mg. lynestrenol, all of the values found were within their respective normal ranges.

Effects on Lipid Metabolism—Plasma triglyceride levels have been found to be elevated in women using a number of different oral contraceptives (211–218). Although statistically significant, the average elevation usually did not exceed the normal upper limit of 150 mg./100 ml. (215). Evidence does suggest that severe endogenous hypertriglyceridemia might develop in response to the use of contraceptive steroids in individuals who already have high triglyceride levels and in whom an excessive insulin response occurs following a glucose load (219). The increased triglyceride levels have been reported by most workers (212, 213, 215, 217) to be associated with concomitant increases in plasma levels of very low density, low density, and/or high density lipoproteins. Seng *et al.* (211), however, found increased triglyceride levels in the absence of increased lipoprotein levels.

Slight, but significant, increases in cholesterol levels also have been reported in some oral contraceptive users (212, 215–217), although not for eight of nine women using a quinestrol–quingestanol acetate preparation (218). The increases were associated with increases in low (215) and very low (212, 215) density lipoproteins, and no consistent changes occurred in high density lipoprotein cholesterol (215). One study reported a significant decrease in cholesterol esterification (213).

Fewer data are available concerning other parameters of lipid metabolism in oral contraceptive users. Phospholipids have been reported to be significantly elevated in association with a rise in high density lipoproteins (215, 218), although Rössner *et al.* (212) found an increase in phospholipids associated with very low density lipoproteins. Free fatty acids were reported to be significantly increased in one study (213) and unchanged in another (212).

Changes in lipid metabolism parameters can be seen within a few weeks after initiation of oral contraceptive therapy (214, 215). They increase progressively in magnitude for several weeks; within 2–3 months the values may reach a plateau which then is maintained throughout therapy (215). Levels of these metabolites may continue to rise during treatment with some preparations, although they can be expected to return almost to pretreatment values within 6 months after cessation of therapy (216). Virtually no reversal of effects was observed, however, within 1 month after withdrawal (214).

Although the evidence is not conclusive, it has been suggested that the estrogenic component of the oral contraceptives may be responsible for the lipid metabolism alterations. Increases in serum cholesterol and triglycerides were seen in women using combination-type preparations (100 mcg. mestranol plus 2.0 mg. norethindrone and 50 mcg. mestranol plus 1.0 mg. norethindrone) but not in those using a progestagen-only preparation (216). However, since the latter contained 0.5 mg. chlormadinone acetate, these data merely indicate that one particular progestagen, but not necessarily any other, appears to have no effect on lipid metabolism. Triglyceride levels, which had been elevated markedly in patients using 100 mcg. mestranol with 3.0 mg. chlormadinone acetate, did indeed decrease, although not to pretreatment levels, when the medication was changed to 3.0 mg. chlormadinone acetate alone (212). Dosage also might be of some importance. Barton *et al.* (216) pointed out that mean serum cholesterol and triglyceride levels were higher in those patients using the higher dose combined preparation. However, no information was given to indicate the degree of variability among patients.

Studies designed to elucidate the mechanism(s) by which oral contraceptives may alter lipid metabolism have focused primarily on the changes produced in triglyceride levels. That impaired removal of triglycerides might be involved was suggested by studies (212, 220–223) in which a decrease in postheparin lipoprotein lipase activity during oral contraceptive use was found. However, neither oral (223) nor intravenous (212) fat tolerance was shown to be impaired in oral contraceptive users, suggesting that increased triglyceride levels in these patients might not be the result of impaired removal of these metabolites.

An alternative explanation for the increased triglyceride levels found during oral contraceptive use is an increase in triglyceride production rate (turnover) (212, 214) due to increased secretion of these compounds by the liver (212). A study (214) of the transport kinetics of plasma triglycerides showed that triglyceride production rate was almost twice as high in a group of oral contraceptive users as in a control group. Furthermore, there actually was a simultaneous increase in the efficiency of triglyceride removal in the experimental

group which, however, only partly compensated for the large increase in triglyceride production.

Oral contraceptive use, therefore, has been associated with both increased insulin levels (223) (*vide supra*) and increased triglyceride levels. Consequently, the hypothesis has been suggested (206, 223) that the increase in triglyceride levels may be secondary to the hyperinsulinemia; that is, the elevated insulin levels might stimulate increased hepatic lipogenesis. What relationship, if any, might exist between such changes in lipid (and carbohydrate) metabolism and the occurrence of vascular lesions in oral contraceptive users (*vide supra*) remains to be determined (15).

Effects on Protein Metabolism—The plasma levels of a number of proteins have been reported to be increased, and for others decreased, in users of a variety of oral contraceptives. However, the relevance, if any, of such changes to the overall health status of the patients is unknown in most cases. Furthermore, protocols of the various studies discussed below have differed markedly, and in some cases the reports concerning specific proteins have been conflicting.

Plasma levels of transferrin, the β-globulin responsible for iron transport, have been shown to increase in oral contraceptive users (224–227). The total iron-binding capacity of the serum, a measure of transferrin levels, also was shown to increase in women given 1.0- or 3.0-mg. doses of norethindrone acetate with 50-mcg. doses of ethinyl estradiol (228); it did not increase, however, when doses of 10–75 mcg. of ethinyl estradiol alone were given.

Plasma levels of copper (229, 230) and ceruloplasm, a copper-binding globulin (224, 225, 229), also have been shown to increase during oral contraceptive therapy. Norethindrone acetate (0.3 mg.) did not have these effects when given alone (229). However, Schenker *et al.* (230) showed that a different progestagen, chlormadinone acetate (2.0 mg.), did cause an increase in serum copper.

Studies of α_2-macroglobulin levels during oral contraceptive use have revealed either insignificant changes (225, 226) or significant increases (224, 231). Since this substance has antiplasmin activity *in vitro*, it has been speculated (226, 231) that increases in its plasma levels might lead to an increased clotting tendency and, hence, play a role in the production of thromboembolism (*vide supra*).

C-Reactive protein, a complex glycoprotein synthesized in the liver, is an abnormal, nonspecific, acute-phase protein seen in pregnancy and with tissue injury and necrosis. This protein also was found in the serums of greater numbers of oral contraceptive (combined and sequential types) users and of women who had been using an intrauterine device for longer than 3 years than of control women (232).

Transcortin (cortisol-binding globulin) is increased during oral contraceptive therapy (233), with the result that increased plasma levels of cortisol can be found in women using these drugs (210, 224, 233) (*vide supra*). Some progestagen-only preparations do not appear to have this effect (210). Furthermore, it appears that the free (active) fraction of cortisol may be increased as well as the bound (inactive) fraction (233).

Thyroxine-binding globulin also is increased during oral contraceptive therapy (224, 234). As a result, the serum protein-bound iodine (PBI) is increased and the triiodothyronine (T_3) resin uptake is decreased (234, 235). Therefore, although the functional status of the thyroid is believed to remain normal during oral contraceptive therapy (234), thyroid function tests in patients using these drugs are likely to yield abnormal results (235). These effects are believed to be due primarily to estrogenic components of the oral contraceptives; except for norethynodrel, administration of oral progestagens did not alter PBI levels or T_3 uptake (234).

Plasma levels of a number of other proteins in oral contraceptive users have been studied less extensively. Haptoglobulins (224, 225, 228), orosomucoid (224, 228), and α_1-acid glycoprotein (225) have been shown to decrease during oral contraceptive therapy, whereas α_1-antitrypsin (224, 225) and β_{1A}-globulin (225) have been found to increase. Albumin levels have been unchanged (225, 226) or decreased (224, 228). Some investigators (224, 225) found no change in immunoglobulin levels in women using oral contraceptives, while others (226, 231) found increases in serum levels of γG-globulin.

Many of the proteins mentioned here are synthesized in the liver. Consequently, it has been suggested (225) that changes in plasma levels of these proteins occurring during oral contraceptive therapy might be the result of actions of the estrogens and/or progestagens on the liver.

Liver Dysfunction and Jaundice—A 1967 review (236) of the hepatic effects of oral contraceptives revealed that a total of 40 cases of jaundice, in patients from five different countries, had been attributed to five different oral contraceptives. This side effect was considered to be rare (236, 237), and an incidence rate of 1/10,000 or lower was estimated (238).

The 40 case histories reviewed (236) displayed a marked similarity. The early symptoms of pruritus, malaise, anorexia, and nausea usually appeared within the first 4 weeks of oral contraceptive therapy. Subsequently, the urine darkened and jaundice appeared. Bilirubin and transaminase levels were elevated, with marked increases in serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT) being found occasionally. Histological examination of liver biopsy revealed: (*a*) canalicular and hepatocellular bile stasis; (*b*) generally slight, but variable, degrees of hepatocellular degeneration and necrosis; and (*c*) minimal or absent inflammatory reaction. Electron microscopy revealed dilatation of the canaliculi, shortening or disappearance of the microvilli, intracytoplasmic dense bodies, myelin figures, and dilation of the smooth endoplasmic reticulum. Cessation of oral contraceptive treatment usually was associated with complete clinical and chemical remission within a few weeks or months. Jaundice recurred, however, in two patients following readministration of oral contraceptives. Of significance is the fact that 13 of these women previously had experienced recurrent jaundice or severe pruritus of pregnancy.

It appeared to the reviewer (236) that, in a small number of women, oral contraceptives could produce jaundice associated with reversible, noninflammatory intrahepatic cholestasis. The finding of other abnormalities of liver function tests in oral contraceptive users was more common, however. Sulfobromophthalein retention, for example, was mildly increased in 21% of the women in a Los Angeles study who had been using norethindrone (2.0 mg.) with mestranol. The same product was associated with mildly increased sulfobromophthalein retention in 42% of the women in a Swedish study. Other oral contraceptive products were reported to have produced an increase in sulfobromophthalein retention in 19–48% of users in Finland and in 7–29% of users in the United States. Various studies demonstrated elevations in transaminase levels in 0–18% of oral contraceptive users and slight elevations in alkaline phosphatase in 2%, or fewer, of the subjects. Minimal elevations of serum bilirubin occurred only rarely or not at all.

Observations that greater numbers of oral contraceptive users in Scandinavia and in Chile than in other parts of the world appear to develop jaundice (234) and/or show abnormalities in liver function tests (234) have suggested to a number of workers (234, 237, 239, 240) that some type of predisposition, possibly genetic, might be involved.

Results of studies reported since Ockner and Davidson's review (236) have tended to support earlier findings. There have been isolated case reports (241, 242) of women developing jaundice and pruritus during use of norethindrone (2.0 mg.) with mestranol. One woman (241) had a history of jaundice during pregnancy. Neither woman developed symptoms when treated subsequently with 0.5 mg. chlormadinone acetate (241) or 80 mcg. mestranol followed by 80 mcg. mestranol plus 2.0 mg. chlormadinone acetate (242).

Liver biopsies from six jaundiced and/or pruritic and six nonjaundiced, nonpruritic oral contraceptive users were compared histologically and found to be similar (243); no samples from untreated patients were studied. The authors did point out, however, that the type of mitochondria-like organelles found were similar to those found in livers of patients with hyperbilirubinemia induced by anabolic steroids. Except for one case of elevated serum glutamic pyruvic transaminase, liver function tests were normal in the asymptomatic patients. Bilirubin, serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, and alkaline phosphatase, but not thymol turbidity, were elevated in most cases in the symptomatic group. Four of the five parous, symptomatic patients, but none of the five parous women in the asymptomatic group, had a history of pruritus during pregnancy.

Two other studies (244, 245) also attempted to correlate liver function test results with liver biopsy findings. In one study (244), data were compared from women with gallbladder disease who were either users or nonusers of oral contraceptives. Histological appearance of the livers from the two groups was similar, but again no healthy, untreated control livers were examined. Levels of bilirubin, serum glutamic oxaloacetic transaminase, and serum glutamic pyruvic transaminase, but not of thymol turbidity or alkaline phosphatase, were elevated in the users as compared with the nonusers. The second study (245) found filamentous mitochondrial inclusions in a small group of oral contraceptive users. However, they were present both in jaundiced and nonjaundiced patients, and in those with extremely or only moderately elevated levels of serum glutamic oxaloacetic transaminase and/or serum glutamic pyruvic transaminase. Although these workers did not find such inclusions in liver biopsies from their one normal female and three normal male patients, they pointed out that others had reported such observations. They suggested that individuals with such inclusions could be the ones more likely to develop toxic hepatitis when using oral contraceptives.

Liver function tests have been performed on other asymptomatic oral contraceptive users. The results of one study (246) suggested that oral contraceptive use was associated with increased numbers of abnormal sulfobromophthalein tests, that the increase was dose dependent, and that the proportion of women with abnormal sulfobromophthalein tests might decrease as the duration of steroid administration increased. Somewhat different observations were made in another study (247). In the latter study, the percentage of abnormal sulfobromophthalein tests increased during the first 3 months of oral contraceptive therapy and then maintained a plateau throughout the remaining nine cycles of observation; however, the criteria for abnormal sulfobromophthalein retention differed between the two studies. Larsson-Cohn (247) also studied serum glutamic oxaloacetic transaminase and serum glutamic pyruvic transaminase levels in his patients; the frequency of elevated transaminases was found to be maximum after 1 month of oral contraceptive use and then was observed to decrease.

It appears that morphological and at least temporary functional changes may take place in the livers of some oral contraceptive users. Such findings lend support to the hypothesis (*vide supra*) that at least some of the changes seen in carbohydrate, fat, and protein metabolism in oral contraceptive users might be mediated by an effect(s) of the medication on the liver. Whether the estrogenic and/or progestagenic component(s) of the oral contraceptives may be responsible for the liver changes has not been resolved. It has been shown, for example, that 17α-alkyl-substituted derivatives of testosterone (anabolic steroids) may interfere with bile excretion at the biliary canalicular level and cause cholestatic jaundice (234), as well as reduce the biliary transport maximum for sulfobromophthalein (239). Moreover, most progestagens in the commercially available contraceptive preparations are chemically very closely related to the former (*vide supra*). However, the estrogenic components, ethinyl estradiol and mestranol, also have unsaturated hydrocarbon groups in the 17α-position (234) and have been shown (241) to impair liver function tests when given to women with a history of jaundice of pregnancy. Although the 19-nortestosterone-derived progestagens and the commercially available synthetic estrogens all may have the potential of affecting the liver, the former are administered in doses of 1.0 mg. or greater while the latter are used in

doses of 100 mcg. or less (247). The details of one case report (242) described previously serve to emphasize this point. The woman became jaundiced while using 2.0 mg. norethindrone with 100 mcg. mestranol but remained asymptomatic while using 80 mcg. mestranol followed by 80 mcg. mestranol plus 2.0 mg. chlormadinone acetate. This latter progestagen, furthermore, is a 17α-hydroxyprogesterone derivative (*vide supra*).

Amenorrhea and Galactorrhea—It was noted that use of injectable progestagen-only contraceptives often results in prolonged amenorrhea (26). However, this phenomenon also has been reported to occur following termination of the use of oral contraceptive preparations of both the combined and sequential types (248–251). Its occurrence obviously would be of concern to women who were using these compounds merely to delay the start of their families or to space their children.

The actual incidence of this phenomenon, variously termed "post-pill amenorrhea" (251) and the "oversuppression syndrome" (252, 253), appears to be low. Arrata and de Alvarez (253), for example, pointed out that various workers estimated the postcontraceptive incidence to be 1–10%. On the other hand, little is known about the incidence of spontaneous secondary amenorrhea in the general population, making it difficult to determine the significance of its incidence in women who have discontinued the use of oral contraceptives. As a possible comparison, it can be stated that reports indicated a 2–7% (15) and 6–22% (254) incidence of secondary amenorrhea in young women exposed to minor life-stresses such as leaving home to live in a new environment. Postcontraceptive amenorrhea has occurred in women who had regular menstrual cycles prior to treatment as well as in those who previously exhibited irregular cycles (250–253, 255). Consequently, inquiries into the true incidence of oral contraceptive-induced temporary amenorrhea following termination of use of the latter should take into consideration the patient's menstrual history prior to its use.

The phenomenon of postpill amenorrhea, providing other causative factors such as a pituitary tumor can be ruled out, represents an extension of the therapeutic effect of the oral contraceptives (*vide supra*). In some patients, apparently, the hypothalamic blockade continues, to varying degrees (253), following cessation of medication. For example, the first posttreatment cycle merely may be prolonged, 36–80 days in length (248). On the other hand, the spontaneous return of menstruation did not occur in one woman until she had been amenorrheic for 6 years (250), while a second woman was still amenorrheic after 8 years.

That some degree of hypothalamic dysfunction probably is responsible tends to be supported by the results of treatment (*vide infra*) and by laboratory determinations. Specifically, although Arrata and Howard (255) did find that total urinary gonadotropins were within normal limits by bioassay criteria, they pointed out that the bioassay method yields grossly inaccurate and nonspecific results. Subsequent measurements of serum LH by radioimmunoassay revealed normal tonic levels but the absence of an ovulatory surge (253). Gambrell *et al.* (251), furthermore, found low to normal serum FSH and LH levels in their amenorrheic patients. Estrogen levels tended to be low in a number of the patients as well (251, 253, 255).

Galactorrhea accompanies the amenorrhea in some women (250–253, 255). The former may begin while the patient is still taking the contraceptive tablets (251, 255) or, alternatively, it may not become manifest until after cessation of therapy. Presumably, this phenomenon also is the result of excessive hypothalamic blockade. In this case, however, the blockade is thought to release the pituitary from hypothalamic inhibition (253). Specifically, secretion of the pituitary hormone, prolactin, is thought normally to be suppressed by a hypothalamic inhibitory factor, PIF. Furthermore, although the exact function of prolactin in the human is poorly understood (256), its concentration is known to be elevated in lactating women.

A comparison of the works cited revealed no relationship between the duration of contraceptive therapy and the occurrence of prolonged amenorrhea and/or galactorrhea. It may be of significance, however, that of the 105 amenorrheic patients reported (248, 250–253, 255), none had taken the medication for less than three cycles.

It should be emphasized that: (*a*) the incidence of postpill amenorrhea is low (251); (*b*) menstruation was reported in one study (248) to recur within 48 days (somewhat sooner for sequential-type users than for users of the combined type) following cessation of therapy in the vast majority of women and that ovulation did occur in a large number of these women during their first three posttreatment cycles; and (*c*) that among the patients in another study (253), normal menses tended to resume within the first 6 months following cessation of oral contraceptive therapy.

Assuming they wish to become pregnant, at least some of the women with secondary amenorrhea following the use of oral contraceptives may be treated successfully. The true success is difficult to evaluate, however, because the number of women reported in the various studies (250–253, 255) is small. It would appear that about half the women may respond to treatment with clomiphene citrate, again supporting the idea that the phenomenon represents hypothalamic dysfunction and/or a desynchronization of normal cyclic events. For clomiphene to be effective, the woman's pituitary must be capable of secreting gonadotropins and her ovaries must contain follicles capable of maturing and rupturing (257). In addition, there should be adequate estrogen secretion (255). Women not responding to clomiphene may respond to gonadotropins [human pituitary (250), human menopausal (251), FSH (252), and/or human chorionic (251, 252)] administered instead of, or in addition to, clomiphene. Despite spontaneous or induced ovulation in these women, however, pregnancy is not always achieved. One possible explanation was suggested by Maqueo *et al.* (258); these workers found histological evidence indicative of postcontraceptive endometrial refractoriness (inactivity) in some patients, a phenomenon which, theoretically, could impair fertility.

Miscellaneous Reactions and Complaints—Numerous reports concerning a variety of reactions and complaints

that might possibly be associated with the concurrent use of oral contraceptives have been cited in the literature (15, 23, 26, 84, 234, 240, 259–262). It has been pointed out (84), however, that many such reports involve observations made on only one or two patients. Consequently, the use of statistical analysis to determine the probability of a cause-and-effect relationship in such cases is an impossibility. On the other hand, the appearance of unusual symptoms during oral contraceptive therapy (in the absence of other drug use or predisposing conditions), their disappearance following drug withdrawal, and their reappearance upon readministration of the oral contraceptives would seem to suggest that unusual reactions may develop in rare cases as a result of oral contraceptive use. Nevertheless, the lack of placebo trials (*vide infra*) in these isolated cases prevents one from concluding positively that these reactions actually were due to the medication and were not merely coincidental occurrences (26).

Jelinek (260), for example, reviewed the available data concerning a number of cutaneous reactions reported to be associated with oral contraceptive use. These reactions include photosensitivity, herpes gestationis (in women who had previous attacks during pregnancy), and the induction or exacerbation (260, 261) of lupus erythematosus. Melasma, brown facial pigmentation, may be the most common cutaneous complication of oral contraceptive use; its incidence in users in the United States has been estimated at 5–8% (260). After cessation of oral contraceptive therapy, melasma appears to fade more slowly than does that which accompanies pregnancy, and it actually may be permanent. In addition, women who have had melasma during pregnancy appear to be more likely to develop the condition during subsequent oral contraceptive use.

Various neurological manifestations similarly have been associated with oral contraceptive use. In some cases, however, the events cited may have had a vascular etiology. Reported symptoms include chorea (262), migraine (15, 26, 259), and decreased visual acuity (259), as well as other ocular disorders (15, 259).

Goldzieher *et al.* (263) recently pointed out that although numerous reports exist in the literature that suggest an association between subjective complaints, such as nervousness and depression, and the use of oral contraceptives, the frequency of such symptoms actually attributable to these drugs is still unknown. Previous studies lacked an experimental design that incorporated: (*a*) randomization of drug and placebo assignment, (*b*) double-blind administration, and (*c*) appropriate crossover of drugs and placebo. Using such a design, these workers showed that: (*a*) the incidence, during a pretreatment cycle, of complaints including nausea, vomiting, abdominal discomfort, mastalgia, headache, and depression could not be used as a baseline, and all of these symptoms, except for nausea and vomiting, diminished markedly upon initiation of placebo treatment; (*b*) significant increases in nausea, vomiting, headache, and nervousness could be demonstrated statistically only in the first treatment cycle with high estrogen agents; and (*c*) although a weight gain of 2.3 kg. (5 lb.) or more occurred in a substantial number of women over a period of four cycles, the weight gain was the same in the placebo group as in the other four groups which had been using, respectively, two different combination-type preparations, a sequential preparation, and a progestagen-only preparation.

The authors pointed out that the results of their study should not be construed as indicating that these various phenomena were not associated with oral contraceptive use, but rather that the true incidence of drug-related complaints was probably much lower than previously had been assumed. In support of this conclusion, Goldzieher *et al.* (263, 264) cited a study in which changes in the color of contraceptive medication had elicited changes in nausea and headache, as well as a decrease in libido. On the other hand, Goldzieher *et al.* (263) indicated that some degree of weight gain, for example, theoretically could be induced by the oral contraceptives since metabolic studies had shown an anabolic effect of progestagenic steroids when they were given to estrogen-primed women. Kudzma *et al.* (265), however, showed that in four women on a constant caloric intake, metabolic balance changes occurring during oral contraceptive-treated cycles were similar in magnitude to those occurring during normal, untreated menstrual cycles. Nevertheless, the results of a study (266) of adolescent users of oral contraceptives suggested that other factors, nutritional or psychological, for example, might play a role in weight gain during oral contraceptive use. The risk of significant weight gain in this study was found to be related directly to the patient's initial weight percentile at the start of contraceptive treatment.

In spite of the drawbacks of non-double-blind studies, a number of such investigations have been carried out in an effort to determine the incidence of various subjective and semisubjective complaints, particularly depression, in users and nonusers of oral contraceptives. Goldzieher (85), for example, compared the answers given by oral contraceptive users and intrauterine device users to nonleading questions regarding their health. Except during the first three cycles of oral contraceptive use, when the incidence of nausea was found to be high, the incidence of various symptoms including nausea, vomiting, diarrhea, malaise, tiredness, weakness, headache, dizziness, nervousness, depression, and decreased libido was found to be similar in oral contraceptive and intrauterine device users. The results of other studies, however, indicated: (*a*) less depression in oral contraceptive users than in intrauterine device users (267) or (*b*) greater depression in oral contraceptive users than in nonusers, the majority of the latter having been diaphragm users (268). Several explanations for the discrepancies have been suggested. With respect to the diaphragm users, it is Hart's (269) opinion that such a group would be highly selected (nonrandom), *i.e.*, that individuals using the diaphragm were likely to be of a more stable temperament than would be oral contraceptive users. With respect to the other study (267), the intrauterine device users had been significantly more depressed than the oral contraceptive users prior to the start of contraception by these groups. Other studies, furthermore, have shown that women with histories of depression (270–272) and other emotional disorders (272, 273) were the ones most likely to

complain of depression (270–272), to have psychotic reactions (273), and/or to experience tension, nausea, dizziness, forgetfulness, and anger (272) while using oral contraceptives.

Other factors also are likely to have an influence on whether or not side effects such as depression may develop in oral contraceptive users. Reactions such as depression, headache, and loss of libido were conspicuously absent from O'Dwyer's (274) patients. These women were strongly motivated to remain well and nonpregnant; the majority already had three or more children and had experienced unhealthy, unpleasant, and dangerous episodes during their pregnancies. Main (275) also emphasized the psychogenic aspect of oral contraceptive-induced depression. He outlined a number of problems that use of such medication produced in certain women: (*a*) sadness that there would be no chance of a slip-up and pregnancy; (*b*) sadness at removal of an "essential" ingredient for sexual pleasure—the risk; and (*c*) a number of other points, all of which suggested that the women studied had a poor adjustment to their sexuality. In conclusion, it is tempting to speculate that similar psychological factors contribute to the discrepancies found between the theoretical effectiveness and the use effectiveness of the various oral contraceptives (*vide supra*), as well as of various other methods of birth control.

OUTLOOK FOR THE FUTURE

The commercially available oral contraceptives are highly effective agents, although patient failures and even method failures can occur. They are also agents whose use has been associated with serious adverse reactions in some women. Consequently, the contraindication of their use in thromboembolic disorders, markedly impaired liver function, and estrogen-dependent neoplasia seems justified. Nevertheless, there is some evidence to suggest that both their effectiveness and the occurrence of severe adverse reactions in patients using them may be partly related to factors such as size of the individual and ethnic group (67) or genetic predisposition (142–146, 234, 237, 239). Furthermore, in the case of women with thromboembolic disorders, care must be taken to provide equivalently effective alternative method(s) of birth control, since the incidence of postpartum thrombosis has been shown to be higher than that occurring with the use of oral contraceptives (104, 119). With respect to women with liver disease, cautious advice (236) has been to avoid oral contraceptives in the presence of any type of acute or chronic disturbance of liver function; others (240), however, have indicated that the only absolute contraindication need be in patients with any type of acute or chronic cholestatic hepatobiliary illness "since the hepatic abnormalities induced by the pill are basically in the bile-secreting function."

Attempts to develop steroid contraceptives that might have less potential for producing serious adverse reactions, the low dose, progestagen-only preparations, for example, unfortunately have resulted in compounds that also are somewhat less effective than the conventional agents. On the other hand, greater effectiveness from the point of view of eliminating patient failures may be achieved by more extensive use of depot preparations, although method effectiveness in comparison with that of the conventional oral contraceptives does not seem to be altered. Furthermore, irregular bleeding seems to be more common with dosage forms and dosage regimens other than those of the commercially available combined and sequential oral preparations. Perhaps it is for this reason that it has been suggested that the injectable preparations may be abandoned as contraceptives for future use (75).

The intrauterine device, of which many types are available (276), seems to offer a good alternative to steroid contraception in that patient failure due to forgetting to take one's medication obviously is eliminated. Effectiveness varies, however, due to a number of factors, although the addition of a chemical, such as copper, to the intrauterine device may increase its effectiveness (277). Nevertheless, the long-term effects of the presence of an intrauterine device, not to mention the presence of a chemical in addition, cannot be anticipated at this time, particularly since the mechanism of action of the intrauterine device is thought to involve a foreign body-induced low grade inflammation in the endometrium (278).

Perhaps the most promising contraceptive means for the future may prove to be the use of agents with abortifacient, luteolytic, and/or menses-inducing properties. Such agents would be used once a month (15) and perhaps only in the event that menstruation was delayed due to fertilization and implantation having taken place. Menstruation has indeed been induced in women by the intravaginal administration of PGE_2 and $PGF_{2\alpha}$ (279). Bleeding was induced in 24 hr. or less in 11 of 12 women in whom menstruation had been delayed for 2–7 days. Eight of the 11 had a positive test for pregnancy. The 12th woman also was found to be pregnant and was aborted with a 5-mcg./min. PGE_2 infusion.

Prostaglandins are thought to be involved in the natural process of menstruation (279). Nevertheless, the mechanism by which intravaginally administered prostaglandins induce menstruation is not clear. It has been suggested that it may be the result of the increased uterine contractility that is produced, although an inhibitory effect on the corpus luteum has not been ruled out. The ease with which prostaglandins could be self-administered intravaginally within a few days of a missed menstrual period [or, alternatively, just prior to the expected time of menstruation every month, regardless of whether or not fertilization might have occurred (280)] gives these compounds a potentially important place in the future of contraception.

Pharmacokinetics of the β-Adrenergic Blocker Sotalol in Dogs

KURT SCHNELLE and EDWARD R. GARRETT▲

Abstract □ The time course of absorption, distribution, and excretion of the β-blocker sotalol was studied in three unanesthetized dogs at three dosage levels of 1, 2, and 4 mg./kg. i.v. and 2, 4, and 8 mg./kg. p.o. The drug was assayed in body fluids and excreta by a spectrophotofluorometric method and by counting of tritiated drug. Unchanged sotalol is excreted up to 90% (±12%) in the urine. There was no protein binding, and the partition coefficient between plasma and red blood cells was unity. The data obtained in the studies were fitted graphically and by analog computer techniques and demonstrated no dose dependence. The graphical fit of the plasma levels following intravenous administration in accordance with a two-compartment open body model revealed a rapid distribution phase with a $t_{1/2}$ of 3.2 ± 1.1 min., which was followed by a disposition phase with a $t_{1/2}$ of 4.8 ± 1.03 hr. The analog computer fittings of the plasma and urine data according to the two-compartment model gave constants similar to those obtained from the graphical fits. The addition of a third tissue compartment that was in slow equilibrium with the central compartment proved necessary for a better fit of the data obtained at the high dosage level and in the ^{3}H-sotalol assays. The 75–90% absorption of sotalol in solution following oral administration was rapid ($t_{1/2}$ = 11–17 min.).

Keyphrases □ Sotalol pharmacokinetics—absorption, distribution, and excretion after intravenous and oral administration to dogs, protein binding and plasma/red blood cell partition studies □ Pharmacokinetics, sotalol—absorption, distribution, and excretion following intravenous and oral administration, dogs □ Absorption, sotalol—following intravenous and oral administration, dogs

Sotalol hydrochloride[1], 4′-[1-hydroxy-2-(isopropylamino)ethyl]methanesulfonanilide monohydrochloride, is a specific and potent β-adrenergic blocking drug. Several studies in both animals and man have demonstrated that the compound reverses isoproterenol- and epinephrine-induced tachycardia (1–3) and reverses the increase in blood levels of free fatty acids, lactic acid, and glucose that follows isoproterenol and epinephrine infusion (4, 5). Since the drug possesses less "quinidine-like" activity, it has been suggested that sotalol therapy may be preferred over other β-blockers with pronounced negative inotropic side effects (6).

It has been indicated that the plasma levels of tritium-labeled drug are related to the drug's pharmacological

[a] The values for a cited experiment were obtained from graphical analysis of the data; the parenthetical values were obtained from analog computer fitting of the data. [b] Values obtained from the graphically determined slope, $\beta = k_e$ of ln(plasma levels) against time. The parenthetical values were calculated in accordance with $t_{1/2} = \ln 2/k_e$ where (12):

$$k_e = \frac{k_{P,U}}{1 + \frac{k_{P,T}}{k_{T,P}} + \frac{k_{P,T'}}{k_{T',P}}}$$

and $k_{P,T'}$ and $k_{T',P}$ values were included when significant and needed for a good fit of the data with the analog computer. [c] The studies were conducted in the tabular sequence at 0, 1, 8, 9.5, 11, and 12.5 months from the initial experiment. [d] The studies were conducted in the tabular sequence at 0, 3.5, 6, 13, and 14 months from the initial experiment. [e] The sotalol concentrations in blood and urine were analyzed by spectrophotofluorometric and radioactive assays simultaneously in the same experiment. The upper listing is based on the radioactive assay. All other studies were conducted by spectrophotofluorometric assays. [f] The sotalol concentrations in blood and urine were analyzed by the spectrophotofluorometric and radioactive assays simultaneously in the same experiment. The upper listing is based on the radioactive assay. In this experiment, bile samples were obtained on a biliary-cannulated dog. All other studies were conducted by spectrophotofluorometric assays. [g] The studies were conducted in the tabular sequence at 0, 1.5, and 2.5 months from the initial experiment.

activity in dogs (2). No significant metabolism occurred in dogs where 90% of the unmetabolized drug was excreted in the urine (2). Therefore, knowledge of the pharmacokinetic profile of sotalol should allow the design of an optimum dosage regimen from the plasma levels. The availability of a reasonably sensitive cold assay for the drug (7) is convenient for such studies. This paper describes the pharmacokinetics in the dog at multiple dosage levels of sotalol administered intravenously and orally.

EXPERIMENTAL

Treatment of Animals—The dogs were conditioned to the metabolic cages and trained for laboratory routine prior to experimentation. They were fasted for 24 hr. before each experiment. On the day of the experiment, the animals were placed on a table in a standing position and restrained by two straps which were tied around the fore and hind legs and then fixed to a horizontal bar above the dog. A jugular vein was punctured with a 14-gauge needle, and a vinyl tubing [0.11-cm. (0.044-in.) i.d., 0.16-cm. (0.065-in.) o.d.] was inserted through the needle. After free blood flow through the tubing was established, the needle was removed and 0.9% saline solution was dripped continuously at a rate of 1 ml./min. This infusion was maintained throughout 24 hr. to compensate for blood loss and to establish an adequate urine flow.

The urinary bladder was catheterized routinely through the urethra by inserting a ureteral catheter[2], French size 6 or 8. This catheter was kept in place for 24 hr. for continuous urine collection.

In one dog, Dog 2, the common bile duct was cannulated 1 week prior to an experiment. A laparotomy was performed under pentobarbital anesthesia (30 mg./kg.). After the cystic duct was tied, two 3.8-cm. (1.5-in.) pieces of polyethylene tubing[3] were inserted into the proximal and distal portions of the common bile duct. The two pieces were then connected by a flexible silicone rubber tubing [0.15-cm. (0.059-in.) i.d., 0.35-cm. (0.138-in.) o.d.] of 1.3-m. length to shunt bile. After the abdomen was closed, the loop was pulled under the skin by a wire to an incision on the back of the neck. There the tubing was cut and reconnected through a 14-gauge metal adapter which could be separated at will. Free passage through the tubing was assured by daily flushing of the distal part leading to the duodenum.

Pharmacokinetic Studies—Three male mongrel dogs, approximately 2 years of age and in apparent good health, were used in the balanced study. Hematocrit, white blood cell count, and erythrocyte sedimentation rate were within normal ranges (8). No dirofilarial larvae in the blood were observed microscopically. Body weights and the sequence of the experiments are listed in Table I.

Intravenous Studies—Sotalol[4] was administered intravenously to each of three dogs at three dosage levels: 1, 2, and 4 mg./kg. The

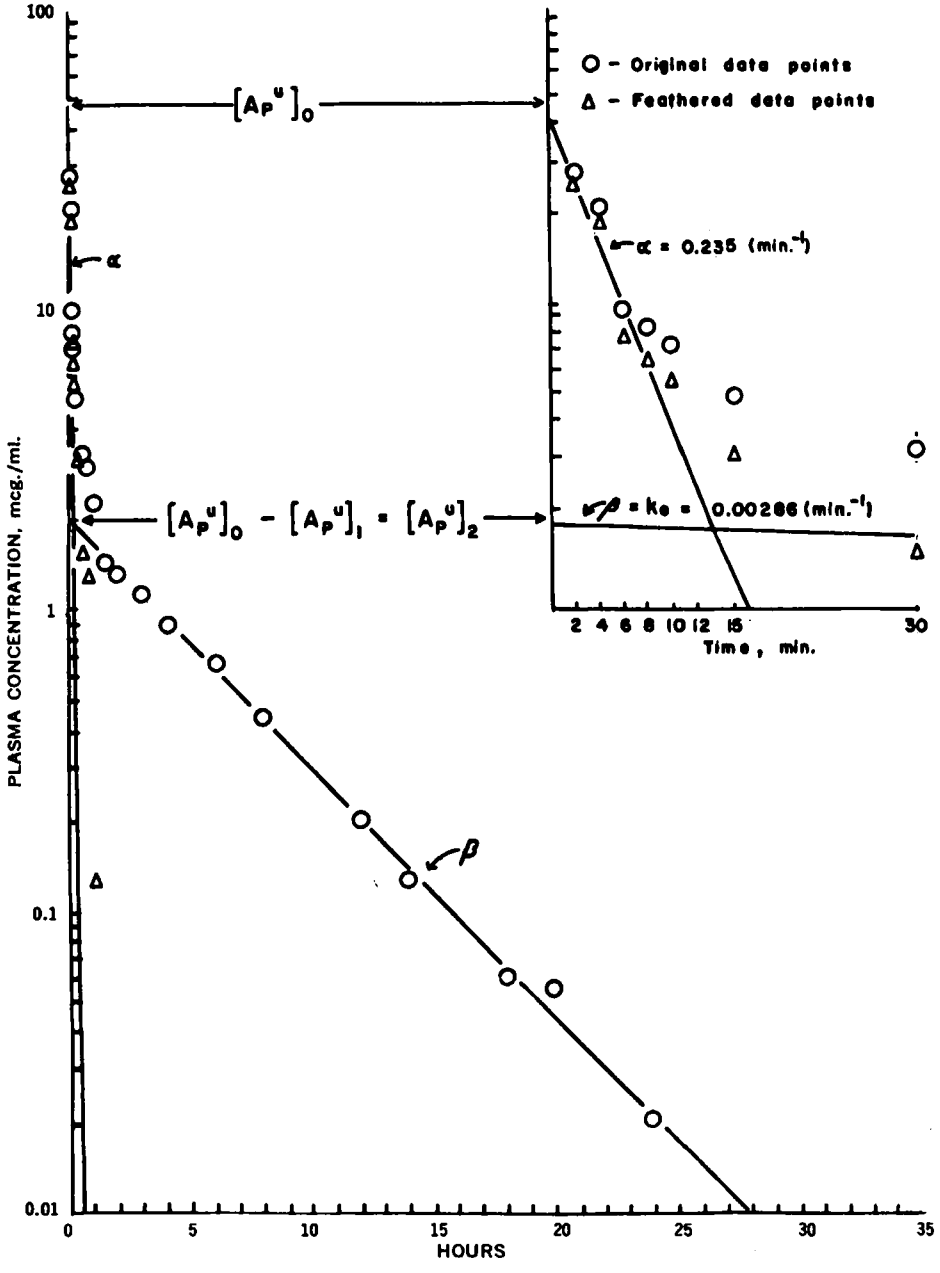

Figure 1—*Semilogarithmic plot of plasma levels following intravenous administration of 4 mg./kg. sotalol to 19.1-kg. Dog 3. The antilogarithmic values of the linear terminal portion with slope β were subtracted from the initial data points, and these feathered points were fitted to a straight line of slope α. $[A_P^u]_0$ is the intercept of the extrapolated line with slope α, i.e., the initial drug concentration in the central compartment, and $[A_P^u]_2$ at zero time is the drug concentration in the equilibrated tissues from the extrapolation of the linear terminal portion of the curve with slope β = k_e in accordance with a two-compartment open body model (Scheme I). The inset is for an expanded time scale. Key: O, original data points; and Δ, feathered values.*

time intervals between experiments in one animal were at least 4 weeks. The drug was injected as its hydrochloride salt in sterile solution containing 10 mg./ml. of the drug through a threeway stopcock into the jugular tubing. The duration of the injection was kept constant at 10 sec. The catheter was flushed with isotonic saline solution after the injection. A distinct reaction due to the rapid administration was only observed after the 4-mg./kg. dose as tachycardia, dyspnea, and increased salivation. Blood samples were withdrawn from the jugular vein at 1, 2, 4, 6, 8, 10, 12, 15, 20, 25, and 30 min. after completion of the injection; then in 15-min. intervals up to 120 min.; in 30-min. intervals up to 4 hr.; hourly up to 12 hr.; and every 2 hr. up to 24 hr. Urine was collected every 30 min. up to 4 hr., hourly up to 12 hr., and every 2 hr. up to 24 hr. The dogs were then transferred to a metabolic cage, and blood and urine were collected at 6-hr. intervals up to 48 hr. and every 12 hr. up to 72 hr. Completeness of urine collection was assured by catheterization. The blood volume withdrawn for each sample was 7 ml. from 0 to 12 hr. and 16 ml. thereafter.

Intravenous Studies with ^{3}H-Sotalol—The tritiated sotalol[4] was prepared as described elsewhere (2). The sterile solution contained 0.5 mg./ml. of the drug with a specific activity of 70 μc./ml. Sterile solutions of cold drug (10 mg./ml.) and labeled material were mixed in a sterile beaker to obtain a drug concentration that was adequate to yield dosages of 1 and 2 mg./kg. of total drug administered to Dog 2. The total activity administered was 1046 μc. at the 2-mg./kg. dose and 1123 μc. at the 1-mg./kg. dose. The schedule for blood and urine sampling was the same as described previously for up to 72 hr. Additional samples were collected every 24 hr. up to 144 hr. Over the same period of time, the feces were collected every 24 hr. in both experiments. Bile samples were obtained in one experiment on Dog 2 (1 mg./kg.) at 2.5, 5, 8, 10, 15, 20, 23, and 30 hr. after injection.

Oral Studies—The same sotalol solution (10 mg./ml.) used in the intravenous study was administered through stomach tubing in doses of 8, 4, and 2 mg./kg. to Dog 1. Blood samples were withdrawn at 2.5, 5, 7.5, 10, and 15 min. after drug administration and at the schedule given previously in the intravenous studies up to 4 hr., every 2 hr. up to 24 hr., and then again as described for the intravenous study. Urine was collected every 30 min. up to 4 hr. and thereafter at the same schedule given for blood samples.

Treatment of Samples—Blood was withdrawn with a disposable syringe and transferred to centrifuge tubes containing 30 USP units of sodium heparin[5] in a volume of 0.1 ml. distilled water to prevent clotting. Blood and urine samples were centrifuged at 3000 r.p.m.

[a] V_{P_e} calculated from the quotient, $A_0/[A_P]_0$, of the dose administered intravenously, A_0, and the initial concentration of total drug in the plasma, $[A_P]_0$, obtained from the intercept of the $[A_P]$ plot of the best computer fits against time with zero time. [b] $V_{P_{true}} = (1 - H)V_{B_{true}}$, where $V_{B_{true}}$ = dog weight in kg. × 100 ml./kg. (17), where the hematocrit, H, is taken as 0.40, 0.35, and 0.40 for Dogs 1, 2, and 3, respectively. [c] Calculated in accordance with $V_P{}^u = V_{P_e}{}^u - HV_{P_{true}}D/(1 - H)$ (Eq. 6). The volume of the central compartment, $V_P{}^u$, in the oral studies was calculated in accordance with Eq. 14 after solving for $V_P{}^u = (\gamma A_0/\text{I.C.}) - V_{RBC}$. When there is no protein binding, as in this case, $V_P{}^u$, the volume of the central compartment referenced to the concentration of total drug in the plasma, is the same as V_P, the volume of the central compartment referenced to the concentration of total drug in the plasma. [d] Calculated in accordance with $V_T = V_P{}^u(k_{P,T}/k_{T,P})$ (Eq. 16); the rate constants were taken as the values obtained from the best analog computer fits. [e] Calculated in accordance with $V_{T'} = V_P{}^u(k_{P,T'}/k_{T',P})$ (Eq. 17). [f] Calculated in accordance with the clearance equation (12), where the renal clearance of sotalol in milliliters per minute was divided by k_e in min.$^{-1}$ to yield $V_{DP}{}^u$ in milliliters. The fraction F of drug renally excreted becomes 1 when, as in this case, virtually all drug is excreted through the kidneys. [g] Calculated in accordance with $V_{DP}{}^u = V_{DP_e}{}^u - HDV_{P_{true}}/(1 - H)$ (Eq. 9), where the $V_{DP_e}{}^u$ was obtained in accordance with $V_{DP_e}{}^u$ = dose/$[A_P{}^u]_0$ (Eq. 7), where $[A_P{}^u]_0$ is the intercept of the extrapolated slope of k_e to zero time. [h] No urine data were obtained in this experiment. [i] The values for V_{P_e}, $V_P{}^u$, and V_T were obtained from values derived from the graphical fitting in accordance with the two-compartment body model (Scheme I). [j] The sotalol concentrations in blood and urine were analyzed by the spectrophotofluorometric and radioactive assays simultaneously in the same experiment. The upper listing is based on the radioactive assay.

for 10 min., and the supernatant plasma and urine were then refrigerated. The samples obtained in the radioactive study were split; one portion was deep frozen and sent away for the counting and chromatographic studies[6], and one portion was kept for the chemical assay.

Assay of Samples—The analyses were based on a modified spectrophotofluorometric method which was reported previously (7). The sensitivity was increased from 0.1 to 0.02 mcg./ml. of the drug by extracting from a larger volume (5 ml.) of deproteinized plasma. The lower limit of detection in the urine was 2.5 mcg./ml. Spiked plasma and urine samples were carried through the analytical procedures and assayed at the same time as the samples of unknown concentration. Radioactivity measurements[6] were conducted with a liquid scintillation spectrometer[7] corrected for background and quenching. Duplicate samples of 0.5 ml. plasma were mixed with 1 ml. of a solubilizer[8] and 10 ml. of a counting solution consisting of 5 g. 2,4-diphenyloxazole[9] and 0.5 g. *p*-bis-(*o*-methylstyrylbenzene)[9]/l. of toluene. Duplicate samples of 0.2 or 0.1 ml. of urine and 0.1 ml. of bile were added to 0.6 ml. of water and 15 ml. of solution of 5 g. 2,4-diphenyloxazole, 0.3 g. *p*-bis-(*o*-methylstyrylbenzene), and 120 g. naphthalene/l. of dioxane. Fecal samples were homogenized with nine volumes of water, and aliquots (100–200 mg.) of the homogenates were mixed with 0.6 ml. water and 15 ml. of the same counting solution used for urine.

The presence of possible metabolites of ^{3}H-sotalol was evaluated by paper chromatography of urine, plasma, and bile samples using the following systems: (*a*) strips of 2.54-cm. (1-in.) Whatman No. 1 paper and a solvent mixture of *n*-butanol–acetic acid–water (30:7.5:12.5), and (*b*) Whatman DE20 paper strips and 0.02 *N* phosphate buffer of pH 7.4 as the developing solvent. In each case, 50 µl. of sample was used. The strips were dried, cut into 1.27-cm. (0.5-in.) segments, and placed in counting vials with 0.6 ml. of water and 15 ml. of the dioxane counting solution already described.

Protein Binding Study—Binding of sotalol to plasma proteins was studied by an ultrafiltration method (9). The cone membranes used in these experiments[10] are retentive for plasma protein and permit only passage of ions and compounds of low molecular weight. Thus, only free diffusable drug was found in the filtrate. Possible binding to the membranes is cancelled out when equally spiked buffer–drug and plasma–drug solutions are carried through the entire procedure.

The binding to plasma protein can be estimated by:

$$100f(\%) = \frac{R_B - R_P}{R_B} \times 100 \qquad \text{(Eq. 1)}$$

where f is the fraction bound to plasma protein, R_B is the fluorescence reading of buffer filtrates, and R_P is the reading of plasma filtrates that were spiked with equal concentrations of drug.

Heparinized dog plasma and isotonic phosphate buffer solutions of pH 7.45 were spiked with sotalol hydrochloride to achieve drug concentrations of 0.3, 0.6, 1.0, 5.0, 10.0, 25.0, 50.0, 100.0, and 1000.0 mcg./ml. Aliquots (6.00 ml.) of these solutions and of plasma and buffer blanks were transferred to cone membranes which were placed in plastic supports on top of 40-ml. centrifuge tubes. The solutions were then centrifuged at 1700 r.p.m. The time needed to obtain approximately half-filtration was 2 min. for the buffer solutions and 25 min. for the plasma solutions. The filtrates were carried through the analytical procedure and assayed spectrophotofluorometrically.

Red Blood Cell Partition—The partition of sotalol into the red blood cells was studied as functions of drug concentration and time. Freshly drawn heparinized whole blood and plasma were transferred into 125-ml. conical flasks which were placed in a slowly shaking water bath at 37.5°. The whole blood was then spiked with sotalol to achieve concentrations of 0.5, 1.0, 10.0, and 100.0 mcg./ml. of the drug. Plasma spiked with 1.0 mcg./ml. and whole blood without drug were processed by the experimental procedure and

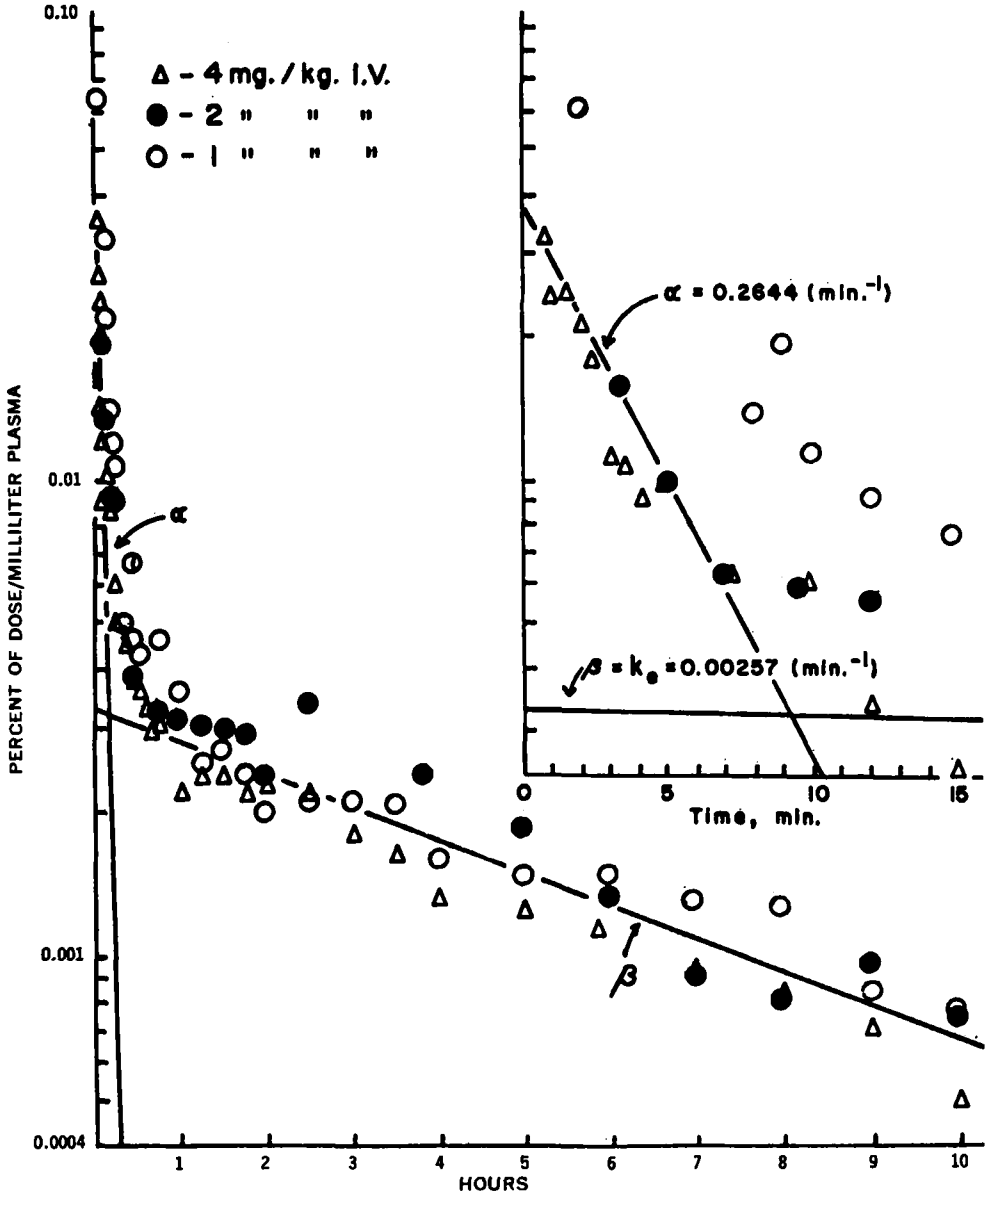

Figure 2—*Semilogarithmic plots of the plasma levels in terms of percent of dose per milliliter plasma against time following intravenous administration of 4 (Δ), 2 (●), and 1 (○) mg./kg. of sotalol to 19-kg. Dog 1. The data points obtained at the three dose levels could be graphically fitted with one common curve in accordance with a two-compartment open body model (Scheme I). The individual values for α and β are given in Table I. The inset is for an expanded time scale.*

the obtained results served as reference standard and blank, respectively. Samples of the blank blood and of the whole blood containing 1.0 mcg./ml. of the drug were withdrawn at 1, 3, 7, 10, 30, 60, and 120 min. after spiking. Samples of the plasma solution of 1.0 mcg./ml. were taken at 1, 30, and 120 min. Samples were withdrawn at 30 min. from all whole blood solutions of the various drug concentrations. Small specimens for the hematocrit determination were taken immediately after sampling, and the blood was centrifuged for 5 min. at 3000 r.p.m. The plasma was stored at 4° until the assay was performed. The fluorescence readings of all samples were compared to a calibration curve in plasma spiked with 0.1, 0.3, 0.6, and 1.0 mcg./ml. sotalol and to the readings of the plasma standard of 1.0 mcg./ml. that was carried through the procedure. The red blood cell/plasma unbound drug partition coefficient could be estimated by (10, 11):

$$D = [A_{RBC}]/[A_P^u] = \{[A_B]/[A_P](1 - f)(1 - H) - [f/(1 - f)] - 1\}(1 - H)/H \quad \text{(Eq. 2)}$$

where $[A_{RBC}]$, $[A_B]$, and $[A_P]$ are the drug concentrations in the red blood cells, whole blood, and plasma, respectively; $[A_P^u]$ is the drug concentration in plasma unbound to proteins; H is the hematocrit; and f is the fraction of drug in plasma bound to plasma proteins. If, as in this specific case, there is no significant protein binding, $f = 0$ and then $[A_P^u] = [A_P]$, which is the total concentration of drug in the plasma, and Eq. 2 reduces to:

$$D = \{[A_B]/[A_P^u](1 - H) - 1\}(1 - H)/H \quad \text{(Eq. 3)}$$

CALCULATIONS AND TREATMENT OF DATA

Plasma—The raw data were plotted in terms of micrograms per milliliter of plasma *versus* time on semilogarithmic paper. In the great majority of cases, the concentrations of unbound drug in the plasma, $[A_P^u]$, on intravenous administration exhibited a biexponential decay of the plasma levels as a function of time (Fig. 1), which can be described as:

$$[A_P^u] = [A_P^u]_1 e^{-\alpha t} + [A_P^u]_2 e^{-\beta t} \quad \text{(Eq. 4)}$$

The value for β was obtained from the slope of the linear terminal portion of the logarithm of the plasma level–time curve where excretion was the rate-determining process. The value for the slope of the rapid distribution phase, α, was estimated by subtracting the corresponding antilogarithmic values of the line of slope β extrapolated to zero time from the antilogarithms of the initial points of the log plasma concentration–time curve (12). Hence, a two-compartment open body model (Scheme I) was assumed, where P_u is amount of drug in the central compartment that is associated with plasma and referenced to the concentration of unbound drug in the

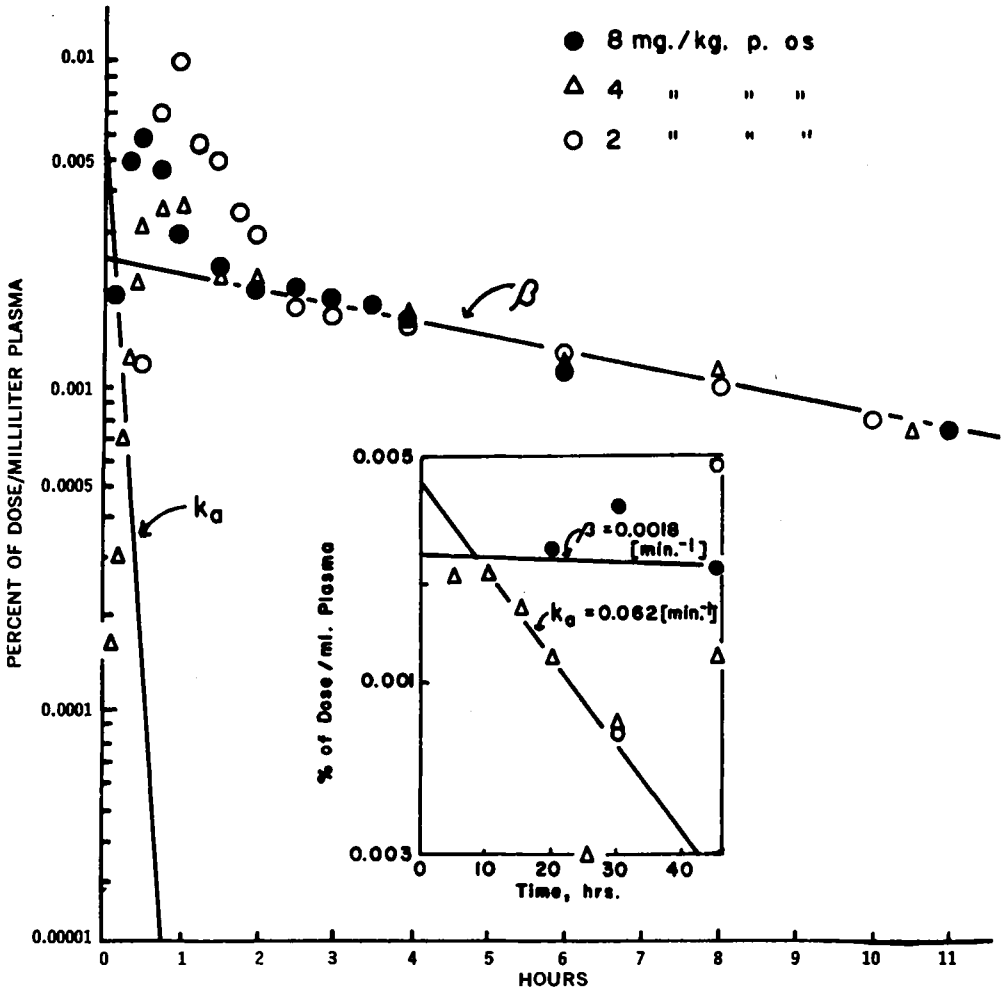

Figure 3—*Semilogarithmic plots of plasma levels in percent of dose per milliliter plasma following oral administration of 8 (●), 4 (△), and 2 (○) mg./kg. of sotalol to 19-kg. Dog 1; the plots show an apparent independence of dose. The extrapolation of the linear terminal portion of the curve cuts off the top of the absorption phase. Therefore, it was not possible to obtain an accurate estimate of k_a by the feathering technique. The individual values for $\beta = k_e$ and the absorption rate constants k_a estimated by graphical and analog computer methods are given in Table I.*

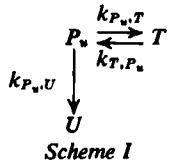
plasma (11, 13), T is the amount of drug in a peripheral tissue that equilibrates readily with P_u, and U is the amount eliminated from the body.

The apparent first-order rates $k_{P_u,T}$, k_{T,P_u}, and $k_{P_u,U}$ were calculated from the α- and β-values obtained (14). Estimates of the half-lives ($t_{1/2}$) of the distribution and disposition–excretion phases were obtained by dividing α and β into ln 2.

The extrapolation of the α-phase to zero time represented the initial concentration, $[A_P{}^u]_0$, of drug in the central compartment that was in the plasma and unbound, where instantaneous mixing of the drug with the plasma and its associated fluids occurred (12). Thus, the apparent volume of distribution of the central compartment, $V_P{}^u$, referenced to the concentration of unbound drug in the plasma would be estimated (11) from:

$$V_P{}^u = \{A_0 - (A_{RBC})_0 - (A_P{}^b)_0\}/[A_P{}^u]_0 = V_{P_s}/(1-f) - HV_{P_{true}}D/(1-H) - V_{P_{true}}f/(1-f) \quad \text{(Eq. 5)}$$

where A_0 is the total amount of drug administered; and $(A_{RBC})_0$ and $(A_P{}^b)_0$ are the initial amounts of drug in the red blood cells and in plasma bound to plasma proteins, respectively. The V_{P_s} is the pseudo-apparent volume of distribution of the central compartment referenced to total drug concentration in plasma, $A_0/[A_P]_0$, where $[A_P]_0$ is the total concentration of drug in the plasma at zero time; D, H, and f are the red blood cell/plasma partition coefficient, the hematocrit, and the fraction of drug in the plasma bound to plasma proteins, respectively. The $V_{P_{true}}$ is the true plasma volume of the animal (11).



Scheme I

If there is no protein binding, $f = 0$ and $(A_P{}^b)_0 = 0$, which is so in this specific case; then $V_P{}^u = V_P$, which is the apparent volume of distribution referenced to total drug concentration in the plasma. Similarly, $V_{P_s}{}^u = V_{P_s}$. Thus, Eq. 5 reduces (11) to:

$$V_P{}^u = V_{P_s}{}^u - HV_{P_{true}}D/(1-H) \quad \text{(Eq. 6)}$$

The sum of the pseudoapparent volumes of distribution of the central compartment and of the readily perfused tissue, $V_{D_{P_s}}{}^u$, referenced to the concentration of unbound drug in the plasma can be estimated (11) from:

$$V_{D_{P_s}}{}^u = V_{P_s}{}^u + V_{T_{P_s}}{}^u = \text{dose}/[A_P{}^u]_2 = A_0/([A_P{}^u]_0 - [A_P{}^u]_1) \quad \text{(Eq. 7)}$$

where the divisor of the last two terms is the concentration of unbound drug in the equilibrated fluids after the rapid equilibration of the α-phase on the assumption of insignificant drug excretion during the time interval of this equilibration.

It has been shown (11) that the sum of the apparent volumes of distribution of the central compartment and of the readily perfused tissues, $V_{D_P}{}^u$, referenced to the total unbound drug concentration in the plasma is actually:

$$V_{D_P}{}^u = V_P{}^u + V_{T_P}{}^u = \frac{\text{dose} - (\text{amounts in red blood cells and bound to plasma protein})}{[A_P{}^u]_2} = V_{D_{P_s}}/(1-f) - HDV_{P_{true}}/(1-H) - V_{P_{true}}f/(1-f) \quad \text{(Eq. 8)}$$

and can be calculated from the equivalent pseudovolume of dis-

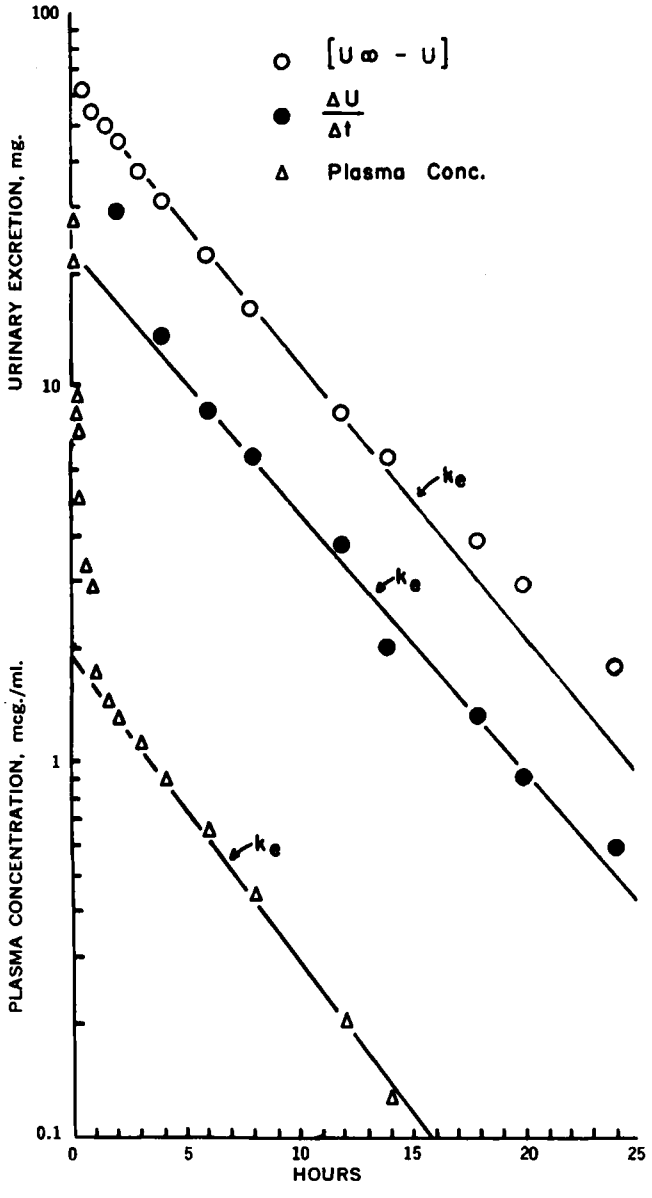


Figure 4—*Semilogarithmic plots of plasma concentrations in micrograms per milliliter (Δ), of the rate of urinary excretion per 2 hr., ΔU/Δt, in milligrams (●), and of the differences between the amount of drug recovered in the urine, U_∞, and the amounts excreted at time t, U, in milligrams (○). Data were obtained following the intravenous administration of 4 mg./kg. sotalol to 19.1-kg. Dog 3.*

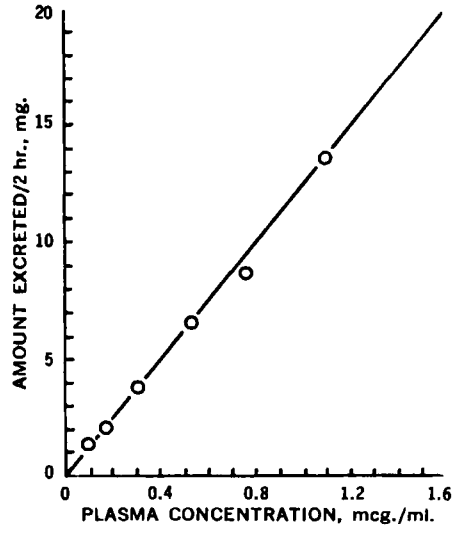

Figure 5—*Linear plot of the rate of urinary excretion per 2 hr., ΔU/Δt, against the plasma concentrations at midpoint of the periods of urine collection. The resulting points were fitted to a straight line through the origin whose slope is the renal clearance in accordance with* $\Delta U/\Delta t = k_{P,U}A_P^u = k_e F V_{D_P}^u [A_P^u]$ *(Eq. 11), where* k_e *is the overall elimination constant,* F *is the drug concentration in the plasma cleared by the kidneys,* $V_{D_P}^u$ *is the apparent volume of distribution, and* $[A_P^u]$ *is the drug concentration at the midpoint of urine collection. Data were obtained following the intravenous administration of 4 mg./kg. sotalol to 19.1-kg. Dog 3.*

tribution (Eq. 7) estimated from the linearly extrapolated intercept, $[A_P^u]_2$, of the β-phase if negligible excretion is assumed in the α-phase.

If $f = 0$, as in this case, the last term of Eq. 8 vanishes and:

$$V_{D_P} = V_{D_P}^u = V_{D_{P_2}}^u - HDV_{P_{true}}/(1 - H) \qquad \text{(Eq. 9)}$$

These estimates of $[A_P^u]_2$ and thus $V_{D_{P_2}}^u$ were obtained from plots such as the typical one given in Fig. 1. The rate constants and the other parameters obtained by graphical procedures are summarized in Tables I and II.

The plasma levels were plotted as percent of dose administered per milliliter of plasma against time for the several doses in the same dog. If those peaks were superimposable, the possibility of dose-dependent pharmacokinetics could be rejected. Such a typical set of plots is given for the intravenous studies in Fig. 2 and for the oral studies in Fig. 3. The β-values, $V_{D_P}^u$, and $t_{1/2}$, in the oral studies were obtained from the linear terminal portion of the semilogarithmic plasma concentration–time plots. A preliminary estimate of the absorption rate constant, k_a, was obtained from feathering the plasma level–time data (15) in accordance with:

$$\ln [A_P^u] = -k_a t + \ln [A_P^u]_0' \qquad \text{(Eq. 10)}$$

where $[A_P^u]_0'$ is an initial estimate of the concentration of the drug in the rapidly equilibrated tissues. It is realized that the validity of this method of k_a and $[A_P^u]_0'$ estimation is based on the premise of negligible excretion during the absorption phase. Since the line extrapolated from the semilogarithmic plot of the terminal data that represented the disposition phase with the slope of β was considerably lower than the actual plasma level data at its maximum values in all three oral experiments (Fig. 3), this feathering procedure could not yield the real k_a. This phenomenon is a consequence of relatively rapid absorption where equilibration of drug among the available tissues is not readily effected during the absorption phase.

Urine—The concentrations determined in the urine were multiplied by the volumes of urine excreted, and these amounts were plotted cumulatively against time to obtain the total recovery of drug, U_∞. Estimates of the overall elimination rate constant, k_e (*i.e.*, β), were also obtained (12) from semilogarithmic plots of the amounts not yet excreted in the urine, $\ln (U_\infty - U)$, *versus* time and the rate of excretion, $\ln \Delta U/\Delta t$, *versus* time (Fig. 4 and Table II). The renal clearance of sotalol was determined by a plot of the rate of excretion, $\Delta U/\Delta t$, against the plasma concentrations taken at the midtime of the interval of the urine collections, where ΔU is the amount of drug excreted in the urine in the time interval, Δt (Fig. 5 and Table II). The slope of this plot, in accordance (12) with:

$$\Delta U/\Delta t = k_{P,U}A_P^u = k_e F V_{D_P}^u [A_P^u] \qquad \text{(Eq. 11)}$$

is the renal clearance, where k_e is the disposition constant β, F is the fraction of the drug in the body that is cleared by the kidneys, $V_{D_P}^u$ is the apparent volume of distribution of the equilibrated tissue referenced to the concentration of unbound drug in the plasma, and $[A_P^u]$ is the concentration of drug in the plasma at the midtime of the interval of urine collection. Since the k_e values are known from other treatments of the data (Figs. 1–4) and F is the ratio of drug renally excreted to the dose administered, this slope also permits the determination of the apparent volume of distribution of the readily equilibrated tissues, $V_{D_P}^u$, referenced to the plasma concentration of unbound drug (Table II).

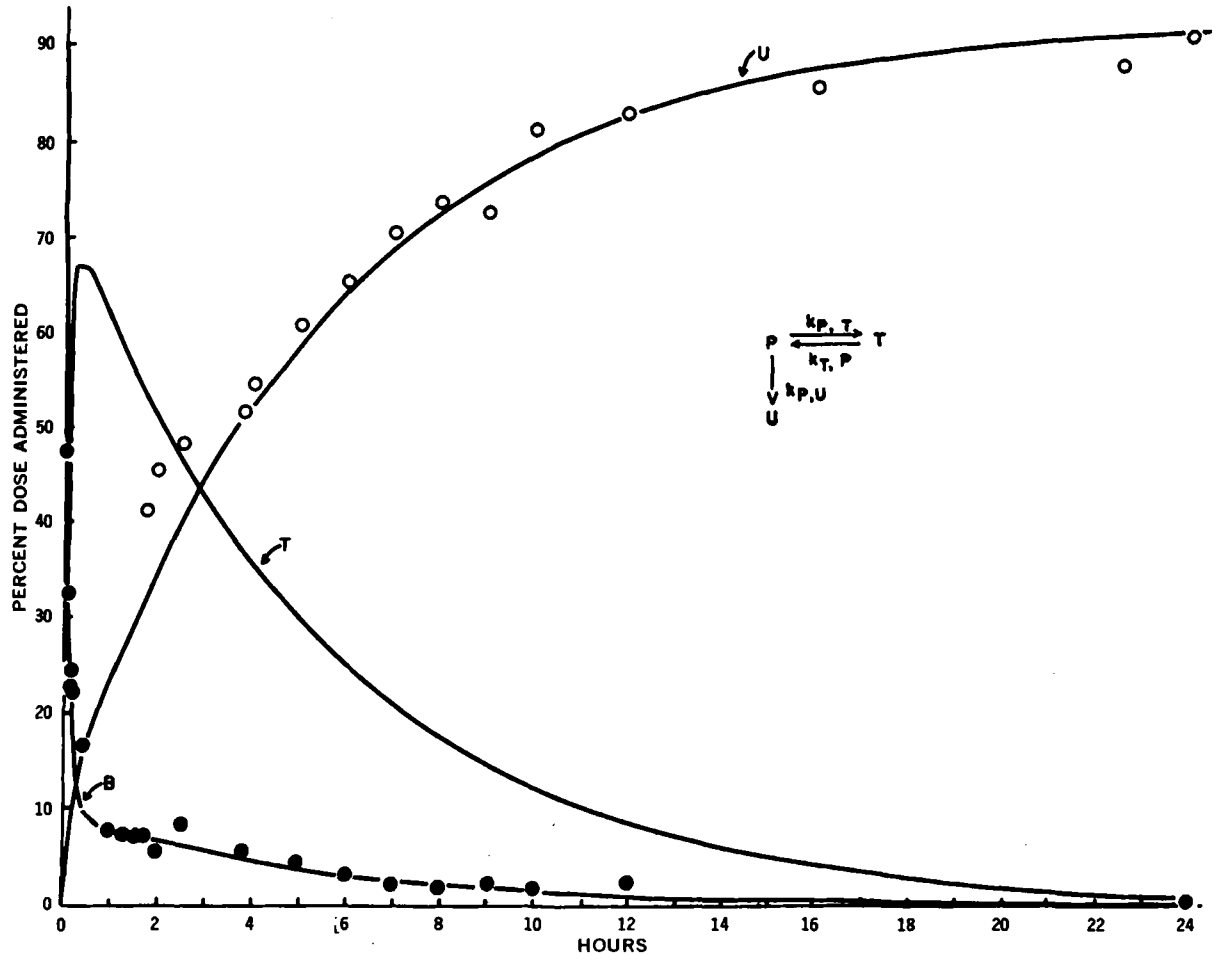

Figure 6—*Analog computer fitting of plasma* (●) *and urine* (○) *data in accordance with a two-compartment body model (Scheme I) following the intravenous administration of 2 mg./kg. to 18.1-kg. Dog. 1.* T *is the generated curve for the tissue compartment.*

Analog Computer Fitting: Programming—The program used in the analog computer[11] fitting of the pharmacokinetic data for a three-compartment body model was given previously (16). The initial conditions that represented the administered dose were fed into the central compartment *P* (plasma) for the data of the intravenous studies and into the GI compartment (gastrointestinal tract) for the data of the oral studies. The time scaling was set with a "ramp function" in such a manner that 0.5 in. on the graph paper equaled 1 hr. of the total 30 hr. of data and consumed 4 sec. of machine time. The recorder speed for the 3- and 6-hr. fits was increased by a factor of 10 and 5, respectively, through different settings of the *x*-axis range switch on the *x*–*y* recorder[12]. The range of the *y*-axis was increased 10-fold when the later portion of the plasma curves was fitted.

Intravenous Administration—The initial drug concentration in the central compartment was obtained from the best analog computer fit of the linear plot of the plasma concentrations against time in accordance with the two-compartment body model (Scheme I) and was considered as 100% of the dose in the plasma and associated fluids. Instantaneous mixing of the drug in the blood was assumed. The other data were represented as fractions of this 100%. The cumulative urinary excretion was plotted in terms of percent of dose administered. The urinary data were plotted over 30 hr.; the plasma data were plotted on a 30-hr. and expanded 6- and 3-hr. time scales and over 30 hr. on a 10 times enlarged ordinate covering 0–10% of dose administered. In this manner, an excellent fitting of the early as well as the later phases of the plasma level–time curves was possible.

As a first approach, the two-compartment body model (Scheme I) was assumed and the rate constants obtained from the graphical fit were used as first estimates for the potentiometer settings. A good fit was obtained with this model for the lower dosages of 1 and 2 mg./kg., and the curves for the latter are shown in Fig. 6. At the high dosage level of 4 mg./kg. and in the radioactive studies where the assay sensitivity was greater, positive deviations of the urinary excretion and terminal plasma data from the best fit with time were observed. A typical fit of such data by the two-compartment body model is given in Fig. 7.

The plateau observed in the terminal plasma data could be assigned to the return of the drug from a deeper compartment. Therefore, to obtain a better fit in these instances, a tissue compartment *T′* with comparatively slow equilibration rate constants, $k_{P,T'}$ and $k_{T',P}$, was added, and the same data were fitted according to the resultant three-compartment body model (Fig. 8). The three-compartment body model fitted the data following administration of lower doses equally well (Fig. 9). The rate constants obtained from the best fits of plasma and urine data following intravenous administration are summarized in Table I.

Oral Administration—The plasma levels after oral administration were plotted in micrograms per milliliter as a function of time. The initial conditions (I.C.) given to the analog computer were placed in the GI compartment. They were estimated on the presumption that they were equal to the initial concentrations, $[A_P^u]_0$, that would appear in the plasma and be unbound to plasma proteins if the fraction γA_0 of the dose were absorbed instantaneously. Such initial conditions, I.C., can be calculated from:

$$\text{I.C.} = [A_P^u]_0 = \frac{\gamma A_0 - (V_{RBC}D + V_{P_{true}})[f/(1-f)][A_P^u]_0}{V_{P^u}} \quad \text{(Eq. 12)}$$

since $[A_{RBC}]_0 = D[A_P^u]_0$ from Eq. 2, and $[A_P^b]_0 = [f/(1-f)]\,[A_P^u]_0$ (11). When there is no protein binding and $D = 1$, as in this case,

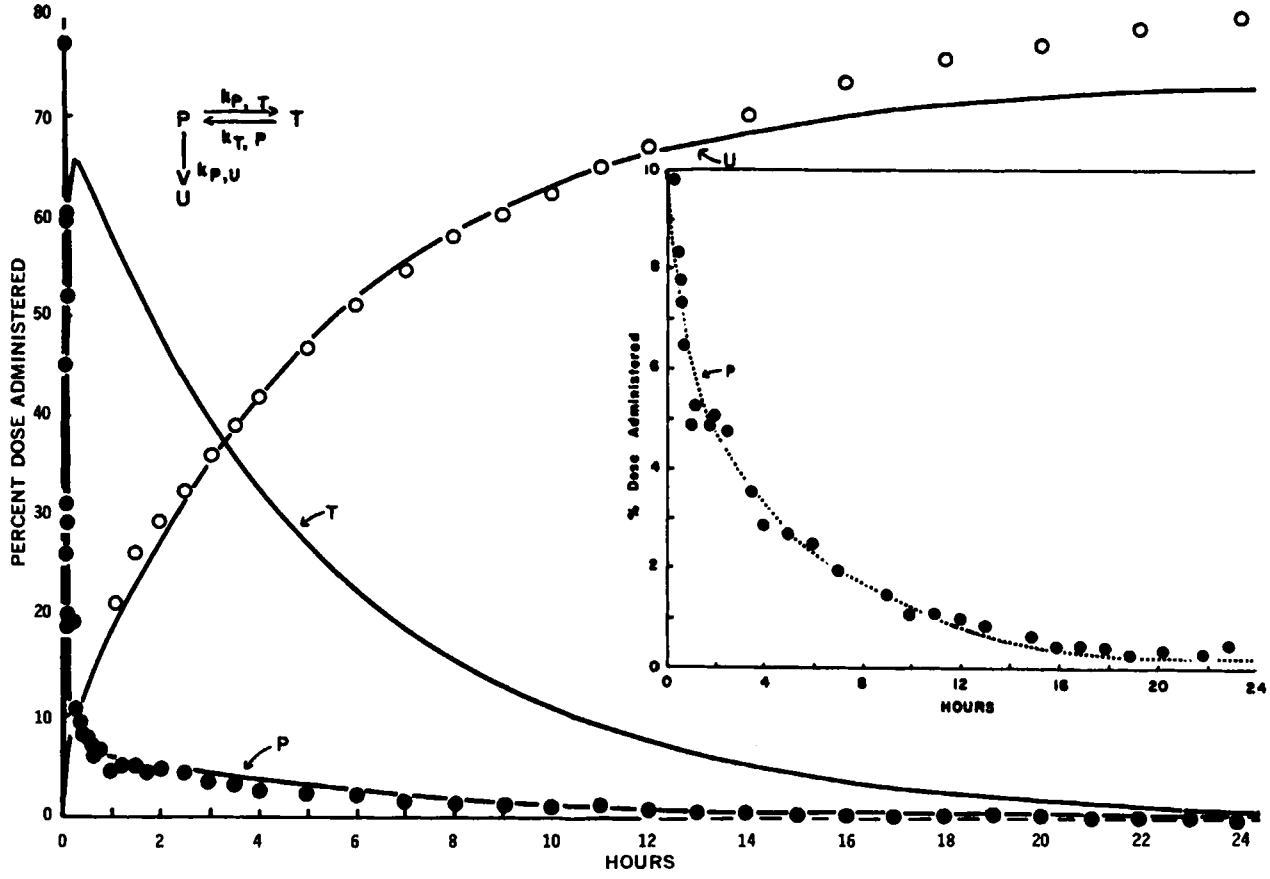

Figure 7—*Analog computer fitting of plasma (●) and urine (○) data following the intravenous administration of 4 mg./kg. sotalol to 17.2-kg. Dog 1 in accordance with a two-compartment body model. The computer curve for urine does not fit the data points in the later time period, indicating a "dribbling out" of drug from a deeper compartment. The inset is for an expanded ordinate scale.*

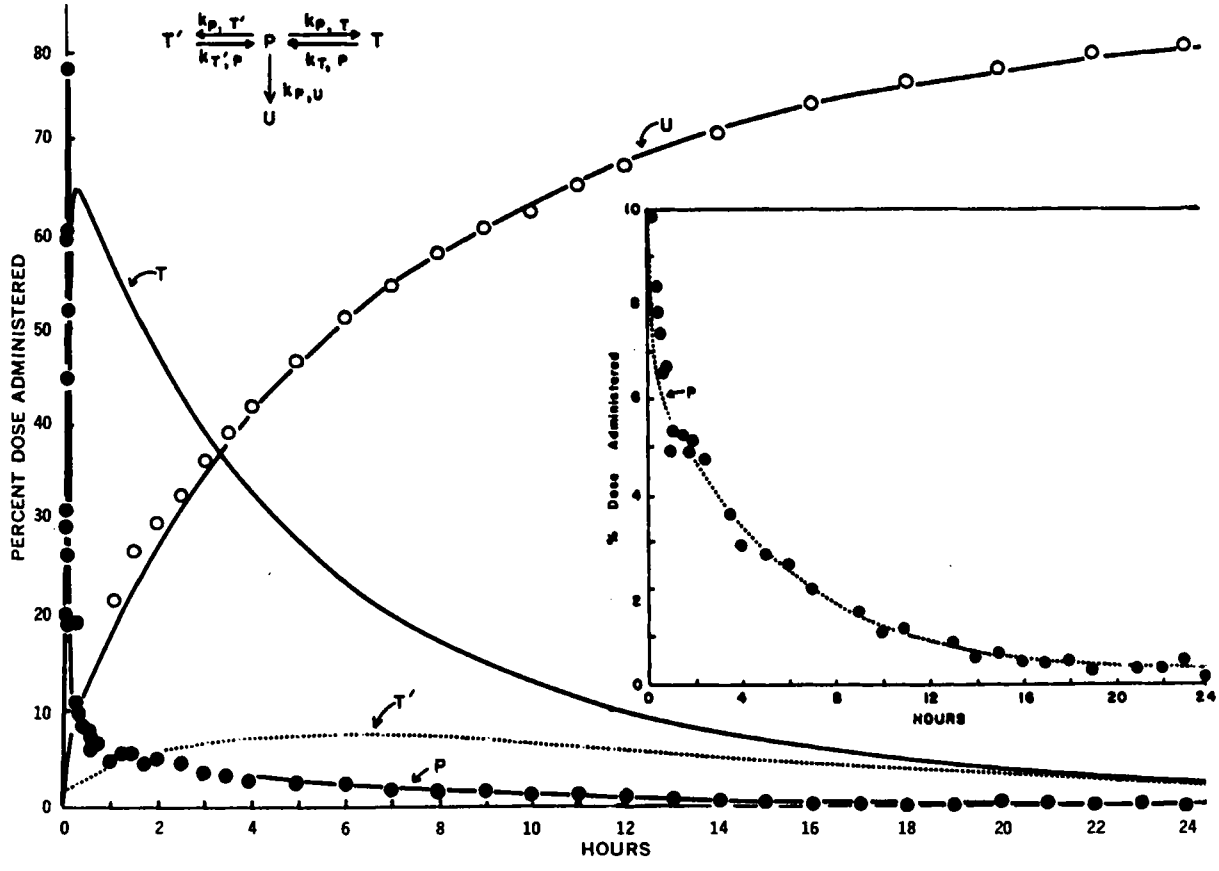

Figure 8—*Analog computer fitting of the same plasma (●) and urine (○) data as in Fig. 7 in accordance with a three-compartment body model. The addition of the tissue compartment, T', represented by the dashed line, that is in slow equilibrium with the central compartment, P, allows good fitting of the terminal portion of the cumulative urinary excretion and the 10-fold enhanced terminal plasma curve (inset).*

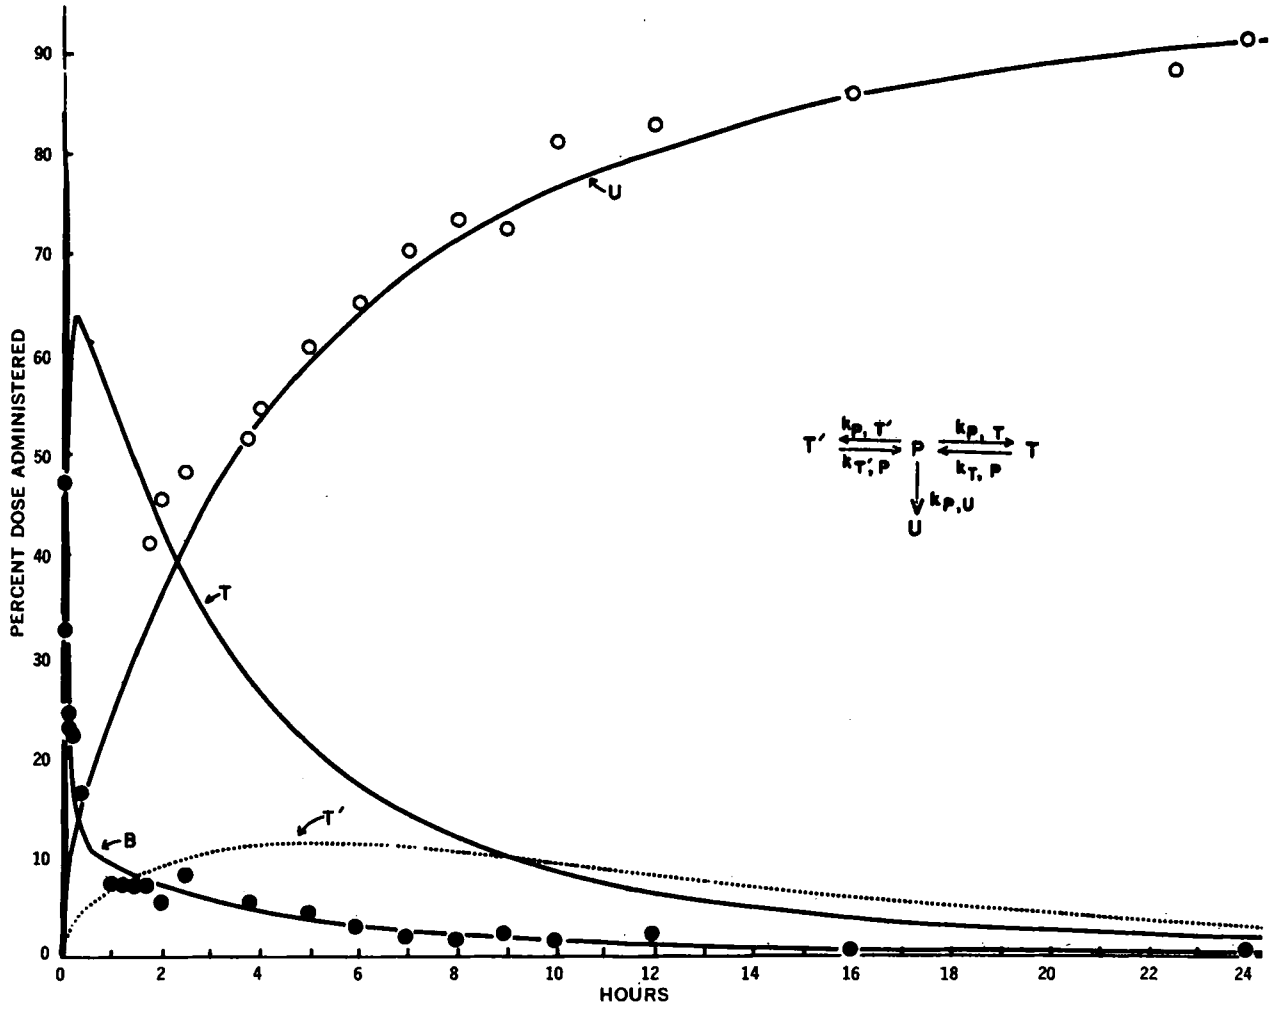

Figure 9—*Analog computer fitting of the same plasma (●) and urine (○) data as in Fig. 6 in accordance with a three-compartment body model (shown in figure). The dashed line represents the generated curve for* T'.

Eq. 12 simplifies to:

$$[A_P{}^u]_0 = \frac{\gamma A_0 - V_{RBC}[A_P{}^u]_0}{V_P{}^u} \qquad \text{(Eq. 13)}$$

Explicit solution of this equation results in:

$$[A_P{}^u]_0 = [A_P]_0 = \text{I.C.} = \frac{\gamma A_0}{V_P{}^u + V_{RBC}} \text{ [mcg./ml.]} \qquad \text{(Eq. 14)}$$

The fraction absorbed, γA_0, may be obtained from the ratio of the areas under the plasma curves of oral to intravenous administration of the same dose in the same dog (15). It may also be estimated from the ratio of the cumulative amounts excreted in the urine on oral administration to the amounts on intravenous administration of equal doses in the same dog. The volumes of distribution of the central compartment, $V_P{}^u$, referenced to unbound drug concentration in plasma were initially postulated to be the same as the corresponding intravenous values (Table II) for the first estimates of the initial conditions, I.C. The volume of the red blood cells was calculated for a blood volume, $V_{B_{true}}$, of 100 ml./kg. (17) and a hematocrit of 40% in this dog as $0.4 \times V_{B_{true}}$.

These I.C. values and the rate constants derived from the best fit of the data obtained from intravenous administration of 4 mg./kg. to the same dog (Table I) were used in the first fittings of the three sets of oral data. The potentiometers representing $k_{P,T'}$ and $k_{T',P}$ were turned to zero, and the data were first simulated according to a two-compartment model (Scheme I) by adjusting only the rate constant for absorption, k_a.

A good fit was obtained with this model for the data of the 2-mg./kg. dose (Fig. 10). The tissue, T', and the pertinent rate constants, $k_{P,T'}$ and $k_{T',P}$, were included for the 4- and 8-mg./kg. dose, and the fit of the oral dose of 8 mg./kg. is given in Fig. 11 as an example in accordance with the three-compartment body model. A lag time for absorption (15–45 min.) had to be assumed to fit the first portion of the data, and a slight decrease in the $k_{P,U}$ setting was needed to give the best fits of the plasma concentrations following oral administration (Table I). Curves for the amounts of drug in terms of the arbitrary microgram per milliliter concentrations for urine and the tissues were generated by the computer from the best fits of the plasma data in accordance with the two-compartment and three-compartment body models.

Since these curves were generated from drug concentrations that were distributed in the volume of the central compartment, $V_P{}^u$, they were all in terms of this $V_P{}^u$, *i.e.*, $T/V_P{}^u$, $T'/V_P{}^u$, and $U/V_P{}^u$, where T, T', and U are the amounts in the tissues and urine, respectively. The capacity of the $V_P{}^u$ in milliliters, *i.e.*, $V^u_{P(est)}$, can be estimated when the experimentally observed amounts excreted in the urine, U in micrograms, are divided by the generated urine curves, $U/V^u_{P(est)}$ in micrograms per milliliter, at the times of urine collection and is related to the true $V_P{}^u$ by:

$$V^u_{P(est)} = V_P{}^u \frac{\gamma A_0}{U_\infty} \qquad \text{(Eq. 15)}$$

If all of the drug absorbed were excreted in the urine as unchanged material, $V_P{}^u = V^u_{P(est)}$. In this case, there was no apparent difference in the percent of the dose recovered in the urine between intravenous and oral studies (Table II). Thus, a plot of U in micrograms divided by $V_{P(est)}$ in milliliters gave the cumulative excretion consistent with the actual data. These plots were only slightly off the computer-generated curves for urine. Small adjustments of the I.C. and of $k_{P,U}$ were sufficient.

The adjusted initial conditions, I.C., *i.e.*, $[A_P{}^u]_0$, were then inserted into Eq. 14, which was solved for the best estimates of $V_P{}^u$ based on the combined fittings of plasma and urine data (Table II).

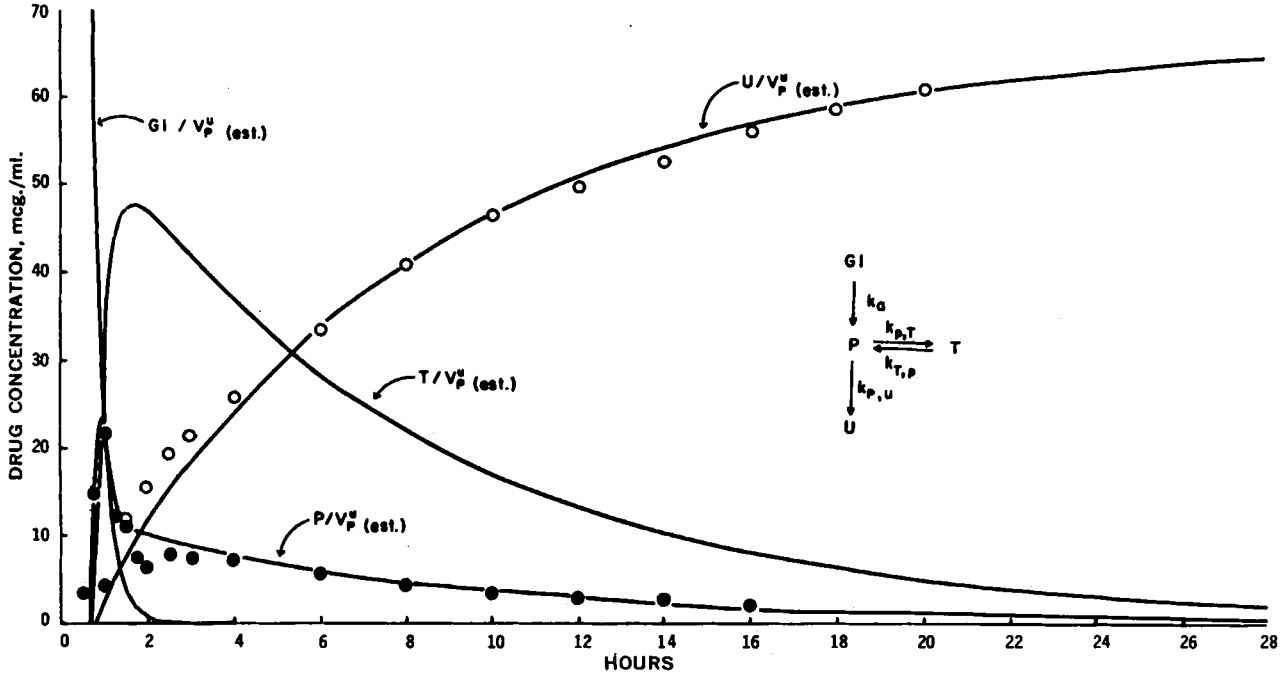

Figure 10—*Analog computer fitting of plasma* (●) *and urine* (○) *data following oral administration of 2 mg./kg. sotalol to 20.2-kg. Dog 1 in accordance with the two-compartment model and addition of a GI compartment. The plasma data in micrograms per milliliter were first fitted with rate constants identical to those of the 4-mg./kg. i.v. dose to the same dog. The I.C.'s were calculated according to Eq. 14 and only the* k_a *was varied. Curves for* $U/V^u_{P(est)}$ *and* $T/V^u_{P(est)}$ *were generated by the computer.* $V^u_{P(est)}$ *was obtained by dividing* U_{exp} *in micrograms by* $U/V^u_{P(est)}$ *in micrograms per milliliter. The final fit was made according to the plot of* $U_{exp}/V^u_{P(est)}$ *to yield the real* $V_P{}^u$ *in accordance with Eq. 14:*

$$V_P{}^u = \frac{\gamma A_0}{I.C.} - V_{RBC}$$

A lag time for gastric emptying of 45 min. had to be assumed to fit the early portion of the plasma curve.

Estimates of Absorption—The plasma concentrations following the intravenous administration of 1, 2, and 4 mg./kg. and oral administration of 2, 4, and 8 mg./kg. were plotted as functions of time, and the area under the curves was determined by a line follower[13] connected to the *x-y* recorder of the computer. The photocell followed the plasma concentration–time curves, and the voltages were accumulated by an integrator. Estimates of the percent of drug absorbed were obtained from the ratio of the area under the plasma level–time curve for oral absorption to that for intravenous administration for the same dosages (15). For the 8-mg./kg. oral dose, the average area under the curves for the three intravenous studies corrected for the different dose was taken as 100%.

RESULTS AND DISCUSSION

Metabolism of Sotalol—The chromatography of plasma and urine samples containing ^{3}H-sotalol revealed spots that were identical to those of the parent compound. Hence, it could be concluded that there was no significant metabolism of the drug. A scattering of spots assignable to radioactive material was observed in the bile. Since this route of excretion contributed less than 1% of the administered dose, it was of negligible significance.

Protein Binding Study—No binding of sotalol to plasma proteins was found in the 0.3–1000.0-mcg./ml. range of drug concentrations, *i.e.*, $f = 0$. The total drug concentrations in plasma assayed spectrophotofluorometrically and radiochemically were identical with the free diffusable drug. Thus, the rate constants and volumes of distribution were directly referenced to unbound drug concentrations in the plasma.

Red Blood Cell/Plasma Partitioning—The partition coefficient, D (Eq. 3), between plasma and red blood cells was found to be unity (1.16 ± 0.21). Equilibrium was achieved within 1 min. and did not change over a period of 2 hr. No drug concentration dependency of the 1:1 distribution between red blood cells and plasma could be detected in the range of 0.5–100.0 mcg. sotalol/ml. of blood.

Fit of Data from Intravenous Studies—The plasma data following intravenous administration were fitted graphically for all experiments in accordance with a two-compartment body model (Scheme I). The rapid initial drop of the drug concentration could be characterized by the α-slope of the first phase of the semilogarithmic plot of the data with time, which was equivalent to a $t_{1/2}$ of 3.2 ± 1.1 min. with extreme values of 1.6 and 5.5 min. and was followed by a comparatively slow disposition phase with the slope β or k_e of the terminal semilogarithmic plot that gave a $t_{1/2}$ of 4.8 ± 1.03 hr. with extreme values of 3.52 and 6.8 hr. (Table I and Figs. 1 and 2).

The k_e values obtained from the slopes of semilogarithmic plots of the rate of excretion, $\Delta U/\Delta t$, and the amounts of drug not yet excreted in the urine, $U_\infty - U$, against time were in good agreement with the estimates from the plasma data (Fig. 4 and Tables I and II). The microscopic rate constants derived from the graphical procedures and from the best analog computer fits were generally in good agreement (Table I). Whereas the plasma data could be fitted to a two-compartment body model by both methods in almost all cases (Figs. 1, 2, 6, and 10), it proved necessary to add a slowly equilibrating tissue compartment to fit the later portion of the urine curves at the high dosage level (Figs. 7 and 8) and in the case of the ^{3}H-sotalol data (Table I). The slow return from this "deep" compartment (12) may be held responsible for the prolonged enhancement of urinary excretion. A maximum of 5–12% of the dose was estimated to be in this compartment on acute administration.

The values for the individual rate constants were consistent within an animal for different doses as well as among the three animals. Dose-independent kinetics could also be demonstrated by the superimposable curves, where the plasma data were plotted in terms of percent of dose administered per milliliter plasma as a function of time (Fig. 2).

Rate Constants and Apparent Volumes of Distribution—The drug distributed instantaneously after bolus injection into the space associated with the central compartment, *i.e.*, $V_P{}^u$. The values in liters (Table II) corresponded generally to the volume of the extracellular space [190–350 ml./kg. (17)].

[13] Autograf Type F-3B, Hewlett-Packard/Moseley Division, Pasadena, Calif.

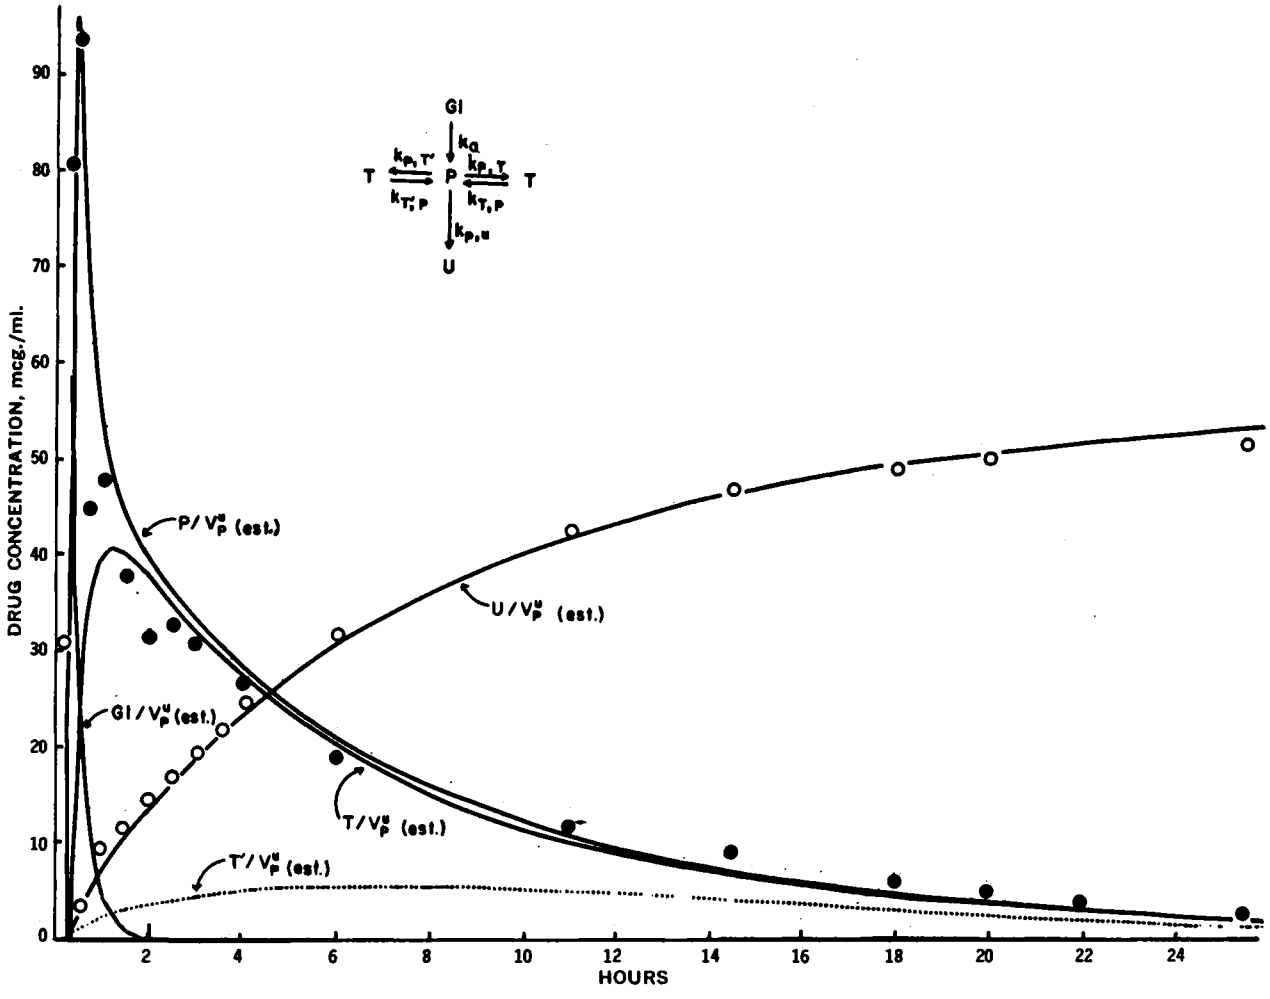

Figure 11—*Analog computer fitting of plasma and urine data following oral administration of 8 mg./kg. sotalol to Dog 1. Here, a lag time of 15 min. was assumed to fit the initial plasma data. For symbols, see Fig. 10.*

The drug diffuses rapidly from the central compartment into the readily equilibrating tissues, T. Since $k_{P,T}$ is 7–10 times greater than $k_{T,P}$, the capacity of this compartment is high. The apparent volume of T can be estimated by (11, 12):

$$V_T = V_P{}^u \frac{k_{P,T}}{k_{T,P}} \qquad \text{(Eq. 16)}$$

referenced to the concentration of unbound drug in the plasma. Similarly, for the apparent volume of the deep compartment, T':

$$V_{T'} = V_P{}^u \frac{k_{P,T'}}{k_{T',P}} \qquad \text{(Eq. 17)}$$

The apparent volumes, V_T, are reasonably consistent with a total body water of 600–800 ml./kg. (17). The fact that the V_T value exceeded this quantity in some cases indicated that the drug may be trapped or bound to the tissue, T, to some extent. It might be speculated that since sotalol is a zwitterion with a narrow pH range allowable for partitioning into fats (7), minute pH differences inside the cells would inhibit back-diffusion to the central compartment. The same phenomenon could rationalize the deeper compartment, T'.

Apparent Volumes of Distribution and Renal Clearance—The renal clearance of sotalol (Table II) was well within the range of a normal inulin clearance of 40–130 ml. for a 20-kg. dog (17). Also, an inulin clearance study in Dog 1 gave a value of 36 ml./min., as estimated from the plasma decay curve. Thus, sotalol can be assumed to be renally excreted essentially by glomerular filtration.

Clearance values of this magnitude affect the estimates of the apparent volumes of distribution that are based on the assumption of pseudosteady state (11) or, as it has also been called, the pseudo-distribution equilibrium (18). These estimated volumes can differ from those calculated for steady-state equilibrium in accordance with Eqs. 16 and 17 (13).

If excretion is significant during the rapid distribution phase, the initial decay in the plasma level of drug will be due to both distribution and excretion. Thus, the extrapolation of the β-phase from the semilogarithmic plots (Figs. 1–4) to zero time will estimate a value for the concentration of drug in the pseudoequilibrated tissues of distribution, $[A_P{}^u]_0$, which leads to values of $V_{D_P}{}^u$ (Eq. 7) and $V_{D_P}{}^u$ (Eq. 9) that are greater than the total apparent volumes of distribution of the central compartment and the rapidly equilibrating tissues T, which are derived from steady-state considerations (Eqs. 8, 16, and 17).

The $V_{D_P}{}^u$ calculated from the quotient of the renal clearance in milliliters per minute and k_e in min.$^{-1}$ (from plasma data, Table I) for the conditions when significant excretion occurs during the α-phase will also be higher than the sum of the steady-state volumes of distribution in Eq. 8 (13).

Estimates of the apparent volumes of distribution based upon these three methods are given in Table II, and it can be seen that the $V_{D_P}{}^u$ estimates based on the pseudosteady-state assumption and the renal clearance/k_e quotient tended to yield larger values than the sum of $V_P{}^u$ and steady-state volumes of the equilibrated tissues (Eq. 16), even when V_T (Eq. 17) was included.

Comparison of Chemical and Radioactive Assays—The semilogarithmic plots of the radioactive data in plasma showed a three-exponential decay and a slow terminal phase with a $t_{1/2}$ of approximately 12 days. This is consistent with the fact that deuterium oxide is cleared from plasma water with a $t_{1/2}$ of 9.3 ± 1.5 days (19). The terminal phase was, therefore, assigned to the clearance of tritiated water, which is a probable result of the exchange between the hydrogens of water and the tritium of labeled sotalol.

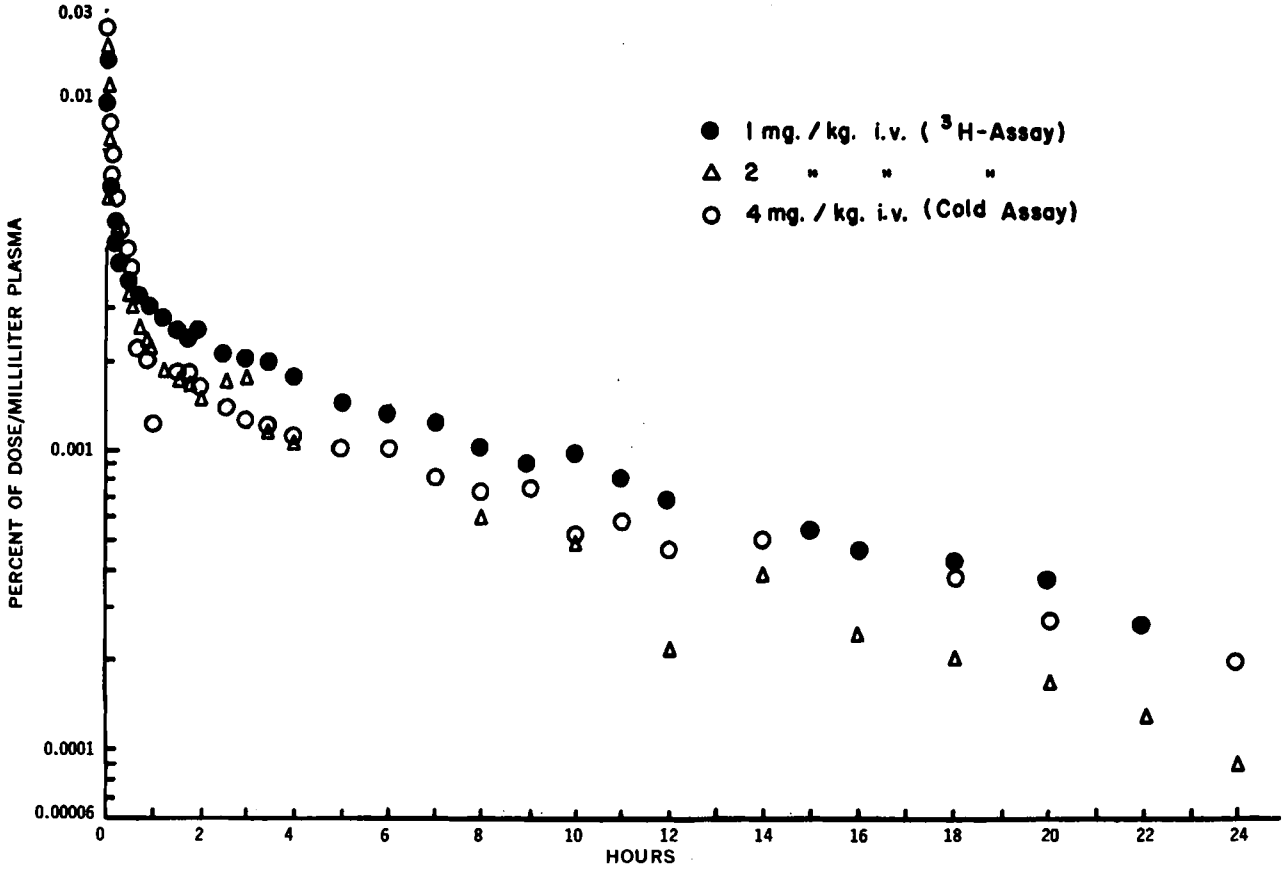

Figure 12—*Semilogarithmic plots of plasma levels in percent of dose per milliliter plasma following intravenous administration of 1 (●) and 2 (△) mg./kg. of ³H-sotalol, assayed by counting procedure, and 4 mg./kg. (○) of sotalol, assayed by spectrophotofluorometric analysis, to 20-kg. Dog 2. The radioactive data were corrected for the longer retention of tritiated water by prior feathering.*

The two assay methods were comparable after the terminal portion of the labeled plasma level–time curves was "feathered" (Fig. 12). The spectrophotofluorometric and radioactive data in plasma and urine could be fitted with identical rate constants in accordance with the three-compartment body model. The estimates for the apparent volumes of distribution of the central compartment, V_P^u, were slightly lower for the radioactive data since the initial concentrations of unbound drug in plasma, $[A_P^u]_0$, upon which these estimates are based (Eqs. 5 and 6) were slightly higher for the radioactive studies.

Unchanged ³H-sotalol, in the amounts of 91 and 93.6% of the dose, was found in the urine by radioactive assay as compared to 90.3 ± 12% (72–116%) from the spectrophotofluorometric data of the other experiments. The extreme overestimates of 108 and 116% recovery (Table II) were obtained in earlier experiments where the assay methodology was not as well established.

The fecal excretion of ³H-sotalol was 0.21 and 3.37% of the total dose in the two radioactive experiments.The former value was due to a constipated dog which permitted few fecal samples. The bile had 0.73% of the radioactive dose given to the biliary-cannulated dog.

Oral Studies—The graphical estimates of the absorption rate constants by feathering of the curves were not accurate since equilibration of drug among the available tissues was not readily effected during the absorption phase (Fig. 3). The $t_{1/2}$'s of absorption obtained from the best analog computer fits were (lag time for absorption in parentheses) 10.9 min. (15 min.) for 8 mg./kg., 16.7 min. (30 min.) for 4 mg./kg., and 10.7 min. (45 min.) for 2 mg./kg.

Such a lag time may be indicative of an intestinal absorption. The differences may be explained by variable gastric motilities in the fasted and achlorhydric dog.

Best fitting was achieved by applying the three-compartment body model, including a GI compartment, for the doses of 4 and 8 mg./kg. (Fig. 11). The data following administration of 2 mg./kg. could be fitted with both two- and three-compartment body models. The two-compartment fit is shown in Fig. 10.

Estimates of the percent of total dose absorbed were made from the total amounts excreted in the urine. They were 87% following a dose of 2 mg./kg., 101.7% for 4 mg./kg., and 78.2% for 8 mg./kg. The estimates from the ratio of the corresponding areas under the plasma level–time curves following intravenous and oral administration were 84.1, 83.0, and 90.5% absorption for the oral dosages of 2, 4, and 8 mg./kg., respectively. Hence, it can be concluded that sotalol is rapidly and rather completely absorbed from the GI tract (probably from the intestine) following oral administration of the drug in solution.

GLC Determination and Urinary Recovery of Bumetanide in Healthy Volunteers

P. W. FEIT▲, K. ROHOLT, and H. SØRENSEN

Abstract □ A GLC determination of bumetanide (3-*n*-butylamino-4-phenoxy-5-sulfamylbenzoic acid), a potent "high ceiling" diuretic, was developed using flash-heater methylation. A mixture of tetramethylammonium hydroxide and trimethylanilinium hydroxide was advantageously used as the methylation reagent. The flash-heater methylation product proved to be methyl 3-(*N*-*n*-butylanilino)-5-dimethylsulfamyl-4-methoxybenzoate by spectroscopic comparison with authentic material achieved by a corresponding gram scale model experiment. The probable sequence of reactions involving methylation under simultaneous Smiles rearrangement is outlined. The GLC determination was found to be accurate at concentrations as low as 0.1 mcg./ml. human urine. In six healthy volunteers, the urinary recovery of bumetanide, the urinary excretion of sodium, potassium, and chloride ions, and the urine volume were determined after oral administration of 0.5 and 1 mg. of the drug. A parallelism between bumetanide excretion and saluretic action over the total period of response is shown.

Keyphrases □ Bumetanide—urinary excretion, man, relationship to saluretic action, GLC analysis after flash-heater methylation □ Urinary excretion, bumetanide—relationship to saluretic action, man □ Saluretic activity, bumetanide—relationship to urinary excretion, man □ GLC—analysis, bumetanide, after flash-heater methylation

Bumetanide (3-*n*-butylamino-4-phenoxy-5-sulfamylbenzoic acid) (I, Scheme I) was recently described as a new "high ceiling" diuretic in the experimental animal (1, 2) and in man (3, 4). In patients suffering from congestive heart failure, bumetanide has shown a diuretic profile and dose response comparable to that of furosemide, but at doses approximately one-fortieth of the latter drug (4). The aim of the present investigation was to develop a sensitive GLC assay for the determination of bumetanide in biological material. Special interests were to evaluate the urinary recovery after oral administration of the drug to healthy volunteers and to obtain information relating the renal drug excretion with the diuretic–saluretic activity.

Since functional groups of bumetanide make the drug unsuitable for direct GLC determination, it was necessary to find a suitable derivative. A relatively simple way of making derivatives of anionic compounds is by methylation in the injection port of the gas chromatograph, using a solution of tetramethylammonium hydroxide or trimethylanilinium hydroxide as the methylation reagent. The principle of flash-heater methylation was first utilized in preparation of methyl esters of carboxylic acid (5) with the aid of tetramethylammonium hydroxide. The advantage of using trimethylanilinium hydroxide was recently shown for barbiturates, phenolic alkaloids, and xanthine bases (6).

EXPERIMENTAL

GLC Determination—*Instruments and Conditions*—The GLC analyses were performed using a gas chromatograph[1] equipped with a flame-ionization detector and the following experimental conditions: column, 2 m. × 3.3-mm. o.d., stainless steel; packing, 1.5% OV-17 silicone[2] on 100-120-mesh diatomaceous earth[3]; column temperature, 270°; injection port temperature, 370°; detector temperature, 300°; carrier nitrogen flow, 30 ml./min.; and recorder chart speed, 0.3 cm. (0.1 in.)/min.

Reagents—For the methylation reagent, two parts of an approximately 1 *M* aqueous solution of trimethylanilinium hydroxide (6) were mixed with one part of a 10% methanolic solution of tetramethylammonium hydroxide. The latter was obtained by evaporating an aqueous tetramethylammonium hydroxide solution[4] in a rotating evaporator and redissolving the residue in the appropriate amount of methanol.

The internal reference solution consisted of 25 mcg. of 4-benzyl-3-*n*-butylamino-5-sulfamylbenzoic acid (7)/ml. in ether.

Procedure—Urine, 5–10 ml., was adjusted to pH 2 by addition of 1 *N* hydrochloric acid. Then 200 μl. of internal reference solution and 15 ml. of ether were added, and the mixture was shaken in a

GLC Determination and Urinary Recovery of Bumetanide in Healthy Volunteers

P. W. FEIT▲, K. ROHOLT, and H. SØRENSEN

Abstract □ A GLC determination of bumetanide (3-*n*-butylamino-4-phenoxy-5-sulfamylbenzoic acid), a potent "high ceiling" diuretic, was developed using flash-heater methylation. A mixture of tetramethylammonium hydroxide and trimethylanilinium hydroxide was advantageously used as the methylation reagent. The flash-heater methylation product proved to be methyl 3-(*N*-*n*-butylanilino)-5-dimethylsulfamyl-4-methoxybenzoate by spectroscopic comparison with authentic material achieved by a corresponding gram scale model experiment. The probable sequence of reactions involving methylation under simultaneous Smiles rearrangement is outlined. The GLC determination was found to be accurate at concentrations as low as 0.1 mcg./ml. human urine. In six healthy volunteers, the urinary recovery of bumetanide, the urinary excretion of sodium, potassium, and chloride ions, and the urine volume were determined after oral administration of 0.5 and 1 mg. of the drug. A parallelism between bumetanide excretion and saluretic action over the total period of response is shown.

Keyphrases □ Bumetanide—urinary excretion, man, relationship to saluretic action, GLC analysis after flash-heater methylation □ Urinary excretion, bumetanide—relationship to saluretic action, man □ Saluretic activity, bumetanide—relationship to urinary excretion, man □ GLC—analysis, bumetanide, after flash-heater methylation

Bumetanide (3-*n*-butylamino-4-phenoxy-5-sulfamylbenzoic acid) (I, Scheme I) was recently described as a new "high ceiling" diuretic in the experimental animal (1, 2) and in man (3, 4). In patients suffering from congestive heart failure, bumetanide has shown a diuretic profile and dose response comparable to that of furosemide, but at doses approximately one-fortieth of the latter drug (4). The aim of the present investigation was to develop a sensitive GLC assay for the determination of bumetanide in biological material. Special interests were to evaluate the urinary recovery after oral administration of the drug to healthy volunteers and to obtain information relating the renal drug excretion with the diuretic–saluretic activity.

Since functional groups of bumetanide make the drug unsuitable for direct GLC determination, it was necessary to find a suitable derivative. A relatively simple way of making derivatives of anionic compounds is by methylation in the injection port of the gas chromatograph, using a solution of tetramethylammonium hydroxide or trimethylanilinium hydroxide as the methylation reagent. The principle of flash-heater methylation was first utilized in preparation of methyl esters of carboxylic acid (5) with the aid of tetramethylammonium hydroxide. The advantage of using trimethylanilinium hydroxide was recently shown for barbiturates, phenolic alkaloids, and xanthine bases (6).

EXPERIMENTAL

GLC Determination—*Instruments and Conditions*—The GLC analyses were performed using a gas chromatograph[1] equipped with a flame-ionization detector and the following experimental conditions: column, 2 m. × 3.3-mm. o.d., stainless steel; packing, 1.5% OV-17 silicone[2] on 100-120-mesh diatomaceous earth[3]; column temperature, 270°; injection port temperature, 370°; detector temperature, 300°; carrier nitrogen flow, 30 ml./min.; and recorder chart speed, 0.3 cm. (0.1 in.)/min.

Reagents—For the methylation reagent, two parts of an approximately 1 *M* aqueous solution of trimethylanilinium hydroxide (6) were mixed with one part of a 10% methanolic solution of tetramethylammonium hydroxide. The latter was obtained by evaporating an aqueous tetramethylammonium hydroxide solution[4] in a rotating evaporator and redissolving the residue in the appropriate amount of methanol.

The internal reference solution consisted of 25 mcg. of 4-benzyl-3-*n*-butylamino-5-sulfamylbenzoic acid (7)/ml. in ether.

Procedure—Urine, 5–10 ml., was adjusted to pH 2 by addition of 1 *N* hydrochloric acid. Then 200 μl. of internal reference solution and 15 ml. of ether were added, and the mixture was shaken in a

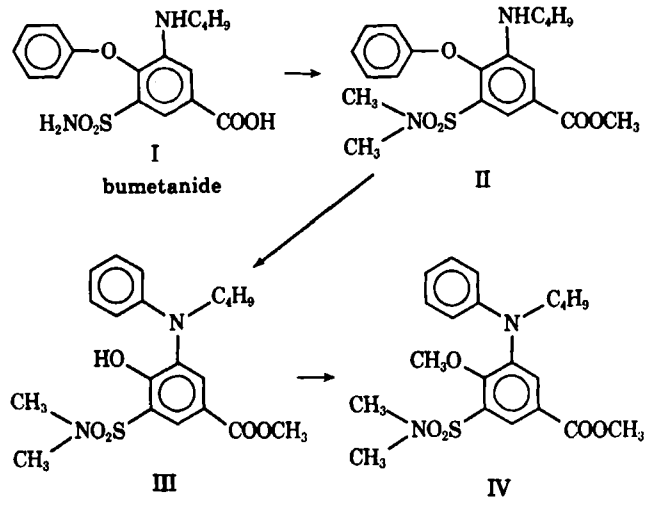
separator for 2 min. The organic layer was washed with three 5-ml. portions of water and then filtered into a tapered centrifuge tube (10 ml.) through a small cotton plug, previously washed with ether and covered with a thin layer of anhydrous sodium sulfate. Then 50 μl. of methylation reagent was added, and the tube



Scheme I—Sequence of reactions during flash-heater methylation of bumetanide

was shaken for 2 min. After centrifugation, 1–2 μl. of the aqueous layer was injected into the gas chromatograph. The amount of bumetanide, in micrograms per milliliter of urine, was calculated from the formula:

$$\text{bumetanide} = \frac{A \cdot 2.5}{B \cdot u} \qquad \text{(Eq. 1)}$$

where A is the peak height ratio (bumetanide/internal reference), B is the peak height ratio in a corresponding standard determination in which 2.5 mcg. of bumetanide is added to 5 ml. of blank urine, and u is the quantity of the urine sample in milliliters. The peak heights were measured from a baseline drawn with the aid of a large French curve.

When the apparatus had been in disuse for some time for the determination of bumetanide, the peaks resulting from the first injections tended to be either very small or absent. This could be rectified by saturating the system with an injection of a concentrated solution of bumetanide and the reference compound in methylation reagent.

Synthesis: Methyl 3-*n*-Butylamino-5-dimethylsulfamyl-4-phenoxybenzoic Acid (II, Scheme I)—An alkaline (sodium hydroxide) solution of bumetanide (3-*n*-butylamino-4-phenoxy-5-sulfamylbenzoic acid) (I) was methylated with excess methyl iodide at room temperature while stirring for 24 hr. The excess methyl iodide was distilled off, and 3-*n*-butylamino-5-dimethylsulfamyl-4-phenoxybenzoic acid was precipitated from the reaction mixture by addition of 4 *N* hydrochloric acid until pH 2 (m.p. 187–188° after recrystallization from aqueous ethanol). The esterification was performed in methanolic hydrochloric acid by standing at room temperature for 24 hr. and was worked up as usual to yield II, m.p. 135–136°, after recrystallization from acetone–benzene.

Anal.—Calc. for $C_{20}H_{26}N_2O_6S$ (mol. wt. 406.49): C, 59.09; H, 6.45; N, 6.89. Found: C, 58.92; H, 6.42; N, 6.93.

Model Experiment: High Temperature Reaction of Bumetanide with Tetramethylammonium Hydroxide—A solution of bumetanide (3 g.) in tetramethylammonium hydroxide (45 ml., 10% in water) was introduced into a glass flask placed in an oil bath at 220–235° for 3 hr. while evaporating *in vacuo*. After heating for an additional 15 min., the reaction flask was cooled and the reaction product was dissolved in a mixture of 1 *N* hydrochloric acid (50 ml.) and ether (50 ml.). The organic layer was dried (magnesium sulfate) and evaporated. Two grams of the resulting residue (approximately 3 g.) was redissolved in ether (50 ml.) and extracted twice with 10-ml. portions of 1 *N* sodium hydroxide while ice cooling. The alkaline extract was immediately acidified with 1 *N* hydrochloric acid (30 ml.). The separated oil was reextracted with ether. After washing with water, drying (magnesium sulfate), and evaporating, 1.6 g. of oily material was obtained. After redissolving in ether, the solution was washed with diluted sodium hydrogen carbonate and dried (magnesium sulfate). After evaporation, oily methyl 3-(*N*-*n*-butylanilino)-5-dimethylsulfamyl-4-hydroxybenzoate

(III, Scheme I) was obtained. Crystallization was afforded from ethanol by slowly adding water. Recrystallization from ethanol–water yielded the analytically pure compound (0.64 g.), m.p. 75–77°; NMR [10% in $(CD_3)_2SO$, tetramethylsilane]: 0.88 (m, 3H, CH_3C), 1.0–1.8 (m, 4H, CH_2CH_2), 2.80 (s, 6H, CH_3NSO_2), 3.55 (m, 2H, CH_2N), 3.84 (s, 3H, CH_3OOC), 6.5–7.4 (m, 5H, C_6H_3N), 7.91 (d, J = 2.2 Hz., 1H, aromatic H), 8.29 (d, J = 2.2 Hz., 1H, aromatic H), and 10.85 (broad s, 1H, HO) p.p.m.

Anal.—Calc. for $C_{20}H_{26}N_2O_5S$ (mol. wt. 406.49): C, 59.09; H, 6.45; N, 6.89. Found: C, 58.83; H, 6.44; N, 6.89.

The remaining ether solution, after sodium hydroxide extraction, was washed with 1 *N* hydrochloric acid and water. Drying and evaporation resulted in crude methyl 3-(*N*-*n*-butylanilino)-5-dimethylsulfamyl-4-methoxybenzoate (IV, Scheme I) (0.45 g.). Recrystallization from ethanol (4 ml.) yielded the analytically pure compound (0.19 g.), m.p. 97–98°; NMR [10% in $(CD_3)_2SO$, tetramethylsilane]: 0.86 (m, 3H, CH_3C), 1.0–1.9 (m, 4H, CH_2CH_2), 2.78 (s, 6H, CH_3NSO_2), 3.72 (m, 2H, CH_2N), 3.75 (s, 3H, CH_3O), 3.88 (s, 3H, CH_3OOC), 6.7–7.5 (m, 6H, C_6H_3N), 8.01 (d, J = 2.2 Hz., 1H, aromatic H), and 8.23 (d, J = 2.2 Hz., 1H, aromatic H) p.p.m.

Anal.—Calc. for $C_{21}H_{28}N_2O_5S$ (mol. wt. 420.56): C, 59.98; H, 6.71; N, 6.66. Found: C, 59.78; H, 6.66; N, 6.54.

Human Volunteer Studies—The study was performed at dose levels of 0.5 and 1 mg. bumetanide. Scored tablets containing 1 mg. of bumetanide were used.

The trial was comprised of six volunteers who were members of the staff and 30–44 years old. All had normal blood urea and electrolyte levels. They took a normal diet and consumed, as far as possible, the same volume of fluid each day. On the 1st day of trial, each subject emptied his bladder at 7 a.m. and the urine was discarded. On the two pretreatment days, urine was collected over the 0–6- and 6–24-hr. periods. On the day of the test, urine was collected over the 0–1-, 1–2-, 2–4-, 4–6-, 6–8-, and 8–24-hr. periods following administration of the drug. On the day following treatment, urine specimens were collected over a 24-hr. period.

The content of bumetanide in urine was measured using the GLC determination as described. Blank urine samples taken before administration of bumetanide were analyzed to exclude the presence of other drugs that might interfere with the method. The presence of furosemide would interfere with the analysis, because it shows a peak with almost the same retention time as the peak originating from bumetanide. Consequently, it was found that the method could be adapted to furosemide.

The urinary excretion of electrolytes was determined using standard procedures.

RESULTS AND DISCUSSION

GLC Determination—A sensitive method was necessary for measuring bumetanide in urine at the low levels estimated to be present in urine. The described procedure is convenient for the determination of the drug in urine at levels as low as 0.1 mcg./ml. The use of the quaternary ammonium bases for the extraction of bumetanide from the organic solvent phase simplified the extraction procedure. No time-consuming evaporation steps were necessary to achieve the concentration of the drug required for GLC analysis. The accuracy of the analysis was tested by adding known amounts of bumetanide (between 0.1 and 0.5 mcg./ml.) to urine samples. The recovery was between 90 and 105%. A chromatogram from urine containing 0.19 mcg. bumetanide/ml. is shown in Fig. 1. A mixture of tetramethylammonium hydroxide and trimethylanilinium hydroxide (1:2) was used for methylation and extraction. Used alone, trimethylanilinium hydroxide resulted in an additional peak in the chromatogram, with a peak height dependent on the surplus of the reagent. Tetramethylammonium hydroxide gave only one peak; but when the reagent was used in a concentration sufficient for extraction from urine samples, a very broad reagent peak disturbed the analysis.

From a theoretical point of view, the target of the flash-heater methylation of bumetanide should be the carboxyl group and the sulfonamide nitrogen resulting in methyl 3-*n*-butylamino-5-dimethylsulfamyl-4-phenoxybenzoate (II). Compound II was prepared by synthesis and proved, by its different retention time, not to be identical with the flash-heater methylation product of bumetanide. Compound II, however, resulted in the same retention time as the bumetanide derivative in question when injected together with the methylation reagent. This indicated that the flash-heater methylation of bumetanide is rather more complicated. The gram scale investigation of the high temperature reaction of bumetanide with tetramethylammonium hydroxide resulted in the formation of methyl 3-(*N*-*n*-butylanilino)-5-dimethylsulfamyl-4-hydroxybenzoate (III, Scheme I) and methyl 3-(*N*-*n*-butylanilino)-5-dimethylsulfamyl-4-methoxybenzoate (IV, Scheme I).

IR, TLC, and GLC analyses of IV, together with the IR and TLC analyses of the peak collected from the GLC effluent of bumetanide in tetramethylammonium hydroxide, showed the derivative measured in this GLC method to be identical with Compound IV. Formation of IV involves Smiles rearrangement (8) and methylation of the intermediate phenolic hydroxyl of III. The probable sequence of reactions is outlined in Scheme I.

Human Volunteer Studies—The mean urinary recovery of bumetanide, excretion of electrolytes, and urinary volume in six volunteers after oral administration of 0.5 and 1.0 mg. of the drug are presented in Table I. The values during 0–6, 6–24, and 0–24 hr. after administration and control mean values are given. The differences for the 0–6-hr. interval are statistically significant except for potassium.

The histograms in Figs. 2 and 3 depict the excretion of bumetanide and corresponding urinary sodium in the urine samples over a 24-hr. period following 0.5 and 1 mg. of drug administration, respectively.

The present data show that the urinary excretion of bumetanide is rapid and attains its maximum, in the majority of cases, between 1 and 4 hr. after administration. Excretion is virtually complete after 8 hr. Apart from two subjects receiving 1 mg. bumetanide, no drug was detectable in the urine after 24 hr. The total 48-hr. urinary excretion of bumetanide amounted to 35 and 44% for the 0.5-and 1-mg. doses, respectively.

After enzymatic hydrolysis of the 1–2-hr. urine samples using β-glucuronidase-arylsulfatase[5], the concentration of bumetanide

[5] C. F. Boehringer GmbH., Mannheim, Germany, Catalog No. 15247 EGAF.

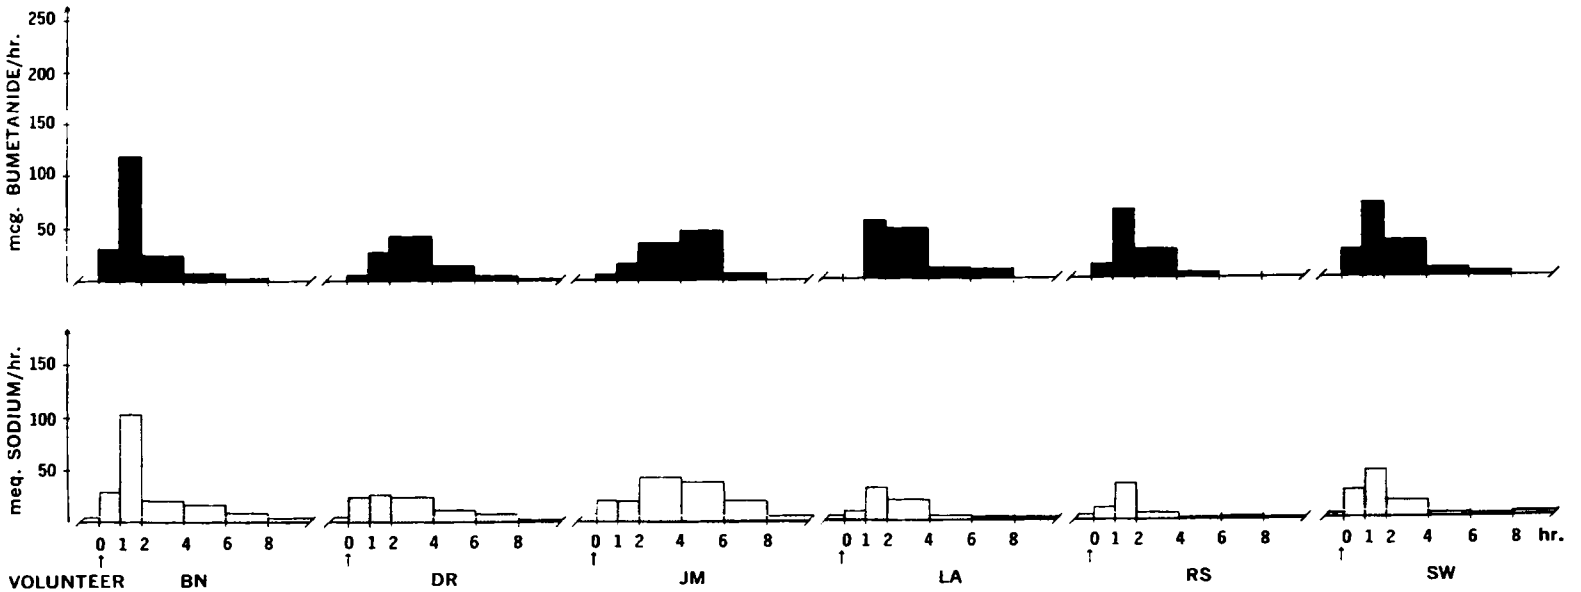

Figure 2—*Urinary excretion of bumetanide (bars upper diagram) and sodium (bars lower diagram) in six healthy volunteers following oral administration of 0.5 mg. of bumetanide.*

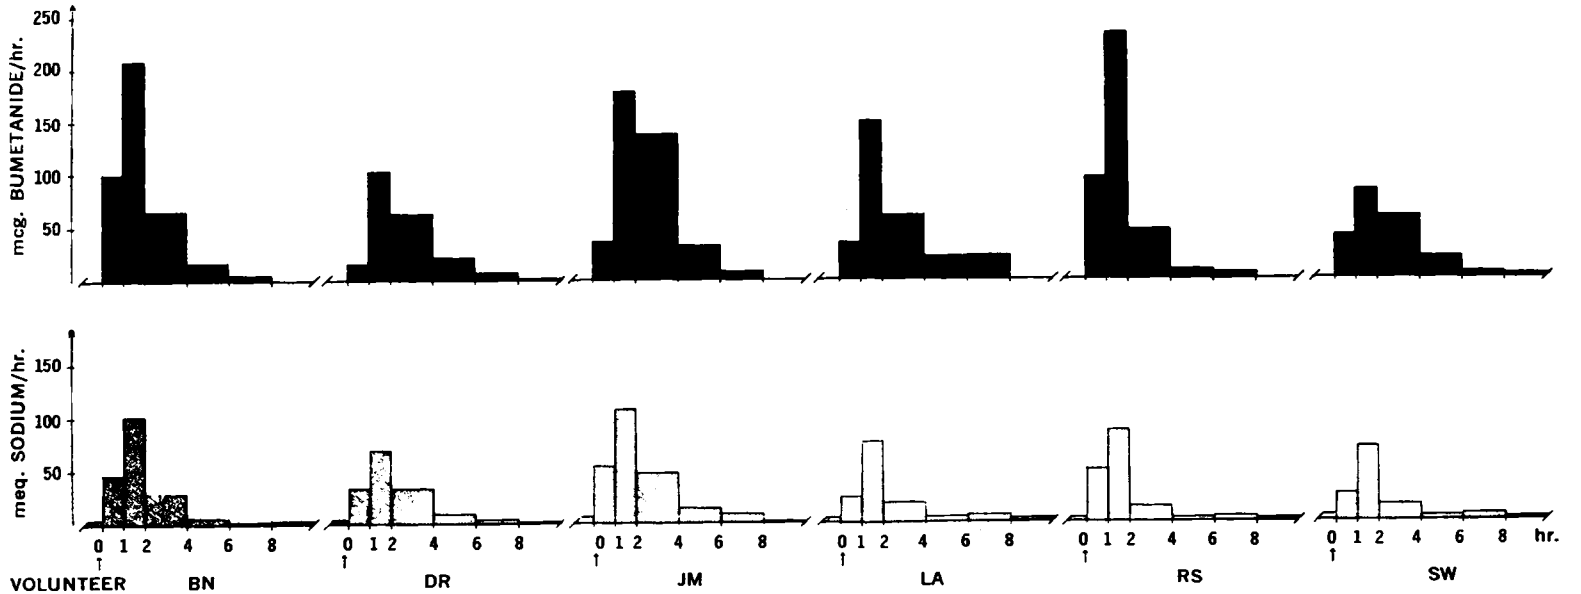

Figure 3—*Urinary excretion of bumetanide (bars upper diagram) and sodium (bars lower diagram) in six healthy volunteers following oral administration of 1 mg. of bumetanide.*

found did not exceed the original level. This indicates that bumetanide is excreted unconjugated in human urine.

However, the urinary excretion of bumetanide cannot be considered as a measure of orally absorbed drug since a biliary excretion of the drug cannot be excluded. Biliary excretion would make the results in accordance with the low dose dog assay, where an almost equal response to the drug was obtained after oral and intravenous administration.

The results confirm the marked saluretic and diuretic effect of bumetanide after oral administration of both 0.5 and 1 mg. to human volunteers and show clearly a parallelism between bumetanide excretion and saluretic action over the total period (Figs. 2 and 3).

SUMMARY

A GLC determination of bumetanide, using flash-heater methylation by means of a mixture of tetramethylammonium hydroxide and trimethylanilinium hydroxide, was developed. The flash-heater methylation product of bumetanide proved to be methyl 3-(*N*-*n*-butylanilino)-5-dimethylsulfamyl-4-methoxybenzoate, formed by methylation under simultaneous rearrangement. The GLC determination was found to be accurate at concentrations as low as 0.1 mcg./ml. human urine. In six healthy volunteers, the urinary excretion of sodium, potassium, and chloride, the urine volume, and the urinary recovery of bumetanide were determined after oral administration of 0.5 and 1 mg. of the drug. A parallelism between bumetanide excretion and saluretic action over the total period of response is shown.

Influence of Solution Electrolyte Content and Dielectric Constant on Drug Adsorption by Kaolin

N. A. ARMSTRONG▲ and C. D. CLARKE*

Abstract □ The adsorption of benzoic acid and crystal violet on kaolin was investigated to elucidate the influence of the system dielectric constant and the electrolyte content on this example of drug–adjuvant interaction. The differing results obtained with the two adsorbates reflect the dissimilar adsorption sites on the kaolin platelet and the different mechanisms involved in the uptake of acids and bases on clays. The experimental data presented are satisfactorily explained by a consideration of the effect of both the dielectric constant and the electrolyte concentration and valency on adsorbent and adsorbate characteristics.

Keyphrases □ Kaolin, adsorption of benzoic acid and crystal violet—location of adsorption sites, influence of dielectric constant and electrolyte content □ Adsorption of benzoic acid and crystal violet by kaolin—influence of dielectric constant and electrolyte content □ Drug–adjuvant interactions—influence of dielectric constant and electrolyte content, drug adsorption by kaolin □ Dielectric constant, electrolyte content—effect on drug adsorption by kaolin □ Electrolyte content, dielectric constant—effect on drug adsorption by kaolin

Previous papers (1, 2) showed that the Langmuir adsorption isotherm represents the adsorption of benzoic acid and crystal violet on kaolin, and they discussed the effect of environmental pH on this equilibrium process. From the results obtained, the probable adsorption sites for acidic and basic materials on clays were suggested, namely that anionic materials were adsorbed on the edge and cationics on the cleavage surface of the clay. The significance of such an evident drug–adjuvant interaction on preservative efficiency or therapeutic potency was briefly discussed. The presence of soluble material in a suspension formulation, for example as active principle, flavoring, coloring, buffering, or peptizing agents will not only influence the formulation's pH but also contribute to the electrolyte content of the system. This increase in electrolyte concentration will also result in an increase in the dielectric constant of the system (3). Both of these factors influence the characteristics of the electrical double layer of the suspended phase, this double layer constituting the area where adsorption and/or ion exchange takes place. It was, therefore, considered desirable to determine the effect of both the system dielectric constant and the electrolyte content (with respect to concentration and valency) on the problem of drug–adjuvant interaction through investigating the influence of these factors on the uptake of benzoic acid and crystal violet on kaolin.

EXPERIMENTAL

Materials—Benzoic acid (Analar grade), crystal violet, sodium salts, and ethanol (reagent grade) were used without further purification. Light kaolin (BP quality) was dried at 100° (3 hr.), blended thoroughly, and stored in sealed containers. The weight mean diameter of the kaolin was 3.3 μm. (sedimentation balance), the surface area was 11.2 $m.^2 g.^{-1}$ (nitrogen adsorption[1]), and the cation-exchange capacity was 10.3 meq./100 g. of clay (ammonium acetate method).

Influence of Electrolyte Concentration on Adsorption—*Benzoic Acid*—One hundred milliliters of a solution containing benzoic acid (40 mg.) in sodium chloride of strengths 0.001, 0.01, and 0.1 *M* was added to flasks containing kaolin (20 g.). Duplicate determinations were carried out in each case. After agitation at 24 ± 0.5° for 24 hr. and centrifugation at 10,000×*g* (2 min.), the supernate was diluted with 0.1 *N* hydrochloric acid and the benzoic acid concentration was determined spectrophotometrically at 275 nm. Solutions of benzoic acid were shown to obey Beer's law, and it was demonstrated that the presence of sodium chloride did not interfere with the assay procedure.

Crystal Violet—To flasks containing kaolin (2 g.) was added 100 ml. of solution containing crystal violet (50 mg.) and 1% w/v disodium ethylenediaminetetraacetate (I) (1 ml.) in sodium chloride solutions of strengths 0.001, 0.01, and 0.1 *M*. The sequestering agent was included to maintain the salts of soil cations in solution, which otherwise have only low water solubility. After agitation at 24 ± 0.5° for 12 hr., a portion of the suspension was centrifuged at 10,000×*g* (2 min.). The supernate was then examined for dye concentration by spectrophotometric assay at 590 nm. It also was examined for magnesium content by atomic absorption spectroscopy, since it was previously shown (1) that cation exchange is the major mechanism for dye uptake by kaolin. Solutions of crystal violet were previously found to obey Beer's law, and it was also shown that the presence of sodium chloride and I did not interfere with the assay methods.

Influence of Electrotype Type on Adsorption—The effect of 0.001, 0.01, and 0.1 *M* concentrations of sodium chloride, sodium sulfate, and sodium citrate on the uptake of benzoic acid and crystal violet on kaolin was investigated. The procedure followed was as described above.

Influence of Dielectric Constant on Adsorption—Solutions of the adsorbate were prepared in solvents of differing water–ethanol proportions, thus providing a range of dielectric constants from 33.6 to 81.7.

Benzoic Acid—Benzoic acid (10 mg.) was dissolved in a water–ethanol mixture (100 ml.), the concentrations of ethanol being 0, 25, 50, 75, and 95% v/v. Kaolin (20 g.) was then added; and after equilibration, centrifugation, and dilution, the benzoic acid concentration of the supernate was spectroscopically determined. Duplicate determinations and appropriate blanks were used.

Crystal Violet—Crystal violet (50 mg.) and I (100 mg.) were dissolved in a water–ethanol mixture (100 ml.), the concentrations of ethanol being identical to those already described. Kaolin (2 g.) was then added; and after equilibration and centrifugation, the supernate was assayed for dye and magnesium content. Higher alcohol concentrations affected the determination of magnesium by atomic absorption spectroscopy, but this was corrected by use of a calibration curve of atomic absorption spectroscopic readings of known magnesium concentrations in the presence of alcohol.

RESULTS AND DISCUSSION

The molecular structure of kaolin, $Al_4Si_4O_{10}(OH)_8$, is composed of two basic units and is well documented (4, 5). One unit is an octahedron of oxygen atoms (or hydroxyl groups) surrounding a central aluminum atom, which forms a continuous sheet through the sharing of oxygen atoms of identical adjacent units. The second unit is composed of four oxygen atoms situated at the corners of a regular tetrahedron, with a silicon atom in the center. The atoms at the base of the tetrahedra are shared by neighboring modules, and the two basic units are joined such that the apexes of the tetrahedron and the top layer of the octahedron form a common plane (6). The origin and nature of the electrostatic charges to which the adsorptive capacity of the clay has been attributed and the variation of these charges with pH were discussed elsewhere (2, 3). It has been pointed out that the kaolin lamella has two distinct areas for adsorption: the kaolin edge surface and the larger cleavage plane surface.

Influence of Electrolyte Concentration and Valency on Adsorption—*Benzoic Acid*—The adsorption of benzoic acid on kaolin is markedly influenced by the electrolyte content of the system (Fig. 1), with sorption of the preservative decreasing with an increase in sodium chloride concentration. A valency increase of the electrolyte anion also further depresses the adsorption of benzoic acid on the clay.

Chloride, fluoride, and oxalate ions are known to be adsorbed on the edges of kaolin particles (7–9) because of their affinity for lattice aluminum. Moreover, phosphate anions are stated to be edge adsorbed on clays (10, 11), such phosphate adsorption being progressively reduced in systems of increasing saline concentrations (12). Citrate ions are also claimed to be edge adsorbed by clay minerals, the affinity of the anion for the adsorption site being greater than that of chloride ions, so that citrate is capable of displacing previously held chloride ions from the positive sites occurring on the edge of the kaolin platelet (13).

The results discussed in a previous article (2) strongly suggest that the adsorption of benzoic acid on kaolin is mediated through the attachment of the negatively charged benzoate anion to sites of positive charge occurring on the edge of the kaolin particles. Since the results of other workers, as briefly reviewed here, also indicate the edge adsorption of other anionic species, it seems reasonable to assume that in systems containing benzoic acid and other anionogenic material, competition will exist between the benzoate and other anions present for the available adsorption sites on the clay. Increasing the concentration of the added salt will favor its preferential sorption and, therefore, reduce the likelihood of vacant sites

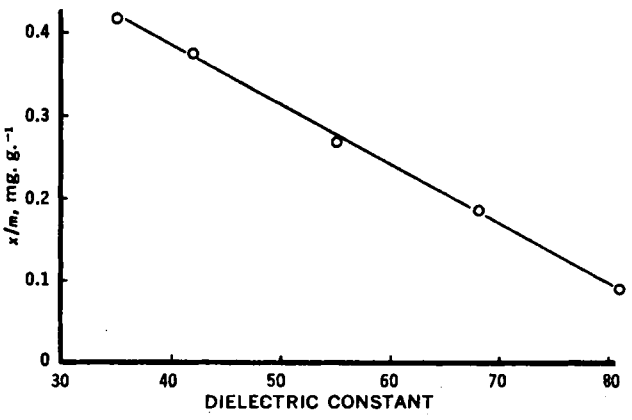

Figure 4—*Variation in the adsorption of benzoic acid on kaolin with the dielectric constant of the suspension medium.*

existing for benzoate anion sorption. The depressive effect of increasing the valency of the added anion is considered to result from its increased affinity for the adsorption sites, the affinity of binding being citrate > sulfate > chloride.

Crystal Violet—Contrary to its effect upon the adsorption of benzoic acid, an increase in the electrolyte content of the system raises the amount of dye taken up by kaolin (Fig. 2). The extent of dye removed from solution is also further increased with an increase in the valency of the added salts (Fig. 2). Blaug and Gross (14) obtained similar results for the adsorption of methantheline bromide by antacids in systems of varying electrolyte conditions.

Since it has been demonstrated that crystal violet uptake on kaolin is mediated through two distinct mechanisms, namely a cation-exchange process and physical adsorption (1), it is necessary to determine the influence of added electrolyte on each of these mechanisms to explain the overall increase in dye uptake.

The distribution of ions in the electrical double layer is a function of the electrolyte content of the bulk solution, the diffuse counterion atmosphere being compressed toward the surface with increasing bulk electrolyte concentration. The effect of the electrolyte addition on the surface potential and the surface charge of the particle depends on the type of double layer. With most hydrophobic colloids, the double layer is created by the adsorption of potential-determining ions when the magnitude of this potential is not affected by the addition of an indifferent electrolyte, providing the presence of the electrolyte does not influence the activity of these potential-determining ions. For this type of double layer, therefore, the surface charge of the particle increases with increasing indifferent electrolyte concentration, and the surface potential remains constant.

The electrical double layer on the cleavage surfaces of kaolin is of a different type, since this surface has a constant charge solely determined by the type and degree of isomorphous replacement of metal cations within the lattice. The charge density of the layer surface is, therefore, independent of the presence of electrolytes in suspension (15). However, an increase in bulk electrolyte concentration decreases the surface potential and the ζ-potential due to the compression of the double layer, which, in turn, favors a decrease in the amount of dye held by physical adsorption. This effect is small, since the added anions are of the same sign as the surface charge. On this basis, the uptake of dye should lessen with an increase in the bulk electrolyte concentration.

The results shown in Fig. 2 indicate an overall increase in dye uptake with increased electrolyte content. It is considered that the influence of the added salts on the cation-exchange process must be responsible for this, the ion-exchange mechanism being responsible for the greater part of the total amount of dye held by kaolin (1). Increasing both electrolyte concentration and valency produces an increase in ion exchange, as indicated by the presence of magnesium ions in the suspending medium (Fig. 3). This increased exchange of sodium for divalent ions produces an increasingly negative charge on the clay, leading to increased dye uptake.

Sorby *et al.* (16) noted the increase of promazine adsorption on kaolin and talc from solutions of increasing sodium chloride concentration. These authors commented that sodium ions, as well as promazine, compete for the anionic sites on the kaolin surface; thus the addition of large amounts of sodium ion would be expected to decrease the extent of promazine adsorption if ion-exchange mechanisms were solely responsible for uptake. They concluded that since adsorption of the phenothiazine derivatives was actually increased in systems of high electrolyte concentration, ion exchange cannot be the only mechanism of adsorption. They suggested that the sodium chloride may be exerting its action through effects on the solubility of the promazine or on the physical properties of the adsorbent. This argument ignores the influence of the exchange of univalent sodium for counterions of higher valency on the imbalance of charge on the clay surface.

The observed increase in uptake on kaolin of positively charged crystal violet from solutions of increasing electrolyte concentration is, therefore, concluded to be due to the increase in the negative charge on the clay surface due to the exchange of divalent compensating cations on the clay surface for the added sodium ions.

Effect of Dielectric Constant on Adsorption—*Benzoic Acid*—The adsorption of benzoic acid on kaolin shows a linear increase in uptake with a decrease in the dielectric constant of the suspension medium (Fig. 4).

Crystal Violet—Contrary to what was observed for benzoic acid adsorption, the overall uptake of crystal violet by kaolin shows a linear decrease with decreasing dielectric constant of the suspending medium (Fig. 5). To determine whether this was due to the effect of the dielectric constant on ion exchange or physical adsorption, the extent of the magnesium replacement under these conditions was determined. The ion-exchange process, as indicated by the appearance of magnesium in the clay supernate, was markedly increased with an increase in the ethanol proportion (Fig. 6); that is, although the total uptake of dye progressively diminished in systems of lowering dielectric constant, the degree of ion exchange occurring increased under these conditions.

The use of ethanol–water mixtures in differing proportions to achieve a range of solvent dielectric constants introduces many

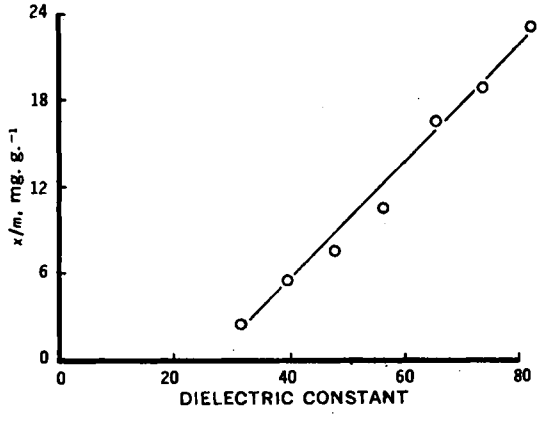

Figure 5—*Variation in the uptake of crystal violet on kaolin with the dielectric constant of the suspension medium.*

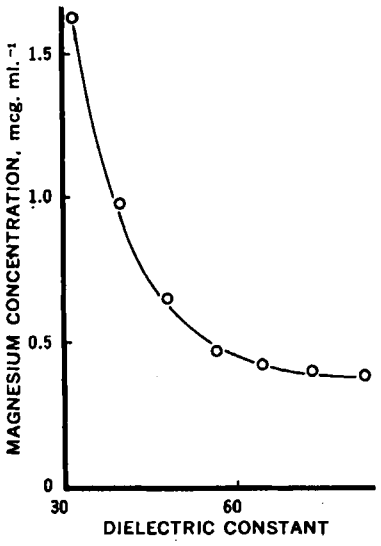

Figure 6—*Influence of the dielectric constant of the suspension medium on the liberation of magnesium from kaolin.*

variable and confusing factors, so the role of the dielectric constant becomes very difficult to identify. Such water–ethanol solutions can influence the characteristics of both adsorbent and adsorbate.

Influence of Water–Ethanol Mixtures on Adsorbent Characteristics—With a decreasing dielectric constant of the system, the diffuse counterion atmosphere surrounding the clay particle is compressed toward the particle surface, thereby reducing the value of the ζ-potential and the surface potential (15). The potential reduction might be expected to diminish the force of attraction between the surface and the adsorbate, leading to a decrease in the amount of drug held by physical adsorption. Indeed, Coulomb's law relates the force of attraction between two charged surfaces, q_1 and q_2, separated by a distance, r, to the medium dielectric constant, D, by the relationship:

$$\text{force of attraction} = \frac{q_1 q_2}{D r^2} \qquad \text{(Eq. 1)}$$

A further effect on the adsorbent is the possible preferential adsorption of alcohol by the clay which may result in displacement of the zero point of charge (15).

Furthermore, increasing concentrations of ethanol alter the viscosity and surface tension of the system when the increased wetting of the solid by solutions of decreasing surface tension might favor increased sorption through enhanced adsorbent–adsorbate contact.

Influence of Water–Ethanol Mixtures on Adsorbate Characteristics—The degree of solvation of the ions in the system (*i.e.*, their effective size) is reduced in solutions of increasing ethanol concentration, this effect favoring better adsorbent–adsorbate contact.

Ionization and dissociation of the adsorbates are depressed in conditions of low medium dielectric constant.

All of these considerations are simultaneously influencing the adsorbent–adsorbate system; hence, pending further investigations, a possible valid explanation can only be tentatively proposed for the results obtained in this study.

On the basis of previously discussed experimental evidence (2), the adsorption of benzoic acid on kaolin is considered to be mediated through the attachment of benzoate anions to the positive adsorption sites located on the edge of the clay particles. However, although dissociation of the acid to benzoate anion is depressed in solutions of low dielectric constant, adsorption is greatest under these conditions (Fig. 4). It is, therefore, to be assumed that these experimental results reflect the increased force of adsorbent–adsorbate attraction under conditions of low dielectric constant as expressed by Coulomb's law, this taking dominance over the other aqueous ethanol effects in the system.

The uptake of dye is more complex, involving as it does the mechanisms of cation exchange and physical adsorption. The total amount of dye taken up by the kaolin is seen to decrease with a decreased medium dielectric constant (Fig. 5), and this may be due to the suppression of dye ionization and dissociation in these solutions. However, a decrease in dye uptake is accompanied by a marked increase in ion exchange, a seemingly contradictory situation. Although ion-exchange mechanisms in aqueous systems have been well documented, little work appears to have been done on exchange in organic or mixed solvent systems, and the data available are often of a conflicting nature.

It is stated (17) that smaller ions will be more tightly held to the exchange surface than larger ions. In solutions of increasing ethanolic concentration, the ionic radius of the exchanging sodium and magnesium ions decrease as the ions become less hydrated. Grim (18) claimed that in alcohol, exchangeable cations are held in the order of their true (nonhydrated) ionic size; magnesium was observed to have a smaller ionic radius than sodium (19) and, therefore, was less likely to be replaced. The results obtained in the study are contrary to this observation.

Moody and Thomas (20) observed that the use of ethanol in a solvent system influences the degree of selection of a cation exchanger toward the available ions in the ambient solution. Wiegner and Jenny (21) studied ion exchange between a calcium zeolite and various alkali chlorides dissolved in aqueous ethanol, and they observed that more sodium ions passed on to the exchanger as the concentration of ethanol was increased. Other workers (22–24), using synthetic cation-exchange resins (hydrogen form) in aqueous ethanol systems, noted an increased exchange of sodium–hydrogen with an increasing ethanol content of the system.

From the results of this study and the observations of previous workers, it seems reasonable to suggest that the selectivity of the clay toward exchangeable cations in the surrounding solution is strongly influenced by the ethanol concentration of the system. The theory is advanced that with an increasing ethanol concentration, the kaolin shows a greater affinity for cation exchange involving sodium ions in preference to those of the dye species. This would produce an increasing negative charge on the clay and, therefore, promote increased crystal violet uptake by physical adsorption. However, cation exchange represents the major mechanism in dye uptake by kaolin; with increased exchange of solution sodium ions, the participation of the dye in this process is suppressed, resulting in the overall decrease in dye uptake in solutions of decreasing dielectric constant.

Determination of Total Salicylates, Phenacetin and/or Total *N*-Acetyl-*p*-aminophenol, and Caffeine in Biological Samples and Analgesic Formulations

HIRA L. GURTOO▲ and BARRIE M. PHILLIPS

Abstract □ An analytical method was developed for the determination of phenacetin (apparent phenacetin), total salicylate (aspirin, salicylic acid, and its conjugates), total *N*-acetyl-*p*-aminophenol (*N*-acetyl-*p*-aminophenol and its conjugates), and caffeine in biological samples. Two 1-ml. samples are required. The first sample, after being acid hydrolyzed (2 *N* HCl, 2 hr., 121°) to convert total salicylate to free salicylic acid and total *N*-acetyl-*p*-aminophenol to *p*-aminophenol, is extracted with chloroform to remove caffeine and salicylic acid. *p*-Aminophenol in the aqueous phase is estimated by its reaction with phenol and sodium hypobromite. Salicylic acid extracted from the chloroform with sodium bicarbonate solution is estimated by reacting it with either Folin–Ciocalteu reagent or ferric nitrate. The caffeine, remaining in the chloroform, is estimated from its absorbance at 276 nm. In the second sample, phenacetin is hydrolyzed (8 *N* HCl, 6 hr., 121°) to *p*-aminophenol (total *p*-aminophenol), which is estimated as before. Time-dependent plasma and kidney levels of caffeine, phenacetin, total *N*-acetyl-*p*-aminophenol, and total salicylate, following the oral administration of a single dose (500 or 900 mg./kg. body weight) of aspirin–phenacetin–caffeine mixture to rats, were determined. The method also was adapted to the analysis of aspirin–phenacetin–caffeine powders.

Keyphrases □ Analgesic formulations—determination of total salicylates, phenacetin and/or total *N*-acetyl-*p*-aminophenol, and caffeine □ Plasma and tissue levels—determination of total salicylates, phenacetin and/or total *N*-acetyl-*p*-aminophenol, and caffeine □ Salicylate content, biological samples and analgesic formulations—determination, mixtures with phenacetin and caffeine □ Phenacetin and/or *N*-acetyl-*p*-aminophenol content, biological samples and analgesic formulations—determination, mixtures with aspirin and caffeine □ Caffeine content, biological samples and analgesic formulations—determination, mixtures with aspirin and phenacetin □ Aspirin–phenacetin–caffeine mixtures—determination of components in biological samples and analgesic formulations

As a result of continuing interest in the elucidation of the biochemical and toxicological mechanisms of "analgesic abuse nephropathy," different groups of researchers have employed single-entity or combination analgesics in their *in vivo* studies. Aspirin, phenacetin, and caffeine, the common components of analgesic mixtures, and their metabolites (1–6) have been studied and the current consensus points to the involvement of analgesic mixtures rather than of any single component in the production of "analgesic abuse nephropathy" (7).

In the final analysis, the availability of an analytical technique suitable for the analysis of caffeine and total amounts of salicylate and phenacetin in the tissue or biological fluid is more meaningful as injury to the tissue is related to the concentration of the injurious chemical in that tissue. This report describes an analytical method developed for the estimation of phenacetin and total *N*-acetyl-*p*-aminophenol (which includes *N*-acetyl-*p*-aminophenol and its conjugates) as *p*-aminophenol, total salicylates (including aspirin, salicylate, and its conjugates) as free salicylate, and caffeine. The major advantages of this method are its accuracy, its applicability to small size samples, and its feasibility for the analysis of aspirin, phenacetin, and caffeine in compound analgesic tablets and powders.

EXPERIMENTAL

For the GC analysis, a gas chromatograph[1] was used under the following operating parameters: column contents, 3% OV-1 on Anakrom Q, 80–100; column size, 0.42 cm. × 1.83 m. (0.125 in. × 6 ft.); column temperature, 160°; carrier gas, helium; carrier gas flow rate, 33 ml./min.; detector, flame-ionization type; injection port and detector block temperatures, 300°; hydrogen flow rate, 3 ml./min.; and air flow rate, 300 ml./min.

Chemicals—Sodium salicylate[2], *p*-aminophenol[3], phenacetin[3], and caffeine[4] of analytical grade were obtained. Analytical grade dichloroethylene, sodium bicarbonate, sodium hydroxide, dibasic potassium hydrogen phosphate, ferric chloride, and hydrochloric acid were used. Solvent grade ether and chloroform were washed successively with 1 *N* NaOH, 1 *N* HCl, and distilled water (three washings) before use. Double-distilled water was used for all purposes.

Biological Materials—The analyses were performed on rat plasma or rat kidney homogenate prepared by homogenizing (Potter-

Elvehjem homogenizers) rat kidneys in water or 0.1 *N* HCl (1 g. wet weight/2 ml. liquid).

Analytical Method—Under suitable conditions of acid hydrolysis of biological samples containing aspirin, phenacetin, and caffeine and/or metabolites, aspirin and its metabolic products are converted to free salicylic acid; phenacetin, *N*-acetyl-*p*-aminophenol, and its metabolic products are converted to *p*-aminophenol. However, caffeine and its metabolites (demethylation and oxidation products) are not likely to undergo any change under these conditions. This knowledge, coupled with the information about the differing solubility of *p*-aminophenol, salicylic acid, and caffeine in chloroform and ether under acidic conditions, made it possible to develop the analytical technique described here.

Table I—Computer-Generated Algebraic Formulas for Calibration Curves of Salicylic Acid, *p*-Aminophenol, and Caffeine

Material	Concentration Range, mg./ml. Plasma	Equation for Calibration Curve	r^a
Salicylic acid[b]	0.0–0.52	$Y = 1.435 \times +0.016$	1.000
Salicylic acid[c]	0.0–1.50	$Y = 0.337 \times +0.006$	1.003
p-Aminophenol	0.0–0.20	$Y = 9.355 \times -0.061$	1.036
Caffeine	0.0–0.60	$Y = 0.711 \times +0.00$	1.001

[a] Regression correlation coefficient. [b] The final color reaction was developed with Folin–Ciocalteu reagent (9). [c] The final color reaction was developed with ferric nitrate (10).

When the acid-hydrolyzed sample is shaken with chloroform and the phases are separated, *p*-aminophenol is retained in the salt form in the aqueous phase while caffeine and free salicylic acid are extracted into the chloroform layer. Salicylic acid is subsequently removed with sodium bicarbonate solution; the caffeine remaining in the chloroform layer, after being thoroughly washed with sodium bicarbonate and ether, is estimated from its spectrophotometric absorption at 276 nm.

The hydrolysis is carried out for 2 hr. in 2 *N* hydrochloric acid in an autoclave at 121° under a pressure of 6.8 kg. (15 lb.)/in.^{2}. To 1 ml. of kidney homogenate or plasma in a 50-ml. centrifuge tube is added 0.67 ml. of concentrated (12 *N*) hydrochloric acid, and the volume is adjusted to 4 ml. with distilled water. After autoclaving and cooling, the mixture is shaken (for 5 min. on an automatic shaker) with chloroform (15 ml.); the phases are separated by centrifugation (5 min.) and analyzed as follows for *p*-aminophenol, salicylic acid, and caffeine.

Determination of Total *N*-Acetyl-*p*-aminophenol—To 2 ml. of the aqueous phase, transferred into a 50-ml. centrifuge tube, are added water (2 ml.), potassium hydrogen phosphate (3 g.), and ether (30 ml.) in that order. The mixture is shaken and either centrifuged or allowed to stand for 20 min. (with stopper on to minimize evaporation of ether). Then 25 ml. of the top layer (ether phase) is transferred to another 50-ml. centrifuge tube containing 5 ml. of 0.01 *N* hydrochloric acid; this mixture is shaken and centrifuged, the ether layer is aspirated, and 3 ml. of the aqueous phase is transferred to a test tube to which is added 1% phenol (1 ml.) and 1 *N* sodium hypobromite solution (1 ml.). The solution is mixed well and allowed to stand for 20 min., and its absorbance at 620 nm. is read. This method of analysis is similar to that described by Brodie and Axelrod (8).

Determination of Total Salicylate (Free Salicylic Acid)—The initial extraction with chloroform yields caffeine and salicylic acid in the chloroform phase. Ten milliliters of the chloroform phase is transferred to a 50-ml. centrifuge tube, and 5 ml. of 1% sodium bicarbonate is added. The mixture is shaken and then centrifuged, and this chloroform phase is saved for the analysis of caffeine. The aqueous phase (sodium bicarbonate solution) is used for the analysis of salicylate as follows.

An aliquot, 3.5 ml., of the sodium bicarbonate solution is transferred to a 50-ml. centrifuge tube containing 0.70 ml. concentrated hydrochloric acid, and the mixture is extracted as described below with ethylene dichloride.

After the addition of ethylene dichloride (30 ml.), the mixture is shaken for 5 min. Then it is allowed to settle and the aqueous layer is aspirated. Twenty-five milliliters of the ethylene dichloride phase is transferred to another 50-ml. centrifuge tube containing 10 ml. of 1% sodium bicarbonate or water. If sodium bicarbonate is used, the mixture is shaken and centrifuged as before. Then 3 ml. of the aqueous phase is transferred to a test tube, and 1 ml. of Folin–

0.000	0.000	0.420	0.018 ± 0.000
0.000	0.000	0.000	0.017 ± 0.000

[a] Average of three determinations. [b] Mean ± *SE*.

Ciocalteu reagent and 1 ml. of 1.5 *N* sodium hydroxide are added in that order. The mixture is mixed well and the absorbance is read at 670 nm. after allowing it to stand for 5 min. (9). In the other method, 0.25 ml. of 1% ferric nitrate is added to the water and ethylene dichloride mixture, which is subsequently shaken and centrifuged. The concentration of salicylic acid is calculated from the absorbance of the colored aqueous phase at 540 nm. (10).

Determination of Caffeine—The 10 ml. of chloroform phase saved from the first extraction is washed (by shaking and centrifuging) twice with sodium bicarbonate solution, first with 30 ml. of 5% solution and then with 30 ml. of 1% solution. The latter is aspirated and 7 ml. of the chloroform phase is transferred to a 50-ml. centrifuge tube, evaporated to near dryness (0.1 ml.), and cooled; then 4 ml. of 2 *N* HCl solution and 30 ml. of ether are added in that order. The mixture is shaken and centrifuged, the ether phase is aspirated, and 2.5 ml. of the aqueous phase is transferred to another 50-ml. centrifuge tube to which 10 ml. of chloroform is added. The mixture is shaken and centrifuged, the aqueous phase is aspirated, and the chloroform phase is read in a spectrophotometer at 276 nm. against chloroform.

Determination of Phenacetin (Apparent Phenacetin[5])—One milliliter of plasma or homogenized kidney tissue is hydrolyzed in the presence of 8 *N* HCl (4 ml. 12 *N* acid, 1 ml. sample, 1 ml. water) by autoclaving for 6 hr. at 121° under a pressure of 6.8 kg. (15 lb.)/in.^{2}. This results in the conversion of phenacetin, *N*-acetyl-*p*-aminophenol, and its conjugates to *p*-aminophenol (total *p*-aminophenol), which is determined by the method already described except that the volume of acid hydrolysate is adjusted to 10 ml. and extracted with chloroform (30–35 ml.), and 2.50 ml. of the aqueous phase (top layer) is transferred to a 50-ml. centrifuge tube containing potassium hydrogen phosphate (4–5 g.) and water (1.5 ml.). Phenacetin in the sample is obtained by subtracting the absolute amount of total *N*-acetyl-*p*-aminophenol (determined earlier) from the absolute amount of total *p*-aminophenol (obtained after 6 hr. of hydrolysis); the resulting difference is multiplied by a factor, mol. wt. phenacetin/mol. wt. *p*-aminophenol, that includes the contribution due to the higher molecular weight of phenacetin.

Analysis of Aspirin–Phenacetin–Caffeine Powders—Three samples of such powders of unknown composition were obtained[6] and analyzed by the methods described for biological samples. However, for each type of analysis, separate calibration curves using aqueous solutions were set up. One hundred milligrams of each powder was dissolved in chloroform (100 ml.), and 1 ml. of the solution after removal of the solvent was hydrolyzed for 2 or 6 hr. under the conditions already described. The hydrolyzed solutions were analyzed for salicylate, *p*-aminophenol, and caffeine. As pro-

[5] Apparent phenacetin obtained as difference. In addition to phenacetin, this should include *N*-acetyl-*p*-aminophenol glucuronide and phenetidin present in the biological sample as a result of biotransformation.

vided by the supplier, the percentage composition of all three powders was 42:42:16 of aspirin–phenacetin–caffeine.

Rat Experiments—Three studies were undertaken in which rats were employed.

Study I—In Study I*a*, male rats[7] weighing 110–150 g. were used. Rats were allowed to acclimatize to the laboratory environment until they reached the desired weight (1 week) and then they were assigned at random to different groups, nine animals in each group. Aspirin–phenacetin–caffeine (42:42:16) powder, prepared as a fine suspension in distilled water containing 0.5% sodium carboxymethylcellulose and 0.4% polysorbate 80 at a constant volume of 10 ml./kg. and at a dose level of 500 mg./kg. body weight in a single dose, was administered orally to all animals in each group. At each specified time interval following the administration of aspirin–phenacetin–caffeine, a group of rats was anesthetized; blood was obtained by cardiac puncture (opened thorax) and both kidneys were removed prior to the sacrifice of the animal. Plasma was separated from blood and stored frozen for future use; in the same way, kidneys were stored frozen after being homogenized in 0.1 *N* HCl (1 g./2 ml.). Plasma and kidney samples were analyzed for total *N*-acetyl-*p*-aminophenol, total salicylate, and caffeine at a later date.

In Study I*b*, male rats of similar weights were used and a similar protocol (three animals in a group) was followed; however, only the kidneys were removed and their phenacetin content was estimated at a later date.

Study II—Protocol was similar to the one described for Study I (three animals in a group). However, the rats, which were of a different weight range (220–260 g.), received 900 mg. aspirin–phenacetin–caffeine/kg. In addition, phenacetin was determined in both kidney and plasma samples.

Study III—About 60 ml. of plasma was obtained from control and experimental groups of male and female rats that had received an aspirin–phenacetin–caffeine mixture (42:42:16) at twice daily oral doses up to 450 mg./kg. 5 days a week for 1 month. The 1-ml. plasma samples were extracted as described for the estimation of caffeine. The final chloroform extracts from these samples were pooled separately for control and experimental groups. The volumes of these pooled samples were reduced to about 1 ml. by evaporation in a water bath, and 2-μl. samples were analyzed by GC for the detection of caffeine and/or its metabolites.

RESULTS AND DISCUSSION

Calibration curves for the estimation of salicylate, *p*-aminophenol, and caffeine in 1-ml. aliquots of rat plasma are described in Table I.

Comparison of extraction between water and plasma showed that about 95% of salicylic acid and *p*-aminophenol is extracted from plasma and quantitative extraction is possible for caffeine. Results of these studies are summarized in Table II. The determinations of either salicylic acid or *p*-aminophenol or caffeine were not interfered with when these chemicals were present either singly or as mixtures. From inspection of the results (Table III), it is apparent that the determinations of salicylic acid, *p*-aminophenol, and caffeine are consistent with the percent recoveries described here. Almost identical results were obtained for similar determinations from kidney homogenates.

After absorption of aspirin–phenacetin–caffeine-containing analgesics, the major chemical species and metabolites in plasma and tissues are likely to be: (*a*) aspirin, salicylic acid, and its conjugates (salicyluric acid and salicylic acid glucuronides); (*b*) phenacetin, *N*-acetyl-*p*-aminophenol, and its conjugates (conjugates of glucuronic acid and sulfate); and (*c*) caffeine and its metabolites (oxidation and demethylation products). Under the hydrolytic conditions described earlier, aspirin, phenacetin, and their major metabolites are converted to free salicylic acid and *p*-aminophenol. If this acid-hydrolyzed mixture is shaken with chloroform and phases are separated, the *p*-aminophenol salt is retained in the aqueous phase, whereas caffeine and salicylic acid are isolated in the lower chloroform phase. Caffeine is soluble in chloroform, but the solubility characteristics (slightly soluble) of salicylic acid in chloroform (11) made it obligatory to estimate the percent isolation of salicylic acid into the chloroform phase over the analytical concentration range. It was found that, on the average, over a wide concentration range (Table I), 95.4 ± 2% of salicylic acid[8] was extracted. Autoclaving for 2 hr. in acidic medium, which is a reported method for the hydrolysis of *N*-acetyl-*p*-aminophenol and conjugated *p*-aminophenol in biological samples to *p*-aminophenol (8), was found to be as good a method for the hydrolysis of aspirin and salicylic acid conjugates to free salicylic acid in biological samples as that described by Bedford *et al.* (5). This concentration of hydrochloric acid (2 *N*) and the duration of hydrolysis (2 hr.) were found to hydrolyze only about 5% of phenacetin. However, phenacetin was quantitatively hydrolyzed to *p*-aminophenol under more intense conditions: autoclaving for 6 hr. in the presence of 8 *N* hydrochloric acid (Table IV). The presence of salicylic acid or caffeine did not interfere with the analysis of phenacetin. Although both salicylic acid and phenacetin have significant absorption at 276 nm., neither is carried over into the final chloroform extract which is used for the estimation of caffeine. Effects of both salicylic acid and phenacetin on the estimation of caffeine were studied, and the results are summarized in Table V.

GC analyses were performed to resolve the question of whether the absorbance at 276 nm. of the final chloroform extract of biological sample obtained from animals that had received aspirin, phenacetin, and caffeine was due only to the presence of intact caffeine or included some contributions from its metabolites. 	Aspirin	42	43.97
	Caffeine	16	14.83
Total			100.64

[a] One-milligram samples were analyzed.

results are illustrated in Fig. 1. Inspection reveals that the only additional peak in samples from treated rats not present in samples from the control group is that of caffeine. Thus, it seems that the method described is specific for the analysis of caffeine; however, if any metabolites are present in the final extract, their concentration must be negligible.

The biological usefulness of this technique is evident from the studies conducted in rats. The results of Studies I*a*, I*b*, and II are summarized in Tables VI–VIII, respectively. Inspection of Table VII reveals that within 4 hr. after the oral administration of a 500-mg. aspirin–phenacetin–caffeine mixture/kg., phenacetin disappears as a result of its conversion to *N*-acetyl-*p*-aminophenol, which is in conformity with the other reported observations (7). However, at higher dose levels of aspirin–phenacetin–caffeine (900 mg./kg.), higher levels of phenacetin are found in the kidney over a longer time following drug administration. Earlier reports (1) also demonstrated the presence of unchanged phenacetin in the dog kidney. Table VIII summarizes the results obtained at various time intervals following the oral administration of 900 mg./kg. aspirin–phenacetin–caffeine in a single dose to rats. The disappearance of the components of the aspirin–phenacetin–caffeine mixture from plasma and kidney occurs at a much slower rate at this dose level. The phenacetin concentration at 24 hr. was negligible, although significant concentrations of total salicylate, total *N*-acetyl-*p*-aminophenol, and caffeine were found in plasma and kidney.

It should be noted that: (*a*) the gentisic acid formed from salicylic acid (about 1% of the dose) and 2-hydroxyphenacetin, constituting about 1% of the phenacetin dose (4), will not be estimated by the procedure described; and (*b*) the phenacetin concentration calculated from the difference between total *p*-aminophenol (obtained after 6 hr. of hydrolysis) and total *N*-acetyl-*p*-aminophenol (after 2 hr. of hydrolysis) represents only an apparent value, because it might include the minor metabolite, *p*-phenetidin (1) and unexcreted *N*-acetyl-*p*-aminophenol glucuronide, the ether linkage of which might be resistant to 2-hr. hydrolysis. However, observations[9] indicated that *N*-acetyl-*p*-aminophenol glucuronide, if present, is completely hydrolyzed to *p*-aminophenol under the conditions described for the hydrolysis of phenacetin.

Since the method was designed to estimate caffeine, total salicylate, and total *p*-aminophenol, it can be employed for the analysis of aspirin–phenacetin–caffeine formulations. The results of the analyses of three such powders are summarized in Table IX. In comparison to currently employed column and GC techniques for the estimation of the percentage composition of aspirin–phenacetin–caffeine formulations (12), the solvent extraction method is simple and requires no equipment other than a spectrophotometer.

[9] Under these conditions of hydrolysis, rat plasma and kidney homogenate and human urine samples obtained following the administration of phenacetin were found to be completely hydrolyzed to *p*-aminophenol.

Optimizing Dermatological Formulations of Retinoic Acid

DAVID A. SCHLICHTING▲, WILLIAM M. WOODING, and MICHAEL BROWN

Abstract □ Formulations of retinoic acid for the topical treatment of ichthyosiform and seborrheic dermatoses were developed. They were evaluated for their skin irritation potential on rabbits, as a measure of pharmacological "activity," by studying erythema and scab-formation times. Different types of vehicles and varying concentrations of retinoic acid were studied. It was found that relatively high concentrations of retinoic acid (0.1–0.2%) were necessary in lipophilic vehicles (in which retinoic acid is relatively insoluble) to achieve a desirable irritation level. Such formulations should be useful for treating ichthyosiform dermatoses. Conversely, it was found that relatively low concentrations of retinoic acid (0.001–0.050%) were preferable in hydrophilic vehicles (in which retinoic acid is relatively soluble) to achieve a desirable irritation level. Such formulations should be useful for treating seborrheic dermatoses.

Keyphrases □ Retinoic acid—development of topical formulations for treatment of ichthyosiform and seborrheic dermatoses □ Topical formulations, retinoic acid—developed for treatment of ichthyosiform and seborrheic dermatoses □ Dermatology—retinoic acid formulations developed for treatment of ichthyosiform and seborrheic dermatoses □ Ichthyosis, treatment—development of retinoic acid formulations □ Seborrhea, treatment—development of retinoic acid formulations

The application of vitamin A acid or retinoic acid to therapy of topical diseases was first reported by Stüttgen in 1962 (1). He observed irritation in which vasodilation and slight perivascular infiltration were seen and in which keratolysis of the epidermis occurred with no observable effects on the dermis. He reported some success in treating ichthyosis vulgaris, senile hyperkeratosis, and acanthosis, using lipophilic ointments containing 0.1–1.0% retinoic acid. He observed minimal pharmacological activity without irritation in ichthyosis, using an ointment containing 0.01% retinoic acid. He found neither activity nor irritation using a 0.01% alcoholic solution.

Subsequently, much new information has been added. Possible effectiveness in Darier's disease (2, 3), keratoacanthomas (4), acne (2, 5–8), psoriasis (2, 9), congenital ichthyosiform erythroderma (2, 10), zosteriform keratosis (11), lamellar ichthyosis (12), and wound healing (13) has been reported. Of special interest are the reports on the treatment of seborrheic conditions such as acne, in which hydrophilic vehicles are preferred, and of ichthyosiform conditions, in which hydrophobic vehicles are preferred.

From the early reports that discuss vehicles and retinoic acid concentration in relation to irritation, it was hypothesized that irritation is probably directly related to retinoic acid activity and that a desirable "activity" level would be mild erythema with little or no scab formation. Thus, screening of vehicles and evaluation of concentration effects could be determined effectively in animal skin irritation tests. Ichthyosiform dermatoses can best be treated with lipophilic vehicles that partially occlude the area, render the skin more pliable, and offer physical protection. The skin barrier is not intact due to the disease; to prevent rapid penetration and to achieve a sustained local effect, retinoic acid should be relatively insoluble in the vehicle. However, seborrheic dermatoses (especially acne) can best be treated with hydrophilic vehicles that tend to remove excess sebum, impart a desirable drying effect, and enhance retinoic acid absorption. This can be accomplished using a vehicle that penetrates well and also dissolves retinoic acid well. Thus, two different types of vehicle are required for broad clinical evaluation.

As a result of these considerations, a series of experiments was planned. The objectives were: (*a*) to determine the purity and stability of retinoic acid and its solubility in various materials that could be used in dermatological formulations; (*b*) to choose the materials in which the retinoic acid showed greater solubility for possible use as hydrophilic vehicles and those in which it showed lesser solubility for use as hydrophobic vehicles; (*c*) to formulate o/w and w/o test vehicles; and (*d*) to carry out a pharmacological screening study to assist in selecting optimal formulations containing sufficient retinoic acid to produce a desirable, mild irritation without undesirable edema and scab formation. The solvents and the formulations used are identified below.

EXPERIMENTAL

Chemicals—All of the commercially available isomers of retinoic acid were investigated, and all-*trans*-retinoic acid[1] was chosen for these studies. This is the most readily available form and has been used in some reported clinical studies. Of course, the activity of physical forms of all-*trans*-retinoic acid other than that used and of other isomers and combinations of isomers may be different than that chosen, so these results will not necessarily be representative of all forms.

The purity of all-*trans*-retinoic acid was verified by UV, IR, differential scanning calorimetry, TLC, and column chromatography, and good evidence of at least 95% purity was obtained.

Sherman (14) demonstrated unusually good stability for an all-*trans*-retinoic acid solution in petroleum ether subjected to UV light. The sclution also showed good stability in various other organic solvents when stored in the dark at room temperature for up to 3 months. These results have been verified in the authors' laboratory for some solvents and for the formulations reported here.

Solubility—Retinoic acid solubility in potential ointment vehicles was determined, and it was found that higher molecular weight liquid alkanols and polyethylene glycol ethers of these alkanols were relatively good solvents, but that fatty esters, cholesterol esters, and hydrocarbons were relatively poor. Representative room temperature solubilities (percent w/w) are as follows: lauryl alcohol[2], 2.5; 2-octanol, 1.8; ethoxylated lauryl alcohol[3], 1.5; polyethylene glycol 400, 0.5; almond oil, 0.2; isopropanol, isopropyl myristate, and acetylated cholesterols[4], 0.2; and mineral oil, 0.008. A supersaturated solution (0.04 at room temperature) was obtained by incorporating retinoic acid in liquid petrolatum at 58°.

Formulation—Using this solubility information, an o/w cream (Formula A) in which retinoic acid is relatively soluble was formu-

19	0.0010	Formula A (o/w, lauryl alcohol)

[a] Retinoic acid incorporated cold. [b] Retinoic acid incorporated hot.

lated. It contained the following ingredients (percent w/w): laury[1] alcohol, 2; ethoxylated lauryl alcohol, 3; propylene glycol, 5; stearyl alcohol, 4; ethoxylated stearic acid[5], 3; glyceryl monostearate, 4; silicone 500 CST[6], 2; and water *qs*. The first three ingredients, based upon the solubility data, apparently contributed most of the solubility characteristics of the cream. For the w/o ointment (Formula B), in which retinoic acid is relatively insoluble, cold cream USP XVII containing spermaceti, white wax, mineral oil, sodium borate, and water were used. None of these ingredients appeared to contribute appreciably to retinoic acid solubility. A w/o cold cream formula, substituting almond oil for mineral oil, was also prepared (Formula C). The ointments were milled so that retinoic acid crystals were reduced to a mean size of about 50 μ. An alternate o/w cream (Formula D), similar to Formula A but containing 5% hexadecyl alcohols[7] instead of lauryl alcohol and ethoxylated lauryl alcohol, was also evaluated. The chemical and physical stabilities of these formulations were determined to be adequate for testing purposes. The formulas are identified in Table I.

Pharmacological Screening—Preliminary work indicated that the albino rabbit would be an acceptable model. For Experiment 1, New Zealand White male rabbits were selected and were equilibrated with plastic collars. It was planned to evaluate 16 formulations (Table I), and 16 rabbits were randomly selected for testing from a larger group. The experimental design was a Youden "square," having six rows and 16 columns, with rows representing positions on each animal's back and columns representing individual rabbits. A unique subset of six of the 16 formulations was to be tested on the six sites on each rabbit's back. This Youden square design has the characteristic that every formulation is tested an equal number of times (six), and every formulation appears together with every other one an equal number of times (twice). The subsequent statistical analysis of the data, described below, ensured that treatment means would be adjusted to isolate the influences of position (if any) and animal differences, so that treatments could be compared in an unbiased fashion.

The dorsal-lateral hair was removed from the backs of the 16 animals by careful clipping on the day before the test began. Tattoos were applied to designate test areas on each back. A template providing six 3.8 × 7.6-cm. (1.5 × 3.0-in.) sites, with 3.8 cm. (1.5 in.) or more between each, was used to locate the six positions. On the 1st day of test, a 100-mg. quantity of test ointment or liquid was applied to each site, using a smooth polyethylene spatula to distribute the test material uniformly. The order of treating the 16 sites on each rabbit's back was randomized, and for each subsequent application, new randomizations were used. Treatments 1–16 were used (Table I).

[7] Enjay.

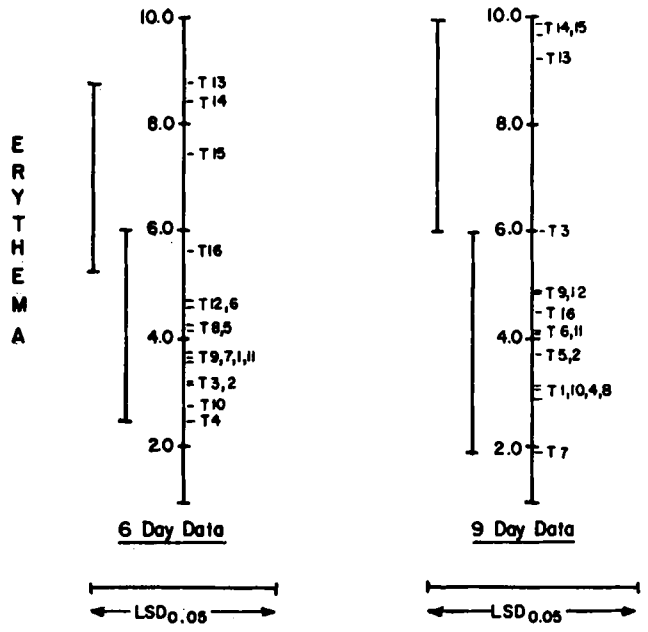

Figure 1—*Tukey multiple-comparison tests for all two-treatment erythema comparisons of the first 16 treatments listed in Table I. Mean scores are arranged in rank order. $LSD_{0.05}$ values are plotted on the same scale.*

The six sites on each back were treated daily for 10 days. Prior to each daily application, each treated area was carefully observed, again in a random order and with the observer having no knowledge of the identity of the formulation used at each site. One observer scored each site for erythema each day in this way, using a scale of 1–12 (1 = "no erythema," 12 = "maximum erythemal response"). Edema was scored similarly and separately by the same observer.

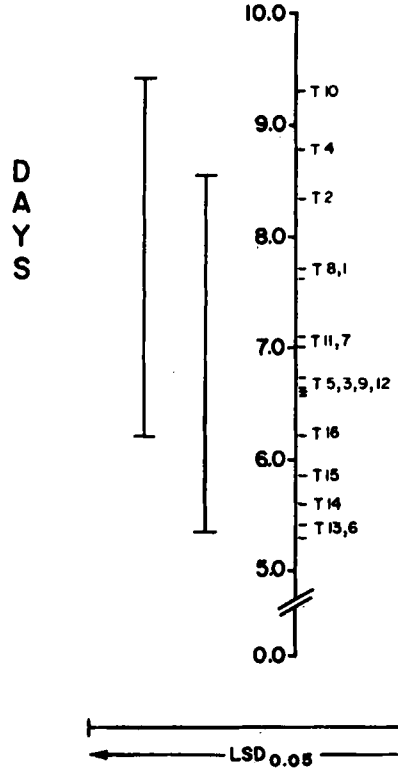

Figure 2—*Tukey multiple-comparison tests for all two-treatment scab formation time comparisons of the first 16 treatments listed in Table I. Mean scores are arranged in rank order. $LSD_{0.05}$ values are plotted on the same scale.*

Table II—Mean Erythema Scores for Formula A (o/w, Lauryl Alcohol)

Treatment	Retinoic Acid Concentration %	Retinoic Acid Concentration p.p.m.	Means[a] Day 3	Means[a] Day 6	Means[a] Day 9
17	0.0000	0	1.81	1.88	1.84
18	0.0001	1	1.91	1.84	1.78
19	0.0010	10	2.56	2.31	2.00
7	0.0100	100	3.06	2.75	2.63

[a] Lowest score (1) = no erythema and highest score (5) = mild erythema.

Table III—Significance Levels (Tukey Tests) for Erythema Scores in Table II

Formula A Concentrations Compared, p.p.m.	Significance Level ($p < 0.10$) Day 3	Day 6	Day 9
(0)—(1)	n.s.	n.s.	n.s.
(0)—(10)	<0.01	<0.01	n.s
(0)—(100)	<0.01	<0.01	<0.05
(1)—(10)	<0.05	<0.01	n.s.
(1)—(100)	<0.01	<0.01	<0.01
(10)—(100)	n.s	<0.05	<0.10

Eschar formation was checked daily for 10 days and recorded so that scabbing formation time could be determined by adopting the convention that there was scab if it was observed in two successive days, in which case the elapsed time to formation was taken as that on the first of the 2 days. Independent statistical analyses of the erythema scores obtained on Days 3, 6, and 9 were done. These three intervals were specified *a priori*. Edema scores did not appear to contribute much information and were not analyzed. Figure 1 shows the results of the comparison of means of erythema score data using computed least-significant difference values[8] for all treatments on Days 6 and 9. Figure 2 shows the results of the comparison of means of scabbing time data using computed least-significant difference values for all treatments.

Experiment 2 was done in a similar manner, but the design provided for the use of all treatments on each animal. In this experiment, four concentrations of Formula A were studied (0, 1, 10, and 100 p.p.m.), and only four sites were used on each rabbit. Since the erythemal scores were expected to occur predominantly at the low end of the original 12-point scale and the observer was sufficiently experienced to score smaller differences, the precision of the measurement was increased by a fourfold expansion of the lower portion of the scale used previously (between 1 and 5). Edema and scabbing time were not considered important to this experiment and were not reported. The same observer scored the results in both experiments. A 4 × 4 Latin square design was used with all four levels of retinoic acid applied to each animal. The Latin square was replicated once; therefore, eight animals were used. The formulas, Treatments 7, 17, 18, and 19, are reported in Table I. The mean erythema scores are reported in Table II. Tukey HSD tests for all possible combinations are reported in Table III.

RESULTS AND DISCUSSION

The data from Experiment 1 were analyzed after replacing missing values by least squares (there were four missing values). Then a residual analysis was done to check the effectiveness of the randomizations and to test the adherence of the data to the assumptions underlying the analysis. Treatment means adjusted for block effects were then computed, and an independent analysis of variance was done on the data from each of the 3 days chosen for analysis. There was a significant effect ($p < 0.05$) for treatments on Day 3 and a highly significant effect ($p < 0.01$) on Days 6 and 9. Scab formation time data were analyzed similarly, showing a highly significant effect for treatments ($p < 0.001$) and a significant effect for positions ($p < 0.05$).

Tukey multiple-comparison tests were done on all two-treatment comparisons for erythema for Days 6 and 9 and are shown in Fig. 1. The means of erythema scores are arranged in rank order, with the Tukey least-significant difference ($p = 0.05$) plotted alongside them on the same scale.

These comparisons show that Treatments 13, 14, and 15 were highest of all treatments on the irritation scale for Experiment 1. Since they contained very different quantities of retinoic acid but used lauryl alcohol exclusively as the vehicle, the data suggest that the alcohol contributed strongly to the irritation observed. In view of the literature, however, it was believed that retinoic acid itself is an irritant; therefore, it was hypothesized that a strong irritating effect of lauryl alcohol was masking differences in irritation due to retinoic acid concentration. The results of Experiment 2 tended to verify this hypothesis.

The poor solvents that were tested (mineral oil and almond oil) either as retinoic acid suspensions or as ointments containing 0.2–0.01% retinoic acid appeared predominantly at the low end of the irritation scale, as desired.

As mentioned, the edema scores were not sufficiently sensitive to give much additional information and are not reported.

Figure 2 presents the means of scabbing times arranged in rank order, with the slowest scabbing time being highest in the order, and the Tukey least-significant difference plotted alongside them on the same scale. These results reinforce the observation that the poor solvents gave low erythema scores.

A Spearman Rank Correlation test, done to investigate the relationship between erythema scores and scab formation time on each of the 3 days, showed rank correlation coefficients of −0.85 and −0.79 for Days 6 and 9, respectively, significant at $p < 0.01$ in both cases. These results show that either response is a reasonably good predictor of the other.

Experiment 2 was designed to investigate the dose–response effect of retinoic acid at lower concentrations (0, 1, 10, and 100 p.p.m.) in Formula A. Residual analyses were carried out, and conventional analyses of variance for Latin squares were done separately for Days 3, 6, and 9 for erythema scores only. Neither edema scores nor scabbing time observations were useful measurements at these low irritation levels. The effect of concentration was strongly significant in all cases—*viz.*, on Days 3 and 6 ($p < 0.001$) and on Day 9 ($p < 0.01$). The mean erythema scores are reported in Table II. Following the ANOVA's, Tukey least-significant difference tests were done for all pairs of concentrations for each of the 3 days. The results are shown in Table III. The table indicates that the concentrations chosen were on an effective portion of the dose–response curve and that a significant difference could be found in comparing all possible combinations except the lowest (0.0001), which was not different from zero.

By assuming that irritation does reflect retinoic acid activity, then the choice of the vehicle and the availability of retinoic acid in that vehicle must be optimized for the intended drug use.

It was concluded that, when extending these results to human clinical work, it would be advisable to treat ichthyosiform dermatoses with w/o emulsions in which retinoic acid is relatively insoluble and preferably at concentrations of 0.10% or more. For treating acneiform or seborrheic dermatoses, the preferable form would be o/w emulsions in which the solubility of retinoic acid is relatively high and preferably at concentrations of 0.05% or less.

Alterations in Absorption of Dicumarol by Various Excipient Materials

M. J. AKERS*, J. L. LACH*, and L. J. FISCHER†▲

Abstract □ A plasma level study was conducted in dogs to determine the effects of various excipient materials on the absorption of dicumarol. The drug was combined with the excipients by an equilibration process and administered orally. Plasma concentrations of dicumarol after administration with excipients were compared to control levels produced by the drug given alone. Significant differences in the plasma levels of dicumarol were observed with six of the 10 excipients used in the study. Significantly higher plasma levels (up to 180% of control values) were observed when dicumarol was administered with magnesium oxide or hydroxide. This effect may be due to chelate formation because the magnesium chelate of dicumarol produced higher plasma levels of dicumarol than the drug administered alone. Dicumarol administration with talc, colloidal magnesium aluminum silicate, aluminum hydroxide, or starch resulted in significantly lower plasma levels of the drug. It is suggested that these types of interactions may be an explanation for differences in the bioavailability of dicumarol from different dosage formulations.

Keyphrases □ Dicumarol absorption—effect of various excipients on plasma levels, dogs □ Absorption, dicumarol—effect of various excipients on plasma levels, dogs □ Plasma levels, dicumarol—effect of various excipients, dogs □ Excipient effect—dicumarol absorption, plasma levels, dogs □ Bioavailability, dicumarol—effect of various excipients on plasma levels, dogs □ Magnesium oxide, hydroxide excipients—effect on dicumarol absorption, dogs

Substantial evidence is available to show that the absorption characteristics and, ultimately, the therapeutic performance of a drug can be significantly altered by changes in the materials and methods used in its formulation. Wagner (1) recently provided a review of studies involving the determination of generic equivalency or inequivalency of different commercial brands of a single drug. Ten of the 12 drugs studied showed significant differences in the bioavailability of drug when two or more commercial brands of the same drug were compared.

Lach and his coworkers (2–4), through diffuse reflectance spectroscopic studies, demonstrated that some adjuvants used in product formulation interact with certain drugs to form complexes. These combinations exhibited markedly different diffuse reflectance spectroscopic characteristics compared to those of the drug alone. The oral anticoagulant dicumarol was shown to interact with various organic and inorganic formulation materials, and it was suggested that these types of interactions may alter the bioavailability of the drug (3). Dicumarol has been shown to be poorly absorbed (5), and its bioavailability may be particularly susceptible to formulation changes. Losinski (6) reported that formulation changes involving the addition or reduction of inert fillers in tablets of dicumarol resulted in significant therapeutic variations.

The purpose of this study was to investigate whether the absorption of dicumarol could be altered by administration of the drug in combination with various formulation materials. The characteristics of its absorption and elimination, coupled with a pharmacological response dependent on plasma concentration, permitted the use of dicumarol to show that drug–excipient interactions may be an explanation for differences in therapeutic efficacy among different dosage formulations.

EXPERIMENTAL

Materials—Dicumarol[1] was recrystallized from dioxane (m.p. 288–289°). Other materials used were: magnesium oxide, heavy[2]; magnesium hydroxide, reagent grade[2]; magnesium stearate USP; dibasic calcium phosphate NF, hydrous[2]; aluminum hydroxide powder[2]; colloidal magnesium aluminum silicate[4]; silicic acid[5]; starch USP; talc USP; polyvinylpyrrolidone[6]; and polysorbate 80[7].

Elemental analysis of the magnesium chelate of sodium dicumarol[8] showed it to have the form $(dicumarol\text{-}Na)_2Mg$. A method for the preparation of the chelate was reported previously (4).

Animals—Eight healthy mongrel dogs of either sex, weighing 10–21 kg., were utilized in the study. The animals were housed in stainless steel cages and fed dog chow[9] between 8 a.m. and noon daily, unless specified otherwise.

Dicumarol–Excipient Mixtures—Dicumarol was mixed with an excipient in two different weight to weight ratios—6 dicumarol:94 excipient and 1 dicumarol:1 excipient. Dicumarol was dissolved in chloroform to make a solution containing 0.3 g. in 50 ml. An appro-

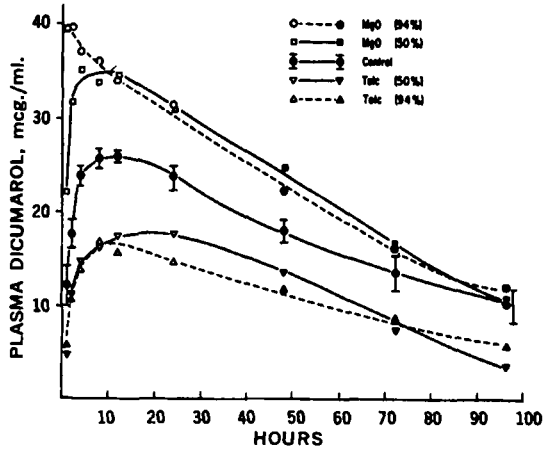

Figure 1—*Plasma concentrations of dicumarol after single oral doses of the drug given alone (control) or with various excipient materials. The values shown are the mean of four animals. Open data points indicate significant differences from control. Variation about the mean values was not statistically different from that of the control values which are shown with* SEM.

priate amount of excipient was added to the solution, and the mixture was stirred briefly by hand and allowed to stand in a glass-stoppered flask for 16 hr. The solvent was removed on a rotary evaporator, and the dry powder was collected after passing through a U. S. Standard No. 100 sieve.

Drug Administration—The dogs were fasted approximately 8 hr. before and 24 hr. after drug administration. Water was allowed at all times during the experiments. Dicumarol alone or the dicumarol–excipient mixtures were administered as aqueous suspensions by gastric intubation using a soft rubber catheter. The suspension was prepared by stirring the required amount of drug with 1–2 ml. of distilled water containing 0.05% polysorbate 80. Additional distilled water was added to bring the volume to 25 ml. and the suspension was immediately administered to the animal. A wash of 50 ml. of distilled water followed the dose to ensure quantitative administration.

The dose of the magnesium chelate of dicumarol was prepared in an identical fashion. In one dog, an intravenous dose of 5 mg./kg. of dicumarol was given after the animal had repeatedly received the same dose of drug orally. The vehicle used was 5 ml. of a dilute sodium hydroxide solution.

Blood Samples—Blood samples (7 ml.) were withdrawn by venipuncture and collected in heparinized Vacutainers[10]. A sample was obtained just prior to dosage administration, and subsequent samples were obtained 1, 2, 4, 8, 12, 24, 48, 72, and 96 hr. after the dose. Starting at 12 hr. after the dose, an additional blood sample (2.7 ml.) was withdrawn at each sampling time in Vacutainers containing sodium citrate for prothrombin time measurements. Heparinized plasma was stored at −20° prior to dicumarol analysis.

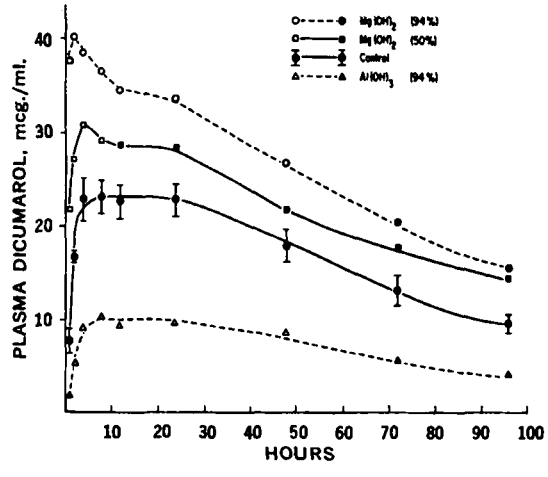

Figure 2—*Same as Fig. 1.*

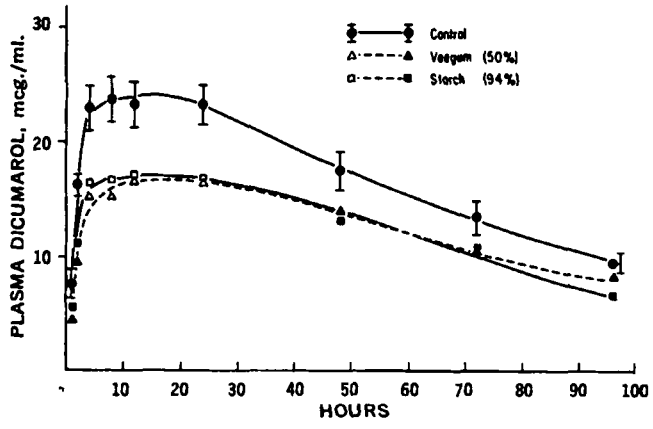

Figure 3—*Same as Fig. 1.*

Analysis of Plasma—Plasma samples were analyzed for dicumarol following the spectrophotometric procedure of Axelrod *et al.* as revised by Nagashima *et al.* (7). Plasma samples were analyzed by the same method after oral administration of the magnesium chelate of dicumarol. The UV absorbance maximum and molar absorptivity of the chelate in 2.5 *N* NaOH were the same as those for dicumarol. Analysis of dog plasma containing known amounts of the magnesium chelate of dicumarol produced an identical standard curve when compared to dicumarol.

Prothrombin Time Measurements—The one-stage method of Quick (8) was used on fresh plasma. Measurements were made on a BBL Fibrometer[11] using rabbit brain thromboplastin[11].

Pharmacokinetic Analysis—Absorption and elimination rate constants were obtained by submitting plasma level data to a nonlinear regression analysis[12]. Areas under the individual animal plasma level curves (0–96 hr.) were calculated using the trapezoidal technique. Areas from 96 hr. to infinity were calculated by the usual method (9), using the elimination rate constant determined by linear regression analysis of the logarithms of the 48-, 72-, and 96-hr. plasma dicumarol concentrations.

Experimental Design—Plasma levels of dicumarol after an oral dose of the drug in a mixture with excipient were compared to those resulting from oral administration of dicumarol powder. To reduce interanimal variation in plasma levels, a recognized characteristic of dicumarol administration (5), the dose of the drug used in each dog was that which produced a peak plasma level of 20–25 mcg./ml. after an oral dose of dicumarol powder. On the basis of the results of a preliminary test dose of dicumarol, the animals received 4, 5, or 7 mg./kg. of the drug. Each of the animals received three control doses (pure dicumarol powder) and from seven to 10 different dicumarol–excipient mixtures. A control dose was given first to each animal, and the subsequent control and dicumarol–excipient doses were given in a completely randomized manner. Blood samples were taken at selected intervals after each dose for plasma dicumarol and prothrombin time analyses. There was at least a 2-week interval between doses of the drug, during which time the drug plasma levels fell to undetectable levels and the prothrombin times returned to normal.

Statistical Analysis—The following parameters were analyzed statistically: plasma concentrations, areas under the plasma level curves, and peak prothrombin responses. The control values for each animal were the averages obtained from three doses of pure dicumarol given at different times. Mean parameters were computed from the data obtained from four dogs. Each dog in a group of four dogs received the same complement of dicumarol–excipient mixtures and three control doses. The means were compared by a one-way analysis of variance randomized complete block design, and statistical

differences from control values were determined by the least significant difference method (10).

RESULTS

Reproducibility of Dicumarol Plasma Levels—Considerable interanimal variation was observed in dicumarol plasma levels after identical oral doses to dogs. Because of this, the oral dose of dicumarol necessary to produce a standard (control) level from which alterations in drug absorption could be evaluated was determined in preliminary experiments on each dog. Adequate plasma levels and prothrombin time responses were produced with oral doses ranging from 4 to 7 mg./kg. Each dog was given the same dose of dicumarol throughout the experiments. Plasma levels of dicumarol after an oral dose were found to be reproducible in each animal. The mean plasma levels resulting from control doses of dicumarol powder administered to each dog at three different times throughout the study are shown in Table I. Analysis of the control plasma levels in each dog showed that time- or drug-dependent changes in dicumarol absorption and elimination did not occur in these experiments. The reproducibility of the control plasma levels of dicumarol is indicated by the low standard errors of the mean values. These mean values were used for comparison to plasma levels resulting when the drug was administered in combination with various excipient materials.

Dicumarol Plasma Levels after Oral Administration with Various Excipients—The mean plasma levels of dicumarol administered alone or in combination with various excipient materials are shown in Figs. 1–3. Significant increases in dicumarol plasma levels over control resulted when the drug was administered with magnesium oxide (Fig. 1). Slightly higher levels were observed with the mixture containing 94% magnesium oxide compared to the mixture containing equal weights of the drug and magnesium oxide. Significant decreases in dicumarol plasma levels were observed when the drug was administered with talc. Decreasing the proportion of talc in the mixture had little effect on the ability of this material to lower drug plasma levels (Fig. 1).

The results in Fig. 2 show that significant increases in dicumarol plasma levels resulted when the drug was given in a mixture containing either 94 or 50% magnesium hydroxide. In contrast, significant decreases in drug plasma levels were observed after administration of dicumarol in a mixture containing 94% aluminum hydroxide. No

[a] Values are mean (*SE*) for four dogs; asterisks (*) indicate a significant difference from control, $p < 0.05$. [b] Normal prothrombin times were not subtracted. Range of normal values was 7.3–8.5 sec.

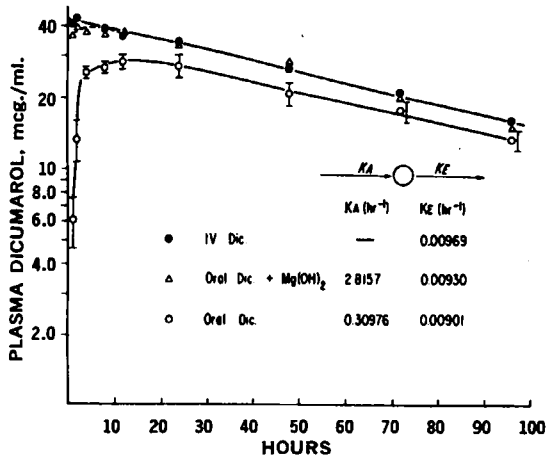

Figure 4—*Semilogarithmic plots of plasma dicumarol concentrations after identical doses of the drug were given intravenously* (●), *orally alone* (○), *or orally with 94% magnesium hydroxide* (△) *to Dog 7. First-order rate constants for absorption and elimination were determined from a nonlinear regression analysis as described in* Methods.

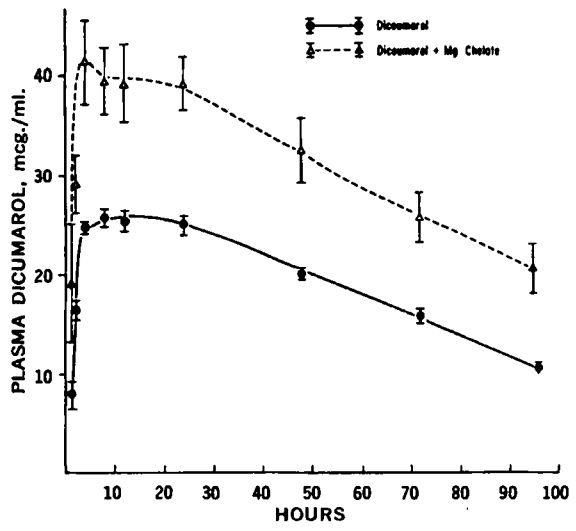

Figure 5—*Mean plasma concentrations of dicumarol after oral administration of the drug or its magnesium chelate to Dogs 3, 4, 8, and 9. Open data points are statistically different from the corresponding values at the same time.*

difference in the dicumarol plasma levels was observed when the drug was administered as a 50% mixture with aluminum hydroxide (Table II). It is evident from the results presented in Fig. 3 that the combination of dicumarol with starch or colloidal magnesium aluminum silicate resulted in lower plasma levels of the drug compared to those resulting from administration of the drug alone.

It can be observed in Figs. 1–3 that the postabsorptive decline in dicumarol plasma levels was similar whether the drug was given alone or with excipients. This suggests that the differences in plasma levels observed were due to absorption of the drug and not to its elimination from the plasma.

Dicumarol administered in combination with several other excipients did not alter the dicumarol plasma levels compared to those produced by the drug given alone. These results are not given in the figures, but the pertinent parameters measured are presented in Table II. The excipients that did not alter dicumarol absorption were silicic acid, magnesium stearate, dibasic calcium phosphate, and polyvinylpyrrolidone.

Comparison of Bioavailability Parameters—Table II presents data commonly used to evaluate bioavailability. Both magnesium oxide and magnesium hydroxide increased the peak plasma concentration of dicumarol in addition to shortening the time necessary to reach the peak levels. The time for peak plasma concentrations to be reached was reduced from 8–12 hr. after administration of the control doses to 1–4 hr. when the magnesium oxide or magnesium hydroxide combinations were administered. Peak plasma levels of dicumarol were increased by as much as 80% compared to controls when the drug was combined with these agents. If it is assumed that these agents do not alter the elimination of the drug from the plasma, these parameters suggest that magnesium oxide or hydroxide increased the absorption rate of dicumarol.

Table II presents the effects of the excipient materials on the areas under the dicumarol plasma level curves. Magnesium oxide and hydroxide, which were observed to increase the peak plasma concentrations of dicumarol compared to control, also increased the area under the 0–96-hr. plasma level curve. A significant increase was observed for magnesium hydroxide but not for magnesium oxide when the 0–∞ areas were compared to control. This indicates that magnesium hydroxide may increase the total amount of drug absorbed.

The rapidity of the absorption of dicumarol when given in a mixture with magnesium oxide was evaluated in one dog by comparing the plasma levels after an oral dose of the mixture to that produced by an identical intravenous dose of the drug. The results (Fig. 4) show that shortly after an oral dose of dicumarol as a mixture containing 94% magnesium oxide, the plasma levels of the drug were nearly identical to those resulting from an intravenous dose. A pharmacokinetic analysis shows that the absorption rate constant (K_a) of dicumarol given with magnesium oxide was 2.8157 hr.$^{-1}$, which is nine times larger than the K_a value of 0.3098 hr.$^{-1}$ obtained when the drug was administered alone. The elimination rate constants (K_e) calculated from oral and intravenous doses to the dog were similar: 0.00901 and 0.00969 hr.$^{-1}$, respectively. Comparison of areas under the plasma level curves indicated that only 70% of a control dose of dicumarol was absorbed and that magnesium oxide increased bioavailability to near 100%.

Prothrombin times were measured after the administration of the anticoagulant either alone or combined with excipient materials. The maximal prothrombin time responses, which usually occurred at 48 hr. after the dose, are also listed in Table II. These values were increased by 50% over the control when dogs were given the drug–excipient combinations containing 94% magnesium oxide or hydroxide, indicating that these agents increased the pharmacological response.

Those excipients, which when combined with dicumarol significantly reduced drug plasma levels, generally delayed the time at which the peak plasma levels were attained. The time for the peak plasma level to be reached was extended from 8–12 hr. after administration of dicumarol alone to 12–24 hr. after a dose of the drug combined with talc (50%) or colloidal magnesium aluminum silicate and to 4–24 hr. after dicumarol was administered with starch. Although aluminum hydroxide did not delay the peak plasma level time, the mixture containing 94% aluminum hydroxide produced the greatest reduction in the concentration of dicumarol at the peak plasma level. This mixture reduced the peak plasma concentration to 44% of that produced by the drug given alone. Both talc and aluminum hydroxide (94%) significantly reduced the areas under the plasma level curves; it is suggested that these materials reduced the total amount of drug absorbed compared to control. Colloidal magnesium aluminum silicate and calcium phosphate showed a small reduction in the area under the 0–96-hr. blood level curve. This reduction was not apparent in the 0–∞ area value.

None of the dicumarol–excipient combinations that exhibited decreased absorption of the drug produced a statistically significant different prothrombin response. A trend existed, however, toward lower prothrombin times when the dicumarol was administered with aluminum hydroxide, talc, or colloidal magnesium aluminum silicate.

Absorption of Magnesium Chelate of Dicumarol—Since dicumarol has been shown to form chelates with metals, including magnesium, the role of chelation in the production of increased dicumarol plasma levels by magnesium oxide and hydroxide was investigated. The magnesium chelate of sodium dicumarol was administered to four dogs. Plasma concentrations of dicumarol resulting from dicumarol–magnesium chelate administration were compared to those produced by oral administration of sodium dicumarol to the same animals. The results (Fig. 5) indicate that the magnesium chelate produced significantly higher plasma levels of dicumarol. The plasma level curve of dicumarol after administration of the chelate was almost identical to that produced by administration of the drug

as a mixture with 94% magnesium hydroxide (Fig. 2). The mean $\pm SE$ peak prothrombin time after administration of the dicumarol–magnesium chelate was 21.7 ± 4.0 sec. This value is statistically larger than that observed after administration of dicumarol alone (15.1 ± 1.0 sec.), showing that the higher plasma levels of the drug resulting from the chelate also increased the biological effect of the drug.

DISCUSSION

The results presented indicate that certain excipient materials can dramatically alter the absorption of dicumarol. Both increases and decreases in the absorption of dicumarol were observed as a result of administering the drug with these materials. The well-recognized adsorbent properties of aluminum hydroxide (11) probably account for the reduced bioavailability of dicumarol when it was administered with this agent. Decreasing the proportion of aluminum hydroxide in the dose mixture to 50% eliminated its inhibiting effects on the absorption of dicumarol. This concentration effect was not seen with talc, which decreased dicumarol absorption at both drug concentrations tested. Thus, it may not be possible to assume in every case that an excipient effect on drug absorption can be reduced by lowering the amount of excipient given with the drug. Colloidal magnesium aluminum silicate and starch were only tested at one concentration, and no assessment of a concentration dependence on their inhibitory effects can be made. It is assumed that the adsorptive properties of these excipients coupled with their water insolubility are the chief characteristics that serve to decrease dicumarol absorption. The lack of effect of polyvinylpyrrolidone on dicumarol absorption was somewhat surprising in view of its recognized ability to complex drugs (12) including dicumarol (13).

Magnesium oxide and hydroxide enhance the absorption rate of dicumarol and also potentiate its anticoagulant action when combined with dicumarol in a mixture containing 94% excipient and 6% drug. Dicumarol is a weak organic acid; as such, it is considerably more soluble in alkaline solutions and is less readily absorbed from the acidic stomach contents (14). When the drug is administered with a basic substance such as magnesium oxide or hydroxide, it is possible that these excipients increase the rate of dissolution and allow a more rapid rate of absorption of the drug from the GI tract.

The administration of the magnesium chelate of dicumarol significantly increased the bioavailability of the drug. Comparison of dicumarol plasma levels produced by the chelate and those produced by the mixture with magnesium oxide or hydroxide show that they are similar except at the earliest sampling time. The mixture produced significantly higher dicumarol levels than the chelate 1 hr. after an oral dose. It is possible that magnesium oxide or hydroxide increases the absorption of dicumarol by a combination of factors: (*a*) increasing the pH of the microenvironment of the drug in the GI tract, thereby increasing the solubility and perhaps the dissolution rate; and (*b*) causing the formation of a dicumarol–magnesium chelate which is more readily absorbed. Administration of magnesium hydroxide 30 min. after a dose of dicumarol significantly increased plasma levels of the drug in dogs (unpublished observations). These results suggest that chelate formation may take place in the GI tract.

It is not known whether the chelate is absorbed as such or whether it releases dicumarol for absorption. The physical characteristics of the magnesium chelate that may explain how it increases plasma levels of dicumarol will be reported separately. Magnesium stearate did not increase the absorption of dicumarol. This material may be so insoluble in the GI fluids that magnesium was not available for chelate formation.

It can be speculated that the interactions between drug and excipient, which were observed in this study to alter the absorption of the therapeutic agent, could account for differences in drug bioavailability from various commercial formulations. The processes involved in tableting may even increase these interactions. Further experimentation is necessary, however, to determine whether the actual physical interactions involved are between drug and excipient or between the excipient and the biological system involved in the absorption of drugs.

Several reviews of drug interactions state that the concurrent administration of antacids reduces the absorption of weakly acidic coumarin anticoagulants (15, 16). The results reported here show that the antacid magnesium hydroxide can increase the absorption of dicumarol. Concurrent administration of milk of magnesia with dicumarol increased plasma levels of the anticoagulant in two dogs (unpublished observations). As a result of this study in dogs, the effects of concurrent administration with antacids on the absorption of dicumarol in man are being investigated.

Compatibility of ^{14}C-Labeled Phenylephrine Hydrochloride in Polyethylene Nasal Spray Containers

ARNOLD KARIG*, GARNET E. PECK▲, and GLEN J. SPERANDIO

Abstract □ The interaction of phenylephrine hydrochloride with low density polyethylene containers was investigated using ^{14}C-labeled phenylephrine hydrochloride. In the first part of the study, nasal spray bottles with and without dip tubes containing 0.25 and 0.5% ^{14}C-phenylephrine hydrochloride were evaluated at temperatures of 7, 22, 40, and 50°. No losses of ^{14}C-phenylephrine hydrochloride were observed. Units stored at 40 and 50° showed apparent increases in concentration of the ^{14}C-phenylephrine hydrochloride. This reflected the loss of water from these units, the loss being confirmed by gravimetric data. This demonstrated a technique for the observation of solvent loss by means of a radioisotopic method. In the second part of the study, the influence of two preservatives, benzalkonium chloride (1:5000) and thimerosal (1:5000) on the phenylephrine hydrochloride–polyethylene container interaction was investigated. The data indicated apparent binding of phenylephrine hydrochloride to low density polyethylene by means of a preservative agent. Interaction was most significant at room temperature, with elevated temperature disrupting the apparent weak binding.

Keyphrases □ Phenylephrine hydrochloride, ^{14}C-labeled—interaction with low density polyethylene nasal spray containers, effect of preservatives □ Polyethylene nasal spray containers—interaction with ^{14}C-phenylephrine hydrochloride, effect of preservatives □ Drug–plastic interactions—^{14}C-phenylephrine hydrochloride and polyethylene nasal spray containers □ Nasal spray containers, polyethylene—interaction with ^{14}C-phenylephrine hydrochloride, effect of preservatives □ Preservatives, benzalkonium chloride and thimerosal—effect on binding of phenylephrine hydrochloride to polyethylene containers □ Plastic (polyethylene) nasal spray containers—interaction with phenylephrine hydrochloride, effect of preservatives □ Liquid scintillation spectrometry—used to study interaction of ^{14}C-phenylephrine hydrochloride with polyethylene

Many different products are packaged in plastics today. Among the first to recognize the versatility and practicality of plastics for packaging were the cosmetic and pharmaceutical manufacturers. The use of plastic containers in the pharmaceutical and cosmetic industry has multiplied rapidly to include a wide range of products. The plastic most frequently used in the manufacture of molded pharmaceutical and cosmetic containers is polyethylene.

Despite the widespread and increasing use of polyethylene containers to package drug and cosmetic preparations, limited information is available in the literature as to the compatibility of medicinal agents and solutions with polyethylene containers. One potential problem is that solutions of a drug in contact with a plastic can lead to sorption of the drug by the plastic, resulting in a significant loss of potency. Another major consideration encountered with polyethylene is that it is permeable in varying degrees to liquids, gases, and volatile substances.

Marcus *et al.* (1) and Kim and Autian (2) studied the sorption of certain bacteriostatic agents and several weak organic acids by polyethylene syringes. Using conventional analytical techniques, they determined that no sorption had occurred after 1 week of storage at 5, 30, and 50°. Neuwald and Schmitzek (3) found that preservative solutions stored in low and high density polyethylene containers showed no apparent reduction in preservative concentration resulting from sorption into plastics. Schoenwald and Belcastro (4) demonstrated the sorption of chlorobutanol by polyethylene strips stored in ^{14}C-labeled chlorobutanol solution. At present, there appears to be no satisfactory general method for predicting which plastic material should be used for one drug or another.

Parliman (5–7) was one of the first to study permeability of polyethylene with regard to containers. He developed an empirical method of determining the transmission rates of certain liquids through polyethylene. More recently, Salame and Pinsky (8) developed the Permachor method for estimating the permeabilities of organic liquids in polyethylene. One reason why permeation data often do not agree is that the particular plastic material influences the permeation rate, so great variations can occur in plastics even when manufactured under the same generic name (9).

One popular treatment employed for the symptomatic relief of nasal congestion is the administration of sympathomimetic-containing nasal solutions from polyethylene squeeze bottles. Phenylephrine hydrochloride is

perhaps the most widely employed agent for this purpose, being the main ingredient in a large number of commercial products available for over-the-counter as well as prescription sales.

The intent of this investigation was to study the behavior of phenylephrine hydrochloride in the complete polyethylene spray bottle unit as it is sold to the consumer. Internal liquid scintillation spectrometry was employed for studying phenylephrine hydrochloride concentrations throughout the study because it is more sensitive to minute changes in concentration than are traditional assay methods.

While previous studies of drug–plastic interactions have been concerned with single-component systems, the use of internal liquid scintillation spectrometry permitted the study of a multicomponent system. One reason for not studying a multicomponent system by traditional methods is that the method of analysis can become quite complex. The ^{14}C-phenylephrine hydrochloride could be studied in the presence of various unlabeled components to see what effect they might have on its interaction with the polyethylene.

EXPERIMENTAL

Polyethylene spraying bottles were used throughout the study[1]. These bottles were made to contain 15 ml. of liquid and were supplied with dip tube, sprayhead, and screw-on cap.

The ^{14}C-phenylephrine hydrochloride[2], with a specific activity of 6.02 mc./mmole, was determined by the manufacturer to have a radiochemical purity greater than 99%. To confirm this value, the upper layer of a butanol–acetic acid–water (5:1:3) solution was used as the developing solvent for the paper chromatographic analysis of the ^{14}C-phenylephrine hydrochloride. Development of the chromatogram was followed by autoradiography on X-ray film, sectioning of the chromatogram, and scintillation counting. A radiochemical purity of greater than 98% was indicated.

Four main groups comprised Part A of the study. Group 1 contained 0.25% ^{14}C-phenylephrine hydrochloride solution in spray containers complete with dip tubes, while Group 2 units had the dip tubes removed. Groups 3 and 4 contained 0.5% ^{14}C-phenylephrine hydrochloride, with Group 3 spray containers being complete and Group 4 containers being without dip tubes.

Each main group was divided into four subgroups of five spray units each. One subgroup was stored at each of the following temperatures: 7, 22, 40, and 50°. Table I depicts the grouping of the units. A duplicate set of units was prepared for all four primary groups. These duplicate units were prepared to study weight loss and to determine the effects, if any, of repeated sample withdrawals on the results obtained with the primary groups.

In Part B of the study, the effects of two preservatives, benzalkonium chloride (1:5000) and thimerosal (1:5000), on the behavior of the ^{14}C-phenylephrine hydrochloride–polyethylene interaction were studied. The units stored at 7 and 22° in Part A (from both the primary and duplicate groups) were used for Part B. No change occurred in these units during the first 10 weeks of Part A of the study.

The preservative solutions were added in such a manner as to yield a final volume of 10.1 ml. in each unit. All units used in Part B were assembled complete with dip tubes. Grouping of the units according to preservative and storage temperature is depicted in Tables II and III.

The spray containers were stored at the respective temperatures in the upright position in both parts of the study. Partitioned cardboard trays, open at the top, were constructed to store the spray units. Each partitioned carton held 20 spray containers.

A 100-μl. Hamilton[3] microliter syringe with a Chaney adapter was used to withdraw 100-μl. samples from the spray containers. A scintillator solution (0.4% 2,5-diphenyloxazole in equal parts of toluene and 2-ethoxyethanol) was used for all samples.

A two-channel, ambient temperature, internal liquid scintillation spectrometer[4], equipped with automatic sample changer and printout, was used throughout the study. Each sample was counted at

optimum gain for a 1-min. interval, with the instrument set to subtract the background count rate automatically. Net counts per minute (c.p.m.) ranged from approximately 14,000 to 16,000. A counting error of less than 1% was obtained, and the counting efficiency was around 78% throughout the investigation. By using a toluene-^{14}C internal standard, the absolute count rate was calculated according to the method described by Wang and Willis (10). All further calculations were based upon the disintegrations per minute (d.p.m.) obtained.

Each container in the duplicate set of units was weighed on an analytical balance at the beginning and at the end of Part A to determine moisture loss. In addition, two units from each subgroup of the duplicate set were weighed periodically. Weighings were conducted each time sampling of the primary group was performed.

RESULTS

Drug–Plastic Interaction: Part A—Table I lists the solution groups investigated in Part A of the study. The mean disintegrations per minute for each five-container group is listed in Tables III and IV. The three major parameters investigated were the effects of solution concentration, temperature, and container components on possible drug–plastic interaction.

The data presented in Table III show that no loss of ^{14}C-phenylephrine hydrochloride occurred in any of the 0.25% solutions. The disintegrations per minute values at the end of 10 weeks were of the same magnitude as the initial values or greater. Table IV shows similar results for the 0.5% ^{14}C-phenylephrine hydrochloride. In all cases, group disintegrations per minute values either remained the same or increased during 10 weeks of storage at 7, 22, 40, or 50°. An increase in concentration of the ^{14}C-phenylephrine hydrochloride had no apparent effect on the behavior of the phenylephrine hydrochloride toward the polyethylene. No sorption was demonstrated, indicating complete compatibility of the drug with the container and its components. There was no difference seen in the units without dip tubes. All units behaved in identical fashion at each temperature regardless of the presence or absence of dip tube components.

Reference to Tables III and IV shows that no loss of ^{14}C-phenylephrine hydrochloride occurred at any of the four temperatures studied. There was no increase or decrease for any of the groups stored at 7 and 22°. Elevated temperatures failed to promote any loss of ^{14}C-phenylephrine hydrochloride through sorption. There was an apparent gain in disintegrations per minute values, however, for each group stored at 40 and 50°. This gain was attributed to the loss of solvent from the spray containers.

Moisture Loss: Part A—Each unit in the duplicate set of units from Part A was weighed at the beginning of the study and at the end of 10 weeks. The units stored at 40 and 50° were also weighed again at the end of 16 and 20 weeks. The weight loss for each unit, represented as percent weight loss after 10 weeks, is listed in Table V. Table VI lists the percent weight loss for each unit stored at 40 and 50° for Weeks 11–16 of the study, while Table VII shows the percent weight loss for these units for Weeks 17–20. Since there was a corresponding increase in disintegrations per minute with weight

loss of the solutions studied, the weight loss was attributed to permeation of the solvent, water, through the polyethylene container. Average percent moisture loss values for all groupings as demonstrated by weight loss are listed in Table VII.

The presence or absence of dip tubes did not affect the moisture loss. Groups having no dip tubes showed moisture losses of the same magnitude as their counterparts with dip tubes. The average 10-week percent moisture loss for all groups stored at 7° was 0.031%, while the average loss was 0.275% for groups stored at 22°. Groups stored at 40 and 50° showed average moisture losses of 1.8 and 4.7%, respectively, during the first 10 weeks. Weight loss data for the second 10-week segment of Part A show an additional average moisture loss of 2.0% for units stored at 40° and of 4.4% for units stored at 50°.

Representative units of each group stored at 40 and 50° were weighed periodically during the first 10 weeks of the study, at the end of 16 weeks, and again at the end of 20 weeks. Figures 1 and 2 show the moisture loss curves for typical units stored at 40 and 50°. Water was lost from the units at a constant rate, the average loss being approximately 19 mg./week for units stored at 40° and 45.5 mg./week for units stored at 50°.

The loss of solvent from the polyethylene spray bottles was also reflected in the increased disintegrations per minute values at the end of 10, 16, and 20 weeks. The percent increase in disintegrations per minute values for both primary (regularly sampled) and duplicate (unsampled until Week 10) groups stored at 40 and 50° is shown in Table VIII. Reference to Table VIII shows that at the end of 10 weeks the percent increase in disintegrations per minute values for both primary and duplicate groups stored at 40° compares favorably with the percent weight loss data. While the percent increase in disintegrations per minute values after 10 weeks for the duplicate units stored at 50° compares favorably with the weight loss data, higher losses were reflected by the primary or regularly sampled units. The higher losses in these units may be attributed to their regular sampling, additional moisture loss occurring each time a unit was opened and a withdrawal made. These data are valuable in projecting what might be observed during normal patient use of these products.

The disintegrations per minute values for all groups stored at 40 and 50° continued to increase during the second 10-week period. The percent increase in disintegrations per minute values for the 20-week period compares favorably with the weight loss data for that period. Figures 3 and 4 show the moisture loss curves for groups stored at 40 and 50°, respectively, as reflected by the disintegrations per minute increase. The solid lines in Figs. 3 and 4 represent the lines of best fit for the data as determined by least-squares calculations.

Container Suitability: Part A—The results of Part A demonstrate that low density polyethylene containers are suitable for the packaging of aqueous solutions of phenylephrine hydrochloride. Phenylephrine hydrochloride showed no interaction with the polyethylene polymer at any of the temperatures studied. Furthermore, phenyl-

ephrine hydrochloride demonstrated no visual evidence of decomposition when stored at 7, 22, or 40° in combination with 2% sodium bisulfite. At 50°, no decomposition was evident after 10 weeks had elapsed. By the end of 16 weeks, the characteristic brownish color of degraded phenylephrine hydrochloride was evident.

The polyethylene containers studied presented a good barrier to moisture transmission. Water permeation through the container walls was negligible at 7° and only 0.03%/week at room temperature (22°). At elevated temperatures, the losses were about 0.2%/week at 40° and 0.45%/week at 50°. Overall, low density polyethylene was shown to be an adequate container for packaging of aqueous solutions of phenylephrine hydrochloride utilizing a radioisotopic method of investigation.

Drug–Plastic Interaction: Part B—In Part B, the influence of two preservatives, benzalkonium chloride (1:5000) and thimerosal (1:5000), on the phenylephrine hydrochloride–polyethylene container interaction was investigated. Table II lists the different solution groups investigated in Part B. Mean disintegrations per minute values for each five-container group are listed in Tables IX and X. Table XI shows the net percentage increase or decrease in disintegrations per minute values for each of the groups investigated in Part B.

Both benzalkonium chloride and thimerosal were found to cause a slight interaction of the ^{14}C-phenylephrine hydrochloride with the polyethylene container. At 7°, the average loss for all units was 1.0% after 14 weeks of storage. At 22°, the loss of ^{14}C-phenylephrine hydrochloride averaged 2.6% after 14 weeks, with the average loss values ranging from 1.9 to 3.0%. The decrease in phenylephrine hydrochloride concentration for groups stored at 22° is depicted in Fig. 5.

After 14 weeks at 40°, there was a small increase in the average disintegrations per minute values. The increase averaged 0.23% for 14 weeks. When this value is compared to the average disintegrations per minute increase (1.75% for 14 weeks) for the unpreserved solutions stored at 40°, a difference of approximately 1.5% is indicated. Thus, there was an apparent 1.5% loss of ^{14}C-phenylephrine hydrochloride offsetting the loss of moisture from the container.

The average percent disintegrations per minute increase for units preserved with benzalkonium chloride and stored at 50° was approximately 0.5%/week or about the same magnitude as the increase per week (0.53%) for unpreserved solutions stored at 50° in Part A. The disintegrations per minute increase for units preserved with thimerosal was greater than that of the units preserved with benzalkonium chloride. The average percent disintegrations per minute increase for the thimerosal-preserved units was 0.71%/week. If the percent increase in average disintegrations per minute values for the thimerosal-preserved units is projected over a 20-week period, a gain of 14.2% is indicated. This value compares favorably with the range

Table IX—Mean Disintegrations per Minute (d.p.m.) for 0.25% ^{14}C-Phenylephrine Hydrochloride, Preservative Solutions, Part B

of percent increase in disintegrations per minute values for unpreserved solutions from Part A listed in Table X. Overall, the moisture loss (as reflected by increased average disintegrations per minute values) for the preserved solutions stored at 50° was the same as that for the unpreserved solutions studied in Part A.

Study of the data from Part B reveals that there is an apparent interaction between the ^{14}C-phenylephrine hydrochloride and the polyethylene container caused by both preservatives. The interaction was strongest at room temperature (22°), with apparent binding of ^{14}C-phenylephrine hydrochloride as high as 3.0% after 14 weeks An increase in temperature appears to disrupt the interacted system For example, at 40° the net loss of ^{14}C-phenylephrine hydrochloride was 1.5%. At 50°, no loss was shown.

The data further reveal that there is no apparent overall trend visible as to any difference between the solutions containing thimerosal or benzalkonium chloride or between solutions containing 0.25% as opposed to 0.5% ^{14}C-phenylephrine hydrochloride. Since the preservative is the limiting factor in the interaction, a

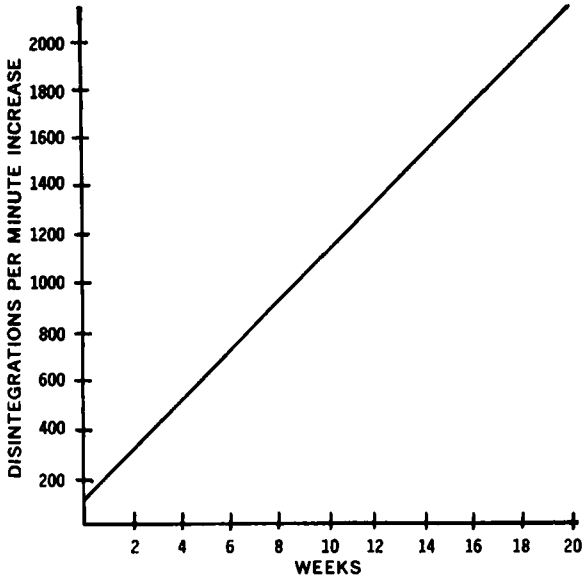

Figure 4—*Average moisture loss as reflected by disintegrations per minute increase for a typical group of units stored at 50°.*

change in preservative concentration would probably alter the percentage lost or bound. Accelerated stability studies at elevated temperatures could not be used to predict the long-term stability of these units at room temperature since the results showed that elevated temperatures disrupt the interaction between container and preservative–drug.

A study of the preservatives as the labeled compound would reveal more about their role in this study and about possible serious loss of preservative due to interaction with the polyethylene container.

SUMMARY

The utility of radioisotopic techniques in evaluating container performance of pharmaceutical packaging was demonstrated by the use of ^{14}C-phenylephrine hydrochloride to investigate the compatibility of phenylephrine hydrochloride in low density polyethylene containers. Phenylephrine hydrochloride in aqueous solution apparently does not bind with low density polyethylene as a blow molded container. Moisture loss from low density polyethylene containers was clearly demonstrated by use of radioisotopic means as well as by conventional gravimetric techniques. It was demonstrated that, at room temperature, phenylephrine hydrochloride binds either to or in combination with a preservative (thimerosal or benzalkonium chloride) to produce an interacted system with low density polyethylene. In this study an elevated temperature disrupted the weak binding. This indicates the necessity of always evaluating polyethylene packaging of liquid pharmaceutical products at room temperature to avoid the possibility of erroneous conclusions based on accelerated testing.

Biosynthetic Production of Aberrant Alkaloids in *Dolichothele sphaerica* (Cactaceae)

H. ROSENBERG▲ and A. G. PAUL

Abstract □ Preliminary studies of the production of aberrant alkaloids were carried out by introducing unnatural precursors of dolichotheline into *Dolichothele sphaerica* in the hope that the corresponding dolichotheline analogs would be formed. Authentic samples of the required dolichotheline analogs were synthesized and served both as standards and as carriers during the extraction procedure. Radioactive analogs were separated from dolichotheline by preparative TLC, recrystallized to constant specific activity, and degraded to localize the label. Using appropriate precursors, the aberrant alkaloids *N*-isocaproylhistamine and 4(5)-[*N*-isovalerylaminomethyl]imidazole were produced by *D. sphaerica*, while the plant appears to be unable to produce *N*-benzoylhistamine, *N*-isobutyrylhistamine, and *N*-isovaleryl-*N*-isopropylhistamine.

Keyphrases □ *Dolichothele sphaerica* (Cactaceae)—biosynthesis of aberrant alkaloids □ Alkaloids, aberrant—biosynthesis of dolichotheline analogs from unnatural precursors in *Dolichothele sphaerica* □ Unnatural alkaloids—biosynthesis of dolichotheline analogs from unnatural precursors in *Dolichothele sphaerica* □ Aberrant alkaloid biosynthesis—*Dolichothele sphaerica* (Cactaceae) □ Biosynthesis of aberrant alkaloids—dolichotheline analogs in *Dolichothele sphaerica*

Studies on the biosynthesis of alkaloids in higher plants have been carried out almost entirely by means of labeled precursor feeding experiments. Such investigations assume that only the natural precursor will be incorporated efficiently into the alkaloid of interest. Yet, there are published accounts that document the incorporation of unnatural precursors into naturally occurring alkaloids (1, 2). In addition, the possibility of the incorporation of unnatural precursors into unnatural or aberrant alkaloids exists. Recently, Leete *et al.* (3) succeeded in inducing the formation of 5-fluoronicotine by feeding 5-fluoronicotinic acid to *Nicotiana tabacum*. Rueppel and Rapoport (4, 5) tested 2- and 3-methyl-substituted pyrrolinium precursors in *Nicotiana glutinosa* and reported their incorporation into the aberrant alkaloids 3′-methylnicotine, 2′-methylnicotine, and 3′,3′-dimethylnicotine.

Dolichotheline (I), a monosubstituted amide alkaloid isolated from the cactus *Dolichothele sphaerica* (Dietrich) Britton and Rose, appears to arise biosynthetically by means of a mechanism involving the condensation of histamine and isovaleryl-CoA (6). Thus, *D. sphaerica* was considered to be suitable for carrying out experiments to determine whether the enzyme(s) responsible for the linkage of histamine and isovaleric acid could also yield aberrant alkaloids following administration of selected precursors to the plant.

The following compounds were tested in the expectation that their corresponding dolichotheline analogs would be formed: isobutyric acid, isocaproic acid, benzoic acid, 4(5)-aminomethylimidazole, and *N*-isopropylhistamine. Authentic samples of the required dolichotheline analogs were synthesized and served both as standards and as carriers during the extraction procedure.

Such investigation into the biosynthesis of unnatural or aberrant alkaloids is of interest for several reasons:

1. There are few reports that deal with the incorporation of an unnatural precursor into an unnatural alkaloid.
2. Such experiments with a series of related unnatural precursors may shed light on the specificity of the enzyme(s) involved.
3. The formation of unnatural alkaloids *in vivo* has broad potential application for the preparation of analogs of biologically active natural products.

EXPERIMENTAL[1]

***N*-Isobutyrylhistamine (II)**—Isobutyric anhydride (2.2 g.) and histamine (1.1 g.) were gently refluxed for 1 hr. Several drops of water were added and the reaction mixture was condensed on a steam bath to a thick, oily residue. The addition of a few drops of acetone caused the crystallization of *N*-isobutyrylhistamine. It was recrystallized from methanol–ether, yielding 1.39 g., m.p. 139–140° [lit. (7) m.p. 123°[2]]; IR (amide) 1640 cm.$^{-1}$. NMR spectral data for all dolichotheline analogs are presented in Table I.

Anal.—Calc. for $C_9H_{15}N_3O$: C, 59.64; H, 8.34; N, 23.19. Found: C, 59.76; H, 8.34; N, 23.25.

***N*-Isocaproylhistamine (III)**—Histamine (0.9 g.) and 4-methylvaleryl chloride (1.7 g.) were refluxed gently for 20 min. The reaction mixture was then cooled, dissolved in 10 ml. of 1 *N* HCl, and extracted three times with equal portions of ether. The aqueous solution was made alkaline with concentrated ammonium hydroxide to pH 9.5 and submitted to extraction with hot chloroform in a liquid–liquid extractor for 24 hr. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to yield the crude *N*-isocaproylhistamine. It was recrystallized from methanol–ether, yielding 0.95 g., m.p. 137–138°; IR (amide) 1635 cm.$^{-1}$.

Anal.—Calc. for $C_{11}H_{19}N_3O$: C, 63.13; H, 9.15; N, 20.08. Found: C, 62.97; H, 9.24; N, 20.14.

***N*-Benzoylhistamine (IV)**—Histamine (1.1 g.) and benzoyl chloride (1.4 g.) were gently refluxed for 15 min. The reaction mixture was then cooled, treated with 10 ml. of 1 *N* HCl, and extracted three times with equal portions of ether. The aqueous solution was made alkaline with concentrated ammonium hydroxide to pH 9.5 and extracted with hot chloroform for 24 hr. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to yield crude *N*-benzoylhistamine. It was recrystallized from methanol–ether, yielding 0.93 g., m.p. 147–149°; IR (amide) 1640 cm.$^{-1}$.

Anal.—Calc. for $C_{12}H_{13}N_3O$: C, 66.96; H, 6.09; N, 19.52. Found: C, 67.13; H, 6.22; N, 19.47.

***N*-Isopropylhistamine Dihydrochloride**—Histamine (1.11 g.), in 25 ml. absolute ethanol and 1.5 ml. of acetone, was hydrogenated over 300 mg. of platinum oxide at atmospheric pressure for 4 hr. After the catalyst was removed, the free base was converted to the

[1] Melting points were determined on a Fisher-Johns melting-point apparatus and are corrected. IR absorption spectra were recorded using KBr pellets and a Perkin-Elmer 337 grating spectrophotometer. NMR spectra were determined in deuterated dimethyl sulfoxide using tetramethylsilane as the reference standard on a Varian A-60 spectrometer. Microanalyses were carried out by Spang Microanalytical Laboratory, Ann Arbor, Mich.

[2] The reported melting point appears to have been interchanged with that of *N*-acetylhistamine, which was also synthesized by the author.

[a] s = singlet, d = doublet, m = multiplet, and t = triplet.

dihydrochloride by dissolving it in 25 ml. of methanol and adding 5 ml. of 6 *N* HCl. The resulting solution was evaporated to dryness and the residue was recrystallized from absolute ethanol–ethyl acetate, yielding 1.23 g., m.p. 195–197° [lit. m.p. 197–199° (14) and 195–196° (15)].

Anal.—Calc. for $C_8H_{17}Cl_2N_3$: C, 42.49; H, 7.58; N, 18.58. Found: C, 42.71; H, 7.74; N, 18.61.

N-Isopropyl-N-isovalerylhistamine (V)—*N*-Isopropylhistamine (0.82 g.) and isovaleric anhydride (2 g.) were gently refluxed for 4 hr. When cool, several drops of water were added to the reaction mixture, which was then condensed on a steam bath to a syrupy residue. This residue could not be induced to crystallize. As a consequence, the picrate derivative was formed by dissolving the residue in 2 ml. of ethanol and adding 10 ml. of a saturated solution of picric acid in ethanol. The crystalline picrate derivative was filtered and recrystallized from water, yielding 817 mg., m.p. 145°; IR (amide) 1640 $cm.^{-1}$.

Anal.—Calc. for $C_{19}H_{26}N_6O_8$: C, 48.92; H, 5.62; N, 18.02. Found: C, 48.89; H, 5.63; N, 18.25.

Imidazole-4(5)-formaldehyde—Hydroxymethylimidazole (13 g.) (8, 9) and nitric acid (19 ml.) were digested in a covered beaker on a steam bath until the evolution of brown fumes was almost complete. The cover was then removed and the liquid was evaporated to dryness.

This residue was dissolved in a warm concentrated solution of sodium carbonate and kept at room temperature for 24 hr., at which time the insoluble imidazole-4(5)-formaldehyde was filtered and dried. It was recrystallized from water, yielding 5.1 g., m.p. 173–174° [lit. (10) m.p. 170°].

Imidazole-4(5)-formaldoxime—The above aldehyde (2.0 g.), hydroxylamine hydrochloride (1.4 g.), and sodium carbonate (1.0 g.) were dissolved in 10 ml. of water and the resulting solution was allowed to stand at room temperature for 24 hr., at which time the insoluble imidazole-4(5)-formaldoxime was filtered and dried. It was recrystallized from alcohol, yielding 1.8 g., m.p. 183° [lit. (11) m.p. 183–184°].

4(5)-Aminomethylimidazole Dihydrochloride—A solution of 1.11 g. of the above oxime in 80 ml. of methanol containing 0.05 mole of dry hydrogen chloride was hydrogenated at 15 lb. pressure over 5% palladium-on-charcoal. After 90 min., the mixture was filtered and the filtrate was evaporated to dryness. The residue was recrystallized from methanol–water to give 1.20 g. of 4(5)-aminomethylimidazole dihydrochloride, m.p. 238–241° [lit. m.p. 246–247° (12) and 244° (13)].

4(5)-[*N*-Isovalerylaminomethyl]imidazole (VI)—The free base of the above amine (0.63 g.) and isovaleryl chloride (1.1 g.) were gently refluxed for 20 min. The reaction mixture was then cooled, dissolved in 10 ml. of 1 *N* HCl, and extracted three times with equal portions of ether. The aqueous solution was basified with concentrated ammonium hydroxide to pH 9.0 and extracted with hot chloroform in a liquid–liquid extractor for 24 hr. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to dryness. Crude VI was recrystallized from methanol–ether, yielding 0.61 g., m.p. 117°; IR (amide) 1630 $cm.^{-1}$.

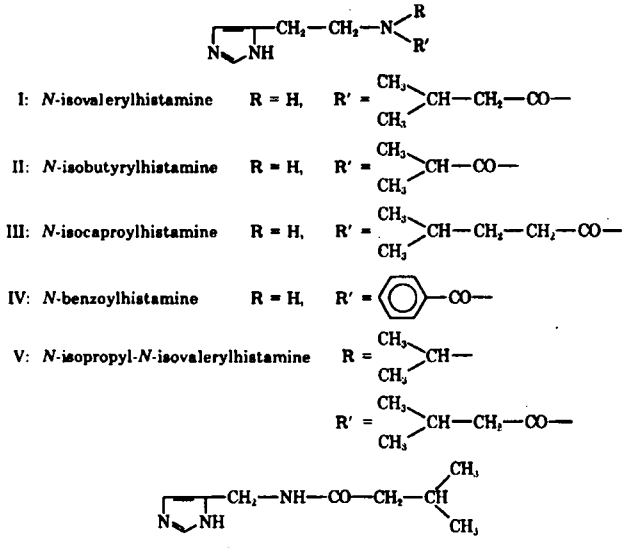
Anal.—Calc. for $C_9H_{15}N_3O$: C, 59.64; H, 8.34; N, 23.19. Found: C, 59.45; H, 8.37; N, 23.23.

Preparation of Labeled Precursors—Isovaleric acid (carboxyl-^{14}C), isocaproic acid (carboxyl-^{14}C), isobutyric acid (carboxyl-^{14}C), and benzoic acid (carboxyl-^{14}C) were purchased from commercial sources.

4(5)-Aminomethylimidazole (ring-2-^{14}C) was prepared by the method of Pyman (13, 16). This synthesis was initially accomplished using nonradioactive material. The product displayed an IR spectrum identical with that of 4(5)-aminomethylimidazole dihydrochloride and showed no melting-point depression when mixed with authentic 4(5)-aminomethylimidazole dihydrochloride. Diaminoacetone dihydrochloride (100 mg.) was added to a hot solution of 66 mg. of potassium thiocyanate-^{14}C in 0.2 ml. of water, and the mixture was heated on a steam bath for 30 min. The resulting crystalline product was filtered, added to 5 ml. of hot water, and filtered again.

The filtrate was added to 900 mg. of ferric chloride in 10 ml. of water, and the mixture was digested for 30 min. on the steam bath. Three milliliters of 10% aqueous sodium carbonate was added, followed by a hot solution of 400 mg. of picric acid in 10 ml. of boiling water. The mixture was boiled with a little charcoal and filtered. On cooling, 96 mg. of 4(5)-aminomethylimidazole-2-^{14}C (ring) dipicrate separated, m.p. 210–212° [lit. (16) m.p. 212°].

The dihydrochloride was prepared by treating the picrate with 5 ml. of 6 *N* HCl, removing the picric acid with four successive 5-ml.



portions of benzene, evaporating the acidic aqueous solution to dryness, and recrystallizing the residue from methanol–water, yielding 22 mg., m.p. 241–243°.

Plants—Living plants of *D. sphaerica*[3] were maintained in a controlled environment lab to provide optimal light, temperature, and humidity (17, 18).

Administration of Test Compounds—All precursors, with the exception of benzoic acid, were dissolved in 1 ml. of sterile water and slowly injected, by means of a 1.0-ml. sterile disposable syringe and a sterile 26-gauge, 1.3-cm. (0.5-in.), hypodermic needle, into the fleshy roots of 10 plants. The benzoic acid was dissolved in 1 ml. of 0.05 *N* NaOH and similarly injected into 10 plants. Nonradioactive *N*-isopropylhistamine was introduced simultaneously with isovaleric acid-1-^{14}C (sodium salt). After each injection, the needle was left in place for a minute to allow the solution to disperse. Following this procedure, the plants were carefully repotted, watered, and returned to the environment lab.

Isolation of Aberrant Alkaloids—Three weeks after the injection of the labeled precursors, the plants were removed from the controlled environment lab and sliced, dried in an oven at 45° for 96 hr., and ground. In each case, 500 mg. of the appropriate, nonradioactive dolichotheline analog was added to the ground material. The method used for the extraction and isolation of dolichotheline and its unnatural analogs was identical to that previously described for the isolation of dolichotheline (19). Any radioactivity residing in the unnatural analog was monitored using TLC and radiochromatogram scanning. When the analog was devoid of activity, no further work was attempted. On the other hand, when the analog did contain radioactivity, it was separated from dolichotheline by preparative TLC.

Separation of III from Dolichotheline—A mixture (600 mg.) of III and dolichotheline was dissolved in a small volume of methanol and applied (100 mg./plate) to a 2-mm. layer of silica gel GF_{254}, 20 × 20-cm. plates. The plates were then subjected to multiple development (three times) using benzene–methanol–chloroform–concentrated ammonium hydroxide (3:1:6:0.1) as the solvent system. The solvent was allowed to migrate to 2 cm. from the top edge of the plate, and the plate was carefully dried each time upon removal from the developing chamber. The R_f value for dolichotheline was 0.20; for III, it was 0.28. The area corresponding to III on each plate was carefully scraped off, and the silica gel was eluted with three 100-ml. portions of methanol. The eluant was filtered and evaporated to dryness. The residue was dissolved in 100 ml. of hot chloroform, which was then dried over anhydrous sodium sulfate, filtered, and reduced to dryness to yield *N*-isocaproylhistamine, 273 mg., m.p. 136–137°.

Separation of VI from Dolichotheline—A mixture (300 mg.) of VI and dolichotheline was separated by a method similar to that employed for the separation of III and dolichotheline. The preparative plates in this case were developed three times using chloroform–ethanol–1 *N* HCl (8:2:0.1) as the solvent system. The R_f for dolichotheline was 0.39; for VI, it was 0.55. The silica gel scraped off the plates was extracted with three 100-ml. portions of methanol. The methanol extract was reduced to dryness and dissolved in 15 ml. of water; the pH was adjusted to 9.5 with concentrated ammonium hydroxide, and the solution was extracted with hot chloroform in a liquid–liquid extractor for 24 hr. The chloroform extract was dried over anhydrous sodium sulfate and evaporated to yield 113 mg. of VI, m.p. 115–116°.

***N*-Isocaproylhistamine Picrate**—III (100 mg.) was dissolved in 1 ml. of ethanol, 1 ml. of a saturated solution of picric acid in ethanol was added, and the mixture was stirred with a glass rod. The resulting yellow crystals were filtered and washed with a few drops of water. The picrate was recrystallized from water, yielding 82 mg., m.p. 138°.

Anal.—Calc. for $C_{17}H_{23}N_6O_8$: C, 46.57; H, 5.06; N, 19.17. Found: C, 46.50; H, 5.11; N, 19.29.

Using an identical procedure, 20 mg. of radioactive III was reacted with picric acid to yield 13 mg. of *N*-isocaproylhistamine picrate, m.p. 137–138°.

4(5)-[*N*-Isovalerylaminomethyl]imidazole Picrate—The amide (100 mg.) was dissolved in 1 ml. of ethanol, and 1 ml. of a saturated solution of picric acid in ethanol was added. The resulting yellow crystals were filtered and rinsed with a few drops of water. This picrate derivative was recrystallized from water, yielding 79 mg., m.p. 171°.

Anal.—Calc. for $C_{15}H_{18}N_6O_8$: C, 43.90; H, 4.42; N, 20.48. Found: C, 43.69; H, 4.38; N, 20.41.

Using the above procedure, 20 mg. of the separated radioactive amide was reacted with picric acid to obtain the picrate derivative, 15 mg., m.p. 170–171°.

Degradation of VI (Scheme I)—The amide (190 mg.) was added to a cold solution of 1 g. of sodium hydroxide in 5 ml. of water. This was followed by the addition of 0.5 ml. of benzoyl chloride and 2 drops of benzene. The mixture was stirred vigorously for 2 hr. with cooling, after which the solid product was filtered, washed with a little water, and dried. The 1,2-dibenzoylamino-3-isovalerylaminopropene-1 was recrystallized from ethanol–water, yielding 170 mg., m.p. 205°.

Anal.—Calc. for $C_{22}H_{25}N_3O_3$: C, 69.64; H, 6.64; N, 11.07. Found: C, 69.46; H, 6.58; N, 11.19.

Using an identical procedure, 40 mg. of the separated radioactive amide was reacted with benzoyl chloride to yield 21 mg. of 1,2-dibenzoylamino-3-isovalerylaminopropene-1, m.p. 204–205°.

Degradation of III (Scheme II)—III was hydrolyzed with 10% HCl, and the resulting histamine and isocaproate were recovered as the dihydrochloride and sodium salts, respectively, by identical procedures described for the hydrolysis of dolichotheline (6). The sodium isocaproate was further degraded by means of a Schmidt decarboxylation essentially as described by Phares (20). The sodium isocaproate and sodium chloride mixture (300 mg.) was dissolved

Table II—^{14}C-Labeled Precursors Tested

Precursor	Position of Label	Specific Activity, mc./mM	Amount Injected, μ	Percent Injected Activity Recovered as Dolichotheline Analog
Isocaproic acid (sodium salt)	1-^{14}C	2.1	300	0.81
Isobutyric acid (sodium salt)	1-^{14}C	30.0	212	—
Benzoic acid	Carboxyl-^{14}C	2.65	179	—
4(5)-Aminomethylimidazole dihydrochloride	2-^{14}C (ring)	0.70	75.5	1.27
N-Isopropylhistamine and isovaleric acid (sodium salt)	1-^{14}C	2.0	70.5	—

Table III—Compound III Obtained from Isocaproic Acid-1-^{14}C-Injected Plants

Compound	Yield, mg.	Melting Point	Reference Melting Point	Mixed Melting Point	Specific Activity, d.p.m./mM
III (crude)	273	136–137°	137–138°	—	2.44×10^6
III recrystallized one time	246	137–138°	137–138°	—	2.44×10^6
III recrystallized two times	208	137–138°	137–138°	137–138°	2.45×10^6
III picrate	13	137–138°	138°	137–138°	2.27×10^6
Histamine dihydrochloride	53	239–243°	243–246°	242–244°	0.002×10^6
Isoamylphenylthiourea	19	100–101°	102°	101–102°	0.019×10^6

in cold 100% sulfuric acid (3 ml.) in a 25-ml. pear-shaped flask, and powdered sodium azide (250 mg.) was added in small amounts, with shaking, to the chilled solution. The flask was immediately connected to two bead towers in series, the first containing 10 ml. of 5% potassium permanganate in 1 N H_2SO_4 and the second containing 10 ml. of 1 N carbon dioxide-free sodium hydroxide. A slow stream of carbon dioxide-free air was drawn through the solution while the flask was heated to 60–65° for 7 hr. The bead tower containing the sodium hydroxide was then washed down with carbon dioxide-free water, and 2 ml. of a saturated solution of barium chloride was added. The resulting precipitate was centrifuged and the supernate was decanted. The barium carbonate was resuspended in water and again centrifuged. This process was repeated with ethanol and the carbonate was finally dried in a desiccator.

To recover the isoamylamine, the contents of the reaction flask were basified to pH 12 with 20% sodium hydroxide and the isoamylamine was extracted three times with equal portions of ether. The isoamylamine was then reacted with phenylisothiocyanate to form isoamylphenylthiourea (21).

Radioactive Assay—The method employed for the preparation of samples for scintillation counting was described previously (17, 18). The aberrant products were recrystallized to constant specific activity, and the single derivative of each product was also counted as a check of the radiopurity. The two degradation products were assayed to localize the label. The barium carbonate (0.5 mg.) was assayed as a suspension in scintillation fluid containing a thixotropic gel[4] (5 g./1000 ml. of scintillation cocktail). All samples were counted in a liquid scintillation system[5] at a preset 2σ statistical counting error of 1%. The external standard ratio method was used to determine losses due to quenching. All counts were corrected for counter efficiency.

RESULTS AND DISCUSSION

The data obtained from the *in vivo* studies on the production of aberrant alkaloids are summarized in Tables II–IV. They indicate that isocaproic acid and 4(5)-aminomethylimidazole can serve as precursors of aberrant alkaloids in *D. sphaerica*. The data also show that isobutyric acid, benzoic acid, and N-isopropylhistamine do not serve as precursors of their corresponding dolichotheline analogs.

When III obtained from plants injected with isocaproic acid-1-^{14}C was hydrolyzed, the activity resided in the isocaproate portion of the molecule. Decarboxylation by the Schmidt reaction provided carbonate which contained greater than 98% of the activity present in the sodium isocaproate. The remaining isoamylamine, isolated as isoamylphenylthiourea, was essentially inactive.

The plants injected with 4(5)-aminomethylimidazole (ring-2-^{14}C) yielded VI which, when benzoylated, yielded nearly inactive 1,2-dibenzoylamino-3-isovalerylaminopropene-1. This degradation demonstrated that greater than 98% of the activity resided in the expected position.

Calculations of percent injected activity recovered as dolichotheline analog are based on the 500 mg. of the analog added as carrier. Since the actual amount of analog formed is less than 1 mg., the error made in calculating percent incorporation based on a total yield of 500 mg. is very small.

Of the five unnatural precursors tested, only two, isocaproic acid and 4(5)-aminomethylimidazole, were incorporated into unnatural or aberrant alkaloids. With respect to the specificity of the enzymes involved, it appears that the activating enzyme(s) is capable of activating isocaproic acid, the higher homolog of isovaleric acid, to isocaproyl-CoA. In addition, the condensing enzyme can utilize the isocaproyl-CoA as a substrate and bind it to histamine in amide linkage. Furthermore, this condensing enzyme can form an amide bond between isovaleryl-CoA and a compound with an aminomethyl side chain at the 4(5)-position of the imidazole nucleus in addition to an aminoethyl side chain.

The differences in the incorporation (0.81% in III and 1.27% in VI) are reasonable because 4(5)-aminomethylimidazole occupies a more proximal position to the final biosynthetic step than isocaproic acid, which must first be activated to isocaproyl-CoA. However, the differences may also be due to differences in *in vivo* metabolism of the two precursors, although such metabolic differences are probably of little significance in this case.

The positive result obtained from the isocaproic acid experiment makes it seem surprising that isobutyric acid was not utilized as a precursor of its corresponding dolichotheline analog. This failure may be attributed to the specificity of the enzymes involved. However, a more plausible explanation is that isobutyric acid was activated to isobutyryl-CoA, a naturally occurring intermediate in the catabolism of valine (22), and then was further metabolized along the normal pathway for valine degradation,

In the animal body, benzoic acid is activated to benzoyl-CoA, which is then condensed with glycine to form hippuric acid (23–25). These reactions may be analogous to the activation of isovaleric acid to isovaleryl-CoA and the subsequent condensation of the latter with histamine. It was reasonable to assume that the benzoic acid injected into *D. sphaerica* would result in the benzoylation of

Table IV—Compound VI Obtained from 4(5)-Aminomethylimidazole-2-^{14}C(ring)-Injected Plants

Compound	Yield, mg.	Melting Point	Reference Melting Point	Mixed Melting Point	Specific Activity, d.p.m./mM
VI (crude)	113	115–116°	117°	—	7.72×10^5
VI recrystallized one time	91	116–117°	117°	—	7.70×10^5
VI recrystallized two times	60	116–117°	117°	116–117°	7.79×10^5
VI picrate	15	170–171°	170°	170–171°	7.73×10^5
1,2-Dibenzoylamino-3-isovalerylamino-propene-1	21	204–205°	205°	204–205°	0.10×10^5

histamine. This expected formation of IV did not take place, possibly because of enzyme specificity and/or *in vivo* metabolism of the benzoic acid.

The remaining unnatural precursor, *N*-isopropylhistamine, also did not yield the expected dolichotheline analog. Perhaps the specificity of the condensing enzyme is such that it requires a primary amine rather than a secondary amine to be present in the histamine side chain in order to form the amide linkage.

These investigations with unnatural precursors are attempts to prepare aberrant dolichotheline analogs in the hope that these model techniques can be applied in the preparation of analogs of biologically active natural products that are difficult to synthesize. Furthermore, this work is an *in vivo* approach to the study of the specificity of the enzyme system that catalyzes the condensation of isovaleric acid and histamine. In this respect, the present experiments not only show that this enzyme system is not completely specific but also partially defines the specificity. Finally, the experiments provide additional support for the hypothesized final step in the biosynthesis of dolichotheline.

Cactus Alkaloids XV: β-Phenethylamine Derivatives from *Coryphantha macromeris* var. *runyonii*

W. J. KELLER, J. L. McLAUGHLIN*, and L. R. BRADY▲

Abstract □ Eleven β-phenethylamine derivatives were isolated and identified from fresh-frozen specimens of *Coryphantha macromeris* var. *runyonii* (Br. and R.) L. Benson. Isolations were accomplished using preparative TLC, and identifications were based on chromatographic properties, IR and NMR spectra, and comparisons with authentic materials. The data provide initial documentation for: the occurrence of *N*-formylnormacromerine in nature; the first recorded detection of metanephrine and *N*-methylmetanephrine in the plant kingdom; the first occurrence of synephrine and *N*-methyltyramine in this cactus; confirmation of earlier GLC–mass spectral data on the presence of *N*-methyl-4-methoxy-β-phenethylamine, *N*-methyl-3,4-dimethoxy-β-phenethylamine, tyramine, and hordenine in the plant; and verification of previous reports on the isolation of macromerine and normacromerine.

Keyphrases □ Cactus alkaloids—isolation, identification of 11 β-phenethylamine derivatives from *Coryphantha macromeris* var. *runyonii* □ *Coryphantha macromeris* var. *runyonii*—isolation and identification of 11 β-phenethylamine derivatives □ *N*-Formylnormacromerine—isolation, identification from *Coryphantha macromeris* □ Metanephrine and *N*-methylmetanephrine—isolation, identification from *Coryphantha macromeris* □ Synephrine—isolation, identification from *Coryphantha macromeris* □ *N*-Methyltyramine—isolation, identification from *Coryphantha macromeris*

Dona Ana [*Coryphantha macromeris* (Engelm.) Br. and R.] is currently being promoted as a "natural and legal" psychedelic agent (1). The hallucinogenic alkaloid, (−)-macromerine (*N*,*N*-dimethyl-3,4-dimethoxy-β-hydroxy-β-phenethylamine), has been isolated from the cactus (2), and *C. runyonii* Br. and R., which is considered currently to be a variety of the former species (3), yielded the same compound (4). *N*-Methyl-4-methoxy-β-phenethylamine, *N*-methyl-3,4-dimethoxy-β-phenethylamine, tyramine, and hordenine (*N*,*N*-dimethyltyramine) were detected as minor alkaloids of *C. macromeris* var. *runyonii* (Br. and R.) L. Benson by combining GLC with mass spectrometry (5, 6). Recently, (−)-normacromerine (*N*-demethylmacromerine) was observed to be a major nonphenolic alkaloid of this variety (7).

The present phytochemical studies of *C. macromeris* var. *runyonii* were undertaken to isolate and confirm the identities of previously detected alkaloids and to continue an examination of the alkaloid fraction of this cactus.

EXPERIMENTAL[1]

Plant Material—Living specimens of *C. macromeris* var. *runyonii*[2] were purchased from two commercial sources[3]. A portion of each shipment was frozen immediately upon receipt, and the remainder was oven dried at 48° and ground to a coarse powder.

Isolation of Crude Alkaloid Fractions—Fresh-frozen plant material (2.54 kg.) was diced and homogenized with 95% ethanol in a large blender[4]. The extraction was carried out before any appreciable thawing had occurred, thereby effectively chilling the extraction mixture. The filtered ethanolic extract was concentrated to approximately one-fourth volume under reduced pressure at 45°. This aqueous solution was acidified by addition of 600 ml. of 25% acetic acid and was extracted with two successive 500-ml. portions each of ether, ethyl acetate, and chloroform to remove the nonpolar, nonalkaloidal material. The resulting aqueous solution was rendered basic with 28% ammonium hydroxide, and the alkaloids were extracted successively with three 500-ml. volumes of chloroform and one 500-ml. volume of ether. Then the combined chloroform–ether extract was filtered through anhydrous sodium sulfate and concentrated to a syrup; this crude alkaloidal mixture was resolved into phenolic and nonphenolic fractions, using an ion-exchange resin as previously described (8).

TLC—A 0.25-mm. layer of silica gel GF_{254} was used for the analytical TLC plates, and the preparative TLC plates were prepared with a 1-mm. layer of silica gel PF_{254}[5]. Five solvent systems were used for the various analytical and preparative separations: A, benzene–chloroform–methanol–28% ammonium hydroxide (8:6:5:1); B, ether–methanol–28% ammonium hydroxide (20:2:1); C, chloroform–*n*-butanol–methanol–28% ammonium hydroxide (145:3:42:10); D, ether–acetone–methanol–28% ammonium hydroxide (9:8:2:1); and E, ethyl acetate–methanol–28% ammonium hydroxide (17:2:1). Alkaloids on the chromatograms were detected under shortwave UV light followed by use of dansyl chloride (0.05% in acetone) and tetrazotized benzidine spray reagents (8).

Synthesis of Reference Nonphenolic Alkaloids—Established synthetic procedures were used to produce racemic macromerine (2) and normacromerine (7). Reference *N*-methyl-3,4-dimethoxy-β-phenethylamine was synthesized by refluxing equimolar quantities of 3,4-dimethoxyphenethylamine[6] and ethyl formate[7] to give an *N*-formyl intermediate, which was subsequently reduced with lithium aluminum hydride to yield the desired product. After purification by preparative TLC with Solvent A, the product was converted to the hydrochloride and then recrystallized from absolute ethanol–ether (49% yield). A similar procedure was employed for the production of reference *N*-methyl-4-methoxy-β-phenethylamine hydrochloride (46% yield), using 4-methoxyphenethylamine[8] as the reactant.

Resolution of Nonphenolic Alkaloids—Analytical TLC using Solvents A, B, and E revealed the presence in this fraction of seven alkaloid-positive substances, two of which were present only in trace amounts. The alkaloid mixture was dissolved in ethanol–chloroform (1:1) and streaked onto 78 preparative TLC plates using

[1] UV spectra were determined in absolute methanol with a Beckman DB spectrophotometer scanning from 340 to 200 nm. IR spectra were obtained neat or using KBr pellets with a Beckman IR5A. NMR spectra were recorded on a Varian T-60 NMR spectrometer using $CDCl_3$ or D_2O solutions. Specific rotations were determined with a Rudolph polarimeter using a sodium lamp and a 2-dcm. tube. Melting points were taken with a Fisher-Johns melting-point apparatus and are uncorrected.

[2] Identification was confirmed by Dr. E. F. Anderson, Department of Biology, Whitman College, Walla Walla, WA 99362. Representative plants are being maintained as greenhouse specimens.

a previously described technique (9). The alkaloid material was eluted from the silica gel scrapings with three portions of 95% ethanol; the extracts were filtered, combined, and concentrated to near dryness under reduced pressure. The residue in each case was taken up in 40 ml. of 5% HCl, and the solution was rendered distinctly alkaline with 28% ammonium hydroxide and extracted immediately with three 50-ml. portions of chloroform. The chloroform extracts were filtered through sodium sulfate, combined, and reduced to a 5-ml. volume with a rotary evaporator. At this point, each alkaloidal solution was monitored for indication of impurities using TLC, the chloroform was evaporated from the solutions under a stream of nitrogen, and the residues were dissolved in 5 ml. of 95% ethanol and stored under nitrogen in a freezer.

This initial resolution of the nonphenolic alkaloid fraction resulted in two chromatographically pure alkaloids and a ternary mixture. Cochromatography with reference materials suggested that the pure alkaloids were (−)-normacromerine and (−)-macromerine and that the ternary mixture consisted of *N*-methyl-4-methoxy-β-phenethylamine, *N*-methyl-3,4-dimethoxy-β-phenethylamine, and an unidentified compound.

Resolution of Ternary Nonphenolic Mixture—An equal volume of chloroform was added to the ethanolic solution of the ternary alkaloid mixture, and the material was streaked onto 44 preparative TLC plates. Solvent B resolved the mixture into three components, which were removed and processed as already described. The chromatographic evaluations revealed no impurities in the isolated constituents.

Identification of Known Nonphenolic Alkaloids—The ethanolic solutions of the isolated alkaloids were evaporated under a stream of nitrogen, the residues were taken up in 0.7 ml. of deuterochloroform[9], and the NMR spectra were recorded. Deuterium-exchange experiments were carried out in the cases of macromerine and normacromerine. The deuterochloroform solutions were then evaporated to dryness under nitrogen, the residues were dissolved in small volumes of absolute ethanol, the solutions were acidified with anhydrous hydrochloric acid in absolute ethanol (5% w/w), and anhydrous ether was added slowly to effect the crystallization of the hydrochloride salts. One recrystallization from absolute ethanol assured chemical purity. The yields of crystalline hydrochloride salts, the melting points, and the IR spectra (KBr pellet) were recorded. Various properties of the isolated alkaloids corresponded with those reported for normacromerine (7), macromerine (2, 4, 10), *N*-methyl-3,4-dimethoxy-β-phenethylamine (11, 12), and *N*-methyl-4-methoxy-β-phenethylamine (11). Identifications were confirmed by direct comparisons of corresponding IR and NMR spectra of the isolated constituents and synthetic reference compounds.

Characterization of Unknown Nonphenolic Alkaloid—The isolated material was a chromatographically homogeneous (Solvent A, R_f 0.70; Solvent B, R_f 0.42; Solvent E, R_f 0.47), golden-yellow oil which possessed some distinctive properties. The constituent failed to react or to give visible chromophores with the dansyl chloride and tetrazotized benzidine reagents, but it could be detected with Dragendorff's reagent. It also failed to form a crystalline hydrochloride salt. The UV spectrum (0.0066 mg./ml. absolute methanol) showed indication of a λ_{max} at 201 (ε 32,200) and peaks at 229 (ε 6100) and 278 (ε 1800) nm., absorption features indicative of a 3,4-dimethoxy-β-phenethylamine (12). The IR spectrum (neat) exhibited a broad hydroxyl band near 3333 $cm.^{-1}$ and an intense carbonyl stretching vibration at 1642 $cm.^{-1}$. The remainder of the IR spectrum was typical for a phenethylamine derivative. An interpretation of the NMR spectrum (deuterochloroform) was quite informative regarding the structure of the unknown alkaloid. A skewed pair of singlets at 7.95 δ integrating for one proton was attributed to an *N*-formyl proton, peaks at 6.99 and 6.91 δ were indicative of three aromatic protons, and a coalescent doublet centered at 3.88 δ indicated two methoxyl groups. A benzylic hydroxyl proton (4.2 δ) exhibited shifts with concentration differences and disappeared with deuterium exchange. Complex multiplets centered at 4.8 and 3.4 δ indicated a benzylic proton and a methylene group, respectively, while a three-proton singlet at 2.9 δ characterized an *N*-methyl group. On the basis of these data, it appeared that the new alkaloid was the *N*-formyl analog of normacromerine. Synthetic normacromerine was refluxed with an equimolar quantity of ethyl formate to obtain a reference sample of *N*-formylnormacromerine. Comparison of the isolated and synthetic materials revealed indistinguishable UV, IR, and NMR spectra and chromatographic properties.

Resolution of Phenolic Alkaloids—Five major constituents and traces of three other compounds were detected using analytical TLC with Solvents C and D. The phenolic alkaloid fraction was dissolved in an ethanol–chloroform (1:1) mixture and streaked onto 38 preparative TLC plates. After development with Solvent C, the individual plates and resulting silica gel scrapings were processed in the same manner described for the nonphenolic fraction. This separation process resulted in four fractions, three of which were chromatographically pure; the fourth fraction was a binary mixture. Chromatographic comparisons[10] indicated that the pure alkaloids were synephrine, metanephrine, and hordenine and that the binary mixture contained tyramine and *N*-methyltyramine.

Resolution of Binary Phenolic Mixture—The binary fraction was dissolved in a suitable volume of ethanol–chloroform (1:1) and streaked onto nine preparative TLC plates. The plates were developed with Solvent D, and the two desired bands were processed in the usual manner.

Identification of Phenolic Constituents—Characterization of the five isolated constituents proceeded essentially as described for the nonphenolic alkaloids. The observed melting points and IR spectra of the hydrochloride salts corresponding to hordenine and *N*-methyltyramine agreed with reported properties for these substances (8, 12–14). Identifications were confirmed by direct comparisons of IR and NMR spectra of the isolated and reference materials.

The melting points and the IR spectra of the salts from the fractions chromatographically identified as metanephrine, synephrine, and tyramine were consistent with anticipated and reported properties for the corresponding salts (14–16), and no distinctive features were noted upon direct comparisons of the IR spectra of isolated and reference compounds. The small quantities of these three constituents obtained from the cactus (Table I) were insufficient for the determination of NMR spectra. Since tyramine had been detected previously in the plant (5), the chromatographic, melting-point, and IR spectral data were considered adequate to confirm the identity of this constituent. However, NMR spectra or some additional evidence appeared desirable with the other two compounds since the occurrence of metanephrine in the plant kingdom was unknown, since the presence of synephrine in this cactus was unrecorded, and since the IR spectra of the racemate and levorotatory isomer of synephrine were known to exhibit some differences (16).

Preliminary experiments with oven-dried cactus material indicated that the integrity and concentration of both metanephrine and synephrine were unaltered, even though the heat-drying process appeared to produce some artifacts. Thus, an available supply of dried cactus was processed to obtain sufficient quantities of metanephrine and synephrine for further characterization. The coarsely powdered plant material (1.55 kg.) was extracted exhaustively with methanol in a large blender, and the methanolic solution was removed by filtration. The thick syrup, which was obtained upon removal of the methanol under reduced pressure, was acidified with 700 ml. of 5% HCl and filtered. The acidic solution was extracted twice with approximately 700-ml. volumes of a series of organic solvents (petroleum ether, ether, ethyl acetate, and chloroform). This aqueous solution was then adjusted to pH 10.5 (pH meter) with 7.5 *N* NaOH and again subjected to partitioning with the series of organic solvents. The resulting aqueous solution, which contained relatively water-soluble constituents including metanephrine and synephrine, was placed under reduced pressure in a rotary evaporator to remove traces of the organic solvents and was freeze dried. The residue from lyophilization was extracted several times with an ethanol–chloroform (1:9) mixture, and the combined extract was concentrated to a small volume under reduced pressure and examined chromatographically. The concentrated extract, which contained a number of nonalkaloidal substances, was subjected to ion-exchange chromatography[11] and an established method (8) to give an aqueous phenolic fraction rich in metanephrine and synephrine with only traces of other phenolic alkaloids and contaminants. This

[9] Tetramethylsilane from Stohler Isotope Chemicals was used as the internal standard.

[10] Sources of reference phenolic alkaloids: hordenine sulfate and tyramine hydrochloride, Nutritional Biochemicals Corp.; *N*-methyltyramine hydrobromide, courtesy of Hoffmann-La Roche, Inc.; synephrine tartrate, K & K Laboratories, Inc.; and metanephrine hydrochloride, Sigma Chemical Co.

[11] Using Amberlite IRA-401S C.P., Mallinckrodt Chemical Works.

phenolic fraction, dissolved in a small volume of equal parts of ethanol and chloroform, was streaked onto 48 preparative TLC plates. Solvent C was used to achieve separation, and processing of the desired bands gave chromatographically homogeneous, ethanolic extracts of the two phenolic alkaloids.

The ethanolic extract containing synephrine was evaporated to dryness under nitrogen. A portion of the residue was taken up in 4 ml. of absolute methanol, the solution was heated to boiling, and 12 mg. of dry oxalic acid was added. Crystals of synephrine oxalate formed upon cooling, and recrystallization from aqueous methanol gave 13 mg. of material, m.p. 223–224° dec. [lit. (16) m.p. 221–222° dec.]. The remaining portion of the isolated alkaloid was dissolved in a minimum volume of absolute ethanol and converted to the hydrochloride salt; one recrystallization gave a yield of 33 mg., m.p. 166–167°. A portion of the hydrochloride salt (13 mg.) was placed in an NMR tube, 0.7 ml. of D_2O and a small quantity of an internal standard (sodium 2,2-dimethyl-2-silapentane-5-sulfonate[12]) were added, and the NMR spectrum was recorded. The number of exchangeable protons was determined by the integration difference of the sample and a D_2O–internal standard blank of comparable volume run at the same spectrum and integral amplitudes. The observed NMR spectrum of the salt of the isolated alkaloid followed a predictable chemical-shift pattern and proved to be identical to the spectrum obtained with reference material. The hydrochloride salt of the isolated synephrine was levorotatory: $[\alpha]_D^{27}$ −52.5° (c 0.010 g./ml. in absolute methanol).

The ethanolic extract of the isolated metanephrine was evaporated to dryness under nitrogen, and the entire residue was converted to the hydrochloride salt. One recrystallization from absolute ethanol–ether gave 9 mg. of crystalline material, m.p. 158–159°. The NMR spectral studies were carried out with the hydrochloride in D_2O solution as described for synephrine. The predicted NMR spectrum and an excellent NMR spectral correlation between the isolated and reference compounds provided the desired evidence to confirm the presence of metanephrine in the plant extracts. The small quantity of isolated material did not permit determination of optical rotation.

DISCUSSION AND CONCLUSIONS

Five nonphenolic and five phenolic β-phenethylamine derivatives were isolated and identified from *C. macromeris* var. *runyonii* (Table I). Trace quantities of two nonphenolic and three phenolic constituents[13] were also detected, but the minimal amounts of these substances in the quantity of cactus employed in the investigation precluded their purification and characterization. The use of a cold extraction process and fresh-frozen plant material, except for certain studies on metanephrine and synephrine, circumvented the possibility of artifact formation during slow thermal drying. Thus, the 10 isolated compounds, as well as the five unidentified alkaloid-positive substances which were detected, were considered to be metabolic constituents of the cactus.

Identifications of the 10 isolated constituents were based on chromatographic properties, melting points of salts, IR and NMR spectra, and direct comparisons with reference materials. The only exceptions to this protocol involved *N*-formylnormacromerine, which did not form a salt, and the omission of NMR data for tyramine.

N-Formylnormacromerine, metanephrine, and synephrine were the most interesting of the isolated constituents. The natural occurrence of *N*-formylnormacromerine was previously unrecognized. Alkaloids with amide functions are uncommon, and within the Cactaceae, only peyote [*Lophophora williamsii* (Lem.) Coult.] had been shown to possess *N*-formyl derivatives (17). The presence of metanephrine in a biological system was initially demonstrated by Axelrod *et al.* (18), and various chemical and physiological parameters of this metabolite of epinephrine have been studied (19, 20). However, all prior reports directly or indirectly restrict the known occurrence of metanephrine to zoological entities. The natural occurrence of synephrine was first reported from tangerine leaves (16), and until recently it was restricted to the Rutaceae. The known distribution of synephrine has been expanded by its reported presence in genera from the Amaryllidaceae and Moraceae (21), its detection in seven species of coryphantha (22), and its isolation from *C. ramillosa* (15). Identification of synephrine as a constituent of *C. macromeris* var. *runyonii* provides a further expansion of knowledge on the occurrence of this sympathomimetic compound.

The data provided the first evidence for the occurrence of *N*-methyltyramine in *C. macromeris* var. *runyonii;* however, this constituent was known to be distributed widely in the Cactaceae (5, 8, 12–14, 22) and had been detected in other plant families (21). The isolation of hordenine, *N*-methyl-3,4-dimethoxy-β-phenethylamine, *N*-methyl-4-methoxy-β-phenethylamine, and tyramine confirmed earlier GLC–mass spectral data (5, 6) on the presence of these constituents in this cactus. The identification of macromerine and normacromerine from the plant verified previous reports (2, 4, 7).

Macromerine (2), synephrine (23), and the less potent constituents (19, 23–25), hordenine, metanephrine, *N*-methyltyramine, and tyramine, are known to possess sympathomimetic properties. The occurrence of these constituents in the cactus may provide a scientific basis for the purported use of Dona Ana as a CNS stimulant.

Table I—Quantities of β-Phenethylamine Constituents Isolated from Fresh-Frozen *C. macromeris* var. *runyonii*

	Yield[a], g.	Concentration in Cactus[b], %
Nonphenolic constituents:		
Normacromerine hydrochloride	2.133	0.0710
N-Formylnormacromerine (oil)	0.195	0.0077
Macromerine hydrochloride	0.062	0.0021
N-Methyl-3,4-dimethoxy-β-phenylamine hydrochloride	0.019	0.0006
N-Methyl-4-methoxy-β-phenethylamine hydrochloride	0.014	0.0005
Phenolic constituents:		
N-Methyltyramine hydrochloride	0.059	0.0019
Hordenine hydrochloride	0.012	0.0004
Metanephrine hydrochloride	0.006	0.0002
Synephrine hydrochloride	0.003	0.0001
Tyramine hydrochloride	0.002	0.0001

[a] Reported yields represent the total quantities of the constituents or their salts, as indicated, obtained upon processing 2.54 kg. of fresh-frozen plant material. [b] Calculated as free β-phenethylamine in fresh plant material.

[13] *Note added in proof:* Further observations have provided tentative identification of one of the trace phenolic alkaloids as *N*-methylmetanephrine. The synthesis of reference *N*-methylmetanephrine involved condensation of *O*-acetylvanillin and nitromethane, catalytic reductive methylation with hydrogen and formaldehyde, hydrolysis, and purification by preparative TLC with Solvent C. A six-proton *N*-methyl peak, rather than a three-proton peak, was the only significant NMR spectral difference between the synthetic product and reference metanephrine. The synthetic *N*-methylmetanephrine and one of the bands isolated (yield approximately 1 mg.) during preparative TLC of the phenolic alkaloid fraction were indistinguishable with TLC Solvents A and C, and both the synthetic and isolated materials were extremely labile. This chromatographic detection provides the first evidence for the occurrence of *N*-methylmetanephrine in the plant kingdom.

Cactus Alkaloids XVI: Isolation and Identification of Alkaloids in *Coryphantha ramillosa*

P. T. SATO, J. M. NEAL, L. R. BRADY, and J. L. McLAUGHLIN▲

Abstract □ The cactus genus *Coryphantha* has been reported to contain certain β-phenethylamine alkaloids. In this investigation, a Texas species, *C. ramillosa* Cutak, yielded five alkaloids which were isolated chromatographically and crystallized as their hydrochloride salts. The isolated compounds were identified as *N*-methyl-4-methoxy-β-phenethylamine hydrochloride, hordenine hydrochloride, *N*-methyltyramine hydrochloride, synephrine hydrochloride, and β-*O*-methylsynephrine hydrochloride, all of which have been previously identified in other *Coryphantha* species.

Keyphrases □ Cactus alkaloids—isolation, identification of alkaloids in *Coryphantha ramillosa* □ *Coryphantha ramillosa*—isolation, identification of alkaloidal content □ Medicinal plants—isolation, identification of alkaloids in *Coryphantha ramillosa* □ TLC—isolation, identification, alkaloids in *Coryphantha ramillosa*

Folk medicine of various peoples of the world has, of necessity, included many different plant drugs (1). One such product is the peyote cactus, which is still used as an amulet, hallucinogen, and panacea by the Indians of Mexico and the southwestern United States (2, 3). Phytochemical investigations of the peyote cactus, or *Lophophora williamsii* (Lem.) Coult., have shown the presence of mescaline, mescaline analogs (β-phenethylamines), tetrahydroisoquinolines, and other compounds, the presence of which explains some of the claimed effects of this plant (4–6). The hallucinogen, mescaline, has also been found in some other cactus species, especially in members of the South American genus trichocereus (7–9).

Knowledge of the alkaloid content of various cacti is significant since it can help to explain or disprove the claimed physiological effects of a particular species. Unfortunately, knowledge of the phytochemical distribution of even the various known cactus alkaloids is quite incomplete. The genus *Coryphantha* is a good example. This genus contains approximately 60 species (10, 11). *C. palmeri* Br. and R. has been reported to have folkloric use as a "narcotic" (12), and *C. macromeris* (Engelm.) Br. and R. has ostensibly obtained some stature as a "natural and legal" psychedelic (13). The presence of macromerine and normacromerine in this latter species may explain these reputed effects (14). The screening of seven species of *Coryphantha* previously demonstrated the presence of alkaloids in all seven, and six β-phenethylamines have been isolated and/or identified in *C. cornifera* (DC.) Br. and R. var. *echinus* (Engelm.) L. Benson (15). No information is available in the literature regarding the phytochemistry of *C. ramillosa* Cutak, a species from southern Texas and north-central Mexico. Although it has no recorded folkloric uses, it was selected for study in a search for unusual cactus alkaloids that might have psychotropic potential.

Cactus Alkaloids XVI: Isolation and Identification of Alkaloids in *Coryphantha ramillosa*

P. T. SATO, J. M. NEAL, L. R. BRADY, and J. L. McLAUGHLIN▲

Abstract □ The cactus genus *Coryphantha* has been reported to contain certain β-phenethylamine alkaloids. In this investigation, a Texas species, *C. ramillosa* Cutak, yielded five alkaloids which were isolated chromatographically and crystallized as their hydrochloride salts. The isolated compounds were identified as *N*-methyl-4-methoxy-β-phenethylamine hydrochloride, hordenine hydrochloride, *N*-methyltyramine hydrochloride, synephrine hydrochloride, and β-*O*-methylsynephrine hydrochloride, all of which have been previously identified in other *Coryphantha* species.

Keyphrases □ Cactus alkaloids—isolation, identification of alkaloids in *Coryphantha ramillosa* □ *Coryphantha ramillosa*—isolation, identification of alkaloidal content □ Medicinal plants—isolation, identification of alkaloids in *Coryphantha ramillosa* □ TLC—isolation, identification, alkaloids in *Coryphantha ramillosa*

Folk medicine of various peoples of the world has, of necessity, included many different plant drugs (1). One such product is the peyote cactus, which is still used as an amulet, hallucinogen, and panacea by the Indians of Mexico and the southwestern United States (2, 3). Phytochemical investigations of the peyote cactus, or *Lophophora williamsii* (Lem.) Coult., have shown the presence of mescaline, mescaline analogs (β-phenethylamines), tetrahydroisoquinolines, and other compounds, the presence of which explains some of the claimed effects of this plant (4–6). The hallucinogen, mescaline, has also been found in some other cactus species, especially in members of the South American genus trichocereus (7–9).

Knowledge of the alkaloid content of various cacti is significant since it can help to explain or disprove the claimed physiological effects of a particular species. Unfortunately, knowledge of the phytochemical distribution of even the various known cactus alkaloids is quite incomplete. The genus *Coryphantha* is a good example. This genus contains approximately 60 species (10, 11). *C. palmeri* Br. and R. has been reported to have folkloric use as a "narcotic" (12), and *C. macromeris* (Engelm.) Br. and R. has ostensibly obtained some stature as a "natural and legal" psychedelic (13). The presence of macromerine and normacromerine in this latter species may explain these reputed effects (14). The screening of seven species of *Coryphantha* previously demonstrated the presence of alkaloids in all seven, and six β-phenethylamines have been isolated and/or identified in *C. cornifera* (DC.) Br. and R. var. *echinus* (Engelm.) L. Benson (15). No information is available in the literature regarding the phytochemistry of *C. ramillosa* Cutak, a species from southern Texas and north-central Mexico. Although it has no recorded folkloric uses, it was selected for study in a search for unusual cactus alkaloids that might have psychotropic potential.

EXPERIMENTAL

Plant Material—Specimens of the cactus were purchased[1], and

[1] From Homer A. Jones, Southwest Cactus Co., Alpine, Tex.

identification of the plants was made by comparison with the description of Benson (16)[2].

The cacti were sliced and thoroughly dried in a forced air oven at 48° for several days. The dry weight of the plant material was 1.3 kg., representing a weight loss of 3.3 kg. (72% moisture). The dried plant material was then comminuted in a large Wiley mill to obtain a coarse powder.

Preparation of Crude Alkaloid Fractions—The powdered plant material was defatted, basified, and extracted *via* chloroformic percolation as previously described (17, 18). Condensing the filtered chloroform extract produced a thick syrup, which was extracted with two successive 250-ml. portions of 1 *N* HCl; emulsions were treated essentially as was previously reported (19). After filtration, the aqueous solutions were combined and extracted with two successive 500-ml. volumes each of chloroform and ethyl ether to remove organic-soluble, nonalkaloidal material. The pH of the aqueous solution was then adjusted to 10.5 (pH meter) with 7.5 *N* sodium hydroxide, and alkaloids were extracted from the basic aqueous solution with three successive 500-ml. volumes each of chloroform and ethyl ether. These organic extracts were dried over anhydrous sodium sulfate, filtered, combined, and condensed under rotary vacuum to yield a residue (crude alkaloid Fraction A).

In previous studies it had been observed that the organic-extracted, basic, aqueous solution would still retain some water-soluble β-phenethylamines such as tyramine (19). Consequently, this solution was placed under rotary vacuum to remove traces of organic solvents and was then freeze dried. The residue from the lyophilization, largely sodium chloride, was extracted repeatedly with portions of an absolute ethanol–chloroform (1:9) mixture until the filtrates appeared colorless. The combined filtrates were then condensed under rotary vacuum to a small volume (crude alkaloid Fraction B).

Crude alkaloid Fraction A was separated into phenolic and nonphenolic portions by using an anion-exchange resin. The alkaloid fraction, dissolved in ethanol, was passed down a basic ion-exchange[3] column, and the phenolic and nonphenolic portions were obtained as previously described (17).

TLC—Previously described TLC techniques were used analytically to provide a tentative identification of alkaloids in the extracts and preparatively to separate the components (15, 17, 18, 20). Analytical TLC plates were prepared with a 0.25-mm. layer of silica gel G, and preparative plates were prepared with a 1-mm. layer of silica gel PF_{254}[4]. Analytical and preparative separations were achieved by the use of the following solvent systems: Solvent A, ethyl ether–methanol–28% ammonium hydroxide (20:2:1); Solvent B, ethyl ether–methanol–28% ammonium hydroxide (17:2:1); and Solvent C, chloroform–methanol–28% ammonium hydroxide (80:20:1). Solvent D, ethyl acetate–methanol–28% ammonium hydroxide (17:2:1), and Solvent E, benzene–chloroform–methanol–28% ammonium hydroxide (8:6:2:1), were used analytically only. The alkaloids were detected using dansyl chloride (0.05% in acetone) and tetrazotized benzidine spray reagents (17). The R_f values are not reported since routine chromatography with reference compounds provided a superior type of presumptive identification.

Resolution of Nonphenolic Alkaloids from Fraction A—Analytical TLC revealed that this fraction contained a single predominant alkaloid with only traces of other compounds. The entire extract, dissolved in ethanol, was streaked as a narrow band (21) onto five preparative TLC plates and developed with Solvent A. The compound was readily detected under UV light, and the appropriate bands were removed. The alkaloid was leached from the combined bands of the five plates by washing with 5 ml. of ammoniacal ethanol (28% ammonium hydroxide–ethanol, 1:19), centrifuging, and rewashing the adsorbent with two additional 5-ml. portions of the basic ethanol.

After filtration, the combined washings were reduced to near dryness under rotary vacuum. The residue was redissolved in a small amount of absolute ethanol. Analytical TLC indicated that the alkaloid was chromatographically pure. The solution was then acidified (moist pH paper) with anhydrous hydrochloric acid in absolute ethanol (5% w/w). Ethyl ether was slowly added and the solution was refrigerated to cause crystallization of the hydrochloride salt.

Identification of Major Nonphenolic Alkaloid—Analytical TLC in Solvents A, B, D, and E of the major nonphenolic alkaloid and comparison with reference compounds (15) suggested that the alkaloid was *N*-methyl-4-methoxy-β-phenethylamine. The melting points[5] and mixed melting point were identical to that of authentic *N*-methyl-4-methoxy-β-phenethylamine hydrochloride (182.5–184°). The IR spectra[6] of the isolated and synthesized compounds were essentially the same, with distinctive absorption peaks noted at 1600, 1510, 1475, and 1095 $cm.^{-1}$. An interpretation of the NMR spectrum[7] of the isolated material was also consistent with that expected and observed for *N*-methyl-4-methoxy-β-phenethylamine hydrochloride. A pair of doublets centered at 7.1 δ integrated for four protons (aromatic), a three-proton singlet was noted at 3.8 δ (*O*-methyl), a diffuse doublet integrating for four protons was centered at 3.1 δ (methylene), and a three-proton singlet was seen at 2.7 δ (*N*-methyl). The molecular ion (*m/e* 165) observed upon mass spectrometry[8] of the isolated material was in agreement with the molecular weight of the proposed structure.

Resolution of Phenolic Alkaloids from Fraction A—Analytical TLC of this fraction revealed the presence of four major alkaloids. The extract was streaked as a narrow band onto eight preparative TLC plates. The first plate was developed once with Solvent B, and the remaining seven plates were developed twice with Solvent B, allowing a 15-min. interval of air drying between developments. Visualization under UV light allowed the detection of four major bands, which were removed and eluted with ammoniacal ethanol as already described. The residues of each of the four bands were dissolved in an amount of absolute ethanol suitable for analytical TLC.

Resolution of Alkaloids from Fraction B—Analytical TLC of this fraction indicated that it contained the same major alkaloids as observed in the phenolic portion of crude alkaloid Fraction A. This observation suggested the possibility of obtaining these phenolic alkaloids without passing the fraction through the anion-exchange column.

Upon storage of this concentrated fraction in ethanol and under refrigeration, abundant crystallization occurred. The crystals were filtered, rinsed twice with cold ethanol, and recrystallized from boiling benzene. The crystals were then converted to the hydrochloride salt as already described.

Separation of the alkaloids in the combined mother liquors from the ethanol and benzene crystallizations was achieved by preparative TLC. This material was applied as a narrow band onto 42 preparative plates, which were developed twice with Solvent B. The four major bands (A, B, C, and D, lettering from the top of the plate downward) were recovered, and each was eluted with 30 ml. of the ammoniacal ethanol followed by two elutions of 30 ml. each of ethanol. The eluants for each band were filtered, combined, and concentrated to dryness under rotary vacuum.

Further analytical TLC (appropriate selection of Solvent B, C, D, or E) with portions of these residues and the residues from the four phenolic alkaloid bands of Fraction A, with 10-mcg. quantities of reference compounds, provided tentative identifications of the phenolic alkaloids. Slight contamination of band B was observed; to purify this band, further preparative TLC was employed with Solvent C. Crystalline hydrochloride salts of the four compounds were then prepared as previously described.

Identification of Major Phenolic Alkaloids—The four major phenolic alkaloids, purified from Fractions A and B, had the same chromatographic properties as hordenine, β-*O*-methylsynephrine, *N*-methyltyramine, and synephrine. Since the alkaloids from Fraction B and the phenolic portion of Fraction A were identical, studies for verification of identity were carried out only with the crystalline alkaloids obtained from the respective bands of Fraction B.

Cochromatography of authentic hordenine and the crystals that were obtained prior to preparative TLC of Fraction B showed that these two compounds were identical. Analytical TLC (Solvents B

[2] A freeze-dried specimen was sent to Dr. L. Benson, Director, Herbarium of Pomona College, Claremont, Calif., who confirmed the identification and assigned the specimen herbarium No. 317944. In addition, living plants are being maintained for future reference in the greenhouse of the Drug Plant Laboratory, University of Washington.

[4] Brinkmann Instruments, Inc.

[5] Fisher-Johns melting-point apparatus, uncorrected.

[6] KBr pellets, Beckman IR5A spectrophotometer.

[7] Varian T-60, using 10 mg. of the hydrochloride in tetradeuterated methanol in a microcell.

[8] Performed at Hoffmann-La Roche Laboratories.

and D) further confirmed that band A corresponded to these crystals. Melting points and mixed melting points of authentic hordenine hydrochloride and the hydrochloride of this alkaloid were identical (180.5–181.5°). The IR spectra of hordenine hydrochloride and the isolated compound were also comparable, with distinctive absorption peaks in both spectra noted at 1610, 1512, 1454, and 1348 cm.$^{-1}$.

Reference β-*O*-methylsynephrine and band B consistently cochromatographed (Solvents B and C); their IR spectra, both as the hydrochlorides, exhibited absorption peaks at 2800, 1610, 1512, 1355, 1265, and 1093 cm.$^{-1}$ and agreed in their characteristic features. Additional analytical TLC revealed the presence of a slight contaminant in the isolated crystals, which was assumed to explain three minor peaks present in the IR spectrum of only the isolated β-*O*-methylsynephrine hydrochloride. The melting point of the isolated material was 182–184°, and no melting-point depression was noted on admixture with synthetic (racemic) material. The isolated compound was optically inactive.

TLC of band C (Solvents B, C, and D) and reference *N*-methyltyramine revealed the same chromatographic properties, and melting points of the isolated *N*-methyltyramine hydrochloride and reference *N*-methyltyramine hydrochloride were identical (150–151°). The IR spectra of both compounds, as the hydrochloride salts, were also comparable, with major absorption peaks noted at 1635, 1555, 1530, 1368, 1232, and 1191 cm.$^{-1}$.

Cochromatography of synthetic (racemic) synephrine and the alkaloid from band D (Solvents B, D, and E) revealed indistinguishable chromatographic properties for the isolated and reference compounds. The major peaks of the IR spectra of the two as hydrochlorides were very similar, with matching adsorption peaks at 1610, 1512, and 1449 cm.$^{-1}$. As previously noted (22), the IR spectra of salts of (−)- and (±)-synephrine present generally comparable absorption patterns but with some differences. The melting point of the hydrochloride of the isolated material was 166–167°, in contrast to racemic synephrine hydrochloride which melted at 156–158°. The salt of the isolated alkaloid was optically active: $[\alpha]_D^{27}$ −52.0°, c 7.6 mg./ml. in absolute methanol.

Cold Extraction Process—To eliminate the possibilities that the alkaloids might have been enzymatically modified during the slow heat drying process, that some thermolabile alkaloids had been destroyed or altered, or that the small amount of basic methanol involved in the maceration and extraction process might have caused β-*O*-methylation of syneprine (23), a second cactus sample was examined using a cold extraction process (24) and freeze-dried plant material.

The freeze-dried plant (45.5 g.) was sliced and ground to a powder in a blender at low speed. Cold ethanol was added and the mixture was blended for 25 min. The extract was filtered with the aid of reduced pressure and concentrated to 50 ml. under rotary vacuum (water bath at 36°). About 50 ml. of 5% hydrochloric acid was added and the mixture was shaken vigorously. This acidic ethanolic solution was extracted twice with 50-ml. portions of chloroform and twice with 50-ml. portions of ethyl ether. The pH of the aqueous fraction was then adjusted to 9.5 (pH meter) with 28% ammonium hydroxide. This extract was then run through a basic anion-exchange column, in the manner previously described, to separate phenolic and nonphenolic portions.

Comparison by analytical TLC of the nonphenolic portion obtained from the two different extraction methods revealed the same alkaloid composition. Resolution of the cold-processed nonphenolic extract to the point of crystallization also yielded the same compound as the procedure involving heat.

Comparison of the cold-processed phenolic extract with the previous phenolic extract from Fraction A substantiated the presence of the same alkaloid components in the phenolic extracts prepared by the two procedures.

DISCUSSION AND CONCLUSIONS

Chromatographic procedures have yielded the isolation of one nonphenolic and four phenolic alkaloids from *C. ramillosa*. Using melting points, spectral properties, and chromatographic similarities in comparisons with authentic compounds, identification of the isolated alkaloids was achieved. The isolated nonphenolic alkaloid was established to be *N*-methyl-4-methoxy-β-phenethylamine, and the identified phenolic alkaloids were hordenine, β-*O*-methylsynephrine, *N*-methyltyramine, and synephrine.

Table I—Quantities of Alkaloids Isolated from Soxhlet-Extracted Sample of *C. ramillosa*

	Yield[a], g.	Proportion of Total Alkaloid Fraction, %	Concentration in Cactus[b], %
Hordenine hydrochloride	11.530	91.8	0.73
N-Methyltyramine hydrochloride	0.692	5.5	0.043
β-*O*-Methylsynephrine hydrochloride	0.241	1.9	0.015
Synephrine hydrochloride	0.090	0.7	0.0057
N-Methyl-4-methoxy-β-phenethylamine hydrochloride	0.015	0.1	0.00092

[a] Reported yields represent the total quantities of alkaloid salts obtained upon processing 1.3 kg. of dried plant material. Phenolic alkaloids were recovered from both Fractions A and B. [b] Calculated as free alkaloid base in dried plant material.

Evidence was also obtained that indicated that the isolated compounds, especially β-*O*-methylsynephrine which is believed to be formed by β-*O*-methylation of synephrine during the extraction of tangerine leaves (23), were not artifacts due to the drying and/or extraction processes. These possibilities were discounted when freeze-dried cactus material processed by a cold extraction procedure with ethanol yielded the same alkaloid composition as the initial extracts. Furthermore, no evidence for β-*O*-methylsynephrine formation was detected when reference synephrine was chromatographed with methanol-containing solvent systems. Presumably, the optical inactivity of the isolated β-*O*-methylsynephrine hydrochloride indicated the occurrence of racemization of the natural material during either natural methylation or extraction and purification.

Analytical TLC evaluation illustrated that the five isolated alkaloids were present in the cactus in concentrations several times those of some unidentified trace alkaloids. The compound identified as hordenine was the major alkaloid; it was present in concentrations greater than 10 times that of any other single alkaloid (Table I). Such a high concentration of hordenine has not been observed in any of our previous studies of the cactus alkaloids.

N-Methyl-4-methoxy-β-phenethylamine was isolated previously from *C. macromeris* (Engelm.) Br. and R. var. *runyonii* L. Benson (24), *Ariocarpus retusus* Scheid. (25), and *C. cornifera* (DC.) Br. and R. var. *echinus* (Engelm.) L. Benson (15). Thus far, the natural occurrence of this compound has only been reported in the Cactaceae. No pharmacological studies concerning any possible psychotropic effects of this compound have been reported.

Hordenine and *N*-methyltyramine were previously isolated from several cactus species as well as from other plant families (8, 15, 17–20, 24, 26 *inter alia*). Both are known to have weak sympathomimetic activity (27–29).

β-*O*-Methylsynephrine was isolated previously from the cactus *C. cornifera* var. *echinus* (15). No reported studies concerning its pharmacological activities were detected in the literature; however, a similar compound, β-*O*-methylepinephrine, produces CNS stimulation (30).

Traces of synephrine itself were detected previously in different coryphantha species, and it was isolated from *C. macromeris* var. *runyonii* (24) as well as from tangerine leaves (22). This compound is a known sympathomimetic (29).

The presence of these sympathomimetic β-phenethylamines in *C. ramillosa* confers physiological activity on the cactus and suggests that consumption of it (minus the abundant spines, of course) might cause some stimulant effects.

SUMMARY

This investigation provides the first reported study of the alkaloid content of the cactus *C. ramillosa*. The isolated and identified β-phenethylamine alkaloids included *N*-methyl-4-methoxy-β-phenethylamine, hordenine, β-*O*-methylsynephrine, *N*-methyltyramine, and synephrine.

Simplified NMR Spectra of Bifunctional Tropanes Induced by the Paramagnetic Shift Reagent Tris(dipivalomethanato)europium(III)

GARY S. CHAPPELL▲, BERNARD F. GRABOWSKI, ROBERT A. SANDMANN, and DAVID M. YOURTEE

Abstract □ Tris(dipivalomethanato)europium(III) has been used as an NMR shift reagent to obtain simplified spectra of tropine, pseudotropine, nortropine, nortropinone, and tropinone. All compounds gave spectra at 60 MHz., which could be interpreted with the aid of spin-spin decoupling. Insofar as the Karplus rule holds for the piperidine ring system, deshielded spectra clearly evidenced a distorted chair form predominating in the conformational equilibrium of α- and β-tropines and tropinones. The results demonstrate the applicability of the shift reagent used with bifunctional systems containing two different heteroatoms. The observed order of coordination was secondary amine > secondary alcohol > tertiary amine ≧ ketone.

Keyphrases □ Tropanes, bifunctional—simplified NMR spectra induced by tris(dipivalomethanato)europium(III) □ Tris(dipivalomethanato)europium(III)—used as NMR shift reagent to produce simplified spectra for bifunctional tropanes □ NMR spectroscopy—tris(dipivalomethanato)europium(III) shift reagent used to produce simplified bifunctional tropane spectra □ Paramagnetic shifts induced by tris(dipivalomethanato)europium(III)—simplified spectra of bifunctional tropanes

Tris(dipivalomethanato)europium(III) (I) has been the most extensively studied of the NMR shift reagents now available. This reagent produces paramagnetic shifts that remarkably simplify the NMR spectra of compounds containing heteroatoms for coordinative bonding with the reagent lanthanide.

Simplified NMR Spectra of Bifunctional Tropanes Induced by the Paramagnetic Shift Reagent Tris(dipivalomethanato)europium(III)

GARY S. CHAPPELL▲, BERNARD F. GRABOWSKI, ROBERT A. SANDMANN, and DAVID M. YOURTEE

Abstract □ Tris(dipivalomethanato)europium(III) has been used as an NMR shift reagent to obtain simplified spectra of tropine, pseudotropine, nortropine, nortropinone, and tropinone. All compounds gave spectra at 60 MHz., which could be interpreted with the aid of spin-spin decoupling. Insofar as the Karplus rule holds for the piperidine ring system, deshielded spectra clearly evidenced a distorted chair form predominating in the conformational equilibrium of α- and β-tropines and tropinones. The results demonstrate the applicability of the shift reagent used with bifunctional systems containing two different heteroatoms. The observed order of coordination was secondary amine > secondary alcohol > tertiary amine ≧ ketone.

Keyphrases □ Tropanes, bifunctional—simplified NMR spectra induced by tris(dipivalomethanato)europium(III) □ Tris(dipivalomethanato)europium(III)—used as NMR shift reagent to produce simplified spectra for bifunctional tropanes □ NMR spectroscopy—tris(dipivalomethanato)europium(III) shift reagent used to produce simplified bifunctional tropane spectra □ Paramagnetic shifts induced by tris(dipivalomethanato)europium(III)—simplified spectra of bifunctional tropanes

Tris(dipivalomethanato)europium(III) (I) has been the most extensively studied of the NMR shift reagents now available. This reagent produces paramagnetic shifts that remarkably simplify the NMR spectra of compounds containing heteroatoms for coordinative bonding with the reagent lanthanide.

The europium deshielded NMR represents a time-averaged spectrum between free substrate molecules

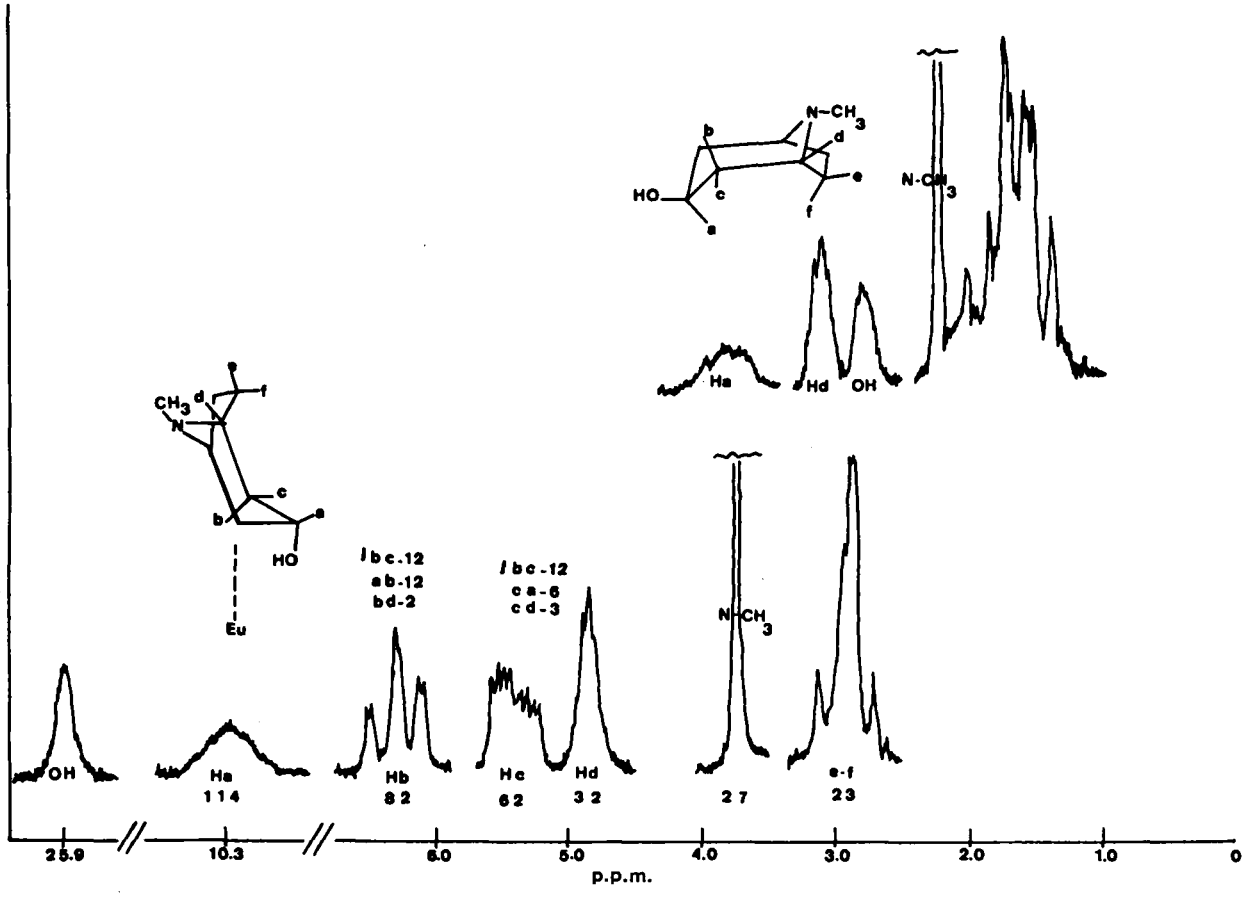

Figure 1—*Pseudotropine (II) at 60 MHz. in deuterochloroform. Key: top, without I treatment; and bottom, shifted spectra resulting at 0.35 mole ratio I/II. Numbers immediately below proton assignments represent the relative rates of proton shift between 0.2 and 0.8 mole ratio* ($\Delta\delta \times 10^1$). *The alignment with the europium complex and the conformation indicated in the molecular diagram are discussed in the text.*

and those associated with the shift reagent through lone-pair electrons. The paramagnetic shifts induced in complexes of europium appear to be the result of a predominately pseudocontact mechanism and do not appreciably broaden peaks or affect the spin-spin coupling constants as proton signals are shifted. The pseudocontact expression given in simplified form is:

$$\frac{\Delta H_i}{H_0} = \left(\frac{3\cos^2\chi_i - 1}{r_i^3}\right)K \qquad \text{(Eq. 1)}$$

where ΔH_i is the average shift defined as the difference in resonance position for the ith substrate proton in the paramagnetic complex and in the diamagnetic ligand. K is a constant incorporating in part the g tensor anisotropy and is a characteristic of the lanthanide under consideration. K is assumed to have the same value for all protons of a substrate molecule. χ_i is the angle between the ith proton and the principal axis, and r_i is the distance from the ith proton to the europium atom[1] (1-9).

Since pseudocontact shifting of NMR spectra offers a simple approach to stereochemical problems, it is useful to assess the effect of such reagents on a wide variety of compounds of biological activity. In conjunction with our interest in the preparation of centrally acting bicyclic amine derivatives (10), investigations were begun on the effect of europium complexes on this class of compounds. Previously, Ohashi *et al.* (11) investigated the effect of small upfield and downfield contact shifts on some tropanes. The current paper reports the effect of I on 3-hydroxy- and 3-ketotropanes (II–VI). This series is attractive in that it (*a*) offers the possibility of much needed simplification while it (*b*) tests the more practical utility of the shift reagent in resolving questions of stereochemistry when the substrate contains dissimilar heterobifunctionality with some conformational mobility present.

The 60-MHz. NMR spectra of 3-substituted tropanes (*e.g.*, Fig. 1, top) show methine (*a*) and bridgehead (*d*) protons as clearly spaced absorptions. The hydroxy proton may be revealed depending on concentration. The *N*-methyl of tropane is seen as a sharp singlet; however, in simple derivatives this signal is found within an uninformative envelope of nearly coincident methylene protons (*b*, *c*, and *e*, *f*). The closely spaced methylene envelope leaves detailed spin decoupling analysis with much to be desired.

Most pseudocontact studies have shown the effect on compounds containing only one type of heteroatom. The tropane series with two different heteroatoms con-

[1] Pseudocontact is defined as the interaction arising from the combined action of an anisotropic g tensor and a through space dipolar hyperfine coupling (as opposed to a through bond spin delocalized hyperfine contact interaction). The lanthanide has a short electron spin lattice relaxation time, contributing to inefficient proton relaxation and little line broadening.

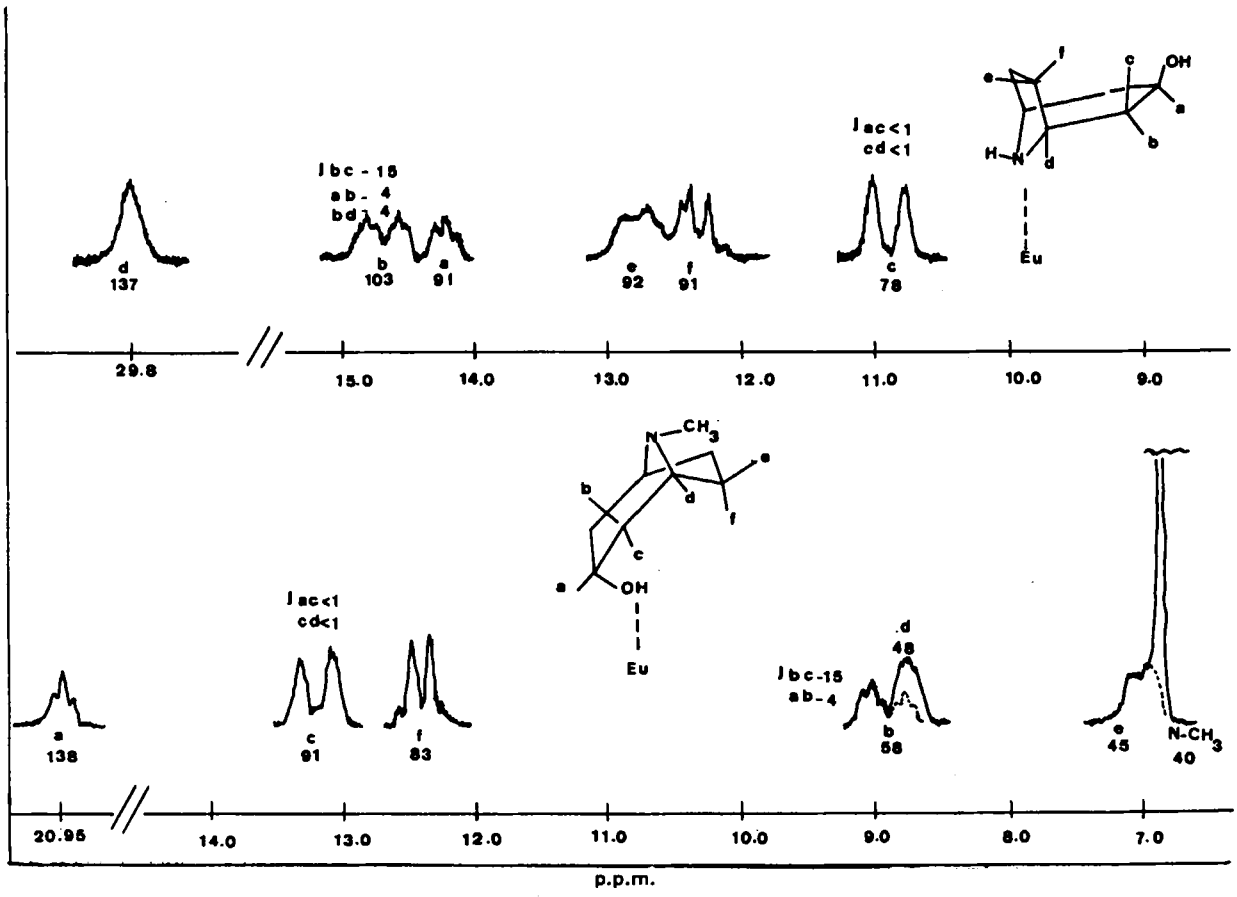

Figure 2—*The 60-MHz. shifted spectra of IV and III as occurring at 0.75 mole ratio I/substrate. Numbers immediately below proton assignments represent* $\Delta\delta$ *as in Fig. 1. The upfield half of resonance for proton* b *(bottom) was taken from the spectrum at a mole ratio where* d *and* b *resonances were independent. Resonance for proton* e *was similarly obtained.*

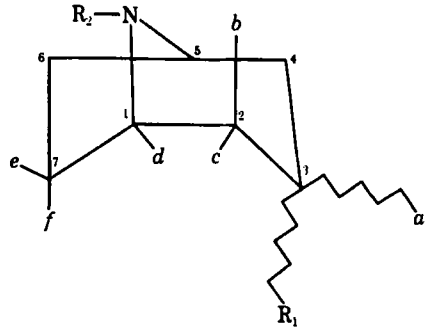
stitutes a practical "intramolecular competition" experiment[2] and tests the ability of the shift reagent to be selective enough in complexation to yield interpretable NMR spectra. In this regard the tropanes are particularly good models for study. With I, only one deshielded signal would be expected for each type of proton (*e.g.*, grouping for *d* integral = 2) since a plane of symmetry exists through both heteroatoms. An additional practical test of the usefulness of the shift reagent comes about through the conformational mobility at C-2 and C-4 of tropane and the axial–equatorial orientation possible about trivalent nitrogen.

The pseudocontact deshielded spectra should lead to structural information on two levels of sophistication. First, as an "empirical approach," the deshielding process should expose spin-spin coupling constants (*J*) that would allow assignment of predominate conformers in a relative manner, *i.e.*, in comparison to Karplus' (22) interpretations. This advantage, so long as resonance lines are sharp and unperturbed by induced conformational changes, is realized whether the exact mechanism producing the shifts has been correctly understood or not. Secondly, as a "parameter approach," the europium–proton distances could, if theory is correctly interpreted, be calculated from the rate of proton shift for a refined stereochemical outline. Shift data from conformationally immobile substrates having constant average europium–proton distances have been used on numerous occasions for testing the second approach. In these cases, data demonstrate a linear relationship between the rate of proton shift and the concentration ratio



amino alcohols

II: $R_1 = \beta$-OH, $R_2 = CH_3$
III: $R_1 = \alpha$-OH, $R_2 = CH_3$
IV: $R_1 = \alpha$-OH, $R_2 = H$

amino ketones

V: R_1, a = (=O), $R_2 = CH_3$
VI: R_1, a = (=O), $R_2 = H$

[2] Hart and Love (12) pointed out the importance of accumulating information regarding preferred sites of complexation and reported effects of I on morpholine and several other polyfunctional molecules. During the time this research was underway, Fleming *et al.* (13) reported the effect of I on the spectra of hydroxy acids. Other reports that have appeared regarding polyfunctional substrates include: Hinckley *et al.* (14) on testosterones, Tjan and Visser (15) on furanones, Osashi *et al.* (16) on contact shifts in nicotine, Brederode and Huysmans (17) on bis(4-aminocyclohexyl)methane, Taylor and Walters (18) on nitrogen–phosphorus bidentate ligands, Skolik *et al.* (19) on lupanine, Tronchet *et al.* (20) on sugar oximes, and Farid *et al.* (21) on hydroxyoxetans.

of shift reagent to substrate (*e.g.*, 21, 23). Hinckley *et al.* (14) appropriately emphasized the cautions and difficulties in the latter approach for bifunctional substrates. Accordingly, it was desired to test the parameter approach in greater detail and to set the stage for further reports by offering here the results with the "empirical approach."

EXPERIMENTAL

Substrates—Nortropine (IV) was prepared by the method of Willstätter (24) and was found to be identical to a product prepared by the method of Perrine (25). Pseudotropine (II) was prepared by lithium aluminum hydride reduction of tropinone (V) (26) and independently from tropine (III) (27). Purification was by silica gel column chromatography and sublimation. Analysis was within accepted limits. Nortropinone (VI) was prepared from 2,5-dimethoxytetrahydrofuran and acetonedicarboxylic acid (28) and was confirmed as its *N*-benzoyl derivative.

Other compounds used were purchased as authentic[3] and then recrystallized or redistilled to literature purity as required. 1-Methyl-4-piperidone, pseudopelletierine, and 3-quinuclidinone were also treated with I or the more soluble tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione)europium (VIII), and their shifted spectra were found useful in the interpretation of results presented in this paper.

NMR Investigation—All NMR work work was performed on a 60-MHz. spectrometer[4]. Deuterochloroform, used as solvent, was dried over preheated (120°) 4-A molecular sieves to remove traces of acid which might decompose the reagent complex. Chemical shift values reported are relative to internal tetramethylsilane (VII) and are in parts per million. Coupling constants (J) are reported in hertzes.

Substrate concentrations ranged from 1.4 to 1.9 $\times$ 10^{-4} mole in 0.4 ml. deuterochloroform. Compound V and pseudopelletierine and III and II were run at the same mole concentrations of 1.46 and 1.91 $\times$ 10^{-4} mole, respectively. Study compounds were analyzed at successive additions of 5–15 mg. of I for six to 12 additions, depending on solubility and the need to separate coalescing peaks for spin decoupling dictated by each substrate. Sample tubes were warmed after each addition of I to effect solution. Solutions were allowed to equilibrate to probe temperature before recording shifted spectra. Sample solutions of tertiary amino ketones gave the lowest solubility (shift reagent/substrate mole ratio of 0.53 for V). Solutions of secondary amines and tertiary amino alcohols permitted mole ratios[5] close to 1.0.

Proton assignments were based on integration and spin decoupling of suitably shifted spectra for each compound and aided by comparisons among substrates. Resonance from the tertiary butyl absorption of the europium reagent complex appeared upfield of VII in all cases except VI and pseudopelletierine. In these cases, reagent absorption moved from just downfield of VII to upfield of VII after several additions of reagent complex. VII was easily located in all spectra. In the usual manner to aid in interpretation of results, the data generated from shifted spectra were plotted on coordinate axis, with the shift of each proton in δ (p.p.m.) units as the ordinate and I/substrate mole ratios as the abscissa. The $\Delta\delta$ values reported were abstracted from these plots.

RESULTS AND DISCUSSION

NMR work with deuterium chloride salts has shown that the *N*-substituent in tropanes is predominantly equatorial. On quaternization, the small proportion of *N*-axial conformer present reacts faster to yield a large proportion of product in which the entering group takes up the equatorial position (29). In recent years there has been considerable research regarding the conformation of the tropane piperidine ring.

Early X-ray analysis of II free base and tropine hydrobromide indicated a chair conformation for both of these compounds (26, 30). IR spectral evidence is contradictory with regard to intramolecular hydrogen bonding in II (31, 32). Dipole moment studies in conjunction with an NMR investigation of partially deuterated tropanes led to the conclusion that α-substituted tropanes (*e.g.*, III) probably exist with a major proportion in the deformed chair and a minor proportion in the boat form. 3β-Substituted derivatives such as the 3-cyano derivative were postulated to exist in the chair form. Conclusions were aided by observations of spin-spin coupling of the exposed methine proton as viewed in light of the Karplus rule. Deuteration permitted the approximate assignment of methylene protons, but the protons of the methylene envelope were not used to refine conclusions (26).

More recent X-ray analysis coupled with NMR work indicated a deformed chair for II (33). Because of the replacement of 6β- and 7β-protons by oxygen in scopolamine and scopine, C-2 and C-4 methylene protons are more evident in the NMR and determination of conformation becomes more conclusive. An elegant study of these derivatives, using spin decoupling at 60 MHz., defined J values and fortified the conclusion that α-substituted tropanes exist in the chair form with some distortion (34). Contact shift studies noted the differences in both upfield and downfield shifts induced in 1,4-dimethylpiperidine on the one hand and those occurring in tropinone and 3-tropine esters on the other. Results led to the conclusion that the tropanes exist in a nearly semiplanar form (11). Our results with the effect of I on tropanes are in general agreement with recent findings of distorted chair forms for the α-tropines and tropinones. Compound II also appears to exist predominately in a distorted chair form.

A Lewis acid–base relationship exists between a europium complex and substrate (3). Selective association between I and the two different heteroatoms would be expected (12). Work with molecular models in consideration of the rate of shift found among the protons in the substrates studied and the required relative proton–europium distance[6] indicates that tertiary amino alcohols associate with europium *via* the hydroxy function whereas secondary amino alcohols associate with the nitrogen atom. Amino ketones appear to associate with the amine function. The latter relation was more apparent in VI and 1-methyl-4-piperidone than in V. The results do not conclusively rule out bidentate behavior for the ligands of V at the low mole ratio obtained with I. However, as a result of the complexation encountered, an adequate separation of proton resonances was evident among shifted spectra. All protons were seen as unique absorption for each compound studied (Figs. 1–3), except for the *e* and *f* resonances of II and IV.

Amino ketones exhibited linear plots of mole ratio *versus* chemical shift throughout the range of study permitted by solubility of the europium complex in deuterochloroform. Amino alcohols, however, showed slight curvature for some protons on these plots. This result could be taken as an indication of conformational change induced by the paramagnetic shift reagent or as a slight change in the predominate bonding equilibrium of the paramagnetic shift reagent between the two basic sites in the molecule. There is evidence that slight deviation from linearity is not a result of induced conformational changes. Conformationally free 1-methyl-4-piperidone gave linear results. The conformational mobility of this derivative was clearly evident in shifted spectra wherein, as a result of conformer averaging, no resolution was obtained between axial–

[4] Varian Associates T-60.

[5] The low solubility of I–substrate complex in deuterochloroform for the compounds in this study prevented evaluation to the limit of saturation of both functional groups. However, 3-quinuclidinone, tropine, and several other substrates were treated with the more soluble VIII, permitting evaluation through a 2-mole ratio. These results will appear in a future publication.

[6] Alignment of the tropanes with europium was immediately apparent because of variation inherent in the series. Results have usually been interpreted considering the angular factor as invarient with r estimated from $\Delta\delta$ values. The importance of the angular variable has been demonstrated (1). Although it is clear that the induced shift decreases with increasing distance between the proton and coordinating functionality, the exponent of r has been questioned (19). Briggs *et al.* (36) pointed out that, for a potentially bidentate ligand, the geometric factor requires two angular variables. Poly(monodentate) molecules may require weighted means of shifts expected for the various modes of coordination with the lanthanide. Dew Horrocks *et al.* (37) suggested, from X-ray crystallographic results with the eight-coordinate bis(4-picoline) adduct of 2,2,6,6-tetramethylheptane-3,5-dionatoholmium, that the assumption of axial symmetry for shift reagent adducts may not be totally valid and detailed structural inferences should be made cautiously. We have thus avoided reporting empirically derived specific r values and prefer to subject data to careful computer analysis before reporting this aspect.

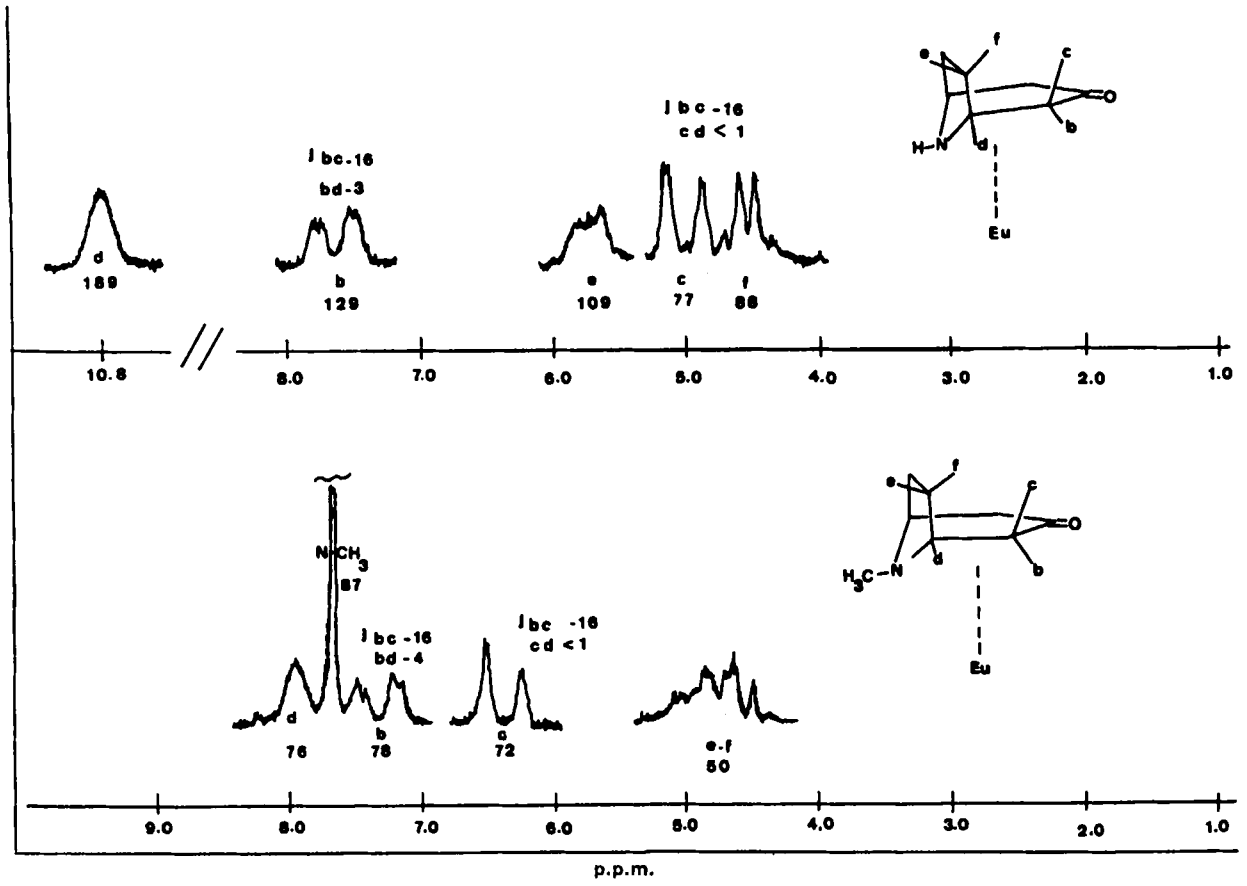

Figure 3—*Protons of VI and V as occurring at 60 MHz. in deuterochloroform solution containing 0.40 mole ratio I/substrate. Numerical data have the same meaning as in Figs. 1 and 2.*

equatorial protons of a methylene set. Moreover, no conformational change was found for the tropanes, as best evidenced by the failure of exposed protons to change significantly[7] in peak width or coupling constant from the normal deuterochloroform spectrum to the final addition of reagent. It has been shown that contact shifts are more important near the point of complex–substrate association (9). Results with the methine protons of III and II, which are geminal to the associating heteroatom, show that contact contribution was insufficient to alter J values significantly. Detailed results in line with empirical approach to data interpretation are presented below.

Amino Alcohols—The NMR of II (Fig. 1) without I revealed the methine resonance as a broad multiplet (W 1/2 = 24 Hz.). On addition of I, the methine remained as a broad multiplet (W 1/2 = 24 Hz.). The coupling constants were found to be $J_{bc} = 12$, $J_{ac} = 6$, $J_{ab} = 12$, $J_{bd} = 2$, and $J_{cd} = 3$. These data suggest a slightly distorted chair conformation. The coupling constant $J_{ac} = 6$ is somewhat larger than is normally observed for axial–equatorial coupling (2–4 Hz.) in chair cyclohexane. This can be explained by a closing of the dihedral angle between Ha and Hc from 60 to 40° which, according to the Karplus rule, would give a larger coupling constant. This closing of the angle leads one to describe the conformation as a slightly distorted chair. The data of the present study are in agreement with crystallography studies (33). Shifts are in the order OH ≫ Ha ≫ Hb > Hc ≫ Hd > N—CH_3 > Hef. A study of molecular models shows that these shift rates require europium–proton distances as indicated in the molecular diagram and evidence association *via* the hydroxy function (Fig. 1).

Both IV and III (Fig. 2) presented the methine proton in deuterochloroform as a simple triplet, $J_{ab} = 4$, $J_{ac} < 1$. These values remained constant in shifted spectra. On deshielding, the following additional J values were determined for the resulting AMXY system of the piperidine ring of the deshielded tropines: $J_{bc} = 15$, J_{ac} and $J_{cd} < 1$, and $J_{bd} = 4$ (J_{bd} was not measurable in III). According to the Karplus curve, J_{ab} and J_{bd} on the order of four or five dictate a 40° dihedral angle between these proton sets. J_{ac} and $J_{cd} < 2.0$ would indicate a dihedral angle on the order of 80° for the two α-substituted derivatives III and IV. For IV, the relative rates of shift found were Hd > Hb > Ha ≃ Hef > Hc, suggesting predominant alignment with the europium ion *via* the nitrogen function during the first mole of reagent addition. A distorted chair form is at least in concert with the observation that the shift rate of Hb is greater than Ha, while the rates for He and Hf are nearly equal and greater than Hc.

The relative rates of shift for tropine suggest the alignment in Fig. 2. The comparative shift rate for tropine protons was found to be Ha > Hc > Hf > Hb > Hd > He > N—CH_3. A boat form for III would require Hc > Ha, while a chair requires Hd > He. Thus, an empirical evaluation of the rate of shift is in relative agreement with the conformation indicated by exposed coupling constants. Measurement of the europium–proton distance and the angle factor would really be required to discriminate further.

Amino Ketones—Spectra of VI and V (Fig. 3) may be interpretated in light of the deshielded ABX coupling revealed on addition of the shift reagent. The following J values were determined: $J_{bc} = 16$, J_{bd} (IV) = 4, J_{bd} (V) = 3, and $J_{cd} < 1$ for both derivatives. These data are consistent with dihedral angles Hd–Hb of 40° and Hd–Hc of 80°, the conditions for a distorted chair form. The rates listed in Fig. 3 appear to be in line with a distorted chair conformation for the amino ketones. The rates for VI evidence alignment of europium ion with the secondary amine function. Rates for V suggest association with the tertiary amine, although both ligands could be simultaneously involved during the first mole ratio of I addition (from the crude data).

CONCLUSIONS

Compound I was found to be a useful NMR shift reagent capable of simplifying the NMR of bifunctional substrates, thus allowing

[7] Compound I is expected to induce a broadening of at least 0.003 Hz./Hz. of shift (38).

for the solution of stereochemical problems from a purely empirical approach. In accordance with the Karplus rule, use of the shift reagent permitted an independent proof of previous indications that a distorted chair form predominates in the conformational equilibrium of α- and β-tropines and tropinones. At mole ratios of I/substrate of less than 1.0, it was possible to observe substrate ligand bonding orders of secondary amine > secondary alcohol > tertiary amine $\geq$ ketone.

Microbiological Determination of Drug Partitioning II: Functional Dependence of Partition Coefficient on Drug Concentration

SADEGH JAVIDAN* and ROBERT G. MRTEK▲

Abstract □ Data were collected pertaining to the partitioning of phenylmercuric nitrate in complex gelatin–acacia coacervate systems. The partition coefficient of the drug could be measured reliably only over a relatively short concentration range using traditional chemical methods. With microbiological analysis the useful range of measurement of partition coefficients was extended significantly by comparing the number of partially inhibited *Escherichia coli* to the amount of drug in the coacervate system. Mathematical relationships were derived which relate the amount of partitioned drug in the complex coacervate to the reduction in growth of *E. coli* B/r.

Keyphrases □ Phenylmercuric nitrate—microbiological determination of partitioning in coacervate systems, partition coefficients, equations □ Microbiological determination of partitioning—phenylmercuric nitrate partition coefficients, equations □ Partition coefficients, phenylmercuric nitrate—microbiological determination, equations □ *Escherichia coli*—used in microbiological determination of phenylmercuric nitrate partitioning □ Gelatin–acacia complex coacervate system—microbiological determination of phenylmercuric nitrate partitioning □ Drug partitioning—microbiological determination, phenylmercuric nitrate in gelatin–acacia coacervate system

In a previous paper, gelatin–acacia complex coacervate systems were developed to serve as the model system for the determination of the partitioning of phenylmercuric nitrate. Partial inhibition in the growth of *Escherichia coli* B/r by the antimicrobial drug was used as the end-point of such investigation. The amount of drug present in an aliquot was determined from reproductive index measurements made with a Coulter counter[1] (1). Coacervate systems have served as models for investigating the partitioning of many types of drug compounds including barbiturates, methylene blue, sugars, phenothiazines, phenol, hexachlorophene, and salicylic acid (2). The partitioning of halothane has been studied in gelatin–acacia, gelatin–benzalkonium chloride (2), and benzalkonium chloride–salicylate or Aerosol OT coacervate systems (3). The results of such investigations have demonstrated the suitability of coacervate model systems for partitioning studies.

In most studies involving various model systems, the partition coefficients of drugs have been determined by traditional chemical analytical techniques. Although the ultimate goal of drug partitioning studies is to obtain a better understanding of the processes by which drug molecules exert their biological activities, chemical measurements do not always seem to serve this goal adequately. For example, drug molecules may undergo physical or chemical alteration to bioinactive forms due to the experimental or analytical process itself. On the other hand, the reliability of biological activity assay procedures has been emphasized extensively, although they are not used as frequently as their applicability may warrant. Apparently one reason that bioassay procedures are not utilized more frequently in drug partitioning studies is that some procedures are not as rapid as the commonly used physical or chemical methods. Since the bioassay is generally accepted as representing an accurate picture of drug activity in various experimental systems, these methods are particularly valuable in analyzing systems that contain drugs specifically used for clinical biological activity, such as the antibiotics and antimicrobial agents. Based on the fact that coacervate systems are increasingly accepted as accurate models of biological systems (4, 5) and the general adaptability of bioassay procedures, the purpose of these studies includes an investigation of the biological determination of drug partitioning in complex coacervate systems.

In this work, phenylmercuric nitrate was incorporated into coacervate and noncoacervate systems. After partitioning was completed between the equilibrium liquid and the coacervate phase, aliquots were withdrawn from the equilibrium liquid and/or the noncoacervate systems and incubated for specific times with rapidly growing microorganisms. Partial inhibition in the growth of *E. coli* was the parameter chosen to determine the amount of drug in each aliquot. The number of organisms was plotted against the total amount of drug in the system, and equations were derived which relate the partition coefficient of phenylmercuric nitrate to its inhibitory effect on the growth of *E. coli*. The general nature of these equations allows the partition coefficient of drugs in any system to be calculated from any biological parameter exhibited by the drug entities.

EXPERIMENTAL

Organisms and Reagents—*E. coli* B/r (ATCC 23227) was used as the test organism. Subculturing of the organism and the preparation of culture media were previously reported (1). Phenylmercuric nitrate[2] was used as the antimicrobial agent. Granulated acacia USP[3] and Bacto gelatin[4] were used as colloidal solutes in the coacervate system. Filtered nitric acid[5] (0.1 *N*) was used to form the coacervates.

Preparation of Coacervate Systems—Gelatin–acacia stock solutions containing 5% (w/v) gelatin and 6% (w/v) acacia were prepared. A sterile stock solution of drug was prepared by filtering a solution of phenylmercuric nitrate (600 mcg./ml.). Into each of a series of 30-ml. sterile graduated glass centrifuge tubes was placed 4 ml. of the gelatin–acacia stock solution. After the addition of

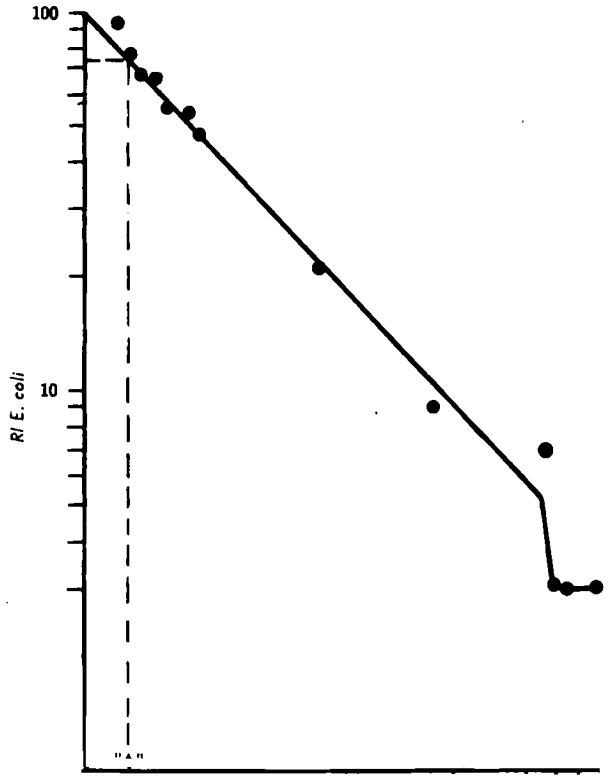
[5] Baker Analyzed Reagent.



1.5 ml. of 0.1 *N* nitric acid, aliquots of phenylmercuric nitrate (Table I) were added to each tube. The contents of the tubes were diluted to 30 ml. by the addition of sterile distilled water and mixed. In another series of tubes, the same amounts of reagents were added, except for the omission of the nitric acid. This series did not form a coacervate because of the absence of nitric acid. All tubes were stored at 37° to allow for the completion of the drug partitioning and the separation of the phases.

Growth Conditions—After 24 hr., aliquots were withdrawn from each coacervate and noncoacervate system and inoculated into flasks containing organisms growing in an exponential phase. After 4.5 hr., a sample of the organisms was counted by a colony-count method and by means of the Coulter counter as previously described (1).

Chemical Assay of Phenylmercuric Nitrate—A modification of the procedure used by Gage (6) was adopted for the assay. The following aqueous solutions were prepared in 100-ml. volumetric flasks: hydroxylamine hydrochloride[6] 20% (w/v), urea[7] 10% (w/v), disodium edetate[8] 2.5% (w/v), and sodium acetate trihydrate[9] 50% (w/v). Dithizone[10] stock solution was prepared by dissolving 20 mg. purified dithizone in carbon tetrachloride[11] to make 100 ml. of solution. The solution was refrigerated until used. A working solution was prepared by diluting 1 ml. of stock solution of dithizone to 20 ml. with chloroform[12]. Potasssium permanganate[13] and sulfuric acid[14] 50% (v/v) were used to oxidize the phenylmercuric nitrate. Mercuric chloride[15] was used to make a standard solution containing 67.7 mg./l., with 0.5 *N* HCl as the solvent.

The chemical method involves the oxidation of phenylmercuric nitrate with acidic permanganate and then titration of the mercury content with dithizone solution. Twenty milliliters of equilibrium liquid from each coacervate system was transferred to 125-ml. conical flasks with stoppers. Two milliliters of 50% (v/v) sulfuric acid was added to the solution; 0.5 g. potassium permanganate and one drop of octanol were then added. The flasks were placed in boiling water for 10 min., and 3 ml. of hydroxylamine hydrochloride solution was added to each flask to decolorize the mixture. The mixture was allowed to cool to room temperature. To the oxidized solution, 2 ml. of urea and 1 ml. of edetate were added. The pH was adjusted to 1.5 with sodium acetate solution, and 0.5 ml. of chloroform was added. Twenty milliliters of the equilibrium phase of a coacervate system containing no drug was treated in the same way as the test solution to prepare a suitable blank.

Diluted dithizone–chloroform was placed in a 25-ml. buret, and small portions were added to each test solution. After each increment, the stopper was replaced and the solution was shaken vigorously. In the presence of mercury, the separating organic layer had an orange color. Increments of dithizone solution were added until a grayish color appeared, which was intermediate between the orange of the mercury complex and the green color of the dithizone solution. The volume of the dithizone was recorded, and the same volume was added to the blank solution. The blank was then titrated to the same grayish color with standard mercuric chloride solution, and the amount of mercury in the original sample was obtained by calculation from the known volume of added standard.

RESULTS AND DISCUSSION

Microbiological Determination of Partition Coefficient—*One-Line Method*—The total number of organisms obtained from Coulter counts were converted into reproductive coefficient (*RC*) and reproductive index (*RI*) values using the following relationships:

$$RC \text{ (reproductive coefficient)} = \frac{\text{total number of organisms in each flask}}{\text{total number of organisms inoculated}} \quad \text{(Eq. 1)}$$

$$RI \text{ (reproductive index)} = \frac{RC \text{ in the presence of drug}}{RC \text{ in the absence of drug}} \times 100 \quad \text{(Eq. 2)}$$

When log *RI* values obtained from noncoacervate systems were plotted *versus* the concentration of drug (micrograms per milliliter) in the noncoacervate system, a straight line was obtained (Fig. 1). The least-squares regression line was calculated using regression models of the univariate normal type, where x = concentration of drug in micrograms per milliliter in the noncoacervate system and y = (log *RI*). The line in Fig. 1 may be used as a standard to predict the concentration of drug corresponding to a measured *RI* value obtained with aliquots of known volume drawn from equilibrium liquids incubated with *E. coli*.

For example, assume that a 1-ml. aliquot was removed from the equilibrium phase of a coacervate system containing some total quantity of phenylmercuric nitrate and that it produced an *RI* value equal to 75 when measured by the technique of the inhibition of *E. coli*. From Fig. 1, a corresponding value on the x-axis equivalent to 30 mcg. of drug is obtained, thereby indicating the actual amount of phenylmercuric nitrate contained in the 1-ml. aliquot drawn from the drug-partitioned equilibrium phase. In this way, any aliquot from a coacervate system equilibrium layer may yield a corresponding concentration of phenylmercuric nitrate that relates to its observed *RI* value.

To derive a mathematical expression for the partition coefficient, let a assume a value that is equal to the actual concentration of drug in the equilibrium liquid expressed in micrograms per milliliter. Considering the total volume of the equilibrium liquid in the coacervate system to V_2 ml., then the amount of drug in the equilibrium liquid is aV_2 mcg. If the total amount of drug added to each system is T mcg., the amount of drug partitioned into the coacervate phase would be $(T - aV_2)$ mcg. Dividing this value by the volume of the coacervate layer itself, V_1 ml., the concentration of the drug in the coacervate phase can be obtained as $(T - aV_2)/V_1$ mcg./ml.

Since the partition coefficient (*PC*) is defined as the ratio of the drug concentration in the coacervate phase over the concentration

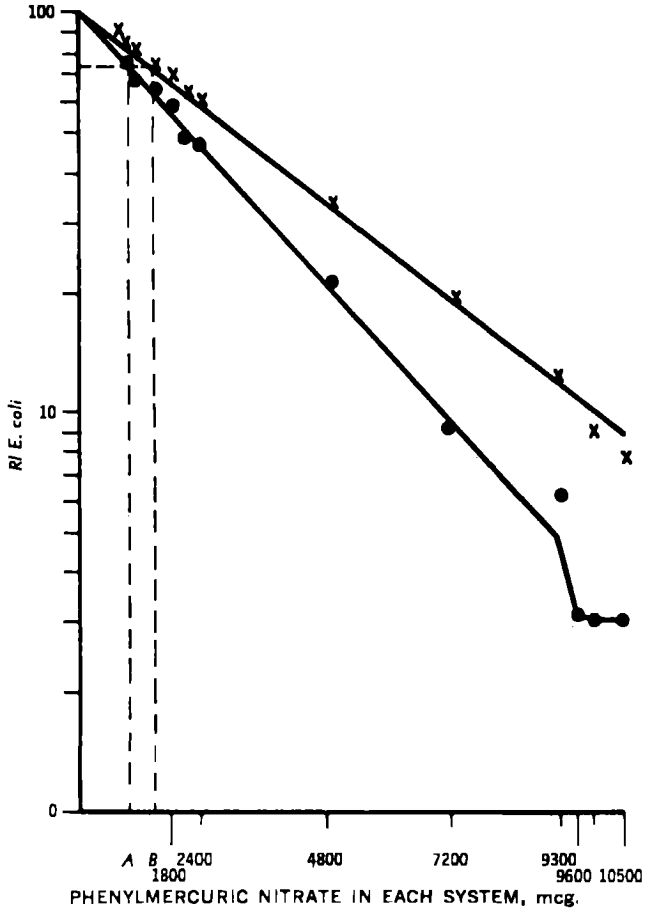

Figure 2—*Effect of phenylmercuric nitrate on the reproductive index* (RI) *of* E. coli *B/r (two-line method). Key:* ×, *aliquots drawn from equilibrium liquids; and* ●, *aliquots drawn from noncoacervate systems.*

of the drug in the equilibrium liquid, an equation may be written:

$$PC = \frac{T - aV_2}{V_1} + a = \frac{T - aV_2}{aV_1} \qquad \text{(Eq. 3a)}$$

or:

$$PC = \frac{T}{aV_1} - \frac{V_2}{V_1} \qquad \text{(Eq. 3b)}$$

Two-Line Method (Derivation I)—Logarithmic *RI* values obtained from both coacervate and noncoacervate systems were plotted against T, the total amount of drug introduced into each system. Figure 2 shows the straight lines obtained when (log *RI*) values are plotted *versus* the microgram quantities of phenylmercuric nitrate present in each system. For any selected value of *RI*, there are two different corresponding values on the x-axis, labeled A and B. These represent the different amounts of drug that must be added to each system (A = noncoacervate, B = coacervate) to yield identical reproductive indexes in the equilibrium liquid of the coacervate system and the noncoacervate system after drug partitioning has taken place. It is assumed that for equivalent *RI* values, the amounts of drug in the aliquots are identical regardless of the total amounts of drug in the system as indicated by A and B. If the concentration of drug in the equilibrium liquid and the noncoacervate system required to produce the same *RI* is designated as C_2, C_1 is the concentration of the drug in the coacervate phase (micrograms per milliliter), and V_1 and V_2 are the volumes of the coacervate phase and the equilibrium liquid in milliliters, respectively, an equation may be written that relates the apparent total amount of drug in the coacervate system (B) as determined from Eq. 4:

$$C_1V_1 + C_2V_2 = B \qquad \text{(Eq. 4)}$$

By dividing Eq. 4 by C_2, the concentration of drug in the noncoacervate system at the same *RI* value (and similarly the concentration of drug in the equilibrium phase), the following equation may be obtained:

$$\frac{C_1}{C_2}V_1 + V_2 = \frac{B}{C_2} \qquad \text{(Eq. 5)}$$

Once again the partition coefficient is defined as the concentration of the drug in the coacervate phase with respect to its concentration in the equilibrium liquid and is expressed as $PC = (C_1/C_2)$. Substitution of PC in Eq. 5 and subsequent rearrangement yield:

$$(PC)V_1 + V_2 = \frac{B}{C_2} \qquad \text{(Eq. 6a)}$$

$$PC = \frac{B}{C_2V_1} - \frac{V_2}{V_1} \qquad \text{(Eq. 6b)}$$

Because the total volume of the noncoacervate systems has been experimentally fixed to equal $V_1 + V_2$ (the volume of the coacervate system) and the amount of drug needed to produce the same *RI* in both systems is equal to C_2, one can write:

$$A = C_2(V_1 + V_2) \qquad \text{(Eq. 7a)}$$

or:

$$C_2 = \frac{A}{V_1 + V_2} \qquad \text{(Eq. 7b)}$$

And by substituting Eq. 7*b* into Eq. 6*b*:

$$PC = \frac{B}{(AV_1/V_1 + V_2)} - \frac{V_2}{V_1} \qquad \text{(Eq. 8a)}$$

or:

$$PC = \frac{B(V_1 + V_2)}{AV_1} - \frac{V_2}{V_1} \qquad \text{(Eq. 8b)}$$

As before, A and B are obtained from straight-line plots such as Fig. 2 and represent amounts of drug needed to give equivalent *RI* values in coacervate and noncoacervate systems. V_1 and V_2 can be measured visually after equilibrium is completed in the coacervate system.

Two-Line Method (Derivation II)—In Fig. 2, B/A represents the ratio of the concentration of drug in noncoacervate systems to that of the equilibrium liquid in the coacervate system needed to produce equivalent values of *RI*. Of course, this relationship holds only when the same amount of drug has been added to both systems. Under these conditions, for any value of *RI* that is selected, the ratio may be expressed as:

$$\frac{B}{A} = \frac{\text{concentration of drug in noncoacervate system}}{\text{concentration of same drug in equilibrium liquid of coacervate}} \qquad \text{(Eq. 9)}$$

Since concentrations in these systems are proportional to the reciprocal volumes, Eq. 9 may be rewritten as:

$$\frac{B}{A} = \frac{\text{ml. equilibrium liquid producing a certain } RI}{\text{ml. noncoacervate system producing the same } RI} \qquad \text{(Eq. 10)}$$

In all instances, 1 ml. was withdrawn from both systems. Therefore, Eq. 10 can be restated as:

$$\frac{B}{A} = \text{ml. equilibrium liquid containing same amount of drug as 1 ml. noncoacervate system} \qquad \text{(Eq. 11)}$$

If T micrograms of drug is added to each system and V is the volume of the noncoacervate system in milliliters, T/V equals the amount present per milliliter of noncoacervate system. These expressions indicate that in B/A ml. of equilibrium liquid, T/V mcg. drug is present. The amount of drug in the total volume of equilibrium liquid is:

$$V_2 = \frac{V_2TA}{VB} \qquad \text{(Eq. 12)}$$

Table I—Partition Coefficient of Phenylmercuric Nitrate (PMN) in Gelatin–Acacia Complex Coacervate Systems Determined by Partial Inhibition in the Growth of *E. coli* B/r and by Chemical Method

1.5	900	30	77.0	76.1	86.2	16.95	12.55	12.67
2.0	1200	40	69.1	68.2	79.3	25.4	9.61	9.7
2.5	1500	50	64.3	65.1	75.0	32.3	9.22	9.10
3.0	1800	60	57.2	56.4	69.91	39.65	8.70	8.89
3.5	2100	70	48.6	49.7	64.7	47.72	8.0	8.30
4.0	2400	80	45.0	47.1	60.7	55.5	7.6	8.0
8.0	4800	160	19.8	20.5	33.7	114.8	6.9	6.51
12.0	7200	240	8.6	9.2	19.2	175.1	6.59	5.92
15.0	9300	310	5.0	6.2	12.3	220.3	5.37	5.11
16.0	9600	320	2.0	3.05	9.02	252.6	5.01	4.62
16.6	9900	330	0	3.01	8.3	260.6	5.00	4.89
17.5	10500	350	0	3.0	6.7	279.11	5.00	4.87

which assumes the units of micrograms. The concentration of drug in the equilibrium liquid can be obtained by dividing the expression for the amount of drug by the volume of the equilbrium liquid:

$$\frac{V_2TA}{VB} \div V_1 = \frac{TA}{VB} \text{ mcg./ml.} \qquad \text{(Eq. 13)}$$

Subtracting Eq. 12 from the total amount of drug in each system (T) gives the amount of drug in the coacervate phase:

$$T - \frac{V_2TA}{VB} = \frac{TVB - V_2TA}{VB} \qquad \text{(Eq. 14)}$$

Similarly, the concentration of the drug in the coacervate phase may be obtained by dividing its amount by the appropriate volume V_1:

$$\frac{TVB - V_2TA}{VB} \div V_1 = \frac{TVB - V_2TA}{V_1VB} \text{ mcg./ml.} \qquad \text{(Eq. 15)}$$

From Eqs. 13 and 15, the definition of the partition coefficient may be written as a ratio of concentrations of drug in coacervate phase to drug in equilibrium phase:

$$PC = \frac{\text{Eq. 15}}{\text{Eq. 13}} = \frac{T(VB - V_2A)}{V_1VB} \div \frac{TA}{VB} \qquad \text{(Eq. 16)}$$

Simplification yields:

$$PC = \frac{VB - V_2A}{V_1A} = \left(\frac{B}{A}\right)\frac{V}{V_1} - \frac{V_2}{V_1} \qquad \text{(Eq. 17)}$$

Since the total volumes of the coacervate and noncoacervate systems were kept equal and $V = V_1 + V_2$, Eq. 17 may be rewritten to give an identity with Eq. 8*b* from the previous derivation. Therefore, it is evident that the expressions obtained for the partition coefficients obtained by the one-line and two-line methods are the same.

Chemical Determination of Partition Coefficient—Each milliliter of the standard mercury solution used in the assay of phenylmercuric nitrate is equivalent to 0.75 mcg. of organic mercury present in the original sample (6). Phenylmercuric nitrate has been reported to contain 63.2% (w/w) mercury (7). Therefore, each milliliter of the standard solution consumed in the titration is equivalent to 375/316 or 1.1867 mcg. of phenylmercuric nitrate. In the experimental studies reported here, the volume of the equilibrium liquid was 20 ml. If n ml. of the standard mercuric chloride solution is used in the chemical assay, then a, the value of the concentration of phenylmercuric nitrate in micrograms per milliliter of the equilibrium liquid, can be calculated from Eq. 18:

$$a = \frac{1.1867n}{20} = 0.0593n \qquad \text{(Eq. 18)}$$

Finally, the partition coefficient of phenylmercuric nitrate in the coacervate system may be determined from Eq. 3*b*. Calculated partition coefficient values from this method are shown in Table I, Column 9.

A comparison of Column 8 in Table I with Column 9 reveals that the partition coefficient for phenylmercuric nitrate in complex coacervate systems as determined by the microbiological method is in agreement with that obtained by the chemical assay procedure for organic mercurial compounds. The deviations at low concentrations of drug are attributed to the limiting sensitivity of the chemical assay method.

The microbiological measurement of drug partitioning in complex coacervate systems need not be confined to antimicrobial agents (8, 9). As long as substances are capable of exhibiting *any type* of biological activity, they are candidates for studies of this type. In nearly every instance, microorganisms may be selected whose growth will be predictably altered by the presence of the drug being studied. In this way, vitamins, cytotoxic agents, nutrient components, *etc.*, could be partitioned in coacervate systems and measured microbiologically by the methods described here.

Microbiological Determination of Drug Partitioning III: Partition Coefficient Profiles of Several Antimicrobial Agents

SADEGH JAVIDAN* and ROBERT G. MRTEK▲

Abstract □ Drug partitioning of four antimicrobial agents in gelatin–acacia complex coacervate systems was studied. Partial inhibition in the growth of *Escherichia coli*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa* permitted the determination of partition coefficients for the antimicrobial agents in coacervates over a concentration range of 0.12–2.4 mg./ml. The usefulness of this method is apparent from a comparison of partition coefficients obtained with the same drugs using traditional chemical analysis. The dependence of partition coefficient on drug concentration in the system demonstrates the suitability of the methods for drug binding studies using coacervates as biological models.

Keyphrases □ Antimicrobial agents—microbiological determination of partitioning in coacervate systems, partition coefficients, compared to chemical assay techniques □ Microbiological determination of partitioning—four antimicrobial agents, partition coefficient profiles, compared to chemical assay techniques □ Partition coefficient profiles, four antimicrobial agents—microbiological determination □ Gelatin–acacia complex coacervate system—microbiological determination of partition coefficient profiles for four antimicrobial agents □ Drug partitioning—microbiological determination, four antimicrobial agents in gelatin–acacia coacervate system, compared to chemical assay techniques

Coacervate systems were introduced and described by Kruyt and Bundenberg de Jong in 1929 (1). Later, these systems were utilized as biological model systems by Oparin and coworkers (2–6) and other investigators (7–9). Several investigators (10–13) adapted complex coacervate systems to serve as biological model systems for the study of drug partitioning. The advantages of these systems over other types of models used for partitioning studies of drug molecules are numerous. Coacervate systems have been reported to be the most suitable model for comparative studies with the biological system (14–16). These systems do not suffer from the simplistic shortcomings common to the lipid-like solvent systems such as octanol–water or chloroform–water when used as biomodels (12). Furthermore, partitioning studies with coacervate models do not necessitate the use of specially devised experimental membrane barriers. Investigation of drug partitioning by means of dialysis membranes introduces certain assumptions concerning the membrane and requires several corrections due to the adsorption of drug entities to the membrane. General freedom from these shortcomings invites the coacervate systems to serve increasingly as models for biosystems in comparative drug partitioning studies.

The similarity between the structure of water in the membraneless coacervate system and the biological system has been repeatedly recognized (2–9, 14–16). This affords additional incentive to utilize coacervate systems as models of biological barriers in the study of drug transfer. Judicious use of these systems may offer additional insight into processes of drug distribution in the body.

Garrett and Miller (17) demonstrated the relationship existing between dilute drug solutions and microbial growth below their minimum inhibitory concentrations. Similar results were obtained by these workers (10, 11) using drug-treated complex coacervate systems. Hansch *et al.* (18) described equations which relate the partition coefficient of drugs with their biological activities. Javidan and Mrtek (11) developed equations whereby the partition coefficient of any drug could be calculated from its biological activity using microbiological systems. It seems desirable to measure the partition coefficient of drugs at various concentrations in coacervate systems using biological parameters as the end-point because such assay procedures satisfy the prime requisite for the determination of the biologically active drug, rather than one or more functional groups on drug molecules which may have undergone alterations to bioinactive forms during the experiment itself.

In this investigation, the partition coefficients of four antimicrobials were studied over an extended concentration range using several organisms with various sensitivities to each drug. Partition coefficients were calculated using the microbiological one-line method previously reported (11), and the results were compared with those obtained by traditional chemical assay techniques.

EXPERIMENTAL

Organisms and Culture Media—*Test Organisms*—*Escherichia coli* B/r (ATCC 23227), *Pseudomonas aeruginosa*[1], and *Staphylococcus aureus*[1] were used as the test organisms. The general preparation of cultures and storage conditions were previously described (10).

Culture Media—The following were used:

1. Difco E. C. Medium[2]. Thirty-seven grams of the dried medium was rehydrated in 1 l. of cold distilled water and stirred at room temperature until a clear solution resulted. This solution was filtered through Millipore[3] filters (2 and 0.22 μ) to remove all cellular and particulate debris. Filtered media were distributed in batches of 18 ml. among 125-ml. conical flasks and autoclaved at 15 lb. of pressure (121°) for 15 min. The pH of the sterilized medium was 6.98.
2. Difco Brain Heart Infusion[2]. Thirty-seven grams of the dehydrated material was dissolved in cold distilled water to make 1 l. The solution was boiled for 1 min. and stirred until it was clear. Then the hot solution was filtered and treated in the same manner as the E. C. medium. The infusion was freshly prepared each week and had a pH of 6.9.
3. Defined Medium. The culture medium developed by Anton (19) was used to obtain a slow rate of growth for microorganisms that were not highly sensitive to the particular antibacterial being

studied or when the concentration of antimicrobial agent was below the minimum inhibitory concentration. The medium was prepared by dissolving all components in cold distilled water, filtering through Millipore filters to remove debris, and autoclaving for 20 min. The pH was 6.9 and did not change throughout the study.

4. Frazier's (20) medium, composed of 4% (w/v) each Bacto tryptone[4] and Soya agar[4] and 0.5% (w/v) Bacto gelatin[4], was prepared by heating all components to about 70° in distilled water while stirring continuously with a glass rod. After all the particulate matter was dispersed, the medium was autoclaved in a 500-ml. flask for 15 min. at 15 lb. of pressure. After the flask had cooled to 45°, the medium was dispensed into sterile plastic Petri dishes under a microbiological hood equipped with a UV light. The solidified medium was used to determine if the organisms used in the study metabolized gelatin, an important component in the coacervate systems.

Reagents—*Drugs*—Phenylmercuric nitrate[5], chloramphenicol USP[6], furazolium chloride[7], and benzalkonium chloride USP[8] were the antimicrobial agents used in the drug partitioning studies.

Biochemicals—The reagents used in the preparation of coacervate systems were described previously (10).

Reagents for Chemical Analysis—Chemicals required for the assay of phenylmercuric nitrate, according to the method of Gage, have been described (11). A mixture of hexanol[5]–heptane[9] (4:1) and 0.1 *N* sodium hydroxide[10] solutions were used in the assay of furazolium chloride. The assay for benzalkonium chloride required orange II[5], which was used to form a salt with the drug. This was subsequently extracted into chloroform[11]. Sodium carbonate[10] and sodium bicarbonate[10] were used to prepare Delory and King's buffer solution.

Preparation of Solutions—*Phenylmercuric Nitrate Stock Solutions*—Sixty milligrams of phenylmercuric nitrate was placed in a sterile 100-ml. volumetric flask wrapped with aluminum foil. Sterile distilled water was the solvent. Dissolution of the drug was accomplished at room temperature with the aid of a magnetic stirrer and a sterilized magnetic stirring bar which was placed in the flask. After dissolution was completed in 4 hr., the solution was filtered through a 0.22-μ Millipore filter. This solution was labeled Phenylmercuric Nitrate Stock Solution I. Ten- and 100-fold dilutions of this solution were prepared in sterile brown bottles using sterile distilled water and labeled Phenylmercuric Nitrate Stock Solutions II and III, respectively. All stock solutions were freshly prepared each week. The concentrations of phenylmercuric nitrate in the Phenylmercuric Nitrate Stock Solutions I, II, and III were 600, 60, and 6 mcg./ml., respectively.

Furazolium Chloride Stock Solutions—By dissolving 1 g. furazolium chloride in 100-ml. sterile distilled water at room temperature, a stock solution labeled Furazolium Chloride Stock Solution I was prepared. The concentration of drug in this solution was 10 mg./ml. Diluting 3 ml. of this solution to 100 ml. with sterile distilled water resulted in a solution labeled Furazolium Chloride Stock Solution II. A third dilution was made by adding 80 ml. of sterile distilled water to 20 ml. Furazolium Chloride Stock Solution II and was labeled Furazolium Chloride Stock Solution III. All solutions were filtered through 0.22-μ Millipore filters and stored at room temperature in brown bottles until used or replenished in 2 weeks. The concentrations of furazolium chloride in Furazolium Chloride Stock Solutions I, II, and III were 10 mg./ml. and 300 and 60 mcg./ml., respectively.

Chloramphenicol Stock Solutions—Chloramphenicol stock solutions were freshly prepared 0.5 hr. prior to use. Four solutions—375, 150, 120, and 60 mcg./ml.—were prepared separately by diluting an accurately weighed amount of chloramphenicol in cold sterile distilled water. The solutions were labeled Chloramphenicol Stock Solutions I, II, III, and IV, respectively, and stored in the refrigerator until used.

Benzalkonium Chloride Stock Solutions—One and one-half milliliters of a 50% (w/v) solution of benzalkonium chloride was diluted to 250 ml. with sterile distilled water. The resulting solution contained 3 mg./ml. drug and was labeled Benzalkonium Chloride Stock Solution I. A second stock solution, prepared by appropriate dilution to contain 1080 mcg./ml. of the antimicrobial agent, was labeled Benzalkonium Chloride Stock Solution II.

Preparation of Coacervate Systems—A stock solution containing 6% acacia and 5% gelatin was prepared according to the method described previously. This solution was labeled A–G Stock Solution and was refrigerated until used. The method of preparation of the coacervate systems from A–G Stock Solution was identical to that described elsewhere (10). The concentration of gelatin in the A–G Stock Solution was increased to 5% (w/v) from that described in an earlier paper to provide a maximum coacervate phase volume.

Effect of Drug Concentration on Coacervation Volume—Into each of a series of 45-ml. graduated centrifuge tubes were placed separately the quantities of different antimicrobials indicated in Table I. Four milliliters of A–G Stock Solution was added. Tubes containing phenylmercuric nitrate were acidified with 1.5 ml. of 0.1 *N* HNO_3 to prevent precipitation of insoluble phenylmercuric chloride. All other drug-containing tubes were acidified with 1.5 ml. of 0.1 *N* HCl. The volume of each tube was adjusted to 30 ml. by the addition of sterile distilled water. Clouding of liquid indicated the formation of a coacervate phase.

After the tubes were capped and secured with a rubberband, they were shaken horizontally in a reciprocating water bath at 37° for 6 hr. to permit partitioning of the drug between the coacervate droplets and the equilibrium liquid. Then the capped tubes were stored undisturbed in a cabinet at 37° for 24 hr. to permit phase separation. The volume of the coacervate layer was recorded visually at the end of this period. The sequence of addition of the different components in the formation of the coacervate or the duration of the shaking period was altered from 0.5 to 6 hr. to study any possible effect on the final volume of the coacervate phase.

Utilization of Gelatin by Microorganisms—Inocula from rapidly growing cultures of *E. coli*, *S. aureus*, and *P. aeruginosa* were streaked onto the surface of three replicate plates of a specially prepared solidified medium to test the utilization of gelatin by these organisms (20). The plates were covered, inverted, and incubated for 24 hr. at 37°. At the end of this time, the surface of each plate was flooded with about 2 ml. of 2% acidic solution of mercuric chloride. The difference in the intensity of the background color was compared with the color of the areas where the organisms had grown. This visual comparison represented the criterion for the determination of gelatin utilization by the microorganisms (20).

Test for Drug Inactivation during Coacervation Process—Into 26 15-ml. graduated cylinders, 2 ml. of A–G Stock Solution and 3 ml. of sterile filtered normal saline were added. Then the cylinders were divided into two groups: A and B. Each cylinder in Group A received 0.8 ml. of 0.1 *N* HNO_3 solution and then the antimicrobial agents were added to the cylinder according to the protocol in Table II. The volume of all cylinders was brought to 15 ml. by the addition of sterile distilled water. After mixing, a clear solution was obtained. Coacervation was prevented in the acidified cylinders (Group A) by addition of sodium chloride [the concentration of sodium chloride in each system was 0.18% (w/v)]. One milliliter of solution from each cylinder was transferred to each of three replicate tubes containing rapidly growing cultures of *E. coli* B/r, which had been inoculated 90 min. previous to the addition of the drugs. Total organism counts were made 4.5 hr. after the antimicrobials were introduced to each culture.

Table III—Components Used to Study Partitioning of Antimicrobials in Gelatin–Acacia Complex Coacervates

Tube	A–G Stock Solution, ml.	0.1 *N* HNO_3 or HCl, ml.	Antibacterial Solution, ml.	Sterile Distilled Water, ml.	Abbreviation of System[a]	Coacervate, ml.
A	4	1.5	0	24.5	C_0	2
B	4	1.5	n[b]	*q.s.* 30	C_+	2
C	4	0	0	26	N_0	0
D	4	0	n[b]	*q.s.* 30	N_+	0

[a] C_0 = coacervate system, no drug; C_+ = coacervate system with drug; N_0 = noncoacervate system, no drug; and N_+ = noncoacervate system with drug. [b] n refers to milliliters antimicrobial shown in Tables IV–XII. (Only one concentration of drug was used in each experiment.)

Drug Partitioning in Complex Coacervate Systems—In each experiment, four 45-ml. centrifuge tubes were designated as A, B, C, and D. Tubes A and B were used to prepare coacervate systems; noncoacervate systems were prepared in C and D. The amounts of different components pipeted into each tube are shown in Tables III–XII. From previously conducted tests, the specific sequence of addition of components was determined to be immaterial. Each of the four tubes was glass stoppered; the stopper was secured to the neck of the tube by means of rubberbands. The system was placed in a reciprocating water bath shaker for 6 hr. as previously described. During this period the partitioning of the drugs was completed. Then the tubes were removed and stored undisturbed at 37° to allow the phases to separate.

Growth Conditions—The techniques of preparing, storing, and subculturing the organisms, the methods of obtaining viable counts and total counts, and the procedures to assess the coincidence of these counts were described in detail elsewhere (10).

Chemical Measurement of Partition Coefficients—*Phenylmercuric Nitrate*—The assay procedure used for this compound was the same as used by Gage (21) in determining trace amounts of phenylmercuric salts in biological materials. The method involves the

oxidation of phenylmercuric nitrate with acidic permanganate and the subsequent titration of the mercury with dithizone solutions. The steps were described previously (11).

Furazolium Chloride—One milliliter of the equilibrium liquid from coacervate systems containing furazolium chloride was transferred to a 15-ml. centrifuge tube and made alkaline by the addition of 2 ml. of 0.1 *N* sodium hydroxide solution. The pH was 11.7. Seven milliliters of a hexanol–heptane mixture (4:1) was added to the tube, and the drug was extracted into the organic phase by shaking the tube for 1 min. The phases were separated by centrifugation at 1200×*g* for 10 min. Three milliliters of the upper layer (solvent mixture) was removed, and the absorbance was determined at 420 nm. One milliliter of equilibrium liquid from the coacervate system containing no drug was treated in the same way and served as a zero blank. A standard curve was constructed by plotting the absorbance at 420 nm. against accurately known amounts of drug present in standard aliquots. A least-squares regression line was fitted to the data, using the regression of *X* (mcg. furazolium chloride) on *Y* (absorbance). The amount of drug in the unknown sample was determined by calculation from the standard curve $X = 0.21\,Y$.

Chloramphenicol—The chemical assay of chloramphenicol was performed using a method described in the FDA monographs (22). One milliliter of the equilibrium liquid was placed directly in a 1-cm. quartz cell and the absorbance was determined in a DB-G spectrophotometer at 278 nm. Aliquots of the equilibrium liquid containing no drug were used as the zero blank. An aqueous solution containing 20 mcg./ml. chloramphenicol was used as the standard solution. Standards were freshly prepared for each experiment.

Benzalkonium Chloride—The method described by Scott (23) was adopted for this assay.

1. Preparation of solutions. One-half gram of orange II was dissolved at room temperature in distilled water to make 1 l. This solution was protected from light. Delory–King's carbonate–bicarbonate buffer was prepared by dissolving 170 mg. of exsiccated sodium carbonate and 1.746 g. of sodium bicarbonate in sufficient distilled water to make 100 ml. of a buffer solution with a pH of 9.2 at 23° (24). A reference solution containing 170 mcg./ml. of benzalkonium chloride in distilled water was prepared from a concentrate.

2. Calibration of reference solution. Five aliquots of 1, 2, 3, 4, and 5 ml. each of benzalkonium chloride reference solution, containing 170, 340, 510, 680, and 850 mcg., respectively, of the antimicrobial were transferred to each of five 125-ml. separators. To each separator was added 1 ml. of 95% ethanol, 5 ml. of Delory–King's buffer, 3 ml. of orange II solution, and 12 ml. of chloroform. Water was added to bring the aqueous volume to approximately 35 ml. Each separator was shaken vigorously for 5 min. Then the lower chloroform layer was collected in a 50-ml. volumetric flask. Three

successive chloroform extractions were made from each separator using additional 12-ml. aliquots. The volumetric flasks were brought to volume with chloroform, and the absorbance was determined at 485 nm. with chloroform as the blank. The absorbance of the reference solutions was plotted against the amount of drug in each aliquot. A least-squares regression line was drawn, which served as a standard curve for the determination of the amount of benzalkonium chloride in aliquots withdrawn from coacervate systems.

3. Determination of benzalkonium chloride in coacervate systems. Twenty milliliters of equilibrium liquid was transferred to a 125-ml. separator and treated exactly as already described. The absorbance was determined at 485 nm. Chloroform extractions from an aliquot withdrawn from a coacervate system containing no drug were used as a blank.

RESULTS AND DISCUSSION

Selection of Drugs—Three criteria were observed in the selection of drugs for inclusion in these studies.

Aqueous Solubility—The concentration of the drug in the coacervate system was increased under conditions of the experiment until the partition coefficient became relatively independent of the amount of drug in the system (Figs. 1–4). According to experimental constraints imposed by the model system, the maximum aqueous solution volume that could be added to each system was 24.5 ml. or 6.375 times the volume of the A-G Stock Solution (Table III). Because of this limitation, the concentration of the drug stock solutions and, therefore, the aqueous solubility of the drug itself must be such that the maximum amount of drug required for a microbiological end-point could be achieved within the allowable volumes that might be added to the coacervate systems. The limitation is of practical consideration only for fairly insoluble drugs. Of course, the addition of cosolvents and surfactants or any other changes in the physical conditions might have resulted in a more concentrated drug

stock solution, but these factors will, in turn, affect the partitioning characteristics of the drug entities as well as the coacervate system itself.

Stability—The pH of coacervation was near 3.67, and all coacervate systems were maintained at 37° for 24 hr. to ensure the attainment of partitioning equilibrium and the complete separation and coalescence of the coacervate phase droplets. These conditions may in themselves cause physical or chemical decomposition of certain drugs such as penicillin. Therefore, the drugs selected for examination in this study were chosen on the basis of chemical and physical stability as well as maintenance of full biological activity under the experimental conditions.

Antimicrobial Spectrum—Since a major objective of this investigation was to examine the partitioning characteristics of drugs in coacervate systems from their lowest measurable concentrations to relatively large amounts where the partitioning behavior in coacer-

vates became independent of amount, drugs were selected that offered a wide spectrum of microbiological activity against common organisms such as *E. coli*, *S. aureus*, and *P. aeruginosa*.

On the basis of these criteria, phenylmercuric nitrate, furazolium chloride, chloramphenicol, and benzalkonium chloride were included in this study.

Effect of Drug Concentration on Coacervate Volume—The volume of the coacervate phase was used as a sensitive and reliable indicator of the effects of different factors on the coacervate process itself. Factors such as heat, acids, and sterilization were described previously (10). To design a reproducible model system for the drug partitioning studies reported here, the effect of various drug concentrations was examined to determine the extent to which the coacervation process itself was altered by the presence of the antimicrobial agent. When different amounts of phenylmercuric nitrate, furazolium chloride, chloramphenicol, and benzalkonium chloride were added to coacervating systems, no differences were observed in the volume of the coacervate phase (Table I). The ratio of the volume of the coacervate phase to the volume of the A–G Stock Solution used was consistently 1:2. These observations suggest that the presence of drug in the coacervate system and the partitioning of antimicrobials under the experimental conditions had no measurable effect on the volume of the coacervate layer. Water structure has been postulated as being, in part, a function of the coacervation process itself. Since the volume of the coacervate layer is highly dependent upon the extent and type of water structuring, it is concluded that the coacervation process in the presence of drugs is similar if not identical to the process in the absence of drugs since no measurable change in phase volume occurred. It was shown under a variety of conditions employed in the formation of coacervates that the sequence of addition of the different components, as well as the length of the shaking period to produce a fine dispersion of coacervate droplets during the drug partitioning experiments, had no effect on the volume of the coalesced coacervate phase.

The addition of phenylmercuric nitrate at concentrations above 320 mcg./ml. caused the temporary formation of a coacervate layer when the drug solution was added to the A–G Stock Solution in the absence of acid. The coacervate phase disappeared when the system was mixed. On the other hand, the addition of tetracycline hydrochloride in concentrations above 2 mcg./ml. to the A–G Stock Solution formed permanent coacervate phases which did not disappear on shaking. This indicates that tetracycline hydrochloride sufficiently reduced the pH of the system (to 3.4) to initiate formation of coacervate droplets. This factor alone may explain, at least in part, the decreased absorption of tetracycline from oral dosage forms when ingested in the presence of considerable dietary or milk proteins. The stomach contents acidify the system sufficiently to suppress coacervation; but when the drug–protein complex is passed into the less acidic portions of the small intestine, the pH rises sufficiently to form coacervation droplets at a pH that is slightly below the iso-

electric point of the dietary proteins. This may provide an additional mechanism to explain the decreased availability of such drugs when coadministered with dietary proteins.

Utilization of Gelatin by Microorganisms—The concentration of gelatin in the equilibrium liquids of coacervate systems is considerably less than in the noncoacervate system, since up to 99% of the colloidal solute of the coacervate system remains in the coacervate phase itself. For this reason, it was important to ascertain whether the growth of the test organisms was directly affected by the difference in the concentrations of gelatin that might be transferred to the incubation tubes along with the antimicrobial agent. The background of all plates inoculated with test organisms turned clear upon the addition of mercuric chloride solution. The zones containing colonies were turbid with a yellow color. Had the organisms utilized gelatin to any extent as a primary nutrient, the background in the areas of colony growth would have appeared clearer than the rest of the plate. From the results of these tests, it was concluded that gelatin was not an important nutrient for any of the organisms under study and that their rate of growth in the nutrient medium used in the bioassay procedure would not be affected by any variation in the concentration of gelatin transferred with the aliquot of antimicrobial agent.

Inactivation of Antimicrobials due to Coacervation Process—To determine whether the reagents used in the preparation of the

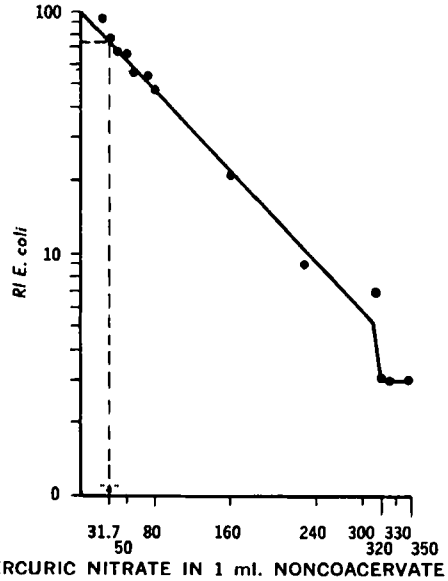

Figure 5—*Effect of phenylmercuric nitrate on the reproductive index* (RI) *of* E. coli *B/r.*

coacervate systems or the coacervation process itself had any effect on the potency of the antibacterial agents, several concentrations of each drug were incorporated into both coacervate and noncoacervate systems. Formation of the coacervate phase was suppressed by the addition of 0.18% sodium chloride. Aliquots were removed from each system and tested for antibacterial activity. The total counts of *E. coli* B/r were converted into reproductive index (*RI*) values, and the results are shown in Table II. Among all antimicrobial concentrations examined, the *t* test showed that the differences between the average *RI* values obtained for the noncoacervate and the suppressed coacervate were not significantly different ($p > 0.05$) except for the highest level of chloramphenicol. When 960 mcg. of chloramphenicol was placed into noncoacervate and suppressed coacervate systems, there was a significant ($p < 0.05$) decrease in antibacterial activity in the salt-treated suppressed coacervate system. This observation is attributed to experimental error, since coincidence of viable counts and total counts for much higher concentrations of chloramphenicol using *E. coli* were obtained, and no similar deviations were observed at these increased drug concentrations.

Coincidence of Total and Viable Counts—Agreement between the total (Coulter) counts and the viable (colony) counts of organisms per milliliter in drug-free and drug-treated cultures is evident for all values shown in Tables III–XII. Correlation of the *RI* values obtained by each method indicates that the drug concentration range selected with each organism was sufficient to inhibit partially the growth of the organisms. Furthermore, agreement between viable

cell counts and particle numbers determined by the Coulter counter technique indicated that only live cells were being counted by the more rapid electronic method. Neither cellular debris nor particulate contamination from the medium was interfering with a true count of the organisms exposed to the effects of the antimicrobial agent. Likewise, the addition of formaldehyde to the cell suspension before electronic counting suppressed further growth but did not disrupt the cells themselves. When systematic deviations occurred between *RI* values obtained from the two types of counting techniques, it was assumed that the amount of drug in the treated systems exceeded the minimum bactericidal concentration for the test organism; only dead organisms were counted by the Coulter counter technique and their number was equal to the number of organisms in the test culture (90 min. after inoculation but immediately before the drug was added).

To study the partitioning of the same drug at higher concentrations in coacervate systems, different microbiological test organisms were selected because of their relative resistance to the concentrations of drug being tested. In this way, a full range of drug concentrations, which exceeded the limit of biological response displayed by any one strain of organism to a particular drug, could be examined in coacervate systems using a variety of organisms (Figs. 1–4). As might be expected, the partition coefficient as determined by the microbiological methods was not dependent upon the particular strain of test organism, but rather there was excellent agreement between the partition coefficients calculated at drug concentrations where more than one organism was used to determine the *RI* values. It is obvious that by selecting organisms with varying sensitivities to the antibacterial or by varying the conditions under which the determinations are made, drug partitioning may be studied over the entire concentration range. In particular, the selection of organisms that were very highly sensitive to the drug permitted the extension of partitioning measurements to ranges far lower than could be detected by conventional chemical techniques.

Drug Partitioning: Calculation of the Partition Coefficient—*Microbiological Method*—In most instances, the experimental conditions were adjusted to produce a constant coacervate volume (V_1) of 2 ml. (Table III) and the total volume of each coacervate system (V) was 30 ml. From these values the volume of the equilibrium liquid (V_2) was calculated to be 28 ml. The partition coefficient of the four antimicrobials was calculated for a variety of total amounts of drug in the system (T) according to the equation developed in a previous paper (11):

$$PC = \frac{T}{aV_1} - \frac{V_2}{V_1} \qquad \text{(Eq. 1)}$$

where PC is the partition coefficient defined as the concentration of drug in the coacervate phase with respect to the concentration of the drug in the equilibrium liquid, and a is the concentration of drug in the equilibrium liquid (micrograms per milliliter). The value of a was determined graphically from growth-inhibition curves for each organism over a biosensitive drug range. The estimation of a may be summarized as follows:

1. Calculate *RI* values based on total organism numbers in flasks in both coacervate and noncoacervate drug systems. Where different sized inocula are used, reproductive coefficients (*RC*) are determined first and *RI* values are computed from the *RC* values. For convenience, designate the reproductive index from noncoacervate systems as RI_n and from coacervate systems as RI_c.
2. Plot log RI_n *versus* the concentration term T/V, where T and V have the same meanings as in Eq. 1. This relationship will yield a straight line which may be used as a "standard" curve for all subsequent determinations with the same drug–organism system (Fig. 5).

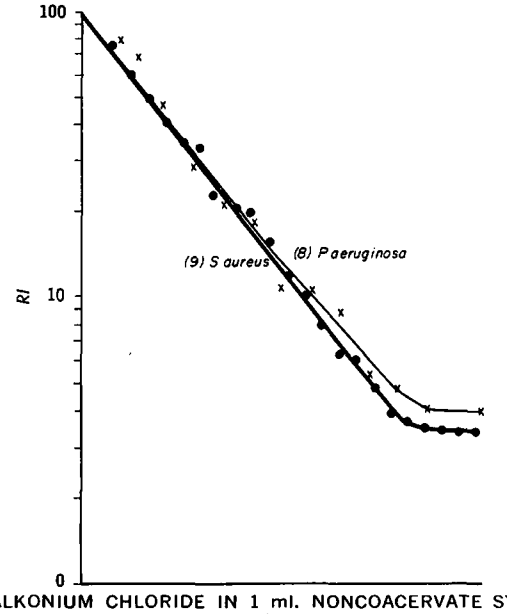

Figure 9—*Effect of benzalkonium chloride on the reproductive index* (RI) *of microorganisms. (Information concerning each line and the* x-*axis is found in Table XIII.)*

3. A drug concentration term may be obtained from the abscissa for each log RI_e value obtained from the coacervate systems. This value (micrograms per milliliter) is termed a and is used directly in Eq. 1 for the calculation of the partition coefficient. Partition coefficients for the antimicrobial agents calculated over a wide range of concentrations are contained in Tables IV–XII and Figs. 6–9.

Chemical Method—The partition coefficient of drug compounds may be calculated directly, using Eq. 1, in a manner that is very similar to that used with the microbiological technique. The concentration term a was determined from an appropriate chemical analysis of an aliquot of equilibrium liquid.

1. Phenylmercuric nitrate. Since phenylmercuric nitrate contains 63.2% (w/w) mercury, the organomercuric assay technique of Gage (21) utilizes a standard titrimetric solution of mercuric chloride which represents 1.1867 mcg. of phenylmercuric nitrate/ml. of titrant consumed in the analysis of 20 ml. of the equilibrium liquid. If n ml. of titrant is used in the assay, then the a value (concentration of drug in the equilibrium liquid) may be calculated directly from the equation:

$$a = \frac{1.1867n}{20} \qquad \text{(Eq. 2)}$$

and the partition coefficient of the drug in the coacervate system is determined once again from Eq. 1. Partition coefficients calculated by this method are given in Tables IV and V.

2. Furazolium chloride. By using the analytical techniques described for furazolium chloride, the concentration of drug in micrograms per milliliter of equilibrium liquid was calculated directly and designated as a. Partition coefficients, calculated from Eq. 1, are presented for furazolium chloride in Tables VI–VIII.

3. Chloramphenicol. The absorptivity (1%, 1 cm.) of the standard solution of chloramphenicol was calculated from the following equation:

$$\text{absorptivity} = \frac{\text{absorbance at 278 nm.} \times 100}{\text{mcg./ml. chloramphenicol standard solution}} \qquad \text{(Eq. 3)}$$

Since absorptivity is concentration independent, the absorbance at 278 nm. of appropriately treated equilibrium liquid samples divided by the absorptivity of chloramphenicol determined under identical conditions yields the concentration of the antimicrobial directly in terms of micrograms per milliliter. From this value the partition coefficient of the drug could be calculated, and Tables IX and X contain values at several drug concentrations.

4. Benzalkonium chloride. When the absorbance values of benzalkonium chloride were plotted against the concentration of the drug in accurately calibrated solutions (micrograms per milliliter), a straight-line standard curve was fitted from which the amount of benzalkonium chloride in the 20 ml. of equilibrium liquid could be calculated. The a value was determined directly, and Eq. 1 was used to calculate the partition coefficient in the usual way. These values are reported in Tables XI and XII.

Reliability of Microbiological Partition Coefficient—One main objective of this investigation was to develop a method whereby the partitioning of drugs in complex coacervate systems could be studied using microbiological end-points over a wide concentration range. The faithful correlation between partition coefficients obtained from both chemical and microbiological methods has established the validity of the newly developed method. However, at low concentrations of drug, deviations arise between the partition coefficient values obtained by the two methods. These are attributed to a general lack of sensitivity of the chemical methods at extremely low drug concentrations. The main advantage of the microbiological method over the chemical analysis (apart from its extended lower limit of sensitivity) is that any subtle physical or chemical alteration in the drug, resulting from the experimental processes, might affect the biological activity of such compounds. Yet such changes are not detected by ordinary chemical methods and generally emerge only when one tests for the biological potency of the compound along with chemical analysis. The sensitivity of microorganisms to biologically active substances provides especially good end-points for the measurement of such compounds. Any changes in the metabolic processes of susceptible organisms as a result of drug action are grossly reflected in the growth rate and reproductive index.

Partition coefficients calculated from the microbiological method described here were plotted *versus* T, the total amount of drug in the coacervate systems (Figs. 1–4). The mechanism of the partitioning of some organic compounds was studied by Takruri (12), who postulated that the effect was based on the differences in water structure between the phases of the experimental model. According to his view, compounds such as benzalkonium chloride and furazolium chloride are "structure makers" and the enhanced structure of water in the coacervate phase at least partially accounts for the unusually high partitioning of these compounds. Diamond (25) showed that tetraalkyl ammonium chlorides exhibited positive deviations from the Debye-Huckel limiting law. According to Diamond, the partitioning of benzalkonium chloride in coacervate systems could be interpreted as a salting-out effect. As seen from Fig. 4, phenylmercuric nitrate shows the same characteristics as furazolium chloride or benzalkonium chloride. The uptake of this salt by the coacervate phase can be interpreted on the basis of an interaction of a hydrophobic ion with water and macromolecules. Chloramphenicol shows a situation opposite to that of the others. But the curves in Figs. 1, 2, and 4 show the same trend; *i.e.*, the partition coefficient is related directly to concentration at low levels of drug and then falls off sharply from a maximum value which varied with each drug.

We postulate that the constant partition coefficient truly represents a saturation of all binding sites on the macromolecular components in the coacervate phase, and the peak found with furazolium chloride (Fig. 2) may represent an alteration in the mechanism of the binding to protein molecules or a complex state of aggregation of the drug in the equilibrium liquid phase. In this way the coacervate model system may become an important adjunct to the study of processes affecting the protein binding of drug molecules to macromolecular components; inflections and peaks in the partition coefficient function with respect to total drug amounts in the system represent the result of ongoing binding and aggregational processes in both the coacervate and equilibrium phases. Further studies are in progress to elucidate more clearly the mechanisms involved in the binding of drug entities with the proteins in the complex coacervate model. Such studies may contribute to the understanding of the component processes involved in the partitioning of small molecules in biological models.

Steady-State and Nonsteady-State Transport through Membranes Using Rotating-Disk Electrode Polarography: Description and Properties of a Rapid Response New Technique

YIE WEN CHIEN*, CARTER L. OLSON, and THEODORE D. SOKOLOSKI▲

Abstract □ A new rapid response technique was developed to measure both steady-state and nonsteady-state flux (mass transport rate, moles per second) through membranes. The system utilizes a rotating-disk electrode, which is covered with a porous membrane and connected to a polarographic module. The rotating-disk configuration provides a uniform flux density over the entire surface of the membrane. Since flux is directly measured as current, there is no need to construct a concentration *versus* time plot to obtain steady-state permeability and there is no need to rely on lag time to measure effective diffusivity. The use of lag times for this purpose has recently been shown to introduce significant errors in estimating diffusivity. In this technique, the membrane is placed on the surface of the electrode. In the receiving compartment, response to flux is so rapid that nonsteady-state diffusion may be characterized. Moreover, it is possible to determine steady-state flux in the same experimental trial in short time periods. The technique and its use are described and theoretically explained through basic electrochemical and diffusion principles. The reproducibility achieved in transport measurements is seen to be quite good.

Keyphrases □ Transport through membranes—methodology, equations for measuring steady-state and nonsteady-state flux using rotating-disk polarography □ Membranes, characterization of transport—methodology, equations for measuring steady-state and nonsteady-state flux using rotating-disk polarography □ Polarography, rotating disk—used to measure steady-state and nonsteady-state transport through membranes, theory, equations □ Rotating-disk polarography—used to measure steady-state and nonsteady-state transport through membranes, theory, equations

Transport processes occurring across a membrane barrier separating a solution phase from another solution or solid phase continue to be of great interest to pharmaceutical scientists. Among these interests are: (*a*) a better understanding of the mechanisms of transport in order to develop new membrane systems having controlled drug-release properties, and (*b*) the characterization, through the use of models, of the probable mechanisms and behavior of complex biomembranes in terms of physicochemical principles.

There have been numerous studies dealing with the measurement of mass transport of drug and drug-like molecules across a large variety of membranes or barriers, ranging from model membranes to biological membranes themselves (1–9). In most instances (1–6, 9), the actual measurement of membrane permeation has been conducted along rather classical lines where the barrier separates two compartments of solution, the contents of which are sampled as a function of time. Light absorption is the measurement technique most commonly used. The usual time course of measurement of mass transport ranges from several hours to over a day, primarily because the ratio of compartment volume to barrier surface area is large. Even in recently developed systems (7, 8) where sampling is not required and where the volume to area ratio is low, the detector is positioned away from the immediate surface of the membrane barrier in the receiving compartment, causing a time lag in transport measurement. The technique described in this paper does not suffer from this disadvantage.

It is apparent from the literature that the design of a suitable diffusion measurement system is complex. Variables such as membrane integrity, area, and thickness; compartment volumes and concentrations; reproducibility of sampling; stirring; and temperature must be controlled. Many diffusional cell prototypes may be found (1–6, 9–16) and, considering that most were designed for similar purposes, their diversity is remarkable. Flynn and Smith (7) classified these cell systems and analyzed their advantages and disadvantages.

One prime concern of making permeability measurements is the ability to determine flux (mass transport

Transport processes occurring across a membrane barrier separating a solution phase from another solution or solid phase continue to be of great interest to pharmaceutical scientists. Among these interests are: (*a*) a better understanding of the mechanisms of transport in order to develop new membrane systems having controlled drug-release properties, and (*b*) the characterization, through the use of models, of the probable mechanisms and behavior of complex biomembranes in terms of physicochemical principles.

There have been numerous studies dealing with the measurement of mass transport of drug and drug-like molecules across a large variety of membranes or barriers, ranging from model membranes to biological membranes themselves (1–9). In most instances (1–6, 9), the actual measurement of membrane permeation has been conducted along rather classical lines where the barrier separates two compartments of solution, the contents of which are sampled as a function of time. Light absorption is the measurement technique most commonly used. The usual time course of measurement of mass transport ranges from several hours to over a day, primarily because the ratio of compartment volume to barrier surface area is large. Even in recently developed systems (7, 8) where sampling is not required and where the volume to area ratio is low, the detector is positioned away from the immediate surface of the membrane barrier in the receiving compartment, causing a time lag in transport measurement. The technique described in this paper does not suffer from this disadvantage.

It is apparent from the literature that the design of a suitable diffusion measurement system is complex. Variables such as membrane integrity, area, and thickness; compartment volumes and concentrations; reproducibility of sampling; stirring; and temperature must be controlled. Many diffusional cell prototypes may be found (1–6, 9–16) and, considering that most were designed for similar purposes, their diversity is remarkable. Flynn and Smith (7) classified these cell systems and analyzed their advantages and disadvantages.

One prime concern of making permeability measurements is the ability to determine flux (mass transport

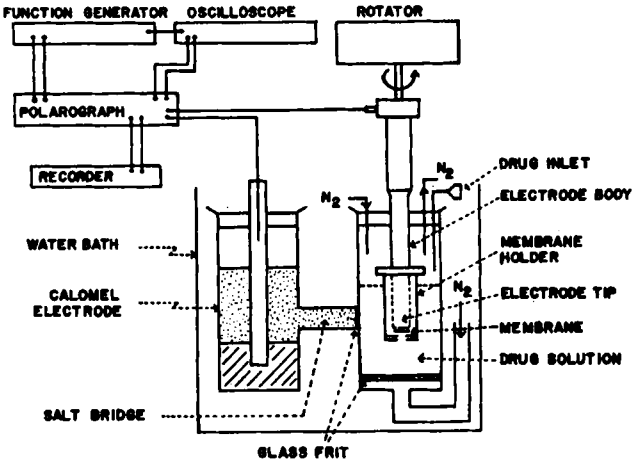

Figure 1—*Schematic representation of the electrochemical system used to measure drug transport.*

rate, moles per second) reliably in as short a time as possible. With this in mind, a relatively simple and easily assembled transport cell was constructed. A membrane is positioned smoothly on the immediate surface of a rotating-disk electrode. The flux or transport of material through the membrane is proportional to the current measured polarographically at a constant potential. The response is very rapid, permitting direct measurement of both the initial nonsteady-state and the steady-state membrane transport. The sensitivity of a diffusional cell is proportional to the available diffusional area divided by the solution volume of the receiving compartment (8). The receiving compartment in the present system has a negligible volume because the detector is positioned directly on the membrane surface. Therefore, the detector signal is directly proportional to the flux across the membrane rather than to the receiving compartment concentration.

The high speed rotating-disk configuration has the advantage of uniform, controlled flux to the outside membrane interface. At high rotation speed, the solution diffusion layer thickness may become negligible with respect to membrane thickness. In any case, the thickness of the convective diffusion layer on the surface of the membrane may be controlled and calculated. The concentration at the electrode surface can be set to zero by setting the voltage on the diffusion current plateau. The high sensitivity, rapid response, and nonsampling method utilized permits the observation of transient phenomena which may be significant to the mechanism of membrane transport but which may be overlooked using slower conventional methodology.

The lag time technique of Daynes (17) and Barrer (18) has been popularly applied in conventional mass transport systems to calculate the diffusivity of drug species. Steady-state transport should be calculated from data taken after two lag times; otherwise, significant errors may result in determining the extrapolated lag time and in calculating diffusivity.

Siegel and Coughlin (19) recently made a theoretical analysis of such calculations and they concluded that the relative errors in lag time calculations can be as much as five times larger than the errors obtained from calculations based on the slope of steady-state permeability. Their analysis suggests that the error in diffusivity will always be several times larger than the error in permeability when such techniques are employed. In the method introduced here, diffusivity can be estimated either directly from steady-state permeability or from kinetic analysis of nonsteady-state transport without the use of lag time estimates.

Although extensive experimental and theoretical studies have been made on the permeation of gases through various materials, diffusion in polymer membranes has received relatively limited attention, particularly with regard to the short-time dynamic nature of drug permeation across barriers. In general, two different phenomenological mechanisms are met in the flow of penetrant species through thin membranes. These are molecular transport involving partitioning of the penetrant into the membrane structure, followed by molecular diffusion across it, and passage of penetrant molecules through membrane pore channels filled with solvent. Transport through a nonporous barrier depends on the relative solubility of the penetrant in the barrier as compared to its solubility in the donor and receiving compartments.

The new technique described in this paper provides a direct measurement of flux both at steady-state and nonsteady-state diffusion conditions.

EXPERIMENTAL

Apparatus—The system used in these studies is shown in Fig. 1. A polarographic H-cell is immersed in a constant-temperature bath[1] at 30 ± 0.1°. The left side of the cell contains a saturated calomel reference electrode (S.C.E.) connected to the working half of the cell (on the right) *via* a salt bridge. The working cell contains 10–20 ml. of test solution. The electrode is immersed in this solution and either rotated or held stationary. The working and reference electrodes are connected to a polarograph[2]. Current is measured either with a strip-chart recorder[3] or an oscilloscope[4]. The recorder is used for time measurements greater than 0.5 sec., and the oscilloscope is used for shorter times. For short-time

[3] Varian model G-14.
[4] Hewlett Packard model 141A.

measurements, the potential from the polarograph is controlled by a function generator[6]. The test solution is deaerated with nitrogen gas, and a nitrogen atmosphere is maintained above the solution during measurements. Drug is introduced into the working side of the electrode by injecting a small volume (0.2–1.0 ml.) of a concentrated predeaerated drug solution *via* the drug inlet from a calibrated microsyringe.

A membrane sheet is positioned on the electrode surface using a cell holder made of Teflon (Fig. 2). A small hole is drilled on the upper edge of the holder to balance pressures across the membrane and to minimize hydrodynamic transport through the covering membrane. The entire assembly is rotated at a constant speed with a rotating electrode assembly[6]. Speeds ranging from 0.6 to 6000 r.p.m. are possible with this assembly. Two types of electrode tips were used: a platinum tip[7], which was coated with mercury according to the method of Ramaley *et al.* (20), and a carbon electrode[8]. The carbon electrode permits the use of a wide potential range, has a low residual or background current, provides good reproducibility, and requires little pretreatment. Both electrodes have a smooth surface. The membrane is placed directly on the electrode surface as shown in Fig. 2.

Materials—The supporting electrolyte used in the studies was 0.2 *M* acetate buffer, pH 4.0. The pH selected assures that the electroactive species, *p*-nitrophenol[9], is totally undissociated (pKa 7.12) and that the buffer is of sufficient concentration to obviate pH changes at the electrode surface due to the consumption of protons. *p*-Nitrophenol was found to be 99% pure by potentiometric titration.

Two membranes were used in the study: (*a*) Millipore membranes[10] of cellulose acetate–cellulose nitrate mixtures and (*b*) dialysis membranes[11] with a pore radius of 24 Å and a dry thickness of 25 μ.

Method—All of the membranes were compatible with the solutions used and were presoaked in the buffer system overnight in a refrigerator before use.

The general procedure used for the measurement of steady-state and nonsteady-state transport of *p*-nitrophenol through the various membranes was as follows. Seventeen milliliters of supporting electrolyte was placed in the working compartment of the polarographic H-cell and deaerated for 5 min. with nitrogen gas. A solution of *p*-nitrophenol was separately prepared in the same supporting electrolyte and deaerated for 3 min. The transport cell containing the membrane was assembled (Fig. 2) and placed on the electrode tip. The electrode assembly was placed in the solution and rotated at a fixed speed until equilibration occurred. The current-potential curves for *p*-nitrophenol were determined, and the results are listed in Table I. A constant potential of −1.0 v. *versus* S.C.E. was applied, and the steady-state residual current was measured. One milliliter of the concentrated *p*-nitrophenol solution was rapidly injected into the cell compartment. The current increased with time until it reached a steady-state value. After steady state was reached, an additional 0.4 ml. of solution was introduced, giving rise to a new steady-state current. The incremental procedure was continued until a suitable calibration curve was obtained.

RESULTS AND DISCUSSION

The current–time relation predicted for a plane electrode in a quiet (unstirred) solution is given by the equation:

$$i = \frac{nFAD^{1/2}C}{\sqrt{\pi t}} \qquad \text{(Eq. 1)}$$

where n is the number of electrons transferred (4 for *p*-nitrophenol at pH 4), F is the Faraday constant (96,500 coulombs per equivalent), A is the electrode surface area in square centimeters, D is the diffusion coefficient (9.18×10^{-6} cm.^{2} sec.$^{-1}$ for *p*-nitrophenol), C is the bulk concentration of electroactive species in millimoles per liter, t is the time after start of electrolysis in seconds, and i is the faradaic current in microamperes. A plot of i *versus* $(t)^{-1/2}$ should be a straight line with slope $nFAD^{1/2}C(\pi)^{-1/2}$. When a membrane covers the electrode surface, the effective area of the electrode is reduced to an amount equal to the porosity of the membrane. Figure 3 shows the results for the reduction of *p*-nitrophenol with and without a Millipore membrane on the electrode surface. The experimental slope without a membrane was 2.89×10^3 μa. sec.$^{1/2}$ M^{-1} compared to a theoretical value of 2.87×10^3 (A = 0.232 cm.^{2}), which is excellent agreement. The experimental slope with the Millipore membrane was 2.23×10^3 μa. sec.$^{1/2}$ M^{-1} compared to a theoretical value calculated to be 2.13×10^3, based on the manufacturer's specifications of 74% porosity, which again is in good agreement.

If a disk electrode is placed into solution and rotated at a constant angular velocity, the mass transport of electroactive material to the electrode surface by means of convective diffusion is much greater than obtained by linear diffusion to a stationary electrode of equal area (22–25). A relationship describing the thickness of the convective diffusion layer, δ_D, at a rotating-disk electrode was derived by Levich (26–27):

$$\delta_D = 1.62D^{1/3}\nu^{1/6}\omega^{-1/2} \qquad \text{(Eq. 2)}$$

where D is again the diffusion coefficient, ν is the kinematic viscosity, and ω is the angular rotation in radians per second. The rotating-disk configuration is the only convective diffusion geometry where flux, *i.e.*, δ_D, is a constant over the entire surface. The

The current obtained at a membrane-covered rotating-disk electrode is controlled by both the permeability of the membrane and the convective diffusion layer at the outer surface of the membrane. Figure 4 shows a typical plot of current *versus* electrode rotation speed for both a bare and a membrane-covered electrode. When the rotational velocity of the electrode becomes sufficiently large, the transport of material to the electrode surface is controlled primarily by diffusion across the membrane. The measured current, therefore, reaches a plateau, becomes independent of increased rotational velocity, and is directly proportional to the diffusion-controlled transport or flux of material across the membrane.

A typical result obtained in measuring transport through a membrane covering a rapidly rotating disk electrode (3000 r.p.m.) is presented in Fig. 5. *p*-Nitrophenol is rapidly injected into the cell at time zero after allowing the system to come to equilibrium. After a short lag time, the current increases with time, eventually reaching a steady-state flux as defined by Eq. 3, where δ_D becomes the sum of the thickness of the stagnant layer and the effective membrane path. At the steady-state condition, a subsequent addition of *p*-nitrophenol from a concentrated deaerated solution leads to a new

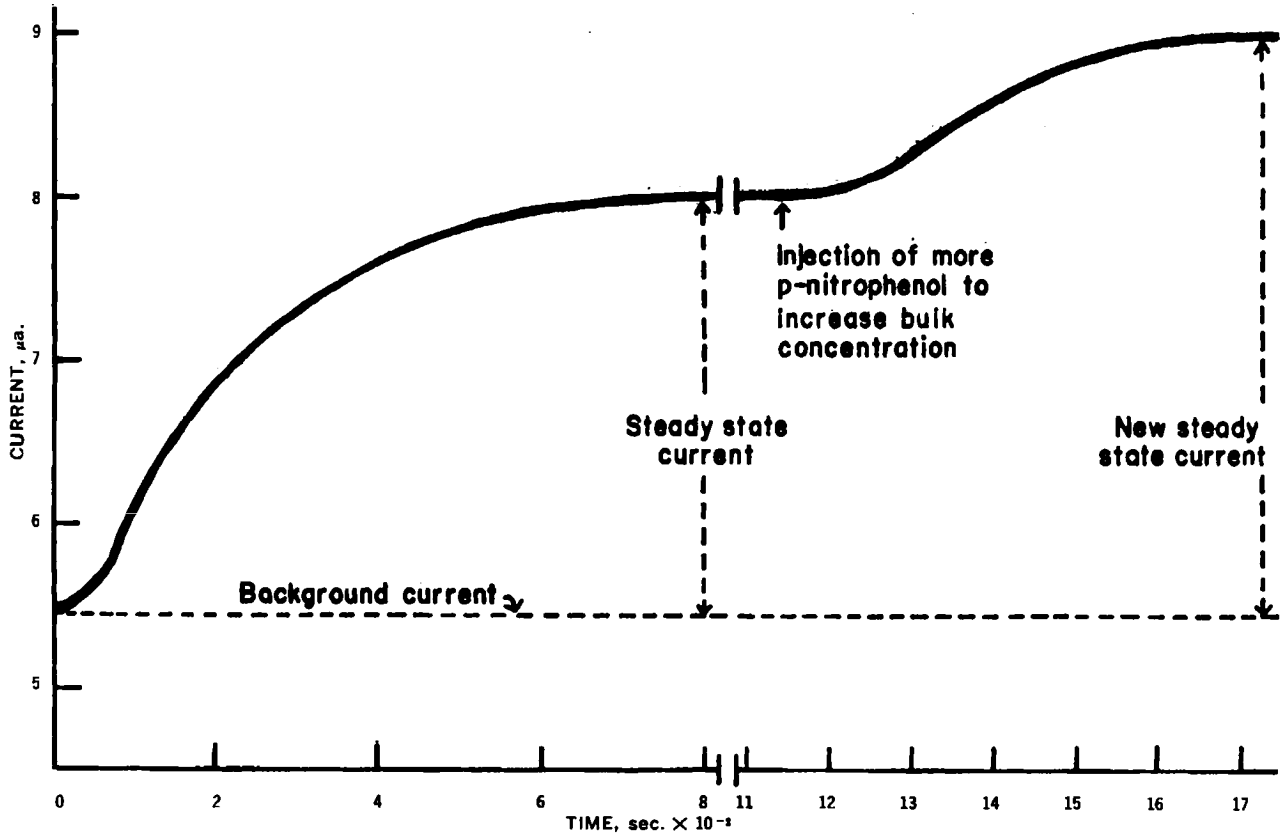

Figure 5—*Relation between current and time in the transport of* p-*nitrophenol through a Millipore membrane, type GS, where successive amounts of compound are added.*

steady-state flux. This procedure may be repeated several times to give additional steady-state currents.

Membrane permeability, P_m, calculated from the steady-state current:

$$P_m = \frac{i_{ss}}{nFC} \qquad \text{(Eq. 5)}$$

is determined by two parameters, porosity and effective membrane thickness, which includes tortuosity effects and the stagnant solution layer on the surface of the membrane. To evaluate porosity and effective membrane thickness, additional experimental data are needed. In the present technique the additional data are derived from the time-dependent (nonsteady-state) flux as presented in Fig. 5. Several investigators have derived expressions describing the flux through a membrane as a function of time following a step or rapid change in concentration on one side of the membrane (28–30). In particular, Bowers and Wilson (31) derived an expression relating current to time for a membrane-covered electrode following a step jump in concentration of electroactive species in the stirred solution outside the membrane:

$$i_t = \frac{nFADC}{\delta}\left[1 + 2\sum_{m=1}^{\infty}(-1)^m \exp(-m^2\pi^2)t/\delta^2\right] \qquad \text{(Eq. 6)}$$

where i_t is the current at time t, δ is the effective diffusional thickness, and the other terms are as previously described. Although the electrode type and solution hydrodynamics are different in the Bowers–Wilson experiment, the boundary conditions for transport are the same and the equation is thus valid for a membrane-covered disk electrode when rotational velocity is rapid and constant. Typical experimental values indicate that the summation terms of Eq. 6 converge very rapidly. For example, if it is assumed that $\pi D/\delta^2 = 1$ sec.$^{-1}$, at $t = 1$ sec. an error of 6% would occur in neglecting terms where $m > 1$, and at $t = 2$ sec. the error is less than 0.1%. Neglecting summation terms of $m > 1$ and substituting Eq. 3 into Eq. 6 give:

$$i_t = i_{ss}[1 - 2\exp(-\pi^2 Dt/\delta^2)] \qquad \text{(Eq. 7)}$$

Thus, the value for the effective diffusional path, δ, can be obtained from the slope of a plot of ln $(i_{ss} - i_t)$ *versus* t where the slope is $\pi^2 D/\delta^2$. A typical semilogarithmic plot is shown in Fig. 6. By using the kinetically determined value of δ, it is possible to calculate the porosity, ϵ, of the membrane through the use of the experimentally determined permeability, P_m:

$$P_m = \frac{i_{ss}}{nFC} = \frac{DA}{\delta}\epsilon \qquad \text{(Eq. 8)}$$

Figure 7 shows a typical experimental result demonstrating the applicability of Eq. 8. The slopes of plots of current *versus* concentration give P_m. Thus, by knowing n, F, D, and A (the area of the bare electrode, 0.232 cm.^{2}), the porosity of the membrane, ϵ, may be calculated.

The experimental results obtained for a series of Millipore membranes are given in Table II. The calculated values for porosity are in excellent agreement with the reported values for the Millipore membranes. It is thought that the methodology described is well suited for studying both the steady-state and transient (nonsteady-state) characteristics of membrane transport. From Eqs. 3 and 4, it can be seen that the steady-state current is directly proportional to bulk solution concentration. If a dialysis membrane is placed on the surface of an electrode, macromolecules and molecules bound to macromolecules are excluded from reaching the electrode surface. The use of the methodology as a rapid means to study protein binding is the subject of another paper (32).

Use of Membrane-Covered Rotating-Disk Electrode to Study Binding of Drugs to Macromolecules: Competitive Binding of 2-(4′-Hydroxybenzeneazo)benzoic Acid and α-(4-Chlorophenoxy)-α-methylpropionic Acid to Serum Albumins

YIE WEN CHIEN*, THEODORE D. SOKOLOSKI▲, CARTER L. OLSON, DONALD T. WITIAK, and RALPH NAZARETH

Abstract □ A new technique is introduced to study the binding of drugs to macromolecules. The method utilizes rotating-disk polarography in which a semipermeable membrane covers the surface of the electrode. The membrane permits passage of an electroactive drug but restricts permeability of the macromolecule and of bound drug. The current generated at the electrode at steady state is directly proportional to the concentration of free drug in bulk solution, from which a calculation of the amount of drug bound may be made. The methodology used provides a complete characterization of binding within about 1 hr. and is, therefore, faster than conventional techniques presently used. Another advantage of this technique is that relatively small amounts of the compounds being studied are required. The method is compared with equilibrium dialysis and ultrafiltration techniques by studying the binding of 2-(4′-hydroxybenzeneazo)benzoic acid (I) to serum albumin and is found to give precisely the same results. α-(4-Chlorophenoxy)-α-methylpropionic acid (II), in previous spectrophotometric studies, showed an anomalous effect on the binding of I to rat serum albumin. At low concentrations, there was an indication that II may increase the binding of I to rat serum albumin. This phenomenon was reinvestigated using the new electrochemical method; it was found that II competitively inhibits the binding of I at all concentration levels of the inhibitor. The conclusion is reached that II affects the nature of the I binding site rather than the number of molecules bound.

Keyphrases □ 2-(4′-Hydroxybenzeneazo)benzoic acid binding to serum albumins—presence, absence of α-(4-chlorophenoxy)-α-methylpropionic acid, rotating-disk polarography method, compared to conventional techniques □ α-(4-Chlorophenoxy)-α-methylpropionic acid—competitive binding with 2-(4′-hydroxybenzeneazo)benzoic acid to serum albumin, rotating-disk polarography method □ Polarography, rotating disk—used in binding studies, compared to equilibrium dialysis and ultrafiltration techniques □ Rotating-disk polarography—used in binding studies, compared to equilibrium dialysis and ultrafiltration techniques □ Serum protein binding, competitive—2-(4′-hydroxybenzeneazo)benzoic acid and α-(4-chlorophenoxy)-α-methylpropionic acid, rotating-disk polarography method □ Binding of drugs to macromolecules—studied using rotating-disk polarography, compared to equilibrium dialysis and ultrafiltration techniques

Classical methods employed to detect and determine the binding characteristics of small molecules to serum albumin have been discussed by several authors (1–3). Techniques such as equilibrium dialysis, ultracentrifugation, light absorption and rotation, and ultrafiltration have been used. The methods conventionally used require long periods of time to collect analyzable data and/or relatively large amounts of reactants, some of which can be costly. Nonequilibrium dialysis techniques (4–7) are generally faster and use less materials than conventional methods but can require cumbersome data analysis. The method of Meyer and Guttman (5), for example, takes about 6 hr. to collect data and requires the use of computer curve-fitting techniques to estimate the number of molecules bound to albumin.

To overcome some of these disadvantages, we applied a technology, developed in these laboratories (8), that was previously used to study mass transport. The technique employed to study mass transport across membranes utilized rotating-disk polarography where a membrane sheet is placed on the surface of a carbon or mercury-coated platinum tip electrode. If the membrane used is semipermeable, allowing only small electrochemically active molecules to penetrate, a system is obtained that is analogous to the thermodynamically well-defined equilibrium dialysis technique. There is,

Classical methods employed to detect and determine the binding characteristics of small molecules to serum albumin have been discussed by several authors (1–3). Techniques such as equilibrium dialysis, ultracentrifugation, light absorption and rotation, and ultrafiltration have been used. The methods conventionally used require long periods of time to collect analyzable data and/or relatively large amounts of reactants, some of which can be costly. Nonequilibrium dialysis techniques (4–7) are generally faster and use less materials than conventional methods but can require cumbersome data analysis. The method of Meyer and Guttman (5), for example, takes about 6 hr. to collect data and requires the use of computer curve-fitting techniques to estimate the number of molecules bound to albumin.

To overcome some of these disadvantages, we applied a technology, developed in these laboratories (8), that was previously used to study mass transport. The technique employed to study mass transport across membranes utilized rotating-disk polarography where a membrane sheet is placed on the surface of a carbon or mercury-coated platinum tip electrode. If the membrane used is semipermeable, allowing only small electrochemically active molecules to penetrate, a system is obtained that is analogous to the thermodynamically well-defined equilibrium dialysis technique. There is,

however, one notable difference. The steady-state current obtained at the electrode at a constant applied potential is directly proportional to the concentration of electrolyzable material in the bulk solution. Since only small molecules can penetrate the membrane, it is possible to measure in a very short time (from 18 to 30 sec.) the concentration of unbound drug in a solution containing a macromolecule with which it interacts. By successively increasing the total amount of small drug molecule in the bulk solution, enough data can be obtained in 1 hr. (up to 16 points in the present study) to characterize completely the binding of the drug. The membrane also functions to protect the surface of the electrode from contamination by protein (9).

This paper describes the binding of 2-(4′-hydroxybenzeneazo)benzoic acid (I) to various serum albumins in the presence and absence of a competitive inhibitor α-(4-chlorophenoxy)-α-methylpropionic acid (II). In addition to showing that the new methodology gives the same binding results as those obtained by conventional equilibrium dialysis and ultrafiltration techniques, it provides further insight into the effect that II has on the interaction of I to rat serum albumin.

In an earlier work carried out in this laboratory (10), the competitive binding of I and II to several different serum albumins was studied using equilibrium dialysis and extrinsic rotatory dispersion. A unique behavior was observed for rat serum albumin; using spectrophotometry, low concentrations of II appeared to enhance the binding of I to the albumin. This observation and concomitant extrinsic rotatory dispersion studies suggested that II was causing a small molecular perturbation in rat serum albumin. The results could be interpreted in a number of ways. Either II liberates additional binding sites for interaction with I, or II affects the nature of the interaction of I without increasing the number of I molecules bound. This study was undertaken to determine which of these possible mechanisms was taking place.

EXPERIMENTAL

Materials—Bovine serum albumin[1] (Fraction V, fatty acid poor) and rat serum albumin[2] (Fraction V) were used as obtained without further purification. Two brands[3] of 2-(4′-hydroxybenzeneazo)-benzoic acid (I) were used; both showed similar electrochemical and binding properties. α-(4-Chlorophenoxy)-α-methylpropionic acid (II) was prepared according to a method previously described (11). All solutions used were buffered at pH 7.4 using 0.1 *M* sodium phosphate.

Dialysis tubing[4] with an average pore radius of 24 Å and a dry thickness of 0.0041 cm. (0.0016 in.) was used. Disks of 0.9 cm. (0.37 in.) diameter were cut and washed several times with boiling double-distilled water and stored in a preserving solution containing 0.3% benzoic acid and 10% glycerin. One day before use, the disk was washed with distilled water and soaked overnight in refrigerated phosphate buffer. The disk was positioned on the surface of the electrode, as described in an earlier study (8), immediately prior to collection of data.

Binding by Electrochemical Method—The apparatus and techniques used in these studies were the same as those described previously (8). A small modification in procedure was made to cope with the tendency of protein and concentrated drug solutions to foam.

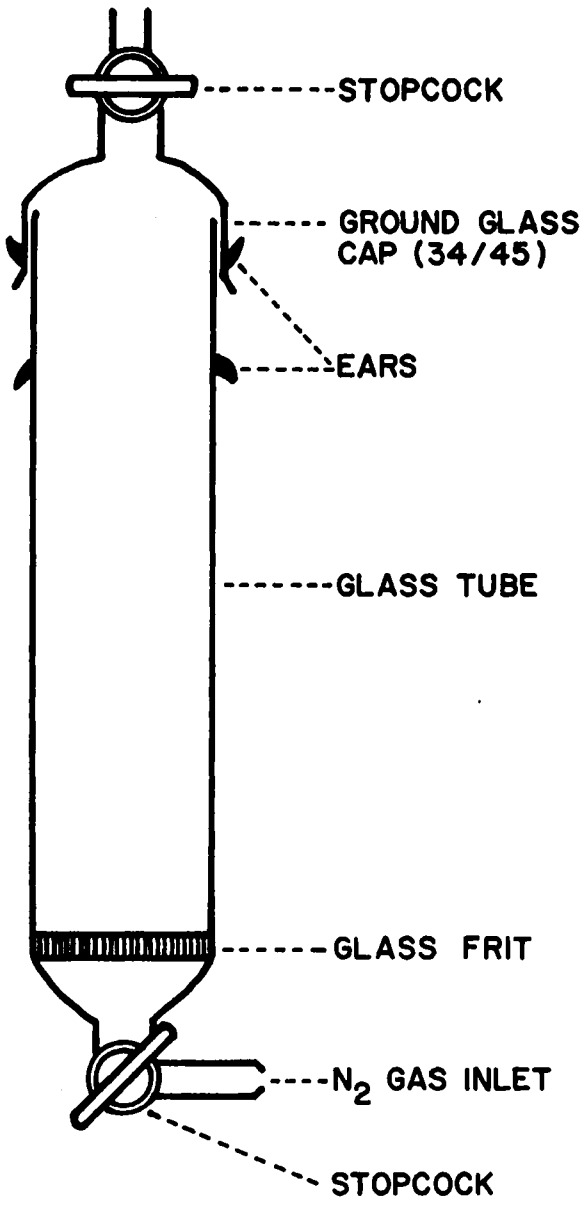

Figure 1—*Deaeration column for concentrated drug solutions or protein-containing solutions.*

Stock solutions of I, II, and albumin were made separately in pH 7.4 phosphate buffer. Deaeration was done in a specially fabricated apparatus (Fig. 1) to avoid subsequent foaming in the electrolysis cell. Adequate deaeration was accomplished in 5 min. Fifteen milliliters of deaerated protein solution was delivered with the use of a syringe to the right-hand side of the polarographic cell; a nitrogen atmosphere was maintained above the solution. The cell holder, containing the dialysis membrane, was assembled with the carbon electrode tip in place as previously described (8). The membrane electrode assembly was mounted on the electrode body and rotated at 1200 r.p.m. This rotation speed was used since it did not produce significant foaming.

A potential of −1.0 v. was applied to the working electrode, and the current was measured[5]. With no I added, the current represents background. Using a calibrated syringe, 1.0 ml. of a concentrated I solution was injected rapidly into the working compartment. After a short induction period, the current increased with time, eventually reaching a steady-state value. Depending on the concentration of I,

[5] The current was recorded on a calibrated Varian model HG-14 recorder.

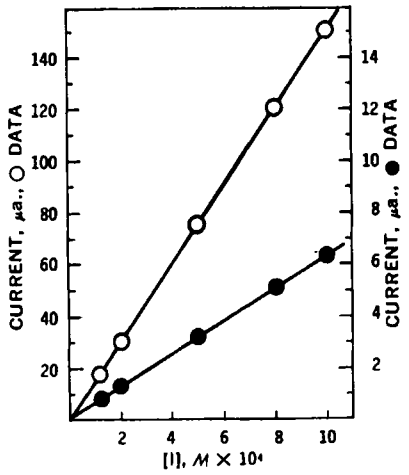

Figure 2—*Relation between steady-state diffusion current and concentration of I in bulk solution. Key: O, bare electrode, slope = 150 × 10³ μa. M⁻¹; and ●, dialysis membrane-covered electrode, slope = 6.3 × 10³ μa. M⁻¹.*

the time needed to reach steady state was 18–30 sec. After the steady-state current was attained, another 0.40 ml. of concentrated solution was injected, thereby increasing the bulk concentration of I and giving a new steady-state current. Additional 0.40-ml. portions of the concentrated solution may be added in a similar manner, giving rise to new steady-state currents. In studying the competitive binding of I and II, 1.0 ml. of a concentrated I solution was added to the protein solution and the steady-state current was recorded. Compound II was then added in consecutively increasing amounts to the I–protein solution, and the change in steady-state current after each addition was recorded. The concentration of all reactants was corrected for the small volume change following the addition of the consecutively added concentrated solutions. The amount of I removed from bulk solution due to reduction at the electrode is negligible. All studies were made at a constant temperature of 30°.

Binding by Equilibrium Dialysis and Ultrafiltration—The procedure used to determine drug binding by equilibrium dialysis studies was identical to the one reported earlier (10). Ultrafiltration measurements were made using a 10-ml. ultrafiltration cell[6] and a membrane[7]. Ten milliliters of drug–protein solution was placed in the cell, and 1 ml. of filtrate was collected. The filtrate was analyzed spectrophotometrically for free I. The absorbance for I at pH 7.4 is 17,682 l. M^{-1}.

RESULTS AND DISCUSSION

Use of Rotating-Disk Polarography to Study Protein Binding—At pH 7.4 and 30°, the azo group of I is electrochemically reduced at the carbon electrode, producing two reduction waves with half-wave potentials of −0.40 and −0.60 v. *versus* the standard calomel electrode, respectively. One electron is consumed at each wave. Compound II is electrochemically inactive in this potential range and does not interfere with the reduction of I. The maximum difference in viscosity between I, albumin, and I–albumin mixtures is about 4%. Thus, any viscosity effect on the electrochemical properties of I is negligible.

At an applied constant potential of −1.0 v. (the plateau or diffusion-controlled potential), the steady-state current at a bare electrode due to the reduction of I is a linear function of the concentration of I (Fig. 2). The slope of this linear relation is 1.5 × 10⁶ μa. M^{-1}. A linear relation between current and concentration also was observed for the membrane-covered electrode (Fig. 2). However, owing to the porosity of the membrane which decreases the effective area of the electrode and increases the diffusional path length, the slope of the line is reduced. The ratio of the slope without membrane to slope with membrane in Fig. 2 is 0.042. Even with this reduction in sensitivity, reliable data are obtained.

When serum albumin is present, the current generated at steady state is reduced due to the binding of I to the macromolecule (Fig. 3). Since the steady-state current is proportional to the concentration of free drug, the difference in current in the presence and absence of protein at a particular total concentration of I added is proportional to the drug bound. By using data as presented in Fig. 3, it is possible to calculate the moles of I bound per mole of albumin using a molecular weight of 67,000 for the albumin. Treating the data thus collected by the Scatchard method (12) shows that more

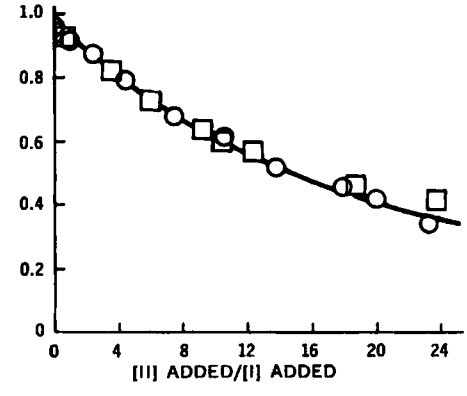

Figure 5—*Relation between the moles of I bound per mole of rat serum albumin r, with varying ratios of II:I added to bulk solution. The rat serum albumin and I concentrations are held constant at 9.4 × 10⁻⁵ and 1 × 10⁻⁴ M, respectively. The concentration of added II varies from 0 to 2.38 × 10⁻³ M.*

than one binding site is involved in the binding of I to bovine serum albumin (Fig. 4). The binding results obtained using the electrochemical method compare very well with those obtained using equilibrium dialysis and ultrafiltration (Fig. 4). However, results utilizing the rotating-disk technique can be obtained in a much shorter time and with considerably smaller amounts of materials.

Competive Binding between II and I—The observation made by Witiak *et al.* (10), indicating an unusual binding of I to rat serum albumin in the presence of low concentrations of II, was reinvestigated using both this electrochemical method and ultrafiltration. The spectrophotometric results in the Witiak *et al.* study could be interpreted in one of two ways: (*a*) II at low concentrations actually increases the number of molecules bound to rat serum albumin, or (*b*) II does not change the number of sites available for interaction but, rather, changes the nature of the binding. Use of the electrochemical method permitted direct measurement of the amount of I free in solution. The early studies (10) were based on indirect spectrophotometric measurement. Ultrafiltration also provided direct measurement of free I.

In the electrochemical studies, the concentrations of I and rat serum albumin were twice those used by Witiak *et al.* (10), but the ratio of I to rat serum albumin was the same (1.07). Hence, the binding character also should be the same. Increasing the II concentration from 0 to 23.8×10^{-4} *M* produced the results shown in Fig. 5. The concentration of II used falls into the range where anomalous effects previously were observed spectrophotometrically. As shown in Fig. 5, identical results were obtained using the ultrafiltration technique. It is clear from this figure that II replaces I from its binding sites even at low concentrations. Therefore, it is apparent that II increases the ϵ^{477} for bound I at lower concentrations (10), and this increase is not a reflection of increased binding of I to rat serum albumin.

The reasons for this increase in ϵ^{477} may, as previously suggested, be due to a small molecular perturbation in rat serum albumin, which changes the I–rat serum albumin extinction coefficient, or to an interaction of bound I with closely bound II.

Model Transport Studies Utilizing Lecithin Spherules III: Transport of Taurocholic Acid-[cholic-^{3}H(G)] in Buffered D-Glucose Solutions

ZAKA-UD-DIN T. CHOWHAN* and WILLIAM I. HIGUCHI▲

Abstract □ The transport of taurocholic acid-[cholic-^{3}H(G)] in liposome dispersions prepared from lecithin–dicetyl phosphate in buffered glucose solutions at different pH's was studied. The transport experiments were carried out using previously developed techniques in which the release of the solute is studied from dispersions contained in the dialysis bags. The experimental results of the direct-release and the uptake-release cases were analyzed by the monosize, multiconcentric layer Model 1 which was developed, evaluated, and used recently for D-glucose transport studies. Uniformly good fits of the experimental data with the model were observed, and the permeability coefficients and the aqueous–lipid partition coefficients for taurocholate transport in liposome dispersions were calculated. The pH dependence of the permeability coefficient indicated that the unionized form of taurocholic acid was being preferentially transported at low pH and that the taurocholate ion was the main species involved at high pH.

Keyphrases □ Permeability coefficients, taurocholic acid, radiolabeled—liposome dispersions □ D-Glucose solution—transport of taurocholic acid-[cholic-^{3}H(G)], lecithin spherule dispersions, permeability coefficients, pH effect □ Taurocholic acid, radiolabeled—transport in D-glucose solution, lecithin spherule dispersions, permeability coefficients, pH effect □ Lecithin spherules—model transport studies, taurocholic acid-[cholic-^{3}H(G)] in D-glucose solution, permeability coefficients □ Transport studies, model using lecithin spherules—taurocholic acid-[cholic-^{3}H(G)] in D-glucose solution, permeability coefficients, pH effect

In previous investigations (1, 2), quantitative methods were developed and used in the determination of permeability coefficients for D-glucose and 3-*O*-methyl-D-glucose in complex aqueous liposome dispersions. The release of the solutes from dispersions contained in a dialysis bag was studied as a function of time using

than one binding site is involved in the binding of I to bovine serum albumin (Fig. 4). The binding results obtained using the electrochemical method compare very well with those obtained using equilibrium dialysis and ultrafiltration (Fig. 4). However, results utilizing the rotating-disk technique can be obtained in a much shorter time and with considerably smaller amounts of materials.

Competive Binding between II and I—The observation made by Witiak *et al.* (10), indicating an unusual binding of I to rat serum albumin in the presence of low concentrations of II, was reinvestigated using both this electrochemical method and ultrafiltration. The spectrophotometric results in the Witiak *et al.* study could be interpreted in one of two ways: (*a*) II at low concentrations actually increases the number of molecules bound to rat serum albumin, or (*b*) II does not change the number of sites available for interaction but, rather, changes the nature of the binding. Use of the electrochemical method permitted direct measurement of the amount of I free in solution. The early studies (10) were based on indirect spectrophotometric measurement. Ultrafiltration also provided direct measurement of free I.

In the electrochemical studies, the concentrations of I and rat serum albumin were twice those used by Witiak *et al.* (10), but the ratio of I to rat serum albumin was the same (1.07). Hence, the binding character also should be the same. Increasing the II concentration from 0 to 23.8×10^{-4} *M* produced the results shown in Fig. 5. The concentration of II used falls into the range where anomalous effects previously were observed spectrophotometrically. As shown in Fig. 5, identical results were obtained using the ultrafiltration technique. It is clear from this figure that II replaces I from its binding sites even at low concentrations. Therefore, it is apparent that II increases the ϵ^{477} for bound I at lower concentrations (10), and this increase is not a reflection of increased binding of I to rat serum albumin.

The reasons for this increase in ϵ^{477} may, as previously suggested, be due to a small molecular perturbation in rat serum albumin, which changes the I–rat serum albumin extinction coefficient, or to an interaction of bound I with closely bound II.

Abstract □ The transport of taurocholic acid-[cholic-^{3}H(G)] in liposome dispersions prepared from lecithin–dicetyl phosphate in buffered glucose solutions at different pH's was studied. The transport experiments were carried out using previously developed techniques in which the release of the solute is studied from dispersions contained in the dialysis bags. The experimental results of the direct-release and the uptake-release cases were analyzed by the monosize, multiconcentric layer Model 1 which was developed, evaluated, and used recently for D-glucose transport studies. Uniformly good fits of the experimental data with the model were observed, and the permeability coefficients and the aqueous–lipid partition coefficients for taurocholate transport in liposome dispersions were calculated. The pH dependence of the permeability coefficient indicated that the unionized form of taurocholic acid was being preferentially transported at low pH and that the taurocholate ion was the main species involved at high pH.

Keyphrases □ Permeability coefficients, taurocholic acid, radiolabeled—liposome dispersions □ D-Glucose solution—transport of taurocholic acid-[cholic-^{3}H(G)], lecithin spherule dispersions, permeability coefficients, pH effect □ Taurocholic acid, radiolabeled—transport in D-glucose solution, lecithin spherule dispersions, permeability coefficients, pH effect □ Lecithin spherules—model transport studies, taurocholic acid-[cholic-^{3}H(G)] in D-glucose solution, permeability coefficients □ Transport studies, model using lecithin spherules—taurocholic acid-[cholic-^{3}H(G)] in D-glucose solution, permeability coefficients, pH effect

In previous investigations (1, 2), quantitative methods were developed and used in the determination of permeability coefficients for D-glucose and 3-*O*-methyl-D-glucose in complex aqueous liposome dispersions. The release of the solutes from dispersions contained in a dialysis bag was studied as a function of time using

direct-release and uptake-release experimental procedures. These data were analyzed using the monosize, multiconcentric layer models which assume that the spherules consist of multiconcentric bilayers of equal thickness separating aqueous compartments.

The purpose of the present investigation was to test the applicability of the previously developed techniques in the study of the transport behavior of an acidic compound, taurocholic acid. These studies were to be carried out under different pH conditions, and the influence of pH in altering the transport characteristics

pH	p	P	k_1	k_2
8 (0.01 *M* phosphate buffer)	1×10^{-9}	2.42×10^{-11}	34	140
8 (0.008 *M* phosphate buffer)	5×10^{-10}	1.21×10^{-11}	56	170
7 (0.01 *M* phosphate buffer)	5×10^{-10}	1.23×10^{-11}	50	260
5 (0.01 *M* acetate buffer)	1.5×10^{-9}	3.83×10^{-11}	82	290
4 (0.01 *M* acetate buffer)	4×10^{-8}	99.15×10^{-11}	95	345
3.6 (0.01 *M* acetate buffer)	8×10^{-8}	194.69×10^{-11}	210	600

of this solute was to be determined. It was hoped that the results of this study would help in the understanding of mechanisms that might be important in the movement of such molecules across biological membranes.

EXPERIMENTAL

General Considerations—The aqueous solution containing 5.1% anhydrous D-glucose was used earlier (1, 2) in the preparation of liposome dispersions. The same solution was used in the sink during a release run. Two reasons existed for the choice of this solution:

1. During the determination of the particle-size distribution by means of the Coulter counter, it was found important to make dilutions in 0.9% sodium chloride solution, which is isotonic, with the D-glucose solution used in the preparation of the dispersion.
2. It was not possible to prepare dispersions in 0.9% sodium chloride solution free from aggregates. Therefore, it was decided to conduct the present studies in buffered D-glucose solution at different pH's.

Materials—The procedures used in the purification of egg yolk lecithin were reported previously (1). Dicetyl phosphate[1] was used without further purification. Anhydrous D-glucose, potassium

phosphate monobasic and dibasic, sodium acetate, acetic acid, and chloroform were analytical reagent grade[2] and were used without further purification. Sodium chloride was also reagent grade[3] and used as such. The dialysis bags[4] were used without pretreatment. The water was double distilled in a glass apparatus. Taurocholic acid-[cholic-^{3}H(G)][5] was obtained in the form of methanol–ethanol (1:3) solution with a specific activity of 2–3 c./m*M*.

Apparatus and Procedures—The apparatus used for the taurocholic acid transport studies was exactly the same as reported previously (1). It consisted of a water-jacketed beaker and a dialysis bag holder–stirring assembly. Five milliliters of the dispersion was added to the dialysis bag, and at zero time the dialysis bag holder–stirring assembly was lowered into 100 ml. of sink solution maintained at 25°. The dispersion and the sink solution were stirred at 150 r.p.m. by two different stirring arrangements. At the end of each sampling time, the dialysis bag holder–stirring assembly was transferred to another water-jacketed beaker containing 100 ml. of fresh sink solution.

For the purpose of determining the bag constant (1, 2), the transport of the solute through the cellophane membrane was studied by the same procedure as used for the dispersion except that a buffered glucose solution containing the radioactive solute was used instead of the liposome dispersion.

The dispersions for the direct-release experiments were prepared (1) by mixing the chloroform solution of lecithin–dicetyl phosphate and the buffered glucose solution containing the radioactive solute. The solvent was then slowly removed using a flash evaporator with vacuum from a water aspirator. After the removal of chloroform, the dispersions were allowed to equilibrate for 2 hr. before starting the release run. The dispersions for the uptake-release experiments were prepared by the same procedure except that the radioactive solute was added to the dispersion after preparation.

The procedures for the determination of radioactive counts and for the Coulter counter particle-size distribution were the same as reported earlier (1).

THEORETICAL

Theoretical analyses carried out in the earlier reports (1, 2) indicated that the transport behavior of liposome dispersions could be quantitatively characterized by the physical models, assuming multiconcentric bilayers of lecithin separating aqueous compartments. The permeability coefficient per segment was related to the

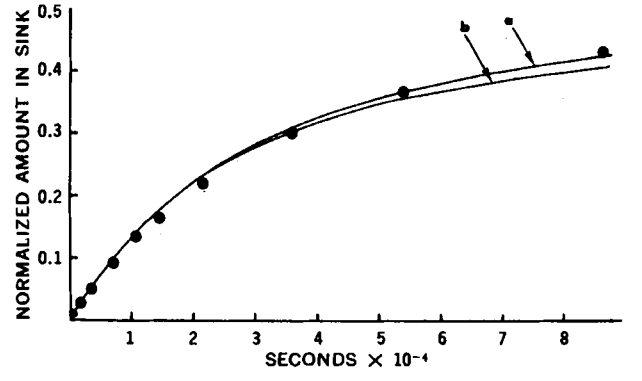

Figure 7—*Comparisons of the direct-release experimental data obtained from lecithin–dicetyl phosphate dispersions for taurocholic acid release in 0.01* M *acetate-buffered glucose solution at pH 5 with the calculations using the monosize, multiconcentric Model 1. For solid curves:* $k_1 = 82$, $k_2 = 290$, $p = 2.5 \times 10^{-6}$. *For broken curves:* $k_1 = 82$, $k_2 = 290$, $p = 1.5 \times 10^{-6}$. *Other parameter values are taken from Table II.*

effective bulk permeability coefficient by the following equation:

$$p = \frac{P \cdot n}{r} \qquad \text{(Eq. 1)}$$

where p is the permeability coefficient per segment; n and r are the number of concentric layers and radius of the spherule, respectively; and P is the effective bulk permeability coefficient.

It was shown that the theoretical release curves converge at constant P as n is increased. On this basis it was proposed that the best P be determined at sufficiently large n.

Since the partition coefficients for D-glucose (1) and 3-*O*-methyl-D-glucose (2) were relatively small, the outermost lipid could be treated both as a part of the external phase (Model 1) and a part of the spherule (Model 2). Therefore, in the determination of permeability coefficients for 3-*O*-methyl-D-glucose, Model 2 was chosen for the data analysis.

Taurocholic acid transport studies indicated that relatively large amounts of solute bind to the lipid. Model 2, which was used for the transport studies of 3-*O*-methyl-D-glucose, failed to give reasonable agreements between the experiment and theory for this solute. Therefore, in the present studies the theoretical analyses were carried out using the monosize, multiconcentric layer Model 1. The equations describing Model 1 are given in the *Appendix* and were solved by means of a digital computer[6] as reported earlier (1).

RESULTS AND DISCUSSION

The results of the bag control experiments carried out in buffered glucose solutions at different pH's are presented in Fig. 1 in the form of semilogarithmic plots. The slopes of these first-order plots, from which the bag constants were determined (1), represent the bag constant divided by the volume inside the bag. At pH 5 and 7, when the glucose solution was replaced by 0.9% sodium chloride, the transport of taurocholic acid essentially followed the same rate. This indicated that the differences in the rate of taurocholic acid transport through the bag membrane at different pH's were mainly due to the differences in the ionic strength of the buffered glucose rather than to pH. Furthermore, the rate of D-glucose transport through the dialysis membrane remained unchanged in the same buffered glucose solution (pH 5 and 7) which gave significantly different slopes for taurocholate (Fig. 1).

The results of the zero-hour uptake-release experiments generally indicated a much greater binding of taurocholic acid with the outermost lipid layer compared with glucose and methyl glucose. Consequently, relatively large k_2 values were found (Table I). To study

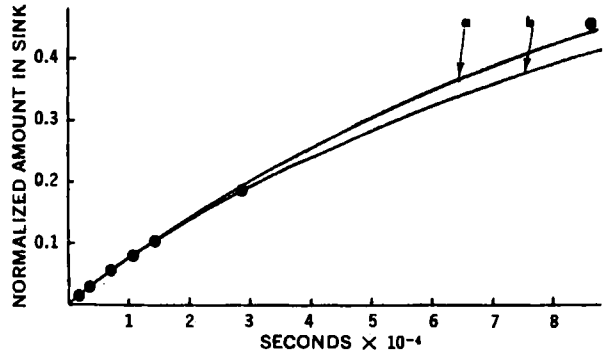

Figure 9—*Comparisons between the direct-release experimental data obtained from lecithin–dicetyl phosphate dispersions for taurocholic acid release in 0.01* M *acetate-buffered glucose solution at pH 4 and the calculations using the monosize, multiconcentric Model 1. Key: ●, experimental data. For curve a:* $k_1 = 120$, $k_2 = 345$, $p = 4 \times 10^{-6}$. *For curve b:* $k_1 = 120$, $k_2 = 260$, $p = 4 \times 10^{-6}$. *Other parameter values are taken from Table II.*

the convergence of the release curves when binding of the solute to the outermost lipid layer is much greater than binding in the inner lipid layers, it is important to keep the amount of solute bound to the last lipid layer constant. The convergence of the theoretical curves with respect to n of this system is typically illustrated by the results of computations given in Fig. 2 for the direct-release case. On the basis of these results, $n = 30$ was considered sufficiently large and was used throughout the present investigation.

The two partition coefficients k_1 and k_2 were determined from the initial rates of the direct-release and zero-hour uptake-release experiments. For a given n, the initial slope of the zero-hour uptake-release experiment is mainly a function of k_2. The determination of k_2 from the zero-hour uptake-release initial data for taurocholic acid in 0.01 M phosphate-buffered glucose solution at pH 7 is illustrated in Fig. 3. The calculations shown in Fig. 3 indicate that the initial slope of the zero-hour uptake-release experiment is insensitive to change in k_1 and p. The initial slope of the direct-release experiment is mainly a function of both k_1 and k_2. Once k_2 was determined, best k_1 values were determined by fitting the initial slope with the direct-release initial experimental points. The initial data of the direct-release experiment carried out in 0.01 M phosphate-buffered glucose solution at pH 7 are presented in Fig. 4. In this figure the theoretical curves show that the initial slope for this situation is insensitive to changes in p and is sensitive to k_1. The results of the direct-release and the uptake-release experiments

carried out in buffered glucose solutions at different pH's for the transport of taurocholic acid are compared with the corresponding calculations in Figs. 5–12. The parameter values are given in Table II. As these data show, the uncertainty in the determination of the permeability coefficients becomes large when the permeability coefficients become very small. In spite of this limitation, the present results clearly show that the permeability coefficients are dependent on the pH of the media in which the taurocholic acid transport studies are performed.

In Fig. 13 the results of the direct-release experiments for the transport of D-glucose in buffered glucose solution (0.01 *M* acetate and phosphate) at different pH's are presented. The curve in this figure represents the results of computations carried out earlier (1) for the glucose transport studies in unbuffered glucose solution. The comparisons between the release data of D-glucose transport in buffered glucose solution at different pH's and the theoretical curve reproduced from the calculations for glucose transport in unbuffered glucose solution indicate no significant changes in the permeability coefficient of liposome membranes due to buffers or to changes in pH of the aqueous solution. This is a strong indication that the physical characteristics of the liposome membranes are not changed because of the changes in pH of the media, which is used for the preparation of dispersion and for the study of transport.

Since physical characteristics of the liposome dispersions do not seem to be significantly altered by changes in pH of the aqueous

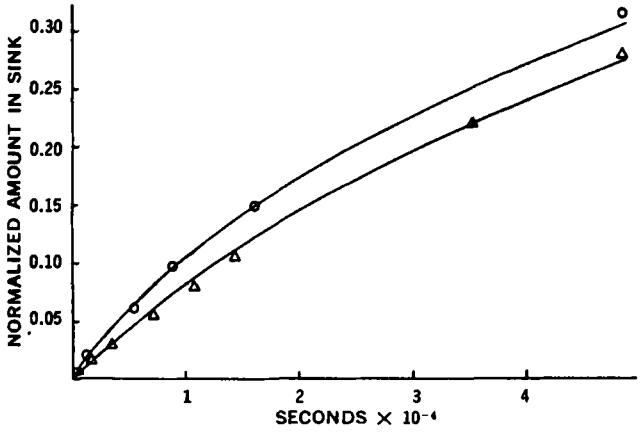

Figure 12—*Comparisons between the uptake-release experimental data obtained from lecithin–dicetyl phosphate dispersions for taurocholic acid release in 0.01* M *acetate-buffered glucose solution at pH 3.6 and the calculations using the monosize, multiconcentric Model 1. solution, it appears that the effect of pH is most likely related to the differences in the species of taurocholic acid in solution. The relationship between the effective bulk permeability coefficient and pH is given in Fig. 14. This relationship could be explained on the basis of the unionized form of taurocholic acid being preferentially transported. This would be in agreement with the pH-partition hypothesis of Shore *et al.* (3). The small, but finite, flux at high pH might be explained on the basis of the transport of the ionized species being the controlling factor under these conditions. This might have important implications in the *in vivo* absorption of taurocholate from bile.

APPENDIX

Monosize, multiconcentric layer models assume that all spherules are of the same size and consist of $i = 1$ to $i = n$ number of segments. In Model 1 the innermost aqueous phase is defined as segment 1. Segment 2 to segment n consists of an aqueous phase and a lipid phase which are of equal thickness. The outermost lipid phase is considered as a part of Compartment II, which is the external phase of the dispersion. In Model 2 the outermost lipid layer is considered as a part of the spherule so that each segment consists of an aqueous phase and a lipid phase. The basic assumptions, the equations, and the procedure used for solving these equations were reported earlier (1, 2). A summary of the equations used in Model 1 is presented here.

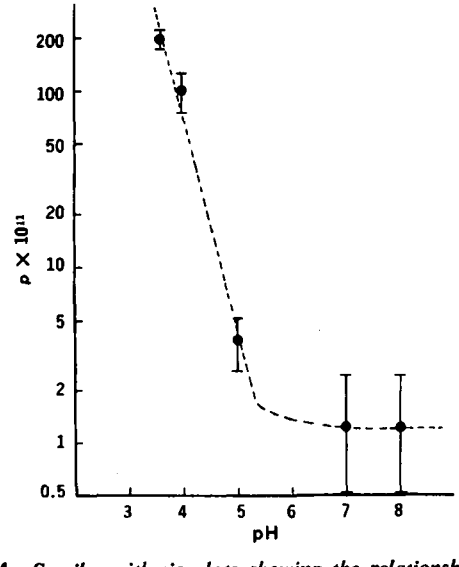

Figure 14—*Semilogarithmic plots showing the relationship between the effective bulk permeability coefficient for taurocholic acid and pH of the buffered glucose solution used in the preparation and in the release studies.*

Table II—Input Data Used in the Calculations Shown in Figs. 5–12 for the Taurocholic Acid Transport at Different pH's

pH	Volume of Spherules, ml.	Mean Surface Radius, μ	Number of Concentric Layers, n	Bag Constant $p_b \cdot S_b \times 10^4$, cm.^{3} sec.$^{-1}$	Permeability Coefficient per Segment, cm. sec.$^{-1}$
8 (0.01 *M* phosphate buffer)	0.922	0.725	30	7.023	1×10^{-9}
8 (0.008 *M* phosphate buffer)	0.922	0.725	30	6.790	5×10^{-10}
7 (0.01 *M* phosphate buffer)	0.930	0.738	30	6.483	5×10^{-10}
5 (0.01 *M* acetate buffer)	1.037	0.766	30	4.986	1.5×10^{-9}
4 (0.01 *M* acetate buffer)	0.973	0.744	30	3.272	4×10^{-8}
3.6 (0.01 *M* acetate buffer)	0.966	0.730	30	2.863	8×10^{-8}

The mass balance considerations for the $i = 2$ to the $i = n$ segment lead to Eq. A1:

$$(V_1 \cdot v_l + V_2 \cdot v_a)C_{2,t} = (V_1 \cdot v_l \cdot k_1 + V_2 \cdot v_a)C_{2,a}$$

$$\vdots$$

$$(V_{n-1} \cdot v_l + V_n \cdot v_a)C_{n,t} = (V_{n-1} \cdot v_l \cdot k_1 + V_n \cdot v_a)C_{n,a}$$

$$(V_n \cdot v_l + V_{II})C_{II,t} = (V_n \cdot v_l \cdot k_2 + V_{II})C_{II,a} \quad \text{(Eq. A1)}$$

where:

$V_1 \ldots V_n$ = volume of segment 1 to segment n
V_{II} = volume of Compartment II (external phase of the dispersion)
v_l = volume fraction of lipid phase
v_a = volume fraction of aqueous phase
$C_2 \ldots C_n$ = average solute concentration of segment 2 to segment n
$C_{II,t}$ = average solute concentration of Compartment II
$C_{2,a} \ldots C_{n,a}$ = aqueous solute concentration of segment 2 to segment n
$C_{II,a}$ = aqueous solute concentration in Compartment II
k_1 = effective lipid–aqueous partition coefficient that applies to the lipid and aqueous phases in the $i = 2$ to $i = n$ segments
k_2 = effective lipid–aqueous partition coefficient that applies to the outermost lipid phase and Compartment II

The rates at which solute leaves segments $i = 1$ to $i = n$ are given by Eq. A2:

$$-V_1 \cdot v_a \cdot \frac{dC_{1,a}}{dt} = S_1 \cdot p(C_{1,a} - C_{2,a})$$

$$(V_1 \cdot v_l \cdot k_1 + V_2 \cdot v_a)\frac{dC_{2,a}}{dt} = S_1 \cdot p(C_{1,a} - C_{2,a}) - S_2 \cdot p(C_{2,a} - C_{3,a})$$

$$\vdots$$

$$(V_{n-1} \cdot v_l \cdot k_1 + V_n \cdot v_a)\frac{dC_{n,a}}{dt} = S_{n-1} \cdot p(C_{n-1,a} - C_{n,a}) - S_n \cdot p(C_{n,a} - C_{II,a}) \quad \text{(Eq. A2)}$$

where:

$S_1 \ldots S_n$ = surface area of segment 1 to segment n
p = permeability coefficient per segment

The rate of appearance of solute in Compartment II is given by Eq. A3:

$$(V_n \cdot v_l \cdot k_2 + V_{II})\frac{dC_{II,a}}{dt} = S_n \cdot p(C_{n,a} - C_{II,a}) - S_b \cdot p_b \cdot C_{II,a} \quad \text{(Eq. A3)}$$

where:

S_b = surface area of dialysis membrane
p_b = effective permeability coefficient of bag

The rate of appearance of solute in the sink is given by Eq. A4:

$$\frac{dAs}{dt} = p_b \cdot S_b \cdot C_{II,a} \quad \text{(Eq. A4)}$$

where As = the amount of solute in the sink normalized with respect to the initial amount in the bag.

Determination of a Benzothiazepin-2-one in Blood by GLC–Electron-Capture Detection

J. ARTHUR F. de SILVA▲, NANCY MUNNO, and ROBERT E. WEINFELD

Abstract □ A sensitive and specific blood level method was developed for the determination of 8-chloro-1-(3-dimethylaminopropyl)-3,5-dihydro-4,1-benzothiazepin-2(1*H*)-one (I) by GLC-electron-capture detection. It involves the selective extraction of the compound into ether from the blood or plasma made alkaline with sodium hydroxide, followed by reextraction into 0.1 *N* HCl. After washing the acid with ether, the aqueous solution is alkalinized and the compound is reextracted into ether. The ether is evaporated, and the residue is dissolved in a 1% solution of diethylamine in *n*-hexane which contains 5-chloro-2-(2-diethylaminoethylamino)-2′-fluorobenzophenone as a reference standard; this solution is analyzed by GLC. The overall recovery of I-hydrochloride added to blood or plasma is of the order of 85%, and the sensitivity limit is about 0.015 mcg. I/ml. blood or plasma using a 4-ml. sample per assay. The method was applied to the determination of plasma levels of the drug in man following single 100- and 200-mg. oral doses of the drug administered 7 days apart.

The tranquilizing properties of the phenothiazines (1) has led to the synthesis of a variety of heterocyclic compounds containing the nitrogen and sulfur moieties in the heterocyclic ring. Many of these compounds have antidepressant activity (2). Thiazesim[1] (3) is a member of the benzothiazepine class of compounds (4) that has shown antidepressant activity in animals (5) and man (6).

8-Chloro-1-(3-dimethylaminopropyl)-3,5-dihydro-4,1-benzothiazepin-2(1*H*)-one hydrochloride (I-hydrochloride) (Table I), another member of this class of compounds, was synthesized by Wenner and Uskokovic (7) and is under clinical investigation as a psychostimulant (8, 9).

A sensitive and specific blood level method was developed for the quantitation of I by GLC–electron-capture detection with a linear range of detection of 10–250 ng. (Fig. 1). The method was applied to the determination of plasma levels of the intact drug (I) in man following administration of single 100- and 200-mg. oral doses.

EXPERIMENTAL

Reagents—All reagents were of analytical grade purity (>98%) and were used without further purification. All aqueous solutions were made up in double-distilled water. The following were used: 6 *N* NaOH, aqueous; 2 *N* NaOH, aqueous; 0.1 *N* HCl, aqueous; 1% diethylamine in spectrograde *n*-hexane[2], 1:99 (v/v), prepared as described under *Standard Solutions;* ether[3], analytical grade, anhydrous; sodium sulfate, anhydrous; and ethanol, absolute.

GLC Conditions—A gas chromatograph[4] with a cylindrical foil electron-capture detector (foil strength 225 mc. of titanium tritide) was used.

Column—A 1.22-m., 0.63-cm. (4-ft., 0.25-in.) o.d. and 0.45-cm. (0.18-in.) i.d., borosilicate glass column containing 5% silicone grease[5] on 60–80-mesh silanized Chromosorb W was conditioned for 72 hr. at 260° prior to use.

Carrier Gas—Nitrogen (oil pumped and dry) was used at a column head pressure of 100 psig. and a flow rate of 100–120 ml./min.

Temperature Settings—The injection port temperature was 250°, the detector temperature was 200°, and the column oven temperature was 230°.

Amplifier Range—The range used was 1.0 × attenuation 8.0 for a full-scale deflection for 100 ng. of I.

Detector—It was operated at plateau voltage (−) 70 v. d.c.

Recorder—A 1.0-mv. dual-pen recorder[6] was operated full scale at a chart speed of 101.6 cm. (40 in.)/hr.

Standard Solutions—Stock solutions of I and 5-chloro-2-(2-diethylaminoethylamino)-2′-fluorobenzophenone (III)[7] (the reference standard) have to be prepared, from which the working solutions containing varying amounts of I to a constant amount of III are prepared for making the GLC calibration curve.

Preparation of Stock Solution of I—Weigh out 11.20 mg. of I-hydrochloride, equivalent to 10.00 mg. of the free base, into a 15-ml. centrifuge tube. Dissolve in 1 ml. of water, add 1 ml. of 2 *N* sodium hydroxide to liberate the free base, and extract three times successively with 6 ml. of ether by shaking for 10 min. on a reciprocating shaker. Centrifuge and transfer the first ether extract quantitatively into a tared 10-ml. volumetric flask, evaporate to dryness, add the second and third ether extracts successively to the residue in the tared flask, and evaporate again to dryness. Vacuum dry the sample for 20-min. intervals until constant weight is achieved. Recovery of the free base should be better than 95%. Dissolve the residue in 1 ml. of ethanol and dilute with sufficient *n*-hexane to yield a stock solution containing 1 mg. (free base)/ml.

Preparation of Stock Solution of III (Reference Standard for GLC)—Weigh out 11.10 mg. of III-hydrochloride (Table I), equivalent to 10.00 mg. of free base (oily residue), and make a stock solution containing 1 mg./ml. exactly as described for I.

Preparation of External Standard Solutions of I (Free Base) Containing the Reference Standard (III) for GLC Calibration—Transfer 1 ml. of each of the above solutions into separate 10-ml. volumetric flasks and make up to volume with *n*-hexane. These solutions contain 100 mcg./ml. of I and III, respectively. Make standard solutions of I containing a constant amount of III in 10-ml. volumetric flasks, making to volume with a solution of 1% diethylamine in *n*-hexane such that each solution contains 2.0 mcg./ml. of the reference standard (III) and 2.0, 4.0, 6.0, 8.0, or 10 mcg./ml. of I. Add approximately 300 mg. of sodium sulfate (anhydrous) as a desiccant to each solution to maintain the anhydrous state of these solutions, which are used to make the analytical calibration curve.

A new calibration curve is prepared on each day of analysis from duplicate 10-μl. injections of each standard solution. The peaks due to I and III have retention times (R_t) of 4.2 and 7.5 min., respectively (Fig. 2), and the peak area (cm.²) of each component

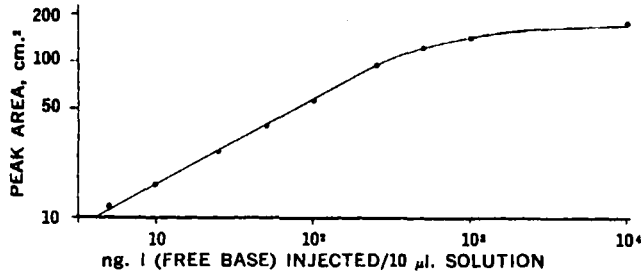

Figure 1—*Linear dynamic range of electron-capture detector response to I.*

is determined by the product of peak height (centimeters) times the width (centimeters) at half-height using the slope–baseline technique. A standard curve is prepared by plotting the peak area ratio of I:III *versus* nanograms of I (Fig. 3).

Preparation of Internal Standards for Determination of Percent Recovery from Blood—Weigh out 11.20 mg. of I-hydrochloride, which is equivalent to 10.00 mg. of free base, and dissolve in 10 ml. of absolute ethanol to give a stock solution containing 1 mcg./ml. Then dilute this solution to yield an internal standard solution containing 1 mcg./100 µl. of ethanol, suitable aliquots of which are added to blood or plasma as internal standards for determining the percent recovery.

Preparation of Stock Solution of 1% Diethylamine in n-Hexane Containing III for GLC Analysis of Biological Samples—Into a 100-ml. volumetric flask, transfer 1 ml. of diethylamine and 0.2 ml. of the 1.0-mg./ml. stock solution of III and make up to volume in spectrograde *n*-hexane. Add about 1 g. of anhydrous sodium sulfate and shake by inversion. This solution contains 200 ng. III/100 µl. and is used for dissolving the residue of the samples prior to GLC analysis.

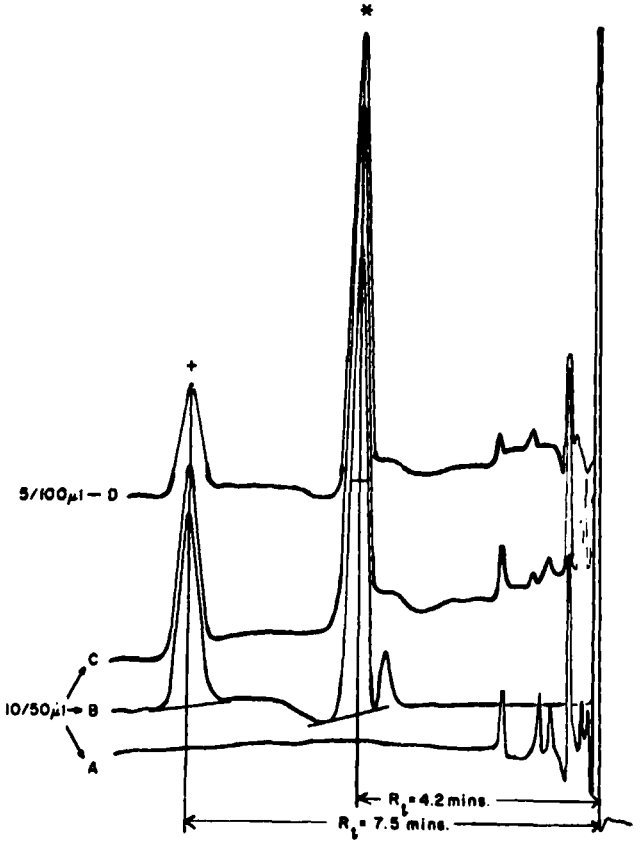

Figure 2—*Gas chromatograms of I extracted from blood. Key: *, I, analytical peak; +, III, reference standard; A, control plasma extract; B, authentic standards of I and III in 1% diethylamine–n-hexane; C, I, recovered from control plasma; and D, plasma extract from a patient dosed with I.*

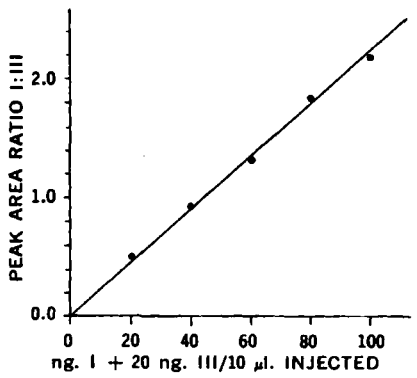

Figure 3—*Calibration curve of electron-capture detector response to I using the benzophenone (III) as a reference standard.*

Experimental Procedure for Extraction from Blood or Plasma—Into a 50-ml. centrifuge tube, add 4 ml. of blood or plasma, 4 ml. of 2 *N* NaOH, and 15 ml. of ether for the first extraction. Along with the samples, run a 4-ml. specimen of control blood or plasma (taken preferably from the patient prior to medication) and four separate 4-ml. specimens of control blood or plasma to which 200, 400, 600, and 800 ng. of I-hydrochloride (20-, 40-, 60-, and 80-µl. aliquots of the internal standard solution evaporated to dryness under nitrogen) are added as internal standards. Seal the stoppers with a drop of distilled water. Shake for 15 min. on a reciprocating shaker, centrifuge for 10 min. at 2000 r.p.m., and transfer the ether into another 50-ml. tube. Repeat the extraction with another 10-ml. portion of ether and combine the ether extracts. Back-extract the ether with 5 ml. of 0.1 *N* HCl, centrifuge, aspirate off the ether, and wash the hydrochloric acid twice with 10-ml. portions of ether; then centrifuge and remove the ether by aspiration as before. Alkalinize the hydrochloric acid to a bromthymol blue end-point with 0.1 ml. of 6 *N* NaOH. Extract with 2 × 10-ml. portions of ether by shaking for 10 min. Then centrifuge and combine the extracts sequentially in a 15-ml. centrifuge tube and evaporate to dryness. Transfer the sample residues to a vacuum desiccator and vacuum dry for 15–20 min. to remove all traces of moisture. Add 50 µl. of a 1% solution of diethylamine in *n*-hexane containing the reference standard (III) (reference standard stock solution) to each tube, and dissolve the residue by mixing for 60 sec. on a mixer[8] at high speed. Prepare two samples at a time for GLC to prevent solvent losses in the tubes. Inject a 10-µl. aliquot for GLC analysis. The peaks due to I and III in the unknowns are identified by their respective retention times of 4.2 and 7.5 min. compared to the retention times of the peaks of the authentic external standards (Fig. 2).

Calculations—The peak areas of I and III are determined as described. The peak area ratios of I:III are calculated, and the

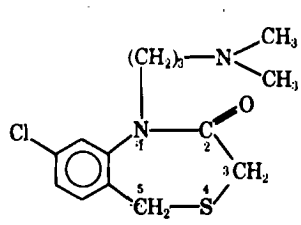
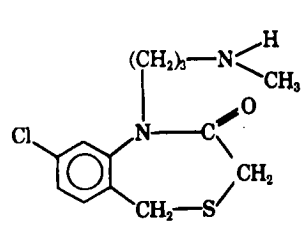
[8] Vortex Super Mixer (Lab-Line).

Table I—Chemical Names, Structural Formulas, and Physical Properties of the Compounds Mentioned

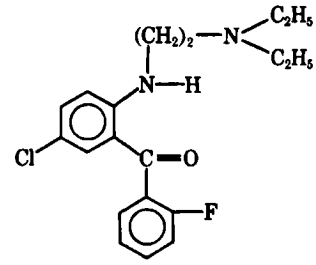
Compound	Chemical Name	Molecular Weight	Melting Point	Reference to Synthesis
I-hydrochloride	8-Chloro-1-(3-dimethylaminopropyl)-3,5-dihydro-4,1-benzothiazepin-2(1*H*)-one hydrochloride	335.31	201–202°	7
II-hydrochloride	8-Chloro-1-(3-methylaminopropyl)-3,5-dihydro-4,1-benzothiazepin-2(1*H*)-one hydrochloride	321.28	230–232°	7
III-hydrochloride	5-Chloro-2-(2-diethylaminoethylamino)-2′-fluorobenzophenone hydrochloride (reference standard for GLC analysis)	385.30	134–143°	



I



II



III

nanogram amounts of I in the unknowns are interpolated from the standard curve of the recovered internal standards or by direct comparison to any given internal standard using the formula:

$$\frac{\text{[peak area ratio] unknown}}{\text{[peak area ratio]internal standard}} \times \frac{\text{mcg. internal standard}}{\text{ml. of sample assayed}} = \text{mcg. I/ml. blood or plasma} \quad \text{(Eq. 1)}$$

The percent recovery of internal standards of I-hydrochloride added to blood or plasma is determined as follows:

$$\frac{\text{ng. I (recovered)}}{\text{ng. I-hydrochloride (added)}} \times \text{aliquot factor} \times 1.122 \times 100 = \%\ \text{recovery of I} \quad \text{(Eq. 2)}$$

where aliquot factor = aliquot of sample injected for GLC (10/50 μl.), and 1.122 = conversion factor for molar weight. The ratio of:

$$\frac{\text{I-hydrochloride}}{\text{I free base}} = \frac{335.31}{298.81} \quad \text{(Eq. 3)}$$

The percent recovery of internal standards should be determined routinely as a check on analytical precision and reproducibility.

DISCUSSION

During the investigation of the intrinsic analytical properties of I, it was noted that the compound had no useful absorbance in either the visible or UV region and, consequently, had no useful intrinsic fluorescence in basic, neutral, or acidic media. However, the free base of the compound was amenable to GLC analysis employing the sensitivity and selectivity of the electron-capture detector response to the halogen, sulfur, and carbonyl groups in the molecule for its detection. The limit of detection of the pure compound was 10 ng. when chromatographed on a 1.23-m. (4-ft.) column of 5% silicone grease[5] at 230°, giving a potential sensitivity limit of 0.015 mcg./ml. of blood or plasma. However, greater sensitivity may be obtained by using the phenyl silicone liquid phases such as OV-1 and OV-17 and the ^{63}Ni (15 mc.) electron-capture detector, especially in the pulsed d.c. operational mode.

The selective extraction of I into ether from the blood or plasma made alkaline with sodium hydroxide was based on the basic nature of the compound (pKa 8.7). Since the compound readily forms acid salts, the free base in ether was back-extracted into 0.1 *N* HCl, which was then subjected to suitable cleanup. The hydrochloric acid solution containing I is made strongly alkaline, extracted into ether, and concentrated by evaporation.

It was noted that I in the final ether residue was not quantitatively dissolved in *n*-hexane, apparently due to strong adsorption on the glass. However, it was determined by GLC that I was solubilized and quantitatively desorbed off the glass with a solution of 1% diethylamine in *n*-hexane. Since diethylamine is very hygroscopic anhydrous sodium sulfate was used to remove traces of moisture in the sample residues which would otherwise severely quench the response of the ^{3}H-electron-capture detector, giving nonlinear and irreproducible results. The reference standard (III) serves as an index of the performance of the electron-capture detector during the assay and monitors the stability of the GLC system.

The electron-capture detector response characteristics of III, its sensitivity limits, and its linear range of detection were compatible with those of I. Its retention time of 7.5 min. ensures complete resolution from I and from extracted impurities, making it a suitable reference standard for GLC analysis.

Application of Method to Biological Specimens—Plasma levels were determined in a female patient (M.F.; age 59 and 68.4 kg. in weight) following single oral doses of 100 and 200 mg. administered 7 days apart. Blood specimens were collected prior to medication (control) and at 0.5, 1, 2, 4, 8, 12, 24, and 48 hr. after dosing; the plasma was separated immediately. Semilogarithmic plots of the plasma levels are shown in Fig. 4 and indicate a slow and prolonged absorption of the drug, with a maximum level being reached 1–2 hr. after administration. These levels were maintained for up to 8 hr. following both the 100- and 200-mg. doses, after which time a progressive decline in the plasma levels was seen up to 48 hr. The plasma level half-life determined by the method of least squares was approximately 15 hr. for both the 100- and 200-mg. doses.

The sensitivity limit of the method was established at 0.015 mcg. I/ml. plasma using a 4-ml. sample per assay in additional studies where blood levels were determined in man following the oral administration of 20 mg. of I-hydrochloride/day in 5-mg. doses (q.i.d.).

Specificity of Assay—Following GLC analysis, the remainder of the 1% diethylamine in *n*-hexane solutions were pooled and analyzed by one-dimensional TLC in acetone–ammonium hydroxide (100:2). The chromatoplates showed the presence of a single spot corresponding to that of authentic I (R_f 0.90). The *N*-monodesmethyl analog (II, R_f 0.17) (Table I), a metabolite seen in dog blood, is absent in human blood extracts after single oral doses. It may, however, appear after chronic administration of the drug. On GLC analysis, Compound II had a retention time of 5.4 min. and was resolved from I whose retention time was 4.2 min. The GLC assay in blood is apparently specific for the intact drug.

Determination of Coating Thickness of Microcapsules and Influence upon Diffusion

LUU SI-NANG▲, PATRICK F. CARLIER, PIERRE DELORT, JEAN GAZZOLA, and DIDIER LAFONT

Abstract □ Experiments in this study appear to show that the diffusion rate of the encapsulated drug is a function of microcapsule size. The object of this paper is to report the influence of the coating upon diffusion and the determination of the thickness of the coating. An equation was established, which was verified by microscopic measurement of microspheres previously sliced with a microtome.

Keyphrases □ Microcapsules—determination of coating thickness, effect on diffusion rate □ Coating thickness, microcapsules—determination, effect on diffusion rate □ Diffusion rate, encapsulated drugs—influence of nature and thickness of coating

The microencapsulation process is comparatively new (1–7). It consists of coating crystals or microdroplets of liquid with a polymer film. It has been applied successfully to a number of products, from gasoline to tetracycline. Its pharmaceutical use enables one to mix substances incompatible with each other, to mask an unpalatable taste, or to induce a prolonged action. Of course, the nature and thickness of the coating determine the diffusion rate.

THEORETICAL

Influence of Coating upon Diffusion—Studying the dissolution in water of cylinders of benzoic acid and lead chloride, Noyes and Whitney (8) gave the following dissolution equation:

$$\frac{dc}{dt} = K(C_\infty - c) \qquad \text{(Eq. 1)}$$

where K is a constant, C_∞ is the solubility of the substance, and c is the concentration at the expiration of the time t.

According to Brunner (9):

$$K = \frac{DS}{V\delta} \qquad \text{(Eq. 2)}$$

where K is the same constant as in the Noyes–Whitney equation, D is the solute molecule diffusion coefficient, V is the volume of solution, δ is the effective diffusion layer thickness, and S is the surface of the solid–solution interface.

The equation:

$$\frac{dc}{dt} = \frac{DS}{V\delta}(C_\infty - c) \qquad \text{(Eq. 3)}$$

allowed the computation of δ.

As reported by Wurster and Taylor (10): "the idealized film layer is not well defined, but it allows the correlation of experimental data with the physical properties of both the solute and solvent."

Dissolution of Microencapsulated Solute—In this experiment, the material to be encapsulated was viscous and sticky; however, the dry microcapsules did not aggregate. Thus one may disregard the possibility of a spontaneous diffusion of this material through the coating wall, and the phenomenon may be considered as follows: when the microcapsules were suspended in a liquid, the penetration of the solvent into the microspheres occurred first, followed by the dissolution of the encapsulated solute and the diffusion of the solution. The phenomena taking place during this exchange were dependent on osmotic pressure and diffusion.

In the event of the encapsulated substance being only slightly soluble in the liquid, one may disregard the effect of osmotic pressure and consider only diffusion. Thus, Eq. 3 may be expressed as:

$$\left[\frac{dc}{dt}\right]_{\text{coating}} = \frac{DS'\epsilon}{Vh}(C_\infty - c) \qquad \text{(Eq. 4)}$$

where S' is the external surface of a microcapsule, ϵ is a coefficient expressing the porosity and tortuosity of the coating, and h is the thickness of the coating. Other symbols are the same as already defined.

If it is assumed that microcapsules with the same radius have the same coating thickness, and that this thickness as well as that of Brunner's (9) layer are small and negligible with respect to the radius of microcapsules, one may write:

$$S = S' = n4\pi\bar{r}^2 \qquad \text{(Eq. 5)}$$

where $\bar{r}$ is the mean radius of the microcapsules and n is the number of microcapsules. The volume V_1 of the microcapsules is expressed as:

$$V_1 = \frac{4}{3}n\pi\bar{r}^3 = \frac{m}{d} \qquad \text{(Eq. 6)}$$

Determination of Coating Thickness of Microcapsules and Influence upon Diffusion

LUU SI-NANG▲, PATRICK F. CARLIER, PIERRE DELORT, JEAN GAZZOLA, and DIDIER LAFONT

Abstract □ Experiments in this study appear to show that the diffusion rate of the encapsulated drug is a function of microcapsule size. The object of this paper is to report the influence of the coating upon diffusion and the determination of the thickness of the coating. An equation was established, which was verified by microscopic measurement of microspheres previously sliced with a microtome.

Keyphrases □ Microcapsules—determination of coating thickness, effect on diffusion rate □ Coating thickness, microcapsules—determination, effect on diffusion rate □ Diffusion rate, encapsulated drugs—influence of nature and thickness of coating

The microencapsulation process is comparatively new (1–7). It consists of coating crystals or microdroplets of liquid with a polymer film. It has been applied successfully to a number of products, from gasoline to tetracycline. Its pharmaceutical use enables one to mix substances incompatible with each other, to mask an unpalatable taste, or to induce a prolonged action. Of course, the nature and thickness of the coating determine the diffusion rate.

THEORETICAL

Influence of Coating upon Diffusion—Studying the dissolution in water of cylinders of benzoic acid and lead chloride, Noyes and Whitney (8) gave the following dissolution equation:

$$\frac{dc}{dt} = K(C_\infty - c) \qquad \text{(Eq. 1)}$$

where K is a constant, C_∞ is the solubility of the substance, and c is the concentration at the expiration of the time t.

According to Brunner (9):

$$K = \frac{DS}{V\delta} \qquad \text{(Eq. 2)}$$

where K is the same constant as in the Noyes–Whitney equation, D is the solute molecule diffusion coefficient, V is the volume of solution, δ is the effective diffusion layer thickness, and S is the surface of the solid–solution interface.

The equation:

$$\frac{dc}{dt} = \frac{DS}{V\delta}(C_\infty - c) \qquad \text{(Eq. 3)}$$

allowed the computation of δ.

As reported by Wurster and Taylor (10): "the idealized film layer is not well defined, but it allows the correlation of experimental data with the physical properties of both the solute and solvent."

Dissolution of Microencapsulated Solute—In this experiment, the material to be encapsulated was viscous and sticky; however, the dry microcapsules did not aggregate. Thus one may disregard the possibility of a spontaneous diffusion of this material through the coating wall, and the phenomenon may be considered as follows: when the microcapsules were suspended in a liquid, the penetration of the solvent into the microspheres occurred first, followed by the dissolution of the encapsulated solute and the diffusion of the solution. The phenomena taking place during this exchange were dependent on osmotic pressure and diffusion.

In the event of the encapsulated substance being only slightly soluble in the liquid, one may disregard the effect of osmotic pressure and consider only diffusion. Thus, Eq. 3 may be expressed as:

$$\left[\frac{dc}{dt}\right]_{\text{coating}} = \frac{DS'\epsilon}{Vh}(C_\infty - c) \qquad \text{(Eq. 4)}$$

where S' is the external surface of a microcapsule, ϵ is a coefficient expressing the porosity and tortuosity of the coating, and h is the thickness of the coating. Other symbols are the same as already defined.

If it is assumed that microcapsules with the same radius have the same coating thickness, and that this thickness as well as that of Brunner's (9) layer are small and negligible with respect to the radius of microcapsules, one may write:

$$S = S' = n4\pi\bar{r}^2 \qquad \text{(Eq. 5)}$$

where $\bar{r}$ is the mean radius of the microcapsules and n is the number of microcapsules. The volume V_1 of the microcapsules is expressed as:

$$V_1 = \frac{4}{3}n\pi\bar{r}^3 = \frac{m}{d} \qquad \text{(Eq. 6)}$$

where m is the mass of n microcapsules, and d is the density of the microcapsules.

From Eq. 6, one may compute n and, reporting its value in Eq. 5, one has:

$$S = S' = \frac{3m}{\bar{r}d} \qquad \text{(Eq. 7)}$$

$$\left[\frac{dc}{dt}\right]_{\text{coating}} = \frac{3Dm\epsilon}{Vh\bar{r}d}(C_\infty - c) \qquad \text{(Eq. 8)}$$

On the other hand, the diffusion that takes place at the Brunner's (9) layer may also be expressed as:

$$\left[\frac{dc}{dt}\right]_{\text{layer}} = \frac{3Dm}{V\delta\bar{r}d}(C_\infty - c) \qquad \text{(Eq. 9)}$$

And the results of both phenomena are:

$$\left[\frac{dc}{dt}\right]_{\text{layer}} + \left[\frac{dc}{dt}\right]_{\text{coating}} = \left[\frac{dc}{dt}\right]_{\text{total}} \qquad \text{(Eq. 10}a\text{)}$$

$$\left[\frac{dc}{dt}\right]_{\text{total}} = \frac{3Dm}{V\bar{r}d}\left[\frac{1}{\delta} + \frac{\epsilon}{h}\right](C_\infty - c) \qquad \text{(Eq. 10}b\text{)}$$

Thus, diffusion is expressed as the sum of a constant and a variable, the latter being a function of the stirring rate.

One may write the empirical relationship:

$$\delta = \frac{a}{(N)^b} \qquad \text{(Eq. 11)}$$

where N is the agitation rate, and a and b are constants. Substituting this into Eq. 10 gives:

$$\left[\frac{dc}{dt}\right]_{\text{total}} = \frac{3Dm}{V\bar{r}d}\left[\frac{(N)^b}{a} + \frac{\epsilon}{h}\right](C_\infty - c) \qquad \text{(Eq. 12)}$$

$$\frac{dc}{C_\infty - c} = \frac{3Dm}{V\bar{r}d}\left[\frac{(N)^b}{a} + \frac{\epsilon}{h}\right]dt \qquad \text{(Eq. 13)}$$

Integrating this equation gives:

$$\ln(C_\infty - c) = -\frac{3Dm}{V\bar{r}d}\left[\frac{(N)^b}{a} + \frac{\epsilon}{h}\right]t + \text{constant} \qquad \text{(Eq. 14)}$$

If it is assumed that for $t = 0, c = 0$, then constant $= \ln C_\infty$:

$$\ln\left[1 - \frac{C}{C_\infty}\right] = -\frac{3Dm}{V\bar{r}d}\left[\frac{(N)^b}{a} + \frac{\epsilon}{h}\right]t \qquad \text{(Eq. 15)}$$

When C is very inferior to C_∞ (generally $C \leqslant 0.1\ C_\infty$), (C/C_∞) is small with respect to 1 and Eq. 15 reduces to:

$$C = \frac{3Dm}{V\bar{r}d}C_\infty\left[\frac{(N)^b}{a} + \frac{\epsilon}{h}\right]t \qquad \text{(Eq. 16)}$$

The curve $C = f(t)$ where N is a constant is interesting because it expresses the diffusion of the solute; the curve $C = f(N)$ where t is a constant is interesting when extrapolated at $N = 0$.

Thus, beyond the area A where the solution is heterogeneous, the equation of this curve is:

$$C = Co + kN^b \qquad \text{(Eq. 17)}$$

where:

$$Co = \frac{3Dm\epsilon C_\infty}{V\bar{r}dh}t$$

and:

$$k = \frac{3DmC_\infty}{V\bar{r}da}t$$

Co is the coating contribution to diffusion; it is representative of ϵ/h and, therefore, of the nature and thickness of the coating. It affords a global view of the coating's rate of diffusion. Thus, it is possible to compare two batches of microcapsules of the same drug by equalizing all of the other parameters.

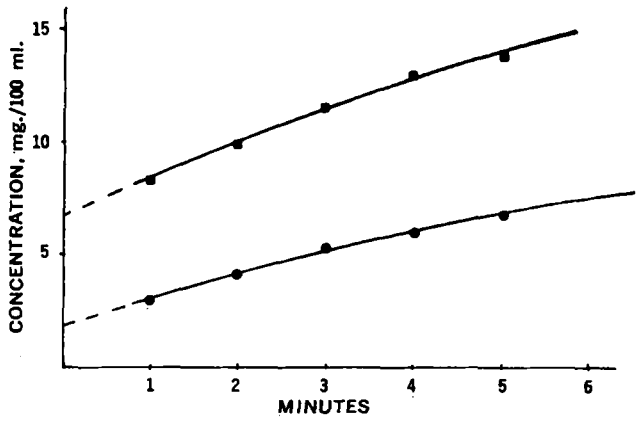

Figure 1—*Liberation rate of microcapsules with* r *different. Key:* ■, r = *140 μ; and* ●, r = *300 μ.*

Determination of Coating Thickness—It follows from Eq. 15 that, for obtaining a prolonged action with microcapsules, it will be advantageous to increase $\bar{r}$ and decrease ϵ/h. Other parameters are determined either by solute and coating (D, d) or by posology (m, V). The formulator is free to work on $\bar{r}$ and h. The mean radius is more easily measured than the coating thickness. The following two methods were used.

Measuring Density and Active Drug Amount—Let us consider a batch of n microcapsules weighing m g. with a mean radius $\bar{r}$. Solute density is d_1, and coating density is d_2.

The solute mass is:

$$m_1 = n\frac{4}{3}\pi(\bar{r} - h)^3 d_1 \qquad \text{(Eq. 18)}$$

The coating mass is:

$$m_2 = n\left[\frac{4}{3}\pi\bar{r}^3 - \frac{4}{3}\pi(\bar{r} - h)^3\right]d_2 \qquad \text{(Eq. 19)}$$

Calling P the relation:

$$P = \frac{\text{solute mass}}{\text{total mass of microcapsules}} \qquad \text{(Eq. 20)}$$

one has:

$$P = \frac{n\frac{4}{3}\pi(\bar{r} - h)^3 d_1}{n\frac{4}{3}\pi(\bar{r} - h)^3 d_1 + n\left[\frac{4}{3}\pi\bar{r}^3 - \frac{4}{3}\pi(\bar{r} - h)^3\right]d_2} \qquad \text{(Eq. 21}a\text{)}$$

$$P = \frac{(\bar{r} - h)^3}{(\bar{r} - h)^3 d_1 + [\bar{r}^3 - (\bar{r} - h)^3]d_2} \qquad \text{(Eq. 21}b\text{)}$$

$$P = \frac{\left[1 - \frac{h}{\bar{r}}\right]^3 d_1}{\left[1 - \frac{h}{\bar{r}}\right]^3 d_1 + \left[1 - \left(1 - \frac{h}{\bar{r}}\right)^3\right]d_2} \qquad \text{(Eq. 21}c\text{)}$$

Assuming that $(h/\bar{r}) \ll 1$, the previous equations reduce to:

$$P = \frac{\left[1 - \frac{3h}{\bar{r}}\right]d_1}{\left[1 - \frac{3h}{\bar{r}}\right]d_1 + \frac{3h}{\bar{r}}d_2} \qquad \text{(Eq. 22}a\text{)}$$

$$1 - P = \frac{\frac{3h}{\bar{r}}d_2}{\left[1 - \frac{3h}{\bar{r}}\right]d_1 + \frac{3h}{\bar{r}}d_2} \qquad \text{(Eq. 22}b\text{)}$$

$$\frac{P}{1 - P} = \frac{\left[1 - \frac{3h}{\bar{r}}\right]d_1}{\frac{3h}{\bar{r}}d_2} \qquad \text{(Eq. 22}c\text{)}$$

Table I—Computation of Coating Thickness from Density and Active Drug Amount Determinations

Mean Radius, μ	Percent of Core Material	Percent of Coating Material	Thickness h, μ
375	0.93	0.07	5.86
300	0.90	0.10	0.80
200	0.89	0.11	5.00
140	0.805	0.195	6.40
87.5	0.755	0.245	5.10

Table II—Computing of Coating Thickness: Number of Observations of Thickness h for the Radius $\bar{r}$

Mean Thickness, μ	Mean Radius, μ 140	200	300	375
3.80	0	1	1	4
4.75	5	6	1	4
5.70	13	10	6	13
6.65	11	8	12	7
7.60	7	10	9	9
8.55	2	4	4	3
9.50	4	5	2	5
Total number	42	44	35	45

$$\frac{3h}{\bar{r}}d_2P = (1 - P)\left[1 - \frac{3h}{\bar{r}}\right]d_1 \qquad \text{(Eq. 22}d\text{)}$$

$$\frac{3h}{\bar{r}}[d_2P + (1 - P)d_1] = (1 - P)d_1 \qquad \text{(Eq. 22}e\text{)}$$

$$h = \frac{\bar{r}}{3}\frac{(1 - P)d_1}{Pd_2 + (1 - P)d_1} \qquad \text{(Eq. 22}f\text{)}$$

d_1 and P are easily measured, and d_2 is computed after measuring of total density and P, from which h is computed.

Direct Measure after Microtome Slicing—Wall thickness is measured with a microscope fitted with a micrometer after slicing with a microtome (slice thickness about 10 μ).

EXPERIMENTAL[1]

This work was carried out using microcapsules containing the liquid organic base, eprazinone, a mucolytic drug, encapsulated by a mixture of gelatin and gum arabic. Eprazinone is 3-[4-(2-methoxy-2-phenylethyl)-1-piperazinyl]-2-methyl-1-phenyl-1-propanone.

The process is carried out in an open top vessel at 40°, and the pH is maintained constant at 6.5 with acetic acid. The core material is dispersed as minute droplets in the solution of the mixture of gelatin and gum arabic; the capsule walls are hardened with glutaraldehyde as a crosslinking agent.

The batch studied was sieve separated into groups with average radii of 375, 300, 200, 140, and 87 μ.

Apparatus—The following were used: a constant-temperature bath kept at 23 ± 0.5°, a mechanical stirrer, a spectrophotometer[2], a chronometer, a pycnometer, a microscope, and a microtome.

Measurement of Diffusion—A volume of 300 ml. of distilled water is stirred until a temperature of 23° is reached. With continuous stirring, 1.5 g. microcapsules is added with the starting of the chronometer. Samplings are made by way of a pipet fitted at its lower end with a small plastic tube filled with glass wool. Each sampling is 3 ml., *i.e.*, 1% of the total volume. After a correct dilution of the sampling, the amount of diffused drug is determined by spectrophotometry at the absorption maximum of 250 nm.

Determination of Thickness—*Calculation*—Densities are determined by way of a pycnometer. Wall density is found by calculation after determination of the total volume of microcapsules and the volume of microencapsulated eprazinone.

[1] The microcapsules were obtained from I.B.F., Paris, France.
[2] Beckman DBG.

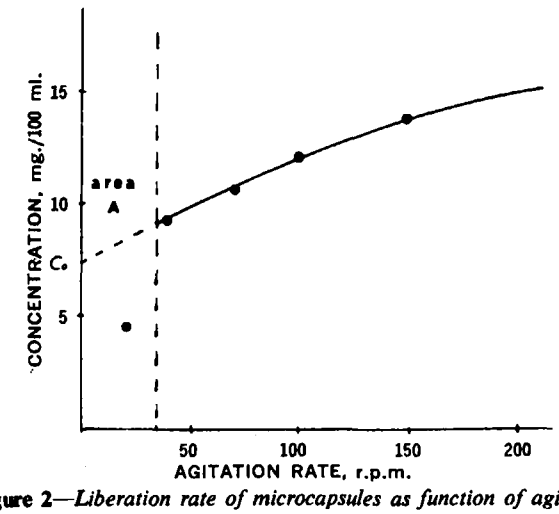

Figure 2—*Liberation rate of microcapsules as function of agitation rate.*

Direct Measure after Microtome Slicing—Microcapsules are imbedded in a gelatin mass according to Baker (11). Paraffin inclusion is unsatisfactory because of the solvent effect of alcohol and toluene and because of the low melting point of the paraffin, which also causes the coating material to melt.

Gelatin is mixed with distilled water in a 1:5 ratio. This mixture is kept 2 hr. at 37° in an incubator. Microcapsules are subsequently added. A separate gelatin bath is used for each size of microcapsules. Cubes of gelatin obtained after hardening are kept at 4°.

The gelatin cubes are subsequently sliced with a congelation microtome. Slice thickness should be about 10 μ. Each slice is placed on an object slide and mounted with levulose syrup, which is water miscible and does not require slice dehydration.

Slides are studied without staining on a microscope fitted with a micrometer and an immersion objective. One can perform a direct measure of coating thickness which appears as a darker zone with respect to the preparation as a whole.

RESULTS AND DISCUSSION

Curves $C = f(t)$ for N = Constant (Fig. 1)—There is good agreement between the experimental curves and the theoretical predictions. The origin of the ordinate is not zero; as a matter of fact, the method for preparing microcapsules requires the pH to be kept constant by adding acetic acid. Thus, some acetate is formed, part of which mixes with the coating. This soluble fraction diffuses at once.

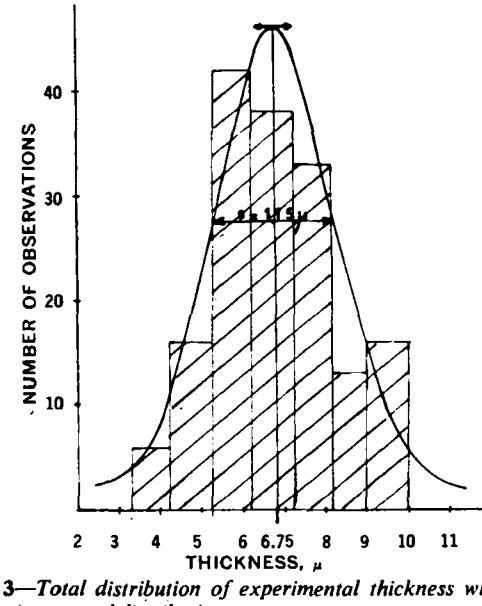

Figure 3—*Total distribution of experimental thickness with an approximating normal distribution.*

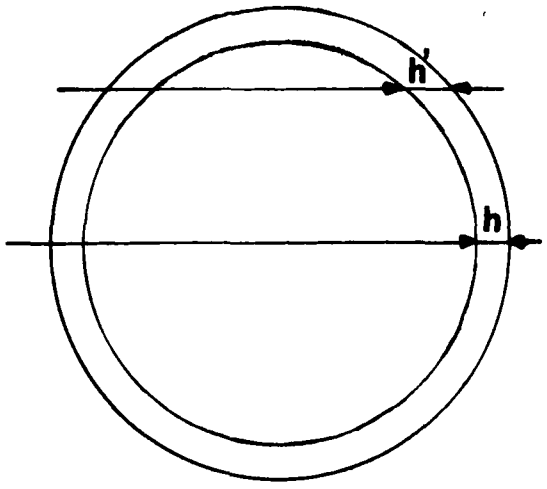

Figure 4—*Section of a microcapsule showing the different values of* h.

Curve $C = f(N)$ for t = Constant (Fig. 2)—Good agreement was found between the experimental curves and the theoretical predictions. The $C0$ value is higher than the ordinate at the origin of the curve $C = f(t)$ for N = constant; acetate dissolution is, therefore, to be disregarded.

Computing Thickness h—*From Densities and Amount of Active Drug*—One finds $d_1 = 1.05$ and $d_2 = 1.60$. The results are given in Table I. The mean value obtained by this method is 5.85 μ.

From Direct Measure—Table II gives the number of observations of thickness h and the total number of measured samples n and $\bar{h}$. The mean value obtained by this method is 6.75 μ.

The coating thickness distribution curve is given with a good degree of precision by microscopic measures (Fig. 3). This curve includes values from 10 to 4 μ. Upper values can be explained by the difficulty in cutting a microcapsule through the center with a microtome (Fig. 4); thus, the resulting coating thickness is larger for one slice than for the other ($h' > h$).

Lower values are not easily explained if thickness is taken as constant. On the other hand, microscopic examination showed that microcapsules are not spherical but rather present a knob at each pole. These knobs appeared only in the smallest microcapsules with a radius between 87 and 140 μ.

For the purpose of simplifying calculation, the microcapsules were assumed to be spherical. The results obtained indicate that this assumption can be made.

In spite of extensive radius differences (×4), the mean coating thickness remains constant, whichever method is used. Differences found with both methods for the mean coating thickness are not significantly different.

CONCLUSIONS

The experiments with microencapsulation seem to demonstrate that, when gelatin and gum arabic are used, the obtained coating is a constant thickness whatever the microcapsule size. Thus, the diffusion rate of the microcapsules will be in direct ratio to the coating material (ϵ) and in inverse ratio to the mean radius ($\bar{r}$).

The proposed equation for determining the coating thickness allows a quick estimation of this thickness, whereas direct microscopic measurement is lengthy and tedious. Knowing the coating thickness would allow the microcapsule manufacturer to determine the best conditions of encapsulation with respect to the objective, and this knowledge would permit the user to verify the constancy of quality of the product.

Drug Purity Profiles

LEE T. GRADY, SUE E. HAYS, ROBERT H. KING, HANNAH R. KLEIN*, WILLIAM J. MADER*, DOROTHY K. WYATT▲, and RUPERT O. ZIMMERER, Jr.

Abstract □ Physical constants and purity determinations are given for 115 drug substances. Phase solubility analysis, differential scanning calorimetry, and chromatographic data are reported. High-low TLC, which has emerged as a useful, if imprecise, tool for purity approximation, is described. The concept of purity profile is discussed and examples are given; general observations on the utility of methods are made based on cumulative experience.

Keyphrases □ Drug purity profiles—phase solubility analysis, differential scanning calorimetry, and chromatographic data for 115 drugs □ Purity-indicating methods—phase solubility analysis, differential scanning calorimetry, and chromatographic data for 115 drugs □ TLC, high-low—analysis, purity profiles for 115 drugs □ Differential scanning calorimetry—analysis, purity profiles for 115 drugs □ Phase solubility analysis—purity profiles for 115 drugs

As a service to pharmaceutical analysts, useful physical constants and purity profile data are recorded here for samples of 115 drug substances, which were examined as candidates for adoption or continued official recognition as reference standards by either the USP or the NF. General observations on the purity-indicating methods are offered based on extensive experiences with this large number of drug substances. Such broad experience is rare in purity-indicating methodology, and these observations may be of value to analysts in preparing purity profiles.

These are not the only data available to the USP or the NF in connection with evaluation of candidates for recognition as standards. Moreover, these data do not represent the full scope of this laboratory's contribution to the USP and NF programs; notably, no results of monograph tests and assays are reported here. The samples cannot be presumed to have been found acceptable[1] when evaluated here or in the collaborating industrial and governmental laboratories. Only data generated by this laboratory are reported.

METHODS AND MATERIALS

Phase Solubility Analysis (PSA)—Collection and interpretation of PSA data were described fully elsewhere (1). The usual procedure, described in NF XIII (2), consists of charging eight ampuls which are then flame sealed and rotated end-over-end at 25° for 2 weeks. Initial solubility data are obtained occasionally by the method of Reilly and Rae (3), but most often by the approximate method detailed here. Supernates are examined for evidence of decomposition, when deemed necessary, by TLC. Nitrogen-sparged or degassed solvents are used for easily oxidized compounds.

Results from a PSA experiment may be evaluated graphically or by the least-squares best-fit treatment which affords a confidence range (1). Arbitrary confidence classes are assigned (Table I) based partly on that calculation and partly on experienced inspection of the graph. Extrapolated solubility values in pure solvents or in azeotropes are accurate within 0.3 mg./g. for Classes A–C; mixed solvents, however, introduce yet another variable. With respect to the testing strategy, these classes have the following meanings: A or B, almost conclusive or strong evidence of the (im)purity of a sample; C, good evidence, but requires several supporting data; and D, possibly useful as supporting evidence in conjunction with strong alternative evidence. Where an adequate number of tubes[2] is used, a poor confidence rating may reflect either minor solute decomposition in that solvent or inadequate equilibration or drying time. Similarly, solid solutions of the solute with its impurities may be revealed so that an alternative approach is needed. Points near the intersection of the graphical 45° line and the saturation line, *i.e.*, those with sample charges less than 20% above the solubility, occasionally have been found to reflect higher apparent solubility which can lead to purity values in excess of 100%; this can arise from two interrelated phenomena: failure to reach equilibrium and the known higher solubility of fine particles.

Some PSA data listed in Table I were reported earlier (1) from this laboratory but are repeated here to support the evaluation of high-low TLC.

Approximate Solubility—This method is not as rapid as some other approximate methods, but it is much more conservative of the sample, which is often a consideration with high purity drugs. It does not require assay of the solution and is designed specifically to identify solvents for PSA rather than to establish sample solubility in a given solvent. The resultant value is usually ±1 mg./g. of the actual value determined by solubility analysis.

Accurately weigh about 30 mg. of sample into a screw-capped test tube and add three 1.0-ml. increments of the candidate solvent by pipet, mixing on a vortex-causing mixer after each addition. Solubility levels of 30, 15, and 10 mg./ml., respectively, are revealed.

If the sample dissolves immediately in 1 ml. or does not dissolve appreciably in 3 ml., this solvent is ruled out for solubility analysis. If the sample is almost dissolved at any of the three increments, place the stoppered tube in a 25° bath overnight and then observe the extent of solution. At this point, solubility values of about 10, 15, or 30 mg./ml. or values lying between 10 and 15 or between 15 and 30 mg./ml. are identified. Prepare one or two additional tubes, each containing 1 ml. of solvent. The addition of 12.5 mg. of sample will allow definition of solubility in the 10–15-mg./ml. range after standing at 25° overnight; similarly, a 22.5-mg. sample, followed by yet another intermediate sample, allows determination of approximate solubility in the 15–30-mg./ml. range. A total of three tubes is usually sufficient, and analyst experience normally allows even more simplification. Correction for solvent density is not made in selecting sample and solvent weights for charging the PSA tubes.

[1] About 15% of these were not suitable for reference standard usage.

[2] Adequate with respect to the plateau values used in least-squares calculation. The number (n) used for the entries in Table I is coupled with the assigned confidence class. The data are, for practical purposes, univariant and calculated accordingly.

Thermoanalytical Purity[3]—Estimations of purity from melting behavior are made by the modified, integrated Van't Hoff relationship presented by Gray (4) for use with thermograms recorded by differential scanning calorimetry (DSC) instruments. Temperature correction using the slope of the indium endotherm is always applied. Usually the sealed pans offered by the manufacturers are used, but a nitrogen environment is needed for some compounds. Work in this laboratory[4] has revealed no significant or predictable difference in estimates of impurities where thermograms from the two commercial systems were handled in similar fashion. The published baseline corrections are not necessary for these purposes and are not included in the entries in Table I. This same observation was made independently by other workers[5].

In Table I, T_0 is the extrapolated thermodynamic melting point relative to indium. Separate calibration is needed to express these values in terms of the USP–NF melting range because the methods are substantially different. There is no significance to the fact that a given T_0, converted to Celsius, falls within or outside monograph limits.

The ΔH_f values for ultrapure compounds are reproducible (5) with an internal precision of about 2% by quantitative differential thermal analysis (DTA). Few of the compounds here are ultrapure, and it is known that the ΔH_f values obtained depend on the sample purity; therefore, these data are not to be construed as highly accurate thermodynamic constants even though they may be the best values available. For this same reason, values with defined internal precision were not collected. All these values are corrected for premelt and are based on ΔH_f indium = 6.78 cal./g.

Qualitative TLC—Commercial, precoated glass plates or aluminum sheets are used exclusively. Silica gel[6] is the most common adsorbent, but neutral alumina and microcrystalline cellulose (MN-254) are also used. Four systems are developed for each drug substance and, because most are ionizable, the usual practice is to identify both acidic and basic developing solvents. Systems giving R_f 0.3–0.7 for the main spot are preferred. Three visualization techniques are identified. Nonreactive solvents are used where possible[7]. Artifact identification is made by: (*a*) spotting fresh and day-old solutions, and (*b*) two-dimensional TLC, involving wetting of the main spot of the first chromatogram with spotting solvent, drying, turning, and then developing the second chromatogram. Total spots listed in Table I reflect all four or three out of four systems, corrected for artifacts revealed by two-dimensional TLC. This allows reasonable estimation of the number and type of impurities.

General High-Low TLC Procedure—*Sample Solution*—Prepare a sample solution in a suitable solvent at a concentration of about 10 mg./ml. Nonreactive solvents are necessary, preferably degassed or nitrogen sparged. Dilute portions of this solution to concentrations of 1 and 0.5 mg./ml. These directions are general, and occasional solubility problems require their modification. Usually it is possible to apply 250 mcg. or more of drug sample and not exceed 25 μl. sample volume.

Reference Solution—A 10-mg./ml. solution of the specified reference standard in the same solvent is used to compare the identity of subsequent batches of the same drug substance.

Preparation—Divide a suitable TLC plate, 20 cm. square, coated with a 0.25-mm. layer of chromatographic silica gel mixture, into three parts: 2, 2, and 16 cm. in width. Spot 2 μl. of the reference standard solution (if available) in the first division on a line 1.5 cm. from the lower edge of the plate, spot 20 μl. (or largest volume to be spotted) of solvent in the second, and spot volumes equivalent to 250 (200, 100), 10, 5, 3, 2, 1, and 0.5 mcg. of the sample in the last, taking care to obtain comparable starting spots. Allow the plate to develop in a suitable chamber, usually lined with filter paper, which has been allowed to equilibrate at least 1 hr. with the specified developing solvent.

When the solvent reaches a height of 15 cm. from the origin, remove the plate from the chamber and air dry. Locate and compare spots and relative intensities under long- and shortwave UV light. Spray with 0.5% I_2 in chloroform and again rate the relative intensities of spots. Allow the iodine vapors to dissipate. Spray with 40% H_2SO_4 in methanol and view under a UV handlamp. Heat the plate and again view under UV light. For each visualization, estimate the relative abundance of spots as follows: compare each impurity spot in the 250-mcg. sample spotting to the main spots from the 0.5–10-mcg. spottings and assign a value to the relative intensities. For example, 0.4% impurity in the 250-mcg. sample has an intensity equivalent to the 1-mcg. main spot: (1 mcg./250 mcg.) × 100 = 0.4%. A densitometer may be used for these comparisons. Compare the reference standard mobility to that of the 10-mcg. sample spotting as an identity test. In most cases, acid–base indicators, ninhydrin, or Dragendorff sprays are used in this scheme. The 200- and 100-mcg. spottings are useful where there is evidence of overloading at the 250-mcg. level. Smaller spottings often are not visualized by one or more of the methods, so sensitivity estimates must be revised.

High Pressure Liquid Chromatography—An instrument[8] fitted with a gradient elution accessory is used with 1.0-m. × 2.1-mm. stainless steel columns. Commercial, coated packings with chemically bounded phases[9] are used usually with hydroalcoholic eluants in a reversed phase, gradient elution mode. Temperatures between 30 and 50° are employed at pressures up to 80 atm. to obtain flow rates between 0.5 and 1.5 ml./min. Only the low pressure mercury line, 254-nm., detector was used for the drugs reported herein. Drugs were dissolved wherever possible in one of the eluting solvents, 10–30 mg./ml., just prior to injection of 10–100-mcg. samples.

GLC—A temperature-programming instrument[10] is used with flame-ionization detectors. Only the relatively inert methyl and methylphenyl silicones (OV-1, OV-17, and OV-61)[11] on silanized diatomite are used after curing and conditioning, as instructed in the General Tests section of NF XIII (2).

DISCUSSION

The objective of this laboratory's examination of these samples is to allow an independent recommendation to the compendia as to the suitability of a sample for adoption or continued recognition as a standard. To accomplish this goal, it is not deemed necessary to discern precisely and reliably between, say, 0.3 and 0.4% impurity; rather, it is important to recognize samples containing, for example, 1% or greater impurities, to detect an increase in impurities of a few tenths-percent in a sample during storage, or to identify relative differences in impurity contents of subsequent batches of the same drug. Thus, those obvious experimental enlargements leading to more precise values are not pursued once information adequate to the objective is in hand. The data presented here, on the whole, are to be considered as having moderate precision.

Purity estimates should not be based on a single type of data. No method is universally applicable or reliable. Purity values obtained are in different units (mass or mole purity, visualization response, flame-ionization response, 254-nm. absorptivity, *etc.*), and these measurement units can be interconverted only where the identity, properties, and proportions of all impurities are known. Such thorough definition is unusual and seldom valuable and is not the case for the samples listed here.

The individual purity-indicating data converge to establish a profile of purity. It is this profile of purity that is meaningful and that permits decisions about the scope of analytical utility of a given sample.

There is no practical value to reconciling differences between purity-indicating data of moderate precision where both or all methods show the material to be satisfactory or unsatisfactory for the intended uses. Testing strategy and evaluation must begin with a statement of the intended uses of a standard. Different weights are placed on purity profile data according to intended standard usage, *i.e.*, as a chromatographic assay standard as opposed to an IR identity test or a limit test.

Alternative approaches to purity determination are known. Certified contents of the main or minor component by a defined

[a] Samples cannot be presumed to have been found acceptable by the responsible compendial body. [b] *a*, *b*, and *c* represent different batches. [c] Confidence classes are defined as: A or B, almost conclusive or strong evidence of the (im)purity of a sample; C, good evidence but requires several supporting data; and D, possibly useful as supporting evidence in conjunction with strong alternative evidence. n = number of tubes used. [d] T_0 = extrapolated thermodynamic melting point related to indium. [e] Values are based on H_f indium = 6.78 cal./g. [f] Total number of impurities as determined by qualitative TLC. [g] For GLC systems: A, 3% OV-17 on 100–120-mesh Gas Chrom Q; B, 3% OV-1 on 100–120-mesh Gas Chrom Q; and C, 3% OV-61 on 80–100-mesh Gas Chrom Q. HPLC = high pressure liquid chromatography. ETH = an ethereal polymer; DSC = differential scanning calorimetry. PSA = phase solubility analysis. ODS = octadecylsilane. OPDN = β,β'-oxydipropionitrile. HCP = a hydrocarbon polymer.

method are necessary for such applications as primary titrimetric, calorimetric, or trace standards[12]. Exhaustive definition of the identity and quantity of every impurity in a given lot of drug standard has been achieved elsewhere for a few compounds, but this approach has been judged unsatisfactory and uneconomical[12]. Practical evaluations of a few ultrapure reagent samples[14] and the strategies involved were discussed recently (6).

Profile Interpretations[15].—Estradiol dipropionate was evaluated by PSA, DSC, TLC, and high pressure liquid chromatography. The material was proposed for use partly as a reference standard in a UV assay. Solubility analysis showed 0.8% mass impurity, and scanning calorimetry revealed 0.5 mole % eutectic impurity. High-low TLC and GLC gave a 1.0–1.2% impurity level. At this point, the material could be used as a standard for IR or thin-layer identification purposes. However, liquid partition chromatography revealed six components and that one of the impurities was intensely UV absorbing, about 15% of the area under the curve at 254 nm. Another sample showed 7% in the 254-nm. data but more mass impurities. Collection of the main impurity showed that it interfered about 6 and 3%, respectively, at the monograph wavelength of 268 nm. Therefore, the material was unacceptable as a UV assay standard. *This is a striking illustration of the necessity of interpreting purity profile data in light of the intended uses of a standard.*

Betamethasone was evaluated by liquid partition chromatography; about 1.4% UV absorbing impurity was evident. Quantitative TLC showed only 0.5% and high-low TLC indicated 1.0% impurity. Thermal decomposition precluded an estimate of eutectic impurity. Solubility analysis in a polar alcoholic solvent revealed that the main component was only 96.3% pure. Because polymorphism could account for a discordant solubility analysis, especially for a steroid, a second solubility analysis, this time in an ethereal solvent, was performed. The result, 96.5%, was confirmative, excluding polymorphism as an explanation for the data. The presence of process-related, saturated steroids was suspected, because these would not absorb UV light and, therefore, would not be revealed by either quantitative TLC (recovered *versus* original) or the 254-nm. detector; less detectability is anticipated with most visualization reagents so that the high-low value would register less than the mass present. A subsequent batch assayed 98.7% by solubility analysis, high-low TLC revealed 1.2% impurity, and liquid chromatography showed only 0.7% impurity. The UV absorbance at the monograph wavelength was about 1% greater than that of the former batch, which partially confirmed the interpretation.

Acetanilid was marked for use as a melting-point standard. The material was chromatographically homogeneous. Calorimetric purity analysis indicated that less than 0.02% eutectic impurities could be present, the most desirable feature for a melting-point standard. On the other hand, estradiol cypionate was shown to contain about 0.8% impurity, mostly estradiol, by chromatography, whereas eutectic impurities registered only 0.1%. Such discordance of calorimetric purity with other methods is particularly severe in steroids where solid solutions are commonplace.

Norethynodrel was evaluated by solubility analysis, calorimetry, and TLC. A three- or four-component mixture was indicated by TLC, and a 1.8% eutectic impurity was in evidence. Solubility analyses in two solvent types both demonstrated a high level of impurity, about 2.7%. A subsequent batch showed unusual correlation of PSA, DSC, and high-low TLC values at the 1.6% level which, for a compound of this type, may be currently the best achievable purity.

Dexchlorpheniramine maleate was found by solubility analysis to contain a less soluble component (13.8%) and soluble impurities (1.6%). The 13.8% component was interpreted as the racemic compound due to the presence of a 6.9% *l*-isomer. The solubility of the racemic compound (4.5 mg./g.), allowing for mass action due to maleate, was consistent with the value predicted from the phase diagram, and chromatographic data also were consistent with this interpretation.

[12] The National Bureau of Standards is the major source of such standards.

[13] C. A. Johnson, British Pharmacopoeia, personal communication.

[14] Ultrapure reagents are needed mostly in trace and inorganic analyses.

[15] Only the specialized purity-indicating data are listed here; monograph tests were performed on each, such as moisture content, spectral characteristics, and optical rotation.

Most of the profiles in Table I are straightforward, and the above examples were chosen to illustrate either the interpretations of discordant data or the variable weight assigned to data with respect to the intended uses of a standard.

COMMENTS ON METHODS

PSA—Procedures and interpretation of results were discussed in detail elsewhere (1, 2, 7, 8). This laboratory has made available systems for 120 drugs [including those of an earlier summary (1)]. Approximate solubilities may not be close enough to the PSA-determined value, particularly where substantial impurities exist, so that additional tubes may be required at a later time to fill in the phase diagram. This open-ended feature of PSA is valuable. Where greater precision or definition is required, more tubes may be added. More importantly, additional solvents or temperatures may be chosen. Indeed, identical results of solubility analyses in two chemically different solvents may be taken as conclusive purity evidence.

PSA is the most generally applicable absolute purity determination. Scrupulous attention must be given to technique and choice of systems. A disadvantage of the method is the lengthy elapsed time[16] before interpretation is possible. Solid solutions (9) and disproportionation of salts (10) are encountered occasionally, but recent modifications show promise of extending the scope of solubility analysis to these difficult situations, Successful analysis (10) of atropine sulfate has been reported using a picric acid system, whereas probable disproportionation has prevented analysis in this laboratory by the usual procedure. Apparent polymorphism in the solvent is a more common problem, particularly with steroids, and this may explain the data for hydrocortisone, norethindrone acetate, and prednisolone acetate. A change of systems would be indicated where other purity profile information does not allow interpretation.

High-Low TLC—The need for a semiquantitative TLC test, one that could be used to validate precise but unselective assays such as titrations, has existed for some time. Obvious theoretical arguments against the accuracy of such a test can be overwhelming; nevertheless, it is one purpose of this report to prove the practical value of one such procedure by comparison of the results of (im)-purity estimates with values obtained by more definitive methods. High-low TLC has been instituted in this laboratory out of a suggestion from Johnson[13]. The need for such a test arose from the reference standard evaluation program, in which samples containing minor impurities must be evaluated without benefit of comparison to other standards. This situation is critical in instances where neither solubility nor calorimetric analysis has yielded interpretable purity data.

Typically, varying sample sizes are spotted on a single plate, the chromatogram is developed, and unselective visualization methods are used. Impurity spots in the heaviest spotting are compared in intensity and size to the main spot in each of the smaller sample applications, and the estimated impurities are summed for an overall estimate. The limiting assumption here is that the drug samples are contaminated with chemically related materials. Even with related materials, responses vary so that the usual practice is to use three unselective visualization methods. This method is a realistic approach only where a few percent of impurities are anticipated.

High-low TLC is most useful exactly where quantitative (by extraction) TLC is not reliable, such as distinguishing between 0.5 and 1.0% impurity and ranking subsequent batches of the same drug. TLC data, in general, have not been useful for materials having less than 0.2% impurities.

Correlation of high-low results in Table I with PSA and DSC data shows that this method is reasonably reliable, usually within 0.5% of the total impurity, with PSA–TLC being better correlated than DSC–TLC. High-low TLC and qualitative TLC are valuable tools in constructing purity profiles, and the use of these procedures in conjunction with DSC is recommended strongly for validation.

Other Chromatography—Qualitative and quantitative TLC evaluation of drug purity and stability is commonplace and requires no discussion. It is important to note that recovery and precision considerations easily obscure purity information, particularly where an established standard is not available for direct comparison. In quantitative thin-layer work, the bias is usually in the direction of underestimating the recovered species, and assays are of little value when a standard of known purity is not available.

GLC purity estimates play only a minor role in initial establishment of, as opposed to comparative assay with, a reference standard. GLC purity alone is valid only for distillates, because only the volatile portion of the sample is eluted for measurement. Similarly, only the least polar phases are of value in general purity work. Multiple products are not unusual with derivatization, and any reaction or extraction can constitute a purification step. Thermal-injection artifacts are all too common but are easily distinguished from impurities by comparison of chromatograms resulting from stepwise variation of injection port temperature from that of the column to 150° hotter ("hot-port" experiment).

High-pressure liquid chromatography has substantial potential for purity-indicating data, but applications of this technique are too recent to allow many generalities. At present, it appears that this recent instrumental development, along with excellent new packing materials, has made available a major purity test. Separate evaluation of this tool is planned.

DSC—As a first proposition, this method cannot be regarded as ever yielding absolute estimates of (im)purity. However, where prudently applied, this method can be of great value in drug purity evaluation. Combined with strong supporting evidence such as TLC, the method is well suited to purity and stability evaluations. The method is capable of considerable precision and reproducibility. Discussions of the experimental details and scope are available (5, 11–14). Reliance on this method requires at least the exact knowledge of the history of a sample and the types of likely impurities. Precalibration against other purity-indicating information and use of defined standards are preferred. Most drug substances are not amenable to calorimetry because of thermal decomposition during melting or, in certain situations, significant vapor pressure. Experience with more than 150 compounds, randomly received, indicates that about 30% of official drug substances yield calculable thermograms. The problem of low ΔH_f compounds was recognized earlier (13). In these cases, and for solid solutions as well, melting-point phase diagrams, as discussed by Marti *et al.* (14), may be of value, but samples with proven purity are needed to construct the diagrams. All these remarks apply only to quantitative DSC and not to the major value of thermal analysis for such phenomena as polymorphism.

Several distinctive problems should be discussed. Only eutectic impurities are revealed; solid solutions lead to impurity estimates that are too low. The thermogram does not reveal solid solutions (12). For example, the presence of 3.6% added norethindrone in norethynodrel was not measured by DSC, although this is measurable by UV spectrophotometry; in contrast, the presence of added mestranol was revealed by DSC.

Correction for the fraction of sample melted prior to instrumental response is a feature of the usual DSC method (11–13). This empirical correction (and resulting slope and impurity value) depends on an arbitrary choice of those areas to be used in the temperature *versus* reciprocal fraction-melted plot. For example, varying the choice of areas in the phenacetin analysis resulted in premelt factors ranging from 1 to 15% and in impurity values ranging from 0.02 to 0.40 mole %.

The T_0 and ΔH_f values are affected somewhat by the random selection of areas, but minor variation in these values has negligible effect on the calculated impurity. The premelt correction is varied until the theoretical linear relationship is visually obtained in the plot. However, many drugs yield S curves in the plot, which cannot be even approximately linearized. Premelt correction then is entirely arbitrary, allowing for great variability in the final impurity calculation. Such was the case with diphenhydramine hydrochloride, ethacrynic acid, hexachlorophene, menadione, methamphetamine hydrochloride, norethindrone acetate, norethynodrel, phenacetin, and phenprocoumon. For example, impurity values between 0.2 and 0.4 mole % could have been reported for phenprocoumon because of visual uncertainty in determining the best line for the data. The values reported[17] in the table for these drugs represent results obtained using the premelt correction yielding the least-squares best fit with the lowest standard error. A three-point estimate is

[16] A vibrational method is used elsewhere but has not been found to be reliable here except in instances of large sample charges.

[17] Calculated by means of a programmable desktop calculator.

also used (15). In cases where S character is strong, we recommend that impurity values be calculated using several premelt correction values as an indication of the confidence. Computer programs that calculate a single value for impurity based on a single best fit should be used with caution, as the degree of S character is not specifically determined even though the premelt correction is well controlled. Studies on the impact of this problem are in progress. The magnitude of the premelt correction in Table I correlates roughly with the level of impurity, as should be expected: 0.0–0.2 mole % impurities averaged 3.3% premelt correction, 0.2–0.5 mole % averaged 6.8% premelt correction, and >0.75 mole % averaged 11% premelt correction. A sample that generates a premelt correction not consistent with this trend should be examined more carefully by other methods before such purity data are interpreted.

SUMMARY

Purity constants and analytical systems are reported for samples of 115 official drug substances analyzed by various combinations of PSA, DSC, high-low TLC, GLC, and high pressure liquid chromatography. General experiences are discussed for these purity-indicating techniques. No one method is universally reliable or applicable, and purity decisions should be based on the largest variety of data available.

The individual purity-indicating data on a given sample converge to establish a profile of purity. It is this purity profile that is meaningful and that allows decisions about the scope of usefulness of the sample as a reference standard. Examples of interpretations are given for a few of the purity profiles.

PSA continues to be the most valuable and generally applicable purity technique. DSC has value in the construction of purity profiles, but it can never stand alone and is applicable to only a minority of drugs. GLC is of minor value in establishing purity profiles. On the other hand, high pressure liquid chromatography has demonstrated a potential for major value in purity work.

Despite the inherent inaccuracies in high-low TLC, a direct correlation exists in the majority of cases between the values obtained by PSA and this method. It is possible, where a rapid method is needed, to determine approximate purity within a day using high-low TLC, especially where a marked correlation exists between purity estimates determined by the methods discussed here.

Freezing Unit Dose Injections prior to Freeze Drying

ARTURO RIGOLI

Abstract □ A new method, used on an industrial scale, for freezing vials to be lyophilized was studied, by which a dried mass in the shape of an internal hollow paraboloid with very thin layers is obtained. The apparatus is also described.

Keyphrases □ Freezing of solutions, emulsions, and suspensions—improvde rotating freezer for liquids in ampuls or small containers □ Injections, unit dose—improved rotating freezer for use prior to freeze drying □ Lyophilization, injectables—improved method for freezing vial contents

Up to the present day, the most used industrial techniques for freezing vials containing pharmaceuticals to be lyophilized have been the: (A) single-cylindric tablet (bottom freezing) (Fig. 1*a*), (B) cylindric tablet composed of two or more separated strata (1, 2) (Fig. 1*b*), (C) shell form (agar slant) tablet (Fig. 1*c*), and (D) double shell (3) (double agar slant) tablet (Fig. 1*d*).

Technique A, being the cheapest and simplest, is the one most used. In this method the vials are placed vertically on suitable trays, which are then transferred to refrigerated shelves or, sometimes, immersed in freezing baths. The freezing is monodirectional and bidirectional in the two cases, respectively, and proceeds from the outer to the inner part of the liquid cylinder. An external layer of frozen liquid is set up which renders rather difficult the heat exchange; as a consequence, a long treatment at low temperature is required to freeze the liquid completely.

Technique C needs specific equipment. The liquid is distributed on part of the vial wall to obtain a larger evaporation surface. By consequence, the mass freezes in thinner layers than in both the A and B techniques while the time required for both freezing the solution and evaporating the solvent is minimized, with an obvious reduction of production costs.

Techniques B and D, much more laborious and expensive than the others, are carried out to avoid the mixing of interreacting substances (4). It is known that the best lyophilization conditions are assured by the quick cooling of large surfaces of material in thin layers (5–7).

During the last 10 years, different kinds of rotating freezers have been patented (8) to reach these conditions. Such equipment allows only the freezing of bottles similar to those containing plasma (9, 10). The liquid mass is spread over most of the internal surface of the bottle, producing a shell form either by a slow or fast rotation of the flasks. The cooling of the bottles is provided either by immersion in a freezing liquid or by spraying the flasks with a cold fluid. This kind of apparatus works with few units at a time, and an external contamination could occur due to the use of the refrigerant fluid. Another type of rotating freezer (11), suggested for flasks, works as a normal centrifugal under vacuum machine, having an inclined rotation axis. The prefreezer does not require a freezing liquid because the cooling is obtained by rapidly rotating the product under vacuum (adiabatic cooling). With this type of freezer, the evaporation may cause the precipitation of the solids even before freezing, with obvious disadvantages in the drying phase and the final product. In fact, with this freezing procedure, fractioned crystallization of some components might occur in relation to their physical properties, and the developing crystals accumulate at the boundary layers of the mass to be frozen due to the centrifugal force.

Up to now, no similar industrial procedure has been applied to liquids to be frozen in ampuls or small containers. We improved and patented (12) a rotating freezer by which frozen solutions, emulsions, and suspensions are obtained in the shape of an internal hollow rotation paraboloid (Fig. 1*e*). With such a system, larger surfaces and thinner layers than those accomplished by the static freezers are obtained and the freezing time is reduced.

EQUIPMENT

The new rotating freezer consists of (Fig. 2):

1. A turning frame (No. 25), with trays containing the ampuls to be frozen, placed in a covered (No. 18) box (No. 17). The box bottom and walls are cooled by a refrigerant group (Nos. 29 and 30), which is able to lower the air temperature of the box to −50° within 25 min.
2. A ventilation system (No. 32) generating a blast of cold air at −45° which passes over the ampuls from the higher to the lower part of the vial at 90 m./sec. and 15 mm. water pressure.
3. A box (No. 17) that can be inclined at a suitable angle, dependent both on the diameter of the ampul and the volume of the liquid to be frozen. In this way, the liquid surface sets itself like an agar slant. By rotating the turning frame at a slow speed (20–30 r.p.m.), the liquid freezes in very thin layers on the inner surface of the ampul, forming a rotating hollow paraboloid (Figs. 3 and 4).

EXPERIMENTAL

The described equipment can be used for freezing mixtures of biological products having different eutectic points. This report concerns the freezing of an aqueous solution containing 15% solids, showing an eutectic point at −12°.

The freezing of 1.2 ml. of solution in vials of 13–13.5-mm. diameter resulted in a frozen mass in which thickness was about 0.2–2 mm. on the walls and 3–3.5 mm. at the bottom (Table I, Column *b*). Under the same conditions using a static freezer, the

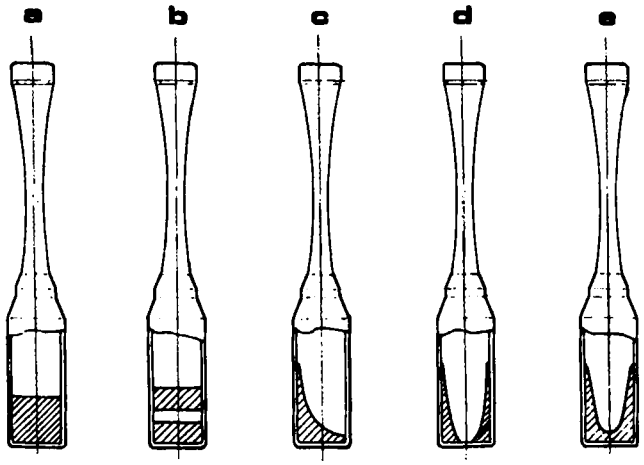

Figure 1—*Freeze-dried vials. Key: a, single-cylindric tablet (bottom freezing); b, cylindric tablet composed of two or more separated stratums; c, shell form (agar slant) tablet; d, double shell (double agar slant) tablet; and e, rotating paraboloid tablet.*

frozen mass thickness was 10–11 mm. (Table I, Column *B*). Moreover, the freezing time of 4–6 hr. (13) (Fig. 5) with static freezers was reduced to 20–25 min. with the study apparatus (Fig. 6) due both to the increased exchange surface (Table I, Column S_2) and the forced circulation of cold air which increases the total heat transfer coefficient. The drying time (Fig. 7) of the frozen vials was also reduced in comparison with that of statically frozen vials (Fig. 8). In fact, the temperature of the heating liquid being 40°, the frozen samples reached 0° within 5 hr., while 13 hr. was required for frozen samples with a cylindric shape.

As shown in Fig. 7, the maximum drying was reached within 1–3.5 hr. while for statically frozen vials the same drying was obtained within 1–10 hr. (Fig. 8). For paraboloid tablets, the maximum difference between the vapor pressure in the drying room and that in the condenser occurs within 3–4 hr. and the pressure in the drying room reaches a minimum value of 10 μ after 9 hr. For the

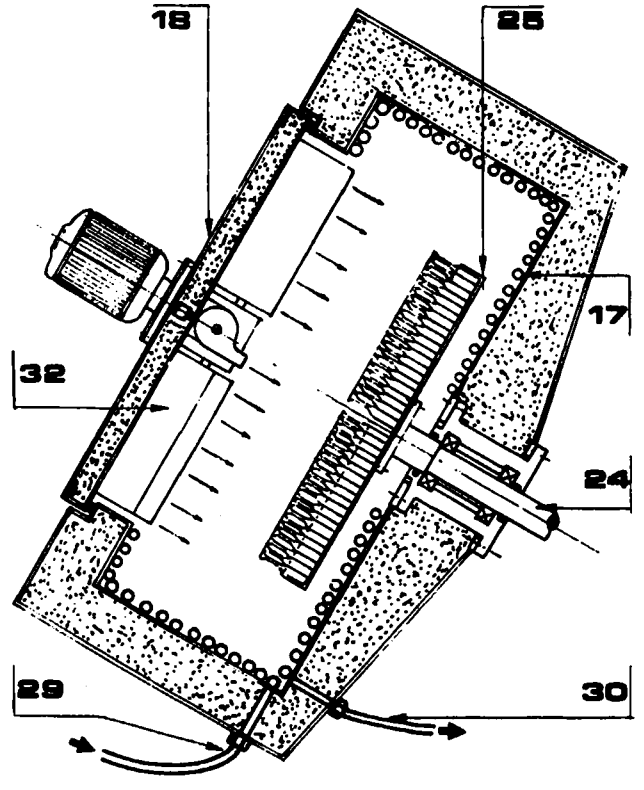

Figure 2—*Cross section of the rotating freezer. (See text for explanation of numbers.)*

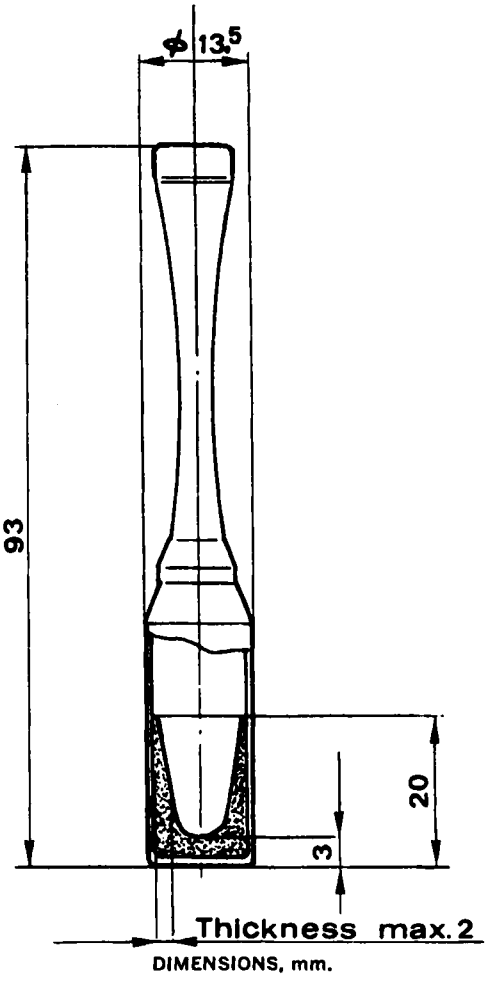

Figure 3—*Frozen vial in the shape of an internal hollow rotation paraboloid. Bottom and sides are 3 and 2 mm. thick, respectively. On the sides the frozen liquid is 20 mm. high.*

cylindric tablets, the maximum pressure difference is reached within 3–7 hr., and the pressure in the drying room reaches the minimum value of 10 μ after 19 hr. These differences are due to the major development of the evaporation surface (Table I, Column *S*), which in the first case is four times (Table I, Column *Rs*) as much as in the second case, and to the reduced resistance offered by the thin layer to the evaporation. In conclusion, the freeze drying of the above-mentioned solution, which would require 22 hr. if performed on the product frozen in a static freezer (Fig. 8), requires only 10–11 hr. in the case of the product frozen in the dynamic freezer (Fig. 7). Therefore, a saving of the required energy and an improved productivity can be obtained.

METHODS

The vials, filled by the usual filling machines, are placed in suitably drilled trays. These trays are placed on the rotating frame of the freezer, previously chilled, and the box is inclined at the suitable angle to distribute the liquid in a shell form, like an agar slant, on the inner side of the vial wall. Both the rotation of the frame and a cold air blast, flowing from the higher to the lower part of the outer surface of the vials, are started up. After 20–25 min., the liquid is completely frozen in contact with the internal wall of the vial. The stratum, having an average thickness of a few millimeters, is formed by several superimposed thin layers showing a spiral form; at the bottom of the vial, the frozen layer is about 3–3.5 mm. thick (Table I, Column *b*), depending on the diameter of the vial and the liquid volume (Table I, Column *VL*). The trays containing the frozen vials are placed into a conventional static freezer until the loading of the drying equipment is completed and are then lyophilized as usual.

Table I[a]—Cubic Paraboloid Measured and Calculated Values[b]

ϕ, mm.	VL, cm.³	V, cm.³	H, mm.	B, cm.	b, cm.	S, cm.²	Rs	S_1, cm.²	S_2, cm.²
12	1.0	1.090	20	0.96	0.28	5.104	4.52	4.77	8.69
13	1.2	1.308	20	0.98	0.32	5.405	4.07	5.33	9.50
14	1.5	1.653	20	1.06	0.42	5.542	3.60	6.20	10.34

[a] For the calculations and solutions, see text. [b] ϕ = vial diameter, VL = volume of 15% aqueous solution still at liquid state, V = VL volume at frozen state, H = height of fluid on wall of frozen paraboloid-shaped vial, B = height and thickness of statically frozen solution, b = thickness of bottom side of solution when frozen in paraboloid shape, S = evaporating surface of frozen paraboloid-shaped solution, Rs = ratio between evaporating paraboloid surface S and one of the same solution statically frozen, S_1 = surface of thermal transfer of statically frozen vial, and S_2 = surface of thermal transfer of same frozen cubic paraboloid-shaped vial as in S_1.

RESULTS

Compared with the usual static procedures, the rotational freezing procedure described here shows the following advantages:

In the Freezing Phase—1. Thinner layers: 0.2–2 mm. on the walls and about 3 mm. at the bottom (Table I, Column *b*) instead of 10–11 mm.

2. Minimized freezing periods (Fig. 6): about 25 min. instead of 4–6 hr. (Fig. 5) (13). This occurs because the heat exchange surface is almost doubled (Table I, Column S_2) and the heat transfer from a paraboloid-shaped mass is much faster than for cylindric tablets; the heat exchange decreases with the increasing frozen layer thickness.

3. Reduced chemical and physical changes: *e.g.*, oxidation reactions on the surface of the tablet, concentration of salts and possible protein (enzymes) denaturation, particle accumulation from suspensions, and emulsion cracking due to the reduced freezing time.

4. Absence of undercooled areas which might be formed in the cylindric tablets due to the rotation of the solution during the freezing time.

5. Absence of fractional crystallization of products contained in the solution to be frozen.

6. Constant thickness of the layers due to the rotation during the freezing. As a consequence, a shorter time and a regular progression in the drying process can be obtained (14).

7. Formation of tiny and compact crystals from which a compact and amorphous freeze-dried product is obtained.

8. Possibility to reduce the amount of support to be added to the solution.

9. Reduced refrigeration energy consumption to overcome the eutectic zone and to get complete freezing.

In the Drying Phase—1. High development of the evaporation surface (Table I, Column *S*), which is about four times as large (Table I, Column *Rs*) as the surface of the solution frozen in single-cylindric tablets in similar vials.

2. Rapid and deep heat penetration into the layer.

3. High drying rate (Fig. 7) due to the minimal resistance of the dried layer to the evaporation of the solvent.

4. Increased drying efficiency as a result of Points 2 and 3.

5. Absence of both visible and invisible fusion areas.

6. Compact and homogeneous aspect of the final product.

7. Higher reconstitution rate of the solution.

8. Reduced thermal energy required for ice elimination.

A comparison of the working conditions of the rotating freezer (Column A) and those of the conventional system (Column B) is shown in Table II. In Case A, a conventional freeze-drying apparatus was used, equipped with a static freezer with 24 trays, a freeze-drier with 24 trays, and a rotating freezer with two trays. In Case B, the same apparatus as in A was used except for the ab-

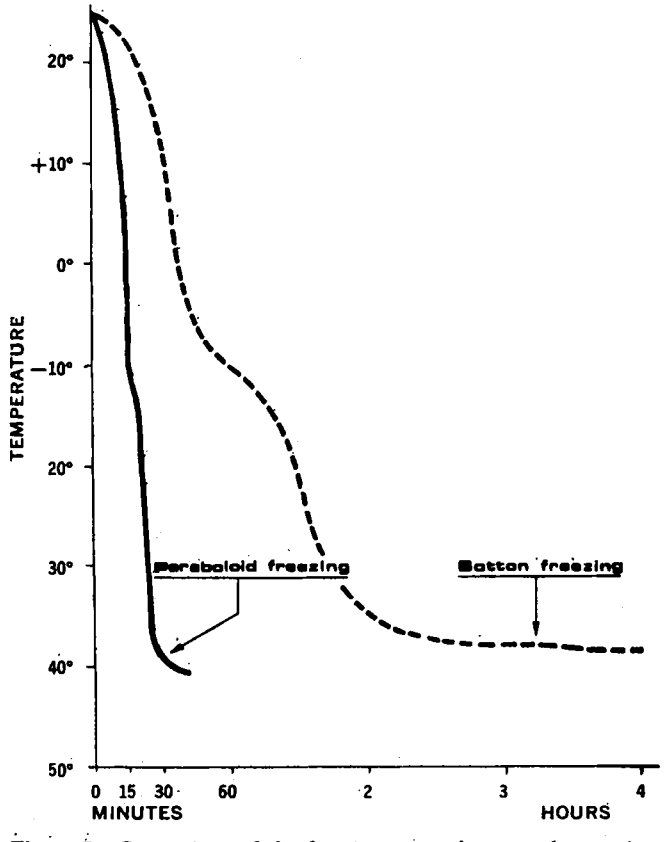

Figure 5—*Comparison of the freezing curves between the rotating paraboloid-shaped vial* (——) *and the cylindric (or bottom freezing) vial* (- - -).

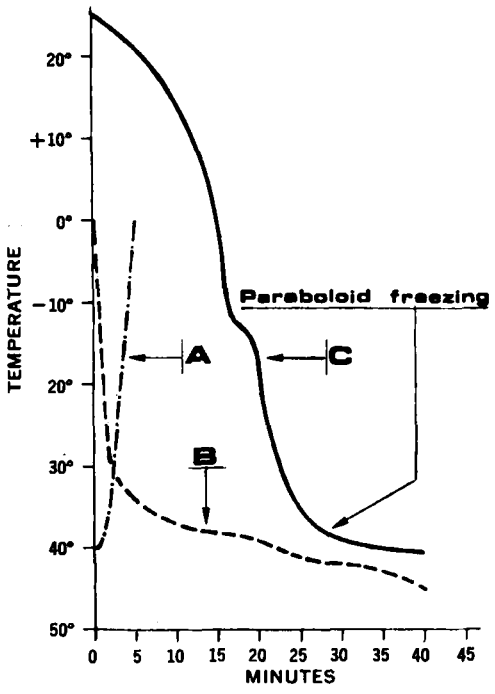

Figure 6—*Graph of the frozen curve of the rotating paraboloid-shaped vial (C). The temperature control was set at −45°. Key: A, temperature of open devia during loading process; B, temperature of closed devia during freezing process; and C, product temperature during freezing.*

sence of the rotating freezer. The minimal times shown in the table are relative to compact cycles without "dead time," while the maximum times represent the real operative time. From the data reported in Table II, it is evident that with A it is possible to reduce the time of operation to 30–50%.

CALCULATIONS

The values of ϕ, VL, and H were measured and the therms were calculated from the cubic paraboloid using the following formulas:

Calculation of V—The volume of the solution when it is at the frozen state is given by:

$$V = \frac{cVL}{0.9} + dVL \qquad \text{(Eq. 1)}$$

where:

VL = volume of solution at liquid state
V = volume of VL at frozen state
c = real percent of water in solution
d = percent of substance dissolved in solution
0.9 = ice density

Calculation of a—This constant of the cubic paraboloid has the following equation:

$$y = ar^2 \qquad \text{(Eq. 2)}$$

Table II—Comparison of Working Hours between Paraboloid (A) and Bottom Freezing (B) Methods

A		B		Remarks
0.5 hr.	6 hr.	6 hr.	15 hr.	Freezing time, 24 trays[a]
10 hr.	12 hr.	20 hr.	24 hr.	Drying time, 24 trays
10.5 hr.	18 hr.	26 hr.	39 hr.	Total hours

[a] This time course is calculated from the moment when the last tray full of dosed vials is placed into the statical freezer to the moment when the first tray with frozen vials is carried from the freezer to the drying room.

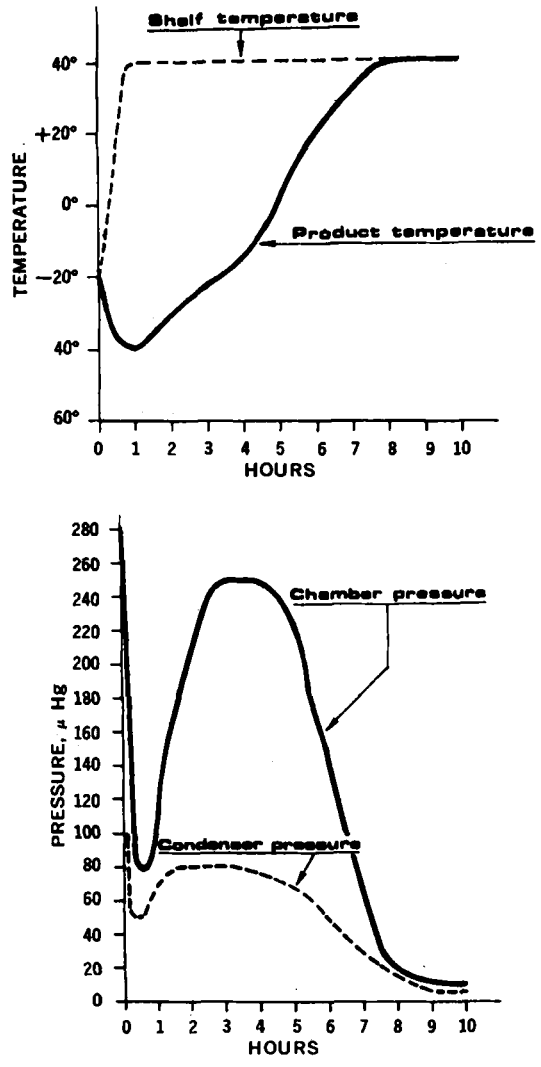

Figure 7—*Temperature–time and pressure–time curves characteristic of the drying cycle for the rotating paraboloid-shaped vials.*

after a series of control measurements. This equation reproduces satisfactorily the shape of the surface of the product frozen in an inclined vial and on a turning support.

$$V = \pi R^2 H - \frac{3}{5}\pi R^5 a \qquad \text{(Eq. 3)}$$

where:

$\pi R^2 H$ = total volume at total height H (Fig. 4)
$\frac{3}{5}\pi R^5 a$ = volume of cubic paraboloid (empty part of Fig. 4)

Equation 3 is used to find out a required to calculate b and S. Thus it becomes:

$$a = \frac{\pi R^2 H - V}{\frac{3}{5}\pi R^5} \qquad \text{(Eq. 3a)}$$

Calculation of b—The bottom thickness (Fig. 4) is given by:

$$b = H - aR^2 \qquad \text{(Eq. 4)}$$

where:

H = total height
aR^2 = paraboloid height

Calculation of S—The inside paraboloid surface is given by:

$$S = 3\pi a \left\{ \frac{R^2}{2} \cdot \left(\frac{1}{9a^2} + R^4 \right)^{1/2} + \frac{1}{18a^2} \ln \left[R^2 + \left(\frac{1}{9a^2} + R^4 \right)^{1/2} \right] - \frac{1}{18a^2} \ln \frac{1}{3a} \right\} \quad \text{(Eq. 5)}$$

Calculation of *Rs*—The ratio between paraboloid (*S*) and the upper surface of a cylindric tablet is given by:

$$Rs = \frac{S}{\pi R^2} \quad \text{(Eq. 6)}$$

Calculation of S_1—The surface of thermal exchange for a statically frozen vial is given by:

$$S_1 = Sf + Scs \quad \text{(Eq. 7)}$$

where:

Sf = base surface
Scs = cylindric lateral surface corresponding to height of statically frozen solution

Calculation of S_2—The surface of the thermal exchange of the frozen paraboloid-shaped vial is given by:

$$S_2 = Sf + Scp \quad \text{(Eq. 8)}$$

where:

Sf = base surface
Scp = cylindric lateral surface corresponding to height of paraboloidally frozen solution

CONCLUSIONS

With the above-described apparatus and technique, solutions, suspensions, and emulsions can be frozen in vials or small containers. An improvement of the freeze-dried product and a reduced cost are obtained due to the large surface and the thickness of the layer.

The increased freezing and drying rates make it possible to carry out two working cycles a day with the same lyostat. The described method is carried out with a rotating freezer, which represents only a further addition to the normally used apparatus of a freeze-drying department. Therefore, it is not necessary to make any substitution or to change the existing plants, except for the collecting vial trays with a drilled bottom. The reported calculations (Table I) are useful to obtain the necessary thickness at the vial bottom with a given height of the frozen paraboloid-shaped liquid. This height depends

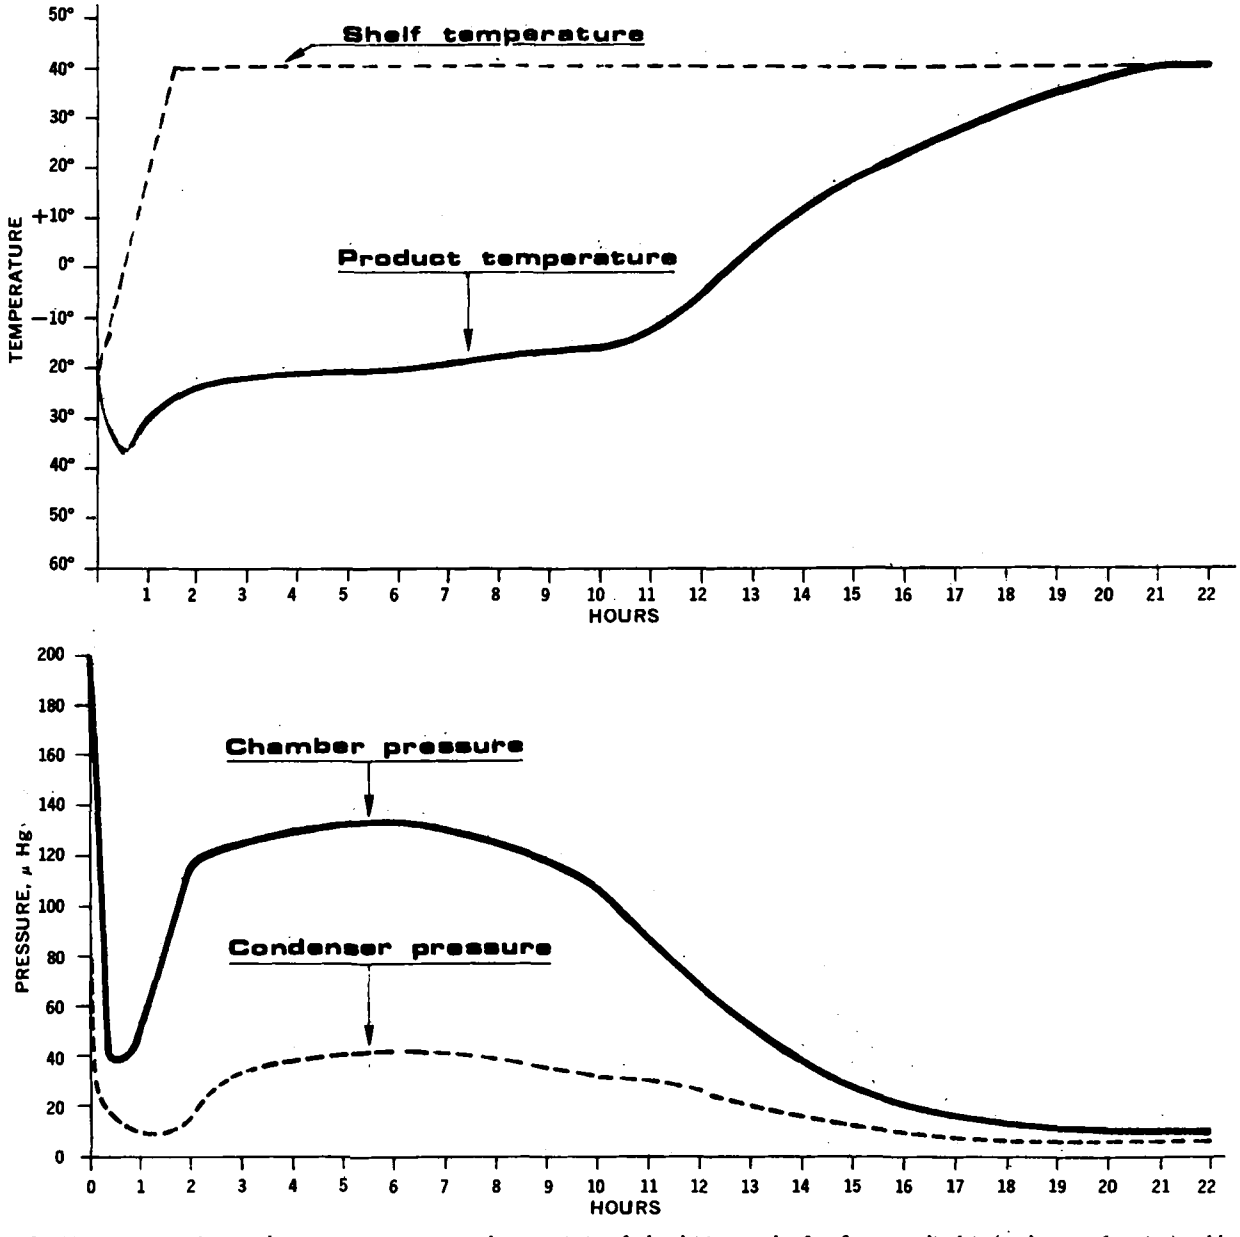

Figure 8—*Temperature–time and pressure–time curves characteristic of the drying cycle for frozen cylindric (or bottom freezing) tablets.*

on the freezer inclination and the volume of the liquid. With a different inclination of the freezer corresponds a different heat exchange surface which, therefore, can be changed according to the working conditions.

Evaluation of Magnetic Basket Dissolution Apparatus I: Differences in Tablet Formulations

T. E. NEEDHAM▲, R. E. SHEPHERD, and L. A. LUZZI

Abstract □ The use of the magnetic basket dissolution apparatus as a means of following the dissolution of tablets was studied. Several different formulations of pentobarbituric acid tablets were manufactured and used to illustrate the ability of the magnetic basket dissolution apparatus to differentiate between the dissolution of tablets with differences in particle size of active ingredients, in formulation, and in hardness. The magnetic basket dissolution apparatus was compared with the USP XVIII and Levy beaker methods for following dissolution. Log probability plots were used as a means of providing a quick and accurate dimension for analyzing dissolution data.

Keyphrases □ Dissolution equipment—comparison of magnetic basket apparatus with compendial and Levy beaker methods for studying differences in tablet formulations □ Magnetic basket dissolution apparatus—differentiation between tablet formulations, compared with compendial and Levy beaker methods □ Tablet dissolution—magnetic basket apparatus used to study formulation differences, compared with compendial and Levy beaker methods □ Log probability plots—used to analyze dissolution data, magnetic basket apparatus compared with compendial and Levy beaker methods

In vitro dissolution profiles are of importance when they can be correlated to *in vivo* studies or when the results can be used to evaluate and examine relative differences in drug dissolution and, hence, availability for absorption between dosage forms or differences from batch to batch of the same formulation. Implied by these qualities is reproducibility of dissolution profiles for the dosage form and drug in question. An *in vitro* technique incorporating these capabilities is, of course, the ideal for which one strives.

In this quest, Levy and Hayes (1, 2) showed that the round-bottom beaker method in combination with slow agitation rates simulates, in physical appearance, the deposition of the dosage form in the stomach and mimics *in vivo* disintegration. In an earlier report (3), it was shown that the magnetic basket yielded reproducible dissolution results for both capsules and tablets. During the initial investigation of the magnetic basket, the concern was to ascertain the degree of reproducibility possible; in addition, it was found that certain characteristics of capsule disintegration and dissolution could be determined from the results. One type of tablet was examined, and it was determined that dissolution from this tablet could be reproducibly followed using the magnetic basket. No attempt at comparisons with other methods was made at that time.

This report delineates the reproducibility for dissolution of tablets, and it shows that the magnetic basket can be used to detect formulation differences in tablets. In this study, comparisons of the dissolution rate using the magnetic basket, the USP XVIII basket, and the Levy round-bottom beaker are discussed.

EXPERIMENTAL

Material—Pentobarbituric acid powder and pentobarbituric acid micronized were supplied by a commercial source[1]. The dissolution medium consisted of a buffer mixture (4) of hydrochloric acid and potassium chloride at pH 2. Fast flow lactose[2], microcrystalline cellulose[3], starch[4], and stearic acid[5] were purchased.

Evaluation of Magnetic Basket Dissolution Apparatus I: Differences in Tablet Formulations

T. E. NEEDHAM▲, R. E. SHEPHERD, and L. A. LUZZI

Abstract □ The use of the magnetic basket dissolution apparatus as a means of following the dissolution of tablets was studied. Several different formulations of pentobarbituric acid tablets were manufactured and used to illustrate the ability of the magnetic basket dissolution apparatus to differentiate between the dissolution of tablets with differences in particle size of active ingredients, in formulation, and in hardness. The magnetic basket dissolution apparatus was compared with the USP XVIII and Levy beaker methods for following dissolution. Log probability plots were used as a means of providing a quick and accurate dimension for analyzing dissolution data.

Keyphrases □ Dissolution equipment—comparison of magnetic basket apparatus with compendial and Levy beaker methods for studying differences in tablet formulations □ Magnetic basket dissolution apparatus—differentiation between tablet formulations, compared with compendial and Levy beaker methods □ Tablet dissolution—magnetic basket apparatus used to study formulation differences, compared with compendial and Levy beaker methods □ Log probability plots—used to analyze dissolution data, magnetic basket apparatus compared with compendial and Levy beaker methods

In vitro dissolution profiles are of importance when they can be correlated to *in vivo* studies or when the results can be used to evaluate and examine relative differences in drug dissolution and, hence, availability for absorption between dosage forms or differences from batch to batch of the same formulation. Implied by these qualities is reproducibility of dissolution profiles for the dosage form and drug in question. An *in vitro* technique incorporating these capabilities is, of course, the ideal for which one strives.

In this quest, Levy and Hayes (1, 2) showed that the round-bottom beaker method in combination with slow agitation rates simulates, in physical appearance, the deposition of the dosage form in the stomach and mimics *in vivo* disintegration. In an earlier report (3), it was shown that the magnetic basket yielded reproducible dissolution results for both capsules and tablets. During the initial investigation of the magnetic basket, the concern was to ascertain the degree of reproducibility possible; in addition, it was found that certain characteristics of capsule disintegration and dissolution could be determined from the results. One type of tablet was examined, and it was determined that dissolution from this tablet could be reproducibly followed using the magnetic basket. No attempt at comparisons with other methods was made at that time.

This report delineates the reproducibility for dissolution of tablets, and it shows that the magnetic basket can be used to detect formulation differences in tablets. In this study, comparisons of the dissolution rate using the magnetic basket, the USP XVIII basket, and the Levy round-bottom beaker are discussed.

EXPERIMENTAL

Table I—Tablet Formulations

	Formula I	Formula II	Formula III	Formula IV
Pentobarbituric acid	—	—	25.0	25.0
Micronized pentobarbituric acid	25.0	25.0	—	—
Lactose	236.0	243.0	236.0	243.0
Microcrystalline cellulose	43.5	43.5	43.5	43.5
Starch	35.0	35.0	35.0	35.0
Stearic acid	10.5	3.5	10.5	3.5

Equipment—The three dissolution systems used included the USP XVIII dissolution apparatus (5), the round-bottom beaker (1, 2, 6), and the magnetic basket (3).

Tablets were compressed using a 16-station rotary tablet press[6] equipped with an induced die feeder. Standard concave punches, 0.95 cm. (0.37 in.), were used. A hardness tester[7] was employed.

Tablet Formulation—Tablets were compressed from the four formulations listed in Table I. All tablets were weighed and measured for thickness. Fifty percent of those tablets meeting specifications were examined for hardness; at least 75 tablets were examined for each hardness variation of all formulations.

Each of the four formulations was compressed at at least two hardnesses as determined by the hardness tester. For example, the range of hardness used for certain tablets was 8.6–9.0 with an average of 8.8; for softer tablets, a range was 3.1–4.0 with an average of 3.7.

Analysis of Tablets—The weight of each tablet was determined prior to dissolution, and the amount dissolved at any time t, reported as a percent of total acid, was determined at 240 nm. using appropriate blanks. Samples were taken at 2-min. intervals for the first 20 min. and then at 4-min. intervals until dissolution was complete. Reproducibility of results was determined by comparison of the variation produced at time intervals for similar tablets. For example, the Formula III tablets illustrated in Fig. 2 showed a standard error of the mean of 3.44, 5.07, 7.33, and 6.36 for the first four time intervals, respectively, with a reduction to 3.91 or less for the remaining samples. Each dissolution profile is the average of at least five tablets.

RESULTS AND DISCUSSION

Previous work (3) indicated that the magnetic basket could reproducibly follow the dissolution of both capsules and tablets. The additional versatility of this method can be seen if different formulations of the same drug are considered. In Fig. 1 the dissolution of tablets composed of Formulas III and IV are compared. By use of the magnetic basket method, differences between formulations that

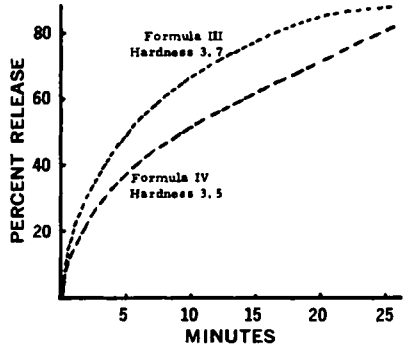

Figure 1—*Comparison of dissolution rates of active ingredients from tablets with different formulations and the same hardness, using the magnetic basket dissolution apparatus.*

[7] Erweka Electronic.

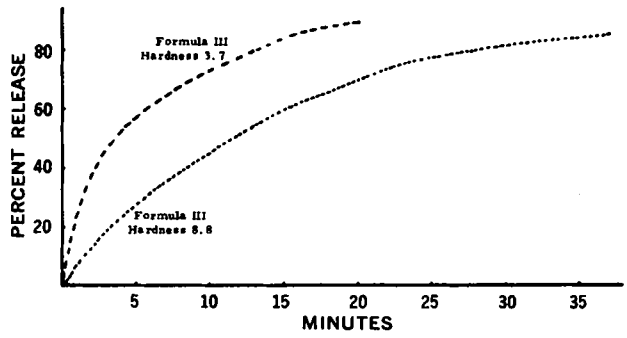

Figure 2—*Comparison of dissolution rate of active ingredients from tablets of the same formulation and different hardness, using the magnetic basket dissolution apparatus.*

are of the same average hardness and weight but differ in stearic acid content may be detected.

Figure 2 illustrates the difference found in dissolution between tablets using Formula III with different average hardnesses of 8.8 and 3.7. A distinct difference in the dissolution profiles of the two different hardnesses is seen, with the softer tablet as expected showing a much faster dissolution rate. The parallel dissolution behavior between the two tablets can be clearly seen using a log probability plot of time *versus* percent dissolved (7). Although the log probability relationship is most frequently used to describe the size distribution of particulate matter, it can be used in this case as a means of illustrating dissolution behavior. In the former case, both straight and curved lines may result. A straight line indicates that the sample examined is composed of a normal distribution, *i.e.*, all particles belong to the same population. A curved line indicates that the sample contains particles from more than one population. If the case of tablet dissolution is considered and the straight line is indicative of dissolution from a relatively unchanging set of parameters, then the correlation of dissolution behavior can be seen.

Figure 3 shows that two straight lines represent the dissolution profile of each tablet. It would seem that the first straight line is indicative of the initial dissolution–disintegration of the tablet when the tablet matrix is still present. That is, the surface area is relatively unchanged since the diminishing surface area of the tablet is offset by the increase in surface area due to disintegration. The second straight line should represent the dissolution phase when the tablet matrix is no longer present and dissolution is taking place from an infinite number of particles residing predominantly at the beaker bottom. Visual observation correlates with the appearance of the second linear segment in the log probability plots. Furthermore, in Wagner's (7) derivation of the rationale for use of log probability

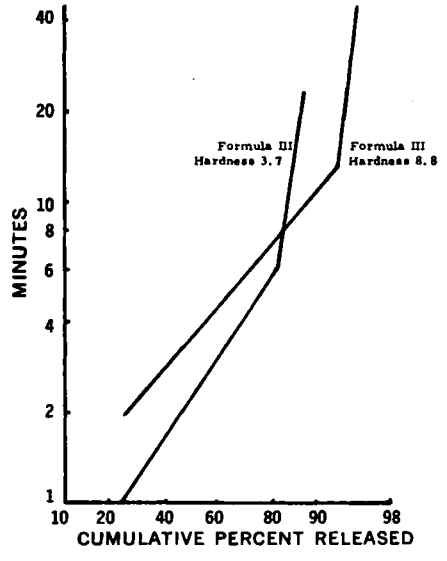

Figure 3—*Cumulative percent released* versus *time as an illustration of the treatment of data for tablets of the same formulation but of different hardness.*

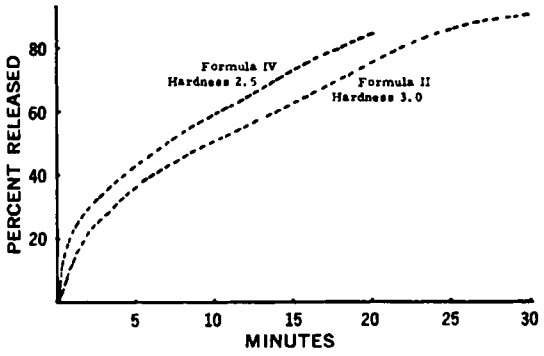

Figure 4—*Comparison of dissolution rates of active ingredient from tablets as a function of particle size of active ingredient, using the magnetic basket dissolution apparatus.*

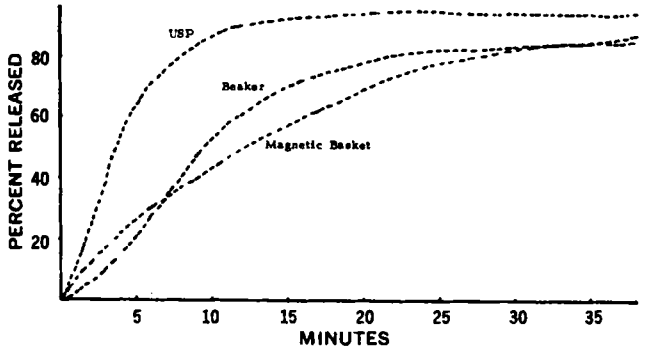

Figure 5—*Comparison of dissolution of active ingredient from tablets of the same formulation using the USP, beaker, and magnetic basket dissolution apparatus. All tablets were from Formula III with a hardness of 8.8.*

plots, his first assumption is that under sink conditions and changing surface area, one may assume that the surface area available for dissolution decreases exponentially with time. This would agree with the second segment of the straight line taking place after the tablet matrix has disintegrated.

One would expect deviation from the straight line concept in two places. The first deviation would be at the apex where the two straight lines intersect, since there is a transitional period when the dissolution–disintegration process and its concomitant "large" particles (small surface area) are changing to a pure dissolution process involving many smaller particles with a large surface area. The second deviation would be at the end of the second straight line when the material is approaching 100% dissolution. Here one is on the plateau of the regular dissolution curve, and the amount of drug dissolving per unit time is somewhat less than that rate witnessed during the initial portions of the second straight line. Therefore, the cumulative percent dissolved would remain virtually unchanged as time increased, giving rise to almost a vertical line. This deviation is small in this case and, although not shown in Fig. 3, may be attributed to a discontinuance of exponential exposure of the particle surface due to an increased shielding of the drug particle by insoluble tablet ingredients. The difference in hardness between the two tablets is readily seen by comparison of the intercepts of the two straight lines. For the tablets with an average hardness of 3.7, this intercept occurs at 6 min. The harder tablets, with an average hardness of 8.8, show this intercept at 13 min., which is what would be expected of a higher compression tablet.

To illustrate the ability of the magnetic basket to differentiate between tablets with different particle size of the active ingredient, Formulations II and IV were used. Formulation II contained micronized pentobarbituric acid, with a mean surface diameter of 4.42 μ; in Formulation IV, the pentobarbituric acid had a mean surface diameter of 9.96 μ. Figure 4 shows the dissolution profiles for these two formulations using tablets of comparable hardness. While the magnetic basket shows a difference between the dissolution profile as a function of particle size, the micronization of pentobarbituric acid does not give faster dissolution. This behavior was also shown to be true when comparing Formulations I and III.

Figure 5 shows a comparison of the official USP XVIII dissolution test, the Levy beaker method, and the magnetic basket method using tablets from Formulation III with an average hardness of 8.8. All three methods show similar dissolution profiles, with the USP method reaching its peak dissolution somewhat faster than the other two methods. A factor that would contribute to faster dissolution rates using the USP XVIII apparatus is the obvious screening, through centrifugal force, imposed on the dosage form placed in the spinning basket. This spinning and resulting rapid dissolution also tends to mask or level relatively small differences in tablet dissolution rates. The Levy beaker and the magnetic basket methods showed similarity in all dissolution comparisons of the various formulations.

While in a previous preliminary study there were indications that reproducibility and detection of formulation differences in both capsules and tablets were possible with the magnetic basket, it may be concluded from this study that the magnetic basket method is versatile in its ability to differentiate between the common parameters of hardness, particle size, and formulation differences found in these tablet studies. Furthermore, it will apparently provide a means of differentiation for both capsules and tablets, presenting the results in a directly comparable manner. Its use in combination with log probability plots provides a quick and accurate means of analyzing dissolution data.

Adsorption–Dissolution Relationship in Sulfamethazine–Benzoic Acid System

R. N. NASIPURI and SALEH A. H. KHALIL▲

Abstract □ Both the equilibrium solubility and dissolution rate of sulfamethazine were remarkably inhibited in the presence of benzoic acid. The effect was dependent on the concentrations of both the benzoic acid and sulfamethazine in the system. The inhibition of sulfamethazine dissolution was synchronous with the adsorption of benzoic acid on the sulfonamide particles. As low as 5 mg.% polyvinylpyrrolidone prevented the adsorption of benzoic acid on sulfamethazine and, consequently, the suppressive effect of benzoic acid on sulfamethazine dissolution was no longer shown.

Keyphrases □ Sulfamethazine–benzoic acid—adsorption–dissolution relationship, effect of polyvinylpyrrolidone □ Benzoic acid–sulfamethazine—adsorption–dissolution relationship, effect of polyvinylpyrrolidone □ Polyvinylpyrrolidone—effect on adsorption–dissolution relationship in sulfamethazine–benzoic acid system □ Dissolution—sulfamethazine in benzoic acid, effect of polyvinylpyrrolidone

During a study on the adsorption of benzoic acid on sulfamethazine particles, it was observed that in certain systems the equilibrium solubility of the sulfonamide was significantly decreased, sometimes reaching only about 6% of its solubility in water. The present article examines the effect of benzoic acid on the equilibrium solubility and dissolution rate of sulfamethazine and compares the dissolution results with the data of benzoic acid adsorption on the sulfonamide particles. The effect of polyvinylpyrrolidone on both adsorption and dissolution in the system is discussed.

EXPERIMENTAL

Materials—Sulfamethazine, BP grade[1], was used; the powder had a mean volume-surface diameter of 32.6 μ. Benzoic acid was of BP quality[2], and polyvinylpyrrolidone was a sample having an average molecular weight of 40,000[3]. Methylcellulose 20 and sodium carboxymethylcellulose of 50 and 100 viscosity grades[3] were used.

Methods—*Adsorption Isotherm*—The procedure described by Bean and Dempsey (1) was followed at 24 ± 0.2°.

Determination of Dissolution Rate—This was determined at 24 ± 0.2° in an oscillating water bath at a speed of 18 ± 2 strokes/min. After the specified time, the contents of the flask were filtered through a sintered-glass funnel[4]. The concentrations of both benzoic acid and sulfamethazine were determined in the filtrate spectrophotometrically by applying the equations of Tinker and McBay (2) for two-component systems. Measurements were made using a spectrophotometer[5] at 230 and 300 nm. (in 0.05 *N* HCl). The validity of the equations used were tested by assaying known mixtures of sulfamethazine and benzoic acid. The percentage errors were ±1.9% for sulfamethazine and ±2.3% for benzoic acid.

Elution Procedure—The suspension left after the adsorption experiment was filtered through a sintered-glass funnel[4], and the precipitate was digested in water (double the volume used in the adsorption experiment). The procedure described under *Determination of Dissolution Rate* was then followed.

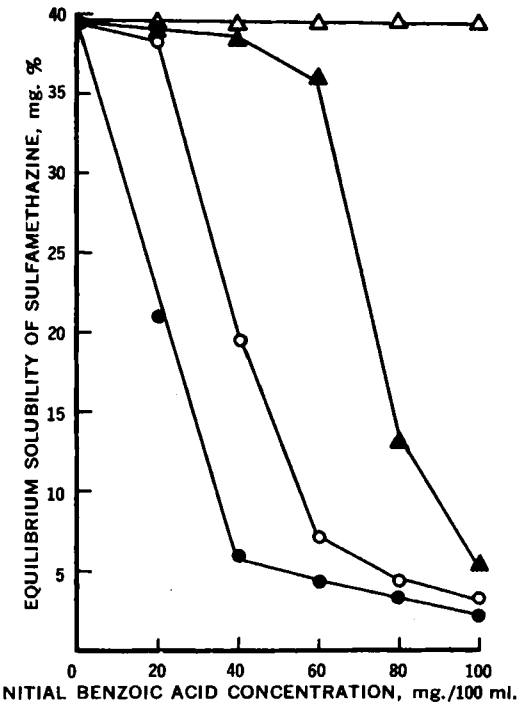

Figure 1—*Effect of benzoic acid on the equilibrium solubility of sulfamethazine. The concentrations of sulfamethazine in the system (g./100 ml.) were: (●) 0.06; (○) 0.1; (▲) 0.2; and (△) 0.3, 0.4, 4, and 10.*

RESULTS AND DISCUSSION

Figures 1 and 2 show, at different initial benzoic acid concentrations, the effect of benzoic acid on the equilibrium solubility of sulfamethazine and its adsorption on the sulfonamide particles. Within the concentration range of benzoic acid used, the equilibrium solubility of sulfamethazine showed a pronounced decrease; the effect was dependent on the concentrations of both benzoic acid and sulfamethazine in the system (Fig. 1). At and above 0.3 g./100 ml., sulfamethazine suffered no significant change in its equilibrium solubility; below 0.3 g./100 ml., a remarkable decrease occurred, reaching about 2.5 mg.% compared with 39.6 mg.% in water.

The decrease in sulfamethazine solubility in the presence of benzoic acid can be attributed to the adsorption of the acid on the sulfonamide particles. The data of benzoic acid adsorption are plotted in Fig. 2. The relationship between the amount of benzoic acid adsorbed per millimole sulfamethazine and the equilibrium

solubility of the sulfonamide is shown in Table I. At a constant initial concentration of benzoic acid, the amounts of benzoic acid adsorbed per millimole sulfamethazine were 0.75, 0.77, and 0.76 mmole for systems containing 2.16, 3.60, and 7.20 mmoles sulfamethazine, respectively. These data may suggest that the sulfonamide particles were "saturated" by benzoic acid, as shown by the plateau regions in Fig. 2. As a result, the equilibrium solubility of sulfamethazine showed a pronounced decrease (Table I). At higher sulfamethazine concentrations, the amount of benzoic acid adsorbed showed a gradual decrease and the sulfonamide solubility exhibited an insignificant change (Table I).

The relationship between adsorption of benzoic acid and its effect on sulfamethazine dissolution, both during an adsorption run and an elution experiment, is shown in Fig. 3. After 30 min. of equilibration, the amount of benzoic acid adsorbed per 0.2 g. sulfamethazine was 66.6 mg. In this system the equilibrium solubility of

	0	5	0	5
0	—	—	39.2	40.1
20	15.2	0.0	38.8	39.9
40	34.6	0.0	38.2	40.4
60	54.6	0.1	36.1	40.2
80	65.8	0.1	13.0	39.8
100	66.1	0.2	4.8	39.9

[a] Sulfamethazine concentration = 0.2 g.%.

sulfamethazine dropped from 39.2 to 4.8 mg.%. In the elution experiment, partial desorption of benzoic acid occurred since only about 10% of the amount originally adsorbed was eluted (Fig. 3B). Nevertheless, this seemed to have produced enough unoccupied sites on the sulfonamide particles as the result of partial desorption of benzoic acid, which could be claimed to be responsible for the increase in sulfamethazine dissolution during the elution experiment (Fig. 3A).

The role of polyvinylpyrrolidone in suppressing the adsorption of benzoic acid by sulfamethazine particles is shown in Table II. The incorporation of 5 mg.% of the polymer in the systems studied resulted in almost complete inhibition of benzoic acid adsorption. This was also reflected in the solubility of sulfamethazine, where no significant change was observed (Table II). It is suggested that polyvinylpyrrolidone, being a protective colloid, would be concentrated at the surface of sulfamethazine particles, thus "insulating" or "shielding" the surface. The work of Simonelli *et al.* (3) showed that polyvinylpyrrolidone inhibited the crystal growth of sulfathiazole due to the transport of the polymer molecules from the bulk to the crystal surfaces. Moriguchi and Kaneniwa (4) showed also that polyvinylpyrrolidone was preferentially adsorbed on talc, thus competing for the adsorption of cyanocobalamin on talc. The inhibition of sulfamethazine dissolution by benzoic acid reported in the present

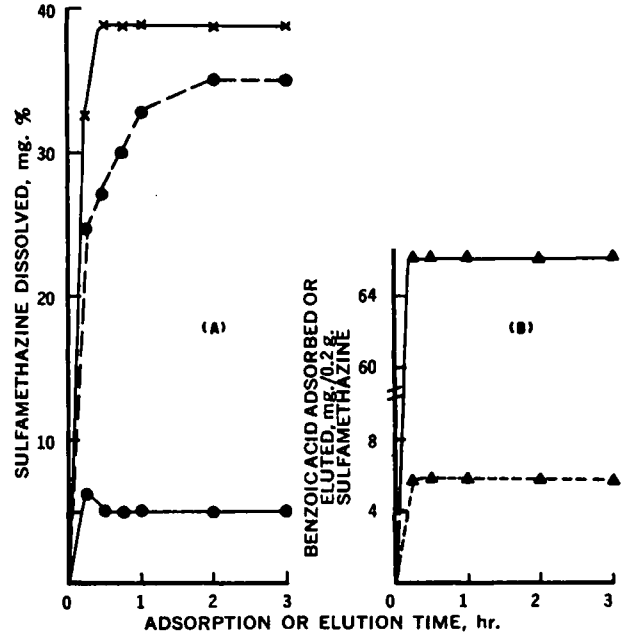

Figure 3—*(A) Effect of benzoic acid on the dissolution rate of sulfamethazine* (●—●) *during an adsorption experiment and* (●- - -●) *during an elution experiment;* (X—X) *is sulfamethazine dissolution in water. (B) Adsorption of benzoic acid on sulfamethazine and its elution. Key:* ▲—▲, *adsorption data; and* ▲- - -▲, *elution data. work is analogous to the work of Piccolo and Tawashi (5), who found that at low concentrations of some dyes, inhibition occurred to single crystal dissolution of a number of drugs.

SUMMARY AND CONCLUSIONS

In the presence of benzoic acid, both the dissolution rate and equilibrium solubility of sulfamethazine were suppressed. The phenomenon was attributed to the adsorption of benzoic acid on the sulfonamide particles. The inhibition of sulfamethazine dissolution was only shown when the sulfonamide particles were saturated by benzoic acid. Due to the protective effect of polyvinylpyrrolidone, as low as 5 mg.% of the polymer prevented the adsorption of benzoic acid and, consequently, its suppressive effect on sulfamethazine dissolution.

Identification of a Rearranged Degradation Product from Carbamazepine-10,11-epoxide

K. M. BAKER, A. FRIGERIO▲, P. L. MORSELLI, and G. PIFFERI*

Abstract □ Carbamazepine-10,11-epoxide, a metabolite of carbamazepine found in human urine, undergoes a rearrangement and degradation to 9-acridinecarboxaldehyde during GLC.

Keyphrases □ Carbamazepine-10,11-epoxide—identification of GLC degradation product as 9-acridinecarboxaldehyde □ 9-Acridinecarboxaldehyde—identified as carbamazepine-10,11-epoxide GLC rearrangement product, synthesis, physical-chemical properties

In previous papers (1, 2), it was reported that carbamazepine-10,11-epoxide was found in human urine as a metabolite of carbamazepine. The epoxide was isolated and identified; however, at the same time it was mentioned that subjection of this compound to GLC resulted in a degradation to another material. This paper reports the isolation, identification, and alternative preparation of the degradation product.

EXPERIMENTAL[1]

Carbamazepine-10,11-epoxide—The synthesis described previously (1) was altered to give better, consistent yields for pharmaceutical requirements.

A solution of carbamazepine (50 g., 0.21 mole) and *m*-chloroperbenzoic acid (47.4 g., 0.27 mole) in 2 l. of ethylene chloride was heated under reflux with irradiation by a sun lamp (200 w.) for 3 hr. After cooling and washing with dilute aqueous sodium sulfite solution and with 5% aqueous sodium bicarbonate, the organic phase was dried and evaporated. The residue was taken up in boiling benzene and cooled, and the precipitate collected. The crude product was recrystallized from ethanol to give carbamazepine-10,11-epoxide as pale-yellow needles (16 g., 30%), m.p. 205–207° dec. [lit. (1) m.p. 190–195°]; IR (mineral oil mull): 3500–3100 (NH_2), 1675 (C=O, urea), 865 (C—O, epoxide), 752 (CH out-of-plane bending) $cm.^{-1}$; NMR (acetone–dimethyl sulfoxide, 2:1): 4.38 (s, 2H, —HCO— epoxide), 5.34 (broad s, 2H, $CONH_2$), and 7.7–7.1 (m, 8H, ArH).

9-Methylacridine—Diphenylamine, acetic anhydride, and anhydrous zinc chloride were heated together at 190° for 5 hr. according to Porai-Koshits and Khaskhazov (3). Separation and crystallization from hexane gave pure 9-methylacridine, m.p. 116–118° [lit. (4) m.p. 117–118°]; IR (mineral oil mull): 1150 (CH in-plane bending) and 755 (CH out-of-plane bending) $cm.^{-1}$.

9-Acridinecarboxaldehyde—This was prepared according to Tsuge *et al.* (5). 9-Methylacridine (0.40 g., 2.07 mmoles), *p*-nitroso-*N*,*N*-diethylaniline (0.55 g., 3.72 mmoles), and concentrated hydrochloric acid (0.1 ml.) were heated together under reflux for 2 hr. The resulting red-brown material, m.p. 235–237° dec., was hydrolyzed with 10% aqueous hydrochloric acid to yield 9-acridinecarboxaldehyde as yellow needles (0.1 g., 21%), m.p. 145–146° (ethanol), [lit. (6) m.p. 147°]; IR (mineral oil mull): 1680 (C=O, aldehyde), 1150 and 1040 (CH in-plane bending), and 870 and 745 (CH out-of-plane bending) $cm.^{-1}$; NMR ($CDCl_3$): 8.8–7.2 (m, 8H, ArH) and 11.38 (s, 1H, CHO).

RESULTS AND DISCUSSION

A clean, single-component gas chromatogram resulted from an ethanol solution of carbamazepine-10,11-epoxide. The mass spectrum (Fig. 1) obtained by hookup to the GLC showed a molecular ion at *m/e* 207 (100%) and a fragmentation to give *m/e* 179 (90%) corresponding to a loss of 28 atomic mass units (CO). This transition was confirmed by the presence of a metastable ion. Also present were ions at *m/e* 152 (15%) and 151 (17%) corresponding

[1] Melting points were determined with a Büchi capillary apparatus and are uncorrected. IR spectra were obtained on a Perkin-Elmer 157 spectrophotometer as mineral oil mulls or as liquid films. NMR spectra were determined with a Varian A60 or XL100/15 spectrometer using tetramethylsilane as an internal reference. Mass spectra were obtained on an LKB 9000 instrument operating under the previously described conditions (1). GLC was carried out on a Carlo Erba Fractovap G1 chromatograph using a 2-m. OV-17 column operating at 220° and an injection port temperature of 250°.

work is analogous to the work of Piccolo and Tawashi (5), who found that at low concentrations of some dyes, inhibition occurred to single crystal dissolution of a number of drugs.

SUMMARY AND CONCLUSIONS

In the presence of benzoic acid, both the dissolution rate and equilibrium solubility of sulfamethazine were suppressed. The phenomenon was attributed to the adsorption of benzoic acid on the sulfonamide particles. The inhibition of sulfamethazine dissolution was only shown when the sulfonamide particles were saturated by benzoic acid. Due to the protective effect of polyvinylpyrrolidone, as low as 5 mg.% of the polymer prevented the adsorption of benzoic acid and, consequently, its suppressive effect on sulfamethazine dissolution.

Identification of a Rearranged Degradation Product from Carbamazepine-10,11-epoxide

K. M. BAKER, A. FRIGERIO▲, P. L. MORSELLI, and G. PIFFERI*

Abstract □ Carbamazepine-10,11-epoxide, a metabolite of carbamazepine found in human urine, undergoes a rearrangement and degradation to 9-acridinecarboxaldehyde during GLC.

Keyphrases □ Carbamazepine-10,11-epoxide—identification of GLC degradation product as 9-acridinecarboxaldehyde □ 9-Acridinecarboxaldehyde—identified as carbamazepine-10,11-epoxide GLC rearrangement product, synthesis, physical-chemical properties

In previous papers (1, 2), it was reported that carbamazepine-10,11-epoxide was found in human urine as a metabolite of carbamazepine. The epoxide was isolated and identified; however, at the same time it was mentioned that subjection of this compound to GLC resulted in a degradation to another material. This paper reports the isolation, identification, and alternative preparation of the degradation product.

EXPERIMENTAL[1]

Carbamazepine-10,11-epoxide—The synthesis described previously (1) was altered to give better, consistent yields for pharmaceutical requirements.

A solution of carbamazepine (50 g., 0.21 mole) and *m*-chloroperbenzoic acid (47.4 g., 0.27 mole) in 2 l. of ethylene chloride was heated under reflux with irradiation by a sun lamp (200 w.) for 3 hr. After cooling and washing with dilute aqueous sodium sulfite solution and with 5% aqueous sodium bicarbonate, the organic phase was dried and evaporated. The residue was taken up in boiling benzene and cooled, and the precipitate collected. The crude product was recrystallized from ethanol to give carbamazepine-10,11-epoxide as pale-yellow needles (16 g., 30%), m.p. 205–207° dec. [lit. (1) m.p. 190–195°]; IR (mineral oil mull): 3500–3100 (NH_2), 1675 (C=O, urea), 865 (C—O, epoxide), 752 (CH out-of-plane bending) $cm.^{-1}$; NMR (acetone–dimethyl sulfoxide, 2:1): 4.38 (s, 2H, —HCO— epoxide), 5.34 (broad s, 2H, $CONH_2$), and 7.7–7.1 (m, 8H, ArH).

9-Methylacridine—Diphenylamine, acetic anhydride, and anhydrous zinc chloride were heated together at 190° for 5 hr. according to Porai-Koshits and Khaskhazov (3). Separation and crystallization from hexane gave pure 9-methylacridine, m.p. 116–118° [lit. (4) m.p. 117–118°]; IR (mineral oil mull): 1150 (CH in-plane bending) and 755 (CH out-of-plane bending) $cm.^{-1}$.

9-Acridinecarboxaldehyde—This was prepared according to Tsuge *et al.* (5). 9-Methylacridine (0.40 g., 2.07 mmoles), *p*-nitroso-*N*,*N*-diethylaniline (0.55 g., 3.72 mmoles), and concentrated hydrochloric acid (0.1 ml.) were heated together under reflux for 2 hr. The resulting red-brown material, m.p. 235–237° dec., was hydrolyzed with 10% aqueous hydrochloric acid to yield 9-acridinecarboxaldehyde as yellow needles (0.1 g., 21%), m.p. 145–146° (ethanol), [lit. (6) m.p. 147°]; IR (mineral oil mull): 1680 (C=O, aldehyde), 1150 and 1040 (CH in-plane bending), and 870 and 745 (CH out-of-plane bending) $cm.^{-1}$; NMR ($CDCl_3$): 8.8–7.2 (m, 8H, ArH) and 11.38 (s, 1H, CHO).

RESULTS AND DISCUSSION

A clean, single-component gas chromatogram resulted from an ethanol solution of carbamazepine-10,11-epoxide. The mass spectrum (Fig. 1) obtained by hookup to the GLC showed a molecular ion at *m/e* 207 (100%) and a fragmentation to give *m/e* 179 (90%) corresponding to a loss of 28 atomic mass units (CO). to dibenzocyclobutane (loss of HCN from *m/e* 179, the acridinium ion).

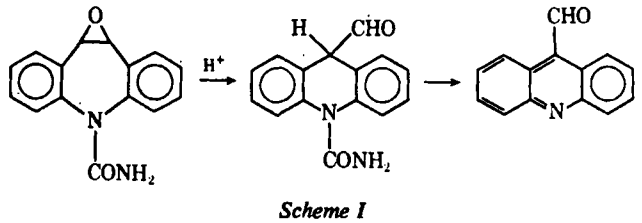
9-Acridinecarboxaldehyde was proposed for this material. For confirmation, the compound was isolated from the GLC column *via* a splitter. Yellow needles, m.p. 138–139°, were obtained [lit. (6) m.p. 147°].

The authentic material prepared was yellow needles, m.p. 145–146° (see *Experimental*). Comparison with the rearranged material proved that they were identical. Both showed the same retention time on GLC, the same UV maximum (264 nm. in methanol), and identical mass spectra.

A mechanism rationalizing the rearrangement is shown in Scheme I. The process is probably catalyzed by the slightly acidic column at high temperature, and then the intermediate imide decomposes to give the much more stable, completely aromatic system, 9-acridinecarboxaldehyde.

It is possible that the rearrangement could take place in a biological system and, therefore, 9-acridinecarboxaldehyde would be found as a metabolite of carbamazepine. Steps are in progress at the moment to determine if this is indeed so.

The result indicates the care that must be taken in identifying drug metabolites. In many cases the quantities available for identification may be very small and GLC–mass spectrometry must be used, but alternative methods should be employed in conjunction wherever possible to check that no rearrangements or degradations take place during one of the physical measurements.



Scheme I

Chemical and Biological Studies on 1,2-Dihydro-*s*-triazines XVIII: Synthesis of 1-(5,6- and 5,7-Dichloro-2-naphthyl) Derivatives and Related Compounds as Candidate Antimalarial and Antitumor Agents

ANDRE ROSOWSKY▲, KATHERINE K. N. CHEN, RICHARD St. AMAND, and EDWARD J. MODEST

Abstract □ 4,6-Diamino-1,2-dihydro-2,2-dimethyl-*s*-triazines with 5,6- and 5,7-dichloro-2-naphthyl groups at position 1 were synthesized and evaluated for biological activity. The 5,6-dichloro compound caused moderate inhibition of *Streptococcus faecium* and of human epidermal carcinoma (KB cells) *in vitro*, as well as a moderate increase in mean survival of mice bearing P1534 leukemia in the ascitic form. The 5,7-dichloro analog was active against *Plasmodium gallinaceum* in chicks.

Keyphrases □ 4,6-Diamino-1,2-dihydro-*s*-triazines, dichloronaphthyl substituted—synthesis, screened as potential antimalarial and antitumor agents □ 1,2-Dihydro-*s*-triazines, 5,6- and 5,7-dichloro-2-naphthyl derivatives—synthesis, screened as potential antimalarial and antitumor agents □ Antimalarial agents, potential—synthesis and screening of 4,6-diamino-1,2-dihydro-*s*-triazines with dichloronaphthyl substitution □ Antitumor agents, potential—synthesis and screening of 4,6-diamino-1,2-dihydro-*s*-triazines with dichloronaphthyl substitution

The availability in this laboratory of several heteronuclear dichloro derivatives of 2-naphthylamine (1) in connection with another investigation (2) afforded an unusual opportunity for the synthesis and biological evaluation of some hitherto inaccessible 4,6-diamino-1,2-dihydro-*s*-triazine antifolates with a halogenated 2-naphthyl moiety at position 1. These compounds, as well as the previously reported 2-naphthyl (3, 4) and 6-chloro-2-naphthyl (5) derivatives, were viewed with interest because of the high level of antifolate activity displayed in various test systems by other aryldihydrotriazines, including especially the phenyl and 1-naphthyl types (6).

The present paper describes the synthesis of 4,6-diamino-1-(5,6-dichloro-2-naphthyl)-1,2-dihydro-2,2-dimethyl-*s*-triazine hydrochloride (*Ia*·HCl) and its 5,7-dichloro-2-naphthyl analog (*Ib*·HCl). Also described are the corresponding naphthylbiguanide salts (*IIa*·HCl and *IIb*·HCl) and guanidinoquinazoline salts (*IIIa*·HCl and *IIIb*·HCl). Biguanides are known intermediates in the three-component synthesis of dihydrotriazines (7), and guanidinoquinazolines were reported recently to be occasional by-products in this reaction (4, 5).

EXPERIMENTAL[1]

4,6-Diamino-1-(5,6-dichloro-2-naphthyl)-1,2-dihydro-2,2-dimethyl-*s*-triazine Hydrochloride (*Ia*·HCl) (Standard Three-Component Synthesis)—A mixture of 10.7 g. (0.043 mole) of 5,6-dichloro-2-naphthylamine hydrochloride (1), 4.51 g. (0.055 mole) of cyanoguanidine, 15 ml. of acetone, and 20 ml. of absolute ethanol was stirred under reflux for 3 hr., allowed to stand at room temperature for 18 hr., and filtered. The solid was washed with acetone (3 × 10 ml.) and dried, yielding 9.57 g. (60%). Two recrystallizations from water with the aid of decolorizing carbon gave analytically pure colorless needles, m.p. 233–235°.

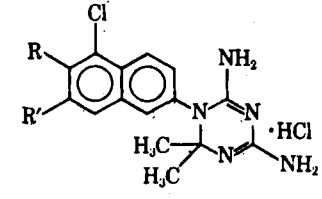
Anal.—Calc. for $C_{15}H_{15}Cl_2N_5 \cdot HCl$: C, 48.34; H, 4.33; Cl, 28.54; N, 18.79. Found: C, 48.46; H, 4.11; Cl, 28.49; N, 18.79.

4,6-Diamino-1-(5,7-dichloro-2-naphthyl)-1,2-dihydro-2,2-dimethyl-*s*-triazine Hydrochloride (*Ib*·HCl) (Two-Component Synthesis)—A mixture of 11.3 g. (0.03 mole) of biguanide *IIb*·HCl, 0.25 ml. of 12 *N* HCl, 50 ml. of acetone, and 50 ml. of absolute ethanol was stirred under reflux for 17 hr., cooled, and filtered. The tan solid was washed with acetone and dried, yielding 9.3 g. (73%). The biguanide test with copper ammonium sulfate (7) was negative (no precipitate). Two recrystallizations from 95% ethanol (charcoal) gave analytically pure *Ib*·HCl as off-white needles, m.p. 221.5–224°.

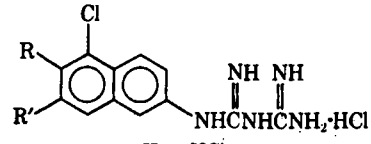
Anal.—Calc. for $C_{15}H_{15}Cl_2N_5 \cdot HCl$: C, 48.34; H, 4.33; Cl, 28.54; N, 18.79. Found: C, 48.43; H, 4.44; Cl, 28.45; N, 18.67.

N^1-(5,6-Dichloro-2-naphthyl)biguanide Hydrochloride (*IIa*·HCl)—A mixture of 10.7 g. (0.0431 mole) of 5,6-dichloro-2-naphthylamine hydrochloride (1), 4.10 g. (0.05 mole) of cyanoguanidine, and 70 ml. of *n*-propanol was stirred under reflux for 3 hr., cooled, and filtered. The tan solid was washed with *n*-propanol (2 × 25 ml.) and dried, yielding 8.18 g. (57%). Three recrystallizations from 95% ethanol (charcoal) afforded colorless needles, m.p. 215.5–216°, with a positive biguanide test (pink solid) (7).

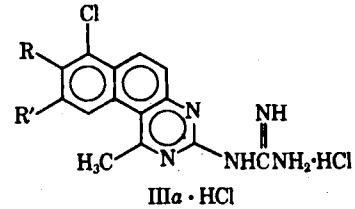
Anal.—Calc. for $C_{12}H_{11}Cl_2N_5 \cdot HCl$: C, 43.33; H, 3.64; Cl, 31.98; N, 21.05. Found: C, 43.23; H, 3.59; Cl, 31.93; N, 20.99.



Ia · HCl
Ib · HCl



IIa · HCl
IIb · HCl



IIIa · HCl
IIIb · HCl

a series: R = Cl, R′ = H
b series: R = H, R′ = Cl

[1] Melting points were taken in Pyrex capillary tubes, using a Mel-Temp apparatus (Laboratory Devices, Inc., Cambridge, Mass.), and are uncorrected. IR spectra were measured in KCl disks with a Perkin-Elmer model 137B recording spectrophotometer. NMR spectra were determined with a Varian A-60 instrument, with trifluoroacetic acid as the solvent and tetramethylsilane as the internal reference.

N^1-(5,7-Dichloro-2-naphthyl)biguanide Hydrochloride (IIb·HCl)—Use of the foregoing procedure with 5,7-dichloro-2-naphthylamine hydrochloride gave a 54% yield of IIb·HCl as an off-white solid. Two recrystallizations from 95% ethanol furnished the analytical sample, m.p. 255–257°.

Anal.—Calc. for $C_{12}H_{11}Cl_2N_5 \cdot HCl$: C, 43.33; H, 3.64; Cl, 31.98; N, 21.05. Found: C, 43.08; H, 3.41; Cl, 32.17; N, 21.04.

7,8-Dichloro-3-guanidino-1-methylbenzo[*f*]quinazoline Hydrochloride (IIIa·HCl)—A solution of 8.88 g. (0.0418 mole) of 5,6-dichloro-2-naphthylamine (1) and 0.5 g. of iodine in 33 ml. of acetone was stirred under reflux for 60 hr., cooled, and evaporated to dryness under reduced pressure. The resulting dark oil was taken up in 50 ml. of 50% ethanol to which were added 6.25 ml. of 12 *N* HCl and 4.75 g. (0.05 mole) of cyanoguanidine. After being stirred under reflux for 1.5 hr., the mixture was refrigerated until crystallization occurred. The solid was filtered, washed with acetone (5 × 5 ml.), and dried, yielding 7.53 g. (51%). Two recrystallizations from 95% ethanol (charcoal) gave colorless crystals, m.p. 312–313° dec. On treatment with copper ammonium sulfate reagent (7), this material gave a light-green precipitate characteristic of guanidinoquinazolines (3).

Anal.—Calc. for $C_{14}H_{11}Cl_2N_5 \cdot HCl$: C, 47.14; H, 3.39; Cl, 29.82; N, 19.64. Found: C, 47.05; H, 3.35; Cl, 29.98; N, 19.61.

7,9-Dichloro-3-guanidino-1-methylbenzo[*f*]quinazoline Hydrochloride (IIIb·HCl) (Modified Three-Component Synthesis)—A mixture of 5.00 g. (0.0235 mole) of 5,7-dichloro-2-naphthylamine (1), 1.97 g. (0.0235 mole) of cyanoguanidine, 0.2 ml. (0.0024 mole) of 12 *N* HCl, 85 ml. of acetone, and 15 ml. of 95% ethanol was stirred at room temperature for 16 hr. and then under reflux for 4 hr. Another 1.75 ml. (0.0211 mole) of 12 *N* HCl was added, refluxing was continued for 70 min., and the precipitated solid was filtered, washed with acetone, and dried, yielding (two crops collected) 4.8 g. (57%); a light-green solid resulted upon treatment with biguanide reagent (3). Two recrystallizations from absolute ethanol (charcoal) gave analytically pure colorless needles, m.p. 337–341° dec.

Anal.—Calc. for $C_{14}H_{11}Cl_2N_5 \cdot HCl$: C, 47.14; H, 3.39; Cl, 29.82; N, 19.63. Found: C, 47.19; H, 3.29; Cl, 29.69; N, 19.56.

RESULTS AND DISCUSSION

5,6-Dichloro-2-naphthylamine hydrochloride was found to give only dihydrotriazine Ia·HCl under the conditions of the standard three-component synthesis (7), with no evidence of the formation of guanidinoquinazoline IIIa·HCl, a comparison sample of which was synthesized *via* the "acetone anil" route described earlier (3). Although IIIa·HCl might have been expected as a by-product on the basis of work with 2-naphthylamine (3), careful NMR spectral analysis of the crude solid filtered from the reaction mixture failed to reveal any of this compound. On the other hand, the standard three-component synthesis with 5,7-dichloro-2-naphthylamine hydrochloride did produce a small amount of guanidinoquinazoline IIIb·HCl, which made it preferable to obtain dihydrotriazine Ib·HCl *via* the two-component synthesis (8) starting from biguanide IIb·HCl. An authentic specimen of IIIb·HCl was synthesized conveniently *via* the recently described (4) modified three-component synthesis, wherein only a limited amount of acid is used at the outset of the reaction. 6-Chloro-2-naphthylamine has been reported (5) to give some guanidinoquinazoline by-product in the standard three-component synthesis, albeit in a much smaller amount than with 2-naphthylamine. Thus, the findings reported here reinforce the previous conclusion that electron-attracting chloro substitution on the aromatic ring diminishes the tendency for guanidinoquinazoline by-product formation (5). However, it appears that 5,7-dichloro substitution is somewhat less effective than 5,6-dichloro substitution in suppressing this side reaction.

Moderate activity was shown against *Streptococcus faecium* (ATCC 8043) (9) by dihydrotriazine Ia·HCl, which gave an ID_{50} value of 0.08 mcg./ml. at a folate level of 0.001 mcg./ml. This may be compared with the ID_{50} value of 0.035 mcg./ml. reported previously by Foley (10) for 4,6-diamino-1-(3,4-dichlorophenyl)-1,2-dihydro-2,2-dimethyl-*s*-triazine hydrochloride, which is closely analogous to Ia·HCl in structure.

Activity was also demonstrated for Ia·HCl against human epidermoid carcinoma (KB cells) in culture (11), with an ID_{50} value of 0.5 mcg./ml. observed. However, both the biguanide IIa·HCl (ID_{50} = 0.2 mcg./ml.) and the guanidinoquinazoline IIIa·HCl (ID_{50} = 0.3 mcg./ml.) were at least as active as the dihydrotriazine. Since IIIa·HCl led to only slight inhibition of *S. faecium* (ID_{50} > 10 mcg./ml.), the cytotoxic action of this compound may perhaps be ascribed to some cause other than folate antagonism such as metal chelation. The ability of guanidinoquinazolines to inhibit KB cell growth was noted previously (3, 5), especially with reference to the possibility of error in the bioassay of dihydrotriazines not completely free from guanidinoquinazoline contamination.

Compound Ia·HCl was tested for experimental antitumor activity *in vivo* as described earlier (12), using two transplantable murine leukemias in ascitic form: L-1210 leukemia in BDF/1 hybrid mice and P1534 leukemia in DBA/2 inbred mice. Against L-1210 leukemia, this compound did not significantly prolong the life of the animals at nontoxic doses (up to 40 mg./kg./day × 4). Against P1534 at a dose of 10 mg./kg./day × 4, however, there was a 27% increase in survival relative to the untreated controls. This may be compared to the 30–40% increase reported previously for the 3,4-dichlorophenyl analog against the P1534 tumor (13).

Also assayed for antitumor activity were biguanides IIa·HCl and IIb·HCl and guanidinoquinazoline IIIb·HCl. Although none of these compounds showed any activity against L-1210, biguanide IIa·HCl produced a 32% increase in survival in the P1534 system at a dose of 10 mg./kg./day × 4. Compounds IIb·HCl and IIIb·HCl were inactive.

The compounds were also tested for antimalarial activity against *Plasmodium berghei* in the mouse and P. *gallinaceum* in the chick (14), as well as in the *in vitro* sporozoite suppression assay employing mosquitoes infected with *P. gallinaceum* or *P. cynomolgi* (15). Compound Ib·HCl was active against *P. gallinaceum* in chicks at 80 mg./kg., prolonging the mean survival time from 4.0 to 8.6 days (a 115% increase); at 320 mg./kg., survival was lengthened to 13.6 days (a 240% increase). Compound Ia·HCl caused 100% sporozoite suppression, with partial to complete occurrence of abnormal oocysts, in the blood of infected mosquitoes at an administered concentration of 0.001%. None of the compounds showed significant activity against *P. berghei* in mice.

Vehicle and Route of Administration as Parameters Affecting Operant Behavioral Effects of Δ⁹-Tetrahydrocannabinol

LOWELL A. BORGEN and W. MARVIN DAVIS▲

Abstract □ Four vehicles for Δ⁹-tetrahydrocannabinol were compared after intraperitoneal and subcutaneous administrations, using the disruption of food-reinforced, operant behavior of rats as the test system for cannabinoid activity. Aqueous suspensions based on polyvinylpyrrolidone, polysorbate 80, and a polysorbate 65–sorbitan monolaurate combination all were effective vehicles for intraperitoneal or subcutaneous absorption of the cannabinoid. An olive oil solution was poorly effective. The polyvinylpyrrolidone dispersion appeared to have the most rapid onset of action, while the polysorbate 65–sorbitan monolaurate combination had the longest duration of action.

Keyphrases □ Marijuana—effect of vehicle and route of administration of Δ⁹-tetrahydrocannabinol on operant behavior, rats □ Δ⁹-Tetrahydrocannabinol—effect of vehicle and route of administration on operant behavior, rats □ Cannabinoid activity—studied by operant behavioral effects in rats, different vehicles and routes of administration

The major psychoactive constituent in marijuana (*Cannabis sativa*) is generally accepted to be (−)-Δ⁹-*trans*-tetrahydrocannabinol (I). The elucidation of the structure and synthesis of I has prompted extensive investigation of its pharmacological and behavioral effects in both animals and man (1, 2). However, the extreme aqueous insolubility of I has made parenteral administration difficult. A number of different aqueous suspensions and oil solutions have been tried by various researchers, but no single preparation has found widespread acceptance. At times, conflicting results between studies have been attributed to differences in the drug vehicle or mode of administration.

The present study compared four such vehicles administered *via* two routes of injection to evaluate the drug effect in a test system previously shown to be sensitive to Δ⁹-tetrahydrocannabinol (3–5). The measure chosen was the depression of operant responding of rats for food reinforcement. In this experiment, both the onset and duration of action of I were examined as a function of eight combinations of vehicle and route of injection.

EXPERIMENTAL

Twenty-four male Wistar rats (225–300 g.) were trained to bar-press for food reward on a fixed-ratio-50 (FR50) schedule of reinforcement; the 50th lever-press resulted in the delivery of a 45-mg. Noyes food pellet. The animals were given 60-min. experimental sessions on 5 days each week, with supplementary postsession feeding sufficient to maintain them at 80% of their free-feeding weights. The operant chambers were controlled by solid-state programming equipment. Cumulative recorders and digital counters were used for data collection. Before initial drug sessions, each rat received 4–5 weeks of training until performance stabilized so that there was less than 10% variation in responses per session over three consecutive sessions.

The four preparations of Δ⁹-tetrahydrocannabinol compared in this experiment were: Vehicle A, olive oil solution; Vehicle B, a 1% polysorbate 80[1] dispersion in saline; Vehicle C, a suspension with 1% polysorbate 65[2] and 1% sorbitan monolaurate[3] in 0.9% saline, as described by Moreton and Davis (6); and Vehicle D, a 10% polyvinylpyrrolidone suspension in 0.9% NaCl, prepared according to the procedure of Fenimore and Loy (7). Each vehicle was tested both intraperitoneally and subcutaneously. The dose of I used was 10 mg./kg. given at an injection volume of 1.0 ml./kg. body weight. The injections of I were given at weekly intervals on Wednesday, vehicle alone was given on Tuesday and Thursday, and saline was injected on Monday and Friday. To examine the relative duration of action of I as well as the time of onset, injections were given either immediately prior to the operant session or 1, 2, or 3 hr. before. At least six determinations were made for each vehicle–route–time combination. The drug effect was assessed by comparing the bar-press performance on drug days to performance on the preceding vehicle control session.

RESULTS AND DISCUSSION

Operant responding following the intraperitoneal or subcutaneous injection of the four vehicles alone did not differ from that following saline administration or no injection. In Table I the effects of Δ⁹-tetrahydrocannabinol upon responding are summarized as a function of the route–vehicle–time combinations. The total number of responses during the 1-hr. test session is expressed as a percentage of the responses per hour in the prior vehicle control session. Gen-

Table I—Effects of Δ^9-Tetrahydrocannabinol on Fixed-Ratio-50 Performance in Rats: Vehicle and Route of Administration as Parameters Affecting Onset and Duration of Behavioral Disruption

Route of Injection	Drug Vehicle	Percent of Predrug Control Responses per Hour[a] 1st hr. Postinjection	2nd hr. Postinjection	3rd hr. Postinjection	4th hr. Postinjection
Intraperitoneal	A, olive oil	102	48	54	105
	B, polysorbate 80	<1	<1	<1	72
	C, polysorbate 65 plus sorbitan monolaurate	4	<1	8	43
	D, polyvinylpyrrolidone	<1	<1	9	90
Subcutaneous	A, olive oil	100	88	83	101
	B, polysorbate 80	54	32	44	59
	C, polysorbate 65 plus sorbitan monolaurate	65	64	68	55
	D, polyvinylpyrrolidone	15	<1	20	83

[a] Each value is the mean of six observations. Δ^9-Tetrahydrocannabinol dose = 10 mg./kg.

erally, all three aqueous suspensions of I showed a prompt onset of action within 1–5 min. following intraperitoneal administration, whereas a significant effect of I in the oil solution did not occur within the 1st hr. after injection. During the 2nd and 3rd hr. after administration of I in aqueous suspension, suppression of operant responding continued, whereas I in oil reduced response output only one-half. When I was administered subcutaneously in these vehicles, a slower onset was observed, as expected. Compound I in Vehicle D appeared to take effect by the subcutaneous route more rapidly than in either Vehicle B or C. Again the olive oil solution was poorly absorbed. Peak behavioral suppression occurred during the 2nd hr. following subcutaneous injection in Vehicles B and D.

Concerning the duration of behavioral depression, data for the 4th hr. after intraperitoneal administration indicate that I in Vehicle C gave the longest activity. In either Vehicle B or C, I given *via* the subcutaneous route still produced significant operant depression 4 hr. postinjection; in Vehicle D, it was only minimally effective. With I in oil, no effect was observed in the 4th hr. after either intraperitoneal or subcutaneous administration.

In a comparison of vehicles for Δ^9-tetrahydrocannabinol, Sophia *et al.* (8) measured the effects of I in four vehicles on the latency to convulsion in mice after electroconvulsive shock. Only the intraperitoneal route was studied. They found that a polyvinylpyrrolidone suspension in saline and a 10% propylene glycol–1% polysorbate 80 suspension in saline were most effective. Polysorbate 80–saline and bovine serum albumin in saline were found to be poorly absorbed preparations. In another recent study (9), emulsions of polysorbate 80 or polyvinylpyrrolidone plus sesame oil in saline were also found to be suitable vehicles for parenteral administration.

By utilizing operant behavioral techniques, the present experiment indicated that Δ^9-tetrahydrocannabinol is absorbed effectively from aqueous suspensions but poorly absorbed from oil solutions following intraperitoneal administration. Absorption from a subcutaneous site is somewhat delayed but is significant. Vehicle D gave the most rapid absorption of the four preparations studied by both routes of administration. To obtain a prolonged duration of action, Vehicle C appeared to be most effective.

Interaction of Cholesterol with Dibenzanthracenes at Air–Water Interface

ALBERT A. BELMONTE and JAMES SWARBRICK▲

Abstract □ A film balance approach using continuous compression was used to study the interaction of the carcinogen 1,2:5,6-dibenzanthracene and the noncarcinogen 1,2:3,4-dibenzanthracene with insoluble monolayers of cholesterol. Surface pressure and surface potential of mixed dibenzanthracene–cholesterol films spread on water and saline were studied. Results showed an association of 1,2:5,6-dibenzanthracene and no association of 1,2:3,4-dibenzanthracene with cholesterol. Surface potential data support the concept of carcinogen–cholesterol association. The data show a useful difference between a carcinogenic and a noncarcinogenic isomer at the air–water interface.

Keyphrases □ Cholesterol–dibenzanthracene—interaction at air–water interface, film balance approach, comparison of carcinogenic and noncarcinogenic dibenzanthracene isomers □ Dibenzanthracene–cholesterol—interaction at air–water interface, film balance approach, comparison of carcinogenic and noncarcinogenic dibenzanthracene isomers □ Carcinogens, 1,2:5,6-dibenzanthracene—interaction with cholesterol at air–water interface, compared to noncarcinogenic isomer, 1,2:3,4-dibenzanthracene □ Films—mixed dibenzanthracene–cholesterol, surface pressure and surface potential, air–water interface

Carcinogens, materials known to cause cancer, pose an interesting area of cancer research. While many investigations have been conducted on carcinogen interactions with nucleic acids, only a few studies have been directed toward carcinogen–cell membrane interactions. Wallach (1) proposed that oncogenic agents may act to introduce an inappropriate protein into cell membranes. Numerous membrane functions may be affected as a result of such an alteration. Weissmann *et al.* (2) reported the effects of tumor-promoting agents on biological and artificial membrane systems. Their results suggested membrane disruption as a prime tumor-initiating step. Selkirk *et al.* (3) compared the phospholipid profiles from plasma membranes of solid hepatoma cells and liver cells in an attempt to understand cancer–membrane phenomena; differences in composition and degree of fatty acid saturation were found. All of these studies support the premise that cell membranes are affected by neoplasia. Since cell membranes can control passage of materials into the cell, membrane interactions, particularly penetration of cell membrane by carcinogens, may be extremely important in understanding the cancer-initiating process.

Many materials have been shown to be carcinogenic *in vivo*, yet the ability to correlate carcinogenicity to *in vitro* behavior is often difficult. In an attempt to differentiate between closely related polycyclic aromatic hydrocarbons, it was decided to utilize a film balance technique. This approach is based on the well-recognized fact that insoluble monolayers can be employed to simulate biological interfaces (4). Snart (5), in 1967, made a preliminary study of some aromatic hydrocarbons in monolayers, showing some association of hydrocarbons with cholesterol and lecithin. Weiner *et al.* (6) showed an interaction occurring with 3-methylcholanthrene and lecithin–cholesterol mixed films. The present investigation was conducted to study some surface interactions of dibenzanthracene with cholesterol.

The polycyclic aromatic hydrocarbon dibenzanthracene was chosen for study for several reasons. These include the facts that 1,2:5,6-dibenzanthracene was the first synthetic chemical compound to induce cancer and that considerable information has been compiled on its properties (7). In addition, 1,2:5,6-dibenzanthracene has a structural isomer that is noncarcinogenic or weakly carcinogenic, 1,2:3,4-dibenzanthracene (8, 9). Cholesterol was chosen because of its function in cell membrane structure.

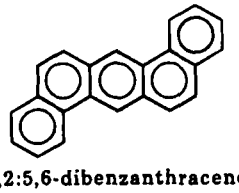
The intent of this report is to relate the monolayer properties of mixed films of cholesterol with dibenzanthracene. The properties will be characterized by: (*a*) the effect of concentration of dibenzanthracene on surface pressure and surface potential parameters, and (*b*) the effect of each dibenzanthracene isomer with respect to their different behavior *in vivo*.

EXPERIMENTAL

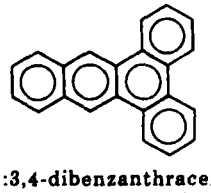
Materials—The mixed films were prepared by dissolving the cholesterol (S.C.W.)[1] in chloroform (nanograde)[2] and the dibenzanthracene[1] in benzene (nanograde)[2]. The appropriate molar ratios of dibenzanthracene–cholesterol were then prepared with the aid of a calibrated syringe[3]. This premixed solution was used as the film-forming material. Double-distilled water from an all-glass still was used as the subphase. The specific conductance of the water was not greater than 1.5 μmhos/cm. When appropriate, normal saline was prepared by adding analytical reagent grade sodium chloride[2].

Film Balance—The film balance was a modified Wilhelmy type which was described previously (10). Surface potential was measured using the ionizing air-gap technique. The apparatus also was described previously (11).

Procedure—Surface pressure was measured continuously using a thin mica plate, of known perimeter, attached to a recording electrobalance. Upon compression, the change in mass of the mica



1,2:5,6-dibenzanthracene (carcinogen)



1,2:3,4-dibenzanthracene (non- or weak carcinogen)

[1] Nutritional Biochemical Corp., Cleveland, Ohio. Purity was checked by TLC using silica gel G and H plates and petroleum ether–ether–acetic acid (90:30:1) and chloroform–methanol–water (65:25:4) as solvents. In all cases, only one spot was found when the plates were developed with bromthymol blue and ammonia gas.

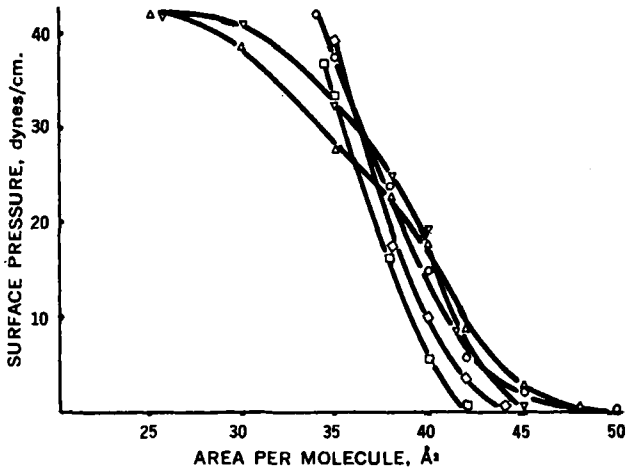

Figure 1—*Surface pressure–area relationship for 1,2:3,4-dibenzanthracene on water. Key: ○, cholesterol; ◇, 1:10 1,2:3,4-dibenzanthracene–cholesterol; □, 1:1 1,2:3,4-dibenzanthracene–cholesterol; ▽, 3:1 1,2:3,4-dibenzanthracene–cholesterol; and △, 5:1 1,2:3,4-dibenzanthracene–cholesterol.*

plate yields a direct measurement of surface pressure. Simultaneous recording of surface potential afforded constant monitoring of monolayers at all stages of compression.

Since preliminary results showed that dibenzanthracene itself does not form surface films, the effect when allowed to react with cholesterol may be evaluated by surface pressure–area per molecule relationships (π–A) directly. Surface potential (ΔV) was also monitored since this can be helpful in interpreting subphase film interactions (4).

Dibenzanthracene–cholesterol films were prepared from solutions containing varying mole fractions. The mixed film solution was pipeted onto the aqueous surface using a micropipet[4] and allowed to spread undisturbed for 10 min. After this equilibration, compression was initiated at a rate of 2.54 cm./min., and data taken from simultaneous recordings of surface pressure and surface potential were used to produce the characteristic π–A isotherms. All runs were performed in triplicate at 25°.

RESULTS

Surface Pressure–Area per Molecule—Figure 1 represents the relationship between surface pressure and area per molecule, expressed in terms of cholesterol, for mixed films of 1,2:3,4-dibenzanthracene–cholesterol. Also shown is the isotherm for pure cholesterol. Similar curves were obtained when saline was substituted as the subphase. The extrapolated area per molecule for cholesterol, which depends on the method of compression, is comparable to that found by Kwong *et al.* (12), who also used continuous compression to generate the surface pressure–area isotherm.

[a] At collapse. [b] DBA = dibenzanthracene; chol = cholesterol. [c] Standard deviation. [d] Significantly different at $p < 0.01$.

Figure 2 illustrates the isotherm resulting from the interaction of the potent carcinogen 1,2:5,6-dibenzanthracene and cholesterol on water. Identical isotherms were observed when experiments were conducted on saline. This figure may be contrasted to Fig. 1, or the noncarcinogenic isomer with cholesterol. The expansion of the carcinogen film at low surface pressures is significant in view of the noncarcinogen film results.

Surface Potential—Surface potential data are shown in Table I. Surface potential was taken at collapse or when the potential failed to change and reached a limiting value. In either case, this generally corresponded to a surface potential of the film at cross-sectional areas per molecule of 35–40 Å². A one-way analysis of variance performed on the data for each subphase showed statistical significance at $p < 0.01$. The individual means within each subphase were then tested using the sequential Q test (13). The 3:1 and 5:1 carcinogenic 1,2:5,6-dibenzanthracene–cholesterol films showed significance with $p < 0.01$ and regardless of subphase.

DISCUSSION

The steric rearrangement of a benzene ring in dibenzanthracene changes this compound from a potent carcinogen to a very weak carcinogen or a noncarcinogen. Although Snart (5) reported some surface interactions of 1,2:5,6-dibenzanthracene, the study did not include 1,2:3,4-dibenzanthracene. The ability to contrast these two compounds *in vitro* may have added importance, since Heidelberger and Moldenhauer (14) showed the noncarcinogen to bind more strongly to protein than the carcinogenic isomer. This binding behavior of dibenzanthracene is generally recognized to be contrary to the usual behavior wherein carcinogens bind more strongly than noncarcinogens.

In the surface interactions with cholesterol, no correlations could be drawn between concentration of noncarcinogenic dibenzanthracene and the isotherms produced. No trend was evident, and the slight differences noted are relatively insignificant when compared to changes evident in the carcinogen films. Mixed films of the strong carcinogenic isomer showed a very different effect with cholesterol. No difference was observed between the cholesterol isotherm and the 1:10 carcinogen–cholesterol film. However, with the films containing higher carcinogen–cholesterol ratios (1:1, 3:1, and 5:1), a significant difference in behavior was noted. There was a dramatic expansion of the film at low surface pressures, attributable to the presence of carcinogen at the interface. There was also a rank correlation between the concentration of 1,2:5,6-dibenzanthracene and the expansion of the film, and this was related to the extrapolated area per molecule.

The extrapolated area per molecule, by tradition, is obtained by continuing a portion of the π–A isotherm to zero film pressure. The assumption was made that, from steric factors and for maximum interaction to occur, the cross-sectional area per molecule of dibenzanthracene was 40–50 Å². By evaluating the expansion effect of the carcinogen–cholesterol films from extrapolated areas per molecule, it was possible to estimate the final molecular association

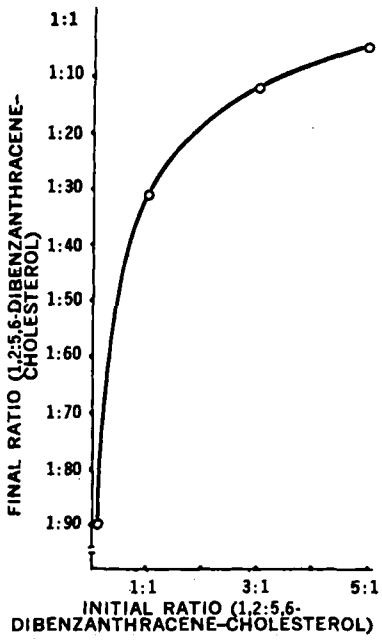

Figure 3—*Degree of association of 1,2:5,6-dibenzanthracene to cholesterol estimated from extrapolated area per molecule.*

present in the film. The molar ratio of carcinogen to cholesterol initially prepared *versus* the association estimated from expansion of the resulting films is plotted in Fig. 3. The data show that after spreading a solution containing a 5:1 carcinogen–cholesterol initial ratio, a 1:4 molecular association results at the interface. Although this association appears to be self-limiting as carcinogen concentration is increased in the film, the limiting value and its significance are still unknown.

Surface potential data reinforced the concept of carcinogen association at the interface. The 3:1 and 5:1 carcinogenic films were statistically different from the noncarcinogenic films regardless of subphase. These results were not unexpected in view of their π–A isotherms, since the 3:1 and 5:1 carcinogen–cholesterol films showed the greatest expanding effect.

These results demonstrate a very useful difference existing between a carcinogenic and a noncarcinogenic or weakly carcinogenic isomer at the air–water interface. This method conceivably may be useful in discriminating between other carcinogenic and noncarcinogenic isomers. Furthermore, cell membrane integrity or disruption at the molecular level may be a cancer-initiating step prior to interaction with other critical targets within the cell.

Constituents of *Mammea americana* L. XII: Biological Data for Xanthones and Benzophenones

R. A. FINNEGAN▲, K. E. MERKEL, and J. K. PATEL

Abstract □ Sarcoma 180 inhibition data are presented for a number of related xanthones and benzophenones; a few showed significant activity. One of these was also tested *in vivo* against Ehrlich ascites tumor. Four hydroxyxanthones isolated from a polar extract of *Mammea americana* L. (Guttiferae) seeds did not account for the activity of the extract. The results of two antibacterial assays for a few of these compounds are also presented.

Keyphrases □ *Mammea americana* L.—xanthone constituents and related benzophenones, antitumor and antibacterial activities □ Xanthones—from *Mammea americana* L., antitumor and antibacterial activities □ Benzophenones—antitumor and antibacterial activities

A previous paper (1) described the isolation and structure determination of a variety of coumarin derivatives from mamey oil (the dewaxed petroleum ether extract of *Mammea americana* L. seeds) and reported the significant antitumor activity (against Sarcoma 180) of the extract as well as that of a number of the constituent coumarins. During these studies the more polar extract, obtained by extraction of the seed residue with

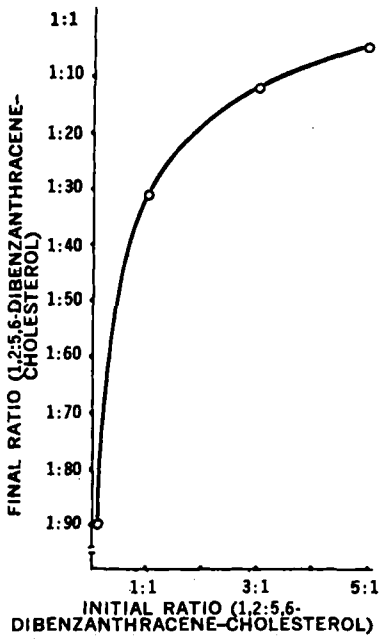

Figure 3—*Degree of association of 1,2:5,6-dibenzanthracene to cholesterol estimated from extrapolated area per molecule.*

present in the film. The molar ratio of carcinogen to cholesterol initially prepared *versus* the association estimated from expansion of the resulting films is plotted in Fig. 3. The data show that after spreading a solution containing a 5:1 carcinogen–cholesterol initial ratio, a 1:4 molecular association results at the interface. Although this association appears to be self-limiting as carcinogen concentration is increased in the film, the limiting value and its significance are still unknown.

Surface potential data reinforced the concept of carcinogen association at the interface. The 3:1 and 5:1 carcinogenic films were statistically different from the noncarcinogenic films regardless of subphase. These results were not unexpected in view of their π–A isotherms, since the 3:1 and 5:1 carcinogen–cholesterol films showed the greatest expanding effect.

These results demonstrate a very useful difference existing between a carcinogenic and a noncarcinogenic or weakly carcinogenic isomer at the air–water interface. This method conceivably may be useful in discriminating between other carcinogenic and noncarcinogenic isomers. Furthermore, cell membrane integrity or disruption at the molecular level may be a cancer-initiating step prior to interaction with other critical targets within the cell.

benzene (2) and ethanol, also was examined (3, 4). That investigation was prompted by the observation that the ethanol extract provided an ID_{50} value of 5.4 mcg./ml. when assayed against S-180 tumor cells grown in stationary cell culture. Two sets of isomeric xanthones, 2- and 4-hydroxyxanthones (III and VI) and 1,5- and 1,7-dihydroxyxanthones (IX and XI), were subsequently isolated from this polar extract. Their structures were determined by comparison with synthetic materials (2–4). At the same time, a number of other xanthones were prepared (5–7) for comparison purposes and these were also included in the S-180 screen.

EXPERIMENTAL

The Compounds—A few of the test compounds (I, XIX–XXI, and XXV) were commercially available. Some (IX, XXIII, XXIV, XXVI–XXX, and XXXII) were prepared in this laboratory for the first time. The remaining compounds were known and were, in general, prepared by using previously reported procedures. A somewhat improved procedure was used to prepare XXXI. Compound XVIII was used as isolated from *Hiptage madablota* Geartn. Synthetic samples of the compounds isolated from *M. americana* L. (III, VI, IX, and XI) were used.

References to the preparation or isolation of all the compounds are given in the tables. In each case except Compound XXX, experimental details are given as well as relevant literature citations. Compound XXX was prepared by the photo-Fries rearrangement of 2,6-diisopropylphenyl pivalate and details will be provided upon request.

The Tests—A description of the S-180 assay (Tables I and II) was given previously (1). Values for ID_{50} (dose for 50% inhibition of growth) of less than 5 mcg./ml. for a pure compound and less than 20 mcg./ml. for a crude extract are considered significant[1].

The antibacterial results (Table III) were determined[2] using procedures described in the literature (8, 9).

RESULTS AND DISCUSSION

The results shown in Table I indicate that the substances isolated from the extract (III, VI, IX, and XI) are not sufficiently active to account for the activity of the crude extract. However, the synthetic 1,3- and 1,6-dihydroxyxanthones (VII and X) showed noteworthy activity. Further hydroxylation in the equivalent positions of the second ring (Compounds XV–XVII) decreased this activity. Compound XVIII was available in the laboratory (10) and was included for comparison.

A method used for the preparation of certain of the xanthones involves the cyclodehydration of an appropriately substituted benzophenone. Several of these precursors (XXII–XXV and XXXII) were on hand and they were also assayed along with benzophenone (XIX) itself and two of its monohydroxy derivatives (XX and XXI). In addition, a pair of benzophenones (XXVI and XXVII) and a group of pivalophenones (XXVIII–XXX) were available from other studies going on in the laboratory (11, 12) and these were also included. The results are listed in Table II. While two of the tetrahydroxybenzophenones, XXII and XXIII, showed excellent activity, the alkylated hydroxybenzophenone, XXVII, showed activity at least on an order of magnitude greater still. This is reminiscent of the activity exhibited by the alkylated hydroxyketones in the coumarin series (1) and gives a direction to further studies involving alkylated hydroxybenzophenones as well as alkylated hydroxyxanthones.

The acute LD_{50} of Compound XXVII in mice was found to be greater than 500 mg./kg., and the 5-day dose LD_{50} was greater than 100 mg./kg.[3]. Against Ehrlich ascites tumor in mice, the ID_{50} (5-day dosing) of XXVII was 100 mg./kg.[3].

Finally, several of the compounds were examined for antibacterial activity against *Escherichia coli* and *Streptococcus faecalis* with the results shown in Table III. A few of the compounds (I, XXI, and

Synthesis and Antifungal Activity of Polyhalophenyl Esters of *p*-Sulfamoylcarbanilic Acid

G. MOHTAT, N. REZVANI, M. EMAMI, and I. LALEZARI▲

Abstract □ Several polyhalophenyl esters of *p*-sulfamoylcarbanilic acid were prepared and tested for antifungal activity against *Candida albicans*, *Penicillium notatum*, and *Aspergillus niger*. Pentachloro-, tribromo-, and triiodophenyl esters were found to be the most active.

Keyphrases □ *p*-Sulfamoylcarbanilic acid, polyhalophenyl esters—synthesized and screened as potential antifungal agents □ Antifungal agents, potential—synthesis and screening of polyhalophenyl esters of *p*-sulfamoylcarbanilic acid

Recently, it was reported that polyhalophenyl esters of *p*-substituted carbamic acids as well as polyhalophenyl esters of pyridyl- and quinolyl-4-carbamic acids (1, 2) showed significant antifungal activities.

In the present work, a series of polyhalophenyl esters of *p*-sulfamoylcarbanilic acid was prepared by interaction of *p*-sulfamoylbenzoyl azide and the appropriate phenol in boiling toluene or xylene (Scheme I).

$$p\text{-}NH_2SO_2C_6H_4CON_3 + ArOH \xrightarrow[\text{or xylene}]{\text{boiling toluene}} p\text{-}NH_2SO_2C_6H_4NHCOOAr + N_2$$

Scheme I

The physical data of all new compounds are reported in Table I. The antifungal activity of all compounds was determined[1] *in vitro* against *Candida albicans* 1959-2, *Penicillium notatum* 154-3, and *Aspergillus niger* A-23. Concentrations of 5, 10, and 25 mcg./ml. of each compound were used.

Compounds II–IV were dissolved in acetone, Compounds I and V were dissolved in 60% ethanol, and Compounds VI–XI were dissolved in 96% ethanol, all at concentrations of 5 mg./10 ml. These solutions were diluted with hot culture medium to the desired concen-

[1] Using BBL Sabouraud dextrose agar medium. The microorganisms were obtained from the Department of Parasitology, Public Health Institute, Iran.

trations and autoclaved at 120° for 2 hr. Five replicates of each concentration were prepared. The antifungal activities of pentachloro-, tribromo-, and triiodophenyl esters are reported in Table II. The antifungal activities of all other compounds were insignificant. The pentachlorophenyl ester was the most active of this series.

EXPERIMENTAL[1]

p-Sulfamoylbenzoylhydrazide was prepared according to Shimizu *et al.* (3).

Preparation of *p*-Sulfamoylbenzoyl Azide—To an ice-cold solution of 2.15 g. (10 mmoles) of *p*-sulfamoylbenzoylhydrazide in 50% acetic acid (25 ml.), a 5% aqueous solution of 0.69 g. (10 mmoles) of sodium nitrite was added with stirring. The resulting precipitate was filtered, washed with cold water, and dried to give 1.92 g. (85%) of *p*-sulfamoylbenzoyl azide, m.p. 100° dec.

Preparation of *p*-Sulfamoylcarbanilic Acid Ethyl Ester—A solution of *p*-sulfamoylbenzoyl azide, 2.26 g. (10 mmoles), in 15 ml. of ethanol was refluxed for 4 hr. The reaction mixture was diluted with water, the resulting precipitate was filtered, and the solid was recrystallized from aqueous ethanol to give 1.70 g. (70%) of the title compound, m.p. 235°; NMR (CF_3CO_2H): τ 9.2 (t, 3H,CH_3), 6.1 (q, 2H, CH_2), 2.7 (q, 4H, ArH), and 2.3 (s, 2H, NH_2).

Preparation of *p*-Sulfamoylcarbanilic Acid Pentachlorophenyl Ester—A solution of 0.452 g. (2 mmoles) of *p*-sulfamoylbenzoyl azide and 0.355 g. (2 mmoles) of pentachlorophenol in 20 ml. of dry toluene was gently refluxed for 4 hr. After evaporation of the solvent under reduced pressure, the residue was recrystallized from 96% ethanol to give 0.650 g. (70%) of the title compound, m.p. 195°; IR (KBr) ν_{max}: 3400, 3320 (C—H and N—H), 1700 (C=O), 1595, 1540 (carbamate)(C—H), 1415, 1390, 1210, 1060 (C—H), 1300, and 1152 (SO_2NH_2) cm.$^{-1}$.

All other carbanilic acid derivatives were prepared similarly (Table I).

[1] Melting points were taken on a Kofler hot-stage microscope and are uncorrected. The IR spectra were determined with a Leitz model III spectrograph. NMR spectra were obtained on a Varian A 60A instrument.

Topical Mosquito Repellents V: Benzyl Ethers

F. GUALTIERI*, H. JOHNSON, H. TONG, H. MAIBACH†, D. SKIDMORE†, and W. SKINNER▲

Abstract □ A series of benzylic ethers with hydroxyl, epoxy, and unsaturated moieties was synthesized and evaluated on human skin for repellency against female *Aedes aegypti* mosquitoes. Compounds exhibiting the longest durations of repellency were those with boiling points of approximately 125°/0.5 mm. The case of two monobenzyl ethers of 3,4-dihydroxycyclopentene-1 having the same boiling points but different repellent activity is of interest. None of the compounds examined was as effective as *N,N*-diethyl-*m*-toluamide in terms of the duration of topical repellency.

Keyphrases □ Insect repellents, topical—synthesis of benzyl ethers, repellency–volatility relationships □ Benzyl ethers—synthesized and screened as potential insect repellents, repellency–volatility relationships □ Repellency–volatility relationships—benzyl ethers as topical insect repellents

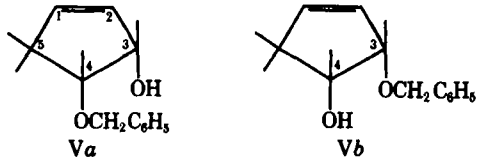
Previous studies (1, 2) suggested that benzyl ethers and polyoxy ethers of the benzyl type were potentially of value in the search for longer lasting topical mosquito repellents. The present compounds were synthesized and evaluated topically on human skin to define the repellency characteristics of such compounds and to determine the effect of other structural moieties such as alicyclic and unsaturated groups.

RESULTS AND DISCUSSION

The compounds (Table I) were obtained by the usual Williamson synthesis using the sodium salt of the alcohol and benzyl chloride; in those cases where a double bond was present, salt formation was *via* sodium hydride in dimethylformamide. With the diols, a double series of compounds, the monobenzyl and dibenzyl ethers, could be obtained using a 1:1 ratio of diol and sodium hydride. The separation of the reaction products by vacuum distillation was not complete, and liquid chromatography was usually required for obtaining suitable analytical samples. The monobenzyl ether fraction of 3,4-dihydroxycyclopentene-1 was further analyzed by VPC, yielding two peaks (FFAP column, 205°, flow rate of 120 ml./min.) with retention times of 10 min. (Compound V*b*, the larger fraction) and 11 min. (Compound V*a*, the smaller fraction).

The indicated structures for the monobenzyl ethers of 3,4-dihydroxycyclopentene-1 were assigned on the basis of NMR as 3-hydroxy-4-benzyloxycyclopentene-1 (V*a*) and 3-benzyloxy-4-hydroxycyclopentene-1 (V*b*). The NMR spectra of these two compounds (Table II) were nearly identical; the major differences were in the τ values of the protons at the 3- and 4-positions.

The 3-proton of Compound V*a* should (5) and does have a lower τ value than the 3-proton of Compound V*b*, since the former is on a carbon with a hydroxyl group and the latter is on a carbon with an ether substituent. Similarly, the 4-proton of Compound V*b* has a lower τ value than that of Compound V*a* for the same reason. Furthermore, the 4-proton of V*a* is a quartet, because of the influence of the 5-methylene protons and the 3-proton. The 4-proton of V*a* also has a higher τ value than its own 3-proton, because the former is an *H*—C—OR proton as compared to an *H*—C—OH proton and because the 3-proton is allylic. In the case of V*b*, its 4-proton should have a lower τ value than its own 3-proton (*H*—C—OH *versus* *H*—C—OR); but since the 3-proton is allylic, it is shifted downfield. The two protons consequently have about the same τ values; 5.6–5.8. The structure of V*b* is further confirmed by its acetyl derivative, whose 4-proton appears at τ 4.65–4.95 as a quartet, having shifted downfield as expected and being split by its neighboring protons; the 3-proton is practically unchanged.



The IR spectrum of the acetate shows the disappearance of the hydroxyl (3 μ) and the appearance of the carbonyl band (5.8 μ). Finally, V*b* is the larger fraction in the reaction product as compared to V*a*, because of the influence of the double bond on the acidity of the 3-hydroxyl group in 3,4-dihydroxycyclopentene-1, thus favoring the formation of the ether derivative in the 3-position.

Similarly, the monobenzyl ether of 3,5-dihydroxycyclopentene-1 was analyzed by VPC. Again, two main peaks were obtained (FFAP column, 210°, flow rate of 120 ml./min., retention times of 17 and 19 min.), collected, and analyzed. Their NMR absorption peaks were identical, suggesting that they are probably *cis*- and *trans*-isomers. Their 4-CH_2 bands (τ 7.8–8.2) confirm the nonallylic nature of these protons in comparison to the 5-CH_2 allylic protons (τ 7.5–7.7) of Compounds V*a* and V*b*.

Compound VI was prepared *via* epoxidation of a mixture of V*a* and V*b*; similarly, the other epoxy compounds were prepared from the corresponding unsaturated ethers. No attempt was made to determine their steric structures.

As in previous studies (1, 2), the present series of compounds exhibited a rather restricted volatility–repellency relationship. Compounds with boiling points higher or lower than those of Compound IV, V*a*, V*b*, and VII did not yield appreciable repellency duration (Table I and Fig. 1). Nonalicyclic benzyl ethers (Compounds XIII–XVIII) of a wide range of boiling points are completely ineffective. Together with previous data (2), the present results suggest that a volatility region corresponding to a boiling point of approximately 115–135°/0.5 mm. is optimal for alicyclic benzyl ethers in terms of topical mosquito repellency. The striking difference in the protection times of Compounds V*a* and V*b*, which are isomeric with the same boiling point, suggests a case of specific structure–activity relationship not commonly reported in insect repellent studies. Similarly, it is of interest that Compounds XIII–XVIII uniformly exhibited poor repellency in spite of the variation in volatility (Table I). The presence of an OH group, an epoxy ring, or a second benzylic moiety does not appear to significantly enhance repellent potency. In terms of duration of protection, Compound V*a* approaches but is inferior to the performance of *N,N*-diethyl-*m*-toluamide (2).

EXPERIMENTAL

The starting materials of the best mosquito repellents in this series, 3,4-dihydroxycyclopentene-1 (b.p. 55–65°/0.5 mm. Hg) and 3,5-dihydroxycyclopentene-1 (b.p. 90–100°/0.6 mm. Hg), were obtained commercially[1] as a mixture and were separated by spinning band distillation. The 3,4-dihydroxy fraction (n_D^{25} 1.4971) was further purified by VPC (FFAP column, 205°, flow rate of 120 ml./min.) and had a retention time of 5 min.; the 3,5-dihydroxy fraction (n_D^{25} 1.5012), under the same GC conditions, had a retention time of 11 min. The 3,5-dihydroxy fraction was oxidized to the dione as previously described (5), and the melting point agreed with that reported. A comparison of the NMR spectra of the derivatives V*a*, V*b*, and VII indicated that the assigned structures as 3,4- and 3,5-dihydroxy compounds were correct.

The alcohol (0.1 mole) was added slowly to a stirred suspension of sodium hydride (0.1 mole) in 50 ml. of anhydrous dimethylformamide. After 3 hr. at room temperature, benzyl chloride (0.1 mole) was added dropwise with stirring and cooling. After 24 hr. at room temperature, the mixture was partitioned between hexane and water. The hexane layer was washed and dried (sodium sulfate), yielding primarily the dibenzyl ether, while extraction of the aqueous phase with ethyl acetate gave primarily the monobenzyl ether following fractionation of the oils resulting from the evaporation of the solvents. In some cases (Compounds V, VII, IX, and XI), chromatography on silica gel (eluant 20:80, ethyl acetate–cyclohexane) was necessary to obtain pure analytical samples. Boiling points are uncorrected.

The compounds were tested on the forearm of human subjects as described previously (1, 2) at a concentration of 0.35 mg./cm.[2].

Potential Psychoactive Indole Derivatives II: Synthesis of 5-Alkoxyindolines *via* Reduction of 5-Alkoxy-2-indolinones

A. MAHAMADI*, P. PARIMOO†, W. G. HANEY, and B. F. GRABOWSKI‡

Abstract □ As part of a continuing program to define further the role of the indole nitrogen in influencing activity of psychoactive compounds, a series of 5-alkoxy-3-alkylamino-1,3-dimethyl-2-indolinones and indolines were prepared for central activity studies. The intermediate substituted 2-indolinones were prepared by C-5 alkylation of 5-hydroxy-1,3-dimethyl-2-indolinone followed by C-3 alkylation with appropriately substituted chloroalkylamines. The substituted 2-indolinones were then reduced to the indoline derivatives with lithium borohydride. IR and NMR spectroscopy were utilized for the structural characterization of the synthesized compounds.

Keyphrases □ Indolinones, 5-alkoxy-3-alkylamino-1,3-dimethyl substituted—synthesized as potential psychoactive agents, structure-activity relationships of indole derivatives □ Indolines, 5-alkoxy substituted—synthesized as potential psychoactive agents, structure-activity relationships of indole derivatives □ Psychoactive agents—synthesis of 5-alkoxyindolines by reduction of 5-alkoxy-2-indolinones

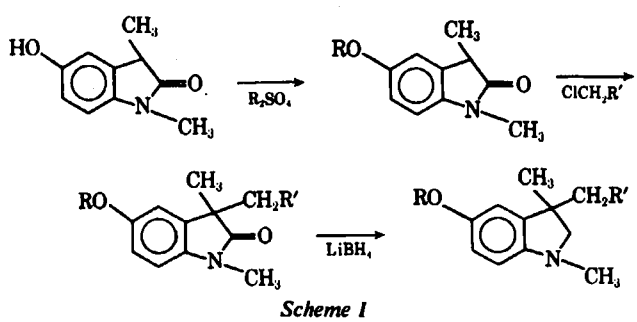
Appropriately substituted indoles have been of interest to the pharmaceutical chemist, especially because of the widespread occurrence of the indole nucleus among both naturally occurring and synthetic psychoactive compounds (1). In particular, those indole derivatives with 3-alkylamino and 4-, 5-, or 6-alkoxy substitutions have been shown to possess central activity, namely antidepressant, depressant, and hallucinogenic (2).

As a result of the large number of indole derivatives that are psychoactive, we became interested in the role of the nitrogen of the indole nucleus in determining both the potency and the spectrum of the psychoactivity of these compounds.

The nitrogen of indoline and of 2-indolinone differs from the nitrogen of indole with respect to electronic character. Hence, the relative psychopharmacological properties of substituted 2-indolinones and indolines should further elucidate the importance of the indole nitrogen in psychoactive compounds.

In a previous work (3), the present authors prepared 3-alkylamino substituted 2-indolinones and indolines for central activity characterization. Since alkoxy substitution in the 4-, 5-, or 6-position of the indole nucleus often leads to changes in psychopharmacological activity, it was of interest to prepare 5-alkoxy derivatives of selected 3-alkylamino substituted 2-indolinones and indolines for their central activity characterization. Therefore, a series of 5-alkoxy-3-alkylamino-1,3-dimethyl-2-indolinones and indolines were prepared in the hope that their psychoactivity relative to that of the corresponding indole derivatives would shed further light on the role of the indole nitrogen in determining central activity of the indole derivatives.

The 5-hydroxy-3-methyl-2-indolinone intermediates were obtained by a procedure based on the methods of Julian *et al.* (4) and Stolle (5). Dialkyl sulfate in benzene was utilized for C-5 alkylation, and further C-3 alkylation was carried out with metallic sodium and the appropriately substituted chloroalkylamine in ethanol. The resulting 5-alkoxy-3-alkylamino-1,3-dimethyl-2-indolinones (Table I) were reduced with lithium borohydride in tetrahydrofuran to give the substituted indoline derivatives (Table II). The synthetic pathway is shown in Scheme I.



Scheme I

EXPERIMENTAL[1]

Preparation of 5-Hydroxy-1,3-dimethyl-2-indolinone Intermediates—The 5-hydroxy-3-monoalkyl-2-indolinones, starting materials for the synthesis of the 3-methyl-3-alkylamino-2-indolinones and indolines, were prepared according to the procedure of Julian and Pikl (6). The yields were in the range of 80% of theory, and IR and NMR spectrophotometric data confirmed the structural assignments.

Synthesis of 5-Alkoxy-3-alkylamino-1,3-dimethyl-2-indolinones (Table I)—The synthetic procedure was adapted from that outlined by Horning and Rutenberg (7). Compounds II*a*–VIII*a* were prepared by the procedure described below for 3-(2-aminoethyl)-5-methoxy-1,3-dimethyl-2-indolinone (Compound I*a*). Pertinent data for these compounds are summarized in Table I.

IR and NMR spectral data were utilized in the characterization of these compounds. The IR spectra showed absorbances at 1725 (amide carbonyl), 1475 (methyl), and 1610, 1500, and 740 (phenyl) cm.$^{-1}$, while the NMR spectra showed peaks (in $CDCl_3$) at 3.8–4.2 (*O*-methyl or methylene), 6.8–7.5 (aromatic substituent), 3.5–3.8 (*N*-methylene), and 0.8–1.1 (3-methyl or methylene) p.p.m.

3-(2-Aminoethyl)-5-methoxy-1,3-dimethyl-2-indolinone (Compound I*a*)—Metallic sodium (2.07 g., 0.09 mole) in ethanol (150 ml.) was mixed with 5-methoxy-1,3-dimethyl-2-indolinone (12.0 g., 0.06 mole) in a three-necked flask equipped with reflux condenser, stirrer, drying tube, and dropping funnel. A solution of 2-chloroethylamine hydrochloride (11.6 g., 0.10 mole) and metallic sodium (2.3 g., 0.10 mole) in ethanol (100 ml.) was added dropwise to the ethanolic substituted 2-indolinone solution. The reaction mixture

[1] Reported melting points are uncorrected. A Thomas-Hoover Unimelt apparatus was used for the melting-point determination. IR spectral analyses were conducted on a Perkin-Elmer model 137 G, while NMR spectra were obtained on a Varian model A-60 spectrophotometer.

was refluxed with stirring for 6 hr. and cooled to room temperature, and then the ethanol was removed under reduced pressure. The resulting brown residue was extracted with ether, and the ether extract was dried over magnesium sulfate. After removal of the ether, the resulting product was recrystallized from ether–hexane to give the compound whose data are summarized in Table I.

Synthesis of 5-Alkoxy-3-alkylamino-1,3-dimethylindolines (Table II)—Reduction of substituted 2-indolinones to indolines was attempted using the procedure outlined by Marion and Kates (8). Since this procedure gave incomplete reduction, the method was altered by utilizing lithium borohydride in tetrahydrofuran. Compounds II*b*–VIII*b* were prepared by the procedure described for 3-(2-aminoethyl)-5-methoxy-1,3-dimethylindoline (Compound I*b*), and their data are summarized in Table II.

The IR spectra of these compounds showed absorbances at 1610, 1500, 740 (phenyl), and 1475 (methyl) $cm.^{-1}$. The amide carbonyl band was absent. The NMR spectra contained peaks at 6.6–7.2

(aromatic), 3.8–4.2 (*O*-methyl or methylene), and 3.5–3.8 (*N*-methylene) p.p.m. with proper multiplicities.

3-(2-Aminoethyl)-5-methoxy-1,3-dimethylindole (Compound Ib)—A solution of 3-(2-aminoethyl)-5-methoxy-1,3-dimethyl-2-indolinone (5.5 g., 0.03 mole) in tetrahydrofuran (30 ml.) was added slowly to a suspension of lithium borohydride (0.04 mole) in tetrahydrofuran (25 ml.). The reaction mixture was refluxed with stirring overnight and then cooled to room temperature. A mixture of methanol–water (10:1) was added slowly to the mixture until effervescence ceased. The tetrahydrofuran was removed under reduced pressure, and the residue was extracted with ether. The ether extract was dried over magnesium sulfate and the ether evaporated. The crude oil was distilled to give the compound whose data are summarized in Table II.

SUMMARY

Sixteen 5-alkoxy-3-alkylamino-1,3-dimethyl-2-indolinones and indolines were prepared. These compounds were characterized with IR and NMR spectroscopy. Pharmacological testing is in progress.

Comptonia asplenifolia: Low Boiling Components

D. C. CLAGETT▲, W. P. DUBINSKY*, and D. PRZYBYL

Abstract □ Room temperature, low pressure vacuum distillation of 920 g. of the fresh leaves from *Comptonia asplenifolia* Ait. typically yielded 3 mg. of methyl acetate, 1 mg. of ethyl acetate, 2 mg. of diisopropyl acetaldehyde acetal, and 5 mg. of cineol. Methyl acetate, ethyl acetate, and diisopropyl acetaldehyde acetal were not previously reported as components of the essential oil and are important contributors to the odor factors of the plant.

Keyphrases □ *Comptonia asplenifolia* Ait.—isolation and identification of low boiling components □ GLC—identification of low boiling components of *Comptonia asplenifolia*

Comptonia asplenifolia Ait.[1] was first investigated phytochemically by Braun (1) and later by de Nicola and Lynn (2). Using distillation techniques, these workers isolated 0.02–0.5% by weight of an oil from fresh or semidried leaves. Only cineol was identified. Other compounds such as lactones, terpenes, esters, and alcohols were suggested to be present. In a more recent study using GLC, this essential oil was shown to contain at least 32 identifiable terpenoids including cineol (3). This work utilized a cohobation still, which allowed isolation of high boiling components but precluded observation of volatile compounds and those that were heat or water sensitive. It was, therefore, of interest to isolate such low boiling components. Compounds determined would add to the chemotaxonomic information about *C. asplenifolia*[2].

Using a sequence of room temperature, low pressure vacuum distillation, ether extraction, and temperature-programmed GLC, small amounts of methyl acetate, ethyl acetate, diisopropyl acetaldehyde acetal, and cineol were isolated. The previously undetected methyl acetate and ethyl acetate are common, expected odor contributors. Diisopropyl acetaldehyde acetal, which was isolated in amounts comparable to about half that of the previously noted cineol (2, 3), appears to be another important odor contributor. This is the first report of this substance being isolated from natural

[1] This plant, a sweet-scented shrub common to the eastern United States, is alternatively designated *Myrica asplenifolia* Endl. or *Comptonia peregrina* L. Coult. and is colloquially named sweet fern. Identification of the plant material used in this study was made by Dr. Fred Barkley of Northeastern University, and a voucher specimen (Clagett and Dubinsky–1) has been deposited with Dr. Barkley, Curator, Husky Herbarium, Northeastern University, Boston, MA 02115

[2] *Comptonia asplenifolia* has been used for many years as a remedy for high blood pressure and as a sickroom air freshener by residents of Appalachia. Its essential oil is patented for use as a perfume fixative (4). The chemotaxonomic information may be useful for chemosystematic evaluations (3).

(aromatic), 3.8–4.2 (*O*-methyl or methylene), and 3.5–3.8 (*N*-methylene) p.p.m. with proper multiplicities.

[1] This plant, a sweet-scented shrub common to the eastern United States, is alternatively designated *Myrica asplenifolia* Endl. or *Comptonia peregrina* L. Coult. and is colloquially named sweet fern. Identification of the plant material used in this study was made by Dr. Fred Barkley of Northeastern University, and a voucher specimen (Clagett and Dubinsky–1) has been deposited with Dr. Barkley, Curator, Husky Herbarium, Northeastern University, Boston, MA 02115

[2] *Comptonia asplenifolia* has been used for many years as a remedy for high blood pressure and as a sickroom air freshener by residents of Appalachia. Its essential oil is patented for use as a perfume fixative (4). The chemotaxonomic information may be useful for chemosystematic evaluations (3).

material. Its presence is somewhat surprising when it is considered that its acid-catalyzed hydrolytic lability[3] is about 13 times greater than that of acetal itself (6).

A preliminary phytochemical survey (by referenced methods) of an alcohol extract from the dried leaves remaining after water and volatile oils were removed indicated little or no sterol (7), alkaloid (8), or saponin matter (9). Tannins (10) and flavonoids (11) were suggested[4]. Separations and identifications of these components are being pursued in these laboratories[5].

EXPERIMENTAL[6]

GLC—Temperature-programmed and isothermal column GLC analyses were performed with a chromatograph[7] equipped with a thermal conductance detector block. All temperature-programmed runs were made at a 10°/min. temperature increase between 60° and the indicated temperature limit. All GLC analyses utilized an injector port temperature of 250° and a detector block temperature of 300°. The columns utilized were: Column 1, 25% Dow 710 silicone oil on 60–80-mesh Chromosorb P, acid washed [2.1-m. (7-ft.) × 0.63-cm. (0.25-in.) o.d. copper tubing]; Column 2, 20% Carbowax 20M on 60–80-mesh Chromosorb P, acid washed [3.04-m. (10-ft.) × 0.63-cm. (0.25-in.) o.d. stainless steel tubing]; Column 3, 13% Apiazon L grease on 60–80-mesh Chromosorb P, acid washed [1.8-m. (6-ft.) × 0.63-cm. (0.25-in.) o.d. copper tubing]; and Column 4, 4% SE-30 methyl silicone oil on 60–80-mesh Chromosorb P, acid washed [2.7-m. (9-ft.) × 0.63-cm. (0.25-in.) o.d. copper tubing]. Collections of GLC-purified material for comparison IR measurements were made using dry ice–acetone-cooled U-tubes.

Isolation of Low Boiling Fractions—Fresh *C. asplenifolia* leaves were packed in a 60 × 15-cm. i.d. cylindrical iron vessel. This was connected in turn to a dry ice-cooled 100 × 5-cm. i.d. tubular trap and 25-l./min. vacuum pump. The evacuated iron vessel was maintained at room temperature (approximately 25°) while the pump developed a pressure of 5–10 mm. Hg. Volatiles were frozen out in the trap over a 6-day period. At the end of this time the trap was warmed and the water–oil melt was collected. This mixture was extracted with ether. The ether solution was treated with anhydrous sodium bicarbonate. Ether solvent was removed using a rotary evaporator. In a typical experiment, fresh leaves (920 g.) yielded water (590 g.) and oil (0.12 g., 0.13% of fresh leaf weight). Analysis of the oil by temperature-programmed GLC (Column 1, limit 240°) indicated methyl acetate (0.003 g.), ethyl acetate (0.001 g.), and diisopropyl acetaldehyde acetal (0.002 g.) as the sole components eluted below 125°. At 150°, cineol (0.005 g.) was eluted among other higher boiling components. Positive identification of methyl acetate, ethyl acetate, and diisopropyl acetaldehyde acetal was made by comparing their IR spectra (GLC-collected samples) and programmed retention times (Column 1 and Column 2, limit 240°) with those of authentic samples[8]. Cineol was similarly identified by comparison of its IR spectra and retention times (programmed Column 1, limit 240°, and isothermal Column 3, 150°) with an authentic sample.

Synthesis of Diisopropyl Acetaldehyde Acetal—Diisopropyl acetaldehyde acetal was synthesized by a method analogous to that used for the preparation of the acetal (15). Freshly distilled acetaldehyde (44 g., 1 mole) was added to a mixture of isopropanol (116 g., 1.9 moles) and anhydrous calcium chloride (22 g., 0.2 mole). The vessel was stoppered, shaken, and allowed to stand at room temperature for 24 hr. The solution was decanted onto 0.3-cm. (0.125-in.) activated molecular sieves[9] and dried for an additional 24 hr. The molecular sieves were removed, and anhydrous ether (100 ml.) followed by sodium metal pellets (23 g., 1 mole) was added. After hydrogen evolution ceased, the solution was distilled and the 82–115° boiling fraction was collected. Redistillation yielded a fraction of boiling range 122–124°; yield 42.6 g. (34%); IR (CCl_4): 1390, 1334, 1140, 1085, and 1002 $cm.^{-1}$; NMR (CCl_4): 8.79 d, 8.88 d, 8.91 d (15), 6.16 broad h (2), and 5.29 q (1).

Anal.—Calc. for $C_8H_{16}O_2$: C, 65.71; H, 12.41. Found: C, 65.77; H, 12.20.

▲ To whom inquiries should be directed.

[3] This hydrolytic lability, which results in acetaldehyde formation, probably explains the irritating nature of its concentrated vapors. In this study the ethereal solution obtained after ether extraction, when treated with 2,4-dinitrophenylhydrazine reagent (5), yielded a derivative which was shown to be identical with that of acetaldehyde by melting point (148–150°) and undepressed mixed melting point. Diisopropyl acetaldehyde acetal, when treated similarly, yielded a derivative identical with that of acetaldehyde and that from the natural oil, as shown by melting point and undepressed mixed melting point.

[4] The authors thank Dr. Robert Raffauf for these survey analyses.

[5] Column chromatography of the alcoholic extract, using Dupont nylon 6 on Celite solid phase (12), yielded at least 20 flavonoid substances. Preliminary paper chromatography/color tests indicated the presence of chalcones, isoflavones, flavonols, flavanonols, flavones, and flavanones (12–14).

[6] Fresh *C. asplenifolia* leaves were harvested in the vicinity of Boston, Mass. IR spectrophotometric determinations were made with a Perkin-Elmer model 21 instrument. Samples were dissolved in spectral grade carbon tetrachloride. NMR spectra were obtained using a Varian model T-60 spectrometer. Samples were dissolved in spectral grade carbon tetrachloride, with 1% tetramethylsilane as the internal reference. Melting points were taken using a Thomas-Hoover apparatus, and melting points and boiling points are uncorrected. Carbon–hydrogen analyses were performed by Galbraith Laboratories. Anhydrous calcium chloride, sodium bicarbonate, sodium, isopropanol, methyl acetate, and ethyl acetate were of reagent grade. Technical grade cineol was purchased from Aldrich Chemical Co.

[7] F&M Scientific Corp., model 500.

[8] The synthesis of diisopropyl acetaldehyde acetal was accomplished with complete analytical and spectral data, because all previous syntheses lacked rigorous structure determinations.

Synthesis and Biological Activity of 1,5-Diphenyl-4-arylazopyrazoles and 5,5-Dimethylcyclohexane-1,2,3-trione Bishydrazones

HARI G. GARG[▲], ANU SINGHAL, and J. M. L. MATHUR

Abstract □ A series of 1,5-diphenyl-4-arylazopyrazoles was synthesized and evaluated for antimalarial activity. The compound possessing the best antimalarial activity of the entire study was 1,5-diphenyl-4-methoxyphenylazopyrazole. Another series of 5,5-dimethylcyclohexane-1,2,3-trione bishydrazones was prepared and tested as anthelmintics. No significant activity was observed.

Keyphrases □ 1,5-Diphenyl-4-arylazopyrazoles—synthesized and screened as potential antimalarial agents □ 5,5-Dimethylcyclohexane-1,2,3-trione bishydrazones—synthesized and screened as potential anthelmintics □ Anthelmintic agents, potential—synthesis and screening of 5,5-dimethylcyclohexane-1,2,3-trione bishydrazones □ Antimalarial agents, potential—synthesis and screening of 1,5-diphenyl-4-arylazopyrazoles

In a previous paper (1) the synthesis and biological data of N^1-substituted arylsulfonylpyrazoles (Ic) were reported. The test results on rodent malaria performed with some of these derivatives (Ic, X = 2-Cl, 4-OCH_3, or 4-NO_2) were not encouraging; the mean survival time of drug-treated, young female, noninbred ICR-HA swiss mice infected with a standard intraperitoneal inoculum of *Plasmodium berghei* (KBG-173) increased by 0.1 day compared to controls. In a search for efficient antimalarials, analogs of 1,5-diphenyl-4-arylazopyrazoles (Ia) were prepared and are reported in this article. The compounds were found to possess marked improvement in potencies over previous candidates.

In view of the anthelmintic activity displayed by Ic, a series of 5,5-dimethylcyclohexane-1,2,3-trione bishydrazones (IV) containing a few of these groupings was synthesized.

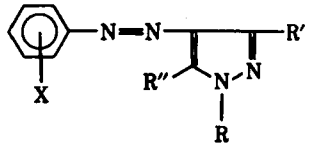
Compounds of general structure I*a* were synthesized by the reaction of the sodium salt of oxymethyleneacetophenone (2) (II) with aryldiazonium salts to give III, which were then condensed with phenylhydrazine.

Bishydrazones (IV) were obtained by the condensation of 2-methyl-4-hydroxy-5-pyrimidylcarbohydrazide (V) with 5,5-dimethylcyclohexane-1,2,3-trione 2-arylhydrazones (VI). Compounds VI were prepared by the coupling of the diazotized anilines with 5,5-dimethylhexane-1,3-dione (3).



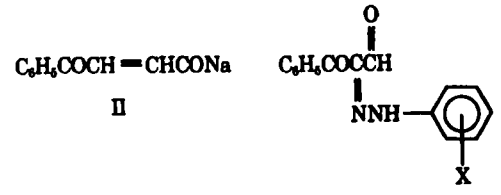
I*a*: R = R″ = C_6H_5, R′ = H

I*b*: R = $C_6H_5CHOHCH_2$, R′ = CH_3, R″ = C_6H_5

I*c*: R = —SO_2—(X), R′ = R″ = CH_3

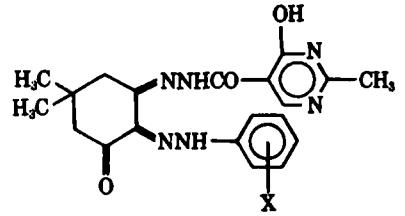
PHARMACOLOGY

Pyrazoles of series I*a* and I*b* appeared weakly active against *P. berghei* 173 in mice, increasing survival time up to 4.4 hr. over controls.

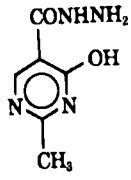


II

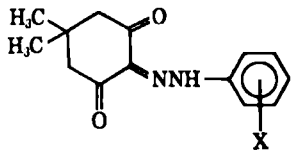
III



IV



V



VI

Anthelmintic activity testing of bishydrazone derivatives (IV) revealed that all were inactive except 2-phenyl and 2-(2-nitrophenyl) derivatives.

EXPERIMENTAL[1]

1,5-Diphenyl-4-arylazopyrazoles (Ia)—The appropriate aniline was diazotized as reported previously (4) and treated with sodium salt of oxymethyleneacetophenone (II). The precipitated arylhydrazone (III) (0.01 mole), on treatment with phenylhydrazine (0.01 mole) in ethanol and acetic acid followed by refluxing for several hours and finally cooling to room temperature, afforded pyrazole derivatives (Ia). All of these compounds were recrystallized from acetone (Table I).

5,5-Dimethylcyclohexane-1,2,3-trione, 1-(2-Methyl-n-hydroxy-5-pyrimidylcarbo)-2-(substituted phenyl) Bishydrazones (IV)—A solution of 2-arylhydrazone of 5,5-dimethylcyclohexane-1,2,3-trione (VI) (3) (0.005 mole) in ethanol (15 ml.) and 2-methyl-4-hydroxy-5-pyrimidylcarbohydrazide (V) (0.005 mole) in glacial acetic acid (1 ml.) was refluxed for 1 hr. On cooling, shining crystals of IV separated out and were recrystallized from dimethylformamide (Table II).

[1] All melting points were determined with a Kofler hot-stage-type apparatus and are uncorrected.

Synthesis and CNS Depressant Activity of Imidazolinone Glyoxylates

NED D. HEINDEL▲ and MARIA C. CHUN*

Abstract □ Six new imidazolinone glyoxylates, which exist in tautomeric equilibria with hydroxyimidazole glyoxylates, were synthesized by a new type of Claisen rearrangement and evaluated in a neuropharmacological mouse profile. CNS depression was observed in several members of the class.

Keyphrases □ Imidazolinone glyoxylates—synthesized and screened as potential CNS agents □ CNS agents, potential—synthesis and screening of imidazolinone glyoxylates □ Imidazoles—synthesis and CNS depressant activity of six imidazolinone glyoxylates

A recent publication (1) described the synthesis and characterization of a new type of imidazolinone glyoxylate (II) by the Claisen-like rearrangement of amide oxime–dimethyl acetylenedicarboxylate adducts (I). Pyrolysis of these adducts in refluxing diphenyl ether gave 41–68% yields of the tautomeric methyl 2-aryl-4-oxo-2-imidazoline-5-glyoxylates (II) (Scheme I). The impressive history of imidazoles as therapeutic agents (2, 3) and, more relevantly, the recent reports that several imidazoles function as centrally acting depressants (4–6) prompted this report of the evaluation of a new imidazole class in a primary Irwin neuropharmacological mouse profile (7).

The amide oximes utilized as starting materials were prepared by addition of hydroxylamine to aromatic nitriles. These amide oximes were condensed with dimethyl acetylenedicarboxylate to yield 1:1 adducts (I) in which —OH addition to the alkyne had occurred.

Simple ketoximes readily add to such acetylene esters (8). When these adducts (I) are heated to 250°, a thermal rearrangement ensues and the imidazolinones result. Several such Claisen-like transformations were reported recently (2, 8, 9).

BIOLOGICAL ACTIVITY

Compounds II*a–f* were administered as a single intraperitoneal injection in water–methylcellulose solution or suspension to each of four mice. The compounds were nontoxic at doses up to 300 mg./kg., and at that level all but II*f* effected marked depression and reduction of spontaneous motor activity. With the exception of the inactive II*f*, all of the compounds induced some writhing and an abnormal gait in the test animals. With II*a* at 300 mg./kg., there was also a loss of righting reflex. The most active member of the class appeared to be II*b*, since physiological signs (depression, lacrimation, body drop, loss of spontaneous activity, and Staub tail phenomenon) were most rapid in onset (6 min. *versus* a minimum of 15 min. for the other analogs at the 300-mg./kg. level). Furthermore, with II*b*, activity persisted down to 30 mg./kg., while no other test agent was active below 100 mg./kg. Moderate hypothermia (approximately 2.5°) was evident at 300 mg./kg. with II*b*, II*c*, and II*e*. None of the compounds was deemed sufficiently active to merit further study.

EXPERIMENTAL[1]

Preparation of the Amide Oximes—Benzamidoxime (10), *p*-chlorobenzamidoxime (11), *p*-methylbenzamidoxime (10), *o*-methylbenzamidoxime (10), and 3,4-dimethylbenzamidoxime (12) were prepared by the Method A_1 described by Eloy and Lenaers (10) and had physical properties in agreement with those reported. The yet unreported 3,4-dimethoxybenzamidoxime was synthesized by Method A_1 in 73% yield, m.p. 163–164° (from methanol).

Anal.—Calc. for $C_9H_{12}N_2O_3$: C, 55.24; H, 6.17. Found: C, 55.22; H, 6.19.

General Procedure for Preparation of Amide Oxime–Dimethyl Acetylenedicarboxylate Adducts (I*a–f*)—Equimolar quantities (0.1

[1] Melting points were obtained between cover glasses on a Fisher-Johns block and are uncorrected. Elemental analyses were provided by Dr. George I. Robertson, Microanalytical Laboratory, Florham Park, N. J.

mole) of the aromatic amide oxime and dimethyl acetylenedicarboxylate were dissolved in 100 ml. of anhydrous methanol. The mixing of the reactants was often mildly exothermic, but the solution was heated at reflux for 3 hr. to complete the reaction. The methanol was removed *in vacuo*, and the resulting oil was induced to crystallize by chilling and scratching (two exceptions as noted in Table I). These low melting solids were purified by repeated recrystallization from methanol to analytical purity.

General Procedure for Thermal Rearrangement to Imidazolinones (IIa–f)—A mixture of approximately 2.0 g. of the amide oxime–dimethyl acetylenedicarboxylate adduct and 25 ml. of diphenyl ether was heated at reflux for 2 hr. The solution was cooled to room temperature and diluted with *n*-hexane, and the precipitated solid was collected. The crude product was recrystallized from methanol with the aid of decolorizing carbon. Yields and melting points are reported in Table II.

Differential Thermal Analysis and X-Ray Diffraction Studies of Griseofulvin–Succinic Acid Solid Dispersions

WIN LOUNG CHIOU▲ and SARFARAZ NIAZI

Abstract □ Differential thermal analysis and X-ray diffraction techniques were employed to study the phase diagrams of griseofulvin–succinic acid systems. The complications of the formation of a thermally decomposed product of succinic acid, succinic anhydride, on the thermograms were discussed. The appearance of typical eutectic peaks and X-ray diffraction peaks of griseofulvin in the resolidified preparations containing 10% or less of griseofulvin indicates that the binary system is a simple eutectic mixture with negligible mutual solid solubilities. This result is partly different from that obtained previously by the microthermal microscope technique, which showed the existence of an extensive solid solution of griseofulvin in succinic acid. The formation of a solid solution was previously concluded to be primarily responsible for the enhanced dissolution of griseofulvin.

Keyphrases □ Griseofulvin–succinic acid solid dispserions—phase diagrams, differential thermal analysis and X-ray diffraction, results compared to microthermal microscope technique □ Succinic acid–griseofulvin solid dispersions—phase diagrams, differential thermal analysis and X-ray diffraction, results compared to microthermal microscope technique □ Differential thermal analysis—phase diagrams of griseofulvin–succinic acid solid dispersions □ X-ray diffraction—phase diagrams of griseofulvin–succinic acid solid dispersions

The classification and pharmaceutical applications of solid dispersion systems were recently reviewed by Chiou and Riegelman (1). A knowledge of the physicochemical properties of a solid dispersion is very important toward an understanding of its applications. Chloramphenicol dispersed in urea was shown to result in faster dissolution and absorption rates (2, 3). The enhancement was thought primarily due to the formation of a solid solution of the drug in the carrier, urea (3). Recently, Chiou (4) used differential thermal analysis and X-ray diffraction methods to reexamine this system, and he concluded that the system is a simple eutectic mixture with negligible mutual solid solubility.

The observed enhancement in both dissolution and absorption rates must, therefore, be mainly due to the reduction of the chloramphenicol crystalline size fol-

This result is partly different from that obtained previously by the microthermal microscope technique, which showed the existence of an extensive solid solution of griseofulvin in succinic acid. The formation of a solid solution was previously concluded to be primarily responsible for the enhanced dissolution of griseofulvin.

Keyphrases □ Griseofulvin–succinic acid solid dispserions—phase diagrams, differential thermal analysis and X-ray diffraction, results compared to microthermal microscope technique □ Succinic acid–griseofulvin solid dispersions—phase diagrams, differential thermal analysis and X-ray diffraction, results compared to microthermal microscope technique □ Differential thermal analysis—phase diagrams of griseofulvin–succinic acid solid dispersions □ X-ray diffraction—phase diagrams of griseofulvin–succinic acid solid dispersions

The classification and pharmaceutical applications of solid dispersion systems were recently reviewed by Chiou and Riegelman (1). A knowledge of the physicochemical properties of a solid dispersion is very important toward an understanding of its applications. Chloramphenicol dispersed in urea was shown to result in faster dissolution and absorption rates (2, 3). The enhancement was thought primarily due to the formation of a solid solution of the drug in the carrier, urea (3). Recently, Chiou (4) used differential thermal analysis and X-ray diffraction methods to reexamine this system, and he concluded that the system is a simple eutectic mixture with negligible mutual solid solubility.

The observed enhancement in both dissolution and absorption rates must, therefore, be mainly due to the reduction of the chloramphenicol crystalline size fol-

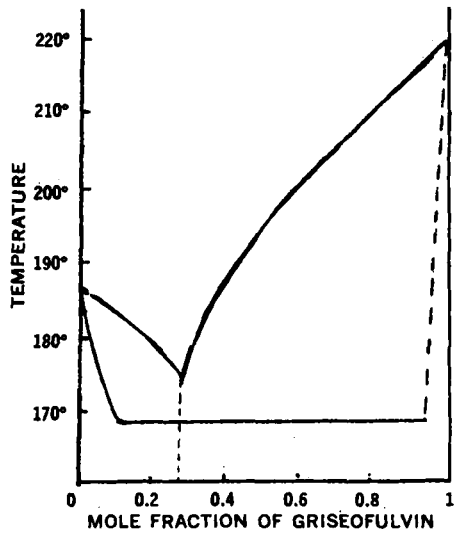

Figure 1—*Phase diagram for griseofulvin–succinic acid mixtures obtained by microthermal techniques. (From* Reference 5.)

lowing the solidification of the melt of the mixture. Griseofulvin dispersed in succinic acid was previously shown by Goldberg *et al.* (5) to produce a much faster dissolution rate and a supersaturation phenomenon. These observations were attributed to the formation of a solid solution of the drug in the carrier. This conclusion was based on their analysis of the phase diagram (reproduced in Fig. 1) determined by the microthermal microscope technique. The purpose of this paper is to report a different finding regarding the griseofulvin–succinic acid phase diagram study obtained through more sophisticated and objective techniques, namely differential thermal analysis and X-ray diffraction.

EXPERIMENTAL

Sample Preparations—Physical mixtures of griseofulvin[1] and succinic acid[2] were obtained by mixing in either a microball mill[3] or mortar. Griseofulvin–succinic acid solid dispersions were prepared by the fusion method (5). The concentration of griseofulvin in each preparation was confirmed spectrophotometrically using a spectrophotometer[4] (5).

Thermal and X-Ray Diffraction Studies—The procedure and instrumentation for differential thermal analysis, X-ray diffraction, and capillary tube melting-point studies were identical to those reported previously (6). Heating rates of 5 and 10°/min. used in this study were found to give almost identical thermograms.

RESULTS AND DISCUSSION

Phase Diagram Determination from Physical Mixtures—It has been generally found that the binary phase diagrams determined from physical mixtures through thermal analyses often correlate well with those determined from fused or evaporated mixtures (7, 8). The phase diagram of the griseofulvin–succinic acid system, determined from their physical mixtures, that has not been previously reported is shown in Fig. 2. The eutectic melting was observed in all samples containing 1–99% (w/w) of griseofulvin. This might be indicative of a lack of an extensive mutual solid solubility between the two components. Similar eutectic peaks were also observed in all physical mixtures of the sulfathiazole–urea binary system (6). However, certain mutual solid solubilities between the two components were found in their solidified fused preparations (6).

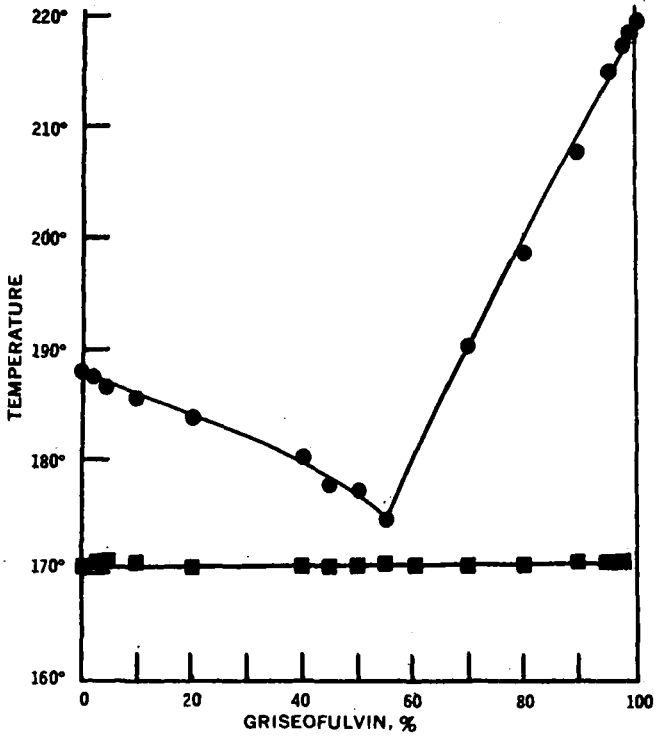

Figure 2—*Phase diagram of griseofulvin–succinic acid binary system determined from physical mixtures. Key:* ■, *thaw point; and* ●, *final melting point.*

The thaw points in this study were determined from the differential thermal analysis thermograms, because differential thermal analysis instruments are more sensitive than the conventional capillary tube method in detecting the beginning of melting of a small fraction of a sample (1, 6). They were all found to be around 170°, which is about 2.5° higher than the previously reported value (5). The final melting points of the samples were determined from both

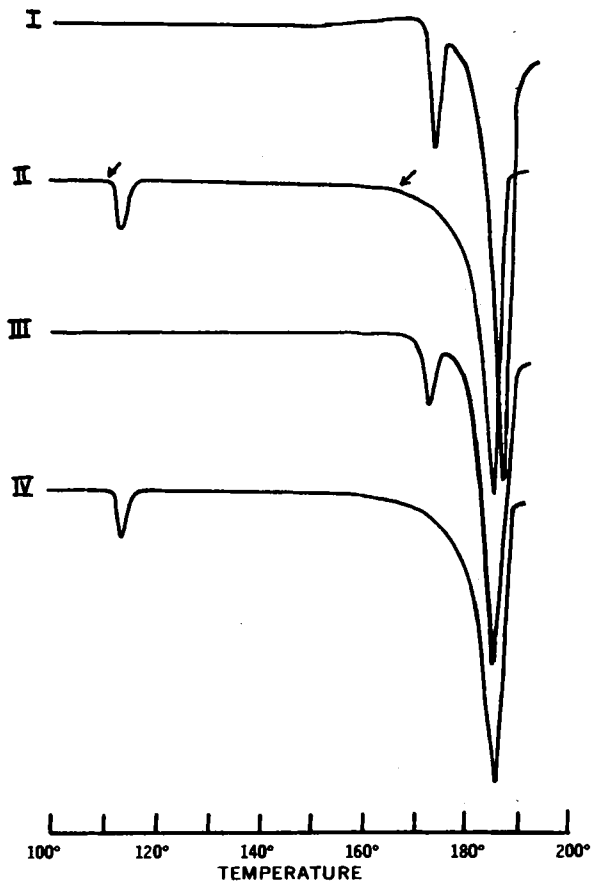

Figure 4—*Thermograms of different samples of 10% griseofulvin. Key: I, physical mixture; II, solid dispersion; III, solid dispersion incubated at 80° for 5 days; and IV, 10% griseofulvin–90% melted succinic acid physical mixture.*

the differential thermal analysis and capillary tube methods. However, for samples that showed ambiguities of the final melting on differential thermal analysis thermograms (6, 8), the values determined from the capillary tube method were used in the construction of the phase diagrams (1, 6).

Thermal Stability of Griseofulvin and Succinic Acid—To determine the phase diagram of a binary system from resolidified fused preparations, it is necessary to study first the thermal stability of both components. If any significant chemical decomposition takes place during the initial melting process, the phase diagram determined might be quite complicated or sometimes misleading because the system now contains three or more components. The thermal stability of griseofulvin was demonstrated by essentially the identical differential thermal analysis thermograms of its original and resolidified pulverized samples. This is in agreement with some previous studies (9, 10). Although succinic acid (m.p. 185–187°, b.p. 235°) has been reported (11) to undergo a partial conversion to succinic anhydride (m.p. 119.6°, b.p. 261°), it appears that no data are available in the literature regarding its thermal stability around its melting point.

The thermogram of the resolidified fused samples obtained from this study showed an extra endothermic peak beginning at 118°. The melting range of its major peak was also widened and considerably shifted to the lower temperature (Fig. 3). Furthermore, the intensity of the extra endothermic peaks and the widening and shifting of the major peaks were all further enhanced when the sample was fused and solidified repeatedly. From a theoretical consideration (1, 13), this observation agrees with a contention that succinic acid will partially decompose after melting and will form a eutectic mixture with its thermally decomposed product. The extent of decomposition also appears to increase with repeated fusion of the acid. It is reasonable to assume that succinic anhydride is also the decomposition product. The thermal decomposition was also confirmed by the sublimed deposition of a thin white layer of film on

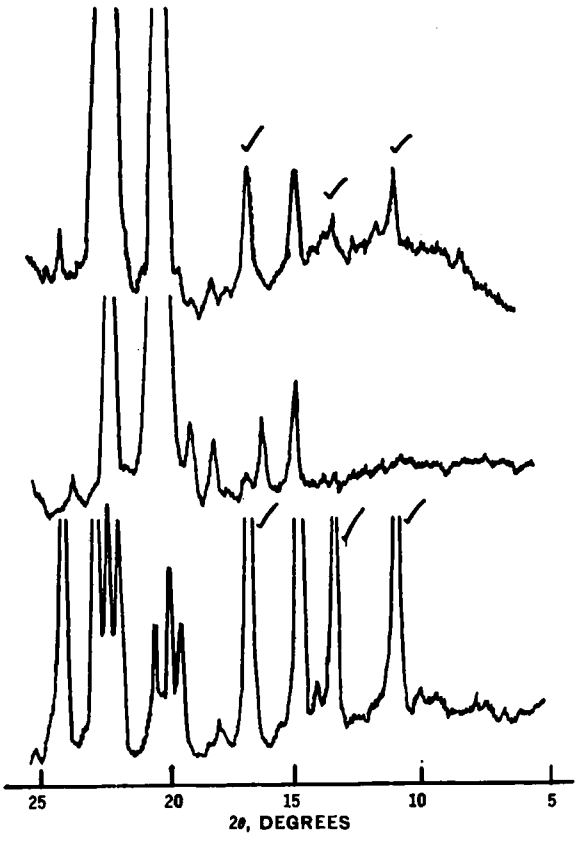

Figure 5—*X-ray diffraction spectra. Key: top, 10% griseofulvin solid dispersion; middle, resolidified succinic acid; and bottom, griseofulvin. Tick marks indicate the characteristic peaks of griseofulvin.*

the cover glass when the resolidified succinic acid powder was heated to about 120° on a hot stage attached to a microscope[5]. Such a sublimation, however, could not be detected when succinic acid was directly heated to 150° without prior fusion and solidification. The sublimation phenomenon of succinic anhydride was reported previously (11). The presence of succinic anhydride in the resolidified succinic acid sample was also confirmed by the preliminary X-ray diffraction study.

Thermal Analyses of Resolidified Fused Mixtures—Although thermal analyses were conducted for many resolidified preparations containing various amounts of griseofulvin and succinic acid, only the 10% (w/w) griseofulvin–90% succinic acid resolidified preparation (or solid dispersion) will be discussed in detail. Since succinic acid might undergo a partial thermal decomposition, its complicating effect on the differential thermal analysis thermogram of the 10% griseofulvin solid dispersion was reasonably anticipated.

Thermograms of both the solid dispersion and the physical mixture are shown in Fig. 4. Two endothermic peaks were present, beginning at 109 and 166°, respectively, in the solid dispersion thermogram (as shown by the arrows). In addition, its final melting peak appeared a few degrees lower than that of the physical mixture. The peak starting at 109° is attributed to the presence of succinic anhydride. This conclusion is also supported by the following evidence: (*a*) a similar sublimation phenomenon was also observed for the solid dispersion at about 120°; and (*b*) a similar thermogram pattern was also obtained from the physical mixture of 10% griseofulvin–90% resolidified succinic acid (Fig. 4) and from the physical mixture of 10% griseofulvin–87.5% succinic acid–2.5% succinic anhydride. It was estimated from the thermograms that about 7% of succinic anhydride was present in the 10% griseofulvin solid dispersion.

During the early stage of this investigation, it was thought that the observed peculiarities of the above solid dispersion thermogram might have been caused by the metastable state of the sample fol-

[5] Kofler.

lowing resolidification of the melt at room temperature. Therefore, the thermogram was again recorded for samples that had been incubated at 80° for 5 days in sealed capillary tubes. Surprisingly, the earlier peak disappeared and the griseofulvin–succinic acid eutectic peak, with an intensity similar to that found in the physical mixture, reappeared (Fig. 4). The disappearance of the earlier peak is thus likely to be due to the sublimation of succinic anhydride to the upper part of the capillary tube during the annealing process. The reappearance of the original eutectic peak also clearly indicates that the majority of griseofulvin is present as griseofulvin crystals and not as solid solution in the solid dispersion.

It must be emphasized that, based on the phase rules and differential thermal analysis principles (1, 4, 6), the thaw point or the beginning of the endothermic peak of the thermogram must be higher than the eutectic temperature if the sample is a solid solution as originally proposed by Goldberg *et al.* (5). The peculiar thermal characteristics of the 10% griseofulvin solid dispersion were also observed in the 1, 2, and 5% griseofulvin solid dispersions. In other words, based on this method of analysis, the solid solubility of griseofulvin in succinic acid at or above the eutectic temperature should be less than 1% or negligible. This is not in agreement with the previous study in which a solid solubility of 25% griseofulvin in succinic acid was reported. As reported (4) earlier for the chloramphenicol–urea system, such discrepancy is probably due to the more subjective visual method used in these previous studies. As beginners in microscopy, the present authors have experienced uncertainty in ascertaining the exact thaw points of the solid dispersion samples using an identical technique to that employed by previous workers (5). The thaw point varied between 110 and 170°. The reported limited solid solubility of succinic acid in griseofulvin was also confirmed by the present study. The resolidified samples containing 95 and 98% of griseofulvin all showed eutectic peaks at about 166°.

X-Ray Diffraction Studies—The X-ray diffraction technique was used recently to study the physical nature of drugs in solid dispersion systems (4, 6, 12). It was employed also in this investigation to support the differential thermal analyses results showing the limited solubility of griseofulvin in succinic acid. Theoretically, the characteristic diffraction peaks of the solid solute should be absent from the diffraction spectrum of a solid solution (1). However, this is not the case for the 10% griseofulvin solid dispersion. Three major peaks of griseofulvin at 10.8, 13.3, and 16.6° (13) were all present in the 10% griseofulvin solid dispersion (Fig. 5). The comparable areas under these peaks between the solid dispersion and physical mixture (10% griseofulvin) also indicate that most of the griseofulvin was present as crystals and not as a solid solution in the preparation. A slight line broadening effect was observed in the freshly prepared solid dispersion which might indicate the presence of ultrafine crystals of griseofulvin. For example, the ratio for the peak height over the peak width at 10.8° was increased about onefold after aging at 80° for 5 days. The effect of peak broadening on the dissolution rate of griseofulvin is currently under investigation in this laboratory.

Quantitative Determination of Morphine in Poppy Capsules by Differential Spectrophotometry

RUBÉN V. D. RONDINA, ARNALDO L. BANDONI, and JORGE D. COUSSIO▲

Abstract □ A procedure for a rapid quantitative analysis of morphine in poppy capsules is described. It is based on differential spectrophotometry between alkaline and acidic solutions. The method was applied to poppy capsules cultivated in Argentina. The results were statistically compared with those obtained using a TLC method. Both methods showed no significant differences.

Keyphrases □ Morphine, in poppy capsules—determination by differential spectrophotometry □ Poppy capsules, Argentine—analysis of morphine content, differential spectrophotometry □ Opium alkaloids—determination of morphine in Argentine poppy capsules, differential spectrophotometry □ Spectrophotometry, differential—determination of morphine in poppy capsules

Morphine is still important in pharmacy for its direct use and as a source of semisynthetic derivatives. It is obtained from poppy capsules and from opium. Both foreign opium and local poppy capsules are used in Argentina (1), but the latter is obtained from domestic harvests of *Papaver somniferum* var. *nigrum*.

Between 1943 and 1970, poppy was cultivated in different provinces of Argentina in search of favorable growing conditions. The province of Mendoza fulfilled the minimum requirements. It was essential to produce an homogeneous race of alkaloid-rich plants to improve the average morphine content of poppy capsules. Thus, it was necessary to devise a method for determining morphine in a single capsule.

A number of gravimetric (2–4), titrimetric (3, 5), spectrometric (6–17), polarimetric (18), chromatographic (19–28), and electrophoretic (21) methods have been reported for the quantitative determination of morphine. The differential spectrophotometric method seemed the most suitable for a crude extract in which many interfering substances were expected to be present.

Differential spectrophotometry in the analysis of pharmaceutical products was studied by Milos (6) and later by Casinelli and Sinsheimer (8) who used 1 *N* sodium hydroxide solutions, finding it inapplicable to morphine unless it had been previously separated by chromatography. Gupta (12) found 0.1 and 0.01 *N* sodium hydroxide solutions to be more suitable and developed a practical way for determining the alkaloid even in mixtures. Recently, a similar method (29) has been developed and applied to the determination of morphine in tablets, suppositories, and eardrops. Up to now, differential spectrometry has not been applied to the determination of morphine in poppy capsules.

EXPERIMENTAL

Apparatus—A spectrophotometer[1] with 10-mm. path rectangular cells was used.

Reagents—Analytical grade reagents were used:

0.1 N *Sodium Hydroxide*—Dissolve 4.00 g. of sodium hydroxide in 1.00 l. of water.

30% Ammonium Phosphate—Dissolve 30 g. of ammonium phosphate, monobasic, in water to make 100 ml. total volume.

0.2 N *Hydrochloric Acid*—Add 16.6 ml. of concentrated hydrochloric acid to enough water to make 1.00 l.

2% Sodium Nitrite—Dissolve 2.0 g. of sodium nitrite in 100 ml. of water.

10% Ammonium Hydroxide—Add 350 ml. of concentrated ammonia to enough water to make 1.00 l.

Plant Material—Dried ripe capsules of *Papaver somniferum* L. var. *nigrum* DC., cultivated in the province of Mendoza (Argentina) in 1970, were used. They were chosen at random and obtained from well-grown, healthy plants.

The capsules were opened and the seeds were discarded. The material was powdered, thoroughly mixed, and dried at 60° to constant weight. The same batch was used throughout the study.

Preparation of Alkaloidal Extract—Transfer an accurately weighed aliquot (about 2.50 g.) into a conical flask with a stopper and add a mixture of 2 ml. of 10% ammonium hydroxide and 6 ml. of 96% ethanol. Add 30 ml. of isopropanol–chloroform (1:3) and stir the mixture for 30 min. Filter the solution through paper into a 50-ml. volumetric flask and bring to volume.

Procedure A: Differential Spectrophotometry—*Standard Preparation*—Accurately weigh about 10.0 mg. of anhydrous morphine or its equivalent of a suitable salt. Dissolve it in 0.1 *N* sodium hydroxide to make 100 ml. total volume. Use this solution immediately.

Calibration—Use 0.1 *N* sodium hydroxide to dilute the standard preparation to obtain 11 solutions containing between 0 and 0.100 mg. of anhydrous morphine per milliliter. Transfer two 2.7-ml. portions of each solution to separate cells (*r* and *s*). Add 0.45 ml. of 30% ammonium phosphate to the reference cell (*r*) and 0.45 ml. of 0.1 *N* sodium hydroxide to the sample cell (*s*); mix carefully. Set the wavelength control knob to 320 nm. and adjust to 100% transmittance. Turn the wavelength control knob to 299 nm. and determine the absorbance of the *s versus* the *r* cell. Use the data thus obtained to calculate the absorptivity (*a*) from Eq. 1:

$$a = \frac{\Sigma AC - (\Sigma C \Sigma A/n)}{\Sigma C^2 - [(\Sigma C)^2/n]} \qquad \text{(Eq. 1)}$$

and the A_0 value from Eq. 2:

$$A_0 = \frac{\Sigma A}{n} - a \cdot \frac{\Sigma C}{n} \qquad \text{(Eq. 2)}$$

[1] Beckman DBG.

Table II—Comparison of Assay Methods for Morphine Applied to Poppy Capsules

Sample Number	Morphine Found, g./100 g. Poppy Capsules Procedure A	Procedure B
1	0.516	0.563
2	0.538	0.542
3	0.541	0.528
4	0.513	0.515
5	0.566	0.529
6	0.537	0.501
7	0.510	0.490
8	0.507	0.470
Average	0.5285	0.5173
SD	±3.9%	±5.8%

where A is the absorbance corresponding to the concentration C, n is the number of observations, and A_0 is the theoretical absorbance when $C = 0$.

Procedure—Transfer 10 ml. of the alkaloidal extract to a separator and extract with 0.1 *N* sodium hydroxide (3 × 15 ml.). Collect the alkaline solution in a 50-ml. volumetric flask, and dilute to volume with 0.1 *N* sodium hydroxide. If necessary, centrifuge to clarify the solution. Transfer two 2.7-ml. portions to separate cells (*r* and *s*). Measure the absorbance of the *s versus* the *r* cell as stated under *Calibration*. The amount of morphine in the sample is calculated using Eq. 3:

$$\text{g. morphine/100-g. capsule} = \frac{(A - A_0)}{a} \cdot \frac{25}{q} \qquad \text{(Eq. 3)}$$

where A is the measured absorbance, a is the absorptivity calculated using Eq. 1, A_0 is the theoretical absorbance when $C = 0$ (previously calculated with Eq. 2), and q is the weight in grams of the sample.

Procedure B: TLC—*Standard Preparation*—Accurately weigh about 40.0 mg. of anhydrous morphine or its equivalent of a suitable salt. Dissolve in isopropanol–chloroform (1:3) to make 100 ml. total volume, and keep the solution in a refrigerator. Renew monthly.

Procedure—A modified version of the method of Heusser and Jackwerth (11) was used. The absorbent was silica gel PF_{254}[2]. Chromatography was carried out on 20 × 20-cm. glass plates coated with a 250-μ layer. They were heated at 130° for 30 min. before spotting. The solvent system was chloroform–acetone–methanol–25% ammonia solution (30:40:10:5). Solutions were spotted with a 1-ml. pipet in 2.5-cm. bands. A total of five bands was used per plate as follows: 1, 0.30 ml. standard preparation; 2, 1.20 ml. alkaloidal extract; 3, 0.60 ml. standard preparation; 4, 1.20 ml. alkaloidal extract; and 5, 1.20 ml. standard preparation.

The plates were developed (ascendingly) to 15 cm. After development, they were dried at room temperature and viewed under UV 254-nm. light. The morphine spots were marked and then scraped off with a spatula. Each spot was transferred to a centrifuge tube and extracted by shaking with 3 ml. of 0.2 *N* hydrochloric acid. An extra tube containing 3 ml. of 0.2 *N* hydrochloric acid was added at this point as a reagent blank. To each tube, 2 ml. of 2% sodium nitrite was added. The tubes were allowed to stand at room temperature for 15 min. and then made basic by the addition of 3 ml. of 10% ammonium hydroxide; the silica layer was separated by centrifugation.The absorbance *versus* the reagent blank was immediately determined at 470 nm. The values of a and A_0 were calculated for each plate using Eqs. 1 and 2 (where C refers to the quantity of morphine applied to each standard band). The assay values of morphine were determined using the relationship:

$$\text{g. morphine/100-g. capsule} = \frac{A_2 + A_4 - 2A_0}{12a} \cdot \frac{25}{q} \qquad \text{(Eq. 4)}$$

where A_2 and A_4 are the absorbances corresponding to bands 2 and 4 of the corresponding plate, respectively, and q is the weight in grams of the sample.

[a] Procedure A − Procedure B = d_i.

RESULTS AND DISCUSSION

By using differential spectrophotometry as described, the concentration of a pure morphine solution was shown to be linear with the absorption (Table I). The average of eight determinations of morphine in the batch gave 0.5285 g. of anhydrous morphine/100-g. capsule. The relative standard deviation was 3.9%. The compatibility of these results with the 0.10–0.60% values found in the literature (21, 32, 33) and with the average industrial yield (0.2%) (32, 34) is of interest.

The method of Heusser and Jackwerth (11), in which morphine is previously isolated by TLC, was selected for comparative purposes. The alkaloidal extract was chromatographed, and then morphine was eluted and submitted to the Radulescu reaction (30), a simple case of phenol nitrosation (31). The nitrosomorphine was measured at 470 nm. An average of eight determinations gave 0.5173 g. of anhydrous morphine/100-g. capsule, and the relative standard deviation was 5.8%. Results of both methods are shown in Table II.

A comparison between averages shows a difference of 0.0112 g. of morphine/100-g. capsule. Statistical analysis of the data showed that this difference was not significant.

As the same alkaloidal extract was used for each pair of trials, the Student *t* test could also be applied to the respective differences (Procedure A − Procedure B = d_i) (Table III).

From the table of *t*, it was found that the chance of obtaining a value of *t* greater than or equal to $\pm t_0'$ (1.104) is slightly greater than 30 in 100 ($t_{0.3} = 1.119$). Hence, the null hypothesis ($\bar{d} = 0$) cannot be rejected at the 5% level of significance. The conclusion is also that the two methods of analysis did not produce significantly different results.

CONCLUSION

The present method allows a relatively rapid determination of morphine in poppy capsules without prior chromatography of the crude extract. It is accurate enough to be used in the selection of the alkaloid-rich capsules.

Inhibition of Pyruvic Acid Oxidation by 2,5-Substituted 1,3,4-Oxadiazoles

H. H. SINGH, S. NAGAR, A. CHAUDHARI, and SURENDRA S. PARMAR▲

Abstract □ Several 2-substituted amino-5-(dichlorophenoxymethyl)-1,3,4-oxadiazoles were synthesized by cyclizing various corresponding 1-(dichloro substituted phenoxyacetyl)-4-substituted thiosemicarbazines. These compounds exhibited the ability to inhibit oxidation of pyruvic acid by rat brain homogenate and showed gross behavioral depression in mice on intraperitoneal administration.

Keyphrases □ Pyruvic acid oxidation—2,5-substituted 1,3,4-oxadiazoles, synthesized and tested as inhibitors, rats, mice □ 1,3,4-Oxadiazoles, 2,5-substituted—synthesis, studied as inhibitors of pyruvic acid oxidation, rats, mice □ Thiosemicarbazines, substituted—synthesis, studied as inhibitors of pyruvic acid oxidation, rats, mice

Several 1-acyl-4-substituted thiosemicarbazines and their cyclized 1,3,4-oxadiazoles have been reported to possess diverse biological properties. The ability of 2,5-disubstituted 1,3,4-oxadiazoles to exhibit analgesic (1, 2), anti-inflammatory (2–4), antipyretic (2), muscle relaxant (5–7), tranquilizing (5, 6), and CNS depressant (8) activities led the present authors to synthesize several 2-substituted amino-5-aryl-1,3,4-oxadiazoles. Furthermore, selective inhibition of nicotinamide adenine dinucleotide-dependent oxidation by CNS depressants such as substituted 4-quinazolones (9–11) prompted the evaluation of the intermediate thiosemicarbazines and cyclized oxadiazoles for their ability to inhibit oxidation of pyruvic acid by rat brain homogenate. Attempts also were made to determine the structure–activity relation of these compounds to their enzyme inhibitory activity. The various oxadiazoles were synthesized according to Scheme I.

EXPERIMENTAL

Ethyl 2,6-Dichlorophenoxyacetate (I)—An equimolar quantity of 2,6-dichlorophenol (8.15 g.), ethyl chloroacetate (6.15 g.), and potassium carbonate (10.35 g.) in dry acetone (50 ml.) was refluxed under anhydrous conditions for 10 hr. The reaction mixture was filtered and the filtrate was poured into 50 ml. of chilled water. The ester was extracted with ether and dried over magnesium sulfate. On removing the excess ether, the remaining liquid was fractionally distilled. The fraction boiling at 180–185° was collected, yielding 9.90 g. (80%).

[a] All melting points were taken in open capillary tubes and are corrected. [b] Each experiment was done in duplicate, and the values are the mean of three separate experiments. The oxygen uptake was measured at 5-min. intervals during a 1-hr. incubation period. The percentage inhibition was calculated from the decrease in the oxygen uptake/125 mg. wet brain weight. The final concentrations of pyruvic acid and the thiosemicarbazines were 10 and 1 mM, respectively. The percent inhibition of 37.3 ± 0.8% observed with an anticonvulsant, 2-methyl-3-O-tolyl-4-quinazolone, in a final concentration of 1 mM under similar experimental conditions was determined for the sake of comparison.

Anal.—Calc. for $C_{10}H_{10}Cl_2O_3$: C, 48.19; H, 4.01. Found: C, 48.00; H, 3.80.

2,6-Dichlorophenoxyacetylhydrazine (II*a*)—To a solution of 7.05 g. of methyl 2,6-dichlorophenoxyacetate (0.03 mole) in absolute ethanol (20 ml.) was added 2.25 g. of 99–100% hydrazine hydrate (0.045 mole), and the mixture was refluxed under anhydrous conditions on a water bath for 2 hr. On cooling, a white solid mass which separated out was collected by filtration and recrystallized from ethanol into a white crystalline solid, m.p. 139°, yield 9.4 g. (80%).

Anal.—Calc. for $C_8H_8Cl_2N_2O_2$: N, 11.91. Found: N, 11.67.

3,4-Dichlorophenoxyacetylhydrazine (II*b*)—A mixture of 3,4-dichlorophenol (8.15 g., 0.05 mole), ethyl bromoacetate (7.65 g., 0.05 mole), and potassium carbonate (10.35 g., 0.075 mole) in dry acetone (40 ml.) was refluxed under anhydrous conditions for 10 hr. The reaction mixture was filtered hot, and the excess of solvent was removed by distillation under reduced pressure. To the residue was added 99–100% hydrazine hydrate (3.0 g.) and absolute ethanol (25 ml.). The mixture was refluxed under anhydrous conditions for 3 hr. Ethanol was removed by distillation. On cooling, a white solid mass which separated out was filtered, washed with a little cold ethanol, dried, and recrystallized from ethanol, m.p. 141°, yield 9.9 g. (85%).

Anal.—Calc. for $C_8H_8Cl_2N_2O_2$: N, 11.91. Found: N, 11.80.

Substituted Phenoxyacetylthiosemicarbazines (III–XXII)—An equimolar quantity (0.005 mole) of substituted phenoxyacetylhydrazine and different alkyl or aryl isothiocyanate was refluxed in ethanol (10 ml.) for 2–3 hr. The solvent was removed by distillation. On cooling, the solid products which separated out were filtered and dried. Recrystallization from ethanol gave pure compounds (Table I).

2-Substituted Amino-5-(substituted phenoxymethyl)-1,3,4-oxadiazoles (XXIII–XLII)—To an ethanolic suspension of an appropriate thiosemicarbazine (0.01 mole) was added 5 ml. of 4 N sodium hydroxide with continuous shaking. Iodine in 5% potassium iodide solution was gradually added to the clear solution with stirring until the color of iodine persisted at room temperature. The contents were then refluxed on a water bath, and more iodine solution was added until a permanent tinge of excess iodine remained. The reaction mixture was then poured into ice-cold water (500 ml.), and the precipitated solid mass which separated out was filtered and washed with water and then with warm carbon disulfide. The crude product was finally recrystallized from ethanol. The compounds thus prepared are recorded in Table II.

BIOCHEMICAL STUDIES

Materials—Commercial chemicals[1] were used in the present study.

Assay of Pyruvic Acid Oxidation by Rat Brain—Male albino rats, kept on an *ad libitum* diet, were used in all experiments. Rat brains isolated from decapitated animals were immediately homogenized in ice-cold 0.25 M sucrose in a Potter–Elvehjem homogenizer. All incubations were carried out at 37°, and the oxygen uptake was measured by the conventional Warburg manometric technique with air as the gas phase. Fresh rat brain homogenate equivalent to 125 mg. wet weight was added to chilled Warburg vessels containing 6.7 mM magnesium sulfate, 20 mM sodium hydrogen phosphate buffer solution (pH 7.4), 1 mM adenosine monophosphate (sodium salt), 33 mM potassium chloride, 10 mM pyruvic acid, and 500 mcg. of cytochrome c in a final volume of 3 ml. The central well contained 0.2 ml. of 20% potassium hydroxide solution. All of the compounds under assay were dissolved in propylene glycol (100%), and an equal volume of the solvent was added in the control vessels.

Effects of Oxadiazoles on Gross Behavior—The studies on the gross behavior in mice were done according to the scheme outlined by Irwin (12). The drugs were taken in 5% gum acacia suspension

[1] Sodium pyruvate, adenosine monophosphate, and cytochrome c were obtained from Sigma Chemical Co., St. Louis, Mo. Other common chemicals were obtained from British Drug House, Bombay, India.

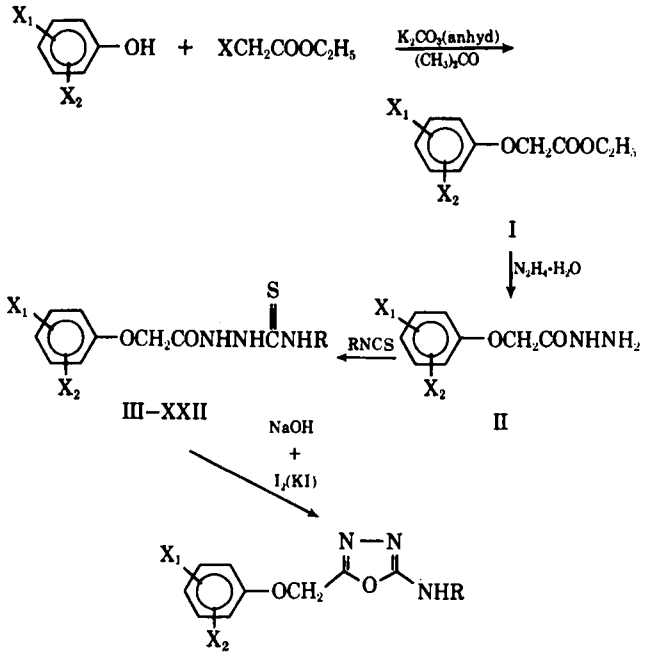
[a] All melting points were taken in open capillary tubes and are corrected. [b] Each experiment was done in duplicate, and the values are the mean of three separate experiments. The oxygen uptake was measured at 5-min. intervals during a 1-hr. incubation period. The percentage inhibition was calculated from the decrease in the oxygen uptake/125 mg. wet brain weight. The final concentrations of pyruvic acid and the oxadiazoles were 10 and 1 mM, respectively.

and administered intraperitoneally. The effect of these compounds on the simple reflexes and gross behavior was observed.

RESULTS AND DISCUSSION

All of the 1-(dichlorophenoxyacetyl)-4-substituted thiosemicarbazines were found to inhibit oxidation of pyruvic acid by rat brain homogenate (Table I). All of the compounds possessing a p-bromophenyl, p-iodophenyl, allyl, or cyclohexyl substituent at position R exhibited greater inhibition. Such an increase in their inhibitory effect was independent of the relative position of the two chlorine atoms present in the phenoxyacetyl moiety of these compounds.

Cyclization of thiosemicarbazines into corresponding oxadiazoles resulted in a significant lowering of their ability to inhibit oxidation of pyruvic acid (Table II). Some oxadiazoles were found to be inactive; a few, however, exhibited greater inhibitory effects than their corresponding thiosemicarbazines. These results failed to provide any direct correlation between the open-chain thiosemicarbazines and their cyclized oxadiazoles. At present, it is difficult



Scheme I

to provide any suitable explanation for the low inhibitory effects of these cyclized oxadiazoles. In general, the steric factors associated with the heterocyclic oxadiazole ring could presumably cause obstruction in the attachment of oxadiazoles on the active site(s) of the enzyme molecule and could, therefore, account for their decreased inhibitory effects. Such a decrease in enzyme inhibitory activities of the oxadiazoles as compared to the thiosemicarbazines could also be due to the loss of C=S, as well as the two acidic hydrogen atoms next to C=O and C=S, respectively, when the thiosemicarbazines are cyclized to their corresponding oxadiazoles. Otherwise, the sulfur and hydrogen atoms in these thiosemicarbazines would form hydrogen bonds with the enzymes to cause greater enzyme inhibition. *In vivo* studies have indicated that almost all compounds produced depression in the gross behavior of experimental mice. Loss of righting reflex was observed with 2-(cyclohexylamino)-5-(3′,4′-dichlorophenoxymethyl)-1,3,4-oxadiazole. In the present study, no correlation could be observed between the enzyme inhibitory activity of substituted thiosemicarbazines and oxadiazoles with behavioral effects.

Inhibitors of Hydroxyindole-*O*-methyltransferase: Indolealkylpiperazines

BENG T. HO[▲], P. M. GARDNER, and WILLIAM M. McISAAC

Abstract □ Two antipsychotic agents, oxypertine and haloperidol, were both found to be *in vitro* inhibitors of bovine pineal hydroxyindole-*O*-methyltransferase. A series of indolealkylpiperazines structurally related to oxypertine was evaluated for inhibitory activity with the enzyme. The most potent inhibitor of this study, 1-(2-chlorophenyl)-4-[2-(5,6-dimethoxy-3-indolyl)ethyl]piperazine, exhibited a mixed-type inhibition. The possible mode of binding of these inhibitors to the enzyme was discussed.

Keyphrases □ Hydroxyindole-*O*-methyltransferase—indolealkylpiperazines as inhibitors, *in vitro* □ Indolealkylpiperazines—tested *in vitro* as inhibitors of hydroxyindole-*O*-methyltransferase, mode of binding □ Haloperidol—*in vitro* inhibition of hydroxyindole-*O*-methyltransferase, mode of binding □ Oxypertine—*in vitro* inhibition of hydroxyindole-*O*-methyltransferase, mode of binding

Oxypertine, 1-[2-(5,6-dimethoxy-2-methyl-3-indolyl)-ethyl]-4-phenylpiperazine (I), a compound that has been reported to be effective in the treatment of schizophrenia (1–4), was found in our laboratories to be a potent *in vitro* inhibitor of hydroxyindole-*O*-methyltransferase. A widely accepted hypothesis proposes the formation of psychotomimetic compounds from endogenous biogenic amines, such as serotonin (5-hydroxytryptamine), as an etiological factor in schizophrenia. The formation of a compound such as *O*,*N*,*N*-trimethylserotonin (*O*-methylbufotenine) in the body can be prevented by an inhibitor of hydroxyindole-*O*-methyltransferase, and this might explain the mechanism of action of antipsychotic agents such as oxypertine. In the present study, a series of indolealkylpiperazines structurally related to oxypertine was evaluated for their inhibitory activities with hydroxyindole-*O*-methyltransferase.

EXPERIMENTAL[1]

Compounds—The compounds (Table I) were dissolved in glacial acetic acid and then diluted with water to a concentration of 0.2% acetic acid.

Assay—Hydroxyindole-*O*-methyltransferase was isolated from beef pineal gland and purified according to the method of Axelrod and Weissbach (5). Incubation was carried out with *N*-acetylserotonin and *S*-adenosyl-L-methionine-methyl-^{14}C according to the procedure previously described (6).

RESULTS AND DISCUSSION

The inhibitory activity of oxypertine (I) increased with the substitution of H for CH_3 in the 2-position. The 1.5-fold increase in activity of VIII over I could indicate a lack of tolerance of the enzyme for the 2-CH_3 group. The undesirable effect of the methyl group at the 2-position in I could be overcome with a 2-ethyl group; VII was slightly more active than VIII and was twice as active as I. The extended carbon chain might have resulted in an involvement of the terminal CH_3 of CH_2CH_3 group to a hydrophobic region of the enzyme.

The inhibitory activity of I did not increase to a large extent with the substitution of a fluorine atom on the *para*-position of the phenyl ring to give II. The introduction of a hydrophobic group or atom such as CH_3 ($\pi = +0.56$) or Cl ($\pi = +0.71$) (7), however, increased the inhibition of the enzyme. Thus, compounds with *o*-CH_3 (IV) and *m*-CH_3 (VI) groups were both better inhibitors (1.5-fold) than I. Similarly, the *p*-Cl of III doubled the inhibitory activity. No increase in inhibition was observed with substitution of an *o*-OCH_3 group in V; this could be attributed to the hydrophilic nature of the OCH_3 group ($\pi = -0.02$), which differs from the other two hydrophobic CH_3 and Cl groups.

In the 2-H series, no increase in activity of VIII was observed by the *p*-CH_3 group of IX; the substitution of an *o*-Cl group in X, however, increased inhibition by more than fivefold.

Extension of the side chain of VIII by inserting CH_2 between the piperazinyl and phenyl groups resulted in about a 1.5-fold loss of activity, indicating the decrease in the tolerance of the enzyme for the $CH_2C_6H_5$ group of XI.

There was a requirement of at least two methylene (CH_2) groups to bridge the indole nucleus with the piperazinyl moiety of VIII, since shortening of the chain to one CH_2, as in XII, reduced the activity 22-fold.

The binding of the two piperazinyl nitrogen atoms remained to be evaluated. In compounds of the present study, the two nitrogens, both being tertiary amines and one of the two also an anilino nitrogen, are in fact weakly basic. No correlation can be found between the inhibitory activities and their pKa values (Table II).

Haloperidol, another antipsychotic drug, was also found to inhibit hydroxyindole-*O*-methyltransferase *in vitro* (Table I); its activity was about one-sixth of the oxypertine (I).

Kinetic studies were carried out with the four indolealkylpiperazines (I, VIII–X) having low I_{50} values. Lineweaver-Burk

New Compounds: Synthesis of Alkyl Esters of D,L-Dopa

CHII MING LAI and WILLIAM D. MASON▲

Abstract □ In the search for possible prodrugs of levodopa, seven alkyl esters of D,L-dopa were prepared using thionyl chloride as the catalyst. The hydrochloride salts were quite stable to hydrolysis in acidic aqueous solutions.

Keyphrases □ D,L-Dopa—synthesis of alkyl esters □ Levodopa—synthesis of alkyl esters of D,L-dopa as a possible prodrug

Extensive clinical trials undertaken during the last decade have shown that levodopa (L-3,4-dihydroxyphenylalanine) is frequently an effective drug in the treatment of Parkinsonism (1–5). It is generally accepted that orally administered levodopa is absorbed into the blood, passes the blood–brain barrier, and is converted to dopamine in the brain. The resulting increase in brain dopamine and related catecholamines is believed responsible for the effectiveness of the drug in treating Parkinsonism. Although levodopa is now considered the drug of choice, there are still problems associated with its use. A significant number of patients do not respond to treatment, while many who do respond require very large doses and often suffer undesired side effects. A recent report indicated (6) the therapeutic response to levodopa depends on the efficiency of absorption and the attainment of adequate blood levels.

Other workers have also studied the biopharmaceutic and pharmacokinetic aspects of this drug. Peaston and Bianchine (7) measured the total radioactivity in the blood of 22 patients after oral doses of ^{14}C-labeled levodopa and found the ^{14}C to be rapidly and almost completely absorbed. Subsequently, three other laboratories reported studies in which levodopa in the blood was measured following oral administration of the drug (8–10). These studies showed that only about 20–30% of the orally administered dose reached the general circulation as the intact drug and suggested that the remainder is biotransformed in the GI tract and/or the liver during its "first passage" to the general circulation. These results are not surprising when the number of degradative reactions to which levodopa is subject is considered (11–14). One possible method for improving the absorption of levodopa and/or making it less labile could be the administration of a prodrug which can be transformed to the active drug following absorption. In this laboratory the use of alkyl esters as possible prodrugs for levodopa is currently under investigation. The preparation of seven esters of the less expensive D,L-dopa is reported in this article.

[a] Analyses were performed by Atlantic Microlab, Inc. [b] I in KBr pellets. [c] UV absorption spectra of 2×10^{-4} *M* solution in 0.1 *N* HCl.

EXPERIMENTAL[1]

Materials—The D,L-dopa used was 3,4-dihydroxyphenylalanine[2], which decomposed between 270 and 272° and was employed without further purification. All other reagents were of the highest quality commercially available and were used without further purification.

Preparation of the Alkyl Ester Hydrochlorides of Dopa—A modification of the procedure presented by Patel and Price (15), in which thionyl chloride acts as the catalyst, was used to prepare seven alkyl esters of D,L-dopa. One hundred milliliters of the appropriate alcohol was placed in a 200-ml. three-necked flask, which was equipped with a reflux condenser and a tube for nitrogen bubbling. The alcohol was cooled to from −5 to −10° and sparged with nitrogen for 10 min. The thionyl chloride (15 ml.) was added slowly over 15 min., and the reaction mixture was stirred for an additional 15 min. After stirring, 4 g. of D,L-dopa was added, the temperature was adjusted to 40°, and the mixture was refluxed for 12 hr. The hydrochloride salts of the isobutyl, pentyl, and isoamyl esters precipitated directly from the reaction solution. The other four ester hydrochlorides were precipitated by adding just enough petroleum ether to make the solution turbid and then placing them in the refrigerator for a few hours. All of the products were collected by filtration and were recrystallized from an absolute alcohol–ether mixture. The crystals were dried in a vacuum desiccator at room temperature and stored in the desiccator until used. For each ester hydrochloride of D,L-dopa, the melting point, IR and UV spectra, and microanalysis data are presented in Table I. The Arnow (16) test for catechol was positive for each ester.

Paper Chromatography—A paper chromatographic method for the qualitative analysis of D,L-dopa in solutions containing one or more of the alkyl esters of dopa was developed. A solvent system consisting of *n*-butanol–water–acetic acid (16:7:1) was found to effect a separation of the amino acid from the various esters when sample solutions were spotted on Whatman No. 1 paper and developed in an ascending manner. The location of the compounds on the developed chromatograms was determined by exposing the paper to ammonia vapors and observing the brown-yellow color develop as they were oxidized. For duplicate runs on solutions of D,L-dopa with each of the seven esters, the R_f value for dopa was between 0.17 and 0.19, while the esters ranged between 0.30 for the methyl ester and 0.85 for the *n*-butyl ester. The possible hydrolysis at 37° of 1 m*M* solutions of each of the seven esters buffered[3] at pH 1, 3, and 5 was evaluated using the paper chromatographic method. No hydrolysis was detected for up to 12 hr.

[1] All IR spectra were obtained with a Perkin-Elmer 237 B grating spectrophotometer. The UV spectra and analyses were obtained with Perkin-Elmer 202 and Beckman DU spectrophotometers, respectively. The melting points were determined on a Thomas-Hoover capillary melting-point apparatus.

Ureide Ring Scission of Phenobarbital by Sodium Borohydride

Keyphrases ☐ Phenobarbital—ureide ring scission by sodium borohydride ☐ Sodium borohydride—used in ureide ring scission of phenobarbital ☐ Ureide ring scission—reaction of phenobarbital with sodium borohydride

Sir:

Phenobarbital was found to react with sodium borohydride in aqueous and organic media, with ultimate formation of 2-phenyl-1-butanol. This finding was unexpected in view of the report by Smissman *et al.* (1) that phenobarbital was not reduced by sodium borohydride in absolute alcohol, tetrahydrofuran, or diglyme.

Solutions (0.1–1 mg./ml.) of phenobarbital in aqueous alkali, methanol, or methanol–ether mixtures were treated with excess sodium borohydride, added as the solid, and the mixtures were monitored at intervals by TLC. When using 0.25-mm. silica gel GF thin-layer plates with chloroform–methanol (4:1) for development and UV light and iodine vapor for detection, all reaction mixtures showed qualitatively identical patterns with time. At first, shrinkage of the phenobarbital spot at about R_f 0.8 was evident with the appearance of two more polar spots, at R_f's about 0.5 and 0.7. After no more phenobarbital was detected on the plates, a new spot became evident at about R_f 0.9, increasing in size and intensity with concomitant disappearance of the lower mobility spots until, finally, only this spot was visible. The reaction proceeded most rapidly in 0.1 *N* alkali and least in methanol–ether mixtures. Heating a solution of phenobarbital with excess sodium borohydride in 0.1 *N* sodium hydroxide for 20 min. was sufficient to effect complete conversion to R_f 0.9 material.

A quantity of the ultimate reaction product was prepared by dissolving 1.06 g. of phenobarbital in 40 ml. of 0.05 *N* sodium hydroxide, adding 4 g. of sodium borohydride in portions, and allowing the mixture to stand for 22 hr. at room temperature. TLC of the reaction mixture showed a single spot at R_f 0.9. Extraction of the mixture with two 50-ml. portions of hexane, washing the extracts with 10 ml. of water, and evaporation under a stream of nitrogen afforded 0.505 g. of faintly yellow liquid (73.6% yield based on phenobarbital). The product was characterized by NMR[1] spectroscopy in deuterochloroform. The signals obtained and their interpretation are summarized in Table I.

Elemental analysis showed no nitrogen, and the carbon–hydrogen values confirmed the structure of 2-phenyl-1-butanol.

[1] Using a Varian A-60 instrument.

Table I—Summary of NMR Spectrum of Phenobarbital Reduction Product

δ, p.p.m.	Multiplicity	Protons	Assignment
0.80	Triplet	3	$-CH_2-CH_3$
1.65	Multiplet	2	$CH_3-CH_2-C(-H)-$
2.05	Singlet	1	—OH (exchanges in D_2O)
2.6	Multiplet	1	$C_6H_5-CH(-)-CH_2$
3.7	Doublet	2	$-CH(-)-CH_2OH$
7.25	"Singlet"	5	$C_6H_5-CH(-)-$

Anal.—Calc. for $C_{10}H_{14}O$: C, 79.95; H, 9.39. Found: C, 80.30; H, 9.50.

Although the mechanism or reaction route was not investigated, we considered that the first step of the reaction might involve hydrolysis of phenobarbital. This hypothesis appears untenable, however, because no spot corresponding to the primary phenobarbital hydrolysis product, phenylethylacetylurea, was seen in chromatograms of the reaction mixtures. Moreover, phenobarbital was demonstrated to be stable when added to reaction mixtures in which the borohydride had been allowed to decompose to borate.

Sir:

Antagonism of histamine-induced smooth muscle contraction by antihistamines is assumed to occur as a result of competitive occupation of tissue receptors by

Ureide Ring Scission of Phenobarbital by Sodium Borohydride

Keyphrases ☐ Phenobarbital—ureide ring scission by sodium borohydride ☐ Sodium borohydride—used in ureide ring scission of phenobarbital ☐ Ureide ring scission—reaction of phenobarbital with sodium borohydride

Sir:

Phenobarbital was found to react with sodium borohydride in aqueous and organic media, with ultimate formation of 2-phenyl-1-butanol. This finding was unexpected in view of the report by Smissman *et al.* (1) that phenobarbital was not reduced by sodium borohydride in absolute alcohol, tetrahydrofuran, or diglyme.

Solutions (0.1–1 mg./ml.) of phenobarbital in aqueous alkali, methanol, or methanol–ether mixtures were treated with excess sodium borohydride, added as the solid, and the mixtures were monitored at intervals by TLC. When using 0.25-mm. silica gel GF thin-layer plates with chloroform–methanol (4:1) for development and UV light and iodine vapor for detection, all reaction mixtures showed qualitatively identical patterns with time. At first, shrinkage of the phenobarbital spot at about R_f 0.8 was evident with the appearance of two more polar spots, at R_f's about 0.5 and 0.7. After no more phenobarbital was detected on the plates, a new spot became evident at about R_f 0.9, increasing in size and intensity with concomitant disappearance of the lower mobility spots until, finally, only this spot was visible. The reaction proceeded most rapidly in 0.1 *N* alkali and least in methanol–ether mixtures. Heating a solution of phenobarbital with excess sodium borohydride in 0.1 *N* sodium hydroxide for 20 min. was sufficient to effect complete conversion to R_f 0.9 material.

A quantity of the ultimate reaction product was prepared by dissolving 1.06 g. of phenobarbital in 40 ml. of 0.05 *N* sodium hydroxide, adding 4 g. of sodium borohydride in portions, and allowing the mixture to stand for 22 hr. at room temperature. 1,5-Diphenyl-3-dimethylaminopyrrolidine: A Long-Acting Histamine Antagonist

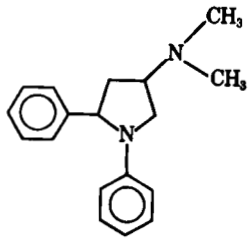
Keyphrases ☐ 1,5-Diphenyl-3-dimethylaminopyrrolidine—evaluation as potent, long-acting histamine antagonist ☐ Antihistamines, potential—1,5-diphenyl-3-dimethylaminopyrrolidine

Sir:

Antagonism of histamine-induced smooth muscle contraction by antihistamines is assumed to occur as a result of competitive occupation of tissue receptors by



I

the antagonist drugs (1, 2). We now report pharmacological data demonstrating that 1,5-diphenyl-3-dimethylaminopyrrolidine (I) is a potent histamine antagonist which exhibits a remarkably long duration of action. Compound I is a cyclic analog of the ethylenediamine antihistamine phenbenzamine. It was synthesized as a single racemic diastereoisomer in which the 3-dimethylamino and 5-phenyl substituents have been tentatively assigned the *trans*-configuration. The synthesis of I and related compounds will be the subject of a future paper.

When I was studied for antihistaminic activity *in vitro* using the isolated guinea pig ileum (3), it was found that concentrations as low as 2×10^{-9} *M* inhibited the contractile response to histamine. However, the antagonistic effect of I could not be readily reversed by washing the tissue. Therefore, experiments were undertaken to compare the duration of action of I with that of the potent ethylenediamine antihistamine tripelennamine. The antagonists (as the hydrochloride salts) were kept in contact with the ileal tissue for 15 min. prior to the addition of agonists. The tissue was then washed at 5-min. intervals with fresh Tyrode's solution, and after each wash either histamine (4×10^{-6} *M*) or acetylcholine (4×10^{-7} *M*) was added. The concentration of histamine employed in these experiments produced a near maximal contraction prior to the introduction of antagonists. Figure 1 shows the recovery of the response to histamine with time after a single exposure of the tissues to the antagonists

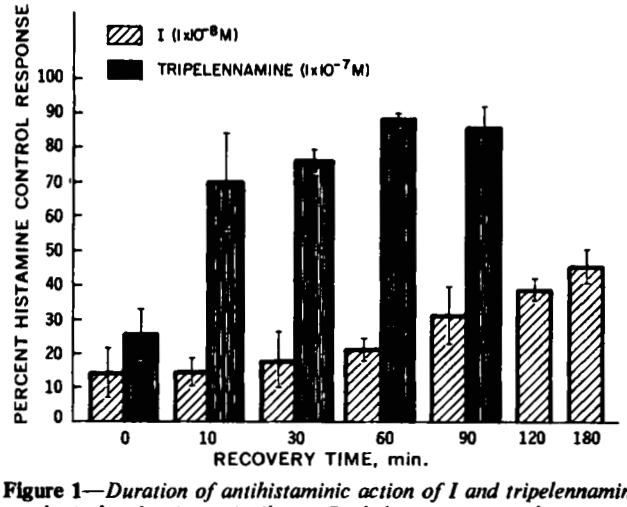


Figure 1—*Duration of antihistaminic action of I and tripelennamine on the isolated guinea pig ileum. Each bar represents the mean of three experiments with I or two experiments with tripelennamine. Vertical lines represent standard error (I) and range (tripelennamine). The 100% control response is defined as the mean response to 4 × 10^{-6} M histamine in these experiments.*

Table I—Percent Decrease in Hind-Limb Perfusion Pressure Produced by Close Intraarterial Injections of Histamine and Methacholine before and after Close Intraarterial Infusion of 5 mg. of I

	Control			
Experiment	Dose 1 (1–2 mcg.)	Dose 2 (2–4 mcg.)	After Infusion of I[a] Dose 1	Dose 2
1	35	44	4	8
2	14	27	0	3
	Methacholine			
	Control			
Experiment	Dose 1 (0.025–0.1 mcg.)	Dose 2 (0.1–0.4 mcg.)	After Infusion of I[a] Dose 1	Dose 2
1	37	43	35	40
2	15	23	13	18

[a] Agonists were administered in 0.9% saline solution 20–30 min. after infusion of I.

followed by repeated washing. The response to histamine did not exceed 45% of control 3 hr. after exposure to I (1×10^{-8} *M* final bath concentration), whereas recovery after treatment with tripelennamine (1×10^{-7} *M* final bath concentration) reached 70% of control within 10 min. The response to acetylcholine was not inhibited by I or by tripelennamine, and the response to acetylcholine did not fall below control levels during the experiments.

In other studies with the guinea pig ileum, a concentration of 4×10^{-6} *M* of I produced an 85% inhibition of the contractile response to acetylcholine (4×10^{-7} *M*). The response to acetylcholine returned to near control levels within 30 min. after exposure of the tissue to this concentration of I. These experiments demonstrate that I is a much more effective inhibitor of histamine than of acetylcholine on the guinea pig ileum.

Experiments were also conducted on the perfused innervated dog's hind limb, employing the preparation described by Zimmerman (4) to examine the relative effectiveness of I in blocking the direct vasodilator responses to close intraarterial injections of histamine and methacholine. The results, expressing the vasodilator responses as percent decreases in perfusion pressure, obtained in two dogs are shown in Table I. The direct vasodilator effect of histamine was greatly reduced, while the perfusion pressure response resulting from the direct vasodilator action of methacholine was only slightly inhibited.

The results of the experiments reported in this communication demonstrate that I is a potent and selective histamine antagonist which inhibits both the contractile response in guinea pig ileum *in vitro* and the vasodilator response in the dog's hind limb *in vivo*. The very long duration of action of I appears to be unique among selective histamine antagonists and may be an important finding with respect to this new antihistamine. We also prepared the other diastereoisomer of I and found it to be a reversible histamine antagonist, having a pA_2 value of 7.97.

Prediction of Dissolution Rates of Drugs

Keyphrases □ Dissolution rates, slightly water-soluble powders—prediction from simple mathematics □ Powders, slightly water soluble—dissolution rates predicted from simple mathematics □ Powders, volume surface diameter—calculation of surface area

Sir:

Hussain (1) recently showed that, by making certain assumptions and using simple mathematics, it was possible to predict the dissolution rates of slightly water-soluble powders using the formula:

$$Q = \frac{A \cdot S \cdot D \cdot t}{h} \qquad \text{(Eq. 1)}$$

where:

Q = amount of drug (in grams) dissolved in time, t
A = surface area occupied by the total weight of the sample
S = solubility of the drug (in grams per milliliter) in the dissolution medium
D = diffusion coefficient of the drug (in square centimeters per second)
h = thickness of diffusional layer (in centimeters)

By assuming that the diffusion coefficient, D, and the thickness of the diffusional layer, h, are constant at 9×10^{-6} cm.²/sec. and 50×10^{-4} cm., respectively, knowledge of only the surface area exposed, A, and the solubility, S, of the drug enables the dissolution rate Q/t to be calculated.

Despite the remarkable correlation between the experimental and calculated results for the dissolution rates of hydrocortisone, benzoic acid, levodopa, and griseofulvin, there appears to be a considerable argument against the use of such predicted results as a routine measure.

Hussain's Eq. 3 is in error by a density factor (ρ):

$$\text{number of particles in } W \text{ grams of powder} = \frac{W}{4/3\pi r^3 \rho} \qquad \text{(Eq. 2)}$$

assuming spherical particles:

$$V = 4/3\pi r^3 \qquad \text{(Eq. 3)}$$

Since the density for benzoic acid is 1.32 (2), the area would be overestimated without this correction by 32%, with a corresponding overestimation in the calculated dissolution rate.

Hussain also used the average particle size on an arithmetic basis, using the two extremes of the mesh fraction in his calculation of the surface area. While this may not lead to gross errors for the comparatively narrow size ranges considered by Hussain, for larger particle-size distributions a better mean size would be the volume–surface mean diameter, d_{vs} (3):

$$d_{vs} = \frac{\Sigma n d^3}{\Sigma n d^2} \qquad \text{(Eq. 4)}$$

and the surface area computed from:

$$A = \frac{W \times 6}{d_{vs}\rho} \qquad \text{(Eq. 5)}$$

Since the volume–surface mean diameter will also be larger than the arithmetic mean diameter, this will add further to the overestimation of the dissolution rate.

To explain Hussain's apparent correlation requires a compensating decrease in the value of the area used in Eq. 1. This may be due to assuming that the particles are spherical, while deviations from either spherical or cubical shape will lead to an increase in the constant value of 6 given in Eq. 5.

Due to the complexity of these compensating mechanisms, it would be rash to adopt Hussain's method for the prediction of the dissolution rate of sparingly soluble drugs without further evidence. Hussain's article dealt with particles in powder form only. However, for solid dose formulations, where it is known that the total area available may not come into contact with the dissolution medium due to failures of disintegration (4), or where the ingredients may invalidate the diffusion assumptions made by Hussain, we must be prepared to continue to determine experimentally the dissolution rate of the drug.

Cannabis sativa L. (Marijuana) II: Standardized and Reliable Microscopic Method for Detection and Identification of Marijuana

Keyphrases ☐ Marijuana—microscopic identification, differential staining with fast blue B ☐ Cannabinoid plant tissues—microscopic identification, differential staining with fast blue B ☐ Fast blue B chromogenic reagent—used to identify marijuana ☐ Chromogenic reagents, fast blue B—used to identify marijuana

Sir:

This preliminary communication describes a highly reliable and easily performed procedure for the microscopic identification of marijuana[1].

It is considered desirable for an investigator to utilize one or more chemical methods as well as the microscopic examination of suspect material to confirm the presence or absence of marijuana (1). Although several chemical test procedures have been reported for this purpose (2), detailed methods dealing specifically with the microscopic detection of marijuana have been lacking in the scientific literature.

The positive microscopic identification of marijuana in a particular sample is based on observing the presence of certain morphological structures such as the glandular hairs, cystolith hairs, and nonglandular hairs (3) which are characteristic and diagnostic for *Cannabis sativa*. However, these diagnostic criteria may be complicated by the fact that marijuana is frequently admixed prior to use with a variety of nonmarijuana plant substances including tobacco (*Nicotiana tabacum*), lavender (*Lavendula officinalis*), catnip (*Nepeta cataria*), and oregano (*Origanum vulgare*). Indeed, in many instances we have examined plant material presumed to be marijuana but which instead proved to be composed entirely or in part of catnip, oregano, or lavender. The latter three plant species, as do many other members of the Labiatae (mint family), exhibit glandular hairs which, particularly if they are crushed and fragmented, may be confused with the glandular hairs of marijuana (4). Furthermore, Nakamura (1) recently described more than 80 different plant species containing cystolith hairs similar to those found in marijuana.

The present study was undertaken to develop a microscopic method that would serve to distinguish marijuana unequivocally from various other plant species having similar morphological features. This method, outlined in stepwise fashion, is presented below:

1. Thoroughly mix a small amount of suspect material (1 mg. or less) with 2 drops of clearing solution [chloral hydrate (75 g.), propylene glycol (10 ml.), and distilled water (sufficient quantity to make 100 ml.)] on a clean microscope slide.

2. Carefully heat the slide from below, using a microburner, until the mixture boils for a total of 3 sec. Cool momentarily, add 1 additional drop of clearing solution, and heat to boiling as before. Allow the slide to cool for 1 min. before proceeding. The chloral hydrate clearing solution serves to dissolve starch and plant pigments and thus allows the diagnostic elements to be more readily observed.

3. Treat the wet mount with 2 drops of *freshly prepared* chromogenic reagent [fast blue B salt[2] (0.3 g.) and clearing solution (sufficient quantity to make 100 ml.)], mix well, cover the preparation with a glass (not plastic) coverslip, and examine the prepared mount microscopically (100–400× magnification). It has been shown that fast blue B salt couples with cannabinoid substances to yield characteristic red to purple-colored compounds (5). Accordingly, upon microscopic examination, cannabinoid-rich plant tissues will be observed to acquire a red-purple color. This phenomenon is particularly intense in the case of the marijuana glandular hairs. Furthermore, when one is dealing with a marijuana-containing sample, the entire wet mount rapidly acquires the characteristic red-purple color which is easily observed with the naked eye.

4. Finally, place 1 drop of glacial acetic acid along one edge of the coverslip, draw the acid beneath the coverslip by touching the opposite edge of the coverslip with a piece of filter paper, and observe microscopically. The presence of cystolith hairs is evidenced by the liberation of gas (carbon dioxide) bubbles from the bases of these calcium carbonate-containing hairs.

The most significant aspect of this procedure concerns the fast blue B chromogenic reagent. The use of this reagent allows the marijuana glandular hairs as well as other cannabinoid-containing elements to be differentially stained. Thus, for example, lactiferous tissue and fragments of resin both acquire the characteristic red-purple color. To assess the possibility of false-positive fast blue B reactions, we studied a large number of different noncannabis plant species, including many having glandular hairs, using the described procedure. In no case did we observe staining of the glandular hairs, although in certain instances we noted that some plant tissues or the entire wet mounts acquired diffuse pink to red-brown colors following treatment with fast blue B reagent. These colors, probably the result of the reaction of fast blue B with plant phenolic substances, were distinct and could usually be differentiated from the characteristic red-purple colors observed with the marijuana samples. Thus, under the experimental conditions described, it appears that fast blue B selectively stains cannabinoid-containing plant tissues.

On the basis of the consistently reliable results obtained from evaluating more than 300 different plant species, we have found this easily performed method to be highly reliable for confirming the presence or absence of marijuana in suspect material. The method should find wide application in the area of forensic science. Further studies utilizing this method together with TLC will be reported subsequently.

[1] The term marijuana as used herein refers to the ground stems, leaves, and flowering tops of *C. sativa*.

BOOKS

REVIEWS

Biochemical Applications of Mass Spectrometry. Edited by G. R. WALLER. Wiley, 605 Third Ave., New York, NY 10016, 1972. xiv + 872 pp. 21 × 28 cm. Price $49.95.

The editor and authors of this encyclopedic work have succeeded admirably in assembling into one volume a large amount of theoretical and practical material.

The book is divided into five parts. Part I is an introduction and historical survey. Part II covers the different types of spectrometers and contains an exhaustive section on data acquisition and processing by most of the world's principal mass spectrometric laboratories.

About 80% of the book is devoted to the interpretation of mass spectra. These parts, consisting of 28 chapters, provide both the novice and experienced investigator with a wealth of information on mass spectrometric applications to the entire range of biochemicals and compounds commonly classified as natural products. In addition, there are excellent chapters on the "Origin of Mass Spectra," how to interpret metastable ions, and field and chemical ionization mass spectrometry. Interdisciplinary areas such as those relating to drug metabolism and clinical applications are also covered.

This well-edited volume is about 60% tables and illustrations. The mass spectra are uniformly and clearly presented. Each chapter is adequately, but not excessively, referenced. A good working index is present so that subjects not discussed under a separate chapter, *e.g.*, mass fragmentometry and GC–MS systems, can be quickly found. If anything, the book suffers somewhat from covering the literature *only* through 1969, since it was that long in preparation. Attempts have been made to update, in proof, some of the newer areas like chemical ionization mass spectrometry by the citation of more recent references.

In summary, the book should be useful to investigators working in any of the areas allied with natural products and as a reference work for others using mass spectrometry as an analytical tool. Insofar as it is not out of date, it represents a how-to manual on the subject of data aquisition. As a final point, one would be remiss in not mentioning the efforts of the editor and various contributors in presenting the history and background of the entire field.

Methods and Techniques in Clinical Chemistry. By P. L WOLF, D. WILLIAMS, T. TSUDAKA, and L. ACOSTA. Wiley, 605 Third Ave., New York, NY 10016, 1972. 417 pp. 14.5 × 23 cm. Price $11.50.

This publication compiles all of the currently significant chemical tests being utilized by the Stanford Hospital Clinical Laboratory. The tests are given in alphabetical order; each test monograph includes a discussion of the principle involved, reagents and equipment, procedure, normal values, references, and clinical interpretation. Throughout the book, the authors have emphasized the practical aspects of clinical chemistry.

REVIEWS

Biochemical Applications of Mass Spectrometry. Edited by G. R. WALLER. Wiley, 605 Third Ave., New York, NY 10016, 1972. xiv + 872 pp. 21 × 28 cm. Price $49.95.

The editor and authors of this encyclopedic work have succeeded admirably in assembling into one volume a large amount of theoretical and practical material.

The book is divided into five parts. Part I is an introduction and historical survey. Part II covers the different types of spectrometers and contains an exhaustive section on data acquisition and processing by most of the world's principal mass spectrometric laboratories.

About 80% of the book is devoted to the interpretation of mass spectra. These parts, consisting of 28 chapters, provide both the novice and experienced investigator with a wealth of information on mass spectrometric applications to the entire range of biochemicals and compounds commonly classified as natural products. In addition, there are excellent chapters on the "Origin of Mass Spectra," how to interpret metastable ions, and field and chemical ionization mass spectrometry. Interdisciplinary areas such as those relating to drug metabolism and clinical applications are also covered.

This well-edited volume is about 60% tables and illustrations. The mass spectra are uniformly and clearly presented. Each chapter is adequately, but not excessively, referenced. A good working index is present so that subjects not discussed under a separate chapter, *e.g.*, mass fragmentometry and GC–MS systems, can be quickly found. If anything, the book suffers somewhat from covering the literature *only* through 1969, since it was that long in preparation. Attempts have been made to update, in proof, some of the newer areas like chemical ionization mass spectrometry by the citation of more recent references.

In summary, the book should be useful to investigators working in any of the areas allied with natural products and as a reference work for others using mass spectrometry as an analytical tool. Insofar as it is not out of date, it represents a how-to manual on the subject of data aquisition. As a final point, one would be remiss in not mentioning the efforts of the editor and various contributors in presenting the history and background of the entire field.

Heparin is a mucopolysaccharide composed of partially sulfated units of α-D-glucuronic acid and 2-amino-2-deoxy-α-D-glucose joined by 1 → 4 bonds. It is mainly noted for its anticoagulant activity in the treatment of myocardial infarction, but it is also an antilipemic agent. Heparin is thought to originate in the mast cells of connective tissue and is found in beef, hog, and dog livers; beef muscle, adipose tissue, and spleen; hog mucin and alimentary canal; skin of rats; fish plasma; sea clams; and scales of carp.

Since its discovery in 1916 by McLean, many studies have been made on its chemical structure and pharmacology, but progress has been much slower in the elucidation of the macromolecular properties of the polysaccharide, particularly the relationship of physical parameters to its biological action.

The early history, chemistry, and clinical applications of heparin were described by Jorpes (1), Whistler and Smart (2), Foster and Huggard (3), and Stacey and Barber (4). Some general accounts of the mucopolysaccharides and heparin were later written by Blonde (5), Brimacombe and Webber (6), Whistler and Rowell (7), Engelberg (8), Meyer (9), and Jeanloz (10).

Relative to physicochemical aspects of heparin, it exhibits typical polyelectrolyte behavior in aqueous

solution due to its high negative charge. Accordingly, physicochemical measurements are sensitive to ionic strength and pH. Heparin is polydispersed and molecular weights from 6000 to 20,000 have been reported. Physicochemical properties in relation to blood anticoagulation are discussed later in this review.

The purpose of this review is to furnish an up-to-date, comprehensive coverage of the many aspects of this extremely interesting and important drug. This review, although comprehensive, is not necessarily exhaustive. The literature search was carried up to May 1, 1972, and the main body of the review consists of information from the literature of the last decade.

SOURCES AND ISOLATION OF HEPARIN

Most of the heparin for pharmaceutical use is extracted from bovine lung tissue. However, the literature contains many examples of heparin or heparin-like substances isolated from other sources.

Marine life has yielded heparin-like materials with high blood anticoagulant activity. Thomas (11, 12) obtained such a substance from the common surf clam, *Spisula solidissima*, which might be chemically similar to heparin. Frommhagen *et al.* (13) extracted mactin-A and B from two species of clams, *Mactra spissula* and *Artica islandica*, which had a higher activity than heparin and a lower toxicity. Heparin was also found in the blood (14), liver (15), and muscles (15) of fish.

The skin of many animals has been claimed to be a source of heparin. Bollet *et al.* (16) located it in the human dermis and subcutaneous tissue. Horner (17), in 1971, isolated heparin with a molecular weight of over 1 million from rat skin. Injured animal skin has yielded desulfated heparin (18).

Heparin has been found in normal human serum in small amounts (19). Nilsson (20) described a method of extraction of an anticoagulant, probably heparin, from normal horse blood, which exhibited strong metachromasia. The data of Smith and Von Korff (21) indicate a heparin-precipitable complex of a fibrinogen-like protein closely combined with heparin which was found in human plasma. The origin of heparin in the blood may be the basophil cells, which are almost functionally identical with mast cells and might release small amounts of heparin into the plasma (22). On the other hand, Ringertz (23) found that heparin can be liberated from the mast cells by a number of agents that cause the disruption of these cells, but no heparin was detected in the blood.

The kidney of the rat has yielded a heparin-like substance (24). Allalouf *et al.* (25) isolated this material and discovered that it acted similarly to heparin in anticoagulant activity (8 units/mg.), protamine antagonism, and the recalcification test. The major component of the mucopolysaccharides extracted from this source was heparin (26).

Healthy human liver was shown by Schmitz-Moorman (27) to contain uronic acid mucoids consisting of approximately equal amounts of hyaluronic acid, chondroitin, chondroitin sulfate, and heparin. In cases of amyloidosis, the mucopolysaccharides of the amyloid liver were found to contain small amounts of heparin (28, 29), which was 60 times as much acidic mucopolysaccharide content as in healthy liver (30). The capsule surrounding the ox liver was shown by Serafini-Fracassini *et al.* (31) to contain heparin in single chains or as a protein–polysaccharide complex rather than as a multichain proteoglycan. The ox liver capsule also yielded a heparin–protein complex (32).

Other sources of heparin include the aorta (33–35), the loin and ham muscles of the pig (36, 37), the sweat (38), the thyroid (16), and the heart (39). Heparin-related glycosaminoglycans also were isolated from the acid-soluble fraction of Chinese hamster fibroblasts (40), from HeLa L mouse embryo, and from rat embryo cells grown in culture medium in the presence of radioactive inorganic sulfate (41).

The method of Charles and Scott (42), with modifications, is used for most extractions of heparin. In their technique the animal tissues are treated with alkali to remove proteins. Homan and Lens (43) did this removal by shaking with phenol. Jeanloz (44) reported other methods of heparin extraction involving enzymic degradation. Barlow *et al.* (45) described a technique of isolating heparin from sheep, dog, beef, and hog tissues by selective fractionation with quaternary ammonium compounds. They claimed that the heparins were biologically, chemically, and physically similar.

CHEMICAL STRUCTURE OF HEPARIN

Many reviews have sections on the nomenclature and classification of the mucopolysaccharides (46, 47) and the chemistry of heparin (3, 4, 6, 48–53).

The elucidation of the structure of heparin has been concerned with the type of glycosidic linkage, the nature of the uronic acid component, the sulfur content and sulfamino group, the carboxyl and other groups, and the amount of branching.

Cifonelli and Dorfman (54) showed that the major linkage in heparin is uronosyl 1 → 6 hexosamine, while that in heparitin sulfate is mostly 1 → 4. Durant *et al.* (55) and Danishefsky and Steiner (56), on the other hand, found a 1 → 4 linkage also for heparin. This was confirmed by Wolfrom *et al.* (57), who also found that the configuration of the 2-amino-2-deoxy-D-glucuronic acid linkage is α-D. The possibility of some β-configuration might also exist (51, 58). Lloyd and Evans (59) reported a method of linkage analysis of heparin and related mucopolysaccharides by forming *N*-(2,4-dinitrophenyl) derivatives of de-*N*-acylated mucopolysaccharides, rather than affecting the labile sulfamino groups, by breaking acid-resistant 2-amino-2-deoxyglycosidic bonds to achieve a graded depolymerization.

The sulfur content of heparin has been shown to be associated with its anticoagulant activity (60). A method of determination of sulfur as sulfate is precipitation with barium (60, 61). Another technique, proposed by Braselmann (62), permits the determination of 0–12 mcg. of sulfate, with an error of ±0.2 mcg., by heating the heparin sample with hydriodic acid, hypophosphorous acid, and hydrochloric acid to reduce sulfate to hydrogen sulfide. A rapid and sensitive method using GLC to analyze sulfate in mucopolysaccharides, including heparin, in micrograms was devised by Srini-

vasan *et al.* (63). This method was based on the ability of mineral acids to form stable salts with the mucopolysaccharides, which, after reaction with sodium hydroxide, liberate amines that are detected by GLC. Even more recently, Wessler (64) measured the sulfate content in less than a microgram of glycosaminoglycans with a method based on the fact that the electrophoretic mobility in 0.1 *M* HCl is proportional to the sulfate content. Hiyama *et al.* (65) indicated that the anticoagulant activity of heparin is, in general, dependent on the degree of sulfation and the number and position of the *O*-sulfate groups as well as the size of the skeletal polysaccharide molecule.

Durant *et al.* (55) claimed that approximately one-eighth of the hexuronic acid units have no *O*-sulfate groups. The evidence of the report by Wolfrom and Wang (66) establishes that the C-6 hydroxyl group of the 2-amino-2-deoxy-D-glucose unit of heparin is sulfated. In a later work, Wolfrom *et al.* (67) definitively placed the two sulfate groups (per tetrasaccharide unit) on C-6 of the 2-amino-2-deoxy-D-glucose residues and demonstrated that D-glucuronic acid residues are not sulfated. Danishefsky *et al.* (68) investigated the position of the sulfate groups by methylation procedures, and they concluded that about one-third of the glucuronic acid moieties in heparin are sulfated on C-2 whereas the rest are not sulfated. Additionally, most of the glucosamine is sulfated on C-6, but nonsulfated glucosamine units and 3,6-di-*O*-sulfoglucosamine units are also present in small proportions. Helbert and Marini (69), on the basis of elemental analysis and titration studies, found that not all of the sulfate forms an integral part of the heparin molecule but it may be closely associated with it.

The extent of carboxylation may be important in the anticoagulant activity of heparin, as reported by Stivala and Liberti (70) based on copper binding studies. It is possible to convert the carboxyl groups of heparin and other mucopolysaccharides into substitution acids of amino acids (71). These were obtained with glycine methyl ester, phenylalanine methyl ester, and alanine amide.

Heparin is usually considered to be an extended linear molecule. Some authors, however, such as Freeman (72) and Bettleheim (51), still believe in the possibility of a branched structure.

The question of whether heparin contains acetyl groups is still unsettled. Rhadhakrishnamurthy *et al.* (73) found varying amounts of acetyl groups in heparin samples from various sources. The presence of these groups might be due to the presence of heparitin sulfate, as shown by NMR studies (74).

It was concluded by chemical means that D-glucuronic acid is the chief uronic acid component of heparin (75, 76). Wolfrom *et al.* (77) isolated L-iduronic from heparin by a periodate oxidation study. Perlin *et al.* (78–80) showed with NMR spectra that heparin contains a substantial proportion (perhaps one-third or more) of L-idopyranosyluronic residues, in addition to the D-glucosyluronic acid and 2-amino-2-deoxy-D-glucose units. Lindahl and Axelsson (81), through a nitrous oxide degradation of heparin and separation by gel permeation and paper electrophoresis, found that almost all of the uronic acid present in certain fractions was iduronic acid. Rhadhakrishnamurthy *et al.* (82) investigated the nature of the uronic acid by the use of GLC and found that the ratio of iduronic acid to glucuronic acid was 1:2.6.

Through degradation studies with *Flavobacterium heparinum* (83), it was concluded that the heparin molecule is composed largely of a repeating sequence of (1 → 4)-linked 4-*O*-(α-L-idopyranosyluronic acid 2-sulfate)-2-(deoxy-2-sulfamino-α-D-glucopyranosyl-6-sulfate) biose residues. Another proposed structure is that of the tetrasaccharide unit of Helting and Lindahl (58) with both uronic and iduronic residues (Structure I).

A reaction thought by Sampson and Meyer (84) to be important in structural studies is that of heparin or heparitin sulfate with alkali to form 3,6-anhydroglucosamine groups, in which the 6-position is sulfated and the 3-position is unsubstituted.

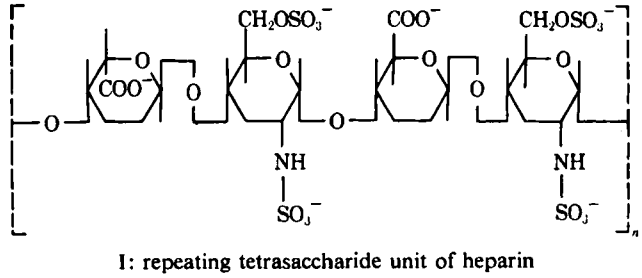
It is evident from the numerous studies conducted on the structure determination of heparin that its true configuration remains to be established unequivocally. The defiance of heparin to be clearly identified may be due to the fact that the heparin derived from different tissues within a given species or from the same tissues from different species may have subtle differences in its structure. Accordingly, it is not surprising that differences in chemical structures have been observed, since heparin is a protein–polysaccharide complex before extraction. The extraction procedure can often leave some undiscernible impurities, which undoubtedly compounds the difficulty in structure determination.

ELECTROPHORESIS AND CHROMATOGRAPHY OF HEPARIN

The techniques of electrophoresis and chromatography of heparin and other acid mucopolysaccharides for separation, identification, fractionation, characterization, and binding studies have been investigated by many workers.

Separation Techniques—One of the oldest separation methods used was electrophoresis. In 1951, Favre-Gilly (85), using the moving boundary method, discovered that the electrophoretic mobility of heparin is 17 × 10^{-5} cm.^{2} v.$^{-1}$ sec.$^{-1}$. Also using the same technique and employing data available on the heparin–streptomycin complex, Barlow and Coen (86) separated heparin free from streptomycin.

Paper and gel electrophoresis have now gained much popularity in separation methods. Bifani and Marcialis (87) discovered that heparin had a higher migration velocity than serum proteins on paper. Conti *et al.* (88) detected heparin in the presence of chondroitin sulfuric



I: repeating tetrasaccharide unit of heparin

acid, hyaluronic acid, or nucleic acid by staining the paper with Auramino O, Malachite green, or Brilliant green. Starch gel electrophoresis has been carried out for the separation of heparitin sulfate from chondroitin sulfate A and B and hyaluronic acid (89). Another sensitive method is zone electrophoresis on cellulose acetate, with alcian blue as a stain (90).

Horner (91) separated heparin and chondroitin sulfate by their differences in charge density on agarose gel. He also noted that heparin had two components on this gel; the slower moving component had the higher anticoagulant activity, whereas the faster moving component had the higher sulfate–carboxyl ratio (92). Jaques *et al.* (93, 94) found that most heparins showed two components by microelectrophoresis on agarose, except for those from the sheep and rat. The use of a microzone cellulose acetate cell[1] enabled Herd (95) to separate heparin; hyaluronic acid; chondroitin sulfates A, B, and C; and keratosulfate. Heparin and heparan sulfate can be separated from other glycosaminoglycans with barium acetate electrophoresis, where the electrophoretic mobility depends primarily on the polysaccharide backbone (96). The relative mobilities of heparin, chondroitin sulfate A (or C), and hyaluronic acid in electrophoresis by polyacrylamide gels were 1.11:1.00:0.67 (97), which are the same as in free solution electrophoresis (98). Another type of electrophoretic separation was performed by Mashburn and Hoffman (99), who used a continuous-flow electrophoretic flow separator for the separation of heparin, chondroitin sulfate, hyaluronic acid, and protein.

Liquid and ion-exchange chromatography are rather old techniques but recently gained new impetus for separations. In 1962, Schmidt (100) obtained a clear separation of the acid mucopolysaccharides on a DEAE-Sephadex anion exchanger. Using the same type of column, Braselmann and Ramm (101) did a microseparation of hyaluronic acid, chondroitin-4-sulfate, dermatan sulfate, chondroitin-6-sulfate, and heparin. In a column chromatographic study, Greiling *et al.* (102) and Egardo *et al.* (103) separated heparin from hyaluronic acid and chondroitin sulfate, utilizing ECTEOLA-cellulose with gradient elution. This type of column was also used for the quantitative estimation of acid mucopolysaccharides in vascular tissue (104). A cellulose microcolumn technique to separate mucopolysaccharides was described by Svejcar and Robertson (105). Microcolumns of Sephadex G-25 (fine) were used to carry out the separation of heparin from D-galactose by Stouffer *et al.* (106), with a hydrogen flame-ionization detector. Another interesting application of this method was the differential precipitation of individual polyanions with quaternary ammonium salts in solutions of specific ionic strength and the subsequent formation of red ion association complexes with the bound quaternary moieties; thus the individual mucopolysaccharides could be identified (107).

Two other major techniques are paper chromatography and TLC. Spolter and Marx (108) separated heparin and chondroitin sulfate by paper chromatography with a solvent of buffer and isopropanol. Bayer (109) used a solvent system containing *n*-propanol. An ascending paper chromatography method with acetate buffer allowed Good (110) to separate heparitin sulfate, heparin, keratosulfate, and chondroitin sulfate B. Aliev and Alekperov (111) used ascending paper chromatography for stepwise control of heparin production. They (112) also reported that commercial heparin gave two spots which might be due to chondroitin sulfate as an impurity. Chondroitin sulfate B (dermatan sulfate) has been identified as a contaminant of bovine heparin during fractionation due to solubility differences of the two substances (see *Physicochemical Studies*). Other methods included microseparation on paper based on the formation of insoluble complexes with cetylpyridinium chloride (113) and the use of salt-gradient ion-exchange paper (114).

In the last few years, TLC has gained support in the separation of mucopolysaccharides. Wustemann *et al.* (115) successfully separated heparin from heparitin sulfate, chondroitin-6-sulfate, and chondroitin-4-sulfate on silica gel, with nitrous indole as a spray specific for detection of the *N*-sulfated aminopolysaccharides. Bischel *et al.* (116) used Sephadex and cellulose as layers, with toluidine blue staining. Other investigators (117) obtained two spots for heparin on cellulose, using ninhydrin as a detection agent.

Fractionation—Chromatography and gel permeation are potent methods for fractionating according to molecular weights and for estimating heterogeneity. In 1958, Payza (118) fractionated heparin on Amberlite IR-45 resin by elution with different molarities of sodium chloride. An ECTEOLA-anion exchanger was later used by Whiteley (119). Laurent (120), after precipitating heparin with cetylpyridinium chloride, used the same system to obtain four fractions. Lasker and Stivala (121) likewise obtained the same number of fractions by ECTEOLA elution, but got 12 fractions by differential solubility in alcohol–water mixtures. (Nine fractions have been obtained by fractional precipitation, using ethanol and dioxane as precipitants; see *Physicochemical Studies*.) The efficiency of DEAE-cellulose as an adsorbent in fractionation was proven by Cleland *et al.* (122), and recently DiFerrante and Popenloe (123) fractionated heparin on Dowex-1.

Further work on fractionation was carried out by Hall *et al.* (124), who submitted pork heparin to gel filtration on a column of Sephadex and found that the heparin was polydispersed with respect to molecular size. Constantopoulos *et al.* (125) and Mathews and Decker (97) determined the degree of heterogeneity of a mixture of acid mucopolysaccharides of different molecular sizes by means of gel filtration.

Characterization—Since exclusion by the gel particles depends on molecular shape, the study of the behavior of heparin on a Sephadex column with changes in the ionic strength of the eluant gave indication that the heparin molecules change in shape and size as well as in solvation, since they are retarded on the column with solvents of higher ionic strength (126).

The work of Hall *et al.* (124) suggests that the anticoagulant activity of a sample could be relatively homogeneous even though it is polydisperse in size. Ferrari and Boffi (127), on the other hand, claimed that

[1] Beckman model R-100.

it was impossible to correlate anticoagulant activity with chromatographic behavior since all samples gave lengthened spots, similar in shape and with the same R_f.

Hilborn and Anastassiadis (128) recently demonstrated how acrylamide gel electrophoresis could be used to: (*a*) estimate the molecular weight of many acidic mucopolysaccharides (including heparin) and (*b*) measure the variations that may exist in their molecular weights and/or the degree of sulfation.

Binding Studies—Boundary electrophoretic studies were conducted by Barlow (129) on the binding of heparin with histamine, using paper electrophoresis. The finding of two different electrophoretic patterns as a function of anticoagulant activity indicates that there is a difference among samples as to their ability to bind histamine; this result could be due to a difference in anticoagulant activity.

Another study of binding was conducted by Accary *et al.* (130) on polysaccharide–sulfate–protein complexes, using paper electrophoresis.

PHYSICOCHEMICAL STUDIES

Deactivation of Heparin and Structure Determination—It has been suggested that anticoagulant activity of heparin is related to sulfation (6, 131–134), to carboxylation (6, 131–134), and to various physical parameters such as molecular weight, shape, and size (6, 131–135). These have been studied by mild hydrolysis of heparin, which results in desulfation (without chain cleavage) accompanied by a decrease in biological activity (deactivation).

Wolfrom and McNeely (136), in 1945, discovered that very mild acidity causes the heparin molecule to lose its blood anticoagulant activity. The rate of loss of activity is proportional to the rate of appearance of a free amino group in the molecule, and substantially complete inactivation occurs when somewhat more than one-half of the nitrogen is released as free amino nitrogen. Jensen *et al.* (135) reported that reaction of heparin with warm acetic acid resulted in a strong decrease in anticoagulant activity without any decrease in molecular weight, sulfate ester, or glucosamine content. There was also an increase in the sedimentation constant and the degree of polydispersity but a decrease in the frictional ratio. They suggested that the amino nitrogen that was first freed during recrystallization of heparin after acid treatment played an important role in anticoagulant activity. The findings of Gauthier *et al.* (137) showed that if the pH was adjusted with acid to 1 or 2 at 25°, there was no change in the biological activity of the heparin within the first 24 hr. Substantiating this finding is the evidence presented by Stock and Warner (138), who observed deterioration of heparin only after 60 hr. at pH 4.4 and 23°. Swarte and Huizinga (139) showed that heparin solutions can be sterilized by steam at 100° for 1 hr. at pH 7.0 with no changes in anticoagulant activity. On the other hand, it is possible to degrade heparin in a strong alkali medium with a rapid loss of antilipemic activity (140).

Foster *et al.* (141) maintained that the anticoagulant activity does not necessarily follow the content of sulfamino groups, since they observed that some heparin preparations with high *N*-sulfate content exhibited low anticoagulant power. In most cases, however, the anticoagulant properties of the sulfated polysaccharides containing no sulfamino groups amounted to only a fraction of that of heparin itself.

Ricketts (142, 143) concluded that the molecular weight of the polysaccharide was more important than the sulfate content, since little activity was found in low molecular weight species of polysaccharides (degree of polymerization = 9) even when the sulfate content was high (2–2.8 sulfate groups per glucose residue). Sulfated dextrans showed a higher anticoagulant activity for the polymer possessing the higher molecular weight. Patat and Elias (144) likewise found that there is a definite dependence of the biological activity of heparin on molecular weight. Laurent (120) claimed a correlation between biological activity and molecular weight in heparin fractions from a single source. Barlow *et al.* (145) and Braswell (146) did not find this relationship; however, their studies were based on unfractionated heparin from various sources. Lasker and Stivala (121) reported that the biological activities of low molecular weight fractions (performed by differential solubility) were uniformly low. Liberti and Stivala (147) discovered that the anticoagulant activity of heparin with molecular weights of 4500–15,500 (fractionation done by precipitation with ethanol and dioxane) increased with molecular weight up to 10,000 but then showed no appreciable change in activity on further increases of molecular weight.

Lasker and Stivala (121) demonstrated that the samples obtained by deactivation of unfractionated heparin with dilute hydrochloric acid showed no detectable changes in molecular weight, intrinsic viscosity, IR spectra, or optical activity. They also found that partially inactivated heparin behaves like active heparin in that there is a drop of activity in an environment of 0.5–1.0 *M* NaCl (148).

The treatment of α-heparin (bovine) and ω-heparin with 40% acetic acid at 37° for almost 1 day, by Yosizawa *et al.* (149), almost completely deprived these heparins of anticoagulant properties, with a loss of 7–8% of *N*-sulfate groups. These results indicate that the anticoagulant activity of α-heparin is more labile and its lipolytic activity less labile than those of ω-heparin. Braswell (146) also degraded heparin with acid, but only until one-half of the activity was removed. There was little change in molecular weight, intrinsic viscosity, or elemental analysis. He postulated that these results are due to the formation of internal esters because acidity is destroyed without losing sulfur.

Opposed to these latter results are the findings of Helbert and Marini (150) who used self-hydrolysis and titration techniques. They found that *N*-sulfate groups were removed twice as fast as *O*-sulfate groups, but they did not perform elemental analyses or anticoagulant assays throughout the course of degradation; therefore, it is difficult to compare their work with that of others.

Stivala *et al.* (133), following the method of Helbert and Marini (150), did a graded hydrolysis on unfractionated heparin and measured the sedimentation co-

efficient, intrinsic viscosity, molecular weight, and axial ratio as functions of hydrolysis time. The data suggest that: (*a*) the decrease in molecular weight is due to desulfation rather than depolymerization, (*b*) hydrolysis results in both *N*- and *O*-desulfation, but the former is greater, and (*c*) the degree of sulfation and size and/or shape are responsible for the biological activity of heparin.

Yuan (151), in a study with Ehrlich (152) on the self-hydrolysis of a heparin fraction, found that the decrease in the anticoagulant activity of the partially hydrolyzed heparin corresponds to the amount of sulfate groups removed. There is also a decrease in the intrinsic viscosity in water, molecular weight, and the axial ratio. Yadlowsky (152A) and Stivala *et al.* (152B) studied the kinetics of the acid hydrolysis of heparin from its Cu (II) complex. They showed that hydrolysis during 5 hr. at various temperatures obeys first-order kinetics, and they obtained specific rate constants of 3.3–26.6 $\times$ 10^{-5} sec.$^{-1}$ in the range of 50–80°. Arrhenius plots of the data yielded 14.7 kcal. as the energy of activation. Yuan (151) also obtained similar results on the self-hydrolysis of heparin. These investigators found that the anticoagulant activities of heparin and the Cu (II) complex were not appreciably different and that the deactivation parallels Cu (II) release from the complex, which in turn parallels desulfation.

Optical rotatory dispersion, NMR, and gel permeation also were utilized to follow deactivation. Stone (153) demonstrated that the induced Cotton effects of the dye diminished in a graded hydrolysis. Changes in conformation were also followed through optical rotatory dispersion by Hirano and Onodera (154). They concluded that *N*-desulfation does not change the original conformation, but complete desulfation causes the original helical conformation of the heparin–dye complex to disappear. Findings by Sumyk and Yocum (155) on elution volumes were consistent in the conformation difference between native and desulfated heparin. Using NMR, Jaques *et al.* (156) found that *N*-desulfation causes a downfield displacement of the signal at 4.75 p.p.m.

The degradation of heparin by UV light and fast electrons was studied by Balazs *et al.* (157) and Sundblad and Balazs (158). Irradiation with UV light gave a decrease in anticoagulant activity and cationic dye binding power of the polyanion. Irradiation with electrons causes depolymerization. The use of γ-irradiation on dilute solutions of heparin by Jooyandeh *et al.* (159) produced depolymerization but no desulfation.

Interaction of Heparin with Dyes, and Optical Rotatory Dispersion—When dyes such as azure A, methylene blue, basic fuchsin, Brilliant green, and other metachromatic dyes are reacted with heparin, there is an absorption at a wavelength that is shorter than with the dye itself. Stone and Bradley (160), in 1967, showed that spectrophotometric titration of mucopolysaccharides with dyes was possible and, because of its high charge density, heparin would best be titrated with proflavine. A review was presented by Stone (161) on the use of metachromasy to induce Cotton effects in glycosaminoglycans.

According to Yen *et al.* (162), two dye molecules react with each tetrasaccharide unit, and apparently the reaction occurs preferentially between two carboxylic or sulfamino groups. Young *et al.* (163), in agreement with the latter investigators, believed that there is an electrostatic interaction between the dye and polyanion sites. Thermodynamic studies on heparin–azure A complexes indicated that the complexation produces a loss of energetic symmetry in the chromaphoric system, resulting in a shift to a lower wavelength. Various other methods, such as electron paramagnetic resonance (164) and pulse radiolysis (165–167), were used by Balazs *et al.* to examine the electrostatic interactions between methylene blue and heparin. Through this latter method, Phillips (168) unequivocally showed that cationic dyes are bound at anion sites of polyanions in such a way that an electronic exchange occurs, which is directed to the metachromasy.

The effect of temperature on polyanion metachromasy was studied by Kelly *et al.* (169). The metachromatic ratios, A_{575}/A_{628}, were found to be inverse linear effects of temperature. Stained sections gave the same results (170).

Dyes have been employed in the identification of heparin. In tissue, the staining with ruthenium red was found by Pihl (171) to be stoichiometric and the bulk of the stain was taken up by heparin in a molar relationship of one dye cationic complex per sulfate group of heparin. Sasai (172), after staining tissues containing acid mucopolysaccharides with alcian blue, discovered that the binding of the dye to mucopolysaccharide decreased as the salt concentration was raised.

The study of the optical rotatory dispersion of heparin has been possible after binding with dyes. Stone (173), in 1969, presented an excellent review on conformations of hexose polysaccharides in solution, dealing with optical rotatory dispersion. In contrast to the views of the previous investigators mentioned, Stone (153) believed in a theoretical card-stack aggregation of dye molecules, with a helical conformation for the heparin–dye complex, since an induced rotation was observed showing anomalous dispersion in the absorption band of the bound dye. Furthermore, the Cotton effect was dependent on helical conformation, since no induced rotation was observed when the dyes were bound to polyglutamic acid in its random coil conformation. This helical structure agrees with that proposed by Velluz (174) for heparin itself. The phenomenon of induced rotation was investigated by Stone and Moss (175), as a function of pH, in the range of ionization of the carboxyl group of heparin, with the result that metachromasy decreased with a decrease in anionic site density. Further investigations by Stone (176) on dye binding indicated that the binding of methylene blue to the negative sites of heparin gives rise to a negative doublet (circular dichroism) in the metachromatic absorption band, indicating a net left-hand chirality for the neighboring dye molecules.

The effect of urea in the destruction of hydrogen bonds that serve to maintain the conformation of the mucopolysaccharides was found (154, 177) to increase slightly the optical rotation of those mucopolysaccharides possessing helical structure. Also, the induced

Cotton effect was lost in urea and a positive plain curve was obtained. A later study by Hirano (178) showed, by optical rotation measured in urea and guanidine hydrochloride, that the tertiary structure of polysaccharide chains is almost destroyed while the tertiary structure remains in water.

Other optical rotatory measurements by Stone (153, 179) on the interaction of histamine and heparin with dye-stacking techniques indicate that there is a decrease in the metachromasy of dye–heparin complexes on the addition of histamine; also, conformational changes in heparin may accompany the release of histamine, which causes anaphylactic shock concomitant with degranulation of the mast cell *in vivo*.

A method of using the optical dispersion effects of mucopolysaccharides was presented by Stone *et al.* (180) for distinguishing between San Filippo and Hurler syndromes, since the UV optical rotatory dispersion and circular dichroism of dermatan sulfate are greatly different from those of heparin sulfate because dermatan sulfate is present only in Hurler's syndromes.

Binding and Complexing of Heparin—Since heparin is a highly charged polysaccharide, binding and complexing with both large and small ions and molecules become possible. It is thought by many to exist in nature bound to proteins as a protein–polysaccharide complex in the mast cells and released when necessary. Also, its anticoagulant and clearing action may be due to binding or complexation.

The binding of heparin to various proteins has been studied by many investigators. Recent reviews were written by Louisot (181) and Meyer (182). Cifonelli *et al.* (183) discovered that concanavalin-A, a globulin protein of Jack-bean meal, combines with heparin to form a precipitate. More recently, DiFerrante and Hrgovcic (184) claimed no interaction between the two, but thought that the presence of other proteins could be responsible for the interaction. However, Doyle and Kan (185) maintained that there is a precipitin-like complex with heparin, but that the interaction is pH, salt, and sugar sensitive.

The binding of heparin to collagen was found to occur in definite proportions by Delaunay and Bazin (186), and an ionic linkage was suspected because of the pH dependence. They (187) also found that other substances, which were unable to form stable combinations with collagen A, had the power to affect the normal combination of collagen–mucopolysaccharide linkage, depending on their acidity. Curves obtained by Serafini-Fracassini (188) of the amount of polyion fixed *versus* pH of heparin and chondroitin sulfate were similar to titration curves of collagen. Németh-Csóka (189) found that the activation energy of collagen at pH 7.35 was increased by heparin. Mathews and Decker (190) showed that heparin increased the rate of fibril formation from collagen solutions. They believed that this is due to electrostatic binding of heparin to collagen.

Kudryashov *et al.* (191, 192) found that complexes of heparin with the blood proteins such as fibrinogen, thrombin, and plasmin had antithrombotic and fibrinolytic activity. The existence of a complex between fibrinogen and heparin was confirmed by Bernfeld (193) with the aid of moving boundary electrophoresis. The mixing of radiolabeled heparin and normal serum was shown by Becker *et al.* (194) to give complexes of heparin in two major electrophoretic regions in starch zone electrophoresis. Lages (195) and Lages and Stivala (195A) quantitatively studied the binding of heparin to fibrinogen in the presence and absence of Cu ions, using equilibrium dialysis and sedimentation velocity. They found that the sedimentation coefficient of the fibrinogen–heparin complex is affected by the Cu ions.

The binding of heparin to other proteins also includes insulin, vasopressin, oxytocin, and corticotropin (196). A heparin–trypsin complex had fibrinolytic activity and showed prophylactic effects against development of thrombosis (197). Aborg and Uvnäs (198) described a protamine–heparin complex which has the ability to bind histamine and monoamines electrostatically. In addition, whale heparin can bind protamine sulfate (199).

The nature of the linkage of heparin to protein has been the subject of much investigation. The findings of Lindahl and coworkers (200–205) indicate that galactose and xylose are both involved in the linkage of heparin to protein. A glycosidic linkage between xylose and the hydroxyl group of serine appears to constitute the carbohydrate–protein linkage. The proposed sequence, given by Helting and Lindahl (58), is shown in Scheme I. Stern *et al.* (206) discovered that dermatan sulfate is similarly bound to proteins. Opposed to this view is that of Scott (207, 208), André *et al.* (209), and Aborg and Uvnäs (198), who believed in an electrostatic linkage.

The binding of neutral pH sulfated polysaccharide to serum low density lipoproteins was observed by Burstein *et al.* (210). Srinivasan *et al.* (211) showed that serum pre-β- and β-lipoproteins formed insoluble complexes with acid mucopolysaccharides in the presence of Ca^{+2}. A mechanism of formation of a complex through Ca^{+2}, acting as a bridge between *N*-sulfate groups of heparin and phosphate groups of the phospholipids of the lipoproteins, was suggested. Similarly, Olivecrona *et al.* (212) presented evidence for an ionic binding of milk lipoprotein lipase to heparin.

The binding of histamine to heparin will be considered in conjunction with the mast cells because heparin may be the histamine binding agent in these cells. The granules of mast cells are known to contain both heparin and histamine (213), and strong evidence has been presented that mast cells produce the heparin. A complex between heparin and histamine was discovered by Werle and Amann (214), which was suggested to be present in the mast cells. Lysis of granules of the mast cells by Hill (215) caused destruction of the protein component and released heparin. The mechanism of binding suggested by Kobayashi (216) was the same type as an ion exchanger. Lagunoff (217) presented evidence that the mast cell granule is a heparin–protein matrix to which histamine and perhaps other nitrogenous bases are attached electrostatically. The findings of Lloyd *et al.* (218, 219) indicate the natural occurrence of mast granule heparin linked to protein *via* alkali-labile covalent bonds. The pH dependence of the binding mechanism of the granules led Aborg and colleagues (220, 221) to suggest that the

histamine is bound ionically, which is easily broken on exposure of the granules to other cations. A study of the heparin–protein complex from ox liver capsule by Serafini-Fracassini *et al.* (222) led to the observation that the mast granules are composed of a random network of elongated heparin–protein macromolecules surrounded by the other components.

The exact correlation between heparin content and mast cell count is not a simple one, according to Jaques and Debnath (223). Also, Drucker-Colin (224) suggested that large amounts of heparin present in the rat intestine are not associated with mast cells. In a study of mast cells in mastocytosis by Zimmer *et al.* (225), it was discovered that heparin, unlike histamine, is only rarely released into the circulation in clinically significant amounts. Experiments by Slorach (226) revealed that both histamine and heparin are released when rat mast cells are exposed to the histamine releasing agent, Compound 48/80. As in the case of mast cells, histamine was shown by Aborg and Uvnäs (227) to be bound to carboxyl groups in a heparin–protein complex in rat thrombocyte granules. The binding of histamine to heparin was used by Barlow (228) to follow desulfation of heparin.

It is possible for heparin to bind with many other organic compounds. Woodside *et al.* (229) interacted heparin with glycogen to form insoluble complexes. Organic dyes such as azure A, toluidine blue, Bismarck brown, and brilliant cresyl blue combine with heparin (230). Acridine orange forms a reversible complex with heparin (231), and alcian blue is fixed to the available binding sites of heparin (232). Heparin combines with many enzymes such as trypsin, chymotrypsin, pepsin, and lysozyme (230). The reaction with lysozyme, according to Bychkov and Kharlamova (233), involves primarily electrovalent forces. Bergman *et al.* (234) mentioned that enzyme–heparin complexes can cause artificial enzyme polymorphism, which can be used both as a diagnostic tool in clinical medicine and in the study of genetic polymorphism. Heparin combines with histones and displaces deoxyribonucleic acid from a bond in deoxyribonucleoprotein (235). It forms complexes with polymyxin B (236), streptomycin (145, 236, 237), monomycin (237), kanamycin (237), and neomycin (237). Popova (238) demonstrated that the binding of chlorpromazine to heparin replaced the storage receptor in the molecule of the acid mucopolysaccharide and released the biogenic amines. In a study of the binding of histamine, carbaminoylcholine, and 5-hydroxytryptamine to heparin, Mordelet-Dambrine *et al.* (239) observed that only histamine was fixed at pH 4, probably because it is most strongly ionized. Evidence was given by Kudryashov and Lyapina (240, 241) that a heparin–adrenalin complex exists which has a possible role in blood coagulation. The complex dissolved nonstabilized clots of fibrin, exhibited antipolymerase activity, and blocked the fibrin-stabilizing activity of factor XIII.

Heparin was shown by Ascoli and Botré (242) to have a high binding capacity for Na^+ and Ca^{+2} ions. Both Jaques (230) and Salminen and Luomanmaki (243) agreed that potassium ion is bound to heparin in preference to the sodium ion. The order of increasing cation activity for heparin was given by Dunstone (244) as Na^+, K^+, Mg^{+2}, Ca^{+2}, Sr^{+2}, and Ba^{+2}. Ohkuma and Furuhata (245) felt that Na^+ ions, in addition to toluidine and albumin, form a complex with heparin, with the suggestion that heparin possesses a cation-exchange behavior. In an investigation of heparin's polyanion affinity to $^{22}Na^+$ and $^{137}Cs^+$, Dorabialska and Plonka (246) discovered that the affinity was greater to the one with the lower total concentration.

The binding of $Co(NH_3)_6^{+3}$ to connective tissue mucopolysaccharides and heparin was investigated by Mathews (247), who concluded that ion-pair formation with $Co(NH_3)_6^{+3}$ is influenced by local binding factors, electrostatic interaction of neighboring charged groups, and competition with other cations for binding sites. Anticoagulant activity was generally associated with affinity for $Co(NH_3)_6^{+3}$. This was also experienced by Moore *et al.* (248) in the interaction of connective tissue and other polyanions with cationic counterions. The binding of Cu^{+2} to heparin forms a basis for studying the anticoagulant activity of heparin (134). It is pH dependent because of competition for sites and is ionic strength dependent because of a change in conformation. In desulfation, reduction in binding sites results in decreased binding of Cu^{+2}. In the work (134) on the Cu^{+2} binding from polarography, it was also shown that the ability of heparin to bind copper is related to blood anticoagulant activity.

The order of calcium binding to hyaluronic acid, chondroitin sulfate, heparin, and heparitin sulfate was examined by Lászlo (249) with the result that chondroitin sulfate had the highest and hyaluronic acid the lowest binding capacity. It was found that most of the Ca^{+2} was bound to the carboxyl groups. The effect of Ca^{+2} ions on the scattering of light by heparin was investigated by Loucas *et al.* (250) who found that the interaction constant was influenced by the ionic strength of the solution.

A study by Quintarelli *et al.* (251) showed that binding between phosphotungstic acid and desulfated heparin only took place between the metal and the desulfated hexosamine amino groups through electrostatic forces. On acetylation of the *N*-desulfated products, no phosphotungstic binding occurred.

Effect of Ionic Strength and pH—An attempt was made by Barlow *et al.* (145) to study the effect of ionic strength on the sedimentation constant and molecular weight, but no previous fractionation was performed on these samples of heparins of different sources. Their results indicated that there is a probable increase of the sedimentation constant with ionic strength until a maximum is reached and then it remains constant. However, they did not use an extrapolated value for the sedimentation constant to allow for concentration dependence. They also found that the molecular weights obtained from light scattering did not change with ionic strength.

Liberti and Stivala (147) found that there is a definite decrease of intrinsic viscosity with an increase of ionic strength. This same effect was experienced by Braswell (146). Yuan (151) also obtained similar results with unfractionated heparin from one source, but the influence of pH was not studied under controlled conditions.

Ehrlich (152) used controlled conditions of pH and ionic strength on a particular fraction and had results for the sedimentation constant that were similar to Barlow's *et al.* (145). Also the axial ratio decreased, the intrinsic viscosity decreased, the molecular weight did not change, and the partial specific volume increased between the ionic strength of 0.5 and 1.0 *M*. This behavior can be explained in that the addition of by-ions results in a lower field strength, with a resulting change in shape offering less frictional resistance to transport.

Size and Shape of Heparin—Stivala *et al.* (252) studied molecular weights, radii of gyration, and persistence lengths of a fractionated sample of heparin by means of low angle X-ray scattering. The molecular weight of the heparin fraction was found to be 12,900. This value is in excellent agreement with the values of 12,600 and 12,500 obtained for the same fraction from sedimentation equilibrium (121) and intrinsic viscosity (147) measurements, respectively. A persistence length of 21.1 Å was calculated. Based on low angle X-ray scattering, the heparin fraction in water (1%) at room temperature may be described as a Gaussian coil molecule.

Since heparin is a polyelectrolyte, plots of specific viscosity *versus* concentration in water are nonlinear. Linearity may be achieved by use of various empirical relationships. Some researchers (121, 133, 147) measured the intrinsic viscosity of numerous heparin fractions of varying molecular weights in water and as a function of pH and ionic strength. Based on various solution theories of linear polymers, heparin exhibits substantial flexibility, approximating a Gaussian coil. From partial specific volume, sedimentation coefficient, molecular weight, and intrinsic viscosity measurements, where charges were swamped (by means of pH and/or ionic strength), Ehrlich (152) and Ehrlich and Stivala (252A) reported that heparin is best approximated as a random coil (Gaussian).

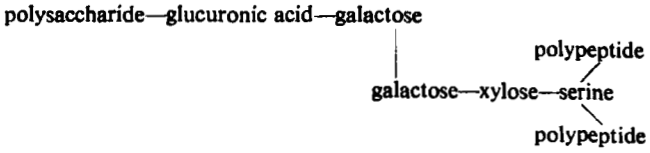
Yuan and Stivala (252B) studied the intrinsic viscosity as a function of dielectric constant and found that the shielded intrinsic viscosity (which is that of a highly shielded polyion) increases linearly with the increasing dielectric constant of the solvent. Furthermore, based on an interaction parameter of a semiempirical relationship containing the shielded intrinsic viscosity, Yuan and Stivala (252B) showed that the interaction parameter is independent of the dielectric constant of the solvent of the various heparin solutions. The significance of this interaction parameter is that it contains a term associated with the equivalent freely jointed segment length when the backbone of a polyion is represented by a Gaussian coil for which the interaction parameter is independent of the dielectric constant.

ASSAY AND ESTIMATION OF HEPARIN

The various methods of heparin determination can be essentially divided into two groups, those involving the reaction of heparin with substances such as protamine or toluidine blue and those measuring directly the specific anticoagulant activity with respect to total blood or plasma.

Metachromatic and Protamine Methods—A recent review of metachromasy of dyes in solution was presented by Padday (253). Awe and Stüdeman (254) found that quantitative measurement of the course of protamine titration and metachromatic dye change from blue to red-violet conformed with USP XV standards, but heparinoids gave erroneous results. They presented two methods for the spectrometric evaluation of the toluidine blue complex of heparin, both involving the metachromatic shift of the complex. The use of azure A and toluidine blue O (tolonium chloride) by Serafin (255), to test activity, gave much larger amounts of heparin in normal blood than previously reported. The ratio between metachromasy and uronic acid content was measured by Bianchini and Osima (256), who found that neither the anticoagulant activity nor the clearing activity is linear with the uronic acid content. According to Jaques *et al.* (257), there is no correlation between activity and chemical analysis except for the finding that increasing metachromatic activity accompanied an increase in sulfur content. A sensitive, accurate, quantitative, colorimetric assay[2] with azure A, with absorption at 505 nm., was presented by Jaques and Wollin (258). A new method for fractionation and determination of heparin by differential colorimetry of metachromatic substances formed by toluidine blue was devised by Satake (259). A method utilizing very small amounts (0.5–5 mcg.) of acidic polysaccharides, employing the shift in the visible absorption spectrum of carbocyanine dye when bound to a polyanion, was given by Edstrom (260). Two colorimetric methods were described by Plekhan *et al.* (261). They involved the: (*a*) reaction of heparin and azure A, and (*b*) reaction with carbazole and concentrated sulfuric acid. A procedure for studying stoichiometry of complexes like heparin and toluidine blue was presented by Singh (262). Qualitative limits of the sensitivity of toluidine blue and azure A as compared with alcian blue and mucicarmine were established by Rahman *et al.* (263). The carbazole method is used widely for determining heparin concentrations. Galambas (264, 265) pointed out that the ratio between maximum absorptivity in sulfuric acid and the carbazole color at 525 nm. is higher for heparin than for the other mucopolysaccharides, probably because of the lack of *N*-acetyl groups in the former. Tsuji *et al.* (266) presented a novel spectrophotometric method for the microdetermination of 2-deoxy-2-sulfamidohexose and 2-acetamido-2-deoxyhexose residues in heparin, using an ion complex which absorbs at 653 nm.

For the determination of tissue heparin, Freeman *et al.* (267) mentioned a method of releasing the heparin from the protein complex that facilitates proteolytic digestion, since proteins interfere with metachromasy of applied dyes (268). The possibility of using acridine



Scheme I—Linkage of heparin to protein

[2] Using a Beckman spectrophotometer.

orange fluorescence for the determination of heparin was explored by Zelenin and Stepanova (269), who found that it had a red fluorescence to pH 7.0 and was resistant to sodium chloride solutions. Zugibe (270) gave many histochemical methods, one of which involves formation of the insoluble polyanion–quaternary salt complex with the mucopolysaccharide, followed by treatment with ferric thiocyanate. Other methods precipitate the acid polysaccharide with dyes such as toluidine blue and alcian blue and then differentially remove the polysaccharides by adding varying amounts of sodium chloride. The critical concentrations of electrolytes for heparin were measured by Sasai (172) by precipitation of alcian blue on cellulose acetate membrane, and he found 0.9 *M* for magnesium chloride and 1.1 *M* for sodium chloride. Scott (271) reviewed the critical electrolyte effects in interactions between acid glycosaminoglycans with organic cations and polycations.

Titration of heparin with protamine sulfate, followed by measurement of the coagulation after a period of time, is another possible method (272). Vincke and Benfey (273) found that 1 mole of protamine sulfate is equivalent to 629 g. of heparin. But Nagasawa and Kimura (274) claimed that there is no relationship between anticoagulant activity and protamine binding capacity. A possible reason for this, given by Lowary *et al.* (275), is that the number of heparin units neutralized by protamine sulfate varies with the source and specific activity of the sodium heparin. Recently, Godal and Gjeugedal (276) found that a transient coagulant effect is observed when heparin is incubated with protamine, possibly due to an excess of protamine. Another method was proposed by Barkagan and Barkagan (277) based on comparison of anticoagulation rates with and without inhibition of heparin by protamine sulfate.

Methods of Determining Heparin Activity in Blood—Reviews on heparin assays were written by Quick (278), Warren and Wysocki (279), Jaques (230, 280), Biggs and MacFarlane (281), and, recently, Jorpes (282). These methods measure directly the specific anticoagulant activity with respect to total blood or plasma.

Blombäck *et al.* (283) determined the heparin level in blood by titrating with thrombin and cofactor. Quick (278) mentioned a thrombin titration method which involves the inactivation of thrombin by heparin and its cofactor albumin X. Another titration method, described by Herbain (284), is a photometric estimation of the specification rate of plasma after the addition of thrombin. Godal (285) argued that the prolongation of the thrombin time is very sensitive to a variation of pH, temperature, and ionic strength; furthermore, calcium ions counteract heparin, especially at alkaline pH. According to Cameron (286), however, the thrombin clotting time is an efficient method of controlling heparin therapy.

The recalcification time was suggested by Belko and Warren (287) to be both useful and timesaving for appraising the heparin effect. The prothrombin time (Quick) method (288) measures the clotting time of recalcified plasma with added thromboplastin. Messerschmidt and Peter (289, 290) used this method with a photometer to measure the beginning of clotting.

Heparin will prolong whole blood clotting time (Howell) to three times the normal level (291). According to Jorpes (282), the main advantage of this technique is that it ensures the presence of the heparin cofactor and all the labile factors entering into the coagulation system without the introduction of additional salts or thromboplastin. Jaques *et al.* (257) found that the results given by whole blood were better than the USP XIV assay which is done in plasma, since the conditions of the former are closer to those used in the clinical control of heparin anticoagulation. The BP assay likewise suffers from the same disadvantages as the USP assay.

Other tests mentioned by Jaques (230) for the anticoagulant activity of heparin include: (*a*) whole blood collected in silicone-clotting tubes, (*b*) plasma time with chicken plasma that does not require recalcification, and (*c*) two-stage tests that are modifications of the previous tests given, with final measurement made on the coagulation time of a separate fibrinogen solution on the addition of an aliquot from the single-stage test.

Other Techniques—Some techniques are not as well known as the ones already discussed. Rosencrantz *et al.* (292) described a method that permits automatic quantitative recording of the formation of clots at 250 nm. An assay of heparin, employing diatomaceous silicate, modified plasma, and a precision coagulation timer[3], was given by Seip *et al.* (293). Attempts to use concanavalin A(I) as a specific reagent for the identification of heparin in biological fluids was found unsuccessful by DiFerrante and Hrgovcic (184). A quantitative method of estimation of acid polysaccharides in the blood of rabbits after the injection of papain, by complexation with cetyltrimethylammonium bromide, was given (294). The determination of heparin activity by an IR spectroscopic method was described by Zhbankov *et al.* (295), where potassium cyanide is introduced as an internal standard and the absorption ratios of 1240–1150 $cm.^{-1}$ and 1240–2065 $cm.^{-1}$ are measured, the latter frequency being due to the CN group. Bohn *et al.* (296) presented an automatic procedure for the determination of mucopolysaccharides (including heparin) based on a turbidity reaction with cetylpyridinium chloride. The thrombo test was described by Owren (297) as differing from earlier methods by measuring the coagulation activity of the absorbable factors in both the intrinsic and extrinsic coagulation systems, thus being insensitive to depression of factor IX during anticoagulant therapy.

For the assay of whale heparin, Matsuno and Hashimoto (298) modified the BP assay by using ox and human sulfated blood and ox thrombokinase. The USP method was more specific than a chemical method based on the shift of the isoelectric point for the estimation of polyanionic compounds like polyestradiol phosphate and polymethylene salicylate (299).

Much controversy exists as to the effectiveness of the various methods. A discrepancy of up to 40% was observed by Walton *et al.* (300) between potencies ex-

[3] Fibrometer.

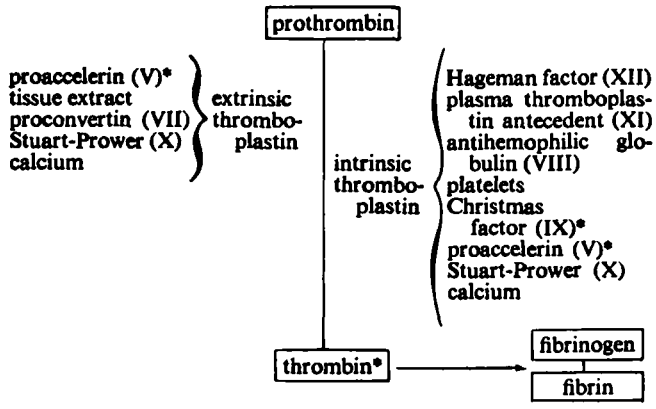
amined by the BP and USP assay procedures. These findings led to a British standard of mucosal heparin of mucosal origin. The results of Bangham and Woodward (301), however, indicate differences between the estimated relative potencies of lung and mucosal heparin, but they were not so consistent as to necessitate a separate international standard for each. The use of animal plasma or human plasma can also alter results (302). The correspondence between the *in vitro* and *in vivo* anticoagulant activities of beef and whale heparin was studied by Hashimoto and Matsuno (303), with the result that the BP unit of whale heparin and its *in vivo* potency in dogs was 1.5-fold more potent than those of beef heparin, whereas USP units of whale and beef heparin were the same. This led to the suggestion that the BP assay method may be better for clinical evaluation than the USP method when the whale lung or intestine is used in the place of the ox lung as the source of heparin.

Andreenko *et al.* (304) compared the method of titration with thrombin in the presence of heparin-cofactor (Blombäck), a colorimetric method based on precipitation of heparin with azure A (Warren–Bozioni method), with the titration with protamine sulfate (Warren–Vysockii). They found that the most suitable for laboratory practice was the first. In a report by Rezansoff and Jaques (305) comparing USP colorimetric, Howell, spectrophotometric, and microelectrophoresis techniques, no assay method consistently described the activity of heparin in another test system, *in vitro* or *in vivo*. This report conforms with that of Magnusson and Nilsson (306) who received different values of anticoagulant activity when using human, bovine, dog plasma, and whole ox blood in one-stage prothrombin, recalcification, and thrombin systems. Kavanagh (307) and Kuo (308) recently discovered no significant correlations between nitrogen, sulfur, acetyl, glucosamine, and other parameters with biological activities determined by Howell assay, USP assay, *in vivo* clotting time, partial thromboplastin time, and *in vivo* lipolytic activity values. Estes (309) claimed that, on comparison of four tests, the whole blood activated partial thromboplastin time provided the greatest precision, information, and economy, followed by (in order) the activated plasma partial thromboplastin time, the whole blood clotting time, and the partial thromboplastin time of plasma. The indication is, nevertheless, that more uniform systems of anticoagulant activity assay must be devised.

PHARMACOLOGY

Pharmacologically, heparin is noted for its anticoagulant action in the treatment of myocardial infarction and in the induction of the clearing reaction as an antilipemic agent in the blood. In addition, many other actions of heparin (antimetastatic, antiviral, and antienzymic) have been reported. Some general surveys of the pharmacology of heparin were written by Jorpes (1), Engelberg (8), Jaques (230, 280), and Gastpar (50).

Effects on Circulatory System—The most important action of heparin is the inhibition of blood coagulation. Surveys on blood anticoagulation were presented by



*Scheme II—Scheme of blood coagulation (*Here it is thought that heparin affects coagulation)*

Wessler and Gaston (310), Rodman (311), Buri and Schneeburger (312), Divald and Jouillié (313), Yen *et al.* (314), and Haas-Weston (315).

Anticoagulants may be divided into two groups: (*a*) the direct type like heparin and the heparinoids, which act rapidly by their presence in the blood, and (*b*) the indirect type (called antivitamin K), the derivatives of coumarin and indandione, which act after some delay. The first class of compounds interferes with the formation of thrombin and thromboplastin, whereas the second class interferes with the formation of prothrombin. The antagonists of the first class are protamine sulfate types, and the antagonists of the second are vitamin K types.

To date, no one has clearly elucidated either the mechanism of blood coagulation or anticoagulation. A recent review on blood coagulation was written in 1971 by Mammen (316). Many theories for blood coagulation have been proposed. A generally accepted scheme of coagulation is presented in Scheme II, according to Fremont (317).

The system offered by Wessler and Gaston (310) is similar to that of Fremont; however, they carry the clotting mechanism to the gelation stage (Scheme III).

Anticoagulant Effects of Heparin—Antithrombic Action—Prothrombin is unaffected in heparinized blood and, therefore, heparin must act on the first part of clotting (318). It is thought to have "antithrombic" activity in the presence of a certain plasma protein named "heparin complement" by Ziff and Chargaff (319) or cofactor (Howell) (317), which is close or identical to antithrombin III (320, 321). The protein forms a complex with heparin which is capable of binding rapidly with thrombin and thus inactivating it. Serotonin and tryptamine can interfere with this reaction (322). Henstell and Kligerman (323) felt that, more likely, three factors are involved: a plasma antithrombin (antithrombin III), a plasma antithrombin inhibitor, and a platelet factor with heparin acting as a catalyst. Porter *et al.* (324) indicated that the anti-

$$\text{fibrin monomer} \xrightarrow{*} \text{fibrin polymer} \quad (1)$$

$$\text{fibrin polymer} \xrightarrow{\text{calcium}} \text{fibrin gel} \quad (2)$$

Scheme III—(Here it is thought that heparin affects coagulation)*

thrombic action of heparin itself is weak in comparison with that of the heparin–cofactor complex.

Inhibition of Thromboplastin—In addition to its antithrombic action, heparin is capable of inhibiting several blood factors for the formation of thromboplastin, which is necessary for the conversion of prothrombin to thrombin, through depression of factors V, IX, XI, and XII (317). The data of Pitlick *et al.* (325) indicate that heparin and hirudin interfere with factor IX*a*, which is the heparin- and hirudin-sensitive factor in plasma when coagulation is initiated *via* factor XI or XII, and that subsequent clotting factors remain in inactive forms. Heparin also inhibits the activation of factor VIII by factor IX*a* (315). Josso (326) pointed out that an important discovery in recent years is that the enzyme activities that operate to transfer prothrombin into thrombin are attached to particulate lipoprotein complexes with which the inactive plasma profactors are transformed into active factors. The interaction between heparin and thromboplastin, observed by Chargaff *et al.* (327), results in a complex formed by heparin and the protein moiety of the lipoprotein. According to Yen *et al.* (314), the scheme of complex formation may be as shown in Scheme IV, where A is the polyanion and C is the polycation. In reaction (4) there is a two-electron transfer. These reactions could also hold for complexation with dyes and heparin antagonists.

Fibrinolysis—In addition to being an anticoagulant, heparin usually enhances fibrinolysis. It was found by Buluk and Januszko (328) to reduce the inhibition of antifibrinolysin. Lackner and Mersk (329) reported markedly accelerated fibrinolytic activity after intravenous injection of heparin. Increased blood heparin in leukemia was thought by Efendiev *et al.* (330) to be responsible for the greater fibrinolytic activity. Heparin and fibrinogen were shown by Godal (331) to react in stoichiometric proportions. Evidence was presented (332) that heparin in solutions of low ionic strengths breaks the bonds holding the fibrin monomers together in clots. It is also able to inhibit the polymerization of fibrinogen. The concentration, according to Silver and Hall (333), in the blood must be greater than 2 mg./kg. to potentiate fibrinolysis.

Olesen (334) suggested that the fibrinolysis is caused by plasminogen activation. However, Holemans *et al.* (335) found that the presence of a cofactor is necessary. Heparin is known also to accelerate catalytically the neutralization of thrombin by antithrombin III and thus prevent reclotting following fibrinolysis (336). The preparation of heparin must be free of protease inhibitors to enhance fibrinolysis (337). Eleparon, a mucopolysaccharide polysulfuric acid ester like heparin, increases fibrinolytic activity (338). Boros (339) discovered that "heparin rebound," the reappearance of heparin in the circulation in open-heart surgery despite its previous complete neutralization, was caused by enhanced fibrinolysis.

$$A:{}^{-}C^{+} + A:{}^{-}Na^{+} \rightarrow CA_{2}{}^{-}\,Na^{+} \quad (4)$$

Scheme IV

Effects on Platelets—Platelets contain a factor with some antiheparin activity (320, 340). This was described by Shanberge and Furuta (341) as platelet factor 4. Heparin was shown by Sawyer *et al.* (342) to prevent conversion of degenerated platelets in solution from forming a gel.

According to Jaques (280), heparin inhibits platelet adhesion to intercellular cement. Aznar (343) and Silver (344) found that small doses of heparin had no effect on platelet adhesiveness, but with larger doses the antiaggregating effects increase in proportion to the dose. Moreover, Gröttum (345) reported that the negative charge of the platelets was reduced by the positive charge of heparin and lowered the electrophoretic mobility, but increasing the concentration of heparin increased their electrophoretic mobility but did not aggregate them. A method was developed by Hohage and Hiemeyer (346, 347) for quantification of the aggregation curves of platelet-rich citrate–heparin plasma.

The adhesiveness of platelets to tannic acid-treated red cells was shown by Zbinden and Tomlin (348) to increase when heparin was added. If adenosine diphosphate is added to unstirred, plasma-rich platelets, no aggregation occurs and platelet-bound heparin-neutralizing activity develops immediately (349). The addition of adenosine diphosphate to platelets leads to shape and volume changes, to the development of stickiness, and to heparin-neutralizing activity (platelet factor IV) (350). O'Brien (351) reported that alcian blue also binds heparin and may influence heparin-neutralizing sites and probably the charge on the platelet; thus it can influence platelet aggregation. Eika (352, 353) found that washed human platelets were aggregated by heparin in the presence of divalent cations, but heparin inhibited the thrombin-induced platelet aggregation and release of adenine nucleotides. In the presence of calcium chloride and also in barium sulfate-adsorbed serum, heparin was shown by Murase *et al.* (354) to produce platelet clumping activity, but this was not the case in citrated plasma, edetate plasma, or serum.

Another action of heparin is to prevent platelet disintegration (355, 356) and release of phospholipids (355). Platelet instability, however, is not affected by heparin (357).

The ability of a heparin-like sulfonic polysaccharide to counteract platelet adhesiveness in rabbits and intravascular red cell aggregation in cats was discovered recently by Bicher (358).

Other Actions of Heparin—According to Jaques (280), heparin decreases blood sugar, the fall in lymphocytes and eosinophils, and hemorrhage from stress and hypertension. Hougie (359) reported that heparin gives prompt relief from acute myocardial infarction. Heparin facilitates the flow of blood by vasodilation (280, 360) and so could be important in Buerger's disease (361). The viscosity of blood was reported by Alberto *et al.* (362) and Meda *et al.* (363) to be lowered by heparin because of its anionic character. According to Hoak *et al.* (364), heparin prolongs the time to produce thrombi. *In vitro*, heparin was found to cause hemolysis (365), possibly because there is a decrease in the mechanical resistance of the red blood cells due to nucleoprotein mobilized from leucocytes under the influence of hepa-

rin, but *in vivo* it inhibits hemolysis and alters the erythrocyte sedimentation rate (315). Heparin prevents decrease of lymphocytes and eosinophils caused by ACTH or cortisone (366, 367) and activates alkaline phosphatase and esterase in the blood (367). Another biological effect is its enhancement of vascular permeability (368).

Pathological conditions exist, termed acquired and hereditary hyperheparinemia, where unusually high concentrations of heparin in the blood produce prolonged clotting or thrombin times. These can be corrected by treatment with protamine sulfate, toluidine blue, or polybrene (288).

Clearing Action of Heparin on Blood Lipids—In addition to the anticoagulant action of heparin, another major effect is the clearing of lipemic plasma. Early reviews were written by Levy (369) and Engelberg (370). Heparin stimulates the release of lipoprotein lipase (the clearing factor), an enzyme that catalyzes the hydrolysis of triglycerides associated with chylomicrons (lipoprotein molecules rich in neutral fat), and thus promotes the clearing of lipemic plasma (361, 367). The possible connection between the pathogenesis of atherosclerosis and heart disease and the clearing action of heparin is of great interest.

Antonni *et al.* (371) found that the clarifying action is more evident in atherosclerotic subjects than in normal ones. Also, myocardial infarction is usually accompanied by an increase in plasma lipoproteins and free fatty acids, which are damaging to the myocardial cells, in addition to an accumulation of tissue triglycerides and increased synthesis of fibrinogen (372).

Some properties of the clearing factor were examined by Korn (373), with the conclusion that it is primarily a tissue enzyme, a heparin-activated lipoprotein lipase that catalyzes the hydrolysis of chylomicrons but not simple triglycerides. The possibility of a separate monoglyceridase activity was also suggested by Vogel *et al.* (374). According to Engelberg (375), heparin is a component of the enzyme and its dissociation from the apoenzyme can be readily brought about. The clearing factor showed activation by low concentrations of heparin and inhibition by higher concentrations and protamine. This, with density centrifugation evidence, led Payza *et al.* (376) to suggest that heparin is not a necessary requirement or a cofactor for the action of the clearing factor.

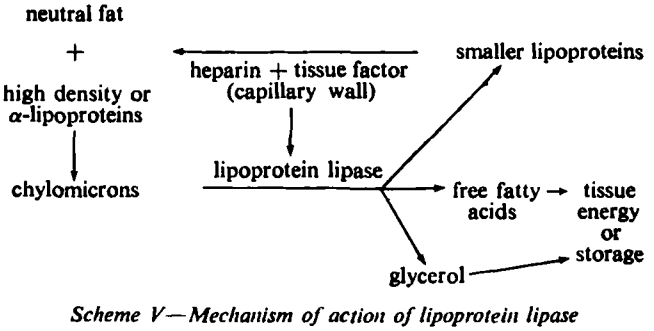
In addition to being found in the plasma, lipoprotein lipase can also be located in the thoracic duct lymph of dogs (377) and near the vascular wall after heparin injection (378). Heparin released lipase from rat epididymal fat pads (379), but Ho *et al.* (380) claimed that heparin only increases the lipolytic activity of the stroma cells of the pads. Ballard *et al.* (381) claimed that heparin increases the release of venous plasma lipolytic activity from perfused canine subcutaneous adipose tissue. From their findings, Gero *et al.* (382) made the observation that heparinoids may act on the tissue level by interfering with the lipid deposition and by locally increasing the lipolytic activity of the vessel wall. Payza *et al.* (383) found that injection of heparin into rats induced an increase in lipase activity of the plasma and a decrease in lipase activity of the tissue. Davis and Heimberg (384) thought that the uptake of chylomicrons from the blood probably is accelerated by a direct action of heparin on the liver.

A mechanism for the action of the postheparin lipidemia clearing factor was given by Engelberg (370) (Scheme V). He believed that the lipoprotein lipase is the major way for the removal of triglycerides from the blood. Rutstein *et al.* (385) argued that heparin leads to increased lipid deposition and that this can be correlated with increased serum levels of nonesterified fatty acids but not with the decreased concentration of triglycerides, cholesterol, and phospholipids. The high nonesterified fatty acid levels are associated with arrhythmias and death in patients with myocardial infarction. Davis and Davis (386) disagreed, their reason being that even though emboli contain lipids, fibrinogen is more important in their formation than lipids. The interpretation of lipase stimulation given by Patten and Hollenberg (387) was that exogenous heparin increases the binding of the enzyme to chylomicrons and then has no effect on either the stability of the extracted enzyme or enzyme activity after the formation of enzyme–chylomicron complexes has occurred. The clearing activity was found by Bianchini and Osima (388) to be independent of the number of sulfate radicals and the presence of uronic acid groups. Also, it does not parallel the anticoagulant activity (389).

Evidence was given by Pav and Wenkeva (390) of the appearance in the blood of another serum esterase in addition to the clearing factor after the injection of heparin. The quantitative inhibition of triton lipidemia by heparin was determined by Haikonen *et al.* (391). Finkelstein *et al.* (392) isolated an extracellular lipase from the culture medium of *Pseudomonas aeruginosa*.

A naturally occurring acid mucopolysaccharide was isolated by Grossman *et al.* (393); it had good lipoprotein lipase-activating effects and cholesterol-reducing ability, with little anticoagulant activity. Sulfovernan, a new heparinoid from a lichen moss, was shown by Stefanovich *et al.* (394) to have anticoagulant activity, but it increased the triglyceride level of the lipids of aortic tissue. The latter effect is not thought to be associated with heparin.

Effects of Heparin on Tumor Growth and Metastasis—Much experimental investigation has been attempted to solve the question of whether heparin actually alters tumor growth and metastasis, but to date this problem remains unsolved. Reviews were written by Balazs and Jacobsen (395), Shats (396), and Regelson (397). The results of Lippman (398) on the Ehrlich ascites tumor in mice show that heparin is a mitotic inhibitor in this



Scheme V—Mechanism of action of lipoprotein lipase

tumor. No effect on the growth of a transplantable lymphosarcoma in mice, however, was found by Kreisler (399). Csaba *et al.* (400) agreed with these results and even thought that some tumors require heparinoid substances for their growth. The findings of Montes de Oca and Dietrich (401) in the incorporation and fate of heparin in L, Le, HeLa, and mouse embryo tissue culture indicate that there is no inhibition by heparin of the four cell lines.

Fisher and Fisher (402) believed that their observed decrease of tumor metastases in rats cannot be explained by an inhibition of tumor cell lodgment and microclot formation but by rheological alterations in the blood as a result of the administration of heparin and previous tumor plasmin. The treatment of tumor-bearing mice by Kudryashov *et al.* (403) did not produce a consistent reduction in tumor growth but actually promoted growth in several animals. If, however, the vegetative nervous system was blocked with chlorpromazine during anticoagulant and fibrinolytic treatment, there was a significant regression of tumor growth. Németh (404), using a combination of heparin and degranol[4], found a reduction in the size of tumors rich in connective tissue.

The effects of heparin and fibrinolysins on pulmonary metastasis were studied by Cliffton and Agostino (405, 406), with the finding that the incidence of metastasis was decreased. Suemasu and Ishikawa (407) discovered a similar result on pulmonary metastasis which they attributed to indicate that tumor cells were flushed away by the anticoagulant through the lung by blocking the formation of fibrin clots around the cells in capillaries that enmesh them. Likewise, Rutstein *et al.* (385) found that heparin has a disseminating influence on pulmonary metastases of experimental tumors. On the other hand, Hagmar and Norrby (408) reported that the average volume of pulmonary metastases became less but their number rose. This was also experienced by Boeryd and Rudenstam (409).

Miscellaneous Effects—The antiviral action of heparin on *Herpes simplex* was mentioned by Jaques (230). The observation of Vaheri (410) was that heparin has a potent reversible inhibitory action on the early interaction of *H. simplex* virus and cells but that it does not have an irreversible effect on the virus. Horváth and Hadházy (411) found that heparin inhibits only the absorption of free virus and does not influence the penetration and cell-to-cell transfer of viruses carried by infected cells. Treatment of chick embryo cells by Mentkevich and Zhdanova (412) inhibited H and B_1 strains of Newcastle disease virus from producing interferon. The stimulation of cell locomotion and pseudopodium formation of the amoeba by heparin was seen by Bell and Jeon (413). Bell (414) suggested that heparin has a depolarizing effect on the cell surface. The antibacterial action of heparin in the presence of blood from regions of injury was mentioned by Regelson (397).

Heparin inhibits the action of many enzymes such as β-glucuronidase (415, 416), renin (417), hyaluronidase (418), alkaline phosphatase (418), chondroitin sulfate glycanhydrolase (418), elastase (418), and collagenase (419). The inhibition of hyaluronidase in the gingiva by heparin was cited by Nord (420) as an important defense mechanism in periodontal disease. Heparin and rifampicin were acclaimed by Neuhoff *et al.* (421) as being the most effective known inhibitors of DNA-dependent RNA polymerase from *Escherichia coli*. It also reduces the action of ribonuclease (367, 421), fumerase (367), serum protease (367), and lecithinase (422). Heparin was found by Wu (423) to inhibit polynucleotide kinase, which catalyzes the transfer of orthophosphate from ATP to the 5^1-hydroxyl terminus of polynucleotides. Freeman (424) suggested that the ability of heparin to inhibit a rather large number of enzyme systems may be due to its acidic character which allows it to combine rather tightly with almost any basic protein. There are some enzymes, such as staphylococcal coagulase, upon which heparin has no action, at least under experimental conditions (425). On other enzymes such as pepsinogen (426) and diamine oxidase (427), it has a stimulating action.

Heparin has some activity in secretion and excretion. Gastric secretion was inhibited by heparin and heparinoids in some dogs (428). It has a diuretic effect and this lowers edema (8, 230). It also inhibits the antidiuretic effect of pitressin (230). The excretion of potassium is decreased and that of sodium is increased (230, 367) after heparin administration.

Its interaction with calcium has been of interest. According to the results of Tidball (429, 430), physiologic histamine release is partially inhibited by heparin, the assumption being that the histamine release may result from the binding of calcium by heparin. Cheymol and Gay (431) found that heparin causes an elevation of alkaline reserve in rabbits. According to Reber and Studer (432), the binding of calcium ions by edetate, sodium citrate, ion exchangers, *etc.*, seems to enhance the intestinal absorption of heparin in rats, as measured by clearing factor activation. However, the work of Koh (433) with dimethyl sulfoxide, diethylsulfone, *etc.*, showed that these also enhance heparin absorption but here they act by a process other than calcium sequestration since they are not chelating agents. Additionally, through chelate-like compounds with calcium ions, heparin may deplete capillary walls and decrease wound strength (281). Heparin inhibits calcification *in vitro* and increases calcification *in vivo*. The explanation for this phenomenon given by Harris *et al.* (434) was that there is binding of calcium by heparin *in vitro* and that heparin acts as a template for calcium deposition *in vivo*. Leonard (435) found that it can cause sequestration of calcium. In addition, it induces a stimulatory effect on bone resorption (367).

Heparin caused developmental anomalies in amphibian and sea urchin eggs. This was explained by DeCarli and Brachet (436) as being due to damage to the transcription of DNA. Skalka *et al.* (437) reported the incorporation of labeled thymidine into the DNA of rat thymocyte and spleen cell nuclei. In the presence of large amounts of heparin, this leads to the disintegration of the nuclei.

The action on various tissues and organs has been given much consideration. Garin and Bassa (438) found that heparin eliminates quickly the action of total spleen

[4] Zitofen.

extract which blocks up medullary inhibition. Sasaki (439) showed that there is a marked decrease of lymphocytes in lymph nodes and the white pulp of the spleen after heparin is administered. The decrease in respiration of animal tissue caused by heparin was described by Schuster (440). Clinical investigation by Fegen *et al.* (441) indicated that heparin aids in prolonged ischemia time in an occluded renal artery after kidney injury. Heparin formed a gel when added to homogenates and nuclear fractions of rat liver, thymus, spleen, and kidney (442). Lazzarini-Robertson (443) found that heparin has a strong inhibitory effect on the uptake of labeled serum-bound lipids by human and animal endothelial-type cells. This is probably due to the very strong negative charge, acting directly at the cell membrane level. Xanthomatosis and burns of the skin are improved by heparin (8), and it stimulates growth of connective tissue (367). The cytotoxic effect of a rabbit antiserum on guinea pig myocardium was eliminated by heparin (444).

Heparin has an inhibitory effect on hormones such as aldosterone (445) and testosterone (446). In euthyroid and hypothyroid patients receiving heparin alone, there were no changes in thyroxine-binding globulin and thyroxine-binding prealbumin; according to Schatz *et al.* (447), it is possible that the heparin competes with thyroxine for binding sites.

In various types of shock, there is an outpouring of heparin from the mast cells (367). However, in a study of anaphylactic manifestations in the rat, Salmon and Lecompte (448) found no inhibition to ovalbumin sensitivity. It was found by Vannas (449) to have a beneficial effect on iritis in the rabbit. In addition to bone loss, another deleterious effect of heparin is increased mortality after its administration in the case of fat embolism (450). Also, the telogen phase in the hair may be precipitated prematurely, producing telogen effluvium (451).

HEPARIN THERAPY AND PHARMACODYNAMICS

Heparin has been reported (452) to be an "ideal" anticoagulant in ease of administration. It is especially desirable because of its safety, rapid onset of activity, and reversibility.

Reviews have been presented on anticoagulant and heparin therapy (8, 311–314, 453–455), discussing indications, dosage, adverse effects, and contraindications.

Indications and Clinical Application—Heparin has its main use in acute thrombotic disease, vascular and cardiac surgery, and acute myocardial infarction (92). Its efficiency in reducing mortality in thromboembolism was questioned by Enger *et al.* (456), but it may decrease chest pain and thromboembolic complications (457).

Its use in the treatment of pulmonary embolism was reported by Zilliacus (458), who claimed that it has certain advantages as compared to vein ligation in legs since it acts on undiagnosed thrombi. Moser (459) found heparin to be the drug of choice in this complication because of its (*a*) immediate onset of action, (*b*) potent inhibition of the coagulation system, (*c*) enhancement of fibrinolytic dissociation of fresh thrombi, (*d*) inhibition of platelet breakdown (and, therefore, serotonin release), and (*e*) prompt reversibility of anticoagulant action.

In the treatment of cerebral thrombosis (460), anticoagulant therapy postpones the arrival of an impending stroke, prevents transient ischemic attacks, and sometimes stops the advance of a progressive thrombotic stroke.

Other uses for heparin were mentioned by Engelberg (8), such as lowering of edema by its diuretic effect, neutralization of snake venom, lowering of hypertension, aid in burns and allergies, and prevention of atherosclerotic disease. Some other possible uses of heparin were said by Jorpes (454) to be in Dupuytren's contracture and fat embolism. It is the anticoagulant of choice for patients under general anesthesia (452).

Method of Administration and Dosage—Heparin is ineffective when given orally. According to Estes (309), the minimum dose required to anticoagulate blood to a clinically desirable level is 35 units/kg. The various routes of administration for acute myocardial infarction and sustaining therapy described by Lomax (461) are: (*a*) continuous intravenous infusion—an initial dose of 5000 I.U. and then 20,000–30,000 I.U. in 1 l. of 5% glucose or 0.9% sodium chloride solution given slowly over the next 24 hr., (*b*) intermittent intravenous infusion—5000 I.U. every 3 hr., (*c*) intramuscular—an initial intravenous dose of 5000–10,000 I.U. and then 20,000–40,000 I.U. injected every 8–10 hr., and (*d*) deep subcutaneous injection—20,000–40,000 I.U. injected subcutaneously, which can prolong coagulation up to 16 hr.

For pulmonary embolism, Moser (459) suggested that 7500 units of heparin be given subcutaneously every 6 hr. or 10,000 units every 8 hr. This dosage is maintained until the patient's cardiopulmonary status has stabilized and all traces of venous thrombosis have departed. Miller *et al.* (462) claimed, however, that streptokinase is more effective after 72 hr. than heparin.

The dose in cerebral thrombosis (460) is 50 mg. every 4 hr. in progressive stroke or with transient ischemic attacks. The therapy is maintained for 1–3 weeks, and then oral coumarin therapy is continued for 1 year or more.

Pharmacodynamics of Heparin—Since heparin is used in emergency prophylactic treatment, its pharmacodynamic properties must be understood. It was found that intravenous injection of heparin follows a logarithmic linear regression curve (463). Studies on the relative volume of distribution and half-life (464) revealed that all log plasma heparin concentration–time curves fitted an equation for first-order kinetics, even at the highest doses. The relative volume of distribution varied with the dose but not the half-life. These data agree with the hypothesis that heparin may leave the plasma by uptake into the reticuloendothelial system and could indicate the reason for the problems found in devising practical and reliable dose schedules. In later investigations, Estes (309, 465) found that the half-life of heparin's anticoagulant activity is approximately 1–1.5 hr., and the equation expressing the relationship between dose ratio and dose interval is:

$$R^* = \frac{D^*}{D} = \frac{1}{1 - e^{-k_{elr}}} \qquad \text{(Eq. 1)}$$

where R^* is the dose ratio, D^* is the initial dose, D is the maintenance dose, k_{el} is the rate constant for elimination, and τ is the dose interval. It is found then that maintenance of anticoagulation to a degree meeting common acceptance is met by administering heparin at intervals approximating the half-life (465).

Contraindications—Heparin should not be given to patients with a history of bleeding diathesis, bleeding ulcer, severe hypertension or cerebral hemorrhage (466), jaundice, purpura, hemophilia, acute bacterial endocarditis, and accessible ulcerated lesions (especially of the GI tract) (378).

Adverse Effects—Rodman (311) stated that prolonged use of large doses of heparin (over 200 mg. daily for 6 months or longer) may produce osteoporosis. He also mentioned as side reactions: (*a*) dysesthesis pedia, which is an intense itching of the soles of the feet, and (*b*) the possibility of inhibition of the adrenal cortical synthesis of aldosterone.

Various other adverse effects, described by Lomax (461), include transient alopecia, spontaneous hemorrhage, hypersensitivity, anaphylactoid reactions, thrombocytopenia, fever, and acute adrenal hemorrhage.

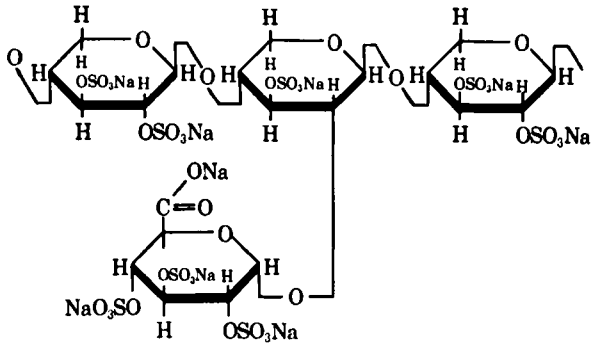
ANTAGONISTS OF HEPARIN

The substances that antagonize the anticoagulant action of heparin are important in the control of heparin therapy and in assay techniques. A review by Agolini (467) discussed the inactivating power of various chemicals on heparin and dextran sulfate. A list of antiheparin agents, given by Stamm (468), includes protamine, clupein, polylysine, lysozyme, polybrene, toluidine blue, fuchsin, and tryptophan.

Garagnini and Fuccini (469) suggested that the inhibiting action of lysozyme on heparin is due to bond formation between the two substances. Protamine sulfate, a low molecular weight protein with a strong basic charge, is antagonistic to the clearing action of heparin (470). The early stages of blood coagulation *in vitro* are inhibited by protamine and polybrene (471) by interfering with the activation of factor IX (plasma thromboplastin component, Christmas factor). Factor IX is activated in the presence of calcium by activated factor XI, a reaction accelerated by thrombin. Protamine prevents this activation by inhibiting the activated XI. Heparin does this by being antithrombic, whereas polybrene acts directly against the inactive IX. This inhibition is probably due to a competitive complex formation since the inhibitory action of each can be overcome by increasing the concentration of its antagonist.

The ratio of protamine sulfate antagonistic to heparin is given as 1:1 by weight (461). According to Lowary *et al.* (472), this is not always true but is also dependent on the tissue source of the heparin in both *in vitro* and *in vivo* studies. Yen *et al.* (473) gave the activity of the antiheparins as β-lipoprotein < thrombin clotting system < Christmas factor < platelet protein < protamine sulfate.

In comparison to toluidine blue, which is very toxic, polybrene administered intravenously promptly and completely neutralizes the anticoagulant action of heparin, with minimal hypotension and no disturbance in pulse rate (474).



II: chemical structure of a sulfonic polysaccharide

Several other less known inorganic and organic substances also have antagonistic properties to heparin. Hexavalent complexes of cobalt and chromium were quite active and complexes of acriflavine, stilbamidine, and viomycin were slightly active (475). Visconti *et al.* (476) discovered that carbon disulfide showed significant antiheparin activity in blood. Substances such as phosphate and sulfate ions, adenosine triphosphate, adenosine diphosphate, and myosin were able to remove the antihemostatic effect of heparin (477).

HEPARINOIDS AND HEPARIN-LIKE SUBSTANCES

This section discusses those substances that have a similar biological action as heparin. The quest for a substance with a high anticoagulant activity and low toxicity still continues.

Sulfur esters of chitin, starch, and cellulose are effective as anticoagulants *in vitro* but are toxic on injection into animals. Dextran sulfate is harmless, but the maximum activity is 15 units/mg. (478). Wood and Mora (479) found that glucose sulfates (degree of substitution 2.6–3.0) had approximately the same activity as clinical preparations of heparin. Amylose, amylopectin, and guaran, after being sulfated, gave low *in vitro* anticoagulant activity, suggesting the importance of *N*-sulfation (480). A sulfated alginic acid[6] has been used as a heparin substitute in therapy (361).

Other heparin-like substances include a sulfonic polysaccharide (Structure II) made by Aznar *et al.* (481). It has marked fibrinolytic activity and is able to inhibit platelet aggregation but has little anticoagulant effect. Wolfrom and Wang (482) prepared an *N*-sulfated heparinoid from amylose which has negligible activity. Chitosan was modified by sulfation and oxidation by Whistler and Kosik (483), converting some of the sugar units to uronic acid. The highest anticoagulant activity attained (60 I.U./mg.) was after all amino groups were sulfated, *O*-sulfate content was increased, and uronic acid groups were introduced. Still another semisynthetic anticoagulant, a Pentosan-polysulfo-ester (SP 54), was introduced by Walb *et al.* (484). In contrast to heparin, *in vitro* this compound has less influence on coagulation and 10 times as great anticomplementary action. Re-

[6] Paritol.

cently, a synthetic sulfated polygalacturonic acid methyl ester[6] was introduced by Jarrett and Jaques (485) which, when administered in conjunction with edetate, has potential as an oral anticoagulant based on the assumption that the chelating agent would form chelate bonds with ions which would otherwise obstruct the absorption of the heparinoid.

Bhattacharya and Singh (299) conducted a comparative study of polyanionic compounds, such as polyestradiol phosphate and polymethylene salicylate, but discovered that they possess only a fraction of the activity of heparin.

Unmodified heparin-like substances from natural sources have shown some promise as anticoagulants. Heparin-like anticoagulants were extracted from clams (11–13, 486). These have acetyl residues but have a high activity (130 I.U./mg. from mantle tissue), low toxicity, and a higher molecular weight than heparin. The polysaccharide, carrageenin, is not an antithrombin and does not inhibit the viscous metamorphosis of thrombocytes as does heparin, but it does decrease fibrin polymerization (487). Matsuoka *et al.* (488) found that charonin sulfuric acid, a polysaccharide from the mucus of *Charonia lampis*, remarkably prolonged whole blood clotting time after intravenous injection in the rabbit but had a toxicity 3.6–7.2 times as strong as heparin. A list of other natural and synthetic anticoagulants was given by Bernfeld (356).

Whale heparin (ω-heparin) was first isolated by Yosizawa (489) from the lungs and intestines of the finback whale (*Balaenoptora physalus*). It contains *N*-acetyl glucosamine, to which the other groups of heparin are attached (490), and has approximately the same molecular weight as heparin (491). The structure was confirmed with NMR by Inoue and Inoue (492). Masao (493) reported that ω-heparin from lung tissue exhibited higher activity than heparin, and it was also found to be longer lasting (494). The heparin isolated from the small intestine of whales showed a much higher anticoagulant activity than bovine heparin (495). Whale intestine heparin was used therapeutically by Abe *et al.* (496) during and after an operation for occlusion of the bilateral iliac arteries. There was prolongation of blood clotting and recalcification time, but the amount of bleeding during and after the operation became insignificant. Nagasawa (497) found, in addition to whale heparin from the small intestines and lungs, that the whale (mucous) heparin also had high activity, 580 units/mg. (BP).

METABOLISM AND ENZYMATIC DEGRADATION

Reviews on the metabolism of heparin were presented in 1966 by Whistler and Rowell (7), in 1968 by Dodgson and Lloyd (498), and in 1969 by Silbert (499).

Studies with Labeled Heparin—With the preparation of a radioactive heparin, the possibility of quantitative metabolic studies could be attempted. A method was described by Lalich (500) for the synthesis of radioactive heparin using a process of *N*-desulfation and *N*-resulfation. The results of Eiber *et al.* (501) indicate that heparin-^{35}S or ordinary heparin given orally would pass into the blood only to a very small extent and would have no effect on blood coagulation. However, when the labeled heparin was injected intravenously, the radioactivity in the blood increased in proportion to increases in clotting time and clearing activity.

Labeling of heparin with tritium and ^{35}S gives a stable product under a variety of conditions which retains the original physicochemical and biological properties (502). Heparin labeled with ^{3}H was found by Barlow and Cardinal (503) to have an activity of 124 USP units.

Dietrich and Montes de Oca (504) isolated radioactive mucopolysaccharides from HeLa, K., mouse, and rat embryo cells grown in the presence of a culture medium with radioactive inorganic sulfate. A ^{51}Cr-labeled heparin was made by refluxing heparin with $^{51}CrCl_3$ by Varga *et al.* (505). This could be important in investigations of the function of heparin *in vivo* and *in vitro* as well as its metabolic fate.

Biosynthesis—Studies by Silbert (506–509) indicate that an *N*-acetylated glycosaminoglycan is transformed into heparin at the polymer stage. Also, the polymerization appears to take place in close proximation to the sulfation in the mast cell. The resulting sulfated polysaccharide remains bound to the same particulate preparation that catalyzes the heparin formation.

In contrast, the results of Rice *et al.* (510) on the mastocytoma showed that there is transfer of sulfate to small molecular weight precursors. Also, the observations of Marx and Eisenman (511) establish that the major portion of the "microsomal" fraction from the homogenates of Furth mast cell tumor was capable of controlling the transfer of radioactive sulfate to *N*-desulfated heparin. Balasubramanian *et al.* (512) concluded that apparently free amino groups are required for the enzymatic *N*-sulfation of glycosaminoglycans.

Most of heparin exists in nature in firm covalent combination with protein and does not appear in appreciable amounts as an extracellular component of connective tissue (498). Helting (513), in 1971, investigated the natural trisaccharide, 3-*O*-β-D-galactosyl-4-*O*-β-D-galactosyl-D-xylose, of the heparin–protein linkage region and found that partial acid hydrolysis of ^{14}C-galactose-labeled endogenous acceptor yielded several fragments with the characteristics of neutral oligosaccharides previously isolated from the heparin–protein linkage regions and, in addition, a compound with the chromatographic qualities of *N*-acetyl lactosamine. This confirmed the biosynthesis scheme of acid mucopolysaccharide production offered by Dorfman (514). Scheme VI (514) shows the biosynthetic pathways of the acid mucopolysaccharides of connective tissue. A more recent scheme (Scheme VII) was presented by Silbert (499).

Studies on Catabolism—Danishefsky and Eiber (515), in 1959, concluded from excretion studies with heparin-^{35}S that the sulfate linkages of heparin were cleaved as a result of metabolic degradation; with small doses, all of the $^{35}SO_4$ in the urine was in the form of inorganic sulfate while larger doses of heparin-$^{35}SO_4$ led to the output of some urinary heparin-$^{35}SO_4$. The findings of Lloyd *et al.* (516) complemented those of Danishefsky and Eiber (515) and also showed the presence in the

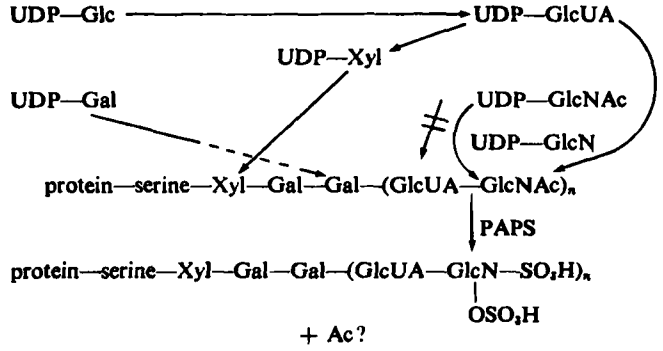
Scheme VI—Biosynthetic pathways of acid mucopolysaccharides of connective tissue (514)

urine of a material with an electrophoretic mobility similar to heparin but a reduced molecular weight. Thus, it appears that greater catabolism is reserved for higher molecular weight materials.

Lemaire *et al.* (517) found the formation of partially desulfated catabolite in the urine and strongly labeled sulfonucleotides in the liver. The heparin excreted in the urine was termed uroheparin by McAllister and Dennis (518) and was shown to have about half of the anticoagulant activity of ingested heparin; the number of moles of sulfate per repeating unit was 3.94 for uroheparin in contrast to 5.6 for heparin.

Degradation by Enzymes—The change in heparin after absorption in the body is thought to be due mainly to bacterial enzymes. Heparinase, isolated by Walker (519) from *Flavobacterium heparinum*, a Gram-negative soil bacterium, reduces heparin and heparitin sulfate to oligosaccharides, with glucosamine or *N*-acetylglucosamine as the reducing end-group. Linker and Hovingh (520) fractionated a crude heparinase on a Sephadex column and obtained two active fractions. The first had the properties of an eliminase, which degraded heparin and heparitin sulfate nonhydrolytically to di- and oligosaccharides containing α,β-unsaturated glucuronic acid. The second had the properties of a glucuronidase, which hydrolyzed the unsaturated uronides to monosaccharides. Dietrich (521) identified the products of such a bacterial degradation as glucosamine 2,6-disulfate, saturated disaccharides made up of uronic acid and glucosamine and containing two and three sulfate residues, and tetra- and hexasaccharides with the same disaccharide units. From this, he concluded that positions 2 and 6 are the positions for the *N*-sulfate and *O*-sulfate, respectively, in the disulfated glucosamine molecule. He (522, 523) also showed that five enzymes from *F. heparinum*, acting in concert, were able to degrade heparin to its monosaccharides. Karapally and Dietrich (524) isolated a uronic acid isomerase from *F. heparinum* which converts glucuronic acid and galacturonic acid to fructuronic



Scheme VII—Biosynthetic pathway of mucopolysaccharides (499)

acid and tagaturonic acid. Hovingh and Linker (525) found that a heparinase and a heparitinase could be obtained from *F. heparinum*, and the specificity appears to be related to the presence or absence of *N*-acetyl groups. Whale heparin was degraded by Yosizawa (490) by crude heparinase to three major monosaccharides: α-keto acid, *N*-sulfated glucosamine, and *N,O*-desulfated glucosamine. There were also minor products: *N*-acetylglucosamine containing unsaturated oligosaccharides.

A group of enzymes from *F. heparinum*, the sulfamidases capable of liberating inorganic $^{35}SO_4^{-2}$ ions, was discovered by Lloyd *et al.* (526). The sulfamidases extracted from bacterial and mammalian sources differed in that the mammalian enzyme liberated inorganic $^{35}SO_4^{-2}$ ions only from ^{35}S-heparin and the bacterial enzyme preferentially degraded authentic 2-deoxy-2[^{35}S]-sulfamino-D-glucose but to a lesser degree [^{35}S]-labeled polymer (527). The actions of sulfamidase and sulfoesterase in the desulfation of the catabolites of heparin were studied by Dietrich (528, 529). Recent work on heparin degradation (530, 531) established the presence in rat tissues of an entirely normal mammalian system which has the ability to degrade the sulfamate groupings of exogenous [^{35}S]-sulfoamino-heparin and thus exhibits the characteristics of a "heparin sulfamidase."

Testicular hyaluronidase was shown by Ogren and Lindahl (532) to digest and degrade heparin from mouse mastocytoma. The results of this investigation suggest that the molecular weight of the newly synthesized heparin is much higher than that of the polysaccharide stored in the mast cell granules; the heparin released from the mast cell *in vivo* is believed to originate from these granules, thus having partially degraded rather than intact polysaccharide chains.

HEPARITIN SULFATE

Heparitin sulfate, also referred to as heparan sulfate or heparin monosulfate, is closely related to heparin. A general review was written by Spiro (533) in 1965. Heparitin sulfate is obtained as a by-product in the preparation of heparin from lung and liver tissue (534). It has a lower sulfate content than heparin (535) and, unlike heparin, the glucosamine residues are partly *N*-acetylated and partly *N*-sulfated. The most important linkage in this mucopolysaccharide is 1 → 4 and there may be branching (536). The major uronic acid of hepa-

ritin sulfate seems to be glucuronic acid, but the presence of L-iduronic acid was also demonstrated as in the case of heparin (537). In contrast to heparin, heparitin isolated from the human aorta has a higher molecular weight (24,000–29,000) and negligible antithrombin activity (534), and it is bound to protein by way of serine (538). On treatment of heparan sulfate with alkali or proteolytic enzymes, it behaves as a multichain proteoglycan such as chondroitin sulfate or keratan sulfate (539).

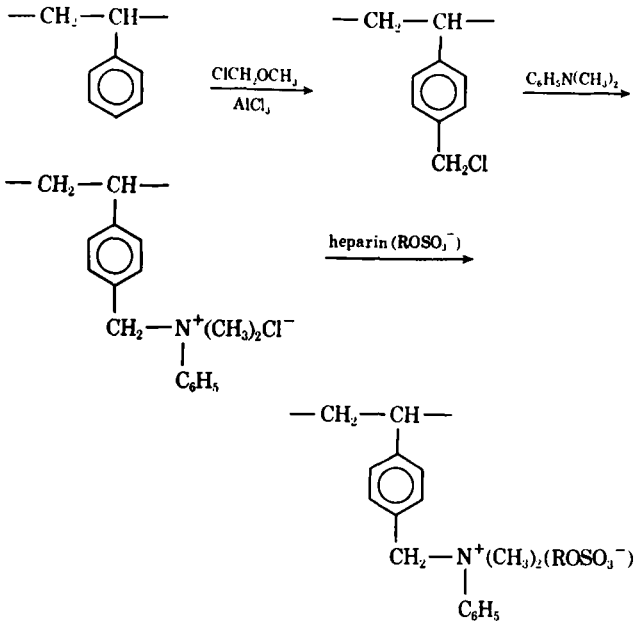
Heparitin sulfate has been isolated in small amounts from human brains (540) and other mammalian brains (541–543). Some evidence (544) indicates that mucopolysaccharides also may be present in the extracellular space in the brain. This could be important in understanding the blood–brain phenomenon, since the distribution of various ions and other high molecular weight substances in the CNS could be influenced by the localization of charged mucopolysaccharides.

Studies report the isolation of small amounts of heparitin sulfate in the dermis of mammalian skin (545) and chicken skin (546). The skin of hogs (547) and that of neonatal rats (548) yielded heparitin sulfate constituents. It was discovered that, in contrast to heparin, the heparitin sulfate content in rat skin increased with age rather than decreased (549).

Other sources of heparitin sulfate include the pig aorta (550), bovine periodontal membrane (551), human umbilical cord (552), and beef lung tissue (553, 554). Normal urine was found to contain heparan sulfate with a molecular weight of 8000–30,000 and calculated Stokes radius of about 60 Å (555). It was separated from dermatan sulfate and chondroitin sulfate in the urine by a cetylpyridinium method (566), electrophoresis (557), and column chromatography (558, 559). Heparitin sulfate was recently isolated from cotton wick granulation tissue of rats (560) and mouse fibroblast line 3T6 (561). It was found also in young mast cells in addition to heparin (562).

Abnormal excretion in the urine of mucopolysaccharides can be related either to disorders of a hereditary character or to a series of conditions where there is a metabolic defect involving the connective tissue. These pathological conditions have been termed the mucopolysaccharidoses, and several reviews have been written concerning them (33, 563–570). Heparitin sulfate was detected in abnormal amounts in the urine of patients with San Filippo's (566), Morquio's (571), Hunter's (565, 567, 571, 572), Hurler's (563, 567, 568, 573–577), and Ulrich-Scheie's (567) syndromes. Some methods of detection of the mucopolysaccharides in Hunter's syndrome were paper chromatography (578) and ion-exchange chromatography (579). Glycosaminoglycans from the liver and spleen of patients with Hurler's syndrome had much lower molecular weights than normal, consisting of single chains of a molecular weight of about 5000 together with multiples of up to four such chains attached to peptide moieties (571).

The mechanism involved in the pathogenesis of mucopolysaccharidosis was indicated by Hers and Van Hoof (580) as: (*a*) the mucopolysaccharides are synthesized in excess by the fibroblasts, released in the circulating fluids, and then excreted in the urine or taken up by the tissues through endocytosis; or (*b*) the mucopolysaccharides are typical inborn lysomal diseases, similar to type II glycogenosis.



Scheme VIII—Reaction for heparinization of quaternary groups on a polymer

BONDING OF HEPARIN TO SURFACES

With the advent of prosthetic circulatory devices, there has been a search for materials that: (*a*) cause no change in the blood, (*b*) stand up for long periods of time, (*c*) are compatible with tissue, (*d*) can be sterilized, and (*e*) are available both as rigid and flexible materials. Of these prerequisites, the first is probably the most urgent, so that clotting is not initiated at the surface and hemolysis of the red cells does not occur.

Heparin appears to be satisfactory for the blood compatibility requirement, but it must be bonded in some way to other materials. In 1963, studies were conducted with colloidal graphite surfaces which had been rinsed with a surfactant capable of bonding heparin (581). The resistance of this new surface was far greater to clot formation and was much better than plastic or silicone, but small amounts of heparin left the surface during a 10-hr. period. Some of the significant features of these heparinized surfaces are that there are no *in vivo* thrombi and the ζ-potential is less than in a benzalkonium surface without heparin (582). Recent reviews were presented by Gott and Furuse (583), Salzman (584), and Yen *et al.* (585).

Polystyrene, polyethylene, butadiene–vinylpyridine, polyvinyl chloride, silicone rubber, and many other materials can be rendered nonthrombogenic by a physical surface bonding of heparin on quaternary groups attached to the polymer (581–591). The procedure involves chloromethylation, quaternization, and heparinization (592) and the typical reaction is shown in Scheme VIII (593). Tests conducted by Fourt *et al.* (594) of some of these heparin-bearing surfaces on nylon and on heparin base with collodion in dilute films present evidence that heparin on the walls may be more effective than heparin in solution.

Milligan *et al.* (595) believed that the antithrombogenic property is not due to heparin, since most of it is eluted and a colloidal graphite coating alone has similar properties to animal tissues. On the other hand, Usdin and Fourt (596) found only partial dilution of heparin from surfaces exposed to whole blood, plasma, or serum. This seems to be dependent on the particular protein fraction used and the nature of the cationic surface (597).

Heparin, chemically bonded to rigid and flexible materials including regenerated cellulose and other hydroxyl-bearing substrates by amination through graft polymerization with ethylene imine, yielded permanently coated surfaces even under high fluid shear (598). Another aminated surface on glass, made from a polymer of 2-hydroxy-3-methacryloyloxypropyltrimethylammonium chloride, showed platelet adhesion but exhibited no attraction of proteins and platelets to the film when exposed to heparin (599). Britton *et al.* (600) demonstrated that heparinized aminoethylated cellulose tubing at low levels of aminoethylation had excellent mechanical strength as well as antithrombogenic properties.

Rubber surfaces that had good blood compatibility were made by chemically binding heparin onto the surface of a diamine-cured polyurethan rubber, but there was a significant thrombosis rate (601). A nonthrombogenic surface on silicone rubber was made by combining graphite, silicone rubber, benzalkonium chloride, and heparin (602). In addition, Hepacone (a combination of heparin and silicone rubber) and Hepacone-6 (a combination of colloidal graphite, heparin, and silicone) were described by Hufnagel *et al.* (603) for intravascular applications.

Other elastomeric complexes were synthesized by Yen and Rembaum (604) from polyether diisocyanates, which had desirable mechanical properties; it was shown that an ionic bond had been formed between the heparin and the quaternized polyether polyurethan. In addition, a new family of linear elastomeric ionenes or cross-linked homo or block polymers containing nitrogen were synthesized, which were capable of bonding with heparin (605, 606).

The use of heparinized polyester fibers in vascular prostheses is finding increased interest. Najjar and Gott (607) suggested that a heparinized, small diameter, Dacron graft would find excellent applications in lower extremity vascular surgery and possibly in coronary artery bypass. Two methods were developed by Hersh *et al.* (608) for heparinizing polyester fiber. One method involves the fixation by heat of a water-insoluble complex of heparin onto the polyester; the second uses an aminosilane coupling agent to bond the heparin ionically to the protonated amine. Conflicting reports as to which is most effective have been issued. According to Hersh and Weetall (609), the thermal method is better since ionically bound heparin eluted from the Dacron quicker. However, in a later report, Hersh *et al.* (610) inferred that the Dacron grafts that had ionically bound heparin yielded the best results on both tissue and blood compatibility.

Membranes for hemodialysis and encapsulation have been constructed from heparin combined with nylon and cellulose. Luttinger and Cooper (611) devised two methods for binding heparin to nylon membranes. In the first, free amino groups are readily quaternized with methyl iodide and the surface is placed in contact with a dilute aqueous heparin solution; in the second, there is surface attachment of quaternary ammonium salt to the membrane surface, followed by heparinization. A heparin-complexed membrane for coating on microcapsules, which might be useful for treating certain enzyme-deficient diseases, was made by combining a benzalkonium–heparin complex with an ether–colloidin solution (612). Promising nonthrombogenic properties were demonstrated by heparinized DEAE CA-cellulose acetate membranes with an indefinite clotting time (613). Measurement of heparin permeability through cellulose membranes gave variable results, possibly because of the polydispersity of commercial heparin (614).

Heparin also may be easily embedded on the surface of biologically derived collagen membranes, which may permit kidney dialysis (615). The effects of heparin on this membrane showed little influence on the recalcified clotting time until levels of 1–10 mg. of heparin/g. of collagen were reached and then there was an increase (616). For extracorporeal connections and membrane assemblies, as well as for potential intravascular implantation, Merrill *et al.* (617) made a hydrogel by heating a homogeneous water solution of polyvinyl alcohol, heparin, glyceraldehyde, and an acid catalyst.

Some other interesting examples of heparin adsorbed physically and chemically on surfaces may find use in cardiovascular surgery. Flexible and rigid epoxy and urethan polymers containing heparin, chemically and uniformly incorporated throughout and/or ionically complexed to quaternized amine groups, were implanted into the vena cava of dogs with no adverse effects on the blood (618). The innominate artery was reconstructed by Murray *et al.* (619) with the use of a temporary heparin-coated shunt bypass. Merenstein (620) flushed umbilical artery catheters with heparinized saline to maintain potency. The absorption of fibrinogen on mica surfaces was inhibited by heparin (621).

An effect that occurs in polymer films after heparin uptake is that only small amounts of protein or oxide and no detectable amounts of fibrinogen or platelets are absorbed at the polymer solid interfaces (622). Another interesting effect is that materials treated chemically so as to introduce negatively charged groups, such as sulfonate, carboxylate, or heparinate, tend to be antithrombogenic, but the surfaces must have a uniform negative charge (623).

The limitation of heparinized surfaces given by Salzman *et al.* (624) is that deposition of platelets occurs on these surfaces which antagonize the action of heparin. Thrombocytopenia, platelet thrombosis, and embolism can complicate heparinized surfaces or extracorporeal surfaces with large surface areas unless methods are developed to reduce heparin platelet interaction. It is also possible for hemolysis to be induced by heparinized polymers (625). According to Friedman and Leonard (626), platelet adhesion on heparinized and nonheparinized surfaces is similar.

According to Salzman (584), some of the problems that remain to be solved are:

1. What is the nature of events that occur at a blood-solid interface?

2. What conditions must be satisfied for a material to be nonthrombogenic?

Since thrombosis is probably most important among the complications with the development of artificial organs, these problems remain foremost in the minds of workers in this field.

pH–Partition Behavior of Amino Acid-Like β-Lactam Antibiotics

EDWARD D. PURICH*, JOHN L. COLAIZZI▲, and ROLLAND I. POUST

Abstract □ The pH–partition behavior of the ampholyte antibiotics ampicillin, cephalexin, and cephaloglycin, using *n*-butanol or *n*-octanol as the lipid phase and aqueous phosphate buffers, was determined at 37° over a pH range of 4.9–7.9. By comparing the pH–partition behavior of these drugs with computer-generated plots of the concentration of their various ionic species as a function of pH, the anion was found to be the major partitioning species. Minimum partitioning occurred in the isoelectric region, suggesting that the zwitterion did not partition to a significant extent. The pH–partition behavior of L-phenylalanine, as a model ampholyte, was studied over a pH range of 2.0–8.9; although the L-phenylalanine cation partitioned into the lipid phase, the anion partitioned to a significantly greater extent, while the minimum partitioning in the isoelectric region indicated that the zwitterion was a poor partitioning species. Studies of surface activity as a function of antibiotic concentration in phosphate buffers showed that there is a relationship between the partitioning behavior of these antibiotics and either the reduction in surface tension or the resulting surface excess at the lipid–water interface. To account for the difference in the pH–partition behavior of the compounds employed in this study and the previously reported data for the tetracyclines, two general types of ampholytes capable of forming zwitterions should be considered, depending on whether or not significant amounts of uncharged species are present in the isoelectric region. Maximum partitioning into the lipid phase should occur if uncharged species is present in significant concentrations (*e.g.*, tetracycline); the compounds in this study were of the other type and thus showed reduced partitioning in the isoelectric pH region.

Keyphrases □ pH–partition behavior—amino acid-like β-lactam antibiotics (ampicillin, cephalexin, cephaloglycin), relationships among surface tension, drug concentration, and pH □ Antibiotics, amino acid-like β-lactam—pH–partition behavior, relationships among surface tension, drug concentration, and pH □ Ampholyte antibiotics (ampicillin, cephalexin, cephaloglycin)—pH–partition behavior

The drug absorption mechanism by which organic ions are absorbed from the GI tract is difficult to explain solely on the basis of the pH–partition hypothesis (1, 2), which states that a drug is absorbed in its unionized form. However, drugs like tetracycline (3), ampicillin (4), cephaloglycin (5), and cephalexin (6) are always ionized and yet are sufficiently absorbed from the GI tract to produce therapeutic effects. Fiese and Perrin (7), noting that dextromethorphan is absorbed from the stomach even though it is completely ionized, found that absorption of this drug was related to its surface activity. Higuchi suggested the formation of lipophilic ion-pairs as one possible mechanism for the absorption of organic ions (8).

Colaizzi and Klink (9) studied the pH–partition behavior of tetracyclines in *n*-octanol–aqueous buffer systems and found that there was maximum partitioning into the lipid phase at the pH corresponding to maximum zwitterion concentration. To account for these results, they suggested that a relatively more lipophilic intramolecular ion-pair was formed, resulting from partial charge cancellation which produced more partitioning into the lipid phase. The tetracyclines, as noted in their paper (9), have a relatively complex dissociation pattern. A simpler model such as ampicillin, cephalexin, or cephaloglycin, each of which exhibits a diprotic dissociation pattern with the single amino and carboxylic acid group, might better illustrate the pH–partition behavior of ampholyte drugs.

Thus, the purpose of this study was to investigate the pH–partitioning behavior of several amino acid-like β-lactam antibiotics. Due to the potential relationship between surface activity of these drugs and their pH–partition behavior, the relationships between surface tension and drug concentration and pH were also studied.

EXPERIMENTAL

Materials—L-Phenylalanine[1] and samples of ampicillin, cephaloglycin, and cephalexin were used as supplied from their manufacturers[2]. Phosphate buffers of pH 4.9, 5.7, 6.4 ,7.2, and 7.9, which were employed in the partition studies with the antibiotics, had a total molar buffer concentration of 0.035 and an ionic strength of 0.10; phosphate buffers of pH 2.0, 4.7, 5.2, 6.6, and 8.9, with a total molar buffer concentration of 0.030 and an ionic strength of 0.14, were utilized for similar studies with L-phenylalanine. Sodium chloride[3] was added to the buffers whenever necessary to adjust the ionic strength. The buffer of pH 2.0 was prepared with phosphoric acid[3] and sodium phosphate monobasic[3]. The buffers for pH 4.7, 4.9, 5.2, 5.7, 6.4, 6.6, 7.2, and 7.9 were prepared with anhydrous dibasic sodium phosphate[3] and sodium phosphate monobasic, while the pH 8.9 buffer was prepared with anhydrous dibasic sodium phosphate and tribasic sodium phosphate[3]. All buffer pH's were measured at 25° using a suitably standardized pH meter[4].

The water for these experiments was prepared by passing distilled water through two glass percolator columns containing a mixture of anionic and cationic resins[5]. The conductivity, as determined with a conductivity meter[6], was maintained below 0.1 p.p.m. (as sodium chloride).

Procedure for Determination of Apparent Partition Coefficients of L-Phenylalanine and of Penicillin and Cephalosporin Antibiotics—Exactly 8.84×10^{-5} mole of L-phenylalanine, 5.72×10^{-4} mole of

ampicillin, or 3.82×10^{-6} mole[7] of the particular cephalosporin was dissolved in sufficient buffer solution to give a total volume of 100 ml. Exactly 15 ml. of *n*-octanol[8] or *n*-butanol[8] was then placed into each of three 50-ml. glass-stoppered conical flasks, and exactly 15 ml. of the previously prepared drug-buffer solution was added to each of the three flasks; 15 ml. of the drug-buffer solution was placed into a fourth flask as a control. The flasks were stoppered and placed into a metabolic shaking incubator[9], regulated at 37 ± 0.1°, and set to maximum shaking speed. Every 15 min. each flask was individually handshaken to ensure rapid distribution between the two solvent phases and then immediately returned to the metabolic shaker.

When equilibrium was achieved[10], a 10-ml. sample of the aqueous phase was withdrawn from each flask. Its absorbance was determined spectrophotometrically[11] at 260 nm. (257 nm. for L-phenylalanine) using a water blank, and its concentration was determined from the appropriate Beer's law plot. By using the concentration of the drug in the fourth flask and the concentration of drug in the aqueous buffer phase, the concentration of drug in the lipid phase was calculated. The concentration of drug in the lipid phase and that remaining in the aqueous phase were utilized to calculate the *n*-octanol–aqueous buffer apparent partition coefficients (or the *n*-butanol–aqueous buffer apparent partition coefficients). The results of the partitioning studies are summarized in Tables I and II. UV spectral measurements revealed no evidence of degradation of the compounds studied during the partitioning experiments.

Procedure for Determination of Reduction of Surface Tension of Buffered Solutions of Ampicillin, Cephalexin, and Cephaloglycin—Buffered solutions of the drugs were prepared using the phosphate buffers previously prepared for the partition studies in concentrations ranging from 0.25 to 7 mg./ml., depending on the drug[12]. The surface tension of the resulting solutions was determined at 25° using a previously calibrated tensiometer[13] equipped with a platinum-iridium ring with a mean circumference of 5.985 cm.

RESULTS AND DISCUSSION

The apparent partition coefficients for ampicillin, cephaloglycin, cephalexin, and L-phenylalanine as a function of pH can be found in Figs. 1–3. To determine the influence of the different ionic species (cation, zwitterion, and anion) on the apparent partition coefficient, the percent of total concentration of each ionic species was calculated as a function of pH. These calculations were performed by a computer program utilizing Eqs. 1–3 for a diprotic acid, where K_1 and K_2 are the acidity constants (10):

$$\% \text{ cation} = (H_3O^+)^2\, 100/[(H_3O^+)^2 + K_1(H_3O^+) + K_1K_2] \quad \text{(Eq. 1)}$$

$$\% \text{ zwitterion} = K_1(H_3O^+)100/[(H_3O^+)^2 + K_1(H_3O^+) + K_1K_2] \quad \text{(Eq. 2)}$$

$$\% \text{ anion} = K_1K_2\, 100/[(H_3O^+)^2 + K_1(H_3O^+) + K_1K_2] \quad \text{(Eq. 3)}$$

The calculated concentrations were then used to prepare Calcomp[14] plots for each compound (Figs. 4–7).

The apparent partition coefficients for ampicillin, cephalexin, and cephaloglycin with *n*-butanol as the lipid phase, plotted as a function of the pH of the aqueous phase, are found in Fig. 1. When the percent of total concentration of each of the drug's ionic species is compared with Fig. 1 from pH 4.9 to 8.0, the apparent partition coefficients are found to increase as the concentration of anion increases.

For ampicillin the percent of total concentration as zwitterion decreases from 99% at pH 4.9 to 12% at pH 7.9, while the percent of total concentration as anion increases from 0 to about 90% over the same pH range. After noting the variation in the apparent partition

coefficients over the same pH range, the anion appears to be the partitioning species. Similar results occurred for cephaloglycin and cephalexin, but, in addition, the cation species (not present in significant concentration over the pH range employed in the partitioning studies for ampicillin) appears to be inhibiting the partitioning into the lipid phase for these drugs.

For cephalexin the percent of total concentration as cation is approximately 60% at pH 4.9 and 0% at around pH 7.5. If it is assumed that the cephalexin anion should partition better than ampicillin anion[15], then the smaller apparent partition coefficients for cephalexin in the pH range from 4.9 to 7.2 may be attributed to the cation forming an ion-pair with the anion and thus reducing the effective concentration of anion that may partition. At pH 4.9 and 5.7, the apparent partition coefficients for cephaloglycin are smaller than for ampicillin; at all other higher pH values, the apparent partition coefficients of cephaloglycin are greater than for ampicillin. The smaller apparent partition coefficients may also be due to the significant concentration of cation reducing the amount of anion available for partitioning.

The apparent partition coefficients for the antibiotics as a function of pH, using *n*-octanol as the lipid phase, are shown in Fig. 2.

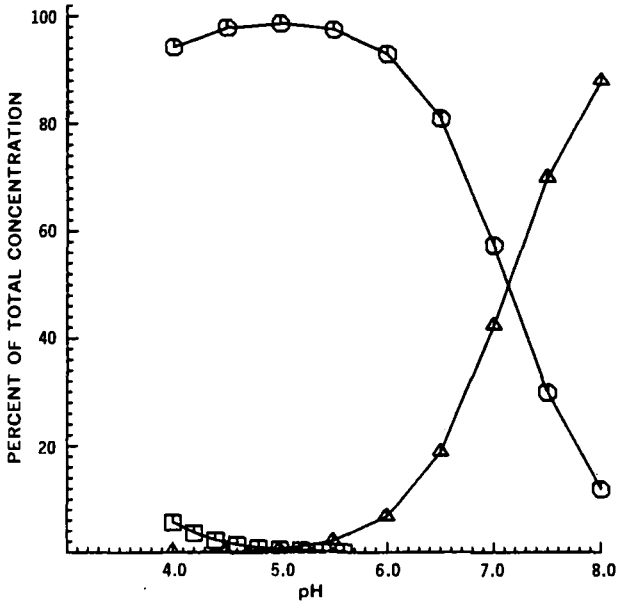

Figure 4—*Percent of total concentration as a particular ionic species of ampicillin in aqueous solution as a function of pH at 25°. Key:* □, *ampicillin cation;* ○, *ampicillin zwitterion; and* △, *ampicillin anion.*

[15] This would be a reasonable assumption since at pH 7.9, where essentially only anion is present for both drugs, the apparent partition coefficient for cephalexin is almost double that of ampicillin.

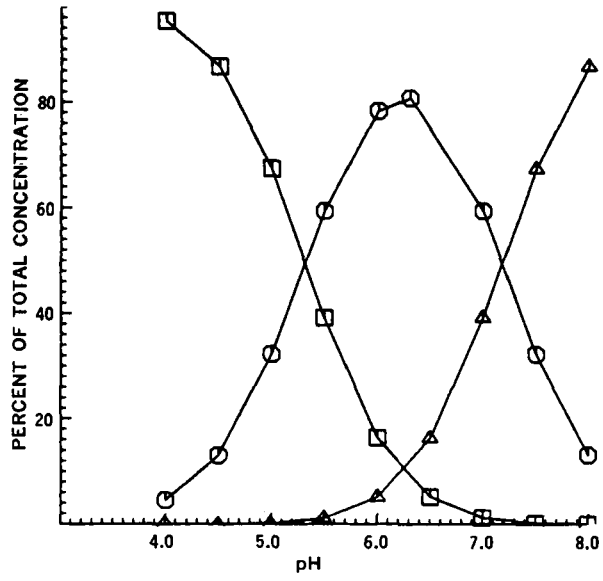

Figure 5—*Percent of total concentration as a particular ionic species of cephalexin in aqueous solution as a function of pH at 25°. Key:* □, *cephalexin cation;* ○, *cephalexin zwitterion; and* △, *cephalexin anion.*

In this system, which is more lipophilic than the *n*-butanol–aqueous buffer system, ampicillin partitions best but the apparent partition coefficients are substantially less than when *n*-butanol is used as the lipid phase. However, the anion appears to be the partitioning species since the apparent partition coefficients appear to be related to the anion concentration. In this system the effect of cation on the partitioning of anion for cephalexin and cephaloglycin is not clear, but it may account for the larger apparent partition coefficients with cephaloglycin than with cephalexin at pH 6.4 and 7.2, since cephalexin has a larger apparent partition coefficient at pH 7.9.

The differences between the apparent partition coefficients in the *n*-butanol–buffer system as compared with those in the *n*-octanol–buffer system are probably due to the large amount of water present in the buffer-saturated *n*-butanol phase, which would tend to increase the amount of ions in the *n*-butanol phase by increasing the dielectric constant of the *n*-butanol phase.

Since the acid instability of the β-lactam antibiotics would cast doubt on the determination of the apparent partition coefficients at a pH where only cation was in high concentration, a model com-

pound without such a limitation was desired. Through the use of L-phenylalanine, a relative comparison of the effects of cation, zwitterion, and anion on the apparent partition coefficients in Fig. 3 with the concentration of the ionic species in Fig. 7 shows that the minimum values for the apparent partition coefficients occurred at the maximum zwitterion concentration. Comparing the apparent partition coefficient at pH 2.0, where the cation species is 80% of the total concentration, to pH 8.9, where the anion concentration is about 50% of the total concentration, suggests that the anion partitions better than the cation even though the cation concentration is 1.6 times greater than the anion.

The partitioning results indicate that the zwitterion is not the dominant partitioning ionic species. This would seem to be contrary to the fact that these compounds exhibit minimal water solubility at the isoelectric point (11). However, this decrease in water solubility is a reflection of the high crystal lattice energy of the zwitterion species as compared to its heat of solution in water and not of an increase in lipid solubility (12). The oil–water partition coefficient would be expected to decrease to a minimum at the isoelectric point since the lipid layer, with its low dielectric constant, would have less tendency to solvate the dipolar ion (zwitterion) than water.

Colaizzi and Klink (9) reported maximum partitioning into the *n*-octanol phase in the pH range where the zwitterion concentration of tetracycline and its derivatives would be at its maximum. These results, also seemingly contradictory to the findings reported here, are probably a result of the apparent fact that for tetracycline a significant concentration of the uncharged molecular species exists in equilibrium with the zwitterion present (Fig. 7 of *Reference 9*). This uncharged species would be expected to be highly lipid soluble and thus partition into the *n*-octanol phase. Leeson *et al.* (13) reported the K_{a1} for tetracycline hydrochloride and tetracycline methiodide to be 4.68×10^{-4} and 2.76×10^{-4}, respectively. As stated in their paper (13), the quaternization of the dimethylamino group of tetracycline hydrochloride to form tetracycline methiodide destroys the dimethylamino acidic center of tetracycline hydrochloride but should not affect other acidic centers since the dimethylammonium group should be electronically similar to the quaternary ammonium group. Therefore, the K_{a1} of tetracycline methiodide should represent the sum of the microionization constants ($k_1 + k_2$) associated with the equilibrium of the cation species with the zwitterion species of tetracycline hydrochloride. The difference in acidity between K_{a1} of tetracycline hydrochloride and tetracycline methiodide (1.92×10^{-4}) should approximate the contribution of the proton associated with the dimethylamino group in tetracycline hydrochloride, *i.e.*, the microionization constant k_3 associated with the equilibrium of the cation species with the uncharged species of tetracycline hydrochloride. Since at any pH, each of the isoelectric forms of tetracycline hydrochloride is in equilibrium with the cation species, they must also be in equilibrium with each other.

Table III—Surface Excess as a Function of pH for Ampicillin, Cephalexin, and Cephaloglycin

Compound	pH	Surface Excess, moles/cm.^{2}, $\times 10^{-11}$
Ampicillin	4.94	30.5
Ampicillin	6.49	16.6
Ampicillin	7.20	9.4
Ampicillin	7.94	8.4
Cephalexin	4.94	5.27
Cephalexin	6.49	5.70
Cephalexin	7.20	5.79
Cephalexin	7.94	6.49
Cephaloglycin	4.94	6.43
Cephaloglycin	6.49	9.11
Cephaloglycin	7.20	9.52
Cephaloglycin	7.94	9.67

The ratio between ($k_1 + k_2$) and k_3, which is independent of pH, should represent the tautomeric equilibrium constant (K_z) between the zwitterion species and uncharged species of tetracycline hydrochloride (14).

The value of K_z calculated[16] for tetracycline is 1.44. From this value for K_z, it is a simple matter to calculate[17] that 41% of the isoelectric species will be in the uncharged form. Thus the enhanced partitioning into the lipid phase when the isoelectric forms are in maximum concentration may be due to the uncharged tetracycline molecules. Colaizzi and Klink (9) also reported that the tetracycline methiodide did not partition into the *n*-octanol phase. This would be expected on the basis of the explanation just put forth, since the drug cannot form an uncharged species (although it does form a zwitterion).

In contrast to tetracycline hydrochloride, the pH–partition experiments of this study tend to indicate that very little uncharged species is present in the cases of ampicillin, cephalexin, cephaloglycin, and L-phenylalanine. This was borne out by Hou and Poole (12), who reported that ampicillin, like other amino acids in aqueous solutions at 25° (*e.g.*, L-phenylalanine), exists essentially as zwitterions within the isoelectric region. Similar behavior would be expected for cephalexin and cephaloglycin due to the similarity in structure with ampicillin. This lack of significant amounts of uncharged lipophilic species would also explain the significantly lower oral absorption observed with ampicillin as compared to its acyloxymethyl esters (15), which can exist as an uncharged molecule.

It can be rationalized that the surface activity of the various dissociative species of the drugs employed in this study may be influencing the apparent partition coefficient by changing the surface excess or reducing the interfacial tension at the interface between the lipid and the aqueous buffer phases. Because the concentrations of the various dissociative species change with pH, the surface activity may not remain constant throughout the pH range employed in the partition studies. To evaluate these affects on the pH–partition studies, the Gibbs adsorption equation (4), which defines surface excess as a function of concentration of drug and surface tension, was used (16):

$$s = (-c/RT)(dv/dc)_T \qquad \text{(Eq. 4)}$$

where s is the surface excess in moles/cm.^{2}, R is the universal gas law constant in ergs mole^{-1} deg.$^{-1}$, T is the absolute temperature, c is the concentration of drug in the bulk solution in moles/l., and v is the surface tension in dynes/cm.

The slopes of the regression lines of surface tension as a function of drug concentration at pH 4.9, 6.4, 7.2, and 7.9 were substituted into Eq. 4, along with appropriate values for R and T, to obtain the surface excess for each drug at a concentration of 1 mg./ml. The

[16] $K_z = (k_1 + k_2)/k_3 = 2.76 \times 10^{-4}/1.92 \times 10^{-4} = 1.44$.

[17] K_z = zwitterion species/uncharged species = 1.44. Let zwitterion species = x. Then the percent of total isoelectric concentration as uncharged species would be $(100 - x)$. $K_z = x/(100 - x) = 1.44$, where $x = 59\%$ of the isoelectric concentration as zwitterionic species. Then uncharged species = $(100 - 59) = 41\%$ of isoelectric concentration.

values for surface excess at each pH are summarized in Table III for each drug. The regression lines from which the slopes were calculated had linear correlation coefficients ranging from −0.879 to −0.994.

The surface excess increased for cephalexin and cephaloglycin as the buffer became more alkaline, while for ampicillin the opposite effect was observed. The molar surface tension reduction for most amino acids is at its minimum in the isoelectric region and increases when the pH is increased or decreased from the isoelectric point (17). The observed values for surface excess may account for some of the larger increases in the apparent partition coefficients for cephalexin and cephaloglycin as pH increases from 4.9 to 7.9, as compared to the similar changes observed for ampicillin. The apparent partition coefficients of cephalexin and cephaloglycin in *n*-butanol–aqueous buffer are, respectively, approximately 11 and 16 times greater at pH 7.9 as compared to pH 4.9. For ampicillin in the same partitioning system, only a threefold increase was observed. It may be that an increase in surface excess and a reduction in surface tension occurring in concert with the anion concentration approaching its maximum, as observed with cephalexin and cephaloglycin, enhance the partitioning of the anion into the lipid phase. However, with ampicillin, the largest surface excess (maximum reduction in surface tension) occurs when the zwitterion concentration is at its maximum and the anion concentration is at its minimum. This could explain the observation that there is much less of a difference in the partitioning coefficients of ampicillin over the pH range studied, as compared to the difference observed with cephalexin and cephaloglycin over the same pH range.

In summary, the partitioning results for ampicillin, cephalexin, and cephaloglycin indicate that the anion is the partitioning species. The cation appears to partition to some extent in the case of L-phenylalanine, but it tends to inhibit the partitioning of the anion for the cephalosporins. The zwitterion does not appear to partition to any extent for any of the compounds studied. The surface activity of the drugs appears to modify the partitioning results by increasing the surface excess of the drug and/or by reducing surface tension at the aqueous buffer–lipid interface.

Pharmacokinetics of Trichloroethanol and Metabolites and Interconversions among Variously Referenced Pharmacokinetic Parameters

EDWARD R. GARRETT[▲] and HOWARD J. LAMBERT

Abstract □ The pharmacokinetics of intravenously administered trichloroethanol, chloral hydrate, sodium trichloroacetate, and trichloroethanol glucuronide were studied in the dog with developed GC analyses of blood, urine, and feces, and analyzed with aid of analog and digital computation. Trichloroethanol pharmacokinetics were evaluated at multiple-dosage levels and showed distribution from a central compartment assignable to extracellular body water into readily available and less available tissues assignable to total body water and lipoidal and other tissues. The major route of removal of trichloroethanol in the dog was by conjugation to the glucuronide, and the first-order rate constants of this metabolic route were dose dependent but did not appear to be a consequence of enzymic saturation or change in apparent volumes of distribution with dose. A possible explanation is that the hepatic lipid–water ratio may vary with the dose of trichloroethanol. The formed trichloroethanol glucuronide, after release from the liver, was rapidly distributed in the extracellular body water of the dog and rapidly eliminated in the urine by glomerular filtration and tubular secretion. Biliary elimination of the glucuronide accounted for about 5% of an intravenous dose of trichloroethanol. Saturation of the bile secretory mechanism was demonstrated at higher trichloroethanol doses, *e.g.*, 100 mg./kg., but the absence of trichloroethanol and its glucuronide in the feces may be explained by hydrolysis of the biliary glucuronide in the GI tract with subsequent reabsorption of the formed trichloroethanol, *i.e.*, an enterohepatic shunt. No assayable trichloroacetic acid was observed in the blood or urine of dogs dosed with trichloroethanol. A long apparent disposition half-life of 75 hr. was observed after intravenous administration of sodium trichloroacetate; this can be explained by the extensive tissue binding of trichloroacetate which gave high apparent volumes of distribution. Intravenously administered chloral hydrate was rapidly and quantitatively converted to trichloroethanol in the dog, with an apparent half-life of 3 min. Protein binding of trichloroethanol and its glucuronide (about 35%) was determined. Although the glucuronide did not partition into the red blood cells, the trichloroethanol did so instantaneously, with a partition coefficient of 2.1 in favor of the red blood cells. Since apparent volumes of distribution and microscopic pharmacokinetic rate constants have quantitative values that vary widely, depending on whether they are referenced to total blood, total plasma, or unbound drug in plasma concentrations, a detailed analysis of the conversions among these variously referenced constants was made and applied to the data of these studies. Estimates of the microscopic rate constants and apparent volumes of distribution referenced to unbound drug in plasma have the most valid physiological significances. These are complex functions of the hematocrit, the degree of protein binding, the true volume of plasma or blood in the animal, and the red blood cell/plasma partition coefficient when the drug is assayed per milliliter of whole blood or per milliliter of plasma. The awareness of these facts will necessitate extensive recalculation of many pharmacokinetic constants now given in the literature.

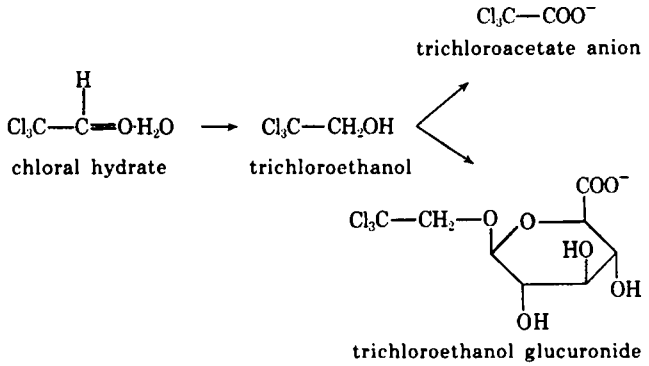
Keyphrases □ Trichloroethanol—pharmacokinetics and metabolites after intravenous administration, dogs □ Chloral hydrate—pharmacokinetics and metabolites after intravenous administration, dogs □ Pharmacokinetics—trichloroethanol, chloral hydrate, and metabolites after intravenous administration, dogs □ GLC—analysis, trichloroethanol and metabolites

The hypnotic effect of 2,2,2-trichloroethanol was first demonstrated in 1882 (1). It was previously reported that the product isolated from the urine of patients dosed with chloral hydrate was a conjugation product of trichloroethanol and glucuronic acid (2). The conjugated glucuronic acid was measured in rabbit urine, and it was concluded that chloral hydrate and trichloroethanol are both converted to the conjugated product in the same proportions (3).

Butler (4) and Marshall and Owens (5) noted that the CNS depression which follows the ingestion of chloral hydrate is due principally, if not entirely, to the trichloroethanol formed by reduction *in vivo*. The same investigators (4–6) demonstrated that the principal metabolic products of trichloroethanol are trichloroacetic acid and trichloroethanol glucuronide (Scheme I). Those metabolites did not appear to have hypnotic activity.

The major route of trichloroethanol metabolism in dogs was glucuronidation, and more than 60% of the dose was found in the urine as the glucuronide (5). This was more than twice that found in the urine of human subjects (5). Some of the glucuronide formed from an intravenous dose of trichloroethanol was secreted and concentrated in the bile of dogs (6). A small fraction of the dose was excreted unconjugated. Comparison of the species difference in trichloroacetate anion formation was stated to be difficult due to its probable metabolic destruction by the dog (5).

This paper presents the results of studies on the pharmacokinetics of trichloroethanol and its metabolites in the dog at various doses administered intravenously. These pharmacokinetic studies were based on analyses expressed in terms of total concentrations of drugs or metabolites in blood that give apparent volumes of distribution and microscopic rate constants referenced to such concentrations. These are different values than would be obtained if the analyses were expressed in terms of total concentrations or unbound concentrations in plasma. The latter values would be most consistent with the physiological referents and the physicochemical realities of drug disposition in the



Scheme I

body. The literature is replete with the presentation of such parameters variously referenced. Since the calculation of one set of reference parameters from another is necessary to compare those of the same and different drugs within and among species, rigorous expressions of such mathematical conversions are developed in a special section and applied to the pharmacokinetic data of this paper. The protein binding and red blood cell partitions necessary for these applications are determined.

The complete model for the pharmacokinetics of trichloroethanol and its metabolites that will be outlined here did not spring into being intuitively as a full-fledged entity. It had to be developed by sequential processes of systems analyses that included graphical analyses, analog simulation, and digital computation in accordance with a consistent model. A section of this paper delineates the systematic technological patterns and sequences of such logical analyses used in model construction and quantification.

The pharmacokinetic studies of trichloroethanol at various intravenously administered dose levels clearly show that the drug distributes by first-order processes into both a shallow and a deep compartment and that the only significant route of removal of trichloroethanol in the dog is by conjugation to the glucuronide. The apparent first-order rate constants of trichloroethanol are dose dependent. This does not appear to be due to changes in the apparent volumes of distribution of the major compartments, nor is it a consequence of enzyme saturation. The latter is denied by the facts that first-order processes persist at all dose levels and that simultaneous challenging *in vivo* with the potent glucuronidation inhibitor sulfobromophthalein indicated a large capacity for glucuronidation. However, an excessively large dose administered did decrease the rate of glucuronidation.

It is shown that the rate of appearance of trichloroethanol glucuronide in the body did not reflect the rate of loss of trichloroethanol. The glucuronide's appearance was delayed, and the maximum blood level was lower than would be predicted from the instantaneous loss of the alcohol. This implies an intermediate storage depot which can be assigned to the liver. The results of balance studies across the liver of a surgically modified dog are consistent with this hypothesis. It is shown that the phenomenon of trichloroethanol dose-dependent pharmacokinetics can be rationalized by postulating that the hepatic lipid–water ratio varies with the dose of trichloroethanol and that this effect on microscopic redistribution of trichloroethanol in the liver from an aqueous metabolic biophase modifies the metabolism rate.

It is explained that the renal clearance of glucuronide that decreases with the higher glucuronide concentration in blood, which results from higher doses of trichloroethanol, can be rationalized by postulating the saturation of the tubular secretory pathway for glucuronide.

The pharmacokinetic study on intravenously administered trichloroethanol glucuronide clearly shows that it is primarily eliminated by filtration and tubular secretion. Although about 5% of the dose is biliary excreted, the lack of significant glucuronide in the feces implicates extensive GI solvolysis and reabsorption of the resultant trichloroethanol. It is demonstrated that saturation of the bile secretory mechanism for glucuronide occurs at higher trichloroethanol doses as well as increased bile flow rates.

The pharmacokinetic studies on intravenously administered trichloroacetic acid demonstrate long dose-independent apparent half-lives of elimination, which can be rationalized by the high apparent volumes of distribution assignable to extensive tissue binding.

The pharmacokinetic studies of intravenously administered chloral hydrate demonstrate that it is rapidly and quantitatively converted to trichloroethanol in the dog, with an apparent half-life of 3 min.

EXPERIMENTAL

Materials—The following were used: glacial acetic acid[1], chloral hydrate USP[1], 5% trichloroacetic acid solution[1], chlorobutanol USP[1], anhydrous ether[2], anhydrous sodium acetate (analytical reagent)[3], mepesulfate (sodium salt of sulfated polygalacturonic acid methyl ester methyl glycoside)[4], and sulfosalicylic acid[5]. The β-glucuronidase was bovine liver B grade and had 50,000 units/vial or 360 Fishman units/mg.[6]. Sulfobromophthalein injection was 50 mg./ml.[7]. The heparin solution had 10,000 USP units/ml.[8]. The sodium pentobarbital[9] was in a sterile solution of 50 mg./ml. The trichloroethanol[6,10] was redistilled at 153° before use. The trichloroethanol glucuronide was the sodium salt of 95% purity on assay (7) and was isolated from the urine of dogs given repeated parenteral doses of trichloroethanol. The isolation procedure was described by Seto and Schultze (8). The acidified glucuronide melts at 142° and its triacetyl methyl ester melts at 158° (8).

Analytical Methods—Sensitive and specific GC assays for trichloroethanol, its chlorohydrate precursor, and its metabolites, trichloroethanol glucuronide and trichloroacetic acid, were described previously (7). These methods were modified as described below.

A gas chromatograph[11] equipped with an electron-capture detector and a recorder[12] was used. A pulse interval of 15 μsec. gave linear calibration curves for all physiologically encountered concentrations of trichloroacetic acid, trichloroethanol, and its glucuronide.

The columns used for all studies were either 1.23- or 2.46-m. (4- or 8-ft.) stainless steel tubes, 0.63-cm. (0.25-in.) diameter, containing 20% Carbowax 20M on 60–80-mesh Chromosorb W.

Conditions—The temperature conditions used for assay of trichloroethanol and trichloroacetic acid were: injection port, 160°; column, 135°; and electron-capture detector, 190°. The carrier gas (helium) flow rate was 60 ml./min. (at 50 psig.), while the purge gas (90% argon–10% methane) was fixed at 140 ml./min. (at 30 psig.).

Blood and Urine Assays—Trichloroethanol, chloral hydrate, and trichloroacetic acid were extracted from 1.00 ml. of whole blood or urine admixed with 1.00 ml. of distilled water and 1.00 ml. of a 10% solution of sulfosalicylic acid containing 0.72 mg. of chlorobutanol/100 ml. The extraction was effected with 2.0 ml. ether after protein precipitation with the sulfosalicylic acid. Chlorobutanol was used as an internal standard. The two-phase mixture, in an injection vial of 6- or 10-ml. capacity sealed with a rubber stopper and an aluminum crimped cap, was agitated for 1 min. on a mixer[13] and centrifuged[14]

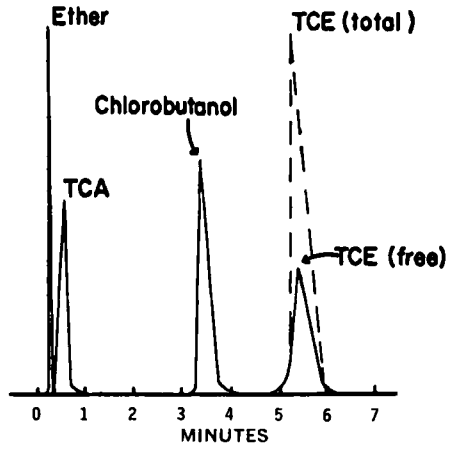

Figure 1—*Typical chromatogram obtained after injection of a 5-μl. aliquot of a 2-ml. ether extract of an acidified 1-ml. blood sample which contained trichloroethanol (TCE), trichloroacetic acid (TCA), and trichloroethanol glucuronide (TCE-G). The solid curve, TCE (free), is a measure of the free trichloroethanol present in the sample, while the broken curve, TCE (total), is a measure of the total trichloroethanol obtained after glucuronidase hydrolysis of the trichloroethanol glucuronide present in the sample. The chlorobutanol was added to the blood sample as an internal standard and permitted calculation of peak height ratios.*

for 2–5 min. until the ether–water emulsion separated and two distinct phases reappeared. The peak height ratios of the peak assigned to the substrate to the peak assigned to the chlorobutanol were used as assay parameters after the injection of a 5-μl. aliquot of the ether solution (Fig. 1).

Trichloroethanol glucuronide in 1.0 ml. of blood or of appropriately diluted urine (1:10, 1:100, or 1:1000) was hydrolyzed with 360 Fishman units (1 mg.) of β-glucuronidase (1.0 ml. of 0.1 *M* pH 4.5 acetate buffer with 1.0 mg. of β-glucuronidase) by incubating at 37°, pH 4.5, for 48 hr., and the trichloroethanol formed was assayed as already described. The difference in the trichloroethanol–chlorobutanol peak height ratios obtained before and after enzymatic hydrolysis was the trichloroethanol glucuronide–chlorobutanol peak height ratio.

The optimum time for complete hydrolysis of trichloroethanol glucuronide by β-glucuronidase was determined by adding a small amount of the purified sodium salt of the glucuronide to urine. One-milliliter aliquots of this urine were treated and incubated as already described for 30, 60, 94, 125, and 180 min. and for 5.0, 8.7, 19.8, 24.5, 27, 31, 50, and 147 hr. Each sample removed at the specified time was immediately refrigerated. The refrigerated samples were chromatographically analyzed for trichloroethanol on the day following the taking of the last sample.

Calibration curves for the substrate were established by adding appropriately graded amounts to the pertinent biological fluid and assaying by the described methods. These methods differed from those previously described (7) in that chlorobutanol was included in the aqueous solution of sulfosalicylic acid added rather than in the ether used for extraction. Also, in the current assay, trichloroacetic acid was directly extracted from acidified blood or urine and subsequently gas chromatographically analyzed in the ether solvent. The previous method cited (7) used an alkaline decarboxylation which yielded assayable chloroform.

The reliability of the assays for trichloroethanol was determined by conducting these analyses on blood (from four different dogs) to which 2.94 mcg./ml. of trichloroethanol had been added. Six samples of similarly spiked, freshly drawn heparinized blood were placed at 5° and analyzed at daily intervals against calibration curves prepared daily.

Protein Binding—Equilibrium dialysis experiments were run with trichloroethanol and its glucuronide to determine protein binding to dog plasma. Two-milliliter samples of dog plasma were separated from whole dog blood by centrifugation and placed inside sealed dialysis sacs[15]. Dialyses were run at 5° for 48 hr. against 10.0-ml. solutions (5, 50, and 500 mcg. trichloroethanol/ml.) in pH 7.4 phosphate buffer. A control dialysis was run at each trichloroethanol concentration with a sac containing only 2.0 ml. of buffer. Aliquots were removed from the solutions outside and inside the dialysis sacs, appropriate dilutions were made, samples were assayed, and the fractional binding was calculated.

Trichloroethanol glucuronide binding to plasma protein was estimated by dialysis of pooled blood plasma containing the glucuronide against pH 7.4 buffer.

Determination of Red Blood Cell/Plasma Distribution of Drug—Since trichloroethanol has high solubility in nonaqueous solvents (9), it was possible that a distribution between red blood cells and plasma would occur when the drug was introduced into a volume of whole blood. Aliquots (0.1 ml.) of trichloroethanol solutions were mixed with 10.0 ml. of heparinized dog blood to give final concentrations of 0.294 and 2.94 mcg./ml., and 1.0 ml. of each blood sample was removed for assay. The remaining 9.0-ml. portions were centrifuged until complete separation of red blood cells occurred and a clear, colorless plasma layer remained. A 1.0-ml. plasma sample was then removed from each tube and assayed. The hematocrit was determined with a hematocrit tube.

Three further determinations were carried out on pooled blood samples obtained from the pharmacokinetic experiments on two other dogs which had been administered 50 mg./kg. of trichloroethanol intravenously. One dog had received 50 mg./kg. of sulfobromophthalein in combination.

Similar studies on red blood cell/plasma distribution were conducted with trichloroethanol glucuronide.

Pharmacokinetics of Trichloroethanol—Female mongrel dogs, 10–20 kg., were fasted for 24 hr. with water *ad libitum*. At 8:30 a.m. on Day 0 (the day of the experiment), the animal was weighed and anesthetized with an intravenous or intramuscular injection of pentobarbital, 30 mg./kg.

One of three pairs of veins was used for cannulation and blood sampling: the external jugular veins of the neck, the cephalic veins of the forelegs, or the lateral saphenous veins of the hind legs. The cannula was frequently flushed with physiological saline solution but was filled with whole blood before 5-ml. samples were taken. These samples were put in 10.0-ml. injectable vials containing 0.1 ml. of 1% mepesulfate solution to prevent blood clot formation.

At least 1 hr. after the pentobarbital was administered, control urine and blood samples were taken. When the animals showed signs of movement and diminished depth of anesthesia, a volume of 5.0% trichloroethanol solution equivalent to the desired dose was injected within 40 sec. The cannula was flushed with 10–20 ml. of physiological saline within an additional 20 sec.

A typical sampling schedule after the time of the saline flush of the trichloroethanol dose was: 2, 4, 6, 8, 10, 15, 30, 45, 60, 75, 90, 105, and 120 min. and then at 30-min. intervals to 720 min. Further samples were taken during the 24–120-hr. interval in several experiments.

Urine samples were collected at least hourly *via* an indwelling urethral catheter in 100-ml. graduated cylinders for 12 hr. on Day 0. When possible, feces were collected after 12 hr. Total urine and feces were collected at t = 24 hr. and at 24-hr. intervals thereafter until no further traces of trichloroethanol or its metabolites were found upon assay.

A minimal period of 14 days was allowed between any two trichloroethanol pharmacokinetic experiments on the same animal. Samples were analyzed for concentrations of trichloroacetic acid, trichloroethanol, and its glucuronide.

Each of four female dogs, A, B, C, and D, received various doses of trichloroethanol ranging from 10 to 150 mg./kg. All studies were grouped within 4 months to avoid possible age, weight, or seasonal effects on the animals.

Pharmacokinetics of Trichloroethanol Glucuronide—Two experiments were performed with intravenous administration of a solution of sodium trichloroethanol glucuronide (100 and 450 mg.) in an anesthetized dog. Blood and urine samples were taken at the intervals previously described for experiments with trichloroethanol and assayed for both trichloroethanol and its glucuronide.

Pharmacokinetics of Trichloroacetic Acid—Twenty milliliters of a 5% trichloroacetic acid solution (1.0 g.) was brought to pH 7.0 with sodium hydroxide and intravenously administered to an anesthetized dog. Blood samples were removed at regular intervals for the first 12 hr. of the experiment, at t = 24 hr., and at 24-hr. intervals thereafter until t = 480 hr.; these samples were assayed for tri-

[15] 0.94-cm. (0.37-in.) flat width, Visking Co., Chicago, Ill.

chloroacetic acid. A second experiment was performed with a 100-mg. dose of trichloroacetic acid.

Pharmacokinetics of Chloral Hydrate—A dose of 500 mg. chloral hydrate (dissolved in physiological saline) was administered through an indwelling jugular vein catheter to a lightly anesthetized dog. Blood samples were taken at intervals and urine samples were taken hourly for a total of 2 hr. and assayed for trichloroethanol, its glucuronide, and for chloral hydrate and trichloroacetic acid.

Studies on Biliary Excretion of Trichloroethanol and Its Glucuronide—Two dogs were anesthetized and laparotomized, and the common bile duct was exposed and cannulated. The renal circulation was not disturbed. The incision was closed with wound clips and covered with gauze pads wet with warm physiological saline solution. Trichloroethanol was injected 1 hr. after surgery was completed.

To obtain maximal data from these experiments, two doses of trichloroethanol were administered in each experiment. In the first experiment, 150 mg. of trichloroethanol (11.6 mg./kg.) was given at $t = 0$ and 600 mg. (46 mg./kg.) at $t = 245$ min. In the second experiment, 500 mg. of trichloroethanol was given at $t = 0$ and 1000 mg. at $t = 370$ min.

Blood samples were collected from the jugular vein and urine samples were collected from a urethral cannula. Bile was collected hourly and assayed for trichloroethanol and its glucuronide in the same manner as urine.

At the end of each experiment, the animal was sacrificed. Gallbladder bile was removed for assay from the second animal but not from the first.

Possible *In Vivo* Inhibition of Trichloroethanol Glucuronidation by Sulfobromophthalein—Dog E, a 10-kg. female, was anesthetized and 600 mg. of trichloroethanol was administered intravenously at $t = 0$. At $t = 250$ min., a second dose of 600 mg. trichloroethanol was given along with 100 mg. of sulfobromophthalein (10 mg./kg.). In addition, a constant intravenous drip of approximately 0.6 mg. sulfobromophthalein/min. was also maintained until $t = 490$ min. The dose of sulfobromophthalein used was twice that recommended (10) for studies on hepatic function.

In a second experiment with the same dog, 600 mg. of trichloroethanol was given at $t = 0$ and samples were taken for 300 min. At $t = 320$ min., a second 600-mg. dose of trichloroethanol was given, which was followed immediately by a dose of 500 mg. sulfobromophthalein. In addition, a constant intravenous infusion of 3 mg. sulfobromophthalein/min. was maintained until $t = 500$ min.

In both experiments, blood and urine samples were taken at regular intervals and assayed for trichloroethanol and its glucuronide.

Hepatic Storage of Trichloroethanol and/or Its Glucuronide—A major problem in the *in vivo* evaluation of hepatic storage of a drug and/or its metabolites by sampling blood flow across the liver is due to the dilution of hepatic venous return by vena cava blood from the lower extremities and kidneys. Whereas blood entering the liver may be easily sampled by catheterization of the hepatic portal vein, hepatic output occurs *via* very short hepatic veins, which immediately merge with the inferior vena cava at the level of the diaphragm in the dog. The vena caval dilution must be circumvented to sample hepatic output *via* the hepatic veins. One approach that was tried was to shunt the vena caval flow into the hepatic portal vein by surgery so that the total blood flow from the lower trunk entered the liver through the hepatic portal vein and all blood exited the liver as hepatic venous output. This surgical approach was attempted on two dogs; one died during surgery and the other expired shortly thereafter.

An alternative solution to the problem was provided by the work of Harris and Riegelman (11). A collateral circulation between a slowly occluded inferior vena cava and the azygous vein was promoted. Slow occlusion was achieved by insertion of a small segment of Tygon tubing in the vena cava 2 weeks prior to the hepatic storage or clearance experiments. An irritation set up by the tubing caused a slow clot and fibrin formation to occlude the vessel. The slow occlusion allowed establishment of the aforementioned collateral circulation. Rapid occlusion of vena caval flow causes death by cardiac arrest. Insertion of the Tygon tubing was performed with sterile surgical technique. The X-rays were taken after cannulation of the inferior vena cava *via* the lateral saphenous vein of the hind leg and clearly showed the occlusion. The radiopaque medium was a 10% solution of meglumine diatrizoate[16] rapidly injected simultaneously with X-irradiation.

One week after X-ray, the animal was anesthetized with pentobarbital and laparotomized and the hepatic portal vein was cannulated *via* a splenic vein. The remaining splenic veins were tied off as was the hepatic artery. Omission of the latter step allows a 25% error to occur due to dilution of hepatic venous flow with hepatic arterial flow. The hepatic venous return was sampled with a cannula inserted in the external jugular vein through the right atrium and into the inferior vena cava (which now only contains hepatic venous blood). After injection of a 50-mg./kg. dose of trichloroethanol *via* the hepatic portal vein, blood samples were simultaneously removed from both cannulas at regular intervals and assayed for trichloroethanol and its glucuronide.

CALCULATIONS, ANALYSIS, AND CURVE FITTING

Calculation of Red Blood Cell/Plasma Distribution Coefficient—The derivation of an expression for the calculation of a red blood cell/plasma distribution coefficient is as follows. The amount of drug, A, in whole blood, A_B, is:

$$A_B = A_P{}^u + A_P{}^b + A_{RBC} \quad \text{(Eq. 1)}$$

where $A_P{}^u$ and $A_P{}^b$ are the amounts of drug in plasma, unbound and bound to plasma proteins, respectively. The amount of drug in red blood cells is represented by A_{RBC}.

When the amount of drug in whole blood is converted to concentration, Eq. 2 becomes:

$$A_B/V_{B_{true}} = A_P{}^u/V_{B_{true}} + A_P{}^b/V_{B_{true}} + A_{RBC}/V_{B_{true}} \quad \text{(Eq. 2)}$$

where $V_{B_{true}}$ is the true volume of whole blood in the animal body.

When $V_{P_{true}}$ and V_{RBC} are the respective true volumes of plasma and red blood cells in the animal body:

$$\frac{A_B}{V_{B_{true}}} = \frac{A_P{}^u/V_{P_{true}}}{V_{B_{true}}/V_{P_{true}}} + \frac{A_P{}^b/V_{P_{true}}}{V_{B_{true}}/V_{P_{true}}} + \frac{A_{RBC}/V_{RBC}}{V_{B_{true}}/V_{RBC}} \quad \text{(Eq. 3)}$$

or:

$$[A_B] = \frac{[A_P{}^u]}{V_{B_{true}}/V_{P_{true}}} + \frac{[A_P{}^b]}{V_{B_{true}}/V_{P_{true}}} + \frac{[A_{RBC}]}{V_{B_{true}}/V_{RBC}} \quad \text{(Eq. 4)}$$

Since the hematocrit (H) may be defined as:

$$H = V_{RBC}/V_{B_{true}} \quad \text{(Eq. 5)}$$

therefore:

$$1 - H = V_{P_{true}}/V_{B_{true}} \quad \text{(Eq. 6)}$$

Substitution of Eqs. 5 and 6 into Eq. 4 yields:

$$[A_B] = [A_P{}^u](1 - H) + [A_P{}^b](1 - H) + [A_{RBC}]H \quad \text{(Eq. 7)}$$

The red blood cell/plasma distribution coefficient is then defined as:

$$D = [A_{RBC}]/[A_P{}^u] \quad \text{(Eq. 8)}$$

Upon rearrangement of Eq. 7:

$$D = \{[A_B]/[A_P{}^u](1 - H) - [A_P{}^b]/[A_P{}^u] - 1\}\,(1 - H)/H \quad \text{(Eq. 9)}$$

If the fraction, f, of drug bound to plasma proteins is known:

$$[A_P{}^b] = [A_P]f \quad \text{(Eq. 10)}$$

and:

$$[A_P{}^u] = [A_P]\,(1 - f) \quad \text{(Eq. 11)}$$

where $[A_P]$ is the total plasma concentration of drug, and Eq. 9 becomes:

$$D = \{[A_B]/[A_P]\,(1 - f)\,(1 - H) - f/(1 - f) - 1\} \times (1 - H)/H \quad \text{(Eq. 12)}$$

[16] Renografin.

$$n[A_P{}^u] + [P] \overset{K}{\rightleftarrows} [A_nP]$$

Scheme II

and the concentration of unbound drug in the plasma can be obtained by a rearrangement of this equation and is:

$$[A_P{}^u] = (1 - f)[A_P] = [A_B] \Big/ \left(DH + \frac{1 - H}{1 - f}\right) \quad \text{(Eq. 13)}$$

The fraction of drug bound to a plasma protein may not be invariant. It may be a function of the unbound concentration of drug (12, 13), *i.e.*:

$$f = 1/(1 + [A_P{}^u]/n[P] + 1/nK[P]) \quad \text{(Eq. 14)}$$

where K is the association constant for the binding of a molecule of drug to one of the equivalent n binding sites of the protein molecule in accordance with Scheme II, where $[P]$ is the concentration of protein.

At low drug concentrations or when the association constant K is small, the second term in the denominator of Eq. 14 becomes negligible and:

$$f \sim 1/(1 + 1/nK[P]) = [A_P{}^b]/[A_P] \quad \text{(Eq. 15)}$$

may be taken as constant for a given protein concentration and is independent of drug concentration.

Distribution of Drug among Blood Components and Fractions of Drug in Blood in Each—The amount of drug in the blood that is in the red blood cells may be calculated on the basis of Eqs. 5, 8, and 11:

$$A_{RBC} = V_{RBC}[A_{RBC}] = HV_{B_{true}}[A_{RBC}] = HDV_{B_{true}}[A_P{}^u] = HDV_{B_{true}}(1 - f)[A_P] \quad \text{(Eq. 16)}$$

The amount of drug in the blood that is bound to plasma protein and in the plasma may be calculated on the basis of Eqs. 6 and 10:

$$A_P{}^b = V_{P_{true}}[A_P{}^b] = (1 - H)V_{B_{true}}[A_P{}^b] = (1 - H)fV_{B_{true}}[A_P] \quad \text{(Eq. 17)}$$

The amount of drug in the blood that is unbound to plasma protein and in the plasma may be calculated on the basis of Eqs. 6 and 11:

$$A_P{}^u = V_{P_{true}}[A_P{}^u] = (1 - H)V_{B_{true}}[A_P{}^u] = (1 - H)(1 - f)V_{B_{true}}[A_P] \quad \text{(Eq. 18)}$$

When Eqs. 1 and 16–18 are considered:

$$A_B = V_{B_{true}}[A_P]\{HD(1 - f) + (1 - H)\} \quad \text{(Eq. 19)}$$

Division of Eqs. 16–18, respectively, by Eq. 19 gives the fraction of drug in the blood that is in the red blood cells as:

$$\gamma_{RBC} = A_{RBC}/A_B = HD(1 - f)/\{HD(1 - f) + (1 - H)\} \quad \text{(Eq. 20)}$$

and the fraction of drug in the blood that is bound to plasma protein and in the plasma as:

$$\gamma_P{}^b = A_P{}^b/A_B = (1 - H)f/\{HD(1 - f) + (1 - H)\} \quad \text{(Eq. 21)}$$

and the fraction of drug in the blood that is unbound to plasma protein and in the plasma as:

$$\gamma_P{}^u = A_P{}^u/A_B = (1 - H)(1 - f)/\{HD(1 - f) + (1 - H)\} \quad \text{(Eq. 22)}$$

Also, the total fraction of drug in the blood that is in the plasma is:

$$\gamma_P = \gamma_P{}^u + \gamma_P{}^b = (1 - H)/\{HD(1 - f) + (1 - H)\} \quad \text{(Eq. 23)}$$

Relations and Conversions among Variously Calculated Apparent Volumes of Distribution of the Central Compartment—Apparent volumes of distribution may be considered as the operational parameters that relate the measured concentrations of drug in the obtainable fluids of the body to the amounts in the individual compartments of the pharmacokinetic multicompartmental model that describe quantitatively the disposition of the drug in the body (12–16).

However, the numerical estimates of these apparent volumes of distribution for these several compartments can vary widely for the same multicompartmental model, dependent on whether the time course of free or total drug concentration is used and on whether blood or plasma is analyzed. Thus, the relations among these several estimates must be delineated to permit the calculation of one from the other. Only then will there be a common basis to compare the pharmacokinetic parameters of the same and different drugs within and among species.

If identification of apparent volumes of distribution with true volumes of body fluids or tissues is to be attempted, the criteria for the choice of the method of calculation of apparent volumes of distribution from pharmacokinetic data must be consistent with the physiological and physicochemical realities of drug disposition in the body.

The concentrations of a drug, A, are measured in aliquots of the fluid of the central compartment and are generally obtained as concentrations in blood, $[A_B]$, or in plasma, $[A_P]$. The apparent volumes of distribution referenced to blood, V_B, or to plasma, V_P, can be estimated from the extrapolation to zero time of the plot of drug concentration in blood or plasma against time on the premise of instantaneous mixing of the intravenously administered drug in the fluids of the central compartment (12, 13).

Thus, the apparent volume of distribution of the central compartment referenced to the total drug concentration in the blood is:

$$V_B = A_0/[A_B]_0 \quad \text{(Eq. 24)}$$

and the apparent volume of distribution of the central compartment referenced to the total drug concentration in the plasma is:

$$V_P = \{A_0 - (A_{RBC})_0\}/[A_P]_0 \quad \text{(Eq. 25)}$$

where A_0 and $(A_{RBC})_0$ are the intravenously administered dose and amount in the red blood cells, respectively; $[A_B]_0$ and $[A_P]_0$ are the total drug concentrations in blood and plasma, respectively, at zero time.

Significance of Variously Calculated Apparent Volumes of Distribution of the Central Compartment—These are fictitious volumes, since they may include the volumes of associated fluids where the drug concentration is in instantaneous equilibration with that of blood or plasma, *i.e.*:

$$V_B = V_{B_{true}} + V_{B_z} \quad \text{(Eq. 26)}$$

where $V_{B_{true}}$ is the true blood volume, and V_{B_z} is the apparent volume of this instantaneously equilibrated fluid or tissue on the presumption that its drug concentration is *exactly* the same as that of the blood. This apparent volume, V_{B_z}, may be termed the *associated* (with the central compartment) apparent volume of distribution *referenced* to the total drug concentration in the blood. Similarly:

$$V_P = V_{P_{true}} + V_{P_z} \quad \text{(Eq. 27)}$$

where $V_{P_{true}}$ is the true plasma volume, and V_{P_z} is the volume of this instantaneously equilibrated fluid or tissue on the presumption that its drug concentration is *exactly* the same as that of the plasma. This apparent volume, V_{P_z}, may be termed the *associated* (with the central compartment) apparent volume of distribution *referenced* to the total drug concentration in the plasma.

If none of the drug is sequestered by, or partitioned into, the red blood cells, all of the drug is assayed in the plasma and a simple relation exists between the respective apparent volumes of distribution. When Eqs. 6, 24, and 25 are considered:

$$V_P = V_{P_s} = A_0/[A_P]_0 = A_0 \Big/ \left(\frac{A_0}{V_{P_{true}}}\right) = A_0 \Big/ \frac{A_0}{V_{B_{true}}(1 - H)} = A_0 \Big/ \frac{[A_B]_0}{1 - H} = (1 - H)V_B \quad \text{(Eq. 28)}$$

and it follows from Eqs. 26–28 that:

$$V_{P_{s_z}} = V_{P_z} = V_{B_z}(1 - H) \quad \text{(Eq. 29)}$$

and the associated apparent volume of distribution referenced to the total drug concentration in plasma is less than the associated apparent volume of distribution referenced to the total drug concentration in blood.

These relations of Eqs. 26–29 are based on the presumption that the concentration in V_{P_x} is the same as that in plasma, $V_{P_{true}}$. The apparent volume V_{P_x} cannot be true plasma; it must be a fluid or tissue readily accessible to drug which is freely diffusible from the plasma water and would be unbound to plasma proteins. If the drug is completely protein bound and not partitioned into the red blood cells, the associated apparent volumes of distribution referenced to total drug concentration in blood and plasma, V_{B_x} and V_{P_x}, are zero and the apparent volumes of distribution, referenced to blood and plasma, V_B and V_P, are the same as the true volumes of blood and plasma, $V_{B_{true}}$ and $V_{P_{true}}$, respectively.

Equations for Calculation of Apparent Volumes of Distribution of the Central Compartment Referenced to Unbound Drug in Plasma from Apparent Volumes of Distribution Referenced to Total Drug Concentration in Blood and Plasma—The apparent volumes of distribution that have the highest probability of physiological significance are those calculated on the premise that only unbound drug in the true plasma volume (*i.e.*, diffusible drug in the plasma water) equilibrates with the other volumes of distribution of the various compartments of the multicompartmental model. The apparent volume of distribution in the central compartment referenced to unbound drug in the plasma water can be formulated as the amount of drug administrated intravenously less the amounts of drug partitioned into red blood cells and bound to plasma proteins at zero time divided by the zero time concentration of unbound drug in the plasma:

$$V_P{}^u = \{A_0 - (A_{RBC})_0 - (A_P{}^b)_0\}/[A_P{}^u]_0 \quad \text{(Eq. 30)}$$

In terms of the respective true volumes of red blood cells and plasma:

$$V_P{}^u = (A_0 - V_{RBC}[A_{RBC}]_0 - V_{P_{true}}[A_P{}^b]_0)/[A_P{}^u]_0 \quad \text{(Eq. 31)}$$

Substitution of values for V_{RBC}, $V_{P_{true}}$, $[A_{RBC}]_0$, $[A_P{}^b]_0$, and $[A_P{}^u]_0$ obtained from Eqs. 5, 6, 8, 10, and 11, respectively, into Eq. 31, with subsequent rearrangement, gives:

$$V_P{}^u = A_0/[A_P]_0\,(1 - f) - HDV_{B_{true}} - (1 - H)V_{B_{true}}f/(1 - f) \quad \text{(Eq. 32)}$$

in terms of the measured total concentration of the drug in plasma at zero time.

The substitution of Eq. 13 into Eq. 32 permits the apparent volume of distribution of the central compartment referenced to unbound drug concentration in the plasma to be expressed in terms of the measured total concentration of the drug in blood at zero time:

$$V_P{}^u = A_0\left(DH + \frac{1 - H}{1 - f}\right)\Big/[A_B]_0 - HDV_{B_{true}} - (1 - H)V_{B_{true}}f/(1 - f) \quad \text{(Eq. 33)}$$

On consideration of Eqs. 6 and 24, this apparent volume of distribution can be expressed in terms of the apparent volume of distribution referenced to the total concentration of drug in blood:

$$V_P{}^u = V_B\left(DH + \frac{1 - H}{1 - f}\right) - HV_{B_{true}}D - (1 - H)V_{B_{true}}f/(1 - f)$$
$$= V_B\left(DH + \frac{1 - H}{1 - f}\right) - \frac{H}{1 - H}V_{P_{true}}D - V_{P_{true}}f/(1 - f) = V_{P_{true}} + V_{P_x}{}^u \quad \text{(Eq. 34)}$$

On consideration of Eqs. 6 and 26, the associated apparent volume of distribution referenced to the unbound drug concentration in plasma can be defined in terms of the associated apparent volume of distribution referenced to the total drug concentration in blood:

$$V_{P_x}{}^u = V_{B_x}\left(DH + \frac{1 - H}{1 - f}\right) \quad \text{(Eq. 35)}$$

When the apparent volume of distribution of the central compartment is referenced to total concentration of drug in the plasma, it is expressed as the quotient of the amount of drug in plasma less the amount in the red blood cells and the total plasma concentration at zero time.

Thus, when Eqs. 25 and 31 are considered, a process similar to the development of Eq. 34 permits the expression of $V_P{}^u$ in terms of the apparent volume of distribution referenced to the total concentration of drug in plasma:

$$V_P{}^u = (V_P - V_{P_{true}}f)/(1 - f) = V_{P_{true}} + V_{P_x}{}^u \quad \text{(Eq. 36)}$$

On consideration of Eq. 27:

$$V_{P_x}{}^u = V_{P_x}/(1 - f) \quad \text{(Eq. 37)}$$

It follows from Eqs. 35 and 37 that:

$$V_{P_x} = V_{B_x}[DH(1 - f) + 1 - H] \quad \text{(Eq. 38)}$$

Pseudoapparent Volumes of Distribution of the Central Compartment and Calculation of Variously Referenced Apparent Volumes—Pseudoapparent volumes of distribution of the central compartment referenced to the total drug concentration in the plasma or to the unbound drug concentration in the plasma have been calculated as:

$$V_{P_s} = A_0/[A_P]_0 \quad \text{(Eq. 39)}$$

and:

$$V_{P_s}{}^u = A_0/[A_P]_0(1 - f) = V_{P_s}/(1 - f) \quad \text{(Eq. 40)}$$

without considering the fact that the numerator of the quotient in Eq. 25 should be lessened by the amount of drug in the red blood cells, $(A_{RBC})_0$.

Thus, consideration of Eqs. 11, 39, and 40 for the pertinent values in Eq. 32 permits the apparent volume of distribution of the central compartment referenced to unbound drug concentration in the plasma to be expressed in terms of these unrealistically calculated pseudoapparent volumes of distribution referenced to total drug concentration (or unbound drug concentration) in plasma:

$$V_P{}^u = V_{P_s}/(1 - f) - HV_{P_{true}}D/(1 - H) - V_{P_{true}}f/(1 - f) = V_{P_{true}} + V_{P_x}{}^u \quad \text{(Eq. 41)}$$

Other pertinent conversions can be obtained. On consideration of Eq. 27:

$$V_{P_x}{}^u = V_{P_{sx}}/(1 - f) - HDV_{P_{true}}/(1 - H) \quad \text{(Eq. 42)}$$

It also follows, on consideration of Eqs. 37 and 42, that:

$$V_{P_x} = V_{P_{sx}} - HDV_{P_{true}}(1 - f)/(1 - H) \quad \text{(Eq. 43)}$$

and:

$$V_P = V_{P_s} - HDV_{P_{true}}(1 - f)/(1 - H) \quad \text{(Eq. 44)}$$

It can be shown from Eqs. 35 and 42 that:

$$V_{B_x} = \frac{V_{P_{sx}} - HDV_{B_{true}}(1 - f)}{DH(1 - f) + 1 - H} \quad \text{(Eq. 45)}$$

so that, on cognizance of Eqs. 6, 23, 26, and 27:

$$V_B = V_{P_s}/[DH(1 - f) + 1 - H] = \gamma_P V_{P_s}/(1 - H) \quad \text{(Eq. 46)}$$

Relations among Variously Referenced Apparent Volumes of Distribution in the Absence of Protein Binding and/or Red Blood Cell Partition—If there is no partitioning into red blood cells, $D = 0$, $V_{P_s} = V_P$, $\gamma_P = 1$, $\gamma_{RBC} = 0$, $\gamma_P{}^b = f$, $\gamma_P{}^u = 1 - f$, and Eqs. 28, 29, 36, and 37 hold.

If there is no protein binding, $f = 0$, $V_P{}^u = V_P$, $V_{P_x}{}^u = V_{P_x}$, $V_{P_s}{}^u = V_{P_s}$, $\gamma_P = \gamma_P{}^u$, $\gamma_P{}^b = 0$ and, from Eq. 34:

$$V_P = V_B(DH + 1 - H) - HV_{B_{true}}D = V_B(DH + 1 - H) - HV_{P_{true}}D/(1 - H) \quad \text{(Eq. 47)}$$

and from Eqs. 35 and 38:

$$V_{P_x} = V_{B_x}(DH + 1 - H) \quad \text{(Eq. 48)}$$

and from Eqs. 41 and 44:

$$V_P = V_{P_s} - HDV_{P_{true}}/(1 - H) \quad \text{(Eq. 49)}$$

and from Eqs. 42 and 43:

$$V_{P_z} = V_{P_{sz}} - HDV_{P_{true}}/(1 - H) \quad \text{(Eq. 50)}$$

and from Eq. 45:

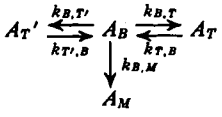
$$V_{B_z} = \frac{V_{P_{sz}} - HDV_{B_{true}}}{DH + 1 - H} \quad \text{(Eq. 51)}$$

and from Eq. 46:

$$V_B = V_{P_s}/(DH + 1 - H) = \gamma_P V_{P_s}/(1 - H) \quad \text{(Eq. 52)}$$

If there is no partitioning of drug into the red blood cells and no binding to plasma proteins, $D = 0, f = 0$, $V_P{}^u = V_P = V_{P_s}$, $V_{P_z}{}^u = V_{P_z} = V_{P_{sz}}$, $\gamma_P = \gamma_P{}^u = 1$, and Eqs. 28 and 29 hold.

Conversions among Microscopic Pharmacokinetic Rate Constants Based on Various Expressions of Drug Concentrations in Blood Components—The differential equation for the loss of drug from the central compartment of the linear three-compartment body model, Scheme III, may be expressed in terms of the amount of drug



Scheme III

in the blood and associated fluids, A_B, and in terms of the amounts of drug in the tissue compartments, A_T and $A_{T'}$:

$$-dA_B/dt = (k_{B,T} + k_{B,T'} + k_{B,M})A_B - k_{T,B}A_T - k_{T',B}A_{T'} \quad \text{(Eq. 53)}$$

It may be expressed in terms of the amounts of drug in the tissues, A_T and $A_{T'}$, and unbound drug, $A_P{}^u$, in the plasma and associated fluids, equilibrated with drug bound to protein and equilibrated with drug partitioned into red blood cells:

$$-\frac{dA_B}{dt} = (k_{P_u,T} + k_{P_u,T'} + k_{P_u,M})A_P{}^u - k_{T,P_u}T - k_{T',P_u}T' \quad \text{(Eq. 54)}$$

When the value for $A_P{}^u$ in Eq. 22 is substituted into Eq. 54:

$$-\frac{dA_B}{dt} = (\gamma_P{}^u k_{P_u,T} + \gamma_P{}^u k_{P_u,T'} + \gamma_P{}^u k_{P_u,M})A_B - k_{T,P_u}T - k_{T',P_u}T' \quad \text{(Eq. 55)}$$

Comparison of Eqs. 53 and 55 clearly shows that $k_{B,T} = \gamma_P{}^u k_{P_u,T}$, $k_{B,T'} = \gamma_P{}^u k_{P_u,T'}$, $k_{B,M} = \gamma_P{}^u k_{P_u,M}$, $k_{T,P_u} = k_{T,B}$, and $k_{T',P_u} = k_{T',B}$.

Estimations of Apparent Volumes of Distribution of Observed Tissue Compartments Referenced to Unbound Drug Concentration in Plasma from Variously Calculated Apparent Volumes of Distribution and Microscopic Pharmacokinetic Rate Constants—The apparent volume of distribution of a tissue compartment in a pharmacokinetic model such as Scheme III should be referenced to the unbound drug concentration in the plasma of the central compartment on the realistic premise that potential equilibration of drug between the central compartment and this tissue is only effected by unbound drug in the plasma water.

On the assumption of the possibility of an eventual equilibration or partition between unbound drug concentration in plasma water and drug concentration in a tissue (*e.g.*, as an ultimate consequence of the steady state resulting from a continuous zero-order infusion):

$$[A_T]_{eq}K = [A_P{}^u]_{eq} = A_P{}^u/V_P{}^u = A_T/KV_{T_P}{}^u \quad \text{(Eq. 56)}$$

where $V_P{}^u$ and $V_{T_P}{}^u$ are the apparent volumes of distribution referenced to the unbound drug concentration in plasma on the presumption that the partition coefficient, K, for the equilibration is unity (12, 13). If the tissue is truly homogeneous and an actual or operational K exists that is not equal to unity, V_T becomes the apparent volume of distribution of the tissue referenced to total drug concentration in that tissue.

The kinetic conditions for this potential steady-state equilibration are:

$$dA_T/dt = dA_P{}^u/dt = 0; k_{P_u,T}A_P{}^u = k_{T,P_u}A_T \quad \text{(Eq. 57)}$$

so that, from Eqs. 56 and 57 on the usually taken premise that $K = 1$, the apparent volume of distribution of the tissue compartment referenced to the unbound drug concentration in the plasma may be defined in terms of the apparent volume of distribution of the central compartment referenced to the unbound drug concentration in plasma and the microscopic pharmacokinetic constants for rate dependence on the amount of unbound drug in the plasma and its associated fluids (12, 13):

$$V_{T_P}{}^u = (k_{P_u,T}/k_{T,P_u})V_P{}^u \quad \text{(Eq. 58)}$$

This relation is valid even when a steady state does not exist between the tissue and plasma compartments.

Thus, as a consequence of the identity between Eqs. 53 and 55, the apparent volume of distribution of the tissue, T, can be related to the microscopic rate constants determined on the postulation of rate dependence on the total amount of drug in the blood as:

$$V_{T_P}{}^u = (k_{B,T}/\gamma_P{}^u k_{T,B})V_P{}^u \quad \text{(Eq. 59)}$$

Similarly:

$$V_{T'_P}{}^u = (k_{B,T'}/\gamma_P{}^u k_{T',B})V_P{}^u \quad \text{(Eq. 60)}$$

where $\gamma_P{}^u$ is defined in Eq. 22.

The apparent volumes of distribution of the tissues, T and T', referenced to the unbound drug concentration in plasma can be calculated from the variously calculated apparent volumes of distribution such as V_B, V_P, and V_{P_s} by appropriate substitutions of the values of $V_P{}^u$ obtained from Eqs. 34, 36, and 41, respectively, into Eqs. 59 and 60.

It can be shown similarly that the apparent volumes of distribution of the tissues, T and T', can be related to the microscopic rate constants determined on the postulation of rate dependence on the total amount of drug in the plasma:

$$V_{T_P}{}^u = (\gamma_P{}^u k_{P,T}/\gamma_P k_{T,P})V_P{}^u \quad \text{(Eq. 61)}$$

and:

$$V_{T'_P}{}^u = (\gamma_P{}^u k_{P,T'}/\gamma_P k_{T',P})V_P{}^u \quad \text{(Eq. 62)}$$

where $\gamma_P{}^u$ and γ_P are defined in Eqs. 22 and 23; and since $\gamma_P{}^u/\gamma_P = 1 - f$, then $k_{P,T} = (1 - f)k_{P_u,T}$, $k_{P,T'} = (1 - f)k_{P_u,T'}$, $k_{P,M} = (1 - f)k_{P_u,M}$, $k_{T,P} = k_{T,P_u}$, and $k_{T',P} = k_{T',P_u}$.

Pharmacokinetic Modeling—At the conclusion of all pharmacokinetic experiments, blood and urine samples were assayed for trichloroacetic acid, trichloroethanol, and its glucuronide. A defined procedure was followed to prepare a model that would be consistent with the observed data and to derive the parameters that quantifiably described the system.

The study of the pharmacokinetics of 30 mg./kg. of trichloroethanol in Dog D (20 kg.) will be used to illustrate the analysis and fitting procedures.

Graphical Analysis of Trichloroethanol Data—A semilogarithmic plot of trichloroethanol concentration in whole blood, given as the trichloroethanol–chlorobutanol peak height ratio per milliliter, is shown in Fig. 2. A peak height ratio per milliliter of 1.0 is equivalent to 8.4 mcg. trichloroethanol/ml.

The concentration of trichloroethanol in blood, $[TCE_B]$, as a function of time can be described by a sum of exponentials (17):

$$[TCE_B] = [A_B] = \sum_{i=1}^{n} [A_B]_i e^{-k_i t} = [A_B]_1 e^{-k_1 t} + [A_B]_2 e^{-k_2 t} + [A_B]_3 e^{-k_3 t} \quad \text{(Eq. 63)}$$

The methods by which the logarithmic plot of such data against time may be analyzed to yield its component $[A_B]_i$ (intercept) and k_i (slope) values were described in detail by Riggs (12).

The sum of the $[A_B]_i$ values, $\Sigma[A_B]_i$, is the time zero concentration, $[A_B]_0$, in the central compartment on intravenous administra-

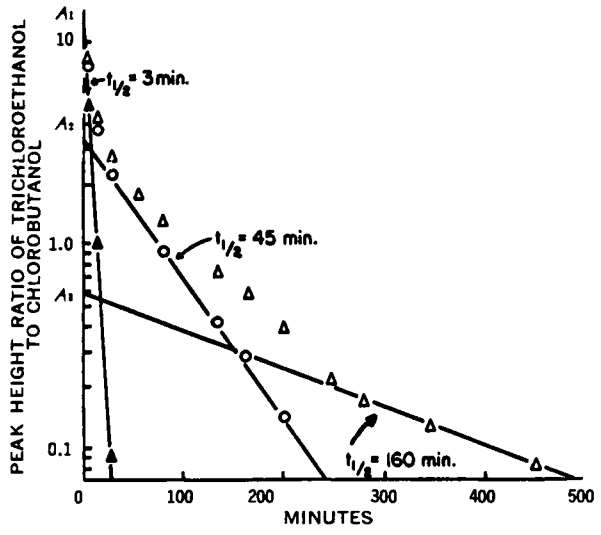


Figure 2—*Feathering of the semilogarithmic plot against time of the peak height ratios (△) of trichloroethanol to the internal standard chlorobutanol derived from the GC assay of 5 μl. of a 2-ml. ether extract of 1 ml. of acidified dog blood after the intravenous administration of 30 mg./kg. of trichloroethanol to the 20-kg. Dog D. A peak height ratio of 1.00 is equivalent to 8.4 mg. of trichloroethanol/ml. of whole blood. The three distinct phases obtained by feathering (the solid triangles, circles, and terminal open triangles) are labeled respectively with their apparent half-lives.*

tion and may be obtained from the calibration curve of peak height ratios *versus* concentrations (7). The trichloroethanol concentration in whole blood can be converted to the concentration of unbound trichloroethanol in plasma (in milligrams per milliliter) by Eq. 13. The apparent volume of distribution, V_B, referenced to the total concentration of trichloroethanol in the blood can be estimated from the dose (in milligrams) by Eq. 24.

The $\Sigma[A_B]_i$ or $[A_B]_0$ in terms of peak height ratio was estimated from the data of Fig. 2 extrapolated to zero time; it was 17.1 and corresponded to an initial whole blood concentration of 0.142 mg. of trichloroethanol/ml. or 0.0237 as percent of dose per milliliter of blood. The separate loading factors for the three exponentials that described the data of Fig. 2 were 13.0, 3.5, and 0.6 for $[A_B]_1$, $[A_B]_2$, and $[A_B]_3$, respectively. Insertion of the $[A_B]_0$ value into Eq. 13 and use of a red blood cell/plasma distribution coefficient D value of 2.1 with a hematocrit, H, of 0.45 (18) and a fraction, $f = 0.35$, of drug bound to plasma proteins (see *Results*) gave an initial concentration of unbound trichloroethanol in plasma, $[A_P{}^u]$, of 0.080 mg./ml.

The fractional amounts of drug in the blood that are in the red blood cells, in the plasma, unbound to protein and in the plasma, and bound to protein and in the plasma are: $\gamma_{RBC} = 0.527$ (Eq. 20), $\gamma_P = 0.475$ (Eq. 23), $\gamma_{P^u} = 0.310$ (Eq. 22), and $\gamma_{P^b} = 0.165$ (Eq. 21), respectively. When each of these fractions is multiplied by the initial milligrams of trichloroethanol per milliliter of blood, 0.142 mg./ml., the amount of drug in each blood component that is initially in 1 ml. of blood is: $(A_{RBC})_0/V_B = 0.075$ mg. for red blood cells, $(A_P)_0/V_{B_{true}} = 0.067$, $(A_P{}^u)_0/V_{B_{true}} = 0.044$, and $(A_P{}^b)_0/V_{B_{true}} = 0.023$. Thus, the respective concentrations are: $[A_{RBC}]_0 = (A_{RBC})_0/HV_{B_{true}} = 167$ mg./ml., $[A_P]_0 = (A_P)/(1 - H)V_{B_{true}} = 122$ mg./ml., $[A_P{}^u] = (A_P{}^u)_0/(1 - H)V_{B_{true}} = 0.080$ mg./ml., and $[A_P{}^b]_0/(1 - H)V_{B_{true}} = 0.043$ mg./ml.

On the premise that $V_{B_{true}} = 2.0$ l. and $V_{P_{true}} = 1.10$ l. for Dog C (20 kg.), where 100 and 55 ml./kg. are given in the literature (18) for dog blood volumes and plasma volumes, respectively, the various apparent volumes of the central compartment can be calculated. The pseudoapparent volume of distribution referenced to total drug concentration in plasma is $V_{P_s} = 4.88$ l. (Eqs. 39 and 46), the apparent volume of distribution referenced to total drug concentration in plasma is $V_P = 3.77$ l. (Eq. 44), the apparent volume of distribution referenced to the concentration of drug not bound to protein in the plasma is $V_P{}^u = 5.10$ l. (Eqs. 34 and 36), and the apparent volume of distribution referenced to drug concentration in blood is $V_B = 4.22$ l. (Eqs. 24 and 46).

The semilogarithmic plot of trichloroethanol concentration in blood *versus* time was resolved by the appropriate "feathering" techniques into three distinct exponential segments. The first exponential, which describes a rapid decline of trichloroethanol concentration in blood to 30% of the calculated initial value within 15 min. after drug administration, may be largely assigned to the diffusion of trichloroethanol from the initial volume of distribution ascribed to the central compartment into a larger volume of a readily available equilibrating body fluid. The low molecular weight of trichloroethanol and its extensive solubility in nonaqueous solvents (9) suggest that such rapid and extensive distribution might be expected.

The sum of the antilogarithms of the extrapolated zero-time intercepts (Fig. 2) assignable to the second and third exponentials of the polyexponential fit of the data (Eq. 63) was $[A_B]_2$ and $[A_B]_3 = 4.1$ in terms of peak height ratio per milliliter. This serves as a preliminary estimate of the assay value of trichloroethanol in blood that would have been observed after the ready equilibration with tissues if no significant drug elimination had occurred in the initial time interval. Insertion of the corresponding whole blood concentration (0.0346 mg./ml.) into Eq. 13 yields a concentration of free trichloroethanol in the plasma that is not bound to proteins of 0.0193 mg./ml. The estimated sum of the apparent volumes of distribution of the central compartment and that of the readily perfused tissues referenced to the total concentration of drug in the blood can be estimated from:

$$V_{D_B} = V_B + V_{T_B} = \text{dose}/([A_B]_2 + [A_B]_3) = A_0/(\Sigma[A_B]_i - [A_B]_1) \quad \text{(Eq. 64)}$$

and was 17.3 l. for a 600-mg. dose where the divisor of the last two terms is the concentration of trichloroethanol in the equilibrated fluids after the ready equilibration on the assumption of insignificant drug excretion or metabolism during the time interval of the equilibration. Subtraction of the initial apparent volume of distribution of the central compartment referenced to total concentration in the blood, $V_B = 4.2$ l., from this value provides an estimated volume of 13.1 l. for the tissue fluids, V_{T_B}, referenced similarly.

It can be argued also (Eq. 30) that if the curves of unbound drug concentration $[A_P{}^u]$ in the plasma against time are analyzed similarly:

$$V_{D_P{}^u} = V_P{}^u + V_{T_P{}^u} = \frac{\text{dose} - (\text{amounts in red blood cells and bound to plasma protein})}{[A_P{}^u]_2 + [A_P{}^u]_3} \quad \text{(Eq. 65)}$$

The estimated sum of the apparent volumes of distribution of the central compartment and of the readily perfused tissues referenced to unbound drug concentration in the plasma, $V_{D_P{}^u}$, can be calculated from the sum of the apparent volumes of distribution, V_{D_B}, referenced to total drug concentration in the blood by an equation derived on the same premises as, and similar to, Eq. 34:

$$V_{D_P{}^u} = V_{D_B}\left(DH + \frac{1 - H}{1 - f}\right) - HDV_{B_{true}} - (1 - H)V_{B_{true}}f/(1 - f) = 28.7 \text{ l.} \quad \text{(Eq. 66)}$$

Subtraction of the initial apparent volume of distribution of the central compartment referenced to unbound drug concentration in the plasma, $V_P{}^u = 5.1$ l., provides an estimated volume, $V_{T_P{}^u}$, of 23.6 l. for the tissue fluids referenced similarly.

More refined estimates of the volumes of distribution were obtained when the data were analyzed with the analog and digital computers, since the value of $[A_B]_0 = \Sigma[A_B]_i$ may be best obtained by computer extrapolation to zero time.

The loss of trichloroethanol from blood during the time period of the second exponential was postulated to be predominantly due to metabolic conversion of trichloroethanol to its glucuronide by hepatic microsomal uridine 5′-diphosphate-glucuronyltransferase. This was verified by the fact that the maximal rates of appearance of the glucuronide in blood and urine occurred in this interval. The rate constant of the second exponential of Eq. 63, k_2, is not equal to $k_{B,M}$, the metabolic rate constant in Scheme III. On the assumption of a predominantly two-compartment body model with rapid

equilibration (13), where k_3 is small or almost zero, k_2 is coincident with k_e (19, 20), the overall disposition rate constant for trichloroethanol where this latter constant can be expressed either in terms of the microscopic rate constants referenced to the total amount of drug in the central compartment of blood and associated fluids or, on consideration of Eq. 22 and the coincidence of Eqs. 53 and 55, in terms of the microscopic rate constants referenced to the amount of unbound drug in the central compartment of plasma and associated fluids:

$$k_2 = k_e = \frac{k_{B,M}}{1 + k_{B,T}/k_{T,B}} = \frac{k_{P_u,M}}{1/\gamma_P{}^u + k_{P_u,T}/k_{T,P_u}} = \frac{k_{P_u,M}}{1 + HD/(1 - H) + f/(1 - f) + k_{P_u,T}/k_{T,P_u}} \quad \text{(Eq. 67)}$$

and where $k_{B,T}$ or $k_{P_u,T}$ and $k_{T,B}$ or k_{T,P_u} are the respective rate constants for diffusion into and out of the rapidly equilibrating fluid compartment responsible for the first exponential of Eq. 63 that characterizes the initial loss of drug from the central compartment referenced to amounts of drug in blood and associated fluids or plasma and associated fluids, respectively.

This latter equation can also be derived from consideration of a general equation when the rate of loss of drug from a complex of rapidly equilibrating compartments is defined as being proportional to the amount of drug in only one of those compartments, *e.g.*:

$$-d(A_B + A_T)/dt = d(A_{RBC} + A_P{}^b + A_P{}^u + A_T)/dt = k_{P_u,M}A_P{}^u \quad \text{(Eq. 68)}$$

When the amount of drug in any one of the components or compartments of this rapidly equilibrating complex can be defined as being in equilibrium with the amount of drug in the rate-determining compartment, *i.e.*, $A_i = K_iA_P{}^u$, where K_i is the respective equilibrium constant for the ith compartment, Eq. 68 can be expressed as:

$$-d(K_{RBC/P_u}A_P{}^u + K_{P_b/P_u}A_P{}^u + A_P{}^u + K_{T/P_u}A_P{}^u)/dt = -dA_P{}^u/dt(1 + K_{RBC/P_u} + K^b_{P_b/P_u} + K_{T/P_u}) = k_{P_u,M}A_P{}^u \quad \text{(Eq. 69)}$$

On consideration of Eqs. 20 and 22:

$$K_{RBC/P_u} = \gamma_{RBC}/\gamma_P{}^u = HD/(1 - H) \quad \text{(Eq. 70)}$$

On consideration of Eqs. 21 and 22:

$$K_{P_b/P_u} = \gamma_P{}^b/\gamma_P{}^u = f/(1 - f) \quad \text{(Eq. 71)}$$

On consideration of Eq. 57:

$$K_{T/P_u} = k_{P_u,T}/k_{T,P_u} \quad \text{(Eq. 72)}$$

Substitution of Eqs. 70–72 into Eq. 69 with subsequent rearrangement reaffirms that Eq. 67 properly represents the overall disposition rate constant for the overall loss of drug from the complex of rapidly equilibrating compartments in terms of microscopic rates and equilibrium constants.

If a third compartment can be discriminated for trichloroethanol distribution in the body and the rate of return from this compartment is extremely slow, the observed k_e may be estimated (19) as:

$$k_e = \frac{k_{B,M} + k_{B,T'}}{1 + (k_{B,T}/k_{T,B})} = \frac{k_{P_u,M} + k_{P_u,T'}}{1/\gamma_P{}^u + k_{P_u,T}/k_{T,P_u}} \quad \text{(Eq. 73)}$$

where $k_{B,T'}$ and $k_{P_u,T'}$ are the rate constants for transfer of drug into this "deep" compartment from the central compartment referenced to the total drug and drug not bound to plasma, respectively.

When such a deep compartment, T', exists and when the return of drug to the central compartment becomes significant, Eq. 73 is inadequate for describing the rate-determining rate constant for the disposition of the drug in the body, and the disposition rate begins to mirror the effects of drug return from the deep compartment (19). The presence of the third exponential demonstrated this deep compartment return, and its k_3 value gave a preliminary estimate of $k_{T',B} = k_{T',P_u}$, the rate constant for transfer of drug from the deep compartment into the central compartment.

To describe mathematically the distribution and metabolism of trichloroethanol, it was necessary to obtain the values of the microscopic rate constants that describe the system of Eq. 63 and the apparent volumes of distribution of the equilibrating compartments.

Initial estimates of $k_{B,T}$, $k_{T,B}$, and $k_{B,T'} + k_{B,M}$ were obtained from the parameters of the first two exponentials that characterize the time course of trichloroethanol in the blood as demonstrated in Fig. 2 ($[A_B]_1$, $[A_B]_2$, k_1, and k_2) by their insertion into the equations of Skinner *et al.* (21) as simplified by Riggs (12). The rate constant estimates, in units of reciprocal minutes (min.$^{-1}$), were: $k_{B,T}$ = 0.128, $k_{T,B} = k_{T,P_u}$ = 0.060, and $k_{B,M} + k_{B,T'}$ = 0.058 so that $k_{P_u,T}$ = 0.413 and $k_{P_u,M} + k_{P_u,T'}$ = 0.187. The k_e estimated from these values by use of Eq. 67 was 0.0185 min.$^{-1}$, which was in good agreement with the value of 0.015 min.$^{-1}$ obtained from 2.303 times the slope of the log A_B plot against time during the period characterized by the second exponential in Fig. 2.

The rate constant for trichloroethanol return from the deep tissue was obtained from 2.303 times the slope for the period characterized by the third exponential in Fig. 2 and was $k_{T',B} \sim k_3$ = 0.004 min.$^{-1}$. The fitting of the data with the analog and/or digital computer was then attempted with utilization of these preliminary estimates of the microscopic pharmacokinetic constants.

Analysis of Trichloroethanol Data by Analog Computation[17]—The bases and details of analog computer programming have been described in several excellent texts and brochures (22–24). Applications to fitting the data to complex pharmacokinetic models have also been given (17, 25–29).

The peak height ratio at any time, PHR_t, of trichloroethanol to chlorobutanol per milliliter of whole blood was plotted against time. The ordinate was scaled from 0 to 100%, where 100% of the dose in the blood was taken as the peak height ratio extrapolated to zero time, *i.e.*, $[A_B]_0 = \Sigma[A_0]_i$, and equated to 10 v., so that the amount of trichloroethanol in the blood at any time could be expressed as the percent of the initial dose that appeared in the blood:

$$\%\ TCE_t = \frac{PHR_t}{[A_B]_0} \times 100 \quad \text{(Eq. 74)}$$

on the assumption of instantaneous homogeneity in the central compartment of the intravenously administered drug. The amount of drug lost in the interval t = 0–30 min. (the time period of the first exponential) was fitted by adjusting the ratio $k_{B,T}/k_{T,B}$ while the rate of its initial disappearance was controlled by the magnitude of these constants (26). A preliminary fit of the remaining data was attempted by holding $k_{T',B}$ at 0.004 min.$^{-1}$ and adjusting the magnitudes of $k_{B,T'}$ and $k_{B,M}$ while their sum remained at 0.058 min.$^{-1}$. Minor adjustments in the rate constant values, to account for the interaction of the two curve segments, were then made to achieve a "best" fit of the data.

The time axis potentiometer was set to generate a time function to drive the X–Y recorder such that 2.54 cm. (1 in.) = 1 v. = 40 sec. of machine time. The data were plotted on a 38.1-cm. (15-in.) abscissa with a scale of 2.54 cm. (1 in.) = 40 min. real time. This choice of time scales permitted the values of rate constants to be read directly from the adjusted rate constant potentiometers. A different choice of settings would have necessitated conversions of potentiometer readings to their corresponding rate constant values.

The analog computer fit of the trichloroethanol blood data for Dog D, dosed at 30 mg./kg. and a total dose of 600 mg., is given in Fig. 3.

Analysis of Trichloroethanol Glucuronide Data by Analog Computation—The total amount of free trichloroethanol excreted in the urine was less than 1% of the administered dose. No assayable trichloroacetic acid was found in blood or urine for the intravenous administration of a 30-mg./kg. dose in Dog D. These facts substantiate the basic pharmacokinetic model for trichloroethanol as given in Scheme III and demonstrate that its only significant pathway for removal from the body in the dog is *via* the route of metabolism to its glucuronide. The analog computer model of Scheme III generated amounts of glucuronide with time in terms of a percent of the total dose of trichloroethanol intravenously administered.

[17] The analog computer used was a model TR-10, Electronic Associates, Long Branch, N. J. A recording X–Y plotter, Moseley model 202, manufactured by Hewlett-Packard/Moseley Division, Pasadena, Calif., was used.

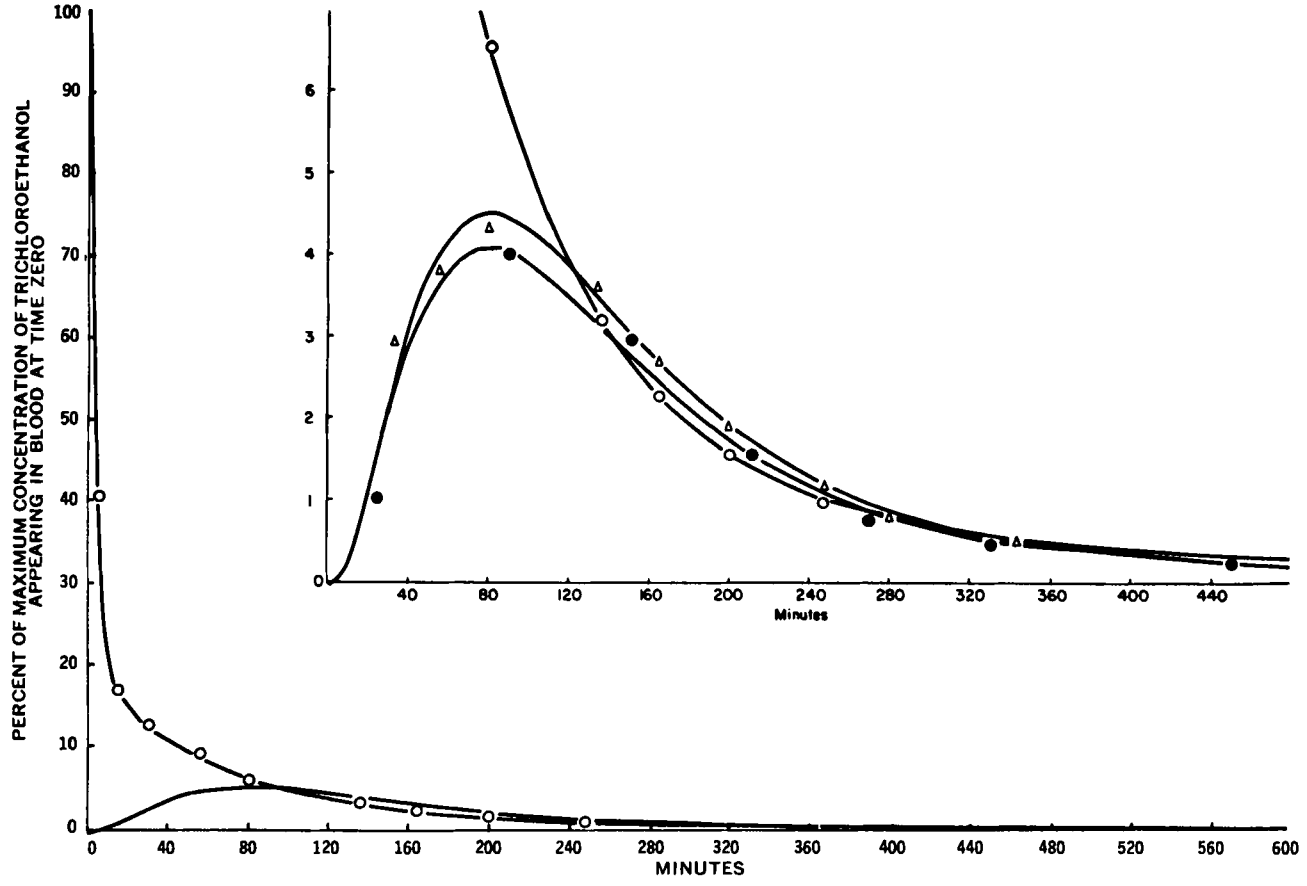

Figure 3—*Analog computer fit of blood and urine data for a dose of 30 mg. trichloroethanol (TCE) per kilogram in the 20-kg. Dog D. The full-scale portion shows the computer fit of the data for trichloroethanol as the percent of the maximum concentration that appears in the blood at zero time* (○), *and the solid line is the predicted trichloroethanol glucuronide in the blood with time. The inset curves are expanded scale plots of the data for trichloroethanol* (○) *and its glucuronide* (△) *with time. The dark circles* (●) *are the urinary excretion rates of trichloroethanol glucuronide (percent dose per minute), which are plotted on a 10-fold smaller scale (0–1%/min.) than that represented on the inset ordinate. The trichloroethanol data were fitted by the program of Scheme V to the specified model by the pertinent microscopic rate constants in Tables I and V, and the computer-generated trichloroethanol glucuronide levels were fitted to the glucuronide data* (△), *which had been multiplied by a factor that represented the ratio of the apparent volumes of distribution of the glucuronide to the trichloroethanol in the central compartment.*

The assayed peak height ratios of trichloroethanol glucuronide to chlorobutanol per milliliter of whole blood were estimated as a percent of the total dose of trichloroethanol administered per volume of whole blood by means of an estimate of the volume of whole blood in the dog on the basis of the preliminary assumption that the glucuronide was only distributed in the central compartment, which was blood. The equation used for this preliminary estimate was:

$$\text{estimated \% of total dose of trichloroethanol as glucuronide in whole blood} = (\text{peak height ratio of glucuronide/chlorobutanol per ml. whole blood}) \times \frac{(8.4 \times 10^{-3}\ \text{mg./peak height ratio})\ (20\ \text{kg.})\ (94\ \text{ml./kg.}) \times 100}{600\ \text{mg.}} \quad \text{(Eq. 75)}$$

where 8.4×10^{-3} mg./peak height ratio is the conversion factor to transform peak height ratios to milligrams of trichloroethanol. The 94-ml./kg. factor has been reported (18) as the whole blood volume of the dog, and 600 mg. is the dose of trichloroethanol administered to Dog D (20 kg.).

The maximum estimated glucuronide in the blood was only 4.2% of the dose. Thus the scale used in the plots of the trichloroethanol was 10-fold, and the estimated percent values as the glucuronide were plotted on the same paper in the expanded range of 0–10% (Fig. 3). This was a reasonable procedure, since the recorder used had a switch that permitted an instantaneous 10-fold amplification of the glucuronide amount in blood generated by the analog computer from an appropriate fitting of the trichloroethanol data. It must be realized that this percent of the dose of trichloroethanol as glucuronide in blood (Eq. 75) was only an estimate of the real situation since the true equilibrated distribution volume, V_{D_B}, of the glucuronide referenced to the total concentration of glucuronide in the blood was not known and only was estimated as being equivalent to the volume of whole blood in the dog. The relationship between the estimated and true values as glucuronide is:

$$\frac{\text{true \% of trichloroethanol dose as glucuronide}}{\text{estimated \% of trichloroethanol dose as glucuronide}} = \frac{[\text{TCE-G}_B] \times V_{D_B}^{\text{true}}}{[\text{TCE-G}_B] \times V_{D_B}^{\text{est}}} = \frac{V_{D_B}^{\text{true}}}{V_{D_B}^{\text{est}}} = \alpha \quad \text{(Eq. 76)}$$

where $[\text{TCE-G}_B]$ is the experimentally observed concentration of glucuronide in whole blood.

The factor α can be estimated from the setting of a variable potentiometer used to multiply the trichloroethanol glucuronide amount in the dog (in terms of percent of trichloroethanol dose as glucuronide) generated from the analog computer fit of the trichloroethanol data in the blood, so that the time course of actual values of glucuronide plotted was fitted when plotted as the estimated values obtained from Eq. 75. This determined α factor would permit a true estimate of the apparent volume of distribution of glucuronide referenced to its total concentration in the blood from a rearrangement of Eq. 75:

$$V_{D_B}^{\text{true}} = \alpha V_{D_B}^{\text{est}} \quad \text{(Eq. 77)}$$

where $V_{D_B}^{\text{est}}$ was taken as 94 ml./kg. (Eq. 76).

The rates of urinary excretion of trichloroethanol glucuronide, $d(\text{TCE-G}_U)/dt$, were determined from the experimental analyses of

total glucuronide in the urine excreted per unit of time in accordance with:

$$\text{urinary excretion rate of glucuronide (\% of dose/min.)} = \frac{100 \times \text{glucuronide excreted in mg. trichloroethanol}}{\text{(dose in mg.) (time interval of excretion in min.)}} \quad \text{(Eq. 78)}$$

These values were plotted on the same graph used for the plotting of estimated glucuronide in the blood as percent of administered trichloroethanol, except that the ordinate was magnified 10-fold to give a range of 0–1% of total trichloroethanol dose excreted per minute (Fig. 3). Since (13):

$$d(\text{TCE-G}_U)/dt = k_e' [\text{TCE-G}_B] \quad \text{(Eq. 79)}$$

the proper multiplication of the amounts of glucuronide in blood as a function of time by a constant k_e' should fit the plotted rates of urinary excretion as a function of time. A selector switch on the recorder permitted instantaneous 10-fold amplification of the generated rate data to conform with the plotted scale. Good fits of both the blood and urine data of glucuronide were necessary before a set of parameters could be said to describe the fate of glucuronide formed from trichloroethanol.

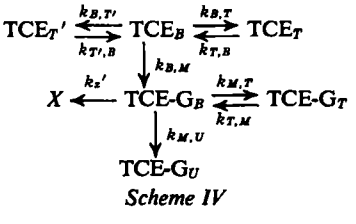
The simplest model for fitting the glucuronide data in blood with the rate constants generated from the fit of trichloroethanol data in blood assumed that the glucuronide appearance in blood reflected trichloroethanol loss as in Scheme III, *i.e.*:

$$d(\text{TCE-G}_B)/dt = k_{B,M}(\text{TCE}_B) \quad \text{(Eq. 80)}$$

If and only if the apparent volumes of distribution of the central compartment referenced to concentrations in blood for both drug, $(V_B)_{TCE}$, and metabolite, $(V_B)_{TCE\text{-}G}$, were the same would this equation be applicable to concentrations. In general:

$$d[\text{TCE-G}_B]/dt = \{(V_B)_{TCE}/(V_B)_{TCE}\} k_{B,M}[\text{TCE}_B] \quad \text{(Eq. 81)}$$

An appropriate expanded model might be as shown in Scheme IV,



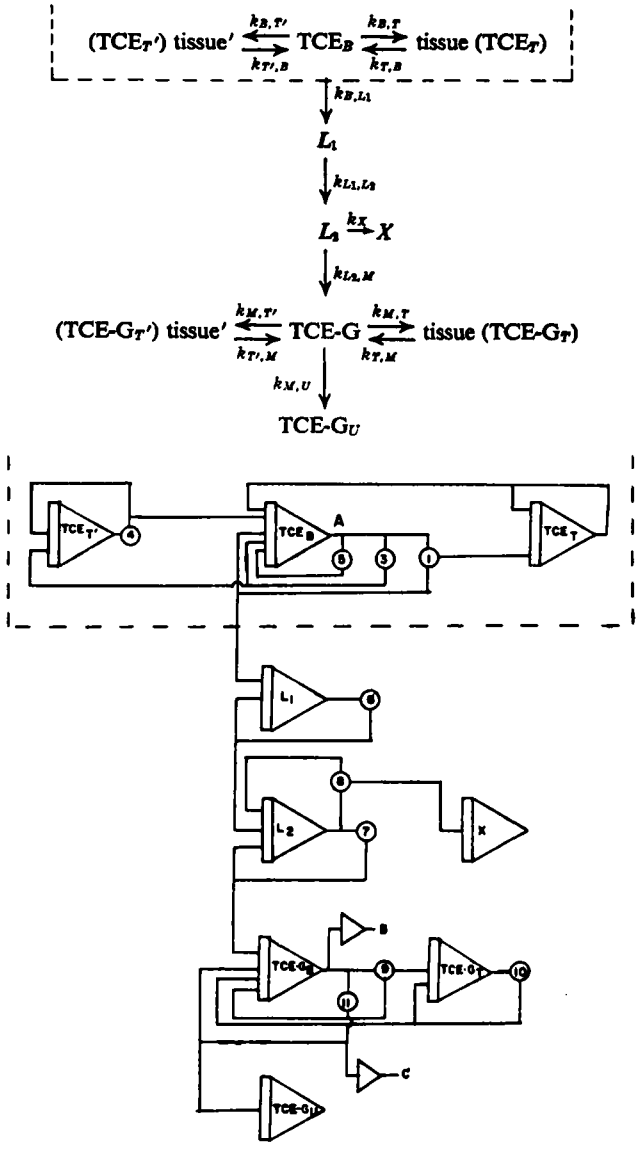
Scheme IV

where the k_e' of Eq. 79 would be defined (13) by the microscopic constants in a manner analogous to Eq. 73 where the glucuronide is rapidly equilibrated with a tissue, TCE-G$_T$, as:

$$k_e' = \frac{k_{M,U} + k_z'}{1 + k_{M,T}/k_{T,M}} \quad \text{(Eq. 82)}$$

where k_z is inserted as a microscopic rate constant for a possible elimination route that occurred simultaneously with the urinary elimination of glucuronide from the body. The urinary excretion rates of glucuronide were always proportional to its concentration in the blood in accordance with Eq. 79. The fact that an intravenous dose of glucuronide was, for all practical purposes, completely excreted into the urine permitted the decision that $k_z' = 0$. The initial estimates of $k_{M,T}$, $k_{T,M}$, and $k_{M,U}$ were obtained from a separate analysis of the pharmacokinetics of the intravenously administered dose of glucuronide.

However, the model of Scheme IV could not be fitted to the glucuronide data plotted as values derived from Eq. 75 against time (Fig. 3). No combination of α values and distribution and elimination rate constants could fit the observed data for glucuronide in blood and urine. The major inconsistencies observed were that the analog computer curves generated from the fits to the trichloroethanol data gave rapid early blood levels, whereas the experimental glucuronide data demonstrated an induction period, a slower rate of glucuronide appearance in the blood, and a broader maximum. It was, therefore, necessary to postulate an additional compartment, L_1, in the model, between trichloroethanol in the blood, TCE$_B$, and the glucuronide in the blood, TCE-G$_B$ (Scheme V), which could serve to accumulate the glucuronide and release it slowly into blood. Although the presence of this compartment improved the fit of calculated to observed data, the lag time required to fit the rate of appearance of glucuronide in blood was still not accommodated. To fit the lag in appearance of glucuronide blood levels while continuing to assume concentration-dependent or first-order processes, it was necessary to insert another compartment, L_2, in the model (Scheme V).



Scheme V—The multicompartmental model and corresponding analog computer program required for the analysis and fitting of pharmacokinetic data. The portions enclosed in dashed lines were used to evaluate trichloroethanol data as analyzed in blood, TCE$_B$, alone while the entire model and program were used to fit trichloroethanol glucuronide data as analyzed in blood, TCE-G$_B$. The potentiometers in the program and their corresponding rate constants in the model were: potentiometer 1, $k_{B,T}$; 2, $k_{T,B}$; 3, $k_{B,T'}$; 4, $k_{T',B}$; 5, k_{B,L_1}; 6, k_{L_1,L_2}; 7, $k_{L_2,M}$; 8, k_x; 9, $k_{M,T}$; 10, $k_{T,M}$; and 11, $k_{M,U}$. Analog computer plots of calculated data were obtained from points A for trichloroethanol in blood, TCE$_B$; B for trichloroethanol glucuronide in blood, TCE-G$_B$; and C for the urinary excretion rate of trichloroethanol glucuronide, d(TCE-G$_U$)/dt.

The presence of compartments L_1 and L_2 (in series between TCE$_B$ and TCE-G$_B$), coupled with an additional compartment (X) to account for the fraction of the dose unaccounted for in urine, allowed for accurate fitting of the glucuronide data in blood and urine in accordance with Scheme V. The analog computer program for this model is also given in the scheme. The portions of the model and program enclosed in dashed lines were used in the preliminary

[a] The microscopic rate constants are defined in Scheme V and are given in minutes^{-1}. The values of $k_{M,T}$, $k_{T,M}$, $k_{M,T'}$, $k_{T',M}$, and $k_{M,U}$ were 0.133, 0.190, 0.008, 0.017, and 0.069 min.$^{-1}$, respectively, and were obtained from the separate studies on trichloroethanol glucuronide pharmacokinetics. The numbers in parentheses are standard deviations of the stated parameters obtained by digital computer fitting with the SAAM program. [b] The computer-fitted zero time concentration of trichloroethanol in blood, $[A_B]_0$, in terms of percent of dose per milliliter of whole blood. The $[A_B]_0$ values were reasonably coincident for all doses in a given dog (Fig. 8). [c] The apparent volume of distribution of the central compartment referenced to total concentration in blood is $V_B = 100\%/[A_B]_0$ in liters. [d] The apparent volume of distribution referenced to the concentration of trichloroethanol in the plasma unbound to protein is $V_{P^u} = V_B\,(1.792) - 1.24\,V_{B_{true}}$ after Eq. 34, where $H = 0.45$, $D = 2.1$, $f = 0.35$, and $V_{B_{true}} = 0.1 \times$ weight of dog in kilograms (16). [e] The apparent volume of distribution referenced to the concentration of unbound trichloroethanol in the plasma of the rapidly equilibrating compartment, T, in liters, where $V_{T_{P^u}} = V_{P^u} - (k_{B,T}/\gamma_{P^u} k_{T,B})$. [f] The apparent volume of distribution referenced to the concentration of unbound trichloroethanol in the plasma of the slowly equilibrating compartment, T', in liters, where $V_{T'_{P^u}} = V_{P^u} - (k_{B,T'}/\gamma_{P^u} k_{T',B})$. [g] The dog weights in these studies were 20 kg. [h] Trichloroethanol, 60 mg./kg. or 600 mg., was administered initially. At 250 min. later, 100 mg. of sulfobromophthalein (10 mg./kg.) was administered concurrently with an additional dose of 600 mg. of trichloroethanol (60 mg./kg.) and an intravenous drip of 0.6 mg. sulfobromophthalein/min. was started and continued until 490 min. [i] Trichloroethanol, 60 mg./kg. or 600 mg., was administered initially. At 320 min. later, 500 mg. of sulfobromophthalein (50 mg./kg.) was administered concurrently with an additional dose of 600 mg. of trichloroethanol (60 mg./kg.) and an intravenous drip of 3 mg. sulfobromophthalein/min. was infused until 500 min.

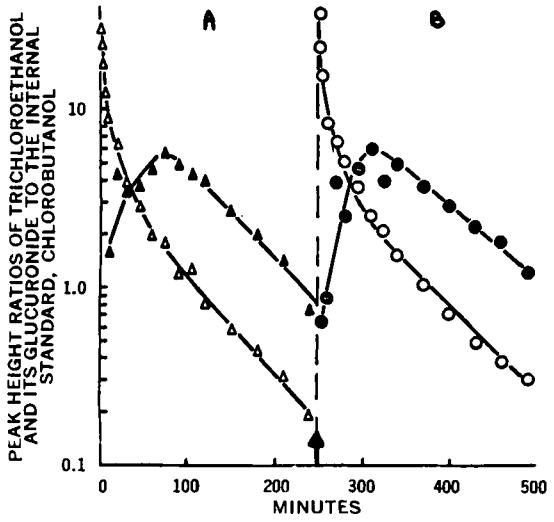

Figure 4—*Semilogarithmic plots of the peak height ratios of trichloroethanol (△,○) and trichloroethanol glucuronide (▲,●) as representative of blood levels with time in the absence and presence of sulfobromophthalein for the 10-kg. Dog E. Segment A is a consequence of dosing 60 mg./kg. of trichloroethanol at zero minute. Segment B is a consequence of dosing 60 mg./kg. of trichloroethanol and 10 mg./kg. of sulfobromophthalein at 250 min. A peak height ratio of 1.0 is equivalent to 8.4 mcg. trichloroethanol or 18.3 mcg. trichloroethanol glucuronide/ml. of whole blood.*

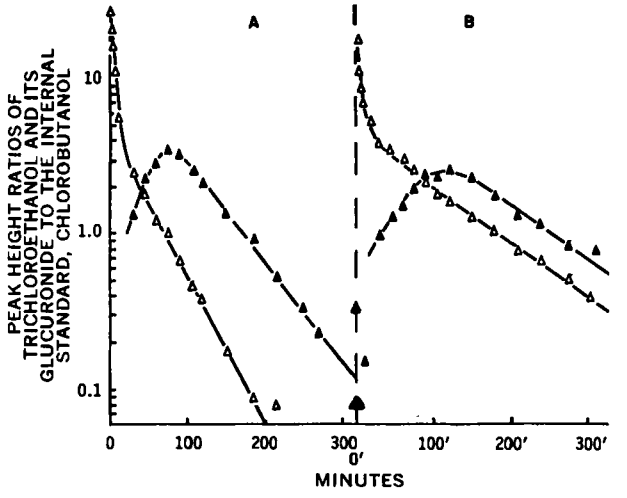

Figure 5—*Semilogarithmic plots of the peak height ratios of trichloroethanol (△) and trichloroethanol glucuronide (▲) as representative of their respective blood levels with time in the absence and presence of sulfobromophthalein for the 10-kg. Dog E. Segment A is a consequence of dosing 60 mg./kg. of trichloroethanol at zero minute. Segment B is a consequence of dosing 60 mg./kg. of trichloroethanol and 50 mg./kg. of sulfobromophthalein at 320 or 0' min. A peak height ratio of 1.0 is equivalent to 8.4 mcg. trichloroethanol or 18.3 mcg. trichloroethanol glucuronide/ml. whole blood.*

fit of the trichloroethanol data in the blood, where k_{B,L_1} is the rate constant given previously as $k_{B,M}$ (Schemes III and IV).

The placement in the multicompartmental model of k_X, a rate constant for elimination of the missing drug fraction, was arbitrary since the route of elimination was unknown. The urinary recovery, for all practical purposes, of all of an intravenous dose of the glucuronide indicated that the TCE-G_B compartment would not be a logical place to remove a fraction of the dose with a rate constant, k_x. Since postulation of this elimination route from the trichloroethanol in the blood, TCE_B, would alter those parameters previously obtained for the loss of trichloroethanol, it was decided that the missing fraction of drug exited from compartment L_2. The fact that an amount of the trichloroethanol dose is secreted into bile as the glucuronide made this choice consistent with physiological reality.

The ratio, $k_X/k_{L_2,M}$, could be estimated (13) from:

$$\frac{k_X}{k_{L_2,M}} = \frac{100 - (\%\ \text{TCE-G}_U)_\infty}{(\%\ \text{TCE-G}_U)_\infty} \qquad \text{(Eq. 83)}$$

where $(\%\ \text{TCE-G}_U)_\infty$ is the total percent of the trichloroethanol dose excreted in the urine.

Analysis of Data by Digital Computation—The major disadvantage of the analog computer in data analysis is that the goodness of fit must be evaluated visually. Statistical determination of the agreement between calculated and observed points would demand a nonlinear regression analysis for every fit. Fortunately, programs are available for the digital computer that include such statistical analysis along with methods to evaluate pharmacokinetic parameters. The SAAM (Simulation, Analysis, and Modeling) program of Berman and Weiss (30) is such a program and was used on a digital computer[18] to fit the pharmacokinetic data.

SAAM is a general-purpose computer program designed to fit physical or mathematical models to data by adjusting the parameter values of the model until a "best" fit is obtained. Any set of mathematical equations (differential, integral, or algebraic) or functions may serve as a model provided an analytical or numerical procedure exists for its solution.

Since the model for trichloroethanol pharmacokinetics (Scheme III) assumed first-order transfers among all compartments, the equations describing the system were linear differential equations with constant coefficients. The equations are solved by the SAAM program with the fourth-order approximative technique of Runge-Kutta (31).

Data to be analyzed were punched out on IBM cards. The data for trichloroethanol in blood were given in terms of percent of total dose, where 100% was the extrapolated zero-time blood concentration (Eq. 74).

Estimates of the rate constants needed to fit the data (lambdas in SAAM program terminology) were those obtained with the preliminary analog computer data fit (Scheme V). These rate constants required iterative adjustment to obtain a least-squares fit of the data. A variable proportionality factor, kappa, was also included within the program to adjust the data in the case of a poor estimate for the initial volume of distribution. If the initial rate constant (lambda) estimates did not provide a good statistical fit of the data, the SAAM program increased or decreased the data by a constant factor, kappa (hence decreasing or increasing the volume of distribution), while simultaneously adjusting the lambda values until the best statistical fit was achieved.

To specify that a parameter be subject to iterative adjustment, upper and lower limits were assigned to each kappa and lambda estimate in the model. Lower limits for lambdas were zero (0.0) while upper limits were twice the value of the initial estimate. Upper and lower limits for kappas were 0.5 and 2.0, twice and one-half the initially estimated volume of distribution, respectively.

A routine printout was produced for every problem deck submitted to SAAM and included: a listing of the problem deck with each card printed as reformatted by SAAM, a computer language reorganization of the information in the program deck, parameter values and a table of the initial solution values (zero iteration), and results for each iteration associated with the fitting of the data and final results including parameter values and the corresponding solution table for the best fit with estimated standard errors and correlation coefficients. An optional arithmetic plot of calculated and observed data could be requested and was used in all trichloroethanol pharmacokinetic analyses.

The final parameter values obtained with the SAAM program were $k_{B,T} = 0.1506$, $k_{T,B} = 0.0602$, $k_{B,T'} = 0.0082$, $k_{T',B} = 0.0030$, and $k_{B,L_1} = 0.0505$ for the 30-mg./kg. dose given Dog D. A kappa value of 1.30 was required to fit the data. This kappa served to raise the calculated initial trichloroethanol concentration from 0.142 mg. trichloroethanol/ml. of blood (or 0.0237 as percent of total dose per milliliter of blood) to 0.185 mg./ml. blood (or 0.031 as percent of total dose per milliliter blood) and hence changed the calculated apparent volume of distribution, V_B, referenced to total concentration in the blood (Eq. 24) from 4.24 to 3.26 l. Thus, the

[18] IBM model 360/50.

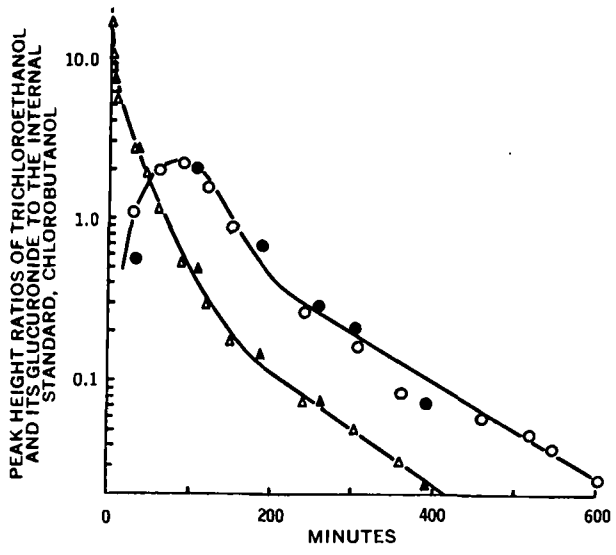

Figure 6—*Semilogarithmic plots of the peak height ratios to the internal standard chlorobutanol of trichloroethanol and trichloroethanol glucuronide blood concentrations with time for a 50-mg./kg. trichloroethanol dose in the absence and presence of pentobarbital anesthesia. The open circles and triangles represent the trichloroethanol and trichloroethanol glucronide blood concentrations for the first dose of trichloroethanol given to the dog in the absence of pentobarbital anesthesia. The solid circles and triangles are the trichloroethanol and trichloroethanol glucuronide data for an identical dose of trichloroethanol given 7 days later to the dog anesthetized with 30 mg./kg. pentobarbital. A peak height ratio of 1.0 is equivalent to 8.4 mcg. trichloroethanol or 18.3 mcg. trichloroethanol glucuronide/ml. whole blood.*

apparent volume of distribution referenced to the concentration of unbound trichloroethanol in the plasma, V_P^u, is 3.37 l. (Eq. 34).

It also follows that the apparent volumes of distribution of the tissue compartments referenced to the unbound drug concentration in plasma are $V_{T_P}^u$ = 26.1 l. from Eq. 59 and $V_{T'_P}^u$ = 29.7 l. from Eq. 60. These are in decided contrast to the apparent volumes of distribution of the tissue compartments if they were referenced to the total drug concentration in blood, since V_{T_B} = 8.1 l. and $V_{T'_B}$ = 8.8 l.

RESULTS AND DISCUSSION

Sensitivity and Reliability of Analytical Methods—A typical chromatogram for a 5-μl. aliquot of the ether extract of a solution of trichloroethanol and its glucuronide, chloral hydrate, and trichloroacetic acid is given in Fig. 1. The dashed line over the trichloroethanol chromatographic peak was the peak observed after 48 hr. of hydrolysis with β-glucuronidase when the glucuronide was present in the sample. It includes free and conjugated trichloroethanol.

The trichloroethanol produced by the β-glucuronidase- (1 mg.) catalyzed hydrolysis of its glucuronide in urine was monitored gas chromatographically as a function of time. A plot of the logarithm of the difference between the peak height ratio (trichloroethanol to chlorobutanol) at infinite time and the peak height ratio at a time, t, against that time was linear and demonstrated a first-order hydrolysis of the glucuronide. The half-life of the solvolysis of glucuronide under the conditions specified in this paper was obtained from the slope of this plot and was 8 hr., so that 98% hydrolysis would be effected after 48 hr. of incubation at 37°.

Concentrations as low as 0.5 mcg. of trichloroethanol, its glucuronide, or chloral hydrate (3.3, 1.54, or 3.0 μmoles, respectively) in 3.0 ml. of water, urine, or blood were assayable. The sensitivity for trichloroacetic acid was 5 mcg. (31 μmoles) in 3.0 ml. Linear calibration curves were obtained for all compounds over a 20-fold concentration range (7). Assay values (trichloroethanol–chlorobutanol peak height ratios) from the trichloroethanol "spiked" blood of four different dogs showed a maximum deviation of less than 3%. Deviation of 2–4.8% resulted between refrigerated blood samples stored up to 168 hr. and calibration standards.

***In Vivo* Inhibition of Trichloroethanol Glucuronidation by Sulfobromophthalein**—The intravenous administration of 10 mg./kg. of sulfobromophthalein concurrently with a 60-mg./kg. dose of trichloroethanol and subsequent infusion of 0.6 mg./min. sulfobromophthalein did not result in any alteration in the pharmacokinetic profile of trichloroethanol and its glucuronide in Dog E when the data were compared with those obtained for an equal dose of trichloroethanol with no sulfobromophthalein administered 4 hr. previously (Fig. 4 and Table I). When the experiment was repeated and the dose of sulfobromophthalein was increased in Dog E to 50 mg./kg., with a subsequent infusion of 3 mg./min. of sulfobromophthalein, a significant decrease in the rate of loss of trichloroethanol from the blood was observed (Fig. 5 and Table I).

Possible Interaction of Pentobarbital Anesthesia with Trichloroethanol Pharmacokinetics—The use of pentobarbital anesthesia in the pharmacokinetic studies of trichloroethanol and its metabolites in the dog was necessitated by the animal's hyperexcitability and difficulty in handling without initial sedation prior to drug administration. However, studies were made in the same animal (Dog E) with the same trichloroethanol doses (50 mg./kg.) with and without pentobarbital anesthesia. The plotted data (Fig. 6) demonstrated no apparent difference in the time course of trichloroethanol or its glucuronide in blood, a valid indication that pentobarbital anesthesia had no significant effect on the pharmacokinetics of trichloroethanol and its glucuronide.

Hepatic Storage of Trichloroethanol and/or Its Glucuronide—The portal and hepatic veins were sampled with time and assayed for trichloroethanol and its glucuronide in the dog that was surgically modified (11) so that the vena cava was occluded and the vena caval flow did not dilute the hepatic output. The trichloroethanol extracted by the liver per milliliter of blood, $[TCE]_L$/ml., was determined from the subtraction of the trichloroethanol concentration in the hepatic vein blood from the concentration in the portal vein blood. The trichloroethanol glucuronide per milliliter of blood, $[TCE\text{-}G]_L$/ml., released by the liver was determined from the subtraction of the glucuronide concentration (as trichloroethanol) in the portal vein blood from the concentration in the hepatic vein blood.

The difference in these two values, $[TCE]_L$/ml. − $[TCE\text{-}G]_L$/ml., represents the storage of trichloroethanol and/or its glucuronide in the liver in terms of concentration per milliliter of blood. When this difference is multiplied by an estimate of the hepatic blood flow, 600 ml./min. for a 15-kg. dog (32), the net amount of trichloroethanol and/or its glucuronide extracted per minute from the hepatic blood is estimated. A plot of such data against time (Fig. 7) indicates that significant accumulation of trichloroethanol and/or its glucuronide in the liver is terminated within an hour of drug administration; *i.e.*, the liver may be considered saturated with respect to the drug and/or its metabolites. When blood hepatic and portal vein samples were analyzed at 90 min., the process was reversed. The amount of glucuronide released by the liver exceeded the trichloroethanol extracted or transformed by the liver so that it can be concluded that the accumulated liver storage of trichloroethanol and/or its glucuronide was being depleted.

The insert of Fig. 7 plots the area under the estimated curve of Fig. 7 against time and thus represents the cumulative amount of trichloroethanol and/or its glucuronide retained by the liver with time. Since the initial rates of drug and/or metabolite retention were estimated from a presumed linear relation with time, the maximum amount of drug and/or metabolite retention in the insert of Fig. 7 is undoubtedly underestimated.

Trichloroethanol Distribution in Dogs—The fractions of trichloroethanol and its glucuronide bound to protein were based on the equilibrium dialysis experiments with dog plasma and calculated from:

$$\text{fraction bound} = \frac{\text{concentration of drug inside dialysis bag} - \text{concentration outside}}{\text{concentration of drug inside dialysis bag}} \quad \text{(Eq. 84)}$$

The values obtained (Table II) were in agreement with those reported by Marshall and Owens (5) for trichloroethanol binding by reconstituted lyophilized human plasma. Control experiments (dialysis in the absence of plasma) gave no evidence that trichloroethanol or its glucuronide was bound by the dialysis sac. Approxi-

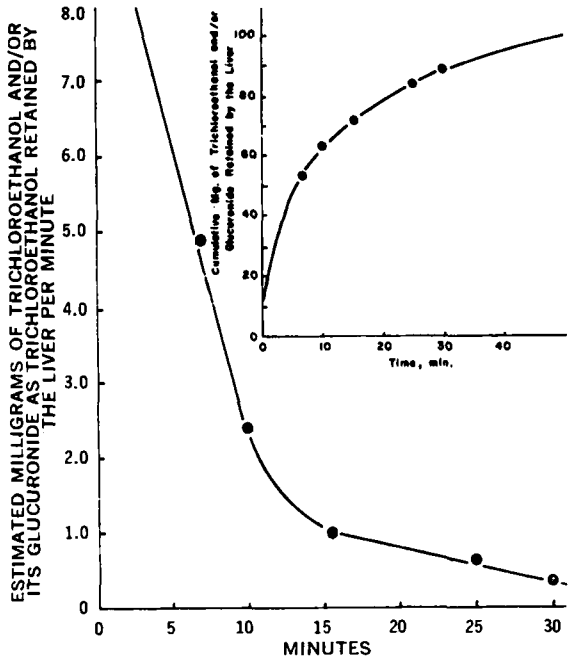

Figure 7—*Estimated amount of trichloroethanol as itself or as its glucuronide that is stored in the liver per minute after injection of a 50-mg./kg. dose of trichloroethanol in the hepatic portal vein in a dog that was surgically modified so that the vena cava was occluded and the vena caval flow did not dilute the hepatic output. The differences in the simultaneously assayed concentrations in milligrams per milliliter of trichloroethanol plus its glucuronide of the hepatic and portal vein bloods were multiplied by an estimated hepatic blood flow of 600 ml./min. to estimate the milligrams of trichloroethanol and/or its glucuronide per minute accumulated in the liver. At 90 min., the glucuronide released by the liver exceeded the trichloroethanol extracted or transformed by the liver. The inset is the cumulative curve for the milligrams of drug and/or its metabolite retained by the liver with time.*

metely 35% of the trichloroethanol found in plasma was bound to protein, and this percent was independent of the plasma concentration of trichloroethanol (Table II). Fifty-three percent of the total trichloroethanol in the entire blood was instantaneously distributed into red blood cells; 16% was bound to plasma proteins and 31% was free (Eqs. 20–22).

The partition coefficient for the ratio of drug concentration in the red blood cells to the drug concentration in plasma unbound to protein, D (Eq. 8), was calculated from Eq. 12 and was taken as 2.1 (Table III). The determined hematocrit, H, was 0.45.

Table II—Data for Estimation of Binding of Trichloroethanol and Its Glucuronide to Plasma Proteins

Compound	Micrograms per Milliliter[a]	Equilibrated Concentration inside Sac[b]	Equilibrated Concentration outside Sac[a]	Percent Bound[d]
Trichloroethanol	5	0.89	0.56	37.4[e]
	50	9.5	5.8	38.7[e]
	500	106.7	70.6	33.8[d]
Trichloroethanol glucuronide	9	0.67	0.4	36.2
	45	2.9	2.2	25.3

[a] Concentrations in 10.0 ml. of pH 7.4 phosphate buffer dialyzed against 2 ml. of dog plasma inside the dialysis sac. [b] Given in terms of trichloroethanol–chlorobutanol peak height ratio, $(TCE/CB)_t$, per milliliter of plasma. [c] Given in terms of trichloroethanol–chlorobutanol peak height ratio, $(TCE/CB)_0$, per milliliter of pH 7.4 phosphate buffer. [d] Percent bound = $100\ [(TCE/CB)_t - (TCE/CB)_c]/(TCE/CB)_t$. [e] The percent errors for total trichloroethanol in the plasma–buffer dialyses *versus* the buffer–buffer controls were 6, 6.7, and 9.4%.

Table III—Red Blood Cell–Plasma Partition Coefficients (D) for Trichloroethanol and Its Glucuronide

Compound	Micrograms per Milliliter	Concentration[a] Whole Blood	Concentration[a] Plasma	D[b]
Trichloroethanol	0.294	0.03	0.02	2.1
	2.94	0.32	0.28	2.0
	47.7	4.68	3.30	2.9[c]
	26.7	3.18	2.17	3.1[c]
	34.0	4.03	3.29	2.3
Trichloroethanol glucuronide	29.1	1.87	3.57	—[d]

[a] Given in terms of trichloroethanol–chlorobutanol peak height ratios per milliliter. [b] Calculated from Eq. 12 for the ratio of concentration of drug in the red blood cells to the concentration of unbound drug in plasma as defined in Eq. 8. [c] Blood samples from a dog that had received 50 mg./kg. of trichloroethanol and 50 mg./kg. of sulfobromophthalein. [d] A value of −0.07 was obtained for the trichloroethanol glucuronide.

The initial apparent volumes of distribution of trichloroethanol referenced to the concentration in whole blood, V_B, and to the unbound concentration in plasma, $V_P{}^u$, were reasonably consistent among the animals studied at all doses (Tables I and IV). The apparent volumes of distribution of the central compartment referenced to the concentration of unbound drug in plasma were approximately equivalent to the extracellular body water of the dog, *i.e.*, 200–350 ml./kg. (18). Thus, it may be assumed that the diffusion of trichloroethanol into the extracellular body water occurred during its first cycles through the circulatory system and the kinetics of its distribution could not be readily observed.

Table IV shows that the apparent volume of distribution of the central compartment which was equated to extracellular water was significantly larger for small dogs (10 kg.) compared to larger dogs (16–20 kg.) on a milliliter per kilogram basis.

The compartment, T (Scheme V), that readily equilibrated with the central compartment had an apparent volume of distribution referenced to the concentration of unbound drug in plasma, $V_{T_P}{}^u$, of 4–6 times the apparent volume of the central compartment similarly referenced (Table IV). Since the total body water is only about 2.5 times that of the extracellular body water (500–750 ml./kg.) in the dog (18), it is implied that trichloroethanol in the central compartment readily equilibrates with lipoidal tissues as well as total body water. The presence of a deep compartment, T', of relatively large capacity in most instances (Table IV) implicates a

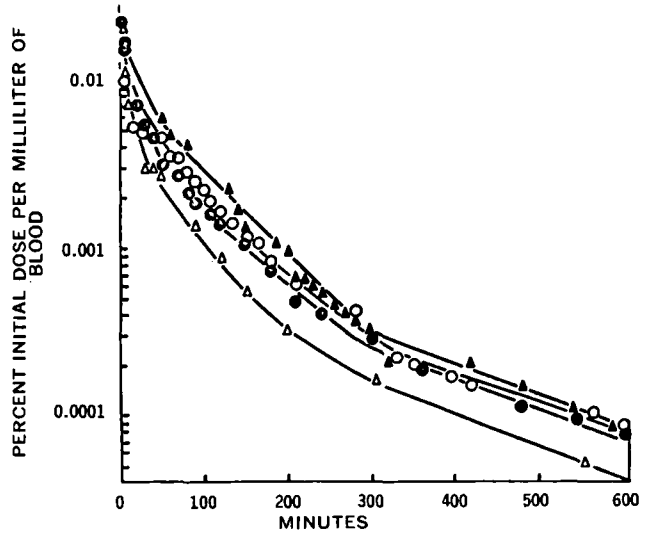

Figure 8—*Semilogarithmic plot of trichloroethanol blood concentrations (as percent initial dose per milligrams whole blood) with time for doses of 17 (△), 50 (●), 100 (○), and 150 (▲) mg. trichloroethanol/kg. in Dog D. The data points were calculated by dividing the trichloroethanol concentration (milligrams per milliliter) by the dose (milligrams) and multiplying by 100.*

Table IV—Range of Apparent Volumes of Distributions for Trichloroethanol (ml./kg.) for All Doses in Dogs

	Dog				
	A	B	C	D	E
Weight, kg.:	16	18.6	10	18	10
V_B	184	180	227	180	240
V_{P^u}	204	198	283	197	303
$V_{T_{P^u}}$	900 ± 10	1130 ± 50	1430 ± 200	1200 ± 100	1100 ± 100
$V_{T'_{P^u}}$	1250 ± 120	310 ± 20	3300 ± 400	1300 ± 300	1800 ± 200

slowly equilibrating, nonvascularized depot in the body which is also most probably lipoidal.

Effect of Dose on Trichloroethanol Pharmacokinetic Parameters in Dogs—Typical semilogarithmic plots of the trichloroethanol per milliliter of whole blood *versus* time for different intravenous doses in a female mongrel dog, Dog D, are given in Fig. 8. The data are plotted as the percent of dose per milliliter of whole blood:

$$\% \text{ dose/ml. whole blood} = \frac{\text{mg. trichloroethanol/ml. whole blood}}{\text{dose in mg.}} \times 100 \quad \text{(Eq. 85)}$$

which normalizes the data for different doses of trichloroethanol to a common scale. If the parameters for drug disposition were independent of dose, the data of Fig. 8 should be superimposable for all doses. This was not so and was typical of the studies in all dogs. Thus, it must be concluded that the pharmacokinetics of trichloroethanol are dose dependent.

Typical semilogarithmic plots for the appearance and subsequent loss of trichloroethanol glucuronide in blood as a function of time after intravenous administration of trichloroethanol are given in Fig. 9 for Dog C. The data are presented as the peak height ratios of trichloroethanol to chlorobutanol per milliliter of whole blood, where a peak height ratio of 1.0 is equal to 19.5 mcg. of the sodium salt of trichloroethanol glucuronide per milliliter of whole blood.

Similar data for Dog D, but given as the percent of the initial dose per milliliter of whole blood *versus* time, are depicted in Fig. 10. The effect of an increasing trichloroethanol dose on the pharmacokinetics of the glucuronide is to delay and broaden the maximum in glucuronide blood level (Figs. 9 and 10). The height of the maximum in terms of percent of the dose is elevated with the increased dose of trichloroethanol (Fig. 10).

The pharmacokinetic parameters of rate constants and volumes of distribution, which describe the distribution and metabolism of trichloroethanol and the appearance, distribution, and urinary elimination of its glucuronide after intravenous administration of different doses of trichloroethanol, are found in Table I for Dogs A–D. Typical analog computer curves generated from the rate constants of Table I are given for widely varied trichloroethanol doses (10 and 176 mg./kg.) in Figs. 11 and 12 for the data of Dog C.

The rate constant, k_{B,L_1} (Scheme V), for the loss of trichloroethanol to the glucuronide decreased as a function of dose in Dogs A–D (Table I and Fig. 13). The dogs formed two groups of similar k_{B,L_1} values, the rate constants for loss of trichloroethanol from the central compartment at an infinitely small trichloroethanol dosage. Curvilinear extrapolation of the data from the two lean dogs, A and C (10 and 16 kg., respectively) gave an estimated k^0_{B,L_1} of 0.086 min.$^{-1}$, while a value of 0.069 min.$^{-1}$ was obtained for the two obese dogs, B and D (18 and 18.6 kg., respectively) (Fig. 13).

The decrease of the rate constant, k_{B,L_1}, for the loss of trichloroethanol to glucuronide with dose is not unique. Similar dose dependency of apparent first-order disappearance of drug from a central compartment was reported for dicumarol (33), ethyl biscoumacetate (34), probenecid (35), and diphenylhydantoin and phenylbutazone (36). As yet, no satisfactory mechanism has been advanced.

A possible explanation is an *in vivo* saturation by a substrate of a metabolic pathway, as described by Levy (37) for salicylate. Probenecid (38) and diphenylhydantoin (39), which also demonstrate dose-dependent pharmacokinetics, also have been reported to be metabolized by glucuronidation. The coumarin derivatives and phenylbutazone have structures that suggest metabolism by the same route. Chloral hydrate (5 m*M*) has been reported to give 50% inhibition of microsomal *O*-aminophenol conjugation (40).

Sulfobromophthalein was shown to be a potent inhibitor of glucuronidation in *in vitro* experiments with rabbit liver homogenate (40). When 10 mg./kg. of this substance was administered simultaneously with 60 mg./kg. of trichloroethanol, no significant change in k_{B,L_1} was observed from the case when sulfobromophthalein was not administered (Dog E, Table I and Fig. 4), even though the sulfobromophthalein dose used was twice that recommended for studies on hepatic function (10). However, when the sulfobromophthalein dose administered simultaneously with 60 mg./kg. of trichloroethanol was increased to 50 mg./kg., a significant 46% decrease in

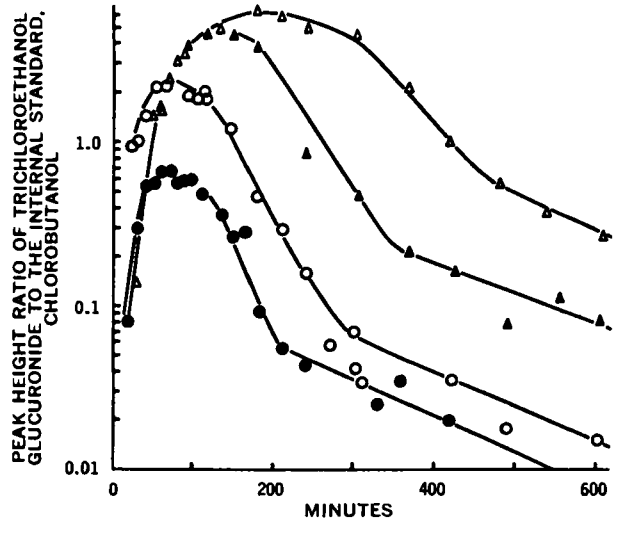

Figure 9—*Semilogarithmic plot of the gas chromatographically obtained peak height ratios for trichloroethanol as trichloroethanol glucuronide to the chlorobutanol internal standard with time for doses of 10 (●), 50 (○), 100 (▲), and 176 (△) mg. trichloroethanol/kg. in Dog C. A peak height ratio, TCE-G/CB, with respect to chlorobutanol (CB) of 1.0 is equivalent to 18.3 mcg. of trichloroethanol glucuronide (or 8.4 mcg. of trichloroethanol)/ml. of whole blood.*

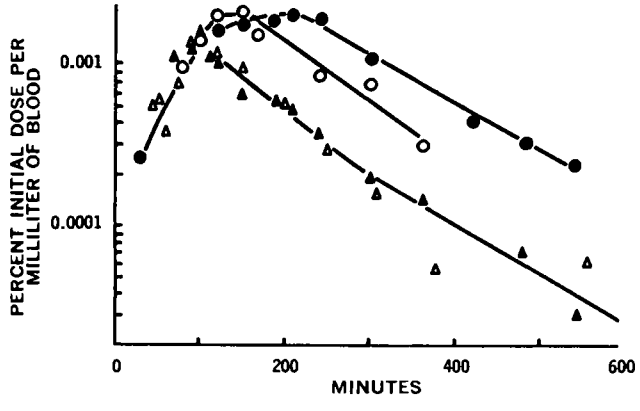

Figure 10—*Semilogarithmic plot of trichloroethanol glucuronide blood levels (as percent initial trichloroethanol dose per milliliter whole blood) with time for doses of 17 (△), 50 (▲), 100 (○), and 150 (●) mg./kg. of trichloroethanol in Dog D. The data points were calculated by converting the glucuronide concentrations to trichloroethanol concentrations (1 mg. glucuronide/ml. = 0.47 mg. trichloroethanol/ml.), dividing by the dose (milligrams), and multiplying by 100.*

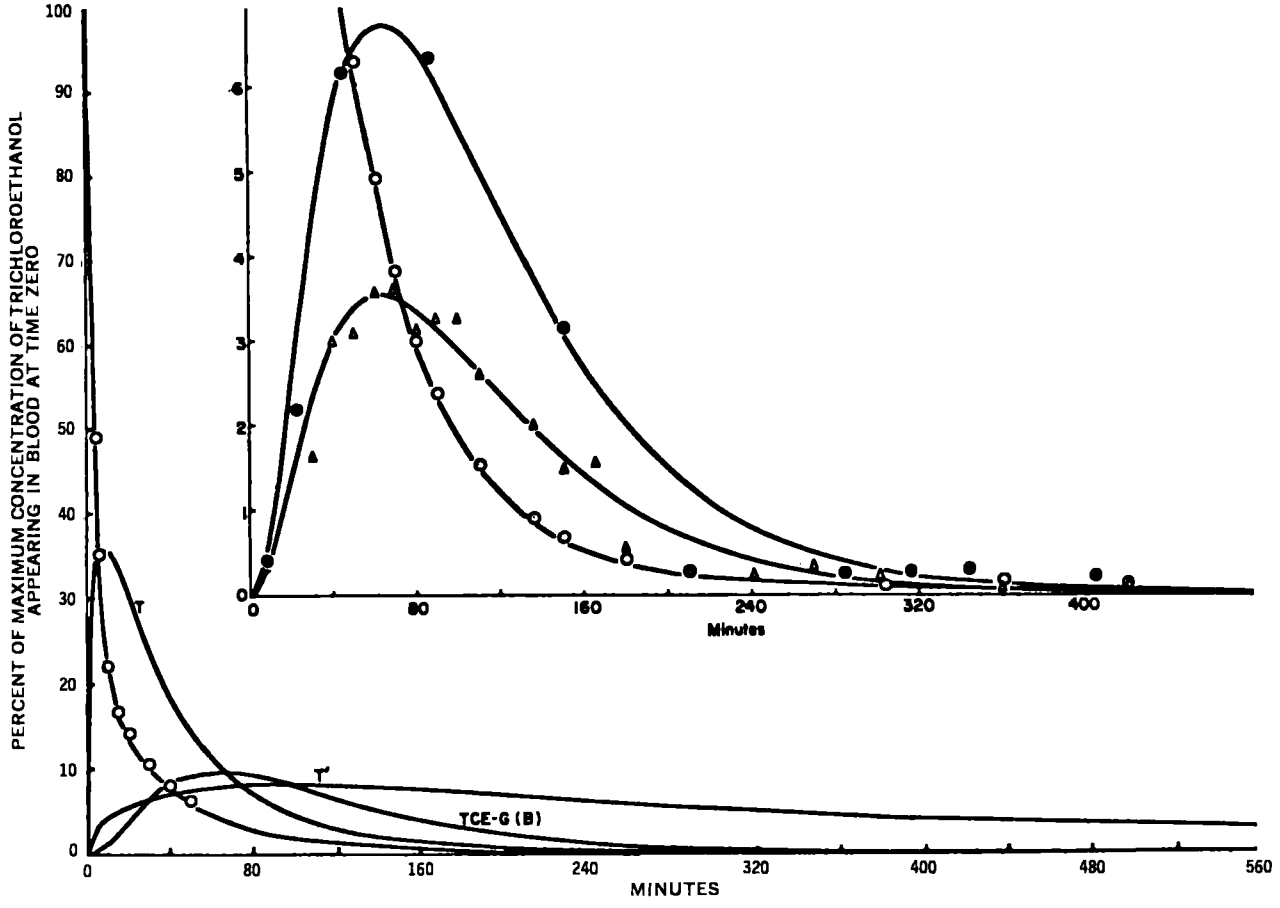

Figure 11—*Analog computer fits of the blood and urine data for a dose of 10 mg. trichloroethanol/kg. in the 10-kg. Dog C. The full-scale portion shows the fit of the data with time for trichloroethanol as the percent of the maximum concentration that appears in the blood at zero time* (○), *as well as the computer curves generated for trichloroethanol in the distribution compartments* T *and* T′ (*Scheme V*). *The remaining curve is for the calculated amount of trichloroethanol glucuronide* (*TCE-G*) *in blood with time. The pertinent microscopic rate constants in Tables I and V were used. The inset curves are expanded scale fittings of the data for trichloroethanol* (○) *and its glucuronide* (△) *in the blood. The latter data were estimated by multiplying the glucuronide blood concentrations by a factor that represented the ratio of the apparent volume of distribution of the glucuronide to that of the trichloroethanol in the central compartment. The solid circles represent the urinary excretion rates of trichloroethanol glucuronide* (*percent dose per minute*) *and are plotted on a 10-fold smaller scale, 0–1.0%/min., than that represented on the inset ordinate.*

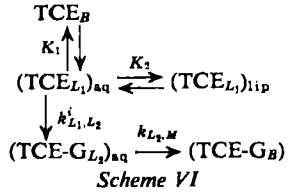
$k_{B\cdot L_1}$ was observed (Dog E, Table I and Fig. 5), which indicated a large capacity for glucuronidation. Since sulfobromophthalein is metabolized by conjugation with glutathione and subsequently eliminated by biliary secretion (41), the observed metabolic inhibition of trichloroethanol metabolism was probably not due to a competition for sites on uridine 5′-diphosphate-glucuronyltransferase.

However, these implications of enzyme saturation or substrate inhibition of enzymic action to explain the metabolic rate decrease with increasing dosage are contradicted by the fact that the loss of trichloroethanol from the blood central compartment can be described by first-order kinetic parameters during its entire time course in the blood for any given dosage (Figs. 2, 3, 11, 12, 14, and 15 and Scheme V). It would be anticipated that the rate of trichloroethanol loss would vary from zero-order dependence at high blood levels to first-order dependence on drug concentrations in the central compartment at low blood levels if enzyme saturation or substrate inhibition occurred (37).

Since the reason for metabolic dependence on dose is probably not at the level of the enzymic conjugation, alternative mechanisms may be considered. They could include decreased availability of the uridine 5′-diphosphate-glucuronic acid cofactor with trichloroethanol dose or decreased uptake of trichloroethanol in the biophase of the hepatic cell with dose. This latter could be rationalized by assuming that the lipid–water ratio of trichloroethanol is altered within cells or among liver tissue components by the initial trichloroethanol dose. The fact that significant storage in the liver of trichloroethanol and/or its glucuronide is indicated (Fig. 7) tends to favor this latter explanation.



Scheme VI

The presence of trichloroethanol may stimulate its permeability into a constant volume of liver fat or may cause an increase in the volume of liver lipids. The phenomenon of fatty liver was reported for polychlorinated hydrocarbons (42) and ethanol (43) and might occur for a drug such as trichloroethanol, which possesses the molecular structure of both substances. Such a premise would necessitate the presumption that fat availability is an immediate and persistent consequence of the initial trichloroethanol dose.

An alternative and more probable, although indistinguishable, effect would be the persistent increase in availability of lipid by the action of increased trichloroethanol concentration, which could conceivably lower the surface tension between lipid and aqueous phases or modify the intervening membranic barriers. On the simple assumption that either of these mechanisms is operative, the intermediate steps between the loss of trichloroethanol and the appearance of its glucuronide in the blood in the pharmacokinetic model of Scheme V may be modified to include an instantaneous distribution of trichloroethanol between an aqueous phase $(TCE_{L_1})_{aq}$ and a lipid phase $(TCE_{L_1})_{lip}$ in the liver with an equilibrium constant K_2 (Scheme VI).

If the rate of glucuronide formation in the liver is a function of the trichloroethanol amount in an aqueous biophase:

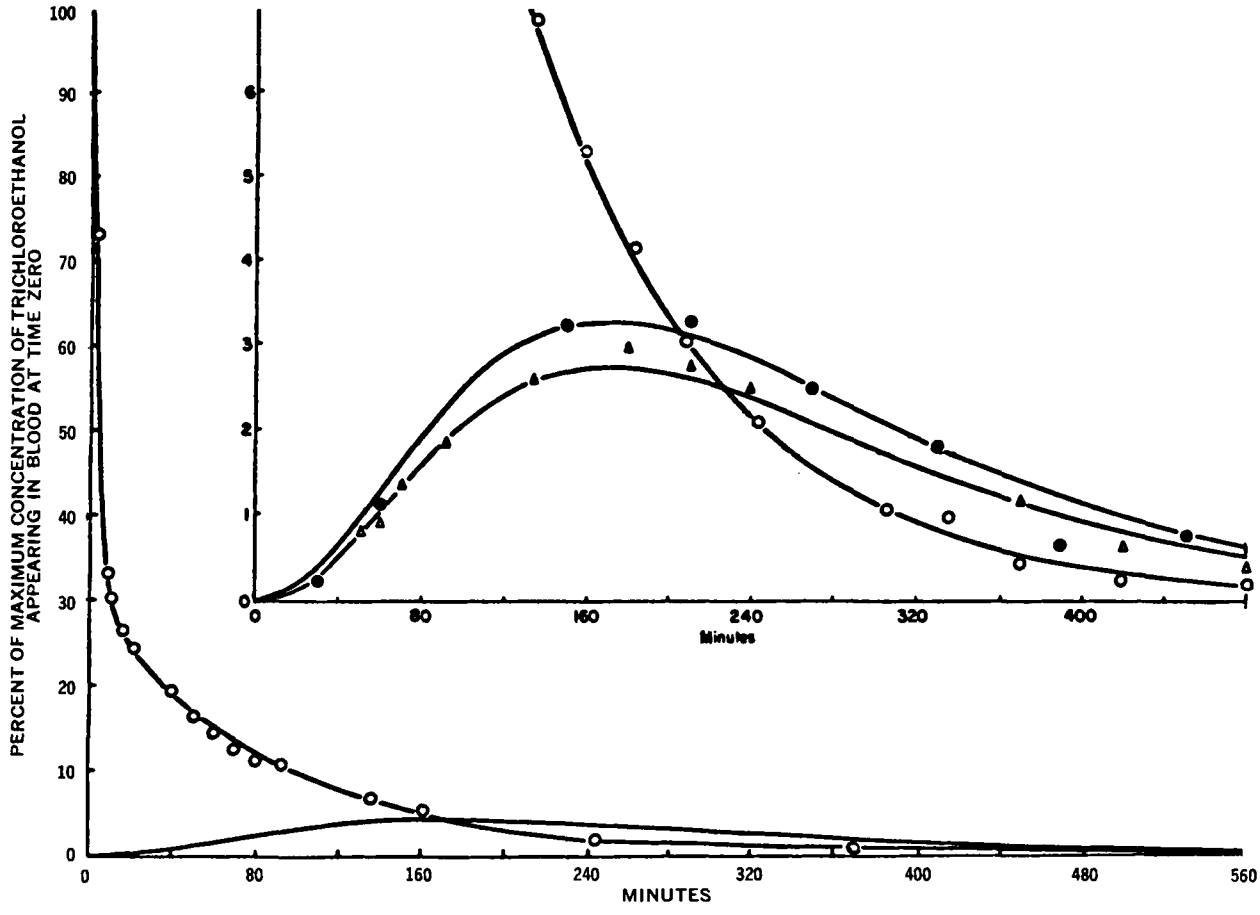


Figure 12—*Analog computer fits of the blood and urine data for a dose of 176 mg. trichloroethanol/kg. in the 10-kg. Dog C. The full-scale portion shows the fit of the data with time for trichloroethanol as the percent of the maximum concentration that appears in the blood at zero time* (○), *as well as the calculated amount of trichloroethanol glucuronide (TCE-G) in blood with time. The pertinent microscopic rate constants in Tables I and V were used. The inset curves are expanded scale fittings of the data for trichloroethanol* (○) *and its glucuronide* (△) *in blood. The latter data were estimated by multiplying the glucuronide blood concentrations by a factor that represented the ratio of the apparent volume of distribution of the glucuronide to that of trichloroethanol in the central compartment. The solid circles represent the urinary excretion rates of trichloroethanol glucuronide (percent dose per minute) and are plotted on a 10-fold smaller scale, 0–1.0%/min., than that represented on the inset ordinate.*

$$d(\text{TCE-G}_{L_1})/dt = -d[(\text{TCE}_{L_1})_{aq} + (\text{TCE}_{L_1})_{lip}]/dt = -d[K_1(\text{TCE}_B) + K_1K_2(\text{TCE}_B)]/dt = k^i_{L_1,L_2}(\text{TCE}_{L_1})_{aq} = k^i_{L_1,L_2}K_1(\text{TCE}_B) \quad \text{(Eq. 86)}$$

It thus follows that:

$$-d(\text{TCE}_B)/dt = \frac{k^i_{L_1,L_2}K_1}{K_1 + K_1K_2}(\text{TCE}_B) = \frac{k^i_{L_1,L_2}}{1 + K_2}(\text{TCE}_B) = k_{B,L_1}(\text{TCE}_B) \quad \text{(Eq. 87)}$$

and the apparent first-order rate constant, k_{B,L_1}, is not an intrinsic constant but a function of the equilibrium, K_2, between the aqueous and fatty phases or its equivalent, the relative volumes of lipid and aqueous phases in the hepatic cell or liver. If either of these factors is a persistent function of the initial trichloroethanol dose so that K_2 increases with dose, the apparent rate constant, k_{B,L_1}, will decrease with dose.

If K_2 is linearly related to dose, A_0, then:

$$K_2 = K_2^0 + mA_0 \quad \text{(Eq. 88)}$$

where K_2^0 is the intrinsic lipid–aqueous distribution in a liver unchallenged by trichloroethanol.

Substitution of Eq. 88 into Eq. 87 yields:

$$k_{B,L_1} = \frac{k^i_{L_1,L_2}}{1 + K_2^0 + mA_0} \quad \text{(Eq. 89)}$$

and, on taking reciprocals:

$$1/k_{B,L1} = \frac{1 + K_2^0}{k^i_{L_1,L_2}} + \frac{mA_0}{k^i_{L_1,L_2}} \quad \text{(Eq. 90)}$$

A plot of the reciprocal of the apparent first-order rate constant for the loss of trichloroethanol from the blood against trichloro-

ethanol dose in accordance with Eq. 90 is given in Fig. 16 and is not inconsistent with the postulated relationship.

Trichloroethanol Glucuronide Distribution and Elimination in the Dog—After immediate equilibration in an initial apparent volume of distribution referenced to the concentration of unbound drug in plasma of 169 ml./kg. (Table V), which is about 3 times the true plasma volume of the dog, the intravenously administered glucuronide rapidly diffused into a compartment (TCE-G_T in Scheme V) of an equivalent apparent volume (Table V). The sum of the two volumes (330 ml./kg.) approximated the 200–380 ml./kg. reported for total extracellular water in dogs (16). The glucuronide did not distribute from plasma into red blood cells. The fraction, f, of glucuronide in plasma bound to protein was taken as 0.35 (Table I).

The urinary elimination of trichloroethanol glucuronide was rapid, with an apparent half-life of 15 min. for the greater portion of drug in the body (Fig. 17). No trichloroethanol or trichloroacetic acid was observed in any assayed blood or urine sample.

The semilogarithmic plot of the decrease in blood concentration of trichloroethanol glucuronide with time (Fig. 17) was triphasic and consistent with the three-component polyexponential expression of Eq. 63. Appropriate feathering, as demonstrated in Fig. 17, permitted preliminary estimates of the parameters of the equation. The cited apparent half-lives in Fig. 17 are inversely related to the k_i constants of Eq. 63. When the logarithm of the amount of unexcreted drug, log $(U_\infty - U)$, obtained from cumulative assays of glucuronide in the urine, was plotted against time (13), similar

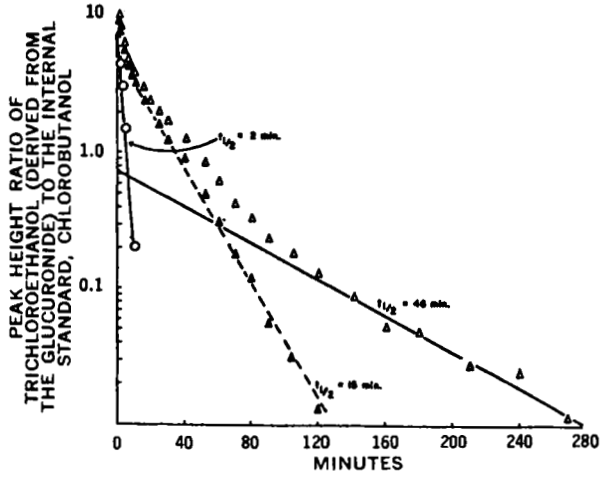

Figure 17—*Semilogarithmic plot of trichloroethanol glucuronide concentrations in blood with time in terms of gas chromatographically obtained peak height ratios of derived trichloroethanol to the internal standard, chlorobutanol, after a dose of 450 mg. (38 mg./kg.) of trichloroethanol glucuronide to Dog C. The original data are represented with open triangles. The three distinct phases obtained by feathering (i.e., the circles, solid triangles, and terminal open triangles) are labeled respectively with their apparent half-lives.*

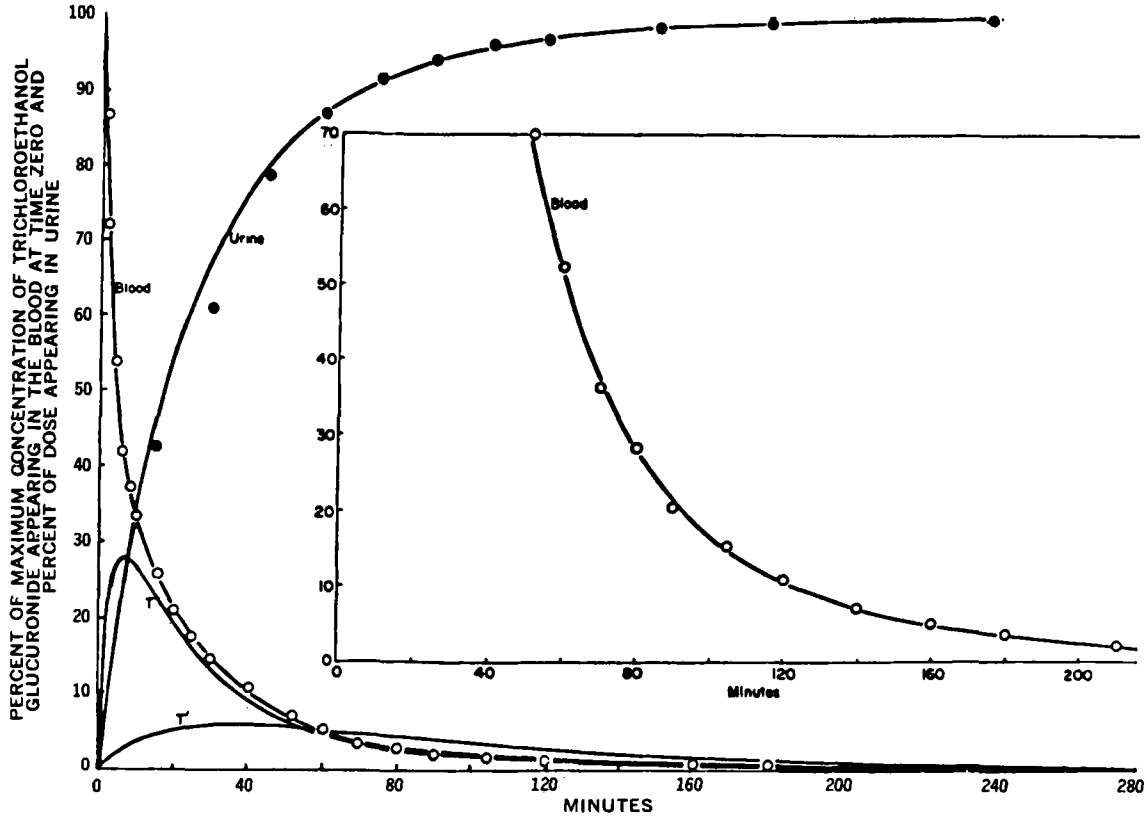

Figure 18—*Analog computer fits of the blood and urine data for trichloroethanol glucuronide in blood and urine after a 39-mg./kg. dose of trichloroethanol glucuronide to the 10-kg. Dog C. The full-scale portion shows the computer fit with time of the data for the glucuronide as the percent of the maximum concentration that appears in the blood at zero time* (○) *and as the percent of the total dose that appears ultimately in the urine* (●). *The curves are also generated for the trichloroethanol glucuronide in the distribution compartments* T *and* T′ *(Scheme V). The inset is an expanded scale fitting of the data for trichloroethanol glucuronide in blood. The microscopic rate constants of Table V were used.*

apparent half-lives for the second and third phases were observed by feathering and were 15 and 45 min., respectively. The first phase of Fig. 17 ($t_{1/2}$ = 2 min.) was not observed in the urinary data. An analog computer fit of trichloroethanol glucuronide data in blood and urine with time in accordance with a model similar to that of Scheme III is given in Fig. 18 (see also Scheme V).

A plot of percent of glucuronide dose excreted in urine per minute against percent of glucuronide dose per milliliter of plasma provided a good linear slope to estimate a clearance of 130 ml./min. This was consistent with the product of $k_{M,U}$ and V_P of 140 ml./min. (13). The $V_P = V_P{}^u(1 - f) + V_{P\text{true}}f$ can be estimated from the $V_P{}^u$ of Table V, where f = 0.30 in accordance with Eq. 36. Since the rena clearance values for inulin (glomerular filtration) for a 12-kg. dog can be calculated to be 51 ±12 ml./min. (44), it is probable that the intravenously administered glucuronide was eliminated by filtration

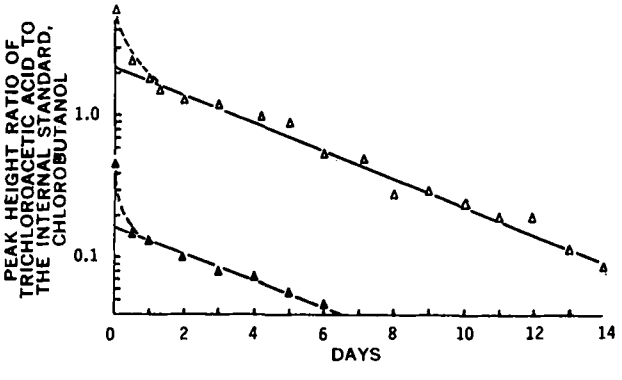

Figure 19—*Semilogarithmic plots of the blood trichloroacetate concentrations with time in terms of the gas chromatographically determined peak height ratios of trichloroacetic acid to the internal standard, chlorobutanol, after doses of 100 mg.* (▲) *and 1.0 g.* (△) *of sodium trichloroacetate to two different dogs. A peak height ratio with respect to chlorobutanol of 1.0 is equivalent to 70 mcg. trichloroacetic acid/ml. of whole blood.*

Table V—Trichloroethanol Glucuronide Pharmacokinetic Parameters[a] of Dog C (12 kg.) Administered 450 mg. of Glucuronide (37.5 mg./kg.)

$[A_B]_0$[b]	0.034
V_B[c]	2.94 l.
$V_P{}^u$[d]	2.03 l.
V_{TP^u}[e]	2.0 l.
$V_{T'P^u}$[f]	1.4 l.
$k_{M,T}$	0.133 (0.013) min.$^{-1}$
$k_{T,M}$	0.190 (0.019) min.$^{-1}$
$k_{M,T'}$	0.008 (0.0006) min.$^{-1}$
$k_{T',M}$	0.017 (0.0007) min.$^{-1}$
$k_{M,U}$	0.069 (0.0006) min.$^{-1}$

[a] The microscopic rate constants are defined in Scheme V for trichloroethanol glucuronide (TCE-G) in the various compartments and are given in minutes^{-1} and are referenced to total amounts in blood. The compartments and transfers for trichloroethanol in Scheme V are to be ignored. The numbers in parentheses are standard deviations of the stated parameters obtained by digital computer fitting with the SAAM program. [b] The computer-fitted zero time concentration of trichloroethanol glucuronide in blood, A_0, in terms of percent of dose per milliliter of whole blood. [c] The apparent volume of distribution of the central compartment referenced to total concentration in blood is V_B = (100%/$[A_B]_0$) in liters. [d] The apparent volume of distribution of the central compartment referenced to the concentration of glucuronide unbound to protein is $V_P{}^u = V_B(2.31) - 0.24V_{B\text{true}}$ after Eq. 34, where H = 0.45, f = 0.30 (Table II), D = 0 (Table III), and $V_{B\text{true}}$ = 0.1 × weight of dog in kg. (16). [e] The apparent volume of distribution referenced to the concentration of unbound glucuronide in the plasma of the rapidly equilibrating compartment, T, in liters, where $V_{TP^u} = V_P{}^u(k_{M,T}/\gamma_P{}^u k_{T,M})$, where $\gamma_P{}^u = 1 - f$ as calculated from Eq. 22. [f] The apparent volume of distribution referenced to the concentration of unbound glucuronide in the plasma of the slowly equilibrating compartment, T', in liters, where $V_{T'P^u} = V_P{}^u(k_{M,T'}/\gamma_P{}^u k_{T',M})$.

Table VI—Renal Clearance of Trichloroethanol Glucuronide at Various Dose Levels of Trichloroethanol

Dog (Weight, kg.)	Trichloroethanol Dose, mg./kg.	Observed Glucuronide Clearance, ml./min.[a]
A	10	139
(16)	50	143
B	10	256
(18.6)	25	256
	100	128[b]
C	10	130
(10)	50	130
	100	60[b]
	176	60[b]
D	17	203
(18)	50	203
	100	101[b]
	150	101[b]

[a] Observed clearance equals percent dose per milliliter plasma/percent dose per minute in urine, as obtained from the slope of plots of glucuronide as percent of trichloroethanol dose excreted into urine per minute plotted against the glucuronide as percent of trichloroethanol dose per milliliter of plasma. [b] At the lower concentrations of glucuronide in plasma, *i.e.*, close to the origin in the plots specified in *Footnote a*, the data follow the straight line drawn through the data for the lower doses of 10–50 mg./kg. of trichloroethanol. The data at the higher concentrations of glucuronide in the plasma fall below this line and become linear at a new and lower slope from which these clearances are estimated.

and tubular secretion at the studied glucuronide dosage of 38 mg./kg.

The glucuronide was distributed into another small compartment of apparent volume, $V_{T'_P}$[u] (Table V). The slow rate of drug return to this compartment was necessary to fit the blood and urine data from 1.5 to 12 hr. after glucuronide dosage (Figs. 17 and 18).

Analyses of the data for glucuronide formed on trichloroethanol dosing in all dogs demanded two compartments between TCE_B and $TCE\text{-}G_B$ (Scheme V) to fit the lag time in glucuronide appearance in the blood and the broad maximum that occurred in the glucuronide blood level–time curves (Figs. 3, 6, 9–12, 14). The rate constant $k_{L_1,M}$ (Table I) from the studies on trichloroethanol administration was remarkably similar to $k_{T',M}$ (Table V) on glucuronide administration. It may be conjectured that the compartment T' for intravenously administered glucuronide represented the hepatic uptake or binding of a small fraction of circulating glucuronide and $k_{T',M}$ was the rate constant for release of this sequestered glucuronide from liver back to blood.

Table VII—Effect of Trichloroethanol Dose on Bile Flow Rate and Biliary Secretion of Trichloroethanol Glucuronide

Dose, mg./kg.	Minutes	Bile Flow, ml./hr.	Percent Dose Excreted in Interval	Total Percent of Dose Excreted as Glucuronide

[a] Weight of dog was 13.0 kg. [b] Weight of dog was 9.6 kg.

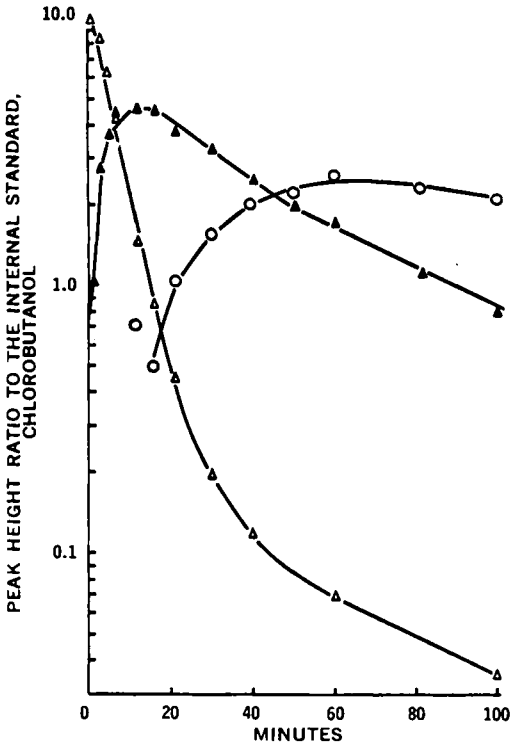

Figure 20—*Semilogarithmic plot of blood concentrations of chloral hydrate (△), trichloroethanol (▲), and trichloroethanol glucuronide (○) in terms of peak height ratio against time for a dose of 500 mg. of chloral hydrate (42 mg./kg.) in Dog C. A peak height ratio to the internal standard, chlorobutanol, of 1.0 is equivalent to 4.3 mcg. chloral hydrate, 8.4 mcg. trichloroethanol, or 18.3 mcg. trichloroethanol glucuronide/ml. whole blood.*

The renal clearances of trichloroethanol glucuronide declined with the higher glucuronide concentration in blood that resulted from the higher doses of trichloroethanol (Table VI). Such clearances were obtained from the slopes of plots of glucuronide as percent of the trichloroethanol dose excreted into the urine per minute against the glucuronide as percent of this dose per milliliter of plasma. These clearances are theoretically the product of the microscopic rate constant for renal excretion of glucuronide, $k_{M,U}$, referenced to total amounts of glucuronide in the plasma and the apparent volume of distribution of the central compartment, V_P, which is also referenced to the drug concentration in the plasma (13) and may be obtained from V_P[u] in Table V by a rearrangement of Eq. 36. The decrease of these clearances with higher blood levels of glucuronide can be assigned to either a lowering of the apparent volume of distribution of the central compartment for glucuronide or a decrease in the $k_{M,U}$ factor for renal excretion of the glucuronide at the higher blood levels. Since the latter is consistent with the claim that a tubular secretory pathway is saturable for carboxylates and other anions (45), it is the preferred explanation.

These decreased glucuronide clearances and the previously discussed lowered rate constant $k_{B,L}$ for the loss of trichloroethanol and glucuronide with increased trichloroethanol dose readily explain the observed retarded time of appearance of maxima in glucuronide blood levels at the higher doses of trichloroethanol (Figs. 9 and 10).

Renal and Fecal Elimination of Trichloroethanol as Its Glucuronide—The excretion of free, unmetabolized trichloroethanol in feces and urine accounted for less than 3% of the administered dose. Essentially, the drug was excreted in the urine as the glucuronide. The average amount of trichloroethanol found in fecal samples collected between 0 and 12 hr. after trichloroethanol administration for 12 experiments was 0.3% of the dose and ranged from 0 to 1.5%. No glucuronide was found in the feces in these experiments. A

mean of 1.5% of the total dose was found in the urine as unconjugated trichloroethanol in 27 experiments. The negligible amounts of fecal elimination of trichloroethanol and its metabolites and urine elimination of trichloroethanol permitted these routes to be ignored in the pharmacokinetic modeling. Any significant amount of trichloroethanol or its glucuronide excreted in the bile must be significantly reabsorbed, with the glucuronide being readily hydrolyzed; *i.e.*, an enterohepatic shunt could be postulated. The highly lipid-soluble trichloroethanol is undoubtedly extensively reabsorbed from the renal tubules and subsequently glucuronidated.

A variable fraction (10–20%) of doses of trichloroethanol could not be accounted for in cumulative urine and fecal assays and most probably was eliminated *via* other routes (*e.g.*, saliva, sweat, and breath), which is to be expected for any low molecular weight alcohol. It is also possible that a small fraction of trichloroacetate was produced and was unavailable for assay because of its tight binding to tissues.

Biliary Secretion of Trichloroethanol and Its Glucuronide—When samples of the bile were assayed from two different dogs administered trichloroethanol, significant biliary concentrations of the glucuronide were obtained. Semilogarithmic plots of the concentration of trichlorethanol and its glucuronide in blood and the glucuronide in bile against time are given in Figs. 14 and 15 for the two experiments.

Maximum biliary concentrations of the glucuronide were 60–85 times the concentrations in whole blood (30–42.5 times the plasma concentration) in the first dog (Fig. 14) for doses of 11.5 and 46.0 mg./kg. However, trichloroethanol concentrations in bile were much less and did not exceed 2.5 times the trichloroethanol blood concentrations so that the total trichloroethanol excreted by this route was not of practical significance.

When the second dog was dosed with 50 mg./kg. of trichloroethanol, the maximum biliary glucuronide concentrations were again greater than 60 times the blood concentration for a 50-mg./kg. dose of trichloroethanol. However, an increase of the trichloroethanol dose to 100 mg./kg. did not increase the biliary concentration of the glucuronide (Fig. 15), which was only 30-fold that of its blood concentration. This apparent inhibition of biliary trichloroethanol glucuronide secretion was concomitant with a slowed loss of trichloroethanol and its glucuronide from the blood (Fig. 15), phenomena which seem to be common to the higher trichloroethanol doses. (See k_{B,L_1} values at various doses in Table I.)

The inhibition by chloral hydrate of the biliary secretion in rats of indocyanine green (a nonmetabolized dye used to evaluate cardiac function) and bilirubin glucuronide was previously reported (40). Doses estimated at 50–100 mg. chloral hydrate/kg. were inhibitory while 10-fold smaller doses had no effect.

Guarino and Schanker (38) reported saturation of biliary secretion of probenecid and its glucuronide at a dose of 0.18 m*M*/kg. The dose of trichloroethanol required for the same effect in these experiments was 0.67 m*M*/kg.

A compilation of the bile flow rates and percentages of the initial dose excreted as the trichloroethanol glucuronide in bile within the specified time intervals is given in Table VII. The data show that bile flow rate increases as a function of increasing trichloroethanol dose. This chloretic effect was previously reported for chloral hydrate (46) and for probenecid (38).

About 5% of the dose was biliary excreted as the glucuronide in the total interval studied. This was consistent with the data of Owens and Marshall (6), from which it was calculated that about 8% of an administered dose was excreted in the bile within 3–4 hr. after intravenous administration of trichloroethanol.

Pharmacokinetics of Trichloroacetic Acid—The apparent disposition half-life for both 0.1- and 1.0-g. doses of trichloroacetic acid as the sodium salt in the dog was 75 hr., which was similar to that in man (47) (Fig. 19). No trichloroacetic acid was found in a pooled 10-day fecal sample. The apparent volume of distribution of 100 and 1000 mg. of sodium trichloroacetate in the central compartment referenced to the concentration in whole blood may be calculated (Eq. 24) from the time zero estimate of blood concentration, $[A_B]_0$ (Fig. 19), as 3.6 l. This value is consistent with the 2.0–3.5 l. (in a 10-kg. dog) or 3.0–5.3 l. (in a 15-kg. dog) of extracellular body water (18), even when a 0.40-l. volume for red blood cells is subtracted. However, since the protein binding of trichloroacetate is in the range of 70–90% (5), the apparent volume of distribution of trichloroacetic acid referenced to unbound drug in the plasma will greatly exceed even the total body water (7.5 l. for a 15-kg. dog). This large value may be the result of the binding of trichloroacetate anions in the readily available tissues and may be the explanation for the comparatively slow elimination of such a highly ionized drug.

The apparent volumes of distribution of 100 and 1000 mg. of sodium trichloroacetate in the total compartments of distribution, *i.e.*, the central compartment plus the more slowly equilibrating tissues, were calculated from the estimates of blood concentrations (Fig. 19) after the linear extrapolation of the terminal points of the semilogarithmic plots of Fig. 13 to zero time and were 7.9 and 6.8 l., respectively, referenced to drug concentration in the blood.

Computer analyses of the data of Fig. 19 in accordance with a model similar to that given in Scheme III (except that $A_{T'} = 0$ and $k_{B,U}$ are substituted for k_B) provided estimates for the microscopic rate constants referenced to blood concentrations for trichloroacetic acid pharmacokinetics, where $k_{B,T} = 0.079$, $k_{T,B} = 0.073$, and $k_{B,U} = 0.22$ hr.$^{-1}$. The overall elimination rate constant, k_e, calculated from Eq. 67 (where $k_{B,U}$ is substituted for the designated $k_{B,M}$) was 0.0105 hr.$^{-1}$ and was consistent with the value obtained from the terminal slopes of the plots of Fig. 19. It was also markedly similar to the value given for man, $k_e = 0.0094$ hr.$^{-1}$ (47).

Pharmacokinetics of Chloral Hydrate—Conversion of chloral hydrate to trichloroethanol in the dog was rapid and quantitative. Blood levels of trichloroethanol (5.5 ± 0.2 mg./ml.) and its glucuronide (36.2 ± 0.2 mg./ml.) 100 min. after intravenous administration of 500 mg. chloral hydrate (42 mg./kg.) were identical (Fig. 20) to those obtained after an equimolar dose of trichloroethanol was given to the same Dog C. The majority (97.5%) of the initial amount of chloral hydrate in blood was lost rapidly, with a half-life of 3 min. ($k_{CH,TCE} = 0.23$ min.$^{-1}$). The semilogarithmic plot was linear for more than five half-lives. The remainder (2.5%) showed a slower decline ($t_{1/2} = 35$ min.).

The appearance of trichloroethanol in the blood was rapid, with a half-life (3 min.) that corresponded to that for loss of chloral hydrate. Maximum trichloroethanol blood levels were observed 12 min. after chloral hydrate administration (Fig. 20). This is consistent with the claim that conversion to trichloroethanol of the chloral hydrate precursor occurs in all body tissues (48). Only a small fraction of the dose shows a deviation from the linear semilogarithmic plot, which can be assigned to a slower return from tissues of equilibration.

The apparent volume of distribution of the 500 mg. of chloral hydrate in the central compartment referenced to concentration in whole blood may be calculated (Eq. 24) from the time zero estimate of blood concentration $[A_B]_0$ (Fig. 20) as 11.5 l., which is very much greater than the values for trichloroethanol (Table I) and its glucuronide (Table V). This undoubtedly implies that chloral hydrate undergoes a more rapid diffusion into, or a more rapid binding with, tissues other than blood during first cycles in the body. No measurable concentrations of trichloroacetic acid were found in blood samples.

The percent of the dose of chloral hydrate excreted in urine as the glucuronide after 2 hr. (46%) was identical to that observed with an equimolar dose of trichloroethanol. In the same period of time, 1.56% of the total dose as unchanged chloral hydrate and 0.27% as trichloroacetic acid were also found in urine.

GLC Assay for 5-Fluorouracil in Biological Fluids

JORDAN L. COHEN▲ and PATRICK B. BRENNAN

Abstract □ A rapid, sensitive GLC method of analysis for 5-fluorouracil was developed to follow the disposition of the drug in patients on 5-fluorouracil therapy. The free drug is removed from aqueous biological samples in a single extraction step, derivatized by silylation, and chromatographed using flame-ionization detection. An internal standard is utilized to quantitate the results. The procedure is rapid, sensitive (0.2 mcg./ml. plasma), specific for the intact 5-fluorouracil molecule, and suitable to support pharmacokinetic studies of 5-fluorouracil in animals and humans.

Keyphrases □ 5-Fluorouracil—GLC analysis in biological fluids □ GLC—analysis, 5-fluorouracil in biological fluids

Detailed pharmacokinetic studies that would provide information useful to the clinician would be desirable to optimize cancer chemotherapy with 5-fluorouracil. The drug is still given empirically by many different dosage schedules, with some recent evidence suggesting that the oral route of administration differs in activity and toxicity from the intravenous route (1). Disposition studies performed previously were limited by the absence of a rapid, sensitive method of analysis capable of determining free 5-fluorouracil in large numbers of biological samples. Studies using radioactively labeled drugs showed wide variability due to extensive metab-

GLC Assay for 5-Fluorouracil in Biological Fluids

JORDAN L. COHEN▲ and PATRICK B. BRENNAN

Abstract □ A rapid, sensitive GLC method of analysis for 5-fluorouracil was developed to follow the disposition of the drug in patients on 5-fluorouracil therapy. The free drug is removed from aqueous biological samples in a single extraction step, derivatized by silylation, and chromatographed using flame-ionization detection. An internal standard is utilized to quantitate the results. The procedure is rapid, sensitive (0.2 mcg./ml. plasma), specific for the intact 5-fluorouracil molecule, and suitable to support pharmacokinetic studies of 5-fluorouracil in animals and humans.

Keyphrases □ 5-Fluorouracil—GLC analysis in biological fluids □ GLC—analysis, 5-fluorouracil in biological fluids

Detailed pharmacokinetic studies that would provide information useful to the clinician would be desirable to optimize cancer chemotherapy with 5-fluorouracil. The drug is still given empirically by many different dosage schedules, with some recent evidence suggesting that the oral route of administration differs in activity and toxicity from the intravenous route (1). Disposition studies performed previously were limited by the absence of a rapid, sensitive method of analysis capable of determining free 5-fluorouracil in large numbers of biological samples. Studies using radioactively labeled drugs showed wide variability due to extensive metab-

olism (2) and illustrated the nonspecificity of this method of analysis for compounds of this type.

Clarkson *et al.* (3) performed some comparative disposition studies on a limited number of patients; they utilized a spectrophotometric assay procedure when the blood levels were greater than 100 mcg./ml. and a microbiological assay for lower blood levels. In most instances the spectrophotometric procedure was not sensitive enough for clinical studies, while the microbiological procedure lacked accuracy and was not readily adaptable to large numbers of samples. Windheuser *et al.* (4) developed a GC method which requires extended (22-hr.) dialysis to remove the drug from blood samples and which would be difficult to perform on a routine basis.

The present work describes an analytical method based upon a single extraction of the drug into a nonaqueous solution, with subsequent formation of a trimethylsilyl derivative for GLC detection. The concentrations of 5-fluorouracil were quantitated using an internal standard. The method is applicable to biological samples including blood and urine and can be performed on a routine basis for clinical studies of patients on 5-fluorouracil therapy.

EXPERIMENTAL

Reagents—All chemicals and solvents used were of analytical reagent grade, and water was glass double distilled.

Procedure for Biological Samples—Blood samples were collected in citrated Vacutainers[1], mixed gently, and centrifuged to allow separation of the plasma. Then the plasma was frozen until the sample was to be analyzed. Urine samples were either collected and directly frozen or lyophilized and stored in a similar fashion.

A plasma or urine sample was adjusted to pH 6 by the addition of a known volume of a pH 4.7, 0.5 *M* acetate buffer (*e.g.*, 125 μl. of acetate buffer was required per milliliter of human plasma). Then 1.0 ml. of this sample was added to a flask already containing 0.4 g. of anhydrous sodium sulfate and 15.0 ml. of a solution of 16% *n*-propanol in ether. This mixture was shaken vigorously for 5 min. and then allowed to stand for 15 min. or until the ether layer cleared. Depending upon the concentration of 5-fluorouracil, a suitable volume (1.0–10.0 ml.) of the ether solution was pipeted into either a: (*a*) 15.0-ml. centrifuge tube if more than 5.0 ml. was used, or (*b*) 5.0-ml. vial[2] if a smaller volume of ether was used. Then 25 μl. of an anthracene solution in pyridine containing 16 mcg./ml. was added as an internal standard, and the solvent was removed under a gentle stream of nitrogen with the reaction vial immersed in a 55° water bath.

Derivatization—The evaporated sample was dissolved in 100 μl. of a freshly prepared solution of 50% *N,O*-bis(trimethylsilyl)-trifluoroacetamide (I), containing 1% trimethylchlorosilane[3] as a catalyst in silation grade pyridine[3]. This reaction mixture was allowed to stand for 5 min. at room temperature, and then 1–10 μl. was injected into the gas chromatograph.

Gas Chromatography—The assay was performed on a gas chromatograph[4] equipped with a flame-ionization detector. A glass coiled column, 1.83 m. (6 ft.) × 0.63 cm. (0.25 in.) o.d., was packed with 3% OV-1 on 100–120-mesh Gas Chrom Q[5], conditioned at 250° for 72 hr. and injected periodically with trimethylsilyl donors[6]. Nitrogen as a carrier gas was maintained at 40 ml./min., while the flow rates for air and hydrogen were 250 and 30 ml./min., respectively. The injector and detector temperatures were both maintained at 200° throughout the procedure.

The sample was injected at a column-oven temperature of 110° and the 5-fluorouracil eluted as a sharp peak at ~5.5 min. The temperature was then increased to 160° (heating rate 50°/min.) and the anthracene (internal standard) peak appeared after 12 min. (from time of injection). After 2–3 days of use, the column was reconditioned at 250° overnight and a mixture of trimethylsilyl donors[6] was injected. The detector was cleaned every 3–4 days with repeated injections of trichlorotrifluoroethane[7] and was removed periodically and further cleaned by sonication in acetone.

RESULTS AND DISCUSSION

5-Fluorouracil is representative of the analytical challenges now faced by workers in biopharmaceutics and clinical pharmacology. Its water solubility, even as the free acid, and nonfluorescent properties make specific, sensitive, routine methods of analysis difficult to develop. The described extraction procedure gives the highest constant percentage extracted (80%) in a single extraction of many explored and was the only method that appeared quantitatively useful. Any increase in the polarity of the "nonaqueous phase" destroys the immiscibility with aqueous samples. Saturation with sodium sulfate also appeared to optimize extraction of 5-fluorouracil by salting it out of the aqueous medium. Since no improvement in extractibility was seen at more acidic pH's, pH 6 was selected, on the basis of the reported pKa of 8.1 (5), to minimize the extraction of other weakly acidic compounds which could be present in blood samples and possibly silate and interfere with the chromatographic assay procedure. This is a critical consideration in this case since the partition coefficient of 5-fluorouracil does not allow a "cleanup" extraction. Plasma blanks were always carried through the assay procedure to verify the absence of any interfering material.

The extraction procedure gave identical results for aqueous, plasma, and blood samples to which 5-fluorouracil had been added[8]. These results (Table I) indicate no interference with the assay in the presence of plasma proteins or red blood cells which would affect the percentage extracted. The percent recovery is based upon the addition of 5-fluorouracil to ether (Table II). In view of this and since the extraction was not complete, a standard curve was prepared by using aqueous samples to which various concentrations of 5-fluorouracil had been added and carrying them through

0.48	0.17

[a] Anthracene concentration was 3.2 ng./μl. injected. [b] Average of three determinations.

the entire assay procedure. Figure 1 shows a typical chromatographic separation from a human plasma sample. The sharpness of the peaks enabled a quantitation to be made using peak height ratios rather than the more cumbersome peak area ratios. A linear standard curve (Figs. 2 and 3) corresponding to original concentrations of 5-fluorouracil of from 0.2 to 80 mcg./ml. was obtained and used to determine directly the drug levels of samples in this concentration range after accounting for any dilution changes. Higher concentrations of 5-fluorouracil required different concentrations of internal standard and the curve was linear up to 300 mcg./ml.

Working from observations of Windheuser *et al.* (4) that 5-fluorouracil could be silylated quantitatively and chromatographed led to development of the final GLC assay procedure. Compound I had the advantage of much more volatile fluorinated by-products after silylation, which appear under the solvent peak and do not interfere with the quantitation of 5-fluorouracil as did *N,O*-bis-(trimethylsilyl)acetamide under our assay conditions. To be certain of the specificity of the method for the free drug molecule, the analysis was performed on a GLC interfaced with a mass spectrometer[9]. The peak corresponding to 5-fluorouracil at 5.5 min. was shown by fragmentation and the appearance of a parent peak at

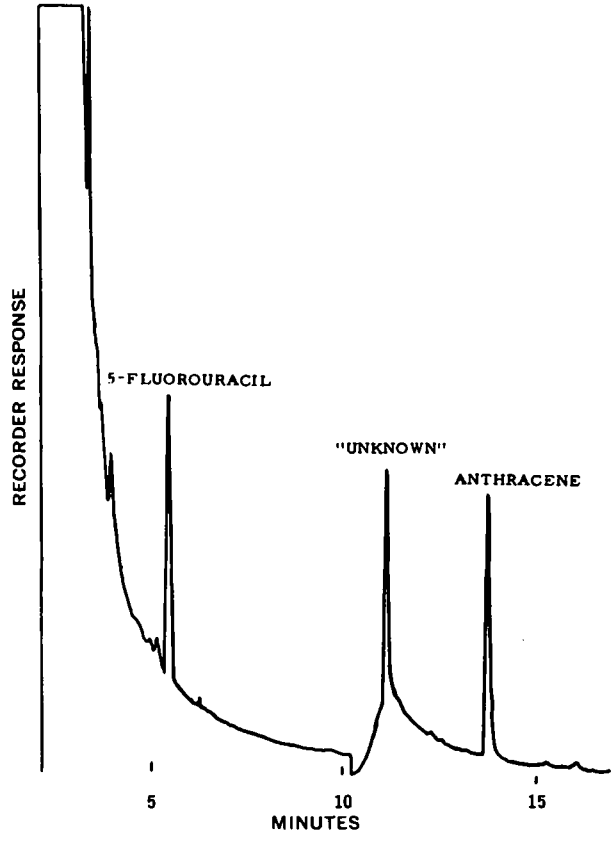

Figure 1—*Gas chromatogram of a plasma sample of 5-fluorouracil with the addition of anthracene. (5-Fluorouracil concentration = 4.83 mcg./ml.; anthracene concentration = 3.2 ng./μl. injected.)*

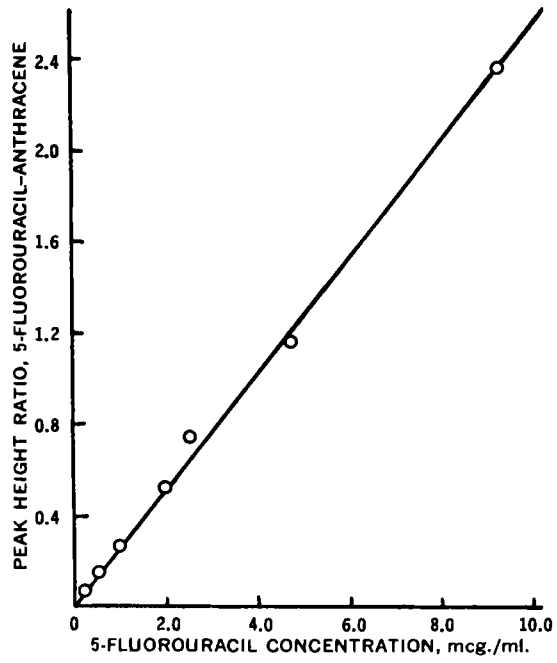

Figure 2—*Calibration curve for 5-fluorouracil extracted from aqueous solution at low 5-fluorouracil concentrations. (Anthracene concentration = 3.2 ng./μl. injected.)*

274 *m/e* to be 5-fluorouracil with the addition of two trimethylsilyl groups.

No suitable internal standard could be found for the column operating temperature at which the assay is performed. Anthracene was selected for its inertness, purity, and good flame-ionization response; however, the column had to be programmed to obtain reproducible results for peak height ratio calculations. This actually turns out to be an advantage, since the higher temperatures elute impurities present in the biological samples before the anthracene peak comes out (the broad peak labeled "unknown" in Fig. 1). Otherwise, to avoid interferences, these impurities would have to be eluted before the next sample could be injected.

The presence of the fluorine atom suggested that electron-capture detection may improve sensitivity and eliminate extraneous plasma peaks and other interferences. Much work has been done correlat-

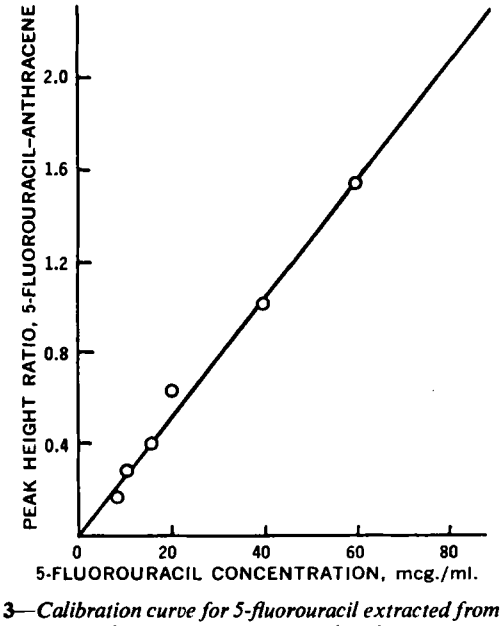

Figure 3—*Calibration curve for 5-fluorouracil extracted from aqueous solution over a wide concentration range. (Anthracene concentration = 3.2 ng./μl. injected.)*

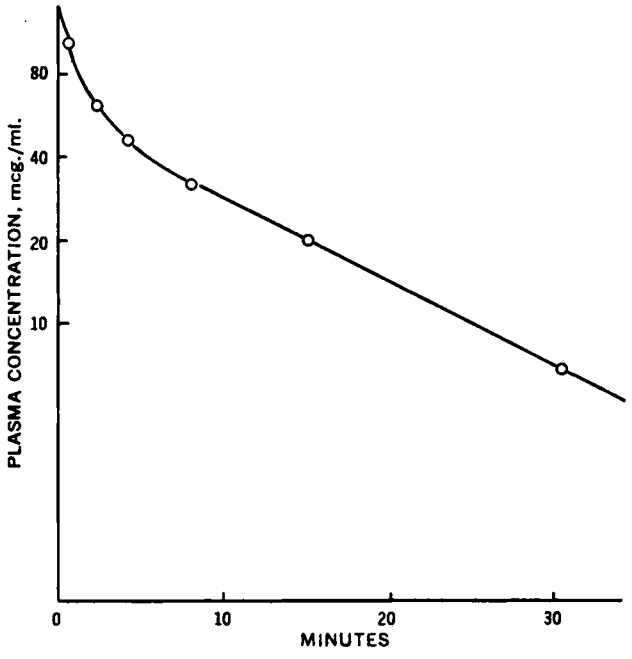

Figure 4—*Plasma concentration of 5-fluorouracil in a patient (E.J.) given a single intravenous dose of 15 mg./kg.*

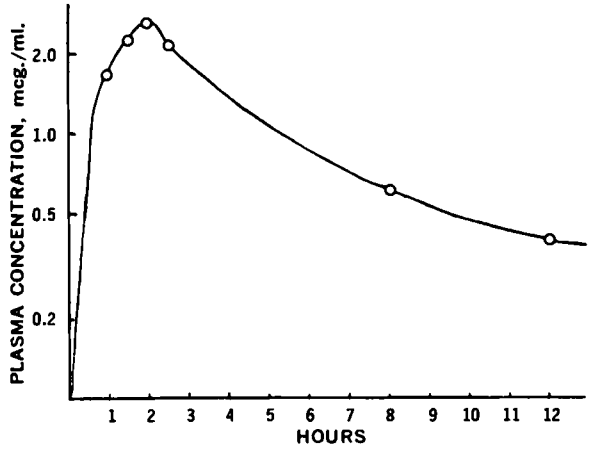

Figure 5—*Plasma concentration of 5-fluorouracil in a patient (I.B.) given a single oral dose (in solution) of 15 mg./kg.*

ing the structures of derivatives with electron-capture sensitivity (6–10), the presence of a single chlorine atom, for example, on chlorpromazine allowed a sensitive electron-capture analysis to be performed (11). Since the analytical conditions were essentially worked out, a ^{63}Ni detector was substituted for the flame-ionization detector; however, sensitivity could not be improved by more than a factor of two using this approach. A modification of the present method is currently being pursued in these laboratories in an effort to increase sensitivity, which may enable the quantitation of 5-fluorouracil in trace concentrations in body tissues and fluids other than plasma and urine.

Since the reason for development of an assay procedure of this type is to support biopharmaceutical and clinical pharmacology studies designed to improve drug therapy, data from two different patients receiving therapeutic doses of 5-fluorouracil have been included. Figure 4 illustrates the plasma time course of the drug in a patient (E.J.) receiving 15 mg./kg. by intravenous push, and Fig. 5 illustrates the same data for a different patient (I.B.) receiving a comparable dose in solution orally. No interfering peaks were encountered either from possible metabolites or other medication taken by these patients. The sensitivity and applicability of the method to these patients indicate that the method is suitable for these types of studies, and several clinical studies are currently being performed.

Kinetics of Dehydration and Isomerization of Prostaglandins E_1 and E_2

D. C. MONKHOUSE[A], L. VAN CAMPEN, and A. J. AGUIAR

Abstract □ The degradation of prostaglandins E_1 and E_2 was studied at 60° at a pH range of 1–10. A consecutive first-order reaction appeared to be operative above pH 4 for the dehydration and rearrangement reactions. Below pH 3 the dehydration appeared to be first order with respect to hydrogen-ion concentration. The rate of dehydration of E_2 was two to three times faster than that of E_1 under the same conditions over a pH range of 4–10. The rearrangement of E_1 and E_2 proceeded at approximately the same rate at pH 10. The rate of E_2 rearrangement progressively exceeded that of E_1 with a decrease in pH such that at pH 6, E_2 rearranged at a rate 15 times that of E_1. These data suggested that the *cis*-Δ^5 double bond participated actively in the rearrangement reaction of E_2, and was responsible for the greater reactivity of this molecule compared to E_1.

Keyphrases □ Prostaglandins E_1 and E_2—dehydration and isomerization kinetics, pH effect □ Dehydration and rearrangement kinetics—prostaglandins E_1 and E_2 □ Kinetics, dehydration and rearrangement—prostaglandins E_1 and E_2 □ UV spectrophotometry—monitoring, dehydration and isomerization of prostaglandins E_1 and E_2 □ pH effect—dehydration and isomerization kinetics of prostaglandins E_1 and E_2

Prostaglandins affect a wide range of physiological processes, from the contraction of the uterus to secretion from the stomach wall. This diversity of action accounts for the great current interest in their use as pharmacological agents.

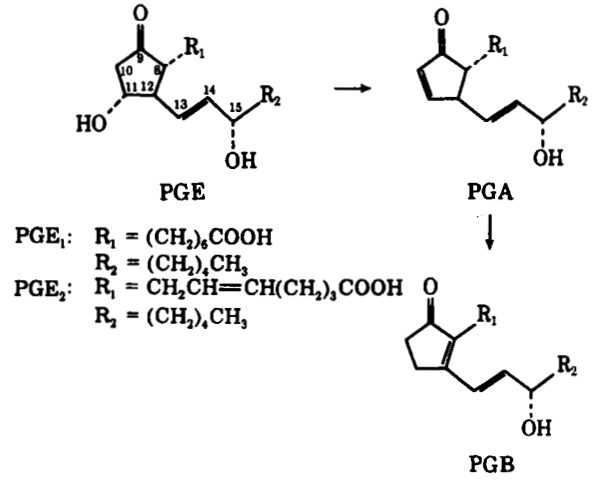
The application of prostaglandins in a number of areas has been severely hampered by their apparent instability in solution. Karim *et al.* (1) measured the biological activity of saline solutions of prostaglandins stored at various pH values at room temperature. The PGE compounds showed 25–40% loss of biological activity after 60 days at pH 5–7. Andersen (2) reported 5–20% conversion to PGA_1, measured spectrophotometrically, in methanolic solutions of PGE_1 after 1 month at 5–10°. Brummer (3) found that, for E_2 in ethanolic solution stored for 4 weeks at 4°, there was no detectable loss of total $E_2 + A_2$; after 6 months, 33% of the E_2 had been converted to PGA_2 and bioassay of the solution showed only 50% potency. As a result of this study, it was recommended that PGE solutions prepared for clinical use be stored as concentrated alcoholic solutions in ampuls. These can be stored for long periods at −20° and diluted with sterile isotonic saline as required within 24 hr. of use.

The β-hydroxyketone moiety of the PGE compounds[1] is extremely reactive. Loss of protons at C-8 or C-10 occurs very readily in both acid and alkaline media. The loss of a proton at C-10 may result in a negative charge, expulsion of the hydroxyl group at C-11, and formation of a Δ^{10} double bond (PGA compound). Under base treatment the PGA compounds undergo internal rearrangement of the double bond ($\Delta^{8,12}$) to form the relatively stable PGB compounds containing a dienone chromophore (Scheme I).

Treatment of PGE_1 (1 mg./ml. in methanol) with 1 ml. of 1 *N* HCl resulted in 80% conversion to a mixture of PGA_1 and methyl PGA_1 after standing for 16 hr. in the dark at room temperature. Systematic studies (4) of the stability of methanolic solutions of PGE_1 in various media for 6 hr. at room temperature revealed that PGA_1 formation was only evident at low pH values (<3) or if the buffer exceeded pH 7.4. Thus, in buffers of carbonate–borate–potassium hydroxide (pH 10.0) or sodium acetate–potassium hydroxide (pH 11–11.5), approximately 50–60% conversion of PGE_1 to PGA_1 was obtained. At the higher pH value, 20% PGE_1 passed into the PGB form after 6 hr. at room temperature. In the presence of oxalic acid (pH 2.5), saturated ammonium chloride in biphthalate buffer (pH 4), potassium acetate–acetic acid (pH 5), or sodium acetate (pH 7.4), PGE_1 was found to be stable (<10% conversion to PGA_1) for 6 hr. at room temperature; longer exposure, however, did result in significant PGA formation.

Oesterling (5) measured the rate of dehydration of E_1 and E_2 and the rate of isomerization of A_1 and A_2 in dilute sodium hydroxide solutions. These processes exhibited a first-order dependency on hydroxide-ion concentration, with activation energies between 13 and 15 kcal./mole. Using TLC and GLC, he found no compounds other than the expected degradation products during the reactions.

Since stability studies appearing in the literature were of a preliminary nature, providing limited kinetic information, the purpose of this study was to obtain



Scheme I

[1] PGE_1 is 11α,15(S)-dihydroxy-9-oxo-13-*trans*-prostenoic acid; PGE_2 is 11α,15(S)-dihydroxy-9-oxo-5-*cis*,13-*trans*-prostadienoic acid.

additional data dealing with the relative rates of the dehydration and rearrangement reactions of both PGE_1 and PGE_2.

EXPERIMENTAL

UV Spectroscopy—An automatic recording spectrophotometer[3] afforded UV measurement at the two wavelengths of choice at definite intervals over extended periods of time. The instrument was equipped with an automatic reference compensator, a wavelength programmer, and an auxiliary dwell unit. A thermistor probe was attached to the sample compartment so that the cell temperature could be automatically recorded prior to the absorbance reading. The temperature was controlled by a constant-temperature circulator[3].

Stock solutions of prostaglandins were accurately prepared at a concentration of 1.0 mg./ml. in 90% aqueous ethanol and stored at 0°. Measurements were made on triplicate stock solutions. A 75-μl. aliquot of the stock solution was measured in a gastight syringe[4] equipped with a Teflon-tipped plunger and Chaney adaption for reproducible delivery. Four 5.0-ml. quantities of aqueous solvent, measured in volumetric flasks, were pre-equilibrated to the temperature at which the study was to be conducted. One aliquot of PGE stock solution was added to each of three solvent flasks at zero time. The fourth solution served as the reference blank. The final concentration of prostaglandin in the solutions was 4.20×10^{-5} *M*. Because absorbance readings were conducted at 218 nm., it was necessary to take certain precautions; for example, special cells[5] were used which have a high percent transmission below 200 nm. In addition, end absorption due to buffer species was overcome by dilution. The buffers used were sodium dihydrogen phosphate–citric acid (pH 2.2–8.0), glycine–sodium hydroxide (pH 8.6–10.6), glycine–hydrochloric acid (pH 2.2–3.6), and hydrochloric acid–potassium chloride (pH 1.1–2.2). In all but the latter system, the buffer solutions were diluted to approximately 0.002 *M*, while the concentration of the hydrochloric acid–potassium chloride buffer was 0.05 *M* in potassium chloride.

Beer's law plots were made for the aqueous PGE_1 solutions, and the values of the absorptivity of the PGA and PGB species were calculated from aqueous acid and base treatments, respectively (λ_{max}PGA = 218 nm., ϵ_{218} = 9500; λ_{max}PGB = 278 nm., ϵ_{278} = 20,500). The measurement of PGE could be made at any time interval during the degradation by calculating the concentrations of PGA and PGB from the absorbances at 218 and 278 nm., respectively. Overlap of the 278-nm. peaks at 218 nm., however, necessitated a correction factor f for the calculation of $A_{PGA(218)}$. This factor maintained a constant value equal to the ratio of the absorbance of PGB at 218 nm. to its absorbance at 278 nm. Therefore:

$$A_{PGA(218)} = A_{obs(218)} - f \cdot A_{PGB(278)} \qquad \text{(Eq. 1)}$$

where $f = 0.135$. Then:

$$X_E + X_A + X_B = 1 \qquad \text{(Eq. 2)}$$

and:

$$X_E = 1 - \frac{A_{PGA(218)}}{\epsilon_{218} \cdot E_i} - \frac{A_{PGB(278)}}{\epsilon_{278} \cdot E_i} \qquad \text{(Eq. 3)}$$

where E_i = initial molar concentration of E, and X represents mole fraction.

The rate constant k_1 in the degradation sequence (Scheme II)

$$PGE \xrightarrow{k_1} PGA \xrightarrow{k_2} PGB$$

Scheme II

was accurately measured by plotting log X_E *versus* time, where $k_1 = -2.303 \cdot$(slope), or by plotting $\log(X_{A\infty} - X_{A_i})$ *versus* time (only in the case where $k_2 \simeq 0$). The rate constant k_2 was estimated by plotting $\log(X_{B\infty} - X_{B_i})$ *versus* time in the region toward the end of the reaction.

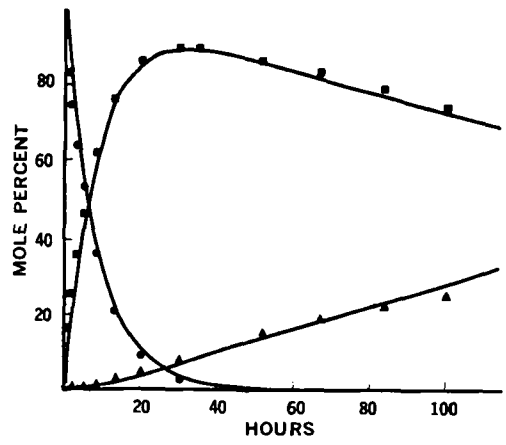

Figure 1—*Reaction profile for $PGE_1 \rightarrow PGA_1 \rightarrow PGB_1$ at pH 8.0 and 60°. Key: ●, PGE_1; ■, PGA_1; and ▲, PGB_1.*

Since the direct measure of B contained the least error, these data points and other required parameters were entered into a computer[6]. By using a consecutive first-order program, the graphically calculated k_1 and k_2 values were used to compute the molar ratios of E, A, and B as a function of time, where:

$$E = E_i e^{-k_1 t} \qquad \text{(Eq. 4)}$$

$$A = E_i k_1 (e^{-k_1 t} - e^{-k_2 t})/(k_2 - k_1) \qquad \text{(Eq. 5)}$$

and:

$$B = E_i[1 - (k_1 e^{-k_2 t} - k_2 e^{-k_1 t})/(k_1 - k_2)] \qquad \text{(Eq. 6)}$$

The average absolute deviation from the observed values was used as a criterion of accuracy for the computed values. The estimated rate constants were varied by an iteration procedure so as to minimize this deviation. The "best fit" values thus obtained were considered to be closer to the true values than were the experimentally observed data calculated from Eqs. 1–3.

TLC—TLC provided a means of checking the initial purity of prostaglandin samples as well as monitoring samples subjected to induced degradation. It also allowed the direct study of PGE's that are transparent to UV light. The chromatographic procedures utilized were extracted from a study of analytical and preparative chromatographic methods for monounsaturated prostaglandins by Andersen (2).

Samples of prostaglandin were prepared for TLC by dissolving PGE in 90% aqueous ethanol at a concentration of 1 mg./ml. Thin-layer plates[7], 15.2 × 20.3 cm. (6 × 8 in.), coated with silica gel GF, were developed in the usual ascending manner following a partial pass in absolute methanol [to approximately 2.54 cm. (1 in.) above the origin] to pull the prostaglandins away from strong base which, if present, interfered with spot mobility. The solvent system used to resolve the parent prostaglandins apart from their degradation products was ethyl acetate–88% formic acid (400:5), and the detection methods were a 5% ethanolic solution of phosphomolybdic acid and 254 nm. UV light.

RESULTS AND DISCUSSION

In the present study the degradation behavior of the two E prostaglandins was investigated under identical buffer conditions covering a wide pH range. A temperature of 60° was chosen to accelerate the decomposition rates so that their measurement would be kinetically convenient. It was assumed that the increased rates were mediated only by thermal phenomena rather than by free radical processes initiated by light or the presence of oxygen.

Since the reaction pathway is of the first-order consecutive type above pH 4, typical concentration *versus* time curves were observed. In Figs. 1 and 2, the change in mole percents of the relevant species with time is shown for the E_1 and E_2 reaction profiles at 60° in pH

8.0 buffer, respectively. These profiles suggest that the concentration of the original β-hydroxyketone moiety (E) decreased by a first-order rate and that E_2 decreased faster than E_1. The intermediate α,β-unsaturated ketone product (A) rose to a maximum after about 13 hr. for E_2 and after 32 hr. for E_1. In addition, the height of the maximum for A_2 was less than that of A_1 (79% *versus* 89%). After this maximum was reached, the A products decreased in an approximately linear fashion. Following an induction period (3 hr. for B_2 and 10 hr. for B_1), the concentration of the rearranged thermodynamically more stable product (B) rose rapidly and tailed off upon approaching completion of the consecutive reaction. Although mechanistic theory dictates these reactions to be reversible, experimental and resulting thermodynamic considerations showed the reaction to favor overwhelmingly formation of the PGB compounds under all testing conditions, resulting in negligible reverse reaction rate constants.

The initial content of the intact E compound only approached the theoretical concentration of 100%. This was possibly due to a small amount of A compound initially present in the stock solutions. These stock solutions, although stored at zero degrees, showed minor degradation after 1 month. When necessary to obtain an approximate "zero time" at which 100% E was present, the plots were extrapolated to 0% A and 0% B on an appropriately adjusted time axis.

Below pH 4 the concentration of E approached a final value asymptotically as the reaction proceeded toward completion. At the pH levels investigated between 1 and 4, the reaction of A → B became insignificant, while the reaction E → A proceeded by a pseudo-first-order rate law since the solvent (water) was present in large excess. At very high acid concentrations, degradation continued beyond the formation of A, as shown in Scheme III, where X was an unidentified product(s) that formed from either E_1 or E_2 and exhibited a molar absorptivity of approximately 20,000 at a λ_{max} of 325–330 nm. ($R_f \approx 0.8$). Under the conditions of the experiments reported here, $k_1 \gg k_2$, for which reason the A → X reaction was neglected in the kinetic treatment of the E → A reaction. When the dehydration step was treated as a first-order reaction, the values of k_1 could be calculated from the slope of the graph represented by Fig. 3. The reaction was also first order with respect to prostaglandin since little variation in the rate constants was observed upon varying initial reactant concentration.

Above pH 4, however, the rearrangement reaction became significant[8]. In the general consecutive reaction (Scheme II), the E component represented the only component that could be described by a simple first-order equation (Eq. 4). Both the A and B components were biexponential functions which had a time course that was dependent upon both k_1 and k_2 (Eqs. 5 and 6). Data representing A or B could not be analyzed for either k_1 or k_2 by the usual first-order plotting techniques. In general, over the pH range studied the rate of rearrangement was exceeded by the dehydration reaction only by an average factor of 10. While the loss of E was dependent on k_1, the formation of A and B was dependent upon both k_1 and k_2. Thus the overall rate process was not governed by a single constant. For this reason, data collected for A and B as a function of time were first treated graphically to obtain approximate values of k_1 and k_2. These values and other required parameters were then treated by numerical integration on a digital computer to fit calculated values to the observed values of the appearance of B. These values of B were considered to be the most accurate data because of the high sensitivity of the absorbance readings (large absorptivity). The values of A at 218 nm. were frequently subject to interference from end absorption of buffer species present which required a high slit width compensation, contributing greater error to the measurement of A. When the computer-optimized values were plotted as a function of pH, characteristic log rate–pH profiles developed (Figs. 4 and 5).

$$E \xrightarrow{k_1} A \xrightarrow{k_2} X$$

Scheme III

The log k_1–pH profiles for the dehydration reactions of E to A are shown in Fig. 4. The pH of maximum stability in aqueous solutions of E_1 and E_2 was about 3–4. Specific hydrogen-ion catalysis (slope = −1) was evident below pH 3.0 for both E_1 and E_2. The pH-independent region of pH 3–4 probably resulted from solvent catalysis. This pH–rate profile represents the comparative rates observed at identical buffer concentrations less than 0.002 *M* (except at pH < 2.5 where buffer concentration reached 0.05 *M*). At higher buffer concentrations, a study of ionic strength effects

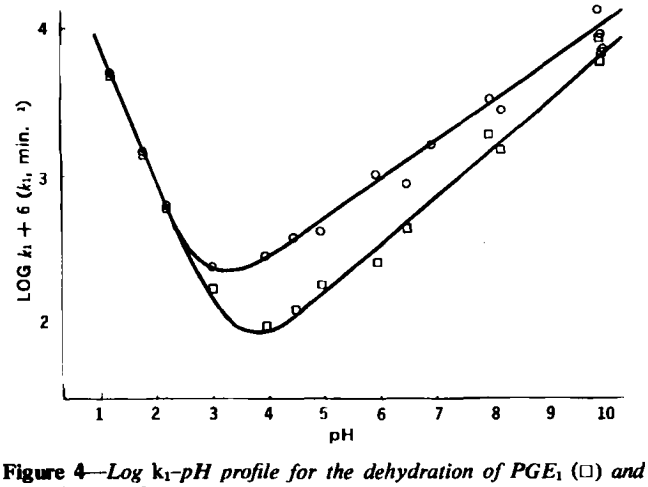

Figure 4—*Log k_1–pH profile for the dehydration of PGE_1 (□) and PGE_2 (○) at 60°.*

[8] Some ester formation could have occurred at the free carboxyl group due to the presence of a small quantity of ethanol in the sample from the stock solution. For present purposes, this esterification was considered to exert an insignificant effect on the rates of dehydration and rearrangement reactions. The occurrence of ester formation was observed on thin-layer chromatograms where the R_f of the ester slightly exceeded that of its corresponding acid.

Table I—Thermodynamic Activation Parameters[a] for Prostaglandins E_1 and E_2

Reaction Type	pH	E_1		E_2	
		E_a, kcal./mole	$\Delta S^{\ddagger}_{298}$, e.u.	E_a, kcal./mole	$\Delta S^{\ddagger}_{298}$, e.u.
Dehydration	1.2	18	−22.4	18	−22.4
Dehydration	8	24	−8.4	24	−7.0
Isomerization	8	20	−25.8	20	−22.3

[a] These are "apparent" values calculated from reaction in dilute aqueous buffer.

was undertaken. Only a minimal effect was noted, however, presumably due to overriding buffer catalysis. No experiments have yet been conducted to extrapolate k values to zero buffer concentration. Therefore, although specific hydroxyl-ion catalysis contributed most significantly to dehydration in alkaline conditions, general acid–base (solvent) catalysis at moderate pH's decreased the slope of the alkaline branch of the catenary to less than +1 (slope ~0.3). The difference in values of the rate constants for the dehydration of E_1 and E_2 under these solvent conditions was evident at alkaline pH's. In general, E_2 dehydrated twice as fast as E_1. Sufficient data were not available at this time to determine if the slopes of the lines were actually parallel. Although the absolute values of k_1 were significantly different, this difference appeared to be relatively independent of pH. At pH 9.0, as in acid media, the rates of reaction were proportional to the initial concentration of reactant, again suggesting first-order dependence on E concentration.

The log k_2–pH profiles for the rearrangement reactions of E_1 and E_2 are represented by the linear graphs shown in Fig. 5. The slopes of these lines were again $<+1$ (0.5 for E_1 and 0.35 for E_2), suggesting that more than simple specific hydroxyl-ion catalysis was involved. Below pH 7.0, the rate of the rearrangement reaction for E_1 became negligible, whereas the rearrangement of E_2 remained significant down to pH 5. In the case of k_2 the relationships of rate and pH between the two E prostaglandins in dilute aqueous buffer were dissimilar. The rate of E_2 rearrangement was significantly faster than E_1 at intermediate pH's, while at high pH their rates became comparable.

From this discussion, no definite conclusions could be reached with respect to the specific mechanisms involved in the reaction. Since k_1 was greater than k_2 only by an order of about 10 over a broad range of pH, the isomerization step could not be considered significantly rate determining. The values of the thermodynamic activation parameters derived from the Arrhenius plot (Fig. 6), listed in Table I, allow some general insight into the mechanistic differences between E_1 and E_2. The differences in their thermodynamic character are attributable to conformational properties that affect molecular orientation during both dehydration and isomerization. Nevertheless, it is difficult to propose a full explanation for the shapes of the reaction profiles at this time.

For the acid-catalyzed dehydration reaction, the slopes of the log rate–pH profiles for E_1 and E_2 were identical (Fig. 4). Furthermore, the rate constants (k_1) under the same conditions were also identical, which implied a similar mechanism of dehydration for both compounds under the given acid conditions. Any intramolecular effect of the carboxyl group on this reaction was presumed negligible because of its lack of physical proximity to the reaction center. Although E_2 is slightly more acidic than E_1 [pKa(E_2) = 5.32, pKa(E_1) = 5.70 as measured in 85% aqueous ethanol], this difference in acidity was considered inconsequential with respect to its influence on reaction rates. Intermolecular participation of the acid moiety also appeared insignificant since studies yielded an invariant rate constant over a moderate range of substrate concentration. The alkaline side of the catenary for the k_1 profile was slightly different for E_1 and E_2. The slopes of their reaction profiles approached the same magnitude, suggesting a constant ratio of k_1 (E_1) to k_1 (E_2), the value of which was approximately 2.5. The apparent energy of activation for E_1 was similar to that of E_2 in the given solvent environment, while their apparent entropies of activation were slightly different. This difference in entropy can be explained by the orientation requirements of solvent molecules around the elimination reaction centers of the two compounds. It is expected that their mechanisms of base-catalyzed dehydration are similar to one another.

In contrast, the slopes in the log rate–pH profile for the rearrangement reactions were markedly different for E_1 and E_2 (Fig. 5). This reaction has two primary driving forces: (*a*) the tetrasubstituted PGB double bond is more stable than that of PGA (6), and (*b*) it contains a system of extended conjugation. The only structural difference between the two molecules is the *cis*-Δ^5 double bond of E_2, which occurs as a saturated bond in E_1. Rotation about the 7–8 carbon–carbon bond could place this double bond of E_2 in a position such that it could interact with the ketone moiety at position 9. Such an interaction, however, would influence the relative reaction rates in the opposite direction to that observed, *i.e.*, inhibit rather than accelerate the E_2 rearrangement with respect to E_1. The apparent minimum energy differences between the reactants and their transition states were identical for both molecules. The apparent

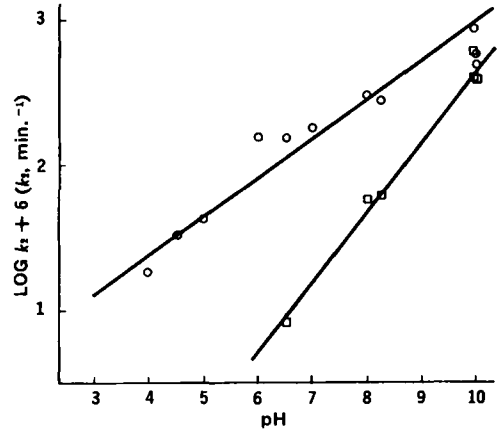

Figure 5—*Log* k_2*–pH profile for the rearrangement of* PGA_1 (□) *and* PGA_2 (○) *at 60°.*

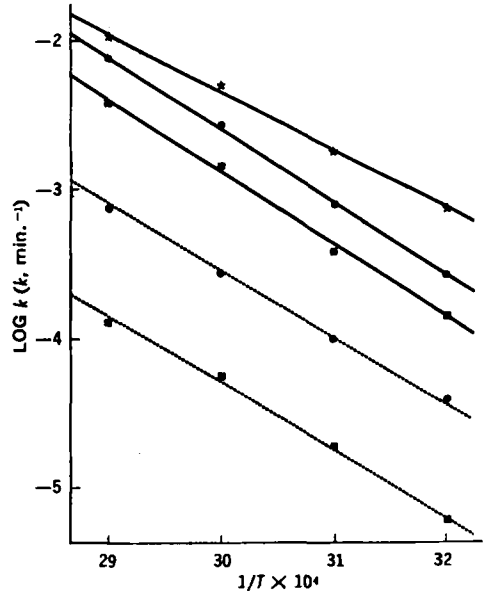

Figure 6—*Arrhenius plot of log* k *against 1/*T *showing temperature dependence of rates of dehydration and rearrangement of* PGE_1 *and* PGE_2. *Key:* ■, PGE_1; ●, PGE_2 *at pH 8.0;* ★, PGE_1 *and* PGE_2 *at pH 1.2;* ——, k_1; *and* - - -, k_2.

entropy of activation values for E_1 and E_2 were different, however, which suggested an explanation for the difference in reaction rates. The large negative values of $\Delta S^{\ddagger}$ reflect a significant requirement in molecular orientation, presumably of the side chains. The *cis*-Δ^5 double bond imposes certain restraints on the free rotation (lowering its degree of freedom) of the C-8 side chain vis-á-vis the C-12 side chain, causing increased nonbonded interactions when both chains lie side by side. These factors become especially important when a carbanion is introduced into the cyclopentenone ring at C-12, forcing the associated side chain and ring to lie flat in one plane. Some of these interactions are relieved if the unsaturation in the C-8 side chain is removed. It then has a more "floppy" nature, which allows it to lie away from the now rigid C-12 side chain. Thus, E_2 contains a lower absolute entropy in its reactant state than E_1, which must accordingly suffer a greater entropy loss during conversion to its carbanion transition state. These interpretations hold only qualitative value since absolute thermodynamic parameters must be determined only at zero buffer concentrations. Nevertheless, the data presented here retain comparative significance and indicate that the difference in behavior between E_1 and E_2 is clearly the result of complicated conformational effects.

In summary, there is a difference in the rates of dehydration and rearrangement between E_1 and E_2. No well-defined mechanism illustrating the reason for this difference can be presented at this time; however, such a mechanism should involve participation of the *cis*-Δ^5 double bond which is present only in E_2.

Metabolism of the Antihypertensive Agent 1,4-Dihydro-2,6-dimethyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic Acid Diethyl Ester

S. S. WALKENSTEIN▲, A. P. INTOCCIA, T. L. FLANAGAN, B. HWANG, D. FLINT, J. WEINSTOCK, A. J. VILLANI, D. BLACKBURN, and H. GREEN

Abstract □ The absorption, distribution, metabolism, and excretion of 1,4-dihydro-2,6-dimethyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic acid diethyl ester, an antihypertensive drug, was studied in rat, dog, and squirrel monkey. The drug, labeled with ^{14}C, was found to undergo aromatization, hydrolysis of its ester groups, and oxidation of a ring methyl and an ethyl group. No dihydropyridyl metabolites or the hypothetical aromatized parent compound were found. The metabolites identified were: 2,6-dimethyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic acid, its monoethyl and mono-2-hydroxyethyl esters, and 2-hydroxymethyl-6-methyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic acid lactone. The form in which the drug was administered was found to have a profound effect on its absorption. The crystalline powder administered to dogs in gelatin capsules was poorly absorbed; solubilization with polyethylene glycol 200 resulted in a fivefold increase in absorption.

Keyphrases □ 1,4-Dihydro-2,6-dimethyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic acid diethyl ester, radiolabeled—absorption, distribution, metabolism, and excretion in rats, dogs, and monkeys □ Antihypertensive agents—metabolism of 1,4-dihydro-2,6-dimethyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic acid diethyl ester, in rats, dogs, and monkeys □ Absorption—1,4-dihydro-2,6-dimethyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic acid diethyl ester, in rats, dogs, and monkeys

1,4-Dihydro-2,6-dimethyl-4-(2-trifluoromethylphenyl)-3,5-pyridinedicarboxylic acid diethyl ester[1] (I) is an effective agent for lowering blood pressure by direct vascular dilatation in normotensive, neurogenic, and renal hypertensive dogs. Hypotensive effects were also observed in rats, rabbits, and guinea pigs. The drug also lowered blood pressure in human subjects at relatively low oral doses (10 mg.).

As part of the preformulation and preclinical investigation of this compound, its absorption, distribution, metabolism, and excretion in rats, dogs, and monkeys were studied. These studies were facilitated by the use of the ^{14}C-labeled drug.

EXPERIMENTAL

Synthesis of Labeled Drug—Compound I-4-^{14}C was prepared as shown in Scheme I. ^{14}C-Labeled drug was shown to be free of radiochemical impurity and had a specific activity of 4 μc./mg.

I

Scheme I—Synthesis of 2,6-dimethyl-3,5-dicarboethoxy-4-(2-trifluoromethylphenyl)-1,4-dihydropyridine-4-^{14}C

GC Assay of I and Metabolites—*Compound I*—Five milliliters of urine containing at least 80 ng. of drug/ml. was adjusted to neutral pH and shaken with 28 ml. *n*-hexane for 20 min. Following centrifugation for 5 min., 25 ml. of the hexane layer was transferred in portions of 10, 10, and 5 ml. to a fresh tube containing 1 ml. methanol. Each portion was blown down, and the sides of the tube were rinsed with methanol before adding a fresh portion. After the final (5 ml.) hexane addition and methanol wash, 0.4 ml. internal standard solution (dichlorodiphenyltrichloroethane, 1.6 mcg./ml. in methanol) was added and the solution was evaporated to dryness under nitrogen in a water bath at 40°. The tubes were kept in a desiccator overnight before derivatizing with an excess of heptafluorobutyric anhydride by heating for 2 hr. at 70°. The samples, after evaporation to dryness at room temperature under a stream of nitrogen, were taken up in 0.5 ml. methanol. A 3-μl. aliquot was taken for injection.

The column was 1.22 m. (4 ft.), glass [0.48-cm. (0.19-in.) o.d.], 3% OV-1, on 100–120-mesh Chrom W at 250°. The carrier gas was argon–methane (95:5); purge 70 ml./min. at 35 ml./min.; purge at 70 ml./min. The electron-capture (Ni) detector temperature was 270°, and the injection block and manifold temperature was 270°. The retention times of I and dichlorodiphenyltrichloroethane were 2.3 and 4.1 min., respectively. The standard curve (peak height ratios) was linear from 80 to 400 ng./ml. urine.

Compound II[2]—Five milliliters of urine containing at least 1 mcg./ml. of II was adjusted to pH 10 by addition of 2 *N* sodium hydroxide and shaken with 28 ml. ether for 15 min. After centrifuging for 5 min., 25 ml. of the organic phase was transferred to a 40-ml. tapered tube, 0.1 ml. of internal standard (dichlorodiphenyltrichloroethane, 250 mcg./ml. in methanol) was added, and the sample was evaporated to dryness with a stream of nitrogen. The samples were then taken up in 0.1 ml. methanol, and a 2.6-μl. aliquot was taken for injection.

The column was 1.22 m. (4 ft.) stainless steel [0.32-cm. (0.125-in.) o.d.], 3% OV-1 on 100–120-mesh Chrom W at 195°. The carrier gas was helium at 40 ml./min. The flame-ionization detector temperature was 270°, and the injection block temperature was 270°. The retention times of II and dichlorodiphenyltrichloroethane were 3.0 and 6.6 min., respectively. The standard curve was linear from 1 to 5 mcg. II/ml. urine.

Compounds III[3] and *IV*[4]—Five milliliters of urine containing at least 1 mcg. of either III or IV was brought to pH 1 with 6 *N* hydrochloric acid and shaken with 28 ml. of ether for 15 min. After centrifuging for 5 min., 25 ml. of the organic layer were transferred to a 40-ml. tapered tube and evaporated to dryness under a stream of nitrogen. To the dried residue were added 0.1 ml. methanol and 0.3 ml. diazomethane and the contents of the tube were thoroughly mixed. After 1 hr., 0.2 ml. 7 *N* sodium hydroxide and 6 ml. of *n*-hexane were added. The tube was shaken for 20 min. and centrifuged for 5 min. As much of the hexane layer as could be removed with a disposable Pasteur pipet was transferred to a 12-ml. centrifuge tube and, after adding 0.1 ml. of internal standard solution (methyl oleate, 250 mcg./ml. in methanol), evaporated to dryness. The residue was taken up in 0.1 ml. methanol, and a 2.4-μl. aliquot was taken for injection.

Except for the column temperature (180° for these two compounds), the column and conditions were the same as for II. The retention times of III, IV, and methyl oleate were 3.1, 4.1, and 6.1 min., respectively. The standard curves for both compounds were linear from 1 to 5 mcg./ml. urine.

Radioassay—Standard techniques were used to assay 0.1-ml. aliquots of blood and urine and 75–100-mg. aliquots of dried feces.

TLC—Three solvent systems were used to separate I and metabolites on 250-μ plates[5]: A, chloroform–methanol–acetic acid (50:50:5); B, toluene–methanol (95:5); and C, chloroform–acetic acid (95:5). The R_f values found are listed in Table I.

Animal Studies—The animal studies were conducted on Charles River Sprague–Dawley strain rats, squirrel monkeys, and beagle

Table III—Effect of Dosage Form on Urinary Output of ^{14}C following Oral Administration of ^{14}C-Labeled I

Dosage Form	Dog Number	Percent of Dose Recovered in Urine, 0–96 hr.	Percent of Dose Recovered in Feces, 0–96 hr.
Crystalline drug in gelatin capsule	1	6.9	91.3
	2	7.7	91.9
1.5% solution in polyethylene glycol 200–water (1:1)	3	39	48.9
	4	32	48.9

Table IV—Effect of Dosage Form on Blood Levels of ^{14}C in Dogs after Oral Administration of ^{14}C-Labeled I

Dosage Form	Dog Number	^{14}C Blood Level (Expressed as ng./ml. of I) Hours 1	2	3	4	6	24
Crystalline drug in gelatin capsule	1	140	150	70	40	30	10
	2	90	140	80	50	40	20
1.5% solution in polyethylene glycol 200–water (1:1)	3	450	920	730	470	260	70
	4	510	910	670	510	360	50

dogs. After an overnight fast, oral doses of suspensions or solutions were administered to rats and squirrel monkeys by gavage. Beagles were given oral doses in gelatin capsules. Polyethylene glycol 200–water (1:1) solutions of drug were used for intravenous dosing. The drug concentration in various dosage media was 1 mg./ml. For collection of urine and feces, animals were kept in metabolism cages.

Enzyme induction studies were conducted in rats kept on an insecticide-free diet for at least 5 days. Following this period and while being maintained on this diet, rats were dosed with a finely ground suspension of drug in 0.5% gum tragacanth, one group receiving a single dose and another group receiving daily doses for 11 days. Amobarbital sleep time and ascorbic acid excretion studies were performed on the same group of rats kept 11 days on the insecticide-free diet and dosed daily with drug (5, 15, or 50 mg./kg.) by the oral route, or with a single intraabdominal dose of phenothiazine (15 mg./kg. in sesame oil) at the end of that period. Ascorbic acid was assayed by a modification of the method of Schaffert and Kingsley (1).

Phenylbutazone plasma half-life studies were conducted in animals kept free of drugs for at least 6 weeks. Phenylbutazone (10 mg./kg.) was injected into a leg vein, and venous blood was sampled from the opposite limb at 0.5, 1, 2, 3, and 5 hr. postdrug. Test drug and phenobarbital groups were dosed for a week and the phenylbutazone treatment was repeated. Plasma assays were performed using the method of Burns *et al.* (2).

For *in vitro* studies, livers were removed from rats kept on the insecticide-free diet. These were divided into groups dosed with saline, I, phenobarbital (chronic dosing), or phenothiazine (single dose). The control (saline) group provided sufficient microsomal enzyme to assay the effects of inhibition or stimulation when I, phenothiazine, or phenobarbital was added directly to the enzyme preparation.

Table VI—Effect of I on Drug-Metabolizing Enzyme Systems

Test	Species		Results		
Amobarbital sleep time	Rat		No significant reduction in sleep time as compared with phenobarbital Vehicle: 84 ± 35 min. Phenobarbital: 10 ± 2.1 min. I: 75 ± 30.3 min.		
Ascorbic acid excretion	Rat		Treatment: urinary ascorbic acid in mcg./g. body weight/24 hr. None: 30 I (5 mg./kg.): 42 I (15 mg./kg.): 46 Phenobarbital: 115 (50 mg./kg.)		
Effect of phenylbutazone plasma half-life	Dog		Dosing for 7 days with phenobarbital significantly speeded reduction of phenylbutazone half-life (from 2.5 to 1 hr.); I was without effect		
Liver microsomes *in vitro*	Rat		Phenothiazine, 15 mg./kg.	Compound I, 5 mg./kg.	Compound I, 15 mg./kg.
O-Dealkylation (*p*-nitroanisole)		Single dose	33%[a]	8%	−11%
Phenyl ring hydroxylation (acetanilide)		Single dose	120%	60%	60%
			Sodium phenobarbital, 50 mg./kg.	Compound I, 5 mg./kg.	Compound I, 15 mg./kg.
O-Dealkylation (*p*-nitroanisole)		Chronic dosing	67%	60%	13%
N-Demethylation (aminopyrine)		Chronic dosing	4%	23%	4%
Phenyl ring hydroxylation (acetanilide)		Chronic dosing	100%	78%	27%
Nitro-reduction (*p*-nitrobenzoate)		Chronic dosing	75%	0	0
Aliphatic side-chain oxidation (hexobarbital)		Chronic dosing	300%	225%	22%

[a] Percent increase over saline controls.

The microsomal enzyme was prepared as follows. Freshly removed livers were rinsed in ice-cold 1.15% potassium chloride before homogenization in chilled pH 7.4 0.2 *M* phosphate buffer (2 ml./g. tissue). No more than three to five strokes in an ice-cooled glass homogenizer tube were required. After centrifugation at 9000×*g* for 30 min. at 2–3° and removal of a white layer from the top of the tube, the supernate was decanted for use. This preparation maintained its activity even after being kept 5 months in the frozen state.

Incubations were carried out in 30-ml. beakers in a Dubnoff shaker–incubator at 37°, 70–75 oscillations/min. Oxygen was used as the gas phase in all but the nitro-reductase experiment, in which nitrogen was used. Gas flow was kept at 1 l./min. Each beaker contained 1 ml. of the enzyme preparation, 25 μM glucose-6-phosphate, 1–2 μM nicotinamide adenine dinucleotide phosphate, 34.5 μM magnesium sulfate, substrate (quantities shown below), and 0.2 *M* pH 7.4 sodium phosphate buffer to a final volume of 5 ml. In the *N*-dealkylation reaction assay with aminopyrine, 45 μM semicarbazide was included in the reaction mixture. The enzyme preparation was added last, following a 10-min. incubation period. The reaction was then followed for varying periods: aminopyrine, 5 min.; acetanilide, 5 min.; *p*-nitrobenzoic acid, 10 min.; *p*-nitroanisole, 3 min.; and hexobarbital, 5 min.

Analytical methods used in the *in vitro* studies were as follows. *N*-Demethylation of aminopyrine was determined by trapping formaldehyde derived from the methyl group in semicarbazone and by the Cochin and Axelrod (3) modification of the Nash method. Ring hydroxylation of acetanilide was determined by the method of Brodie and Axelrod (4). Reduction of *p*-nitrobenzoic acid to *p*-aminobenzoic acid was determined by measurement of the latter using the Bratton–Marshall reaction (5). *O*-Demethylation of *p*-nitroanisole was followed by spectrophotometry of the product, *p*-nitrophenol, at 396 nm. (6). Disappearance of hexobarbital was determined by the method of Brodie *et al.* (7).

RESULTS AND DISCUSSION

Biotransformation[6]—The ester linkages of I are highly resistant to hydrolysis, withstanding boiling in the presence of acid or base or incubation in the presence of various enzyme preparations. However, upon oxidation of the dihydropyridyl ring, hydrolysis takes place readily. This was borne out by the failure to find in

[6] Details to be published separately.

Table VII—Distribution of ^{14}C in Blood of Human, Dog, and Rat following Equilibration with ^{14}C-Labeled I *In Vitro*

Species	Percent of Added Drug Found		
	Plasma Proteins	Cells	Plasma Water
Human	83 ± 5	16 ± 5	0.9 ± 0.7
Dog	86 ± 7	13 ± 8	0.8 ± 0.3
Rat	91 ± 4	8 ± 4	1.4 ± 0.3

urine any aromatized parent drug (II), the expected intermediate (Scheme II). Nevertheless, both expected deesterified metabolites were found (III and IV). Two remaining metabolites, both unanticipated, were the results of β-oxidation of an ethyl group (V) and oxidation of a 2-methyl group which apparently underwent spontaneous lactonization with an adjacent carboxyl (VI), respectively.

Quantitative differences in the metabolites were observed in the urine of three species, with III predominating in the rat and dog and IV in the squirrel monkey. Both metabolites, however, account for half or more of the urinary ^{14}C (Table II).

The relative amounts of the dose excreted in urine and feces were highly dependent upon the dosage form. When the drug was given to dogs as the crystalline drug (in gelatin capsules), only about 7% was recovered in urine. However, when dissolved in a mixture of polyethylene glycol 200–water (1:1), a four- to fivefold increase in urinary output was observed, indicating enhanced absorption of the solubilized drug (Table III).

Blood levels were correspondingly higher in the animals dosed with the solution (Table IV). The mean blood level over the 24-hr. period following the dose of the polyethylene glycol 200 solution of drug was almost seven times that attained in the dogs dosed with crystalline drug. Peak levels in the dog dosed with either form appeared at about 2 hr. Similar results were seen in one squirrel monkey following doses of polyethylene glycol solutions of drug (Table V), but another monkey showed a delayed peak at 6 hr.

Irrespective of dosage form, the major portion of ^{14}C excreted in feces of the dog and squirrel monkey appeared from TLC to be the parent drug, which accounted for roughly half of the radioactivity excreted by this route.

Enzyme Induction Studies—Because I is intended for a condition requiring chronic treatment, it was of interest to determine its effect during chronic use on metabolizing enzymes, since either inhibition or stimulation of the enzymes could conceivably alter the physiological response to a given dose. Accordingly, a number of widely used tests were run and the results are summarized in Table VI.

These tests indicated that a weak to moderate induction of some metabolic pathways (ascorbic acid excretion, phenyl ring hydroxylation, *O*-dealkylation, *N*-demethylation, and aliphatic side-chain oxidation) occurred following oral administration of I. The reverse effect, inhibition of the same microsomal enzyme systems, was also tested *in vitro* by incubation of I with the liver microsomal preparations and the various test compounds referred to in Table VI. Compound I was found to be without significant effect on the metabolic pathways investigated.

Protein Binding Studies—Because of the possible influence of binding to plasma proteins on the sojourn and distribution of the drug following absorption, it was of interest to determine the extent to which binding could occur. The results (Table VII) indicate that very little (about 1%) drug remains "free" in the plasma of human, dog, or rat blood; over 80% was bound to protein and the remainder to cellular components.

These findings may not, however, be of much significance since, at times of peak ^{14}C concentrations in blood following an oral dose, only about one-quarter of the low levels present could be accounted for as parent drug (Table VIII) in the rat and squirrel monkey and

Table VIII—^{14}C "Fingerprint" of Animal Blood following Oral Dose of ^{14}C-I[a]

Species	^{14}C Peak Time, hr.	^{14}C Concentration, mcg./ml.	Percent of Dose on TLC at R_f of Metabolites			
			Parent	II	III	IV–V[b]
Rat	7	1.81	30	59	1	5
Dog	2	0.91	2	7	10	45
Squirrel monkey	3	0.40	24	19	26	6

[a] 5 mg./kg. in polyethylene glycol 200–water (1:1). [b] Expressed as equivalent amounts of I.

only 2% in dog. Only the more significant metabolites are shown; at least six or eight additional metabolites appearing on the radioscans were not identified.

CONCLUSION

Compound I, as a consequence of its poor aqueous solubility, was found to require prior solubilization to enhance absorption. It appears to be rapidly metabolized in the species investigated (rat, dog, and squirrel monkey), which may account for its relatively short duration of action[7]. None of the metabolites identified nor the postulated intermediates was found in animal studies[8] to approach the hypotensive effect of the parent drug in potency. Because of the observed weak inductive effect on some of the drug-metabolizing enzyme systems, subjects treated concomitantly with other drugs should be observed for the possibility of drug interactions.

Effect of 3-Phenylpropan-1-ol, 2-Phenylethanol, and Benzyl Alcohol on *Pseudomonas aeruginosa*

R. M. E. RICHARDS[▲] and R. J. McBRIDE

Abstract □ 3-Phenylpropan-1-ol, 2-phenylethanol, and benzyl alcohol were investigated for their inhibitory action against *Pseudomonas aeruginosa*. 3-Phenylpropan-1-ol was the most effective and benzyl alcohol was the least effective as shown by: (*a*) growth rate studies using subinhibitory concentrations of the alcohols, (*b*) determination of minimum inhibitory concentrations, and (*c*) determination of sterilization times. The three compounds enhance the bactericidal action of benzalkonium chloride against *P. aeruginosa* in the same ranking order. It is suggested that 3-phenylpropan-1-ol may be a suitable preservative for oral suspensions and mixtures.

Keyphrases □ 3-Phenylpropan-1-ol effect on *Pseudomonas aeruginosa*—compared to 2-phenylethanol and benzyl alcohol with/without benzalkonium chloride □ 2-Phenylethanol effect on *Pseudomonas aeruginosa*—compared to 3-phenylpropan-1-ol and benzyl alcohol with/without benzalkonium chloride □ Benzyl alcohol effect on *Pseudomonas aeruginosa*—compared to 3-phenylpropan-1-ol and 2-phenylethanol with/without benzalkonium chloride □ Bactericidal activity—comparison of 3-phenylpropan-1-ol, 2-phenylethanol, and benzyl alcohol with/without benzalkonium chloride □ *Pseudomonas aeruginosa* inhibition—effect of 3-phenylpropan-1-ol, 2-phenylethanol, and benzyl alcohol with/without benzalkonium chloride

As the result of a survey of the contamination of pharmaceutical preparations, Hooper (1) stated that: "... aqueous medicines containing no preservative were very favourable breeding grounds for water-borne Gram-negative bacteria including Pseudomonas/Alcaligenes/Achromobacter groups. Mixtures such as magnesium trisilicate, aluminum hydroxide, ammonia and ipecacuanha, kaolin, magnesium carbonate, magnesium sulphate and magnesium hydroxide were often found to contain enormous numbers of organisms, counts of 10^6 per ml were often commonplace." Thus there is an urgent need for a preservative suitable for inclusion in such preparations.

The aim of this present investigation was to compare 3-phenylpropan-1-ol[1], 2-phenylethanol, and benzyl alcohol, both as single compounds and in combination with benzalkonium chloride, for their effects on *Pseudomonas aeruginosa*.

The initial member of this series of phenyl-substituted aliphatic alcohols is benzyl alcohol, which has been used for its antibacterial and analgesic properties in injections over the past 20 years. Gershenfeld (2) stated that, in a concentration of 1% or more, benzyl alcohol is bacteriostatic to a number of organisms. Its sharp burning taste, however, curtails its usefulness in oral products (3).

2-Phenylethanol is active against Gram-negative organisms (4) and is compatible with many ophthalmic solutions (5). Therefore, it is recommended in USP XVIII (6) and NF XIII (7) for preserving ophthalmic solutions. 2-Phenylethanol also has been shown to enhance the activities of a number of preservatives commonly used in ophthalmic solutions (8–13).

3-Phenylpropan-1-ol, the homolog of 2-phenylethanol having the synonym hydrocinnamyl alcohol, is a liquid with a cinnamon-like odor and is slightly soluble in water. The antibacterial properties of this compound have not been reported previously, but it was thought that it may prove to be a suitable preservative for mixtures and suspensions.

EXPERIMENTAL

Materials—Benzyl alcohol[2], 2-phenylethanol[2], and 3-phenylpropan-1-ol[2] were of laboratory reagent grade, and benzalkonium chloride BP[3] was used. The liquid growth medium was oxoid[4] nutrient broth No. 2 and the incubation temperature was 37°. *P. aeruginosa* NCTC 6750[5] was the test organism and was maintained as stab cultures in oxoid[4] nutrient agar at a temperature of 4°. The inactivating medium was that described by Riegelman *et al.* (14).

Methods—The evaluations used either log phase cultures for growth rate studies or overnight cultures for determinations of

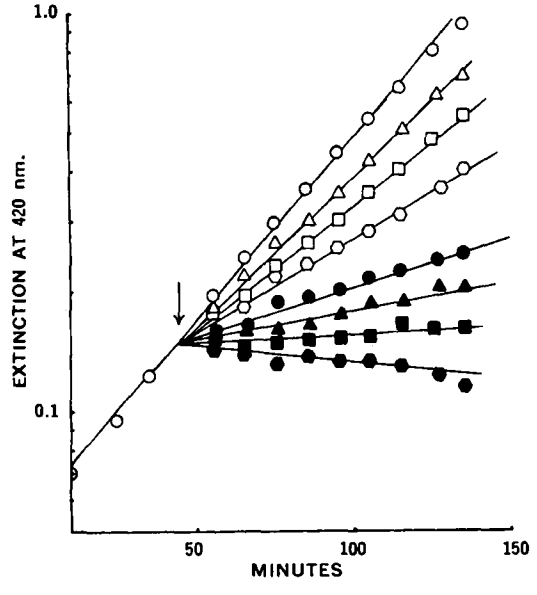

Figure 1—*Effect of various concentrations of phenylethanol on the growth of* P. aeruginosa *NCTC 6750. Sufficient phenylethanol was added at the time indicated by the arrow to give the final concentrations as follows:* ○, *no phenylethanol added;* △, *0.05% phenylethanol;* □, *0.1% phenylethanol;* ○, *0.15% phenylethanol;* ●, *0.2% phenylethanol;* ▲, *0.25% phenylethanol;* ■, *0.3% phenylethanol; and* ●, *0.35% phenylethanol.*

Table I—Minimum Inhibitory Concentrations for 3-Phenylpropan-1-ol, 2-Phenylethanol, and Benzyl Alcohol against *P. aeruginosa* NCTC 6750 in Nutrient Broth at 25°

Alcohol	Minimum Inhibitory Concentration, %—Log Phase Cells	Minimum Inhibitory Concentration, %—1.9×10^7 Overnight Cells/ml.
Benzyl alcohol	0.41	0.42
2-Phenylethanol	0.30	0.34
3-Phenylpropan-1-ol	0.27	0.26

growth inhibition and cell death. Cell numbers were estimated by colony counts as previously described (13).

Effect on Growth Rate—Log phase cultures were prepared by inoculating 100 ml. prewarmed nutrient broth with 1 ml. of an overnight culture, prepared from a stored stab culture of *P. aeruginosa*, and incubating in a shaking incubator[6] at 100 throws a minute. (Each stab culture was used once only.) Growth was followed by measuring the absorbance of samples in a spectrophotometer[7] at 420 nm. When the absorbance reading was 0.3–0.35, 1-ml. samples were transferred to each of the required number of 100-ml. quantities of prewarmed broth in 250-ml. conical flasks. Chemicals were subsequently added to these log phase cultures when the absorbances were approximately 0.1.

Effect of Alcohol Concentration—Varying concentrations of one of the alcohols were added to a number of similar cultures and simultaneously an equivalent volume of water was added to the control culture. (All liquids, as well as the pipets used in making their addition, were prewarmed to 37°.) The growth in each culture was followed by making absorbance measurements over the next 1.5–2.5 hr. The log of the absorbance so obtained for each concentration of alcohol was graphed against the time over which the determinations were made to give a result similar to that in Fig 1. By using the method of least squares, the equation for each line was calculated to obtain the slope which is the growth rate. The growth rate for each concentration, when expressed as a percentage of the growth rate of the control culture, was then plotted against the concentration of alcohol to produce a graph such as Fig. 2. The point where the baseline is crossed indicates the concentration of alcohol that will inhibit log phase cultures of *P. aeruginosa*, and these values are given in Table I.

Comparative Activity of Alcohols—To three log phase cultures, sufficient benzyl alcohol, 2-phenylethanol, and 3-phenylpropan-1-ol were added to give final concentrations of 0.178, 0.2, and 0.223% (w/v), respectively. An equivalent volume of water was added to the control culture. The concentrations used gave equimolar concentrations of the three alcohols. The growth in all flasks was followed as already described; the results are expressed in Fig. 3.

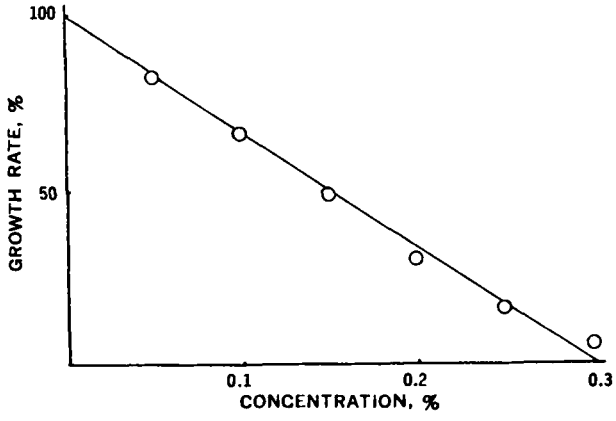

Figure 2—*Correlation between subinhibitory concentrations of phenylethanol and growth rate of* P. aeruginosa *NCTC 6750 in subinhibitory concentrations of phenylethanol expressed as a percentage of the growth rate in the absence of phenylethanol.*

Table II—Sterilization Times at 25° for 5.6×10^6 Cells/ml. *P. aeruginosa* NCTC 6750 in Aqueous Solutions of Benzyl Alcohol, 2-Phenylethanol, and 3-Phenylpropan-1-ol Alone and in Combination with Benzalkonium Chloride, 0.01% (w/v)

Antibacterial Concentrations, %	Sterilization Time, min.—Single Substance	Sterilization Time, min.—Combination
Benzalkonium chloride, 0.01	50–60	—
Benzyl alcohol, 0.4	>24 hr.	25–30
2-Phenylethanol, 0.4	>24 hr.	20–25
2-Phenylpropan-1-ol, 0.4	75–90	<5

Alcohol–Benzalkonium Combinations—To eight log phase cultures the following were added: (*a*) water; (*b*) benzalkonium chloride, 0.003%; (*c*) benzyl alcohol, 0.175%; (*d*) 2-phenylethanol, 0.175%; (*e*) 3-phenylpropan-1-ol, 0.175%; (*f*) benzyl alcohol, 0.175%, and benzalkonium chloride, 0.003%; (*g*) 2-phenylethanol, 0.175%, and benzalkonium chloride, 0.003%; and (*h*) 3-phenylpropan-1-ol, 0.175%, and benzalkonium chloride, 0.003%. The growth of each culture was followed as before and the results form Fig. 4.

Effect on Growth Inhibition and Cell Death—*Minimum Inhibitory Concentration*—A series of concentrations of benzyl alcohol, 2-phenylethanol, and 3-phenylpropan-1-ol were prepared in 10-ml. volumes of nutrient broth. Each tube was inoculated with 0.1 ml. overnight culture of *P. aeruginosa* to give a final viable concentration of approximately 1.9×10^7 cells/ml. The tubes were incubated for 5 days and observed for growth daily. The lowest concentration of each alcohol showing no growth is given in Table I.

Sterilization Times—Tubes containing 9.9-ml. volumes of the aqueous solutions under test were equilibrated in a water bath at 25°, after which 0.1 ml. of overnight culture of *P. aeruginosa* was added to give a final inoculum of approximately 5×10^6 cells/ml. At intervals of 5, 10, 15, 20, 25, 30, 40, 50, 60, 75, 90, 105, and 120 min. and 24 hr. after the addition of the inoculum, 0.5-ml. samples were added

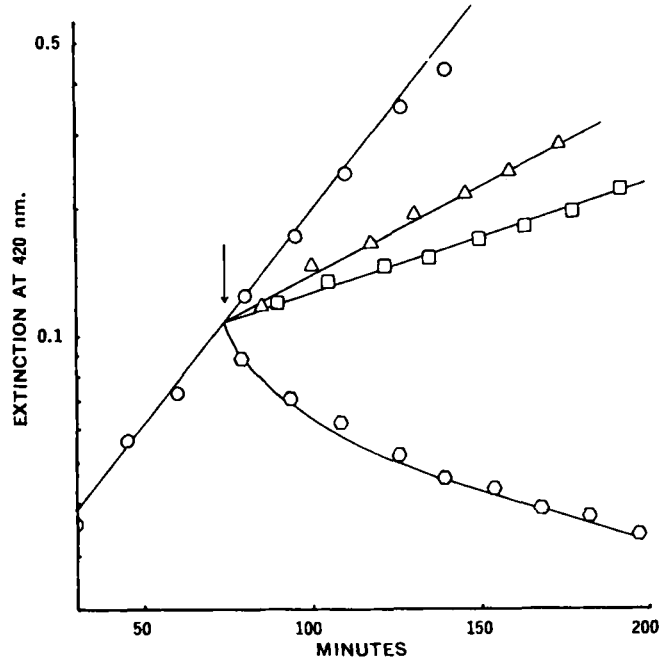

Figure 3—*Comparison of the effect of equimolar concentrations of benzyl alcohol, phenylethanol, and 3-phenylpropan-1-ol on the growth of* P. aeruginosa *NCTC 6750. Sufficient alcohol was added at the time indicated by the arrow to give a final concentration of* 1.6×10^{-3} M. *Key:* ○, *no alcohol;* △, *benzyl alcohol;* □, *phenylethanol; and* ○, *3-phenylpropan-1-ol.*

to 9.5 ml. of inactivating recovery medium and incubated for 3 days. Positive controls were prepared by adding 0.1 ml. of a 10^6 dilution in nutrient broth of an overnight culture of *P. aeruginosa* to tubes of recovery medium separately containing 0.5 ml. of each of the preservative solutions under test; all showed growth. The results are tabulated in Table II.

RESULTS AND DISCUSSION

After the addition of subinhibitory concentrations of either of the three alcohols, the log phase cultures continued to grow exponentially but at a rate dependent on the alcohol concentration. Typical results for phenylethanol are given in Fig. 1. Lang and Rye (15), using a different experimental technique, investigated the growth inhibitory properties of benzyl alcohol and phenylethanol against *Escherichia coli*. These workers found that growth occurring in the presence of benzyl alcohol was exponential, but that the growth rate in the presence of phenylethanol occurred at a gradually decreasing rate throughout the period of incubation. It was not apparent why the response of the *E. coli* to the action of the alcohols was different.

The concentration of each alcohol causing inhibition of growth of log phase cultures was then determined by plotting the growth rate for each concentration of alcohol, as a percentage of the growth rate of the control containing no alcohol, against the alcohol concentration. Figure 2 shows the results for phenylethanol, and the same linear response was obtained with the other two alcohols; these findings demonstrate the effectiveness of these antibacterials under the conditions of the test. Unpublished results[8] with benzalkonium chloride, however, showed a different response pattern to that of the alcohols. When the percentage of the control growth rate was plotted against the concentration of benzalkonium chloride, a straight line was obtained at low concentrations but this became asymptotic at higher concentrations. This lack of linearity shows that the antibacterial action of benzalkonium chloride is inadequate under the conditions of the growth rate experiments using *P. aeruginosa* as the test organism. This technique might prove useful in determining the suitability of a given antibacterial for use as a preservative against a given organism.

The concentrations of the alcohols causing inhibition of log phase cultures of *P. aeruginosa* are given in Table I, together with the minimum inhibitory concentrations for overnight cultures. The closeness of the two sets of values indicates that the alcohols have a uniform activity against *P. aeruginosa* cells in different phases of the growth cycle.

Figure 3 shows that at a concentration of 1.6×10^{-3} *M*, 3-phenylpropan-1-ol is more active against log phase *P. aeruginosa* than 2-phenylethanol, which is more active than benzyl alcohol.

2-Phenylethanol has been shown to enhance the antibacterial effect of benzalkonium chloride on log phase cultures of *P. aeruginosa* (10) and to give shorter sterilization times in ophthalmic preparations (11). Figure 4 shows that all of the alcohols increase the effect of benzalkonium chloride. Again 3-phenylpropan-1-ol is the most effective and benzyl alcohol is the least effective. This result is confirmed by the sterilization times for aqueous solutions of the preservatives alone and in combination with 0.01% benzalkonium chloride against large inocula of *P. aeruginosa* (Table II). 3-Phenylpropan-1-ol sterilized in less than 90 min., but phenylethanol and benzyl alcohol both gave positive samples after 24 hr. No growth was detected in any of the samples from the 3-phenylpropan-1-ol–benzalkonium chloride combination.

SUMMARY AND CONCLUSION

3-Phenylpropan-1-ol is more effective than 2-phenylethanol which, in turn, is more effective than benzyl alcohol in inhibiting the growth of *P. aeruginosa* and in enhancing the activity of benzalkonium chloride against *P. aeruginosa*. The compound 3-phenylpropan-1-ol with its cinnamon-like odor is quite pleasant at a concentration of 0.4% in water and may be suitable, either alone or in combination, for use in the preservation of oral preparations.

Ergoline Alkaloidal Constituents of Hawaiian Baby Wood Rose, *Argyreia nervosa* (Burm. f.) Bojer

JEW-MING CHAO* and ARA H. DER MARDEROSIAN▲

Abstract □ Chemical analysis showed that the seeds of *Argyreia nervosa* contain the highest percentage of indole alkaloid constituents (0.5–0.9%) of the genera of the Convolvulaceae thus far studied. A total of 19 indole alkaloids were identified by thin-layer and paper chromatographic procedures. Of these, lysergene, festuclavine, setoclavine, isosetoclavine, agroclavine, elymoclavine, ergine, and isoergine were isolated by column chromatographic procedures and characterized by TLC and IR analyses. Penniclavine, chanoclavine-I, chanoclavine-II, ergometrine, ergometrinine, lysergic acid α-hydroxyethylamide, isolysergol, racemic chanoclavine-II, molliclavine, lysergol, and isolysergic acid α-hydroxyethylamide were identified by TLC only. Of these, lysergene, setoclavine, isosetoclavine, chanoclavine-II, racemic chanoclavine-II, isolysergol, and molliclavine were identified for the first time in species of the Convolvulaceae. Ergine (0.136%) and isoergine (0.188%) were found in the highest concentration. In addition, 11 unidentified indole alkaloids were detected, these being found in very low concentration. Although the pericarp showed the same alkaloid pattern as the seeds, the concentration was much lower (0.0015%). No alkaloids could be detected in the vegetative tissues of nonflowering specimens.

Keyphrases □ Alkaloidal constituents, *Argyreia nervosa* seeds—isolation, identification of 19 indole alkaloids □ *Argyreia nervosa* (Burm. f.) Bojer seeds—isolation, identification of 19 indole alkaloids □ Morning-glory seeds—isolation, identification of 19 indole alkaloids □ Ergoline alkaloids—isolation, identification from *Argyreia nervosa* (morning-glory)

Argyreia nervosa (Burm. f.) Bojer is a member of the Convolvulaceae (morning-glory family) and is characterized by heart-shaped leaves with dense, white, silky hairs beneath. The plant is believed to have its origin in India. Historically, its roots have been used by the Hindus as an alternative, tonic, antirheumatic and in the treatment of diseases of the nervous system (1). The leaves have been used as a local stimulant, rubefacient, and vesicant. Because the under surface of the leaf is covered by a thick layer of silky hairs, it has been used as a natural impermeable temporary covering and poultice for minor skin abrasions by natives in India. However, Dymock (2) reported the leaves to be ineffective for this purpose.

This species is commonly and widely cultivated as a garden plant in several tropical countries because of its showy flowers. The mature capsules are handsome and persistent and are widely used in ornamental dried-flower arrangements. To date, no significant pharmacological or phytochemical studies on *A. nervosa* have appeared in the literature.

Since Aztec times in the uplands of southern Oxaca in Mexico, the seeds of *Rivea corymbosa* (known as "Ololiuqui") and *Ipomoea violacea* (known as "badoh negro") have been used for divinatory and hallucinatory purposes during religious ceremonies. The native use of these seeds for ceremonial purposes was extensively reported by Schultes (3–5) and Wasson (6). Following these publications, there occurred a rash of use of morning-glory seeds for hallucinatory purposes in the United States.

Among the morning-glories that have become quite popular is *A. nervosa* (Hawaiian Baby Wood Rose); it is readily available from the southern parts of California and Florida as well as from Hawaii. The availability of this plant in the United States has led to its use by juveniles who seek hallucinatory experiences through ingestion of the seeds. Contributing to its popularity among juveniles is the potency of seeds of *A. nervosa* compared to seeds of ipomoea species. To achieve a psychotomimetic response, relatively few seeds of *A. nervosa* are needed as opposed to a few hundred of *I. violacea*. Hylin and Watson (7) reported that each gram of seeds contains approximately 3 mg. of total alkaloids, of which 0.36 mg. is represented by one of the psychoactive constituents, ergine. The results from the present study indicate that the seeds contain even higher concentrations of ergine and total indole alkaloid constituents.

Prior to 1960, ergoline-type alkaloids were known to occur only in certain lower fungi, particularly the genus claviceps. Hofmann and Tscherter (8) were the first to find and isolate these ergoline alkaloids from higher plants. Later, several investigators (9–37) showed a wider distribution of the ergoline-type alkaloids in the Convolvulaceae (morning-glory family). These currently include the genera rivea, ipomoea, argyreia, cuscuta, and stictocardia.

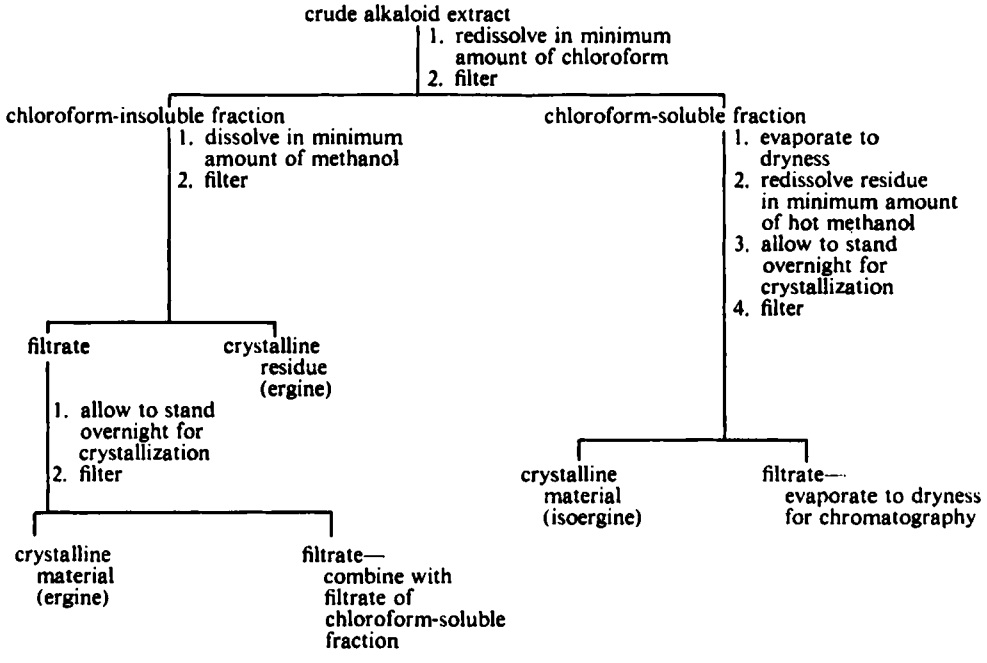
Noteworthy among the genera is argyreia because it possesses very high concentrations of a large number the ergoline alkaloids and until now it has not been subjected to extensive chemical studies. Only two compounds—*viz.*, ergine (lysergic acid amide) and isoergine (isolysergic acid amide), have been identified in *A. nervosa*, by Hylin and Watson (7) using TLC. Recently these two compounds were confirmed by McJunkins *et al.* (35) and isolated by Miller (37).

EXPERIMENTAL

Extraction of Crude Alkaloids and Isolation of Ergine and Isoergine—The total alkaloid was extracted by using a modification of the method of Genest (27). Due to the high concentrations of ergine and isoergine, they could be easily separated first without involving the chromatographic procedure. The diagrammatic isolation procedure is shown in Scheme I.

TLC—The following solvent systems were used for TLC: 1, silica gel plates, methanol–chloroform (20:80); 2, silica gel plates, diethylamine–chloroform (10:90); 3, silica gel plates, methanol–chloroform–concentrated ammonia (20:80:0.2); 4, silica gel plates, ethyl acetate–ethanol–dimethylformamide (86:7:7); 5, alumina plates, ethanol–chloroform (4:96); and 6, alumina plates, chloroform–benzene–glacial acetic acid (45:45:10).

For two-dimensional TLC, the method of Agurell (38) was used. A sample was spotted in the left-hand corner of the plates, 1.5 cm. from each side. The chromatograms were developed first in Solvent



Scheme I—Procedure for isolation of ergine and isoergine

System 1 and, after air drying for 5 min., were run in the second direction in Solvent System 2.

The fluorescent alkaloids were detected using both short- and longwave UV light. Ehrlich's spray reagent was used to locate all indole alkaloids. Dragendorff's reagent was used for general alkaloid detection.

Paper Chromatography—The method reported by Pöhm (39) was used for paper chromatography. The R_A value was calculated by using the R_f value of agroclavine as R_A 100. The solvent system is abbreviated as FBP.

Fractionation of Crude Alkaloids Using Column Chromatography—In these experiments, a minimum of 1.5 g. of crude alkaloid mixture (after ergine and isoergine were isolated) was redissolved in 50 ml. of a chloroform–benzene (1:1) mixture (containing 2% of methanol) and then transferred to a 100 × 2.5-cm. glass column. The column was previously packed with 90 cm. of a thick slurry of an alumina[1] and chloroform–benzene (1:1) mixture. Elution was started with 200 ml. of 50% chloroform in benzene and then developed by increasing the polarity (increasing the percentage of chloroform) in the solvent system. The procedure used was to increase the chloroform percentage by 5% for every 200 ml. of eluent collected until the solvent system contained no benzene. Methanol was then used to increase the polarity of chloroform by increasing its concentration at a rate of 1% for every 200 ml. of solvent collected until the solvent system reached 16% methanol in chloroform. At this point, pure methanol was used to elute the column. Ten-milliliter fractions were collected at a rate of 1 ml./min. until 580 fractions were obtained. All fractions were analyzed using TLC (Solvent System 1) as previously described.

Quantitative Analysis of Indole Alkaloid—The assay for total indole alkaloid was a modification of the procedure of Michelon and Kelleher (40). Isoergine was used as a reference compound. For individual alkaloids, an aliquot of crude alkaloid mixture was separated on a two-dimensional TLC plate as previously described. The individual alkaloids were marked under UV light. Each spot was scraped off the plate and then assayed using the same procedure as for the total indole alkaloid.

RESULTS

Fractionation and Separation of Crude Alkaloids by Column Chromatography—The fractions collected after separation by column chromatography were pooled according to similarity of alkaloid patterns as determined by TLC monitoring of the eluent. A total of 580 fractions was collected, and 30 alkaloids were isolated by this procedure. Nineteen of them were identified by IR or various chromatographic systems.

Thin-Layer and Paper Chromatographic Results (R_f and R_A Values) of Isolated Ergoline-Type Alkaloids—The R_f and R_A values of ergoline-type alkaloids isolated from the seeds of *A. nervosa* in various chromatographic systems are shown in Table I. A diagrammatic map of the two-dimensional TLC system (using Solvent System 1 first and Solvent System 2 second) is given in Fig. 1. Thirty compounds were found by this two-dimensional TLC system.

The crude alkaloidal extract from the pericarp showed the same alkaloidal pattern as the seeds.

Reference compound	19	38	24	56	17	17	12
Isolysergic acid α-hydroxyethylamide	54	41	53	—	—	—	—
Reference compound	—	—	—	—	—	—	—

[a] R_A values were calculated by using the R_f value of agroclavine as R_A 100. R_f values were calculated on the basis of a solvent front of 15 cm. and multiplied by 100. —: compounds were not available, the values were not determined.

The FBP solvent system is effective for separating most clavine-type alkaloids except chanoclavine-I and chanoclavine-II; however, it is ineffective for separating mixtures of both clavine- and lysergic acid-type alkaloids. None of the six TLC systems could separate the crude alkaloidal mixture from the seeds of *A. nervosa*. To obtain good separation, the two-dimensional TLC system was used for this mixture. Chanoclavine-I and chanoclavine-II showed very poor resolution in most systems but were separated well in Solvent System 2. Pennicalvine, lysergol, and elymoclavine were not separated by Solvent System 1 but were well separated by Solvent System 2. Agroclavine, festucalvine and racemic chanoclavine-II were well separated by most systems except 2 and 5.

Because of the limited amount of materials isolated, the R_f values of lysergol and isolysergic acid α-hydroxyethylamide were not obtained in Solvent Systems 3–6.

The R_f values represent the average of three chromatograms except for isolysergic acid α-hydroxyethylamide and lysergol; only one chromatogram was run for these compounds.

Quantitative Determination of Total and Individual Alkaloids—Various batches of seeds from different sources showed a 0.5–0.9% range of total indole alkaloid constituents. The results of one typical detailed assay (Table II) indicate the total percent of alkaloid to be 0.60, with isoergine (0.189%) and ergine (0.136%) being found in the highest concentrations in the seeds. These are followed, in order of decreasing indole alkaloid content, by ergometrine, lysergic acid α-hydroxyethylamide, isolysergic acid α-hydroxyethylamide, elymoclavine, ergometrine, chanoclavine-I, and agroclavine.

Table II—Major Alkaloid Content in the Seeds of *A. nervosa* (Burm. f.) Bojer

Alkaloids	Values Expressed as Percent of Total Alkaloid	Values Expressed as Percent of Dry Seed Weight
Agroclavine	1.09	0.006
Chanoclavine-I	2.65	0.016
Elymoclavine	3.62	0.022
Ergine	22.68	0.136
Isoergine	31.36	0.188
Ergometrine	8.20	0.049
Ergometrinine	1.81	0.011
Lysergic acid α-hydroxyethylamide	5.79	0.035
Isolysergic acid α-hydroxyethylamide	3.98	0.024
Tailing, minor, and unidentified alkaloids	18.82	0.113
Total	100.00	0.600

The tailing and minor alkaloids were scraped from the TLC plate and combined in the assay to give a total percentage of 0.113%.

The crude alkaloidal extract of the pericarp showed 0.0015% of total indole alkaloid constituents.

DISCUSSION

In comparison to other members of the Convolvulaceae investigated so far, *A. nervosa* apparently contains one of the largest concentrations of ergoline derivatives. Various batches of seeds have assayed from 0.5 to 0.9% of total indole alkaloid constituents. The various components of the total alkaloidal mixture, as isolated and characterized by chromatographic and IR spectral data, include lysergic acid amide (ergine), isolysergic acid amide (isoergine), agroclavine, elymoclavine, lysergene, festuclavine, setoclavine, isosetoclavine, and racemic chanoclavine-II (no nonindole alkaloids were detected). Those characterized by chromatographic data alone include penniclavine, isolysergol, molliclavine, lysergol, chanoclavine-I, chanoclavine-II, ergometrine, ergometrinine, and the isomeric pair of isolysergic acid and lysergic acid α-hydroxyethylamides. Limited quantities of the isolated clavine- and lysergic acid-type alkaloids have precluded further chemical studies on these constituents.

Nineteen identified ergoline alkaloids are present in the seeds of *A. nervosa*. Of these, lysergene, setoclavine, isosetoclavine, chanoclavine-II, racemic chanoclavine-II, isolysergol, and molliclavine have been identified for the first time in species of the morning-glory family.

The various unknown minor indole alkaloidal constituents are considered to represent *bona fide* minor clavine- or lysergic acid-type alkaloids or decomposition products. The inability in many cases to obtain reproducible R_f values for these tends to indicate the latter, although the former should not be entirely discounted. The possibility that certain of the alkaloids isolated or described are decomposition products has been minimized by careful experimental procedures (avoidance of light, rapid TLC separation, rapid analysis, *etc.*) and reproducibility of results.

The results of the tentative identification of several ergoline alkaloids of 13 other argyreia species and two closely related species, *Stictocardia tiliifolia* and *R. corymbosa*, will be given in a separate paper dealing with the chemotaxonomic implications of these indole alkaloids.

Clindamycin Dose–Bioavailability Relationships

CARL M. METZLER▲, RAY DeHAAN, DIANA SCHELLENBERG, and WILLIAM D. VANDENBOSCH

Abstract □ Analyses of dose-related changes in pharmacokinetic variables indicating bioavailability and of dosage equivalence were performed on data from single-dose studies on three preparations of the antibiotic clindamycin [7(*S*)-chloro-7-deoxylincomycin]: clindamycin hydrochloride hard-filled capsules, clindamycin palmitate flavored granules, and clindamycin phosphate sterile solution. The variables studied were serum clindamycin bioactivity and parameters calculated from a single-compartment pharmacokinetic model. In general, the changes with dose were linear but not proportional and the pharmacokinetic model fit the data well. There were, however, some suggestions of nonlinear kinetics, particularly in the clindamycin hydrochloride study. Within the dose ranges (150–450 mg. clindamycin hydrochloride, 150–600 mg. clindamycin palmitate, and 300–600 mg. clindamycin phosphate), the average response to a dose could be predicted well. An equivalent dose analysis for the three clindamycin preparations offered some insight into their absorption and disposition characteristics and the relative bioavailability of clindamycin from them. A single equivalent dose could not be computed; there were different equivalent doses for peak serum concentration, area under the serum concentration–time curve, and other variables.

Keyphrases □ Clindamycin formulations—absorption, disposition, and relative bioavailability of hydrochloride capsules, palmitate flavored granules, and phosphate sterile solution □ Dose–bioavailability relationships—clindamycin hydrochloride capsules, clindamycin palmitate flavored granules, clindamycin phosphate sterile solution □ Bioavailability—absorption, disposition of clindamycin capsules, flavored granules, and sterile solution □ Pharmacokinetics—absorption, disposition, and relative bioavailability of three clindamycin formulations

Two problems frequently confront researchers testing new drugs: prediction of response to a particular dosage and equivalence of formulations. In the case of antibiotics, it is often assumed that the desired response, eradication of pathogens, is closely related to the concentration of drug in the serum and, therefore, that

ACKNOWLEDGMENTS AND ADDRESSES

Received December 13, 1971, from the *Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104*

Accepted for publication October 13, 1972.

Presented at the ASP-DGA meeting in Vienna, Austria, September 1970.

Abstracted in part from a dissertation submitted by J. Chao to the Philadelphia College of Pharmacy and Science in partial fulfillment of the Doctor of Philosophy degree requirements.

The authors express their appreciation to Dr. Albert Hofmann of Sandoz Limited, Basel, Switzerland, for his provision of reference compounds, and to the Philadelphia College of Pharmacy and Science for financial support during this study.

• Present address: New Jersey State Police Laboratory, West Trenton, NJ 08625

Clindamycin Dose–Bioavailability Relationships

CARL M. METZLER▲, RAY DeHAAN, DIANA SCHELLENBERG, and WILLIAM D. VANDENBOSCH

Abstract □ Analyses of dose-related changes in pharmacokinetic variables indicating bioavailability and of dosage equivalence were performed on data from single-dose studies on three preparations of the antibiotic clindamycin [7(*S*)-chloro-7-deoxylincomycin]: clindamycin hydrochloride hard-filled capsules, clindamycin palmitate flavored granules, and clindamycin phosphate sterile solution. The variables studied were serum clindamycin bioactivity and parameters calculated from a single-compartment pharmacokinetic model. In general, the changes with dose were linear but not proportional and the pharmacokinetic model fit the data well. There were, however, some suggestions of nonlinear kinetics, particularly in the clindamycin hydrochloride study. Within the dose ranges (150–450 mg. clindamycin hydrochloride, 150–600 mg. clindamycin palmitate, and 300–600 mg. clindamycin phosphate), the average response to a dose could be predicted well. An equivalent dose analysis for the three clindamycin preparations offered some insight into their absorption and disposition characteristics and the relative bioavailability of clindamycin from them. A single equivalent dose could not be computed; there were different equivalent doses for peak serum concentration, area under the serum concentration–time curve, and other variables.

Keyphrases □ Clindamycin formulations—absorption, disposition, and relative bioavailability of hydrochloride capsules, palmitate flavored granules, and phosphate sterile solution □ Dose–bioavailability relationships—clindamycin hydrochloride capsules, clindamycin palmitate flavored granules, clindamycin phosphate sterile solution □ Bioavailability—absorption, disposition of clindamycin capsules, flavored granules, and sterile solution □ Pharmacokinetics—absorption, disposition, and relative bioavailability of three clindamycin formulations

Two problems frequently confront researchers testing new drugs: prediction of response to a particular dosage and equivalence of formulations. In the case of antibiotics, it is often assumed that the desired response, eradication of pathogens, is closely related to the concentration of drug in the serum and, therefore, that

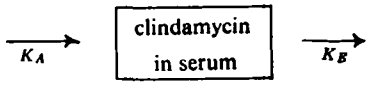
Table I—Subject Characteristics

Study Number	Compound and Dosage	Number of Men	Age (Years), Mean (Range)	Weight (kg.), Mean (Range)	Height (cm.), Mean (Range)
1	Clindamycin hydrochloride				
	150 mg.	10	36.4 (26.0–44.0)	80.0 (67.7–86.8)	182.1 (173.8–190.4)
	300 mg.	8	31.1 (22.0–46.0)	81.6 (70.9–95.0)	183.1 (173.8–198.2)
	450 mg.	8	35.4 (25.0–42.0)	82.5 (71.8–94.1)	181.3 (173.1–192.3)
2	Clindamycin palmitate				
	150 mg.	12	27.8 (23.0–35.0)	75.5 (61.4–91.4)	185.6 (176.9–193.6)
	225 mg. / 300 mg.	12	29.1 (22.0–42.0)	75.9 (65.9–93.6)	177.9 (143.6–191.0)
	600 mg.	6	30.0 (25.0–42.0)	70.6 (62.7–78.6)	176.7 (171.8–182.1)
3	Clindamycin phosphate				
	300 mg. / 450 mg. / 600 mg.	12	36.3 (25.0–48.0)	82.8 (69.1–105.0)	179.3 (172.4–193.6)

equal bioavailability implies therapeutic equivalence. Which measure(s) of drug absorption and distribution best reflects bioavailability remains to be established. This report considers several variables as indicators of bioavailability of three preparations of the antibiotic clindamycin[1] [7(*S*)-chloro-7-deoxylincomycin] undergoing clinical trials: (*a*) clindamycin hydrochloride hard-filled capsules; (*b*) a pediatric oral preparation of the 2-palmitate ester, clindamycin palmitate flavored granules; and (*c*) a parenteral preparation of the 2-phosphate ester, clindamycin phosphate sterile solution. The goal of administering any of the three is to attain therapeutically adequate concentrations of clindamycin bioactivity.

Wagner *et al.* (1) first described the clinical pharmacology of clindamycin hydrochloride, and their observations have been confirmed and extended by others (2–6). Clindamycin palmitate flavored granules, first prepared by Sinkula *et al.* (7), were shown in pharmacokinetic studies in adults (8) and children (9, 10) to be a satisfactory oral delivery agent for clindamycin. Results in clinical efficacy studies[2] in more than 1500 children with infectious diseases are confirmatory. The ester, which is inactive against bacteria *in vitro*, is readily hydrolyzed in the gut to microbiologically active clindamycin before absorption occurs. Preliminary studies did not reveal quantifiable amounts of the intact ester in human serum after a 300- or 600-mg. dose[3].

When clindamycin hydrochloride proved too irritating to use parenterally (11), the 2-phosphate ester was developed (12). Tolerance findings indicate that it is suitable for clinical use. However, to improve local tolerance the concentration of drug was halved from the 300 mg./ml. used in the first clinical pharmacology study reported here to 150 mg./ml., used in all subsequent studies. Microbiologically inactive 2-phosphate ester is absorbed intact after intramuscular injection. The kinetics of hydrolysis of the ester to active clindamycin will be dealt with in future publications.



Scheme I

In the three studies described here, healthy men were given single doses of 150, 300, and 450 mg.[4] clindamycin hydrochloride orally; 150, 225, 300, and 600 mg. clindamycin palmitate orally; or 300, 450, and 600 mg. clindamycin phosphate intramuscularly. Serum clindamycin levels were determined by bioassay, and the observations were subjected to pharmacokinetic analyses. In evaluating antibiotics, serum concentrations at various times after dosing, area under the serum concentration–time curve, peak serum level, and time of peak have all been considered clinically important by some workers. This paper considers these pharmacokinetic variables and others in assessing dose–bioavailability relations. The two aspects focused on are: (*a*) relationship between dose level and values of the pharmacokinetic variables for each compound, and (*b*) comparison of bioavailability of active clindamycin from the three compounds.

Urinary excretion of drug, sometimes used as an indicator of drug absorption, could not be estimated precisely for clindamycin in the studies reported here. Urine assays were run, but the bioactivity measured was due to a mixture of clindamycin and bioactive metabolites, one of which (*N*-demethylclindamycin) is more active and another (clindamycin sulfoxide) much less active than clindamycin itself. To report only the total amount of bioactivity excreted might perpetuate the misleading concept that the amount of bioactivity excreted represents the amount of drug excreted. Definitive studies of excretion of metabolites are not yet completed.

THEORETICAL

A single-compartment model (Scheme I) was used in studying serum clindamycin concentrations after all three clindamycin preparations, where K_A is a first-order rate constant for appearance of clindamycin in the blood (absorption) and K_B is a first-order rate constant for elimination from the blood. Both are expressed in liters

per hour. The concentration of clindamycin in the serum as a function of time after dosing is described by the equation:

$$\text{concentration} = \frac{\text{dose } K_A}{V(K_E - K_A)}[\exp(-K_A t^*) - \exp(-K_E t^*)] \quad \text{(Eq. 1)}$$

where $t^* = t - t_0$; t is time measured in hours from dosing and t_0 is a time lag before measurable amounts of clindamycin can be observed in the serum. Dose is in milligrams, and V is the apparent volume of distribution in liters. In addition to being a volume factor, V also adjusts for the fraction of the dose absorbed; in this paper (dose/V) corresponds to the (FD/V) parameter of Wagner and Nelson (13). Parameters that can be calculated from this model include the absorption half-life $A(^1/_2) = (\ln 2)/K_A$ (in hours), the elimination half-life $E(^1/_2) = (\ln 2)/K_E$ (in hours), the peak serum concentration (in micrograms per milliliter), the time of peak (in hours), and the total area under the serum concentration–time curve (in micrograms per milliliter × hours). The use of this model in both single-dose and multidose studies of clindamycin hydrochloride was discussed elsewhere (6).

In this model, serum concentrations are related to dose in a linear manner. If the model holds over all doses, then serum concentrations at a given time should increase in the same proportion as do doses. Thus, if the dose is doubled, serum concentrations at a given time should double, as should the parameters directly dependent upon concentration (peak and area under the curve). However, rate constants, half-lives, time lag, time of peak, and volume should not change. Deviation from this behavior may provide information about the drug and different formulations; it may also indicate that the model does not give a complete description of the drug kinetics.

One way to compare bioavailability of the two formulations is to calculate the dose of one formulation ("equivalent dose") that will produce the same average value of a chosen variable as does a specified dose of the standard formulation. In this paper, 150 mg. clindamycin hydrochloride is used as the standard and, where feasible, the equivalent doses of palmitate and phosphate esters that will produce the same average values for serum concentrations and parameter estimates from the pharmacokinetic model are estimated. The composite means of pharmacokinetic variables found in six studies with 150 mg. clindamycin hydrochloride (6) were used as the reference values. Values obtained with clindamycin hydrochloride in Study 1 described here were also compared with the composite means, using the same method of inverse estimation.

Since for the chosen variables the dose–bioavailability relationship is assumed to be linear over the doses used for each formulation, the equation:

$$\text{value of pharmacokinetic variable} = \text{intercept} + (\text{slope} \times \text{dose}) \quad \text{(Eq. 2)}$$

was used. Thus, for a pharmacokinetic variable, the dose of the ester that is equivalent to 150 mg. clindamycin hydrochloride is given by the equation:

$$\text{equivalent dose} = \frac{P - I}{S} \quad \text{(Eq. 3)}$$

where P is the average value of the pharmacokinetic variable observed in subjects receiving 150 mg. clindamycin hydrochloride in the six studies, and I is the intercept and S is the slope of the linear dose–bioavailability relation computed for all the observed dose

levels of that ester. This is called inverse estimation in the statistical literature (14).

EXPERIMENTAL

Design of Studies—Study 1 was described in detail (as Study 7) by DeHaan *et al.* (6). Results after the first 150-mg. dose were included in the six single-dose studies referred to previously.

The other two studies were carried out with prisoners as subjects[5]. In Study 2 the 12 men who took 150 mg. clindamycin palmitate also took 150 mg. clindamycin hydrochloride in a two-way crossover with a week between doses; data from the clindamycin hydrochloride part of the study were reported (as Study 3) previously (6). Another panel of 12 received the 225- and 300-mg. doses in a two-way crossover with a week between doses. In the 600-mg. phase of the palmitate study, six men were given clindamycin palmitate and another six received placebos (vehicle for clindamycin palmitate) as a tolerance control group.

Study 3 was a three-way crossover study in which each of 12 men received intramuscular injections of 300, 450, and 600 mg. clindamycin phosphate with a week between doses.

The volunteers were required to be within 20% of ideal body weight for height and build; to have no known GI, hepatic, or renal disease; and to have screening clinical laboratory values, physical examinations, and vital signs within normal limits. Table I summarizes subject characteristics.

Clindamycin hydrochloride hydrate (Lot 15,759-15) was given as 150-mg. hard-filled capsules, and clindamycin palmitate hydrochloride flavored granules (Lot 16,110-1) were given as a suspension reconstituted with distilled water to a concentration of 15 mg./ml. In both oral studies the subjects fasted (except for water *ad libitum*) overnight before the dose and for 3 hr. after the dose, and they drank 180 ml. (6 fl. oz.) water after the dose. Study 3 utilized clindamycin phosphate sterile solution containing 300 mg. clindamycin base equivalents/ml. (Lot 15,953); this lot did not contain the disodium edetate that was added to subsequent lots. Injections of 1.0, 1.5, or 2.0 ml. drug were made deep into the gluteal muscles, using a 3.8-cm. (1.5-in.) 22-gauge needle.

Microbiological Assay[6]—Serum specimens were obtained for microbiological assay at the times indicated in Tables II–IV, and the samples were frozen promptly and stored at −20°. To estimate clindamycin bioactivity (clindamycin plus bioactive metabolites), a cylinder-plate method was used. Sterile Pen Assay Seed Agar[7] was inoculated with the test organism, *Sarcina lutea* ATCC 9341. Primary standards were prepared in commercial pooled human serum[8], and secondary standards were prepared in the subject's own pretreatment serum specimen. Specimens were assayed undiluted and calculated *versus* their respective secondary standards, all specimens from an individual subject being assayed on the same day. Reported values of less than 0.9 mcg./ml. were extrapolated from the standard curve, and zero indicates less than 0.2 mcg./ml. Before assaying for free clindamycin activity in serum following clindamycin phosphate administration, phosphate buffer was added to the specimen immediately after it was thawed to halt hydrolysis of any clindamycin phosphate present. Wagner *et al.* (1) found that nearly all of the bioactivity in serum after clindamycin hydrochloride is due to clindamycin *per se*.

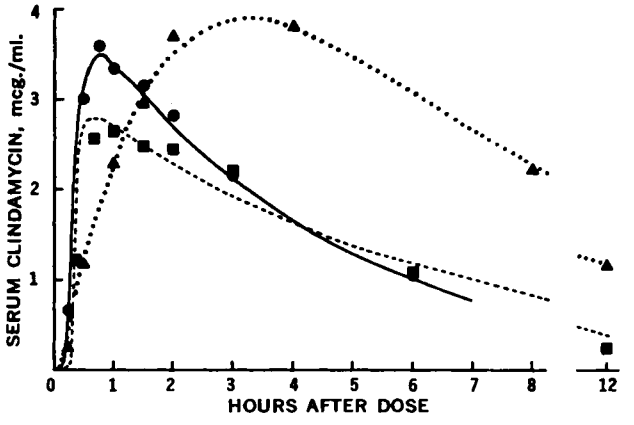

Figure 1—*Mean serum clindamycin (micrograms per milliliter) after a 300-mg. dose of three clindamycin preparations. Key: ●——●, clindamycin hydrochloride (eight men); ■- - -■, clindamycin palmitate (12 men); and ▲...▲, clindamycin phosphate intramuscularly (12 men).*

RESULTS AND DISCUSSION

Serum Levels—Mean serum clindamycin concentrations observed at the various sampling times are listed in Tables II–IV. Figure 1 illustrates the differences and similarities in the serum concentration–time curves following a 300-mg. dose of the three preparations.

Differential assay results in several clindamycin phosphate studies, including Study 3 described here, indicate that a substantial amount of unhydrolyzed ester appears in the serum shortly after intramuscular injection. In this study the ester reached a mean peak value between 1 and 2 mcg./ml. at 30 or 60 min. and virtually disappeared within 4 hr. Presumably the flattened, delayed peak in clindamycin bioactivity (compared with the oral dose curves) reflects hydrolysis of the ester to clindamycin in the serum, as well as various absorption and excretion factors.

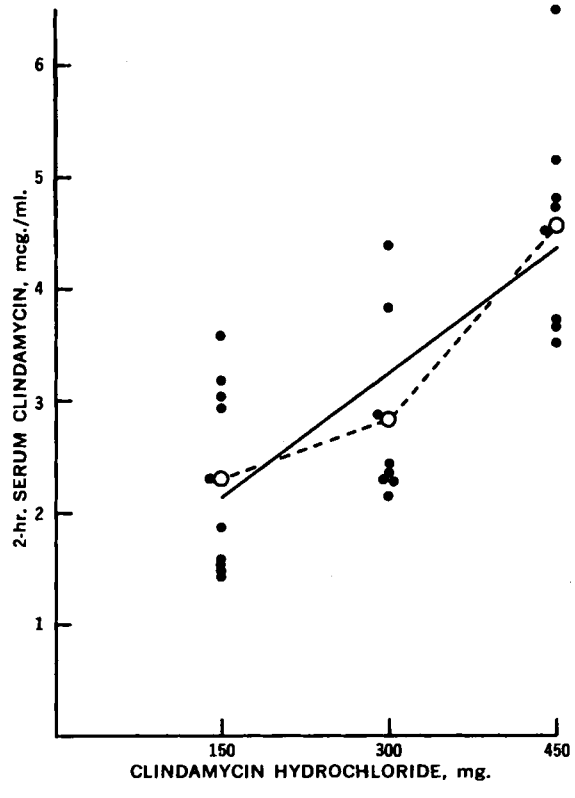

Figure 2—*Dose–bioavailability relation: 2-hr. serum clindamycin concentration after clindamycin hydrochloride. Key: ——, predicted means from linear model; O- - -O, observed means; and ●, individual values.*

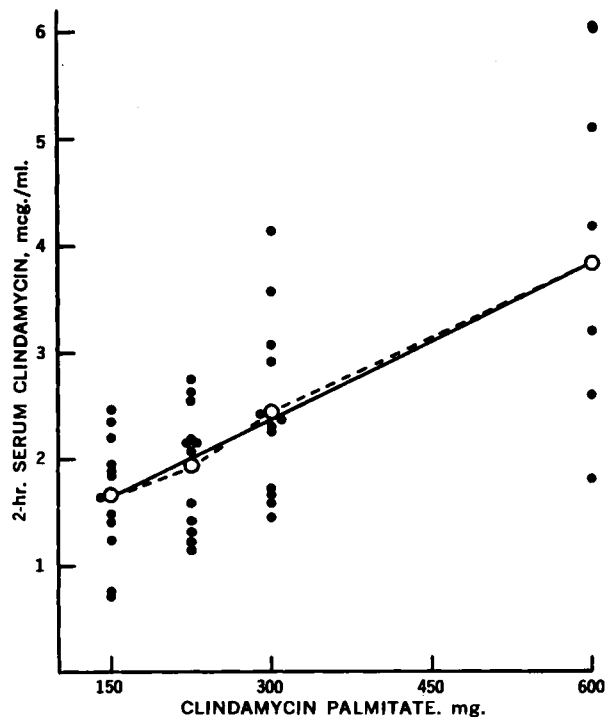

Figure 3—*Dose–bioavailability relation: 2-hr. serum clindamycin concentration after clindamycin palmitate. Key: ——, predicted means from linear model; O- - -O, observed means; and ●, individual values.*

Definitions and units for the estimated model parameters listed in Tables II–IV are given in the *Theoretical* section. The estimates were obtained by use of the nonlinear estimation program NONLIN (15).

Dose–Bioavailability Considerations—For all three formulations and all pharmacokinetic variables considered, where there was a change due to dose, the relation between dose and response was linear. Since at least three dose levels of the formulations were studied, a quadratic relation could be fitted to the data and, in fact, was calculated for all formulations and all variables; however, the resulting fit to the data was not significantly better than the linear fit. This linearity may hold only over the range of doses studied here. Since the intercept was in most cases nonzero, linearity would not hold for small doses and probably would not hold for very large doses.

For each variable (observed value or estimated parameter), a linear regression was computed with the dose as the independent variable and the value of the pharmacokinetic variable as the dependent variable. The strength of the relation was evaluated by a statistical test of the estimated slope; the t-statistic tests whether the slope is significantly different from zero. If the t-statistic was less than 2, that response was judged to be independent of dose [indicated by N.R. (no regression) in Tables II–IV].

Even though the mean values of the pharmacokinetic variables at each dose level fall on a line, there is so much variability about the means at each dose level that only a fraction of the total variability is due to changes in dose. The proportion of the variability of a pharmacokinetic variable that could be explained by change in dose is represented by r^2 (the square of r, the correlation coefficient). To express this proportion as a percent, multiply r^2 by 100. For example, as illustrated in Fig. 3, although the mean 2-hr. serum clindamycin levels at the four dose levels of clindamycin palmitate lie very close to a straight line, the individual values vary considerably about the mean. From Table III in the r^2 column for the 2-hr. serum concentration, it is apparent that only 43% of the total variation of the 2-hr. serum concentration is due to increasing dose levels.

Much of the overall variability in blood level studies is due to between-subject variability (16). Where the same panel of subjects

is used for all doses of a formulation, it is possible to remove this component. In Study 3 the same 12 subjects received the three dose levels in a crossover design. In Table IV, R^2 is the square of the correlation coefficient for the linear dose-bioavailability relations after the between-subject component of variance is removed. Consider, as an example, the 2-hr. serum concentrations. Of the total variability, only 26% is due to the different dose levels; but after removing the between-subject variability, 45% of the remaining variability is due to the different dose levels. Thus the small values of r^2 in Tables II–IV reflect between-subject variability as much as deviations from the linear dose–bioavailability relations.

Tables II–IV list the t-statistic, r^2, and mean observed value at each dose level. For those pharmacokinetic variables for which the regression was significant (t-statistic >2), the slope and intercept of the regression line and the mean of the pharmacokinetic variable predicted from the linear regression are also reported. By comparing the observed and predicted means at each dose level, it is possible to get some idea of how closely the means fit the computed linear relations. Space limitations prohibit illustrating all these relations, but the 2-hr. serum concentrations for the three preparations are shown in Figs. 2–4. The use of the 2-hr. serum concentrations to illustrate the methods used does not imply that these values have any special therapeutic importance.

Equivalence Considerations—As described in the *Theoretical* section, for appropriate variables the dose of clindamycin ester equivalent to a 150-mg. dose of clindamycin hydrochloride was determined, using the composite means from six studies in adults (6) as the standard of comparison. This comparison was also carried out with the data from Study 1 reported here to see how closely this study fit the overall results from six studies of 150 mg. clindamycin hydrochloride.

Figure 5 illustrates graphically how the equivalent dose was computed. The mean 2-hr. serum concentration is plotted against clindamycin palmitate dose. The arrowed line enters the graph at the composite mean of the 2-hr. serum concentrations observed in the six clindamycin hydrochloride studies (1.94 mcg./ml.). The clindamycin palmitate dose level (206 mg.) at which this arrowed line intercepts the regression line is the "equivalent dose"; this is the estimated dose of clindamycin palmitate that yields the same average value for the pharmacokinetic variable as does 150-mg. clindamycin hydrochloride. The equivalent dose could be computed only for those variables for which the regression with dose was significant (t-statistic >2); other variables are designated N.R. in the tables.

Clindamycin Hydrochloride (Table II)—The relation of the 2-hr. serum concentration to dose (Fig. 2) is representative of all the serum concentrations in that at all sampling times the mean serum level after the 300-mg. dose was less than predicted from the line fitted through all the data. Even though the means did not lie exactly on a straight line, as noted previously, the quadratic component of the regression line was not significant. This is because the variation of the individual observations about the means was greater than the deviations of the means from a straight line. In Study 1 the different dose levels were administered to different panels of subjects at different times. The deviation of the mean responses in the 300-mg. dose group cannot be explained.

At all serum sampling times, there was a highly significant relation between dose and serum level, as evidenced by the large values of the t-statistic. The slopes of the regression lines were quite similar. Because of between-subject variation in serum concentrations at each dose level, no more than 59% ($r^2 = 0.59$) of the variance at any sampling time could be ascribed to changes in dose. Serum concentrations increased only about half as much as dose; *i.e.*, when the dose increased by 100%, the mean serum levels increased by about 50%.

Three of the model parameters that should not be dose dependent, K_A, $E(^1/_2)$, and volume of distribution, did show a significant regression with dose (t-statistics 2.86, 2.17, and 4.29, respectively). As noted previously (6), because of the rapid absorption of clindamycin hydrochloride, it is difficult to obtain enough prepeak serum concentration values to make good estimates of K_A. In all of our clindamycin hydrochloride studies, estimates of K_A have

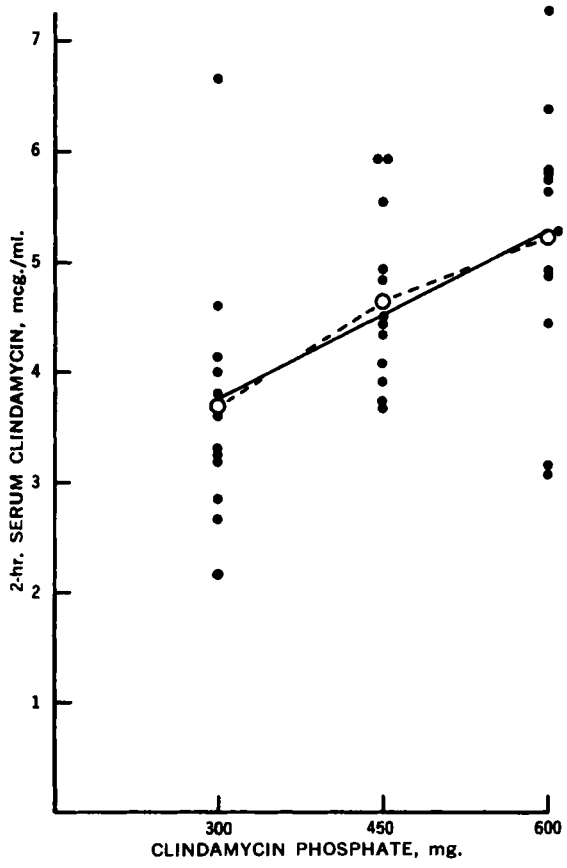

Figure 4—*Dose-bioavailability relation: 2-hr. serum clindamycin concentration after clindamycin phosphate. Key: ——, predicted means from linear model; O- - -O, observed means; and ●, individual values.*

had large standard deviations; K_E is much easier to estimate and has had much smaller standard deviations. While $E(^1/_2)$ tended to increase with dose level for the first dose of clindamycin hydrochloride, after a postequilibrium dose on a *q6h* regimen, $E(^1/_2)$ values did not differ significantly, having mean values of 3.58, 3.12, and 3.32 hr. with 150-, 300-, and 450-mg. regimens, respectively (6). The changes in K_A, $E(^1/_2)$, and volume with changes in the first dose are unexplained but could reflect inappropriateness of the model. Compartmental models of drug kinetics are based on assumptions of linear kinetics. There are several possible causes of nonlinear kinetics; DiSanto and Wagner (17) showed that if one of these, tissue binding, is significant, then the use of a compartmental model will lead to the erroneous conclusion that some of the kinetic parameters change with dose.

The two model parameters that should increase with dose, estimated peak and area under the serum concentration–time curve, did so but, like the serum levels, they did not increase in the same proportion as did dose.

The computed equivalent doses in Table II compared Study 1 with the composite results in six studies of clindamycin hydrochloride. All of these equivalent doses should be close to 150 mg., of course, and any deviation indicates that in some respect this study is different from the average results. Absorption was slower in this study, as reflected in higher equivalent doses at early sampling times and lower ones at later sampling times. That the average total absorption in this study was similar to the overall experience is indicated by the equivalent doses to attain the area under the curve and estimated peak (139 and 174 mg., respectively). The equivalent dose was 153 mg. for volume of distribution.

Clindamycin Palmitate (Table III)—The relation between dose and 2-hr. serum level (Fig. 3) is representative of all the clindamycin palmitate variables. Mean values for the four doses lie very close to the regression line computed from all the data. Despite this good fit, variability within each treatment group was great enough that difference in dose accounted for less than 50% of the variation.

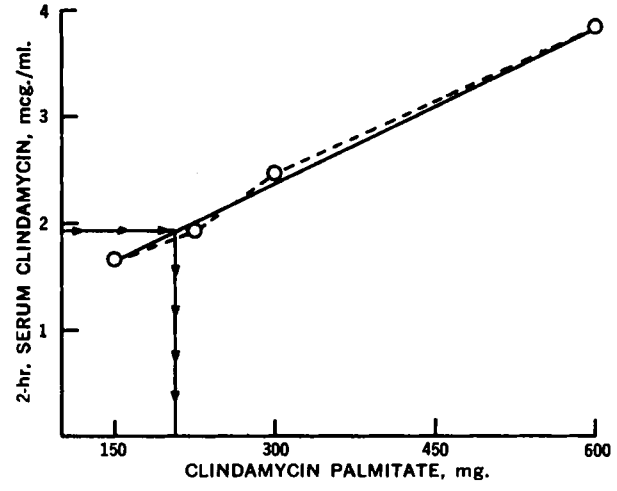

Figure 5—*Estimated dose of clindamycin palmitate required to produce 2-hr. serum clindamycin bioactivity equivalent to that produced by 150 mg. clindamycin hydrochloride in six studies. Key: ——, linear dose–response (predicted means); and O- - -O, observed mean responses. Equivalent dose = 206 mg. clindamycin palmitate.*

Most of the model parameters showed the expected linear relation with dose; rate constants, half-lives, time of peak, and time lag were all independent of dose, while peak and area were dose dependent. Volume, however, did increase significantly with dose (t-statistic, 2.95). Until more information about the distribution and metabolism of clindamycin and about the correctness of the model is available, any explanation for this remains speculative. As noted previously, the volume term in the model includes F, the fraction of dose absorbed. In the 225/300-mg. crossover group, the volume estimate was greater after the lower dose than after the higher dose.

The equivalent doses calculated for clindamycin palmitate illustrate that it is absorbed more slowly than is clindamycin hydrochloride. Equivalent doses are more than double 150 mg. at early serum sampling times but only about one-third larger than 150 mg. at later times. The lower peak levels are reflected in an equivalent dose of 278 mg. to achieve the same peak. However, the equivalent dose (177 mg.) computed for area under the serum curve suggests that total absorption of clindamycin is about the same after the two preparations.

Estimating equivalent doses was a primary purpose in designing Study 2, and the information proved helpful in predicting appropriate dosages for clinical trials with this compound.

Clindamycin Phosphate (Table IV)—Although area under the serum concentration curve almost doubled with a doubling of clindamycin phosphate dose, serum concentrations increased only by about 50% when the dose was doubled. Again the linear dose–bioavailability model, although it fits the serum concentration–time curves very well, dose not completely describe the kinetics of the drug. Although time of peak and time lag had statistically significant dose–bioavailability relations, the estimated equivalent doses are meaningless. Since estimation of absorption of the intramuscular dose is confounded by estimation of rate of hydrolysis of the ester to clindamycin, the absorption rate constant K_A and half-life $A(^1/_2)$ were not included in this analysis.

The delayed peak and flatter, higher serum clindamycin curve after intramuscular clindamycin phosphate injection are reflected in the calculated equivalent doses. As expected from inspection of the curves, calculation of equivalent doses for serum levels at individual sampling times did not yield useful information. However, the equivalent dose for area under the serum concentration–time curve suggests that nearly twice as much clindamycin is absorbed into the circulation from clindamycin phosphate given intramuscularly as from clindamycin hydrochloride given orally.

CONCLUSIONS

For clindamycin hydrochloride, clindamycin palmitate, and clindamycin phosphate, the dose–bioavailability relations for serum

clindamycin bioactivity are linear but not proportional. Means of the pharmacokinetic variables for the different dose levels lie on (or nearly on) a straight line, but the response does not double when the dose is doubled.

Within the dose ranges in the three studies described, the *average* effect of a dose can be predicted well. An individual's serum concentration cannot be predicted as precisely as the average; in no case in these studies did the regression of serum level with dose account for more than 60% of the total variability. In those situations where the between-subject variation could be removed, the regression of serum levels with dose accounts for as much as 84% of the remaining variability.

Analysis of the dose–bioavailability relations is one check on the validity of the one-compartment model as a model of clindamycin absorption and elimination. In general, those model parameters that should be dose related had significant regressions and those that should not change with dose had nonsignificant regressions. The exceptions, especially in the study of clindamycin hydrochloride, suggest that perhaps there is some nonlinearity in the kinetics of clindamycin.

Attempts to compute equivalent doses of the three preparations showed that it is not meaningful to talk about a single equivalent dose, even for compounds producing serum concentration curves as similar as those after clindamycin hydrochloride and clindamycin palmitate. The equivalent doses will be different for peak, area, *etc.* An equivalent dose analysis does provide some understanding of the similarities and differences of formulations.

APPENDIX

Tolerance Monitoring—There were no serious side effects or indications of toxicity in any of the studies. Tolerance of multiple dosing with clindamycin hydrochloride has been described elsewhere (6), but tolerance findings in Studies 2 and 3 have not. The following clinical laboratory determinations[9] were performed during screening and before and after dosing in both studies, except where indicated otherwise: complete blood count, complete urinalysis, serum alkaline phosphatase, serum glutamic oxalacetic transaminase (SGOT), serum glutamic pyruvic transaminase (SGPT), serum bilirubin, serum creatinine (Study 2), blood urea nitrogen, and serum creatine phosphokinase (CPK) (Study 3). In Study 2, two subjects developed mildly abnormal SGOT values (normal = <45 K units) after dosing with clindamycin palmitate. One, whose SGPT also became mildly abnormal, was found to have a history of heavy alcohol consumption and slightly elevated SGPT values (although his screening and pretreatment values were normal). The other subject, who had an extremely high CPK but normal SGPT, admitted indulging in strenuous activity; these findings indicated muscle as the source of SGOT elevation in this case. In Study 3, SGOT typically rose after intramuscular injection, along with CPK; SGPT, however, scarcely changed, suggesting muscle trauma as one source of the SGOT increase.

Vital signs (blood pressure, pulse, temperature, and respiration) were recorded before and after each dose. Physical examinations, performed during screening, were repeated after dosing, and in Study 3 audiometric examinations were conducted before and after dosing. Subjects were questioned about systemic side effects. In Study 2, one subject developed signs of a urinary tract infection. Symptoms admitted on repeated questioning were loose or watery stools in three, headache in six, nausea in two, vomiting in one, gas in two, rectal itching in one, and bad taste (1 hr. after dosing) in two. All were transient and most were mild, but one subject had moderate vomiting and loose stools after the 225-mg. dose and then nausea and watery stools after the 300-mg. dose a week later. In the placebo-controlled 600-mg. trial, one subject developed transient dizziness and nausea after drug and one had nausea after placebo. In Study 3, changes in stools (softer, more frequent, or loose stools or diarrhea) were reported in six, rectal itching in four, abdominal pain in one, heartburn and gas in one, and itching of back and buttocks in one. Audiometric evaluations showed no drug effect.

In Study 3 repeated subjective and objective evaluations of tolerance at the intramuscular injection sites indicated that the drug caused more discomfort than saline placebo. However, this was less severe and shorter lived than that reported after intramuscular clindamycin hydrochloride (11).

[9] All determinations were performed by the Clinical Research Laboratory.

UV Spectrophotometric Method for Determination of Phenacetin in Biological Specimens

JACK E. WALLACE*▲, JOHN D. BIGGS†, HORACE E. HAMILTON†, LLOYD L. FOSTER†, and KENNETH BLUM‡

Abstract □ A UV spectrophotometric procedure for determining phenacetin in biological specimens is described. The drug is extracted from biological material by ether and oxidized to a quinone product by cobaltic oxide. The primary metabolite of phenacetin, *N*-acetyl-*p*-aminophenol, is assayed by providing a salting-out step in the extraction process. Better than 90% of phenacetin added to urine and serum specimens *in vitro* at concentrations of 5–50 mcg./ml. was recovered. From homogenized tissue, 83% of added phenacetin was recovered.

Keyphrases □ Phenacetin—UV analysis in biological fluids □ UV spectrophotometry—analysis, phenacetin in biological fluids

Abuse of the analgesic drug phenacetin[1] may lead to certain nephropathies in humans (1, 2). This danger, coupled with the drug's widespread use, necessitates specific and rapid detection of the compound in biological specimens. Phenacetin is a neutral drug that absorbs UV radiation noncharacteristically in the 230–260-nm. portion of the light spectrum. Normal constituents and numerous other pharmacological agents extracted from biological specimens can provide significant interference and make direct UV spectrophotometric analysis of the unchanged drug unrewarding.

Brodie and Axelrod (3) described the metabolic fate of phenacetin in man using an elaborate time-consuming colorimetric procedure. They determined the levels of phenacetin and several metabolites, including *N*-acetyl-*p*-aminophenol and *p*-aminophenol, in biological specimens. Other methods were reported by Welch and Conney (4), Büch *et al.* (5), Cummings *et al.* (6), and Routh *et al.* (7). Each of these techniques is nonspecific, time consuming, or lacking in sensitivity. Prescott (8) reported a sensitive and specific method for the estimation of phenacetin and *N*-acetyl-*p*-aminophenol in plasma and urine by a GLC technique using trimethylsilyl derivatives. The disadvantages of this method are that it has a significant time requisite and absolute dryness is required to achieve an effective silanizing reaction (9, 10).

This report describes a quantitative UV spectrophotometric technique for determining phenacetin in serum, blood, urine, or tissues. Phenacetin is oxidized to a products(s) that has a dissimilar, yet sensitive, response to UV radiation. The phenacetin product is subsequently extracted into sodium hydroxide solution, which results in a highly specific bathochromic shift of the UV spectrum and an increase of sensitivity.

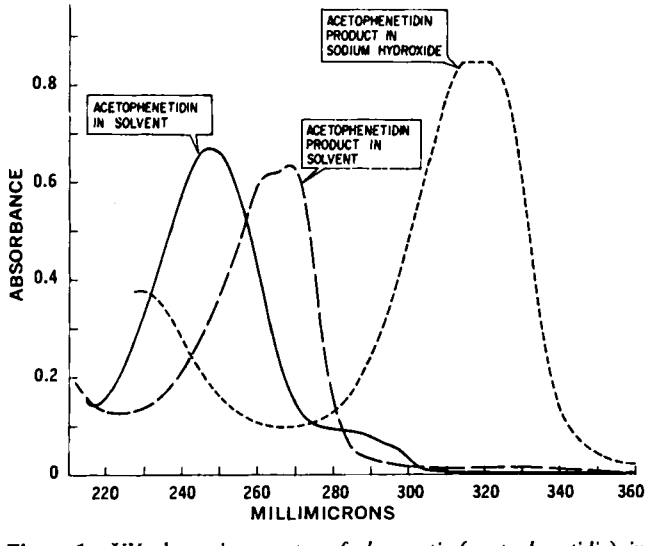

Figure 1—*UV absorption spectra of phenacetin (acetophenetidin) in isopropanol* (——), *the phenacetin product in hexane–*tert*-butanol* (— —), *and the phenacetin product in sodium hydroxide solution* (- - -), *each at a concentration of 8 mcg./ml. corresponding to phenacetin.*

EXPERIMENTAL[2]

Five milliliters of serum or 10 ml. of urine is adjusted to pH 7.0 ± 1.0 and extracted with 50–100 ml. of ether (diethyl). For tissue analysis, 5–10 g. of homogenized tissue is made alkaline (pH 12.0) by addition of several milliliters of 1.0 *N* NaOH and extracted with 100–200 ml. of ether. After extraction the aqueous phase is discarded and the ether layer is washed twice with 20–50 ml. of 1.0 *N* NaOH and once with 20–30 ml. of 1.0 *N* HCl. The organic solvent is filtered through fast-flowing filter paper. The volume recovered is noted and the loss of ether is included in the final calculations.

A major metabolite of phenacetin, *N*-acetyl-*p*-aminophenol, which is itself a commercially available analgesic[3], may be determined by a modification of this procedure. Ten milliliters of urine is adjusted to pH 1.0 ± 0.5 and saturated by the addition of 5 g. of sodium chloride. The original procedure is followed verbatim, except that the two alkali washes of the ether are not performed.

The washed ether is evaporated to dryness under vacuum in a 250-ml. round-bottom flask. Ten milliliters of 2.0 *N* HCl, 20 ml. of a 4:1 mixture of *n*-hexane (spectroquality)–*tert*-butanol, and 200 mg. of cobalt (III) oxide are added to the flask, and the contents are refluxed slowly for 10 min. with constant magnetic stirring. The optimum reflux conditions are achieved by applying 35 v. a.c. to a 270-w. heating mantle containing the flask with attached water-cooled condenser, the mantle being positioned upon a magnetic stirrer. After the flask contents are cooled, the solvent layer is recovered and scanned on the spectrophotometer. A 5-ml. aliquot of the solvent layer is then vigorously extracted with an equal volume of 4.0 *N* NaOH, and the aqueous layer is centrifuged for 5 min. at 3000 r.p.m. and scanned over the 220–360-nm. region; analyses at a single wavelength are achieved by measuring the absorbance at 268 and 320 nm., respectively.

[1] Acetophenetidin.

[2] UV absorption data were obtained with a Beckman DK-2A ratio recording spectrophotometer. A Beckman IR-9 spectrophotometer utilizing KBr disks was used for IR absorption measurements.

[3] Acetaminophen.

Table I—Standard Curve Data of Phenacetin Reaction Product

8.0	0.649	0.081	0.852	0.106
6.0	0.492	0.082	0.623	0.104
4.0	0.321	0.080	0.397	0.099
2.0	0.162	0.081	0.194	0.097

[a] Determined at 268 nm. [b] Determined at 320 nm.

RESULTS

Phenacetin, upon oxidation with cobaltic oxide (Co_2O_3) in dilute hydrochloric acid, was converted to a derivative whose spectrum exhibited maximum absorbance in hexane–*tert*-butanol at 268 nm. and in sodium hydroxide at 320 nm. (Fig. 1). At the levels investigated, a linear relationship exists between the absorbance of the reaction product and the concentrations of drug present (Table I).

Ten milliliters of serum, 10 ml. of urine, and 10 g. of homogenized tissue, to each of which phenacetin was added to provide concentrations of 50, 25, 10, and 5 mcg./ml. (g.), were analyzed; 50 ml. of hexane–*tert*-butanol rather than 20 ml. was used with the 50-mcg./ml. specimens. The recovery of phenacetin by the method of this report is summarized in Table II. Recoveries greater than 90% were obtained from serum and urine, while approximately 83–85% of the drug was recovered from the homogenized liver preparations.

The distribution of phenacetin among the various tissues of the rat, 2 hr. after the animals received 200 mg./kg. body weight of the drug orally, is shown in Table III. Phenacetin, because of low aqueous solubility, was administered to the rats in a suspension of 0.5% methylcellulose in isotonic saline solution. Concentrations of the drug were found in decreasing levels in the following tissues: lungs, brain, kidneys, blood, muscle, and liver. With the exception of the liver, the findings are in agreement with the levels observed by Brodie and Axelrod (3) in dog tissues.

Several drugs, particularly neutral or solvent-soluble agents, were investigated for possible interference (Table IV). The nontherapeutic compound *p*-aminophenol gave an oxidation product with an absorption maximum at 240 nm. in solvent. Extraction of the *p*-aminophenol product into 4.0 *N* NaOH produced a spectrum very similar to that of the phenacetin product. The primary metabolite of phenacetin, *N*-acetyl-*p*-aminophenol, was oxidized by cobaltic oxide to a product with UV spectra (both in hexane–*tert*-butanol and sodium hydroxide solutions) identical to that of the phenacetin derivative. However, *p*-aminophenol and *N*-acetyl-*p*-aminophenol did not interfere with the determination of phenacetin in biological specimens, because both compounds are removed from the final ether extract by the sodium hydroxide wash solution. Compounds other than *p*-aminophenol or *N*-acetyl-*p*-aminophenol provided little or no interference in the determination of phenacetin.

Table II—Recovery of Phenacetin after *In Vitro* Addition to Biological Specimens

Phenacetin Added, mcg./ml.	Recovery[a], Mean[b] ± *SD*		
	Serum	Urine	Liver
50	48.27 ± 1.59	47.31 ± 1.15	43.37 ± 1.08
25	24.26 ± 0.52	22.95 ± 0.78	20.10 ± 0.65
10	9.75 ± 0.24	9.24 ± 0.23	8.30 ± 0.36
5	5.21 ± 0.07	4.71 ± 0.25	—[c]
Average recovery	98.8%	93.2%	83.4%

[a] Determined from readings in 4.0 *N* sodium hydroxide. [b] Average of at least seven determinations. [c] Not determined.

Table III—Distribution of Phenacetin[a] in the Rat

Tissue	Concentration in Tissue: Range of Values, mcg./ml. or g. (Wet Weight)	Concentration in Tissue: Distribution Ratio (Concentration in Tissue/Concentration in Blood), Mean ± *SD*
Blood	20.6–26.4	1.00
Brain	30.8–38.9	1.47 ± 0.12
Kidney	29.4–42.3	1.35 ± 0.13
Lung	31.9–52.9	1.40 ± 0.12
Liver	17.6–20.5	0.70 ± 0.14
Muscle	16.7–24.7	0.92 ± 0.11

[a] Suspension of phenacetin in 0.5% methylcellulose was administered in intraperitoneal doses of 200 mg./kg. body weight, and the animals were sacrificed after 2 hr. Average of determinations for eight rats.

DISCUSSION

Previous methods for the determination of phenacetin in biological specimens are primarily for determining the pharmacological agent in urine and plasma. The method described by Brodie and Axelrod (3) was the only previous report that presented tissue concentrations. Oxidation of phenacetin with cobaltic oxide to a product extractable into aqueous alkali provides a quantitative UV spectrophotometric method for determining the unmetabolized drug in biological specimens. Certain tissues contain large amounts of solvent-extractable material that interfere with the oxidation process. For example, brain tissue is frequently difficult to assay because of its high phospholipid content. The proposed method is applicable to most biological specimens with the exception of fat.

Since *ortho*- and *para*-dihydroxybenzenes, diamines, aminophenols, and related disubstituted benzenes may generally be oxidized to quinones, dependent upon the electronegativity of the substituents and the oxidizing conditions, the method presented in this paper may appear to be quite nonspecific. However, the alkali and acid washes of the ether eliminate all but the most solvent-soluble compounds. Thus, *p*-aminophenol and *N*-acetyl-*p*-aminophenol, very closely related compounds, do not interfere with the analysis of phenacetin. In the absence of solvent washing, considerable specificity is achieved by observing the wavelength of maximum absorbance for different disubstituted benzenes after their oxidation to quinones. Phenacetin and *N*-acetyl-*p*-aminophenol both yield a product absorbing maximally at 268 nm., whereas *p*-aminophenol and *p*-phenetidine apparently yield *p*-benzoquinone which absorbs maximally at 241 nm.

N-Acetyl-*p*-aminophenol, the principal metabolite of phenacetin and itself a commercially available analgesic, is present in high concentrations in the urine. This metabolite is highly water soluble, but it can be determined by the cobalt oxidation technique provided the biological specimen is adjusted to an acidic pH and is saturated with sodium chloride prior to extraction with ether. In addition, the

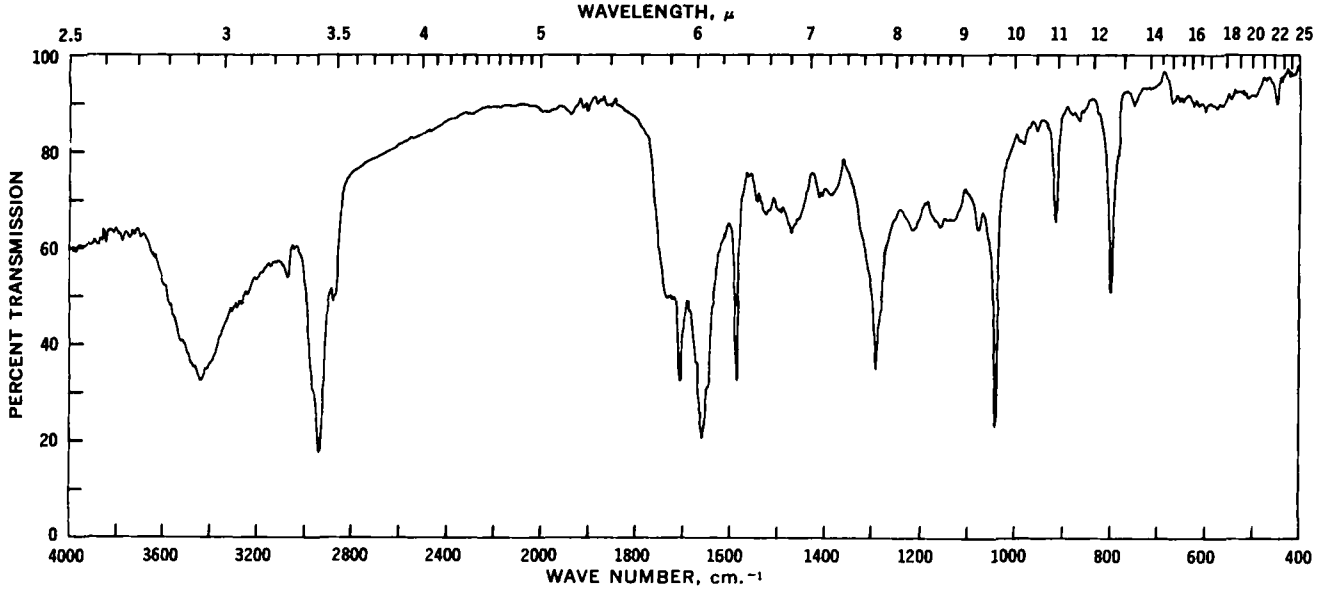

Figure 2—*IR absorption spectrum of the cobaltic oxide oxidation product from phenacetin.*

alkali wash steps must be eliminated to prevent the removal of metabolites from the ether solvent.

IR data indicate that the phenacetin oxidation product(s) consists of a carbonyl group, as evidenced by the strong absorbance (Fig. 2) in the 6-μ region. Aliphatic C—H stretching was conspicuous at 3.4 μ. The phenacetin product(s) is suggested to be a mixture of quinone- or quinonimine-type compounds with aliphatic substituents. The exact chemical structure has not been elucidated for the product(s) but this information is not essential for routine application and effectiveness of the procedure.

SUMMARY

Biological specimens can be analyzed spectrophotometrically for phenacetin after oxidation of the drug by cobaltic oxide. The procedure has an excellent amount of specificity, with no other group of pharmacological agents affording interference. The particular extraction technique required to recover the neutral drug phenacetin from biological environments makes specimens with high lipid concentrations difficult to analyze.

Drug Permeation through Membranes I: Effect of Various Substances on Amobarbital Permeation through Polydimethylsiloxane

EDWARD G. LOVERING[▲] and DONALD B. BLACK

Abstract □ The effect of some excipients, nutrients, surfactants, and adsorbents on the permeation of amobarbital through polydimethylsiloxane was measured. At a pH of 5, the permeability coefficient, P, of amobarbital is $(7.70 \pm 0.34) \times 10^{-8}$ cm.^{2} sec.$^{-1}$. The rate of drug transfer across the membrane depends on pH because only the unionized species is eligible for transfer. If P is calculated from the actual concentration of unionized drug, then transfer is not a function of pH. Excipients typical of those used in Canadian formulations of amobarbital or its sodium salt have no significant effect on the coefficient of permeability. Bovine albumin has no effect, but the coefficient is depressed by skim milk, perhaps due to binding of the drug. The drug is strongly adsorbed by charcoal. The permeation coefficient is reduced by anionic, cationic, and nonionic surfactants in a way that is consistent with the concept of drug partition between the aqueous and surfactant phases present when surfactant micelles form in water. After dissolution, the permeability coefficients of all Canadian amobarbital preparations tested were found to be identical.

Keyphrases □ Drug permeation through membranes—effect of excipients, nutrients, surfactants, and adsorbents on amobarbital permeation through polydimethylsiloxane □ Amobarbital, permeation through polydimethylsiloxane membranes—effect of excipients, nutrients, surfactants, and adsorbents, permeability coefficients of 14 formulations □ Permeation, amobarbital through polydimethylsiloxane membranes—effect of excipients, nutrients, surfactants, and adsorbents □ Surfactant effect—amobarbital permeation through polydimethylsiloxane membranes □ Excipient effect—amobarbital permeation through polydimethylsiloxane membranes

While always a matter of concern (1), bioavailability and drug absorption have become topics of enlarged interest because of the economically motivated need to compare the effectiveness of different formulations of the same drug. Drug absorption can be envisaged as a two-step process: disintegration and dissolution in the GI tract followed by permeation through the gut wall into the blood. Both of these processes can be modeled *in vitro*. Extensive *in vitro* dissolution studies were carried out and led to USP (2) and NF (3) dissolution specifications for certain drugs.

Drug permeation measurements, while not used as a means to control and evaluate formulations, have been applied to the study of interactions between drugs and other materials liable to affect absorption from the GI tract. The theoretical aspects of drug absorption were discussed by Suzuki *et al.* (4) and Wagner (5), while *in vitro* experimental work with animal membranes was reported by a number of workers (6–8). Synthetic membranes are of value in studying the interactions of drugs that cross the gut wall primarily by a partition–diffusion mechanism, where the rate of transfer across the membrane depends mainly on the membrane–aqueous phase partition coefficient and the solubility of drug in the membrane. If permeation rates of a series of similar drugs through a synthetic membrane are arranged in rank order, one would expect to find the same order of permeation rate *in vivo*, provided no significant interaction between drug and membrane takes place. This behavior is exhibited by the barbiturates (9).

In comparison to animal membranes, synthetic membranes are uniform, reproducible, easy to handle, stable, and cheap. For convenient, reproducible rates of permeation, the membranes should be elastomeric and well above their glass temperature. The material used should be noncrystalline at the temperature of the experiment to avoid variations in permeability due to changes in the degree of crystallinity. The latter depends upon the temperature and rate of crystallization, molecular weight, molecular weight distribution, degree of branching, and other factors (10). Variations in membrane permeability may also arise from the presence of filler, plasticizer, and changes in the degree of crosslinking (11). While a number of synthetic polymers have been tried for drug interaction studies (9), most workers choose polydimethylsiloxane, probably because it is one of the most permeable, nondialysis types of elastomers known (11). The effect of high surface area silica filler, present in commercially available polydimethylsiloxane membranes, was examined by Most (12) and Flynn and Roseman (13). Filler adds to the difficulty of membrane characterization and may lead to variation in the coefficient of permeability between different specimens of polydimethylsiloxane. Drugs and drug interactions studied by this technique include barbiturates, phenylalkylamines (9), aminophenones (14, 15), chlorpromazine (16), and various organic molecules (17).

This paper reports the effect of typical excipients, endogenous substances, adsorbents, emulsifiers, and foods on the permeation of amobarbital through polydimethylsiloxane and rat intestinal membranes. The work is part of an extensive program of biopharmaceutical studies involving the economically most important drugs sold in Canada.

EXPERIMENTAL

Permeation Apparatus—Steady-state permeation coefficients were measured using a cell of the type described by Garrett and Chemburker (18), modified by placing a magnetic stirring bar inside the cell. The cell was placed in a beaker containing a buffered solution of the drug, and both the cell and beaker, stirred magnetically, were thermostated at 37 ± 1.0°. The cell membranes, made of polydimethylsiloxane, were 0.014 cm. thick and contained about 30 parts of silica filler (13). During an experiment the cell contained borate buffer solution at pH 10 and the beaker contained about 160 ml. of sodium amobarbital solution at a concentration in the region of 3.0×10^{-3} *M*. Under these conditions, steady-state diffusion was reached about 1 hr. after beginning the experiment. The permeation coefficient did not change when the same membrane was used in successive experiments.

		Mean	7.51 ± 0.33

[a] Calculated from the total drug concentration, C. [b] Calculated from C_0, the concentration of unionized drug.

Analysis—The desorbing borate solution was pumped continuously through the cells of a UV spectrometer, and readings at 240.5 nm. were taken manually at appropriate time intervals. The time correction due to the external loop was less than 10 sec. and was neglected. Calibration of the spectrometer was with USP grade sodium amobarbital. Beer's law was obeyed. The extinction coefficient was 9830 in borate buffer containing 3.092 g. l.$^{-1}$ boric acid, 3.782 g. l.$^{-1}$ potassium chloride, and sufficient sodium hydroxide to yield a final pH of 10.00 (about 1.75 g. l.$^{-1}$).

Intestinal Preparation—Intestinal segments were obtained from fasted, male, Sprague–Dawley rats, weighing 240–280 g., after killing by decapitation or carbon dioxide. Ten-centimeter segments of the proximal jejunum under a tension of 20 g. were mounted, noneverted, in a system of glass and polyethylene tubing, which permitted continuous flow of fresh 2.0 $\times$ 10^{-3} M sodium amobarbital in Krebs–Ringer bicarbonate buffer (19) at a pH of 7.4 through the segment to discard (20). Drug transfer across the intestine was into 50 ml. of serosal solution of the buffer without the drug. All solutions, at 37 ± 1°, were continuously oxygenated by bubbling an oxygen–carbon dioxide (95:5) mixture through them. Two-milliliter aliquots were taken at 10-min. intervals for analysis and replaced by fresh buffer solution.

Drug Extraction and Analysis—Blank experiments made in the absence of drug showed that some substance which absorbs strongly in the UV is extracted from the intestinal segments under the experimental conditions, making a direct UV analysis impossible. For analysis, the serosal aliquot pH was lowered to 3.2 by adding 1 ml. of 0.05 N hydrochloric acid. The drug was extracted into 10 ml. chloroform by shaking overnight at room temperature. Eight milliliters of the chloroform layer was shaken for 30 min. with 2 ml. 0.45 N sodium hydroxide. About 76% of the drug was recovered by this procedure. Absorption in the aqueous layer was read at 255 nm., and the drug concentration was read from a calibration curve.

Materials—The following were used: sodium amobarbital USP[1]; lactose USP[2]; calcium sulfate dihydrate[2]; acacia USP[4]; starch USP[4]; calcium stearate, technical[5]; talc, fine powdered, acid purified[6]; activated charcoal[7]; bovine albumin, fraction V[6]; skim milk, household; caffeine USP[8]; sodium lauryl sulfate USP[4]; cetrimonium chloride[8]; polysorbate 80[9]; sodium cholate[10]; and gelatin BP[6].

RESULTS AND DISCUSSION

Permeability Coefficient—The effect of various substances on the permeation of amobarbital through a polydimethylsiloxane membrane is expressed in terms of a permeability coefficient, P:

$$P = kD \qquad \text{(Eq. 1)}$$

where k is a constant for a given set of experimental conditions and D is the diffusion coefficient. Permeation refers to the transfer of drug from solution on one side of the membrane to solution on the other side, whereas diffusion is movement of drug within the membrane. If the concentration of drug in the membrane at the absorbing side is c and it is zero at the desorbing side and if steady-state conditions prevail, then the quantity of drug, q, transferred across the membrane at time t is:

$$q = \frac{Dc}{l}\left(t - \frac{l^2}{6D}\right) \qquad \text{(Eq. 2)}$$

where l is the thickness of the membrane (21). The concentration of drug in the membrane at the surface in contact with the solution is proportional to C_0, the concentration of unionized drug in solution and to the conditions of the experiment. Thus:

$$c = kC_0 \qquad \text{(Eq. 3)}$$

and Eq. 2 can be written as:

$$q = \frac{DkC_0}{l}t - \frac{kC_0l}{6} \qquad \text{(Eq. 4)}$$

The experimental results were plotted as q *versus* t. Upon reaching the steady state, the slope, dq/dt, is given by DkC_0/l. Substitution into Eq. 1 yields:

$$P = \frac{(dq/dt)l}{C_0A} \qquad \text{(Eq. 5)}$$

where A is the area of membrane in contact with the drug solution and dq/dt is the rate of drug transfer.

Table III—Effect of Charcoal on the Permeability Coefficient

Charcoal Concentration[a], g. l.$^{-1}$	Apparent Permeability Coefficient[b], P_a, (cm.^{2} sec.$^{-1}$) × 10^6	Permeability Coefficient[c], P, (cm.^{2} sec.$^{-1}$) × 10^6

6.8	0.68	7.58
16.7	0.00	—
	Mean	7.55 ± 0.59

[a] The solution pH was 5. [b] Calculated from the original concentration of amobarbital before mixing with charcoal. [c] Calculated from the concentration of amobarbital measured spectroscopically in the supernatant liquid after mixing with charcoal.

Dependence of Permeability on pH—The permeability coefficient of amobarbital going from an acetate buffer at pH 5.00 ± 0.02 was found to be 7.70 × 10^{-6} cm.^{2} sec.$^{-1}$, with a standard deviation of ±0.34 cm.^{2} sec.$^{-1}$ based on 10 determinations. The rate of drug transfer across the membrane is pH dependent because only the nonionized form is soluble in the membrane and hence eligible for transfer. The concentration of nonionized drug in solution, C_0, is given by:

$$C_0 = C[1 + \exp[2.303(\text{pH} - \text{pKa})]]^{-1} \quad \text{(Eq. 6)}$$

where C is the total concentration of drug substance, pH is the pH of the drug solution, and K_a is the ionization constant of the drug. Taking pKa = 7.865 for amobarbital (22), only 0.1% of the drug is ionized at a pH of 5. Permeability coefficients obtained from measurements at pH values in the range where C_0 changes rapidly with pH are given in Table I. The apparent permeability coefficient, P_a, is calculated from Eq. 5 using C, the total concentration of amobarbital present in the system, and reflects the effect of pH on drug transfer. The coefficient P, calculated from the actual concentration of unionized drug, is obtained from Eq. 5. The permeability coefficient P is (7.51 ± 0.33) × 10^{-6} cm.^{2} sec.$^{-1}$ and does not vary significantly over the pH range examined. This constancy indicates the only effect of pH on permeability is the effect on concentration of unionized drug.

Effect of Excipients and Charcoal—The effect of a number of substances, commonly present as excipients in Canadian formulations of amobarbital, on the permeability coefficient was measured. The results (Table II) show these substances to have no significant effect on the permeability coefficient.

The consequence of adding activated charcoal to a drug solution is shown in Table III. This material presumably adsorbs drug, thereby reducing the solvent concentration and hence the coefficient of permeability calculated on the basis of the original drug concentration (23). If the actual concentration of drug is used to calculate the coefficient, it should be, within experimental error, the same as that calculated for drug with no additive, namely (7.70 ± 0.34) × 10^{-6} cm.^{2} sec.$^{-1}$. This is the case with P = (7.55 ± 0.59) × 10^{-6} cm.^{2} sec.$^{-1}$ in the presence of charcoal. There is a good correlation (r^2 = 0.92) between the weight and, hence, surface area of the activated charcoal and the apparent permeability coefficient. The result suggests that administration of activated charcoal might be of value in the early stages of amobarbital poisoning.

Effect of Nutrients—The effect of bovine albumin and skim milk on the permeation of amobarbital is reported in Table IV. There appears to be little, if any, interaction between amobarbital and bovine albumin, at least under the conditions of these experiments. There is a clear interaction with skim milk, but if the interaction occurs to the same extent *in vivo*, it is not of such magnitude as to have much effect on the absorption of the drug by the body. An attempt was made to study the effect of caffeine on the permeation coefficient, but the membrane was found to be permeable to caffeine. The latter absorbs at 240.5 nm., interfering with the amobarbital analysis. The permeation coefficient of caffeine is (2.8 ± 0.5) × 10^{-6} cm.^{2} sec.$^{-1}$.

Surfactant Effects—Drug in an aqueous system containing surfactant micelles is expected to partition between the aqueous phase and the micellar, oil, phase. The total quantity of drug in the system, Q, is given by:

$$Q = C_m V_m + C_w V_w \quad \text{(Eq. 7)}$$

where C_m and C_w are the concentrations in the micellar and water phases, respectively, and V_m and V_w are the corresponding volumes. Substituting weight for volume in Eq. 7 and rearranging yield:

$$\frac{Q}{C_w W_w} = \frac{K_p}{\rho_m} \cdot \frac{W_m}{W_w} + \frac{1}{\rho_w} \quad \text{(Eq. 8)}$$

where ρ_m and ρ_w are the densities of the micellar and water phases, respectively, and K_p is the partition coefficient of drug between the micellar and aqueous phases: $K_p = C_m/C_w$. Equation 8 can be plotted as a straight line with slope K_p/ρ_m and intercept $1/\rho_w$. In Eq. 8, Q and W_m are known directly from the concentrations of drug

and surfactant in the solution and W_w is obtained by taking the density of the surfactant to be unity and the change in volume on mixing with water to be zero. This approximation introduces an error of less than 1% for the surfactants and concentrations used in this study. The concentration of drug in the aqueous phase, C_w, was calculated from the known permeation coefficient (7.70×10^{-6} cm.^{2} sec.$^{-1}$) and the measured apparent permeation coefficient, P_a. This assumes that the membrane was unaffected by surfactant and that the only effect of the latter was to remove drug from aqueous solution by incorporation into micelles. For sodium cholate studied in the region of pH 7.5, the aqueous phase concentration of nonionized drug was calculated from P_a, which was used to calculate the total aqueous concentration, C_w, from Eq. 6. Results for the four surfactants studied are presented in Tables V–VIII. The data for each surfactant were analyzed according to Eq. 8. The slope, intercept, and K_p obtained in each case are given in Table IX, along with the coefficient of correlation r.

The experimental results are adequately described by Eq. 8 and are consistent with the concept that partitioning of amobarbital between the aqueous and micellar phases takes place. Equation 8 is valid only above the CMC, which is about 2.5, 0.4, and 0.1 g. l.$^{-1}$ for sodium lauryl sulfate (24), cetrimonium chloride (24), and polysorbate 80 (25), respectively. Below the CMC, the surfactant has little effect on the permeation rate. This presumably means that there is little if any complexing at a pH of 5 between amobarbital and the surfactants studied. The results also indicate that there is little interaction between the surfactant and the membrane. Generally the type of interaction that could occur would be inbibing of the low molecular weight surfactant by the membrane. The swelling of synthetic elastomers by organic molecules is well known and may lead to substantial increases in the rate at which permeant molecules traverse the membrane (10, 21). The extent of imbibation depends upon the solubility of the low molecular weight species in the membrane, solubility usually being greatest for materials of similar chemical structure. The structures of the surfactants examined here and that of polydimethylsiloxane are quite different and little swelling would be anticipated, as is borne out by the results. The structure of animal membranes is closer to that of typical surfactants. Perhaps it is the dissolution of the surfactant in these membranes that leads to enhanced *in vivo* absorption of certain drugs as, for example, absorption of secobarbital by goldfish (25, 26).

Table X—Effect of Sodium Lauryl Sulfate on Transfer of Amobarbital across Rat Intestine

Concentration of Sodium Lauryl Sulfate, g. l.$^{-1}$	$\bar{R}$[a]
0.00	1.17 ± 0.09
0.01	1.15 ± 0.22
0.30	1.29 ± 0.22
10	0.49 ± 0.07
20	0.36 ± 0.06
40	0.34 ± 0.04
80	0.19 ± 0.05

[a] $\bar{R}$ is the ratio of the average drug transfer rate without surfactant to the average transfer rate in the presence of surfactant.

Results obtained for the transfer of amobarbital across the rat intestine are given in Table X. The quantity, R, is the ratio of transfer rate in the presence, and the absence, of surfactant in the same segment of gut, following the crossover procedure described by Reuning and Levy (6). Results from two or more segments were averaged to obtain $\bar{R}$. At surfactant concentrations greater than the CMC, the transfer rate clearly decreases as the surfactant increases. Results below the CMC are insufficiently precise to permit one to say whether there is a surfactant effect or not.

The partition coefficients, K_p, in Table IX indicate that amobarbital is most soluble in sodium lauryl sulfate and cetrimonium chloride. Both of these compounds have alkyl chains which might be expected to be highly compatible with the nonpolar side chains of amobarbital. There is also a good possibility of reaction between cetrimonium ion and barbiturate ion leading to a decrease in concentration of nonionized drug available for transfer. Polysorbate 80 contains repeating polar groups, while cholic acid has a dense ring structure of perhaps limited compatibility with amobarbital.

Amobarbital Formulations—The permeability of amobarbital in 14 Canadian formulations was measured. Each dosage form was stirred in phosphate buffer at 37° for about 2 hr., and the pH and concentration of the solution were measured before measuring the permeation rate. For all formulations the average coefficient of permeability was (6.87 ± 0.26) × 10^{-6} cm.^{2} sec.$^{-1}$ with a range of 6.50 to 7.29 × 10^{-6} cm.^{2} sec.$^{-1}$. Thus, from the point of view of *in vitro* permeability, all formulations are equivalent.

Distribution of Dibenzoxazepines Bearing the Carboxamide or Other Side Chains in Ocular and Other Tissues of Dogs

JACQUES DREYFUSS▲, JAMES M. SHAW, JOHN J. ROSS, Jr., GENG MEI WANG, KEITH K. WONG, and ERIC C. SCHREIBER

Abstract □ The distribution of four substituted dibenzoxazepines in tissues of dogs was examined 7–14 days after oral administration to intact dogs and 7 hr. after intravenous administration to dogs with externalized bile ducts. 4-[3-(7-Chloro-5,11-dihydrodibenz-[*b,e*][1,4]oxazepin-5-yl)propyl]-1-piperazine ethanol hydrochloride, its trifluoromethyl analog, and 5-[(2-dimethylamino)ethyl]-5,11-dihydrodibenz[*b,e*][1,4]oxazepine maleate were present in organs in greater concentrations than in blood, particularly in the brain, liver, lungs, and melanin-containing portion of the eye consisting of the combined retina, choroid, and sclera. These same compounds were bound to various extents to melanin granules of beef eyeball *in vitro*. 7-Chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepine-5-carboxamide, which bears a carboxamide substituent, was neither localized in any tissues of dogs, relative to concentrations in blood, nor bound to melanin granules *in vitro*. It is concluded that the presence of the carboxamide side chain alters the affinity of 7-chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepine-5-carboxamide for tissues, especially those containing melanin.

Keyphrases □ Dibenzoxazepines, carboxamide and other side chains—tissue distribution, affinity for melanin, dogs □ Carboxamide-substituted dibenzoxazepines—tissue distribution in dogs, affinity for melanin □ Tissue distribution—dibenzoxazepines, melanin affinity, dogs □ Melanin tissue distribution—dibenzoxazepines, dogs □ Ocular tissue distribution—dibenzoxazepines, dogs

It is generally accepted that substituted phenothiazines can adversely affect the eye and skin when large amounts are ingested chronically (1–3). Some compounds, like chlorpromazine, produce primarily opacities of the lens and cornea, whereas others, like thioridazine, can produce a loss of vision by their effect on the retina. Because of these past findings, studies were conducted with some substituted dibenzoxazepines that have exhibited CNS activity in animals (4, 5). The results of these studies show that the presence of a carboxamide side chain alters the localization of the compound and/or its metabolites in the tissues of dogs, including the melanin-containing portion of the eye, as well as the binding of the parent molecules to melanin granules of beef eyeball *in vitro*.

METHODS AND MATERIALS

Purity and Specific Activity of Compounds—The radioactive compounds studied had the following chemical names, radiochemical purities, and specific activities, respectively: I, 4-[3-(7-chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepin-5-yl)propyl]-1-piperazine-$^{14}C_2$-ethanol hydrochloride, 96%, 21.6 μc./mg.; II, 4-[3-(7-(trifluoromethyl)-5,11-dihydrodibenz[*b,e*][1,4]oxazepin-5-yl)propyl]-1-piperazine-$^{14}C_2$-ethanol hydrochloride, 99%, 24.9 μc./mg.; III, 5-[(2-dimethylamino)ethyl-1,2-$^{14}C_2$]-5,11-dihydrodibenz-[*b,e*][1,4]oxazepine maleate, 99%, 6.9 μc./mg.; and IV, 7-chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepine-5-^{14}C-carboxamide, 99%, 5.0 μc./mg.

Surgical Preparation of Dogs—Purebred male beagles were anesthetized with 30 mg./kg. of sodium pentobarbital administered intravenously. A catheter was inserted into the bladder for the collection of urine. The radial vein was then cannulated, and infusion of the following solution was begun at the rate of 3 ml./min.: mannitol (100 g.), potassium dihydrogen phosphate (200 mg.), potassium hydrogen phosphate (900 mg.), sodium pentobarbital (25.5 mg./kg. of body weight), and sufficient water to make 2 l. Mannitol was included to ensure an adequate flow of urine. A midline incision was made, and the entrance to the gallbladder was clamped at its juncture with the common bile duct. A polyethylene

It is generally accepted that substituted phenothiazines can adversely affect the eye and skin when large amounts are ingested chronically (1–3). Some compounds, like chlorpromazine, produce primarily opacities of the lens and cornea, whereas others, like thioridazine, can produce a loss of vision by their effect on the retina. Because of these past findings, studies were conducted with some substituted dibenzoxazepines that have exhibited CNS activity in animals (4, 5). The results of these studies show that the presence of a carboxamide side chain alters the localization of the compound and/or its metabolites in the tissues of dogs, including the melanin-containing portion of the eye, as well as the binding of the parent molecules to melanin granules of beef eyeball *in vitro*.

METHODS AND MATERIALS

Purity and Specific Activity of Compounds—The radioactive compounds studied had the following chemical names, radiochemical purities, and specific activities, respectively: I, 4-[3-(7-chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepin-5-yl)propyl]-1-piperazine-$^{14}C_2$-ethanol hydrochloride, 96%, 21.6 μc./mg.; II, 4-[3-(7-(trifluoromethyl)-5,11-dihydrodibenz[*b,e*][1,4]oxazepin-5-yl)propyl]-1-piperazine-$^{14}C_2$-ethanol hydrochloride, 99%, 24.9 μc./mg.; III, 5-[(2-dimethylamino)ethyl-1,2-$^{14}C_2$]-5,11-dihydrodibenz-[*b,e*][1,4]oxazepine maleate, 99%, 6.9 μc./mg.; and IV, 7-chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepine-5-^{14}C-carboxamide, 99%, 5.0 μc./mg.

Surgical Preparation of Dogs—Purebred male beagles were anesthetized with 30 mg./kg. of sodium pentobarbital administered intravenously. A catheter was inserted into the bladder for the collection of urine. The radial vein was then cannulated, and infusion of the following solution was begun at the rate of 3 ml./min.: mannitol (100 g.), potassium dihydrogen phosphate (200 mg.), potassium hydrogen phosphate (900 mg.), sodium pentobarbital (25.5 mg./kg. of body weight), and sufficient water to make 2 l. Mannitol was included to ensure an adequate flow of urine. A midline incision was made, and the entrance to the gallbladder was clamped at its juncture with the common bile duct. A polyethylene

catheter was then inserted about 1.27 cm. (0.5 in.) into the common bile duct. The catheter was tied in place, and the midline incision was closed with wound clips.

Analysis of Blood—A sample (0.2 ml.) of heparinized blood was digested in 0.5 ml. of 1 *N* NaOH by heating overnight at 80°. The digest was then bleached with 30% hydrogen peroxide, neutralized with 0.2 ml. of 2-ethylhexanoic acid, and counted with 15 ml. of scintillator (6).

Collection and Analysis of Urine, Bile, and Feces—Purebred beagles (9–11 kg.) and monkeys, *Macaca mulatta* (3.2–4.1 kg.), were fasted overnight prior to drug administration and were housed in metabolism cages[1] designed to allow the separate collection of urine and feces. All animals were dosed between 8 and 10 a.m. Samples of feces were homogenized with 2–3 volumes of methanol. About 50–100 mg. of homogenate was transferred to a weighed scintillation vial, and 1 ml. of a solubilizer[2] was added. The sample was shaken for at least 1 hr., bleached with 30% hydrogen peroxide, and counted in 15 ml. of scintillator (6). Samples of urine and bile were counted directly in 15 ml. of scintillator (6).

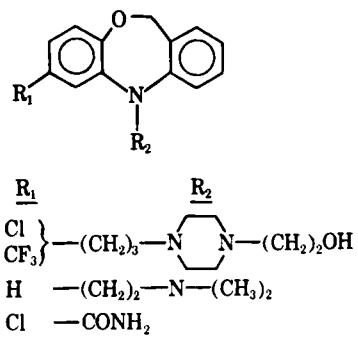
Analysis of Tissue—Samples of brain tissue were homogenized in water, using an all-glass Potter–Elvehjem homogenizer; about 200 mg. of homogenate was transferred to a weighed scintillation vial and digested in 2 ml. of solubilizer. Certain portions of the eye (lens, cornea, aqueous and vitreous humors, and combined retina, choroid, and sclera) were digested directly in 2 ml. of solubilizer. Similarly, representative portions of omental fat, skin (without hair), and the adrenal gland were digested directly in the solubilizer. Samples of tissue from the heart, kidneys, liver, lungs, thigh muscles, and testes were analyzed by first grinding the tissue in a meat grinder and then solubilizing about 100 mg. of the well-mixed sample in 2 ml. of solubilizer. All samples of tissue were counted in 15 ml. of toluene scintillator solution, which contained 5 g. 2,5-diphenyloxazole and 0.3 g. 1,4-bis-2-(4-methyl-5-phenyloxazolyl)-benzene/l. of toluene. Since these analytical methods are normally reproducible to within 5%, replicate determinations were not routinely performed.

Binding to Melanin Granules *In Vitro*—Melanin granules were prepared from the eyes of oxen, according to the method of Potts (7). Since IV is only slightly soluble in water (I, II, and III are readily water soluble), *all* compounds were first dissolved in 100% dimethylformamide. Then a stock solution of each drug at a concentration of 3.5×10^{-3} *M* in 10% dimethylformamide–90% 0.0165 *M* sodium phosphate buffer, pH 6.0, was prepared. The final incubation mixtures, for drug concentrations of 0.75×10^{-4} and 1.5×10^{-4} *M*, contained 2.15 and 4.30 ml. of the stock drug solution and 6.85 and 4.70 ml. of buffer, respectively, and 1 ml. of a suspension of melanin granules (7.1 mg. dry weight/ml.). Thus, the final concentration of dimethylformamide was 2.15% at 0.75×10^{-4} *M* and 4.30% at 1.5×10^{-4} *M*. The final pH was about 6.9. Samples were incubated, with shaking, at 25° for 30 min. and then centrifuged at 35,000×*g* for 15 min. Aliquots of the resulting supernate and of a control sample prepared with water, instead of with melanin granules, were counted in Bray's scintillator. Control experiments with I, II, and III, carried out in an entirely aqueous medium, indicated that the presence of dimethylformamide at the concentrations employed did not appreciably alter the binding of these compounds to melanin granules.

Counting of Samples—Radioactivity in each sample was measured by a liquid scintillation spectrometer[3]. Counting efficiency was determined with automatic external standardization and the use of previously prepared quench curves.

RESULTS

Dogs with externalized bile ducts were dosed intravenously, each with one of the four dibenzoxazepines (5 mg./kg.). The single animals treated with each compound were sacrificed 7 hr. after they had been dosed, and selected tissues were examined for their content of radioactivity (Table I). After the administration of I, II, and III, radioactivity, considered relative to that present in the blood, was highly localized in tissues. The highest concentrations of radioactivity were located in the pigmented portion of the eye,



Compound	R_1	R_2
I	Cl	$-(CH_2)_3-N\langle\rangle N-(CH_2)_2OH$
II	CF_3	
III	H	$-(CH_2)_2-N-(CH_3)_2$
IV	Cl	$-CONH_2$

structures of substituted dibenzoxazepines

consisting of the combined retina, choroid, and sclera, and in the liver and lungs. Most of the other tissues contained levels of radioactivity that were several times those present in the blood but not as high as those just mentioned. By contrast, levels of radioactivity in most of the tissues of the dog that had been dosed with IV were actually lower than those present in the blood, except for the liver and kidneys, the organs of excretion. For IV, there was no localization of radioactivity in the combined retina, choroid, and sclera.

The distribution of radioactivity was examined in selected tissues of intact animals that had been dosed orally with each of the four dibenzoxazepines. The animals were sacrificed 7 or 14 days after being dosed, at which time the residual levels of radioactivity in tissues were determined (Table II). For I, both dogs and monkeys were studied. As it had been after the intravenous administration of I, radioactivity was still localized in certain tissues relative to that present in the blood, most notably in the combined retina, choroid, and sclera of both dog and monkey. For II, radioactivity was localized in the pigmented portion of the eye and in most of the other tissues as it was after the administration of I. The apparent half-life for the elimination of radioactivity from these tissues was about 7 days for most of the tissues and substantially longer for the combined retina, choroid, and sclera. After the administration of III, radioactivity also persisted in the pigmented portion of the eye and in several of the other tissues. The distribution of residual radioactivity in tissues of dogs following the administration of IV, however, was quite different from that observed for the other three dibenzoxazepines. Here, with the marginal exception of the cornea, none of the tissues contained levels of radioactivity higher than that present in the blood and, in most cases, only traces of radioactivity were present.

The distribution of radioactivity after the oral administration of IV was also studied in tissues of intact dogs that were sacrificed 3.5 hr. after being dosed (Table III). Once again, the distribution

[a] The time when the animals were sacrificed is cited in parentheses. [b] Dogs were given 5 mg./kg. by gavage. Two dogs of each sex were employed, except for III for which one male and two females were used. [c] Monkeys (one of each sex) were given 2.5 mg./kg. by nasogastric intubation. [d] Dogs (two of each sex) were given 10 mg./kg. by capsule. [e] Aqueous and vitreous humors were combined before analysis. [f] Concentrations in the combined retina, choroid, and sclera were divided by the concentrations in blood. These ratios were statistically different ($p < 0.025$) by Student's t test from concentrations found in dogs dosed with IV.

of radioactivity found in the tissues of these dogs was very different from that seen for the other substituted dibenzoxazepines. Here, only the liver and kidneys contained levels of radioactivity that were higher than that present in the blood. Radioactivity was rather uniformly distributed in most of the other well-perfused tissues, with the exception of the brain in which low levels were found. Thus, the results obtained with intact dogs dosed orally were similar to those found with the dog having the externalized bile duct that had been dosed intravenously. This finding suggests that the administration of IV intravenously in 50% aqueous dimethyl sulfoxide did not influence the distribution of IV in tissues of dogs.

To determine whether the mode of excretion of the four dibenzoxazepines had any bearing on the distribution of the parent compound or its metabolites in tissues, the excretion of radioactivity in the urine and feces or bile was examined following the administration of each compound (Table IV). The data show that dogs with externalized bile ducts that had been dosed intravenously excreted radioactivity in the urine and bile in a manner very similar to that found in the urine and feces of the dogs dosed orally. Dogs dosed with the nonpiperazine-containing compounds, III and IV, excreted much more radioactivity in the urine than did dogs dosed with I and II, compounds substituted with the piperazine-containing side chains.

To provide additional evidence for the affinity of the four substituted dibenzoxazepines for the melanin-containing portion of the eye, each radioactive parent dibenzoxazepine was incubated *in vitro* with melanin granules from beef eyeball (Table V). Whereas I, II, and III were significantly bound to the malanin granules, IV was bound only to an extent that is within the error of the method.

DISCUSSION

A number of studies showed that chlorpromazine (8–10) and other phenothiazines (11) are localized in various tissues, particularly in the brain, lungs, and liver. The substituted dibenzoxazepines, I, II, and III, and the dibenzoxepin, doxepin (12), are all localized in tissues of dogs to various degrees. In addition, all of these compounds bind to the pigmented portion of the eye. Bolt and Forrest (13) reported on the interaction of chlorpromazine and 7-hydroxychlorpromazine with melanin. The persistence of radioactivity in the fetal and maternal eyes, but not in other tissues, of mice given ^{35}S-chlorpromazine was also reported (14). It is not known if a common mechanism underlies the formation of cataracts and the development of retinopathy. However, chlorpromazine-induced cataracts have been studied experimentally in both albino and pigmented guinea pigs (15). On the basis of those studies, it was concluded that the development of cataracts had no apparent relationship to the presence of melanin. Thus, the binding of compounds to melanin apparently should not be considered as an indicator of potential cataractogenesis.

The excretion of the dibenzoxazepines reported in the present studies appears to follow the pattern established for the phenothiazines (16). Thus, those compounds substituted with piperazine-containing side chains (I and II) were excreted primarily in the feces or bile, whereas the excretion of a compound substituted with the aliphatic amine side chain (III) was shifted toward the urinary route. Compound IV, which bears the carboxamide side chain, was appreciably excreted in the urine after intravenous administration. After oral dosing, IV is incompletely absorbed; nevertheless, 23% of the dose was excreted in the urine, a considerably larger fraction than that excreted in the urine of the dogs dosed with I and II (5–9% of the dose) (17).

An earlier report described the metabolism of I and II in dogs (17). No significant differences could be found in the excretion, distribution, or biotransformation of these two compounds, which differ by the fact that I contains a chloro substituent on the tricyclic ring system whereas II bears a trifluoromethyl group. The binding of these two compounds to melanin granules *in vitro* was comparable. Likewise, III, but not IV, bound to melanin granules *in vitro*. Interestingly, I, II, III, and IV all appear to undergo hydroxylation on the tricyclic ring system, since mass spectral studies of metabolites of I and II showed the presence of the hydroxyl group (17), and other experiments in this laboratory indicated that glucuronide conjugates of all four compounds were excreted in the bile of dogs. For the phenothiazines, chlorpromazine (9) and fluphenazine (18), 7-hydroxylation has been identified as a prominent metabolic pathway. Additional findings in this laboratory showed

Table IV—Excretion of Radioactivity by Dogs after Oral or Intravenous Administration of Some Substituted Dibenzoxazepines

Compound[a]	Dose, mg./kg.	Route[b]	Time of Sacrifice	Percent of Dose ± *SE*		
				Urine	Feces or (Bile)	Total
I (1)	5	i.v.[c]	7 hr.	5.82	(68.01)	73.83
I (4)	5	p.o.	14 days	9.30 ± 1.07	83.28 ± 4.80	92.58 ± 4.50
II (1)	5	i.v.[c]	7 hr.	4.25	(59.58)	63.83
II (4)	5	p.o.	14 days	5.34 ± 0.50	80.88 ± 2.86	86.22 ± 2.42
III (1)	5	i.v.[c]	7 hr.	35.40	(22.76)	58.16
III (2)	5	p.o.	7 days	55.04 ± 9.47	33.96 ± 7.52	89.00 ± 1.95
IV (1)	5	i.v.[c]	7 hr.	31.55	(46.60)	78.15
IV (4)	10	p.o.	7 days	23.25 ± 0.71	62.12 ± 4.15	85.37 ± 3.74

[a] The number of dogs is indicated in parentheses. [b] All drugs were administered orally in aqueous solution by gavage, except IV which was given in capsules. Intravenous dosing for all drugs except IV was as an aqueous solution infused over a 5- or 10-min. interval. IV was administered in 9.6 ml. of 50% aqueous dimethyl sulfoxide. [c] These dogs had their bile ducts externalized.

Table V—Binding of Some Substituted Dibenzoxazepines to Beef Eyeball Melanin Granules *In Vitro*

Compound	Percent Bound[a]	
	0.75×10^{-4} *M*	1.5×10^{-4} *M*
I	52.6	40.1
II	44.1	35.8
III	23.5	19.5
IV	1.3	1.1

[a] The numbers cited are the average of two or three replicate determinations with the same granule preparation. The percent bound is based on the total radioactivity present in the incubation mixture.

that little, if any, unchanged I, II, III, or IV was excreted in the urine and bile of dogs dosed intravenously. Thus, it seems likely that I, II, and III can bind to melanin *in vitro* and that metabolites of these same compounds can bind to the melanin-containing portion of the eye *in vivo*.

In animals, IV has antidepressive, rather than neuroleptic, properties (5) that are similar to some of those exhibited by doxepin and amitriptyline. The latter two compounds bind to melanin, although not to the extent found for chlorpromazine (12), an electron donor that forms charge-transfer complexes with melanin (9, 19, 20). It is suggested that the carboxamide side chain in some way alters the affinity of IV and its metabolites for tissues, including those that contain melanin.

Microcapsules XIV: Effects of Membrane Materials and Viscosity of Aqueous Phase on Permeability of Polyamide Microcapsules toward Electrolytes

KOUICHI TAKAMURA*, MASUMI KOISHI, and TAMOTSU KONDO▲

Abstract □ The effects of membrane materials and the viscosity of the aqueous phase on the permeability of several kinds of polyamide microcapsules toward electrolytes were studied. The permeation rate of electrolytes was higher in the microcapsule membranes consisting of polyamide molecules with a polymethylene chain than in those having an aromatic ring. The viscosity of the microencapsulated aqueous phase decreased the permeation rate of electrolytes to a great extent, indicating that the diffusion of electrolytes in the interior of microcapsules is rate determining in the permeation process.

Keyphrases □ Polyamide microcapsules—permeation rate of electrolytes □ Permeability, polyamide microcapsules—effect of membrane materials and viscosity of aqueous phase □ Microcapsules, polyamide—permeation rate of electrolytes, effect of membrane materials and viscosity of aqueous phase □ Electrolyte permeation through polyamide microcapsules—effect of membrane materials and viscosity of aqueous phase

Permeability is one of the most important properties of microcapsules when they are used in the medical and pharmaceutical fields. However, only a few papers have been published on their permeability. Chang and Poznansky (1) measured the permeability of large nylon microcapsules (200-μ mean diameter), suspended in saline solution, toward low molecular weight solutes labeled with radioisotope. The measurements were made at very early stages of the permeation, using a rapid mixing and sampling technique; the half-time for equilibration of the solutes was less than 60 sec. Takamura *et al.* (2) studied the permeation rate of various electrolytes through the membranes of polyphthalamide microcapsules (2-μ mean diameter) in quasisteady state by means of conductometry, and they reported that the permeability constant for the electrolytes is of the order of 10^{-8} cm./sec. The surprisingly low permeation rate was ascribed to the formation of a stable diffusion layer of the electrolytes in the interior of microcapsules.

Although the works cited have thrown much light on the permeability of microcapsules, many uncertainties remain with regard to the fundamentals of the permeation process. Consequently, extensive work is needed to elucidate the detailed character of the process. This paper deals with the effects of membrane materials and the viscosity of the aqueous phase on the permeability of polyamide microcapsules toward electrolytes.

EXPERIMENTAL

Materials—The diamines used in this work were *p*-phenylenediamine, piperazine, 2,5-dimethylpiperazine, and 1,6-hexamethylenediamine. Sebacoyl dichloride and *p*-phthaloyl dichloride were employed as acid dichlorides. All of these chemicals were of reagent grade. Sodium chloride and sodium sulfate (analytical reagent grade) were used for permeability experiments without further purification. Polyvinylpyrrolidone (mol. wt. 360,000) was a commercial product.

Preparation of Microcapsules—Polyamide microcapsules containing water were prepared by the same method as that described earlier (2) by making use of the interfacial polycondensation reaction between diamine in the aqueous phase and acid dichloride in the organic phase. The polyamide microcapsules prepared from the diamines with the acid dichlorides were as follows: polyphenylene phthalamide, polyphthaloyl piperazine, polyphthaloyl 2,5-dimethylpiperazine, polyhexamethylene phthalamide, and polyhexamethylene sebacamide microcapsules. All of these microcapsules were dialyzed in the same manner as already reported (2) and were dispersed in deionized water containing 1% (v/v) polysorbate 20 as the dispersing agent.

Polyphthaloyl piperazine microcapsules containing aqueous solution of polyvinylpyrrolidone were prepared, dialyzed, and dispersed in 1% polysorbate 20 solution in the same way as already mentioned. In some cases, polyphthaloyl piperazine microcapsules containing aqueous polymer solution were dispersed in polymer solution containing 1% polysorbate 20.

Estimation of Permeability—As in the previous work (2), the permeability of microcapsules was estimated from the change in electrical conductance of the mixture of microcapsule dispersion and electrolyte solution in 1% polysorbate 20 solution.

To 200 ml. of 0.05 *N* NaCl or Na_2SO_4 solution in a conductance cell immersed in a constant-temperature bath, 100 ml. of the microcapsule dispersion previously kept at the same temperature was quickly added with stirring. The conductance reading was started shortly after mixing and was taken at suitable time intervals.

The electrical conductance measurements[1] were carried out at 10 ± 0.1°. The stirring was continued throughout the measurements.

The permeability constant for the electrolyte, P, was calculated by the equation:

$$P = -\frac{2.303 C_f V_m}{C_i A t} \log \frac{C_t - C_f}{C_i - C_f} \qquad \text{(Eq. 1)}$$

which was derived in the earlier work (2) based on Fick's first law of diffusion. In this equation, C_i, C_t, and C_f are the initial, intermediary (at time t), and final concentrations of electrolyte, respectively, in the dispersion medium determined by conductance measurements; V_m is the total volume of microcapsules; and A is the total surface area of microcapsules.

The validity of Eq. 1 can be checked by plotting $\log (C_t - C_f)/(C_i - C_f)$ against time. If the plot gives a straight line, the equation strictly holds and the permeability constant can be evaluated from the slope of the line.

The permeability constant thus obtained was converted to the apparent diffusion coefficient in the microcapsule membrane, D, by the following relation given in the previous paper (2):

$$D = P\Delta x \qquad \text{(Eq. 2)}$$

where Δx denotes the membrane thickness.

Estimation of Membrane Thickness—The thickness of microcapsule membranes was calculated by the equation:

$$\Delta x = \frac{wr}{dA} \qquad \text{(Eq. 3)}$$

where w is the weight of microcapsule membranes in unit volume of dispersion, assuming the complete reaction of diamine and acid dichloride; r is the experimentally determined percent reacted of

[1] Model CM-1DB conductance meter, Toa Electric Co., Tokyo, Japan.

Table I—Apparent Diffusion Coefficients for Electrolytes in Various Microcapsule Membranes

Microcapsule	Apparent Diffusion Coefficients, $\times 10^{14}$ cm.²/sec. Sodium Chloride	Sodium Sulfate
Polyphenylene phthalamide	2.6	2.6
Polyphthaloyl piperazine	2.4	2.5
Polyphthaloyl dimethylpiperazine	3.1	3.2
Polyhexamethylene phthalamide	3.0	3.8
Polyhexamethylene sebacamide	4.4	4.9

diamine; d is the density of microcapsule membrane; and A is the total surface area of microcapsules in unit volume of dispersion.

The percent reacted of diamine was determined in the following way. Polyamide microcapsules were broken down by centrifugation, and a clear aqueous phase containing unreacted diamine was obtained. A 4-ml. portion of the aqueous phase was mixed with 3 ml. of 5% (v/v) *p*-dimethylaminobenzaldehyde solution and 1 ml. of 15% (v/v) sulfuric acid solution in methanol, and the mixture was allowed to react at 60° for 10 min. The amount of diamine remaining unreacted was determined by measuring spectrophotometrically the absorption of colored complex formed between the diamine and *p*-dimethylaminobenzaldehyde (3). The wavelengths of maximum absorption were 425, 415, and 500 nm. for the piperazine, 1,6-hexamethylenediamine, and *p*-phenylenediamine complexes, respectively. The amount of 2,5-dimethylpiperazine could not be determined by this method, because this diamine did not react with *p*-dimethylaminobenzaldehyde. Instead, 2,3-dinitrofluorobenzene was used as the coloring agent. That is, a 2-ml. portion of the aqueous phase was mixed with an equal volume of 1.2% (v/v) 2,3-dinitrofluorobenzene solution in methanol and 1 ml. of aqueous 0.1 *M* $NaHCO_3$ solution, and the absorption at 396 nm. was measured spectrophotometrically (4). In all cases, the percent reacted of diamine was calculated from its concentrations in the aqueous phase before and after microencapsulation.

The microcapsule membranes obtained by breaking down polyamide microcapsules through centrifugation were collected, washed, and dried under reduced pressure. The specific gravity of the dried sample was determined with a pycnometer. The density of the membranes was obtained by multiplying the specific gravity by the density of water.

The total surface area of microcapsules was estimated in a way similar to that adopted in earlier works (5–7).

Measurement of Viscosity—The viscosities of aqueous polyvinylpyrrolidone solutions containing sodium chloride or sodium sulfate of the concentration at distribution equilibrium were measured with a viscometer[1] at 10 ± 0.1°.

Key: microcapsules:* □, *polyphenylene phthalamide;* ◇, *polyphthaloyl piperazine;* ⬭, *polyphthaloyl dimethylpiperazine;* △, *polyhexamethylene phthalamide; and* ○, *polyhexamethylene sebacamide.*

Table II—Characteristics of Polyamide Microcapsules

Microcapsule	Membrane Density, g./cm.³	Membrane Thickness, *A*	Surface Area, m.²/cm.³
Polyphenylene phthalamide	1.38	123	1.79
Polyphthaloyl piperazine	1.37	133	2.12
Polyphthaloyl dimethylpiperazine	1.35	166	2.03
Polyhexamethylene phthalamide	1.28	167	2.21
Polyhexamethylene sebacamide	1.14	224	2.15

RESULTS AND DISCUSSION

Effect of Membrane Materials—The distribution equilibrium of electrolytes was established within 2 hr. between the inside and outside of all polyamide microcapsules studied in this work.

Figure 1 shows the plot of log $(C_t - C_f)/(C_i - C_f)$ against time for the entry of sodium chloride into polyamide microcapsules, indicating the validity of Eq. 1 between 3 and 30 min. after mixing the electrolyte solution and microcapsule suspension. The electrolyte entry into microcapsules proceeds in a quasisteady state since the permeation process is supposed to have been about 90% completed at the time when the conductance measurement is started.

The permeability constants for sodium chloride and sodium sulfate calculated by Eq. 1 were always of the order of 10^{-8} cm./sec. and were dependent on the membrane constituents. Table I lists the apparent diffusion coefficients in the microcapsule membranes converted from the permeability constants by means of Eq. 2. Inspection of the table reveals that the diffusion rate of the electrolytes is higher in the membranes consisting of polyamide molecules with a polymethylene chain than in those having an aromatic ring.

Table II gives some characteristics of the polyamide microcapsules. The data are useful in discussing the effect of the membrane constituent on the permeation rate of the electrolytes through the polyamide microcapsule membranes.

As stated previously (2), polysorbate 20 molecules are undoubtedly adsorbed on the polymer molecules constituting microcapsules,

1.31	1.78	1.90
1.43	1.72	1.76
1.54	1.62	1.63
1.68	1.50	1.50

Table IV—Effect of Viscosity of Microencapsulated Aqueous Phase on the Permeability Constants of Electrolytes for the Entry into Polyphthaloyl Piperazine Microcapsules

Viscosity, cps.	—Permeability Constants, $\times 10^5$ cm./sec.— Sodium Chloride	Sodium Sulfate
1.31	1.78	1.90
1.43	1.69	1.74
1.54	1.64	1.57
1.68	1.54	1.59

thereby making the membranes hydrophilic. Consequently, sodium chloride and sodium sulfate are quite likely to diffuse through the interspace filled with water of polymer chains in a random arrangement of the membranes. It is then expected that the dimension of interspace of polymer chains greatly affects the diffusion rate of the electrolytes. Since polyamide molecules having polymethylene groups are more flexible than those with aromatic rings, the dimension of interspace of polymer chains would be larger in polyhexamethylene sebacamide and polyhexamethylene phthalamide microcapsules than in polyphenylene phthalamide, polyphthaloyl piperazine, and polyphthaloyl dimethylpiperazine microcapsules.

This situation is reflected in the densities of the microcapsule membranes shown in Table II and in the diffusion coefficients for sodium chloride and sodium sulfate given in Table I. It may be inferred, therefore, that the diffusion rate of electrolytes is lower in the microcapsule membranes of high density than in those of low density.

The difference in the diffusion rate between sodium chloride and sodium sulfate would be caused either by the different hydration of chloride and sulfate ions or by the different electrostatic interaction of the two anions with polyoxyethylene chains of dispersing agent molecules adsorbed on the polyamide molecules of the microcapsule membranes. However, the former possibility is ruled out because the permeability constants for sodium sulfate are, in general, greater than those for sodium chloride, while sulfate ions are more strongly hydrated and consequently should diffuse more slowly than chloride ions in the interspace of polymer chains. This leads one to the second possibility.

As described earlier (2), anions of higher valency are likely to interact more strongly than those of lower valency with weakly cationic polyoxyethylene chains of dispersing agent molecules adsorbed on the polymer molecules constituting microcapsules. As a consequence, there would be a richer accumulation of sulfate ions than chloride ions in the microcapsule membranes. This may result in the higher permeation rate for sulfate ions than for chloride ions.

Effects of Viscosity of Aqueous Phase—Earlier (2), it was proposed that the diffusion of electrolyte in the interior of microcapsules is rate determining in the permeation process, because the formation of a stable diffusion layer of electrolyte is highly probable inside the microcapsules. If this is really the case, the viscosity of the microencapsulated aqueous phase would affect the permeation of electrolyte through the microcapsule membranes to a great extent.

Figure 2 shows the effect of viscosity of microencapsulated and intercapsular aqueous phases on the rate of entry of sodium chloride into polyphthaloyl piperazine microcapsules. The viscosity was raised by dissolving polyvinylpyrrolidone in the aqueous phases. An increase in the viscosity clearly gives rise to a decrease in the rate of entry of sodium chloride. It is quite unlikely that polyvinylpyrrolidone molecules are adsorbed on the membrane by competing with dispersing agent molecules and thus offer resistance to the entry of sodium chloride since the former molecules are far less surface active than the latter molecules.

Table III lists the permeability constants for sodium chloride and sodium sulfate when both the microencapsulated and intercapsular aqueous phases contain polyvinylpyrrolidone. Table IV gives the permeability constants for sodium chloride and sodium sulfate in the case where the polymer is present only in the microencapsulated aqueous phase. Comparison of the two tables indicates that the permeation rate of electrolytes strongly depends on the viscosity of microencapsulated aqueous phase. This would support the view that the diffusion of electrolyte in the microencapsulated aqueous phase is rate determining in the permeation process. The tables also suggest that the increase in the viscosity of the microencapsulated aqueous phase tends to diminish the difference in the diffusion rate in the microcapsule membranes between sodium chloride and sodium sulfate.

Relationship between CNS Depressant and Enzyme Inhibitory Properties of Substituted Quinazolone 1,3,4-Oxadiazoles

J. P. BARTHWAL, S. K. TANDON, V. K. AGARWAL, K. S. DIXIT, and SURENDRA S. PARMAR▲

Abstract □ Substituted quinazolone 1,3,4-oxadiazoles were synthesized and evaluated for their MAO and acetylcholinesterase inhibitory activity. These compounds were also screened for their anticonvulsant activity, reserpine reversal response, and analgesic activity. Anticonvulsant activity of these compounds against pentylenetetrazol-induced seizures was related to some extent to their MAO and acetylcholinesterase inhibitory properties.

Keyphrases □ Quinazolone 1,3,4-oxadiazoles—synthesis, anticonvulsant and analgesic activity, relationship to MAO and acetylcholinesterase inhibition □ 1,3,4-Oxadiazoles, quinazolone—synthesis, anticonvulsant and analgesic activity, relationship to MAO and acetylcholinesterase inhibition □ Anticonvulsant activity—synthesis and evaluation of quinazolone 1,3,4-oxadiazoles □ MAO inhibitors—synthesis and evaluation of quinazolone 1,3,4-oxadiazoles □ Acetylcholinesterase inhibitors—synthesis and evaluation of quinazolone 1,3,4-oxadiazoles

Anticonvulsant (1) and hypnotic (2) properties exhibited by quinazolones and the specific inhibition of MAO [E.C. 1.4.3.4 monoamine O_2 oxido reductase-(deaminating)] by 1-isonicotinoyl-2-isopropylhydrazine (3) prompted the synthesis of substituted quinazolone hydrazides as MAO inhibitors (4, 5). Furthermore, the ability of substituted 1,3,4-oxadiazoles to exhibit analgesic (6, 7), anti-inflammatory, antipyretic (8, 9), muscle relaxant (9), and CNS depressant activities (10, 11) led us to synthesize substituted quinazolone 1,3,4-oxadiazoles. In the present study, attempts were made to correlate pharmacological properties exhibited by these compounds with their ability to inhibit MAO and acetylcholinesterase.

CHEMISTRY

The various substituted quinazolone 1,3,4-oxadiazoles were synthesized by the route outlined in Scheme I. Acetanthranils (II) were synthesized by refluxing 1 mole of the appropriate anthranilic acid (I) with 2 moles of acetic anhydride. Quinazolone esters (IV) were synthesized by heating equimolar quantities of appropriate acetanthranils (II) and ethyl glycine ester (III). Quinazolone hydrazides (V) were synthesized by refluxing a mixture of quinazolone esters (IV) and hydrazine hydrate. Substituted quinazolone thiosemicarbazides (VI) were prepared by refluxing the appropriate hydrazide (V) with a suitable arylisothiocyanate in ethanol. These quinazolone thiosemicarbazides were cyclized into substituted quinazolone 1,3,4-oxadiazoles (VII).

EXPERIMENTAL

Melting points were taken in open capillary tubes and are uncorrected.

Anthranilic Acids (I)—The method of Atkinson and Milton (12) was used for the synthesis of 5-chloro- and 3,5-dichloroanthranilic acids. 5-Bromoanthranilic acid was prepared by the method of Wheeler and Oats (13), while 5-iodoanthranilic acid was synthesized following the method of Klemme and Hunter (14).

Acetanthranil (II)—Appropriate anthranilic acids (1 mole) were refluxed with acetic anhydride (2 moles) for 1 hr. After excess acetic anhydride was distilled off, the acetanthranil that separated out as a solid mass was dried quickly and used without further purification.

Ethyl Glycine Ester (III)—This ester was prepared by following the method of Kuprozewski and Sokolowaska (15).

Quinazolone Esters (IV)—Equimolar quantities (1 mole) of the appropriatea cetanthranil and ethyl glycine ester were heated directly to yield the desired esters, which were recrystallized from ethanol (Table I).

Quinazolone Hydrazides (V)—A mixture of the appropriate quinazolone ester (0.1 mole) and hydrazine hydrate (98%) (0.12 mole) was refluxed in absolute ethanol for 6–8 hr. On removing the excess solvent, the quinazolone hydrazides that separated out were filtered and recrystallized from ethanol (Table I).

Quinazolone Thiosemicarbazides (VI)—Equimolar quantities of hydrazides and arylisothiocyanate (0.01 mole) were refluxed in ethanol for 3–4 hr. The solution was cooled to obtain corresponding thiosemicarbazides, which were recrystallized from suitable solvents (Table II).

Quinazolone 1,3,4-Oxadiazoles (VII)—The quinazolone thiosemicarbazides were cyclized into quinazolone 1,3,4-oxadiazoles by following the method of Silberg and Cosma (16). To a cold ethanolic suspension of an appropriate thiosemicarbazide (0.01 mole) was added 5 ml. of 4 *N* NaOH solution, followed by 5% solution of iodine in potassium iodide which was gradually added to the clear solution with stirring until the color of iodine persisted at room

temperature. The contents were then refluxed on a steam bath, and more iodine solution was added until a slight excess of iodine remained. The reaction mixture was cooled and poured into 500 ml. of ice-cold water. The solid masses that separated out were filtered, washed with water and then with carbon disulfide, and recrystallized from suitable solvents (Table III).

BIOCHEMICAL STUDIES

***In Vitro* Determination of MAO Activity**—MAO activity of rat liver homogenate was determined spectrophotofluorometrically using kynuramine as the substrate (17). The enzyme activity was determined by measuring the 4-hydroxyquinoline formed during oxidative deamination of kynuramine. The reaction mixture, in a final concentration of 3 ml., consisted of 83 m*M* phosphate buffer (pH 7.4) and 1 ml. of the liver homogenate (10% w/v). Water, kynuramine, and the test compounds were added to adjust the final volume to 3.0 ml. The reaction was conducted in test tubes, and incubations were carried out at 37° for 30 min. After incubation, 2 ml. of 10% trichloroacetic acid (w/v) was added to each test tube and the precipitated proteins were removed by centrifugation. Suitable aliquots of the supernate, taken in 1 *N* NaOH solution, were assayed for 4-hydroxyquinoline fluorometrically in a spectrophotofluorometer[1], using activating light of 310 nm. and measuring fluorescence at the maximum of 380 nm. An increase in absorbance provided a direct measurement of 4-hydroxyquinoline as an index of kynuramine utilization and, consequently, of MAO activity. A decrease in kynuramine utilization in experiments containing the test compounds was used to calculate the degree of MAO inhibition.

***In Vitro* Determination of Acetylcholinesterase Activity**—Acetylcholinesterase activity was determined colorimetrically, using acetylthiocholine iodide (0.015 *M*) as the substrate, according to the method of McOskar and Daniel (18). The reaction mixture in final concentration consisted of 43 m*M* tromethamine buffer (pH 7.4), 350 m*M* sodium chloride, and 0.3 ml. brain homogenate (10% w/v).

Water and acetylthiocholine were added to adjust the final volume to 2.0 ml. The reaction mixture, with or without inhibitor, was incubated at constant temperature (37°) for 10 min. prior to the addition of acetylthiocholine. The incubation was continued for 10 min. more subsequent to the addition of the substrate. The reaction was stopped by the addition of 0.5 ml. of 25% (w/v) trichloroacetic acid, and the resultant solution was centrifuged for 5 min. at 500× *g*. An aliquot of the clear supernate was withdrawn, and the enzymatically formed thiocholine content was determined colorimetrically. Each assay was done in triplicate, and tissue and substrate blanks were substracted to give the actual value for the hydrolysis of acetylthiocholine. Results are expressed as changes in absorbance/100 mg. fresh tissue/10 min.

PHARMACOLOGICAL STUDIES

Toxicity—The approximate 50% lethal dose (LD_{50}) was determined in albino mice by the method of Smith (19). The dose of each compound was taken as one-fifth of its observed LD_{50} in an attempt to evaluate it in its effective therapeutic range. The test compounds were administered to each group of 10 mice orally in 5% gum acacia.

Reserpine Reversal Test for *In Vivo* Determination of MAO Inhibitory Activity—Reserpine was administered intraperitoneally in a dose of 5 mg./kg. after 3 hr. In the control group of mice, without pretreatment of drugs, reserpine always produced sedation, ptosis, and miosis. In animals treated with phenelzine and pargyline, the well-known MAO inhibitors, administration of reserpine caused excitation, piloerection, mydriasis, and increased motor activity. Failure to produce the reserpine reversal response by the test compounds indicated that the compound was inactive in producing *in vivo* MAO inhibition.

Anticonvulsant Activity—The anticonvulsant property was determined in albino mice of either sex, weighing between 20 and 30 g., divided into groups of 10; the group weights were kept equal as far as possible. One group of 10 animals was used as the control. The test compounds were suspended in 5% aqueous gum acacia and were fed orally 3 hr. prior to subcutaneous injection of pentylenetetrazol[2], 80 mg./kg., under the loose skin of the back. This dose of pentylenetetrazol caused convulsions in almost all of the normal control group of animals. The animals were observed for 60 min. for the occurrence of seizures; an episode of clonic spasm persisting for at least 5 sec. was considered a threshold convulsion. Animals not exhibiting even a threshold convulsion during 60 min. were considered protected. The number of animals protected in each group were recorded. Transient intermittent jerks or tremulousness were not taken into account. Phenelzine and pargyline were used for comparison.

Analgesic Activity—*Mouse Tail-Pinch Test*—Morphine-like analgesic activity was tested by the mouse tail-pinch method (20). An artery clip, with branches enclosed in a thin rubber tube, was applied to the root of the tail of a mouse for 30 sec. The animals made continuous attempts to remove the noxious stimulus by biting the clips. Mice were administered test compounds by the intragastric route 3–4 hr. prior to the application of the artery clips. The insensitivity to the noxious stimulus was taken as the positive response, and the results were expressed as percentage of mice showing analgesic activity. Morphine hydrochloride was used as a reference standard for comparing the effective analgesic property of these compounds.

Writhing Test—Aspirin-like analgesic activity of the test compounds was investigated by their ability to protect a painful writhing syndrome. This syndrome is characterized by abdominal torsion, drawing up of hind limbs to the abdominal wall, marked contraction of the abdominal area, and periodic arching of the back to rub the abdominal wall on the glazed surface on which the mouse was kept. It was consistently produced by intraperitoneal injection of 2 mcg. aconitine (100% effective dose) per mouse weighing 20–25 g. The test compounds were given 3 hr. before the induction of the writhing test. The typical response appeared within 5 min. after injection of aconitine and persisted up to 15–20 min. The mice were observed for 30 min., and results are expressed as percent of mice showing protection. Aspirin was taken as a standard reference drug for comparison.

RESULTS AND DISCUSSION

The test compounds exhibited low *in vitro* MAO inhibitory activity (Table IV) as compared to the 78% inhibition produced by phenelzine and pargyline when used at final concentrations of 1×10^{-5} and 1×10^{-6} *M*, respectively.

[a] Compound numbers are as recorded in Tables I, II, and III.

As is evident from Table IV, acetylcholinesterase inhibitory properties of substituted quinazolone hydrazides were lower than those of their corresponding esters. Attachment of a halogen substituent at position 6 or 8 of the quinazolone nucleus in no way reflected any basis for their structure–activity relationship with respect to their ability to inhibit MAO and acetylcholinesterase. However, the anticonvulsant activity exhibited by quinazolone hydrazides, as reflected by the protection observed against pentylenetetrazol-induced convulsions, was found to be more than that observed with the corresponding quinazolone esters. The anticonvulsant activity of phenelzine and pargyline, used for comparison, was found to be 50% at a dose of 30 mg./kg. under similar experimental conditions. Most of the quinazolone esters and quinazolone hydrazides were devoid of reserpine reversal response. These results thus indicated their weak *in vivo* MAO inhibitory activity. Furthermore, a number of compounds in the group of quinazolone thiosemicarbazides and 1,3,4-oxadiazoles exhibited slight stimulation on administration of reserpine which, however, was found to have no relationship with their MAO inhibitory potency. Compounds 16, 19, and 22 showed over 50% inhibition but were devoid of reserpine reversal response, while slight stimulation on administration of reserpine was observed with compounds possessing a low MAO inhibitory property (Compounds 7, 8, 12, and 28).

The results in Table IV show that a large number of compounds provided protection against aconitine-induced writhing response where 2-methyl-6,8-dibromo-3-(acetylhydrazino)-4-quinazolone (Compound 12) exhibited appreciable analgesic activity of 80%. None of these quinazolone esters, hydrazides, thiosemicarbazides, and 1,3,4-oxadiazoles gave a positive response when tested for their morphine-like analgesic activity by the tail-pinch method; the standard reference drug, aspirin, showed 80% protection when administered at a dose of 40 mg./kg. Such analgesic activity warrants further detailed investigation for the possible usefulness of this compound as a nonsteroidal, anti-inflammatory agent. In addition, the high LD_{50} values observed with these compounds reflected their low toxicity.

Conversion of the quinazolone hydrazides into the corresponding quinazolone thiosemicarbazides resulted in increased MAO and acetylcholinesterase inhibitory potency. Significant MAO inhibition, ranging from 69.38 to 82.22%, was observed with these substituted quinazolone thiosemicarbazides even at half of their concentration of 3×10^{-4} M as compared to 6×10^{-4} M used for substituted quinazolone esters and hydrazides (Table IV). (Compare Compounds 1 and 2 with 13, 14, and 15; 5 and 6 with 16 and 17; and 9 and 10 with 18, 19, and 20.) Greater inactivation of MAO and acetylcholinesterase was similarly observed with substituted quinazolone 1,3,4-oxadiazole as compared to the corresponding quinazolone esters and hydrazides which, however, were less potent than the quinazolone thiosemicarbazides. Although these results indicated the greater sensitivity of the quinazolone thiosemicarbazides to inhibit MAO and acetylcholinesterase than the corresponding substituted quinazolone hydrazides and quinazolone 1,3,4-oxadiazoles, no clearcut relationship of their enzyme inhibitory effects as a function of their chemical structure could be observed. These results also failed to provide similarity of substituted quinazolone esters, hydrazides thiosemicarbazides, and 1,3,4-oxadiazoles in their inhibitory effects on MAO, a dehydrogenase in which flavins seem to be implicated, and acetylcholinesterase, a hydrolase without any cofactor requirements.

The anticonvulsant activity exhibited by these compounds, by affording protection against pentylenetetrazol-induced seizures, was found to be related with their MAO and acetylcholinesterase inhibitory properties. These studies reflected a greater anticonvulsant property, ranging from 50 to 70% of substituted quinazolone thiosemicarbazides which were also found to cause greater inhibition of MAO and acetylcholinesterase. In the present study, enzyme inhibitory effects and anticonvulsant activity of these compounds were in the order of: thiosemicarbazides > oxadiazoles > hydrazides > esters.

Solubility and Dissolution of Triamcinolone Acetonide

L. H. BLOCK▲ and R. N. PATEL

Abstract □ Available data on the solubility of triamcinolone acetonide in aqueous media are neither complete nor in agreement. Solubility of the steroid in distilled water and in potassium chloride solutions of varying ionic strength was determined at 28, 37, and 50°. Dissolution rates of the steroid in the aqueous media were determined at 28° *via* a rotating-disk method. Triamcinolone acetonide solubility in distilled water ranged from 21 mcg. ml.$^{-1}$ at 28° to 33.6 mcg. ml.$^{-1}$ at 50°. The differential heat of solution was 4207 cal. mole^{-1}. The intrinsic dissolution rate constant at the maximum agitation intensity employed was 4.51×10^{-3} hr.$^{-1}$ cm.$^{-2}$. Solubilities and dissolution rates were markedly lower in potassium chloride solutions. "Salting-out" coefficients were calculated, for the effect of potassium chloride on triamcinolone acetonide solubility, using the empirical Setschenow equation.

Keyphrases □ Triamcinolone acetonide—solubility and dissolution in water and potassium chloride solutions □ Solubility, triamcinolone acetonide—water and potassium chloride solutions, Setschenow salting-out coefficients □ Dissolution rates, triamcinolone acetonide—water and potassium chloride solutions

Lange and Amudson (1), using a gravimetric procedure, determined the aqueous solubility of triamcinolone acetonide to be 26.4 mg./100 ml. at 25°. Malkinson and Kirschenbaum (2), in their study of the percutaneous absorption of triamcinolone acetonide, noted that the steroid had an aqueous solubility of 1 mg./100 ml., although neither the temperature of the system nor the method used in determining solubility was specified. Florey (3) recently reported solubilities for the compound in water as well as isotonic saline (pH 7) at 23 and 37° as 0.004 ± 0.002% (40 mcg./ml.). The solubility data available thus far are neither adequate nor in agreement. No data have been reported on the effect of ionic strength on the steroid's solubility, nor are dissolution rate data available. Since the solubility and dissolution of the steroid can ultimately affect its release from matrixes in which it is suspended, these physicochemical properties of triamcinolone acetonide were evaluated.

MATERIALS AND METHODS

Materials—Hydrochloric acid[1], potassium chloride[1], recrystallized blue tetrazolium[1], tetramethylammonium hydroxide (10% in water)[2], and triamcinolone acetonide[3] were used as received.

One potential source of error—the polymorphic form of the steroid—was eliminated following differential thermal analyses of the three lots of steroid received. No marked differences in the thermograms obtained[4] were noted. It could thus be concluded that the steroid employed was of a single polymorphic form.

Reagents—Blue tetrazolium solution (0.2% w/v) was prepared by accurately weighing 100 mg. of blue tetrazolium, suspending the material in 35 ml. of alcohol, and agitating the suspension at 45° until dissolution was complete. Following the attainment of ambient thermal equilibrium, the solution volume was adjusted to 50 ml. with alcohol. The solution was freshly prepared before use. Tetramethylammonium hydroxide solution (1% v/v) was prepared from the commercial 10% solution by accurately transferring 10 ml. of the concentrate to a volumetric flask and adjusting the volume to 100 ml. with alcohol. Hydrochloric acid (1 *N*) was prepared by diluting 12.5 ml. of concentrated acid to 100 ml. with distilled water.

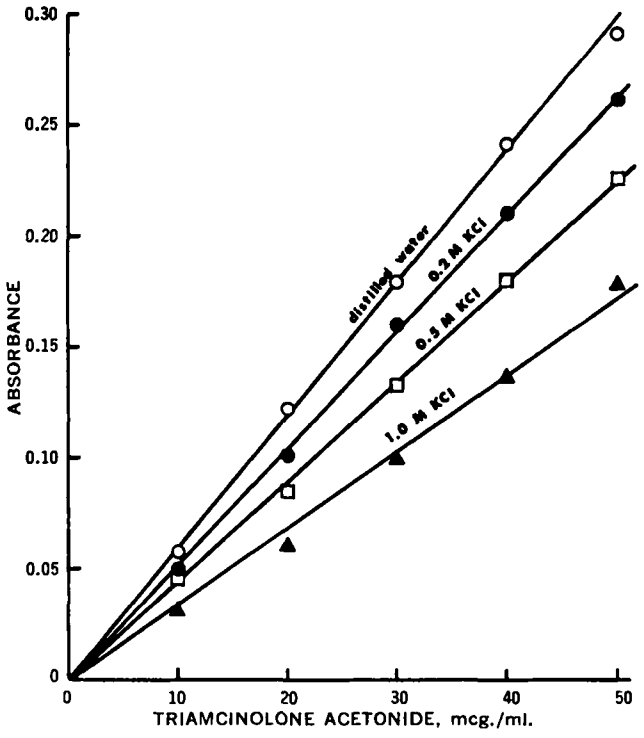

Figure 1—*Beer's plots for triamcinolone acetonide–blue tetrazolium reaction in distilled water and potassium chloride solutions.*

Assay of Aqueous Solutions of Triamcinolone Acetonide—*Standard Solution*—A standard solution of triamcinolone acetonide (1000 mcg./ml.) was prepared by dissolving 100 mg. of steroid, accurately weighed, in enough alcohol to yield a final solution volume of 100 ml.

Assay Procedure—The analytical method employed was that of Umeda *et al.* (4); 1.0 ml. of the steroid-containing solution, 1.0 ml. of alcohol, 2.0 ml. of blue tetrazolium solution, and 1.0 ml. of tetramethylammonium hydroxide solution were transferred to a screw-capped test tube. The mixture was kept at 30–35° in a water bath for 25–30 min., and 1.0 ml. of 1 *N* hydrochloric acid was then added. A blank solution was prepared using 1.0 ml. of the dissolution medium instead of the steroid-containing solution. The absorbance of the steroid-containing solution, relative to the blank, was measured at the λ_{max}, 525 nm., for each dissolution medium employed (distilled water and 0.2, 0.5, and 1.0 *M* potassium chloride)[5]. Beer's plots are shown in Fig. 1. The slopes of the curves were calculated by the method of least squares with the aid of a programmable calculator[6]. The reciprocals of the absorptivities thus calculated were used in the calculation of solution steroid concentrations.

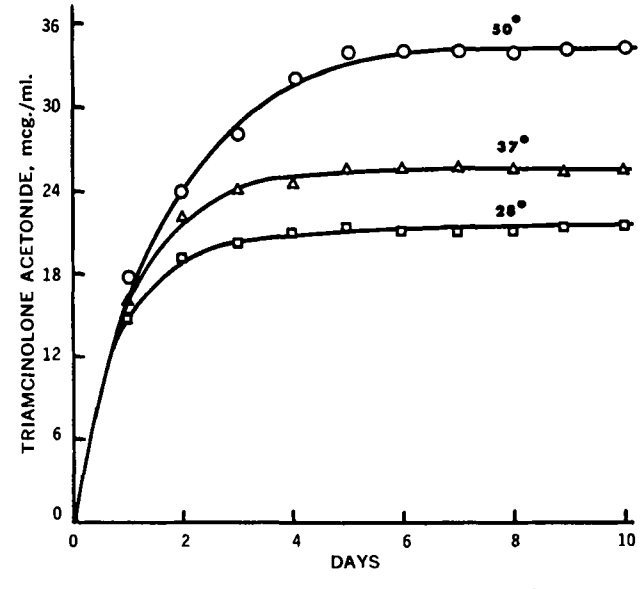

Figure 2—*Solubility of triamcinolone acetonide in distilled water as a function of time.*

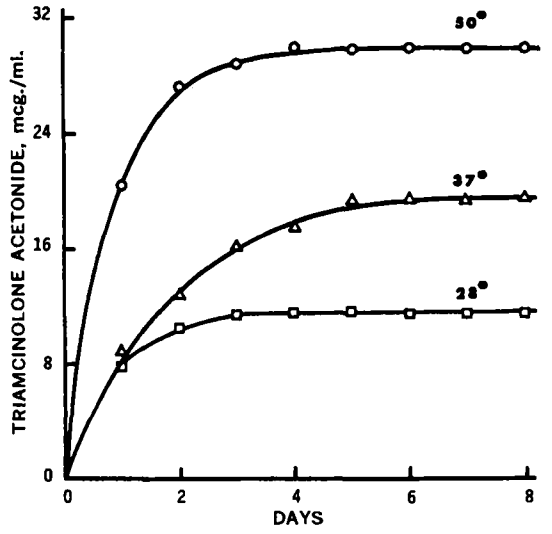

Figure 3—*Solubility of triamcinolone acetonide in 0.2 M potassium chloride solution as a function of time.*

Solubility Determinations—Triamcinolone acetonide solubility in distilled water and in 0.2, 0.5, and 1.0 *M* potassium chloride solutions was determined as a function of temperature in the following manner. An excess of steroid (50 mg.) was added to amber, screw-capped, 180-ml. (6-oz.) bottles containing 100 ml. of the appropriate dissolution medium. A Saran[7] liner was inserted and the bottle cap was tightened in place. The bottles were manually shaken and then suspended in constant-temperature baths[8] maintained[9] at 28 ± 0.5, 37 ± 0.5, and 50 ± 0.5°, respectively. The bottles were shaken periodically. Samples were withdrawn from the con-

tainers every 24 hr. using 2-ml. tuberculin syringes[10] fitted with Whitacre spinal needles[11]. The samples were filtered through 0.22-μ filters[12] and assayed for triamcinolone acetonide.

Dissolution Rate Studies—The dissolution apparatus employed consisted of a 2000-ml., three-necked, round-bottom flask immersed in a constant-temperature bath and an acrylic turbine-bladed stirrer/pellet holder attached to an electronically controlled precision stirring motor[13].

Flat-faced, 1.3-cm. (0.5-in.) diameter pellets of pure triamcinolone acetonide were prepared by suitable compression with a pellet press[14]. The pellets were then mounted in the acrylic pellet holder, with the aid of beeswax, in such a way that only one flat face of a pellet was exposed. The pellet holder, with the pellet in place, was attached to a metal shaft connected to an electronically controlled precision stirring motor.

After adding 1500 ml. of the dissolution medium to the three-necked flask immersed in the constant-temperature bath, the temperature of the dissolution medium was allowed to equilibrate with

Table II—Differential Heats of Solution of Triamcinolone Acetonide in Dissolution Media, Calculated from Arrhenius Plots of the Solubility Data

Dissolution Medium	ΔH_{soln}, cal. mole^{-1}
Distilled water	4207
Potassium chloride solution:	
0.2 *M*	8340
0.5 *M*	8722
1.0 *M*	9855

that of the bath (28 ± 0.5°). The pellet holder, with pellet in place, was then immersed in the dissolution medium to a depth of 5 cm. The stirrer was switched on and maintained at constant speed. Aliquots of 2.0 ml. were removed from the flask at appropriate time intervals, using tuberculin syringes fitted with Whitacre spinal needles, and then filtered through 0.22-μ Millipore filters.

RESULTS AND DISCUSSION

Solubility—The approach to equilibrium, as a function of time, is shown in Figs. 2–5. Concentration plateaus were reached within 4–5 days. The solubility of triamcinolone acetonide as a function of temperature in distilled water and in potassium chloride solutions is shown in Fig. 6. The saturation equilibria are summarized in Table I. The differential heats of solution, ΔH_{soln}, of the steroid in the dissolution media were calculated by the method of least squares in accordance with the Arrhenius relationship:

$$\log X = -\frac{\Delta H_{soln}}{2.303R} \cdot \frac{1}{T} + b \qquad \text{(Eq. 1)}$$

where X is the mole fraction of steroid in solution, R is the molar gas constant, T is the absolute temperature, and b is a constant. The values are tabulated in Table II.

The effect of electrolyte on the solubility of the steroid is particularly evident (Fig. 7); it is apparent that a "salting-out" phenomenon

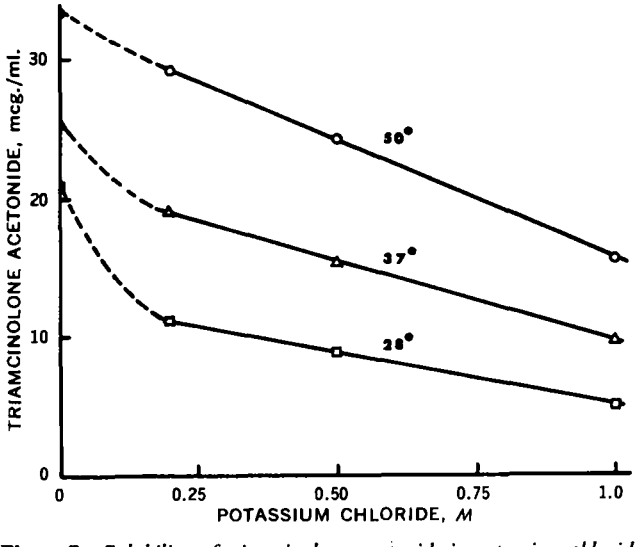

Figure 7—*Solubility of triamcinolone acetonide in potassium chloride solutions.*

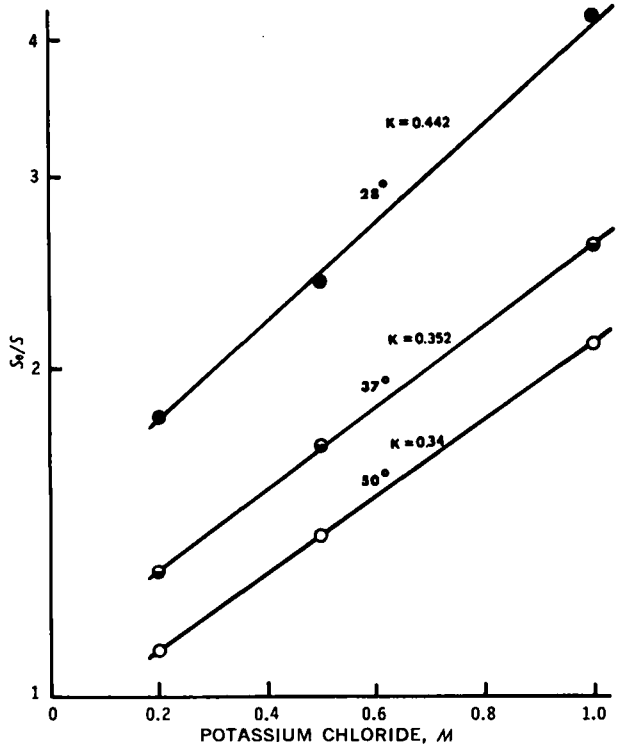

Figure 8—*Setschenow plots for triamcinolone acetonide in potassium chloride solutions.*

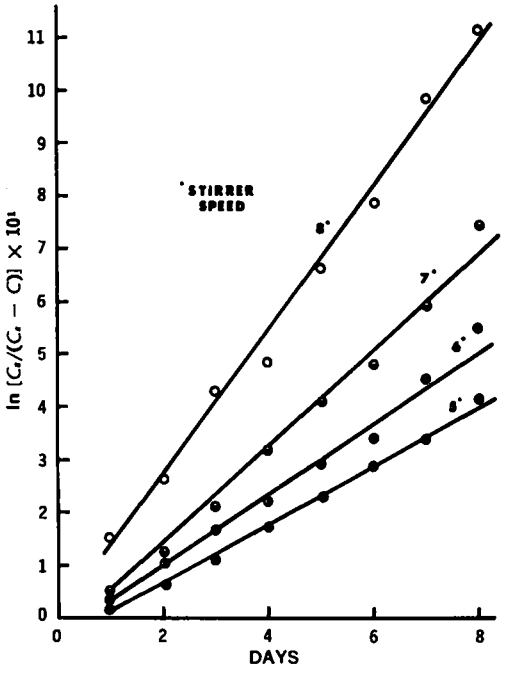

Figure 10—*Triamcinolone acetonide dissolution in distilled water, plotted in accordance with the integrated form of the modified Noyes–Whitney equation.*

is encountered. Setschenow (5, 6) proposed an empirical relationship for the effect of an electrolyte on the solubility of a nonelectrolyte:

$$\log (S_0/S) = kC \qquad \text{(Eq. 2)}$$

where S_0 is the solubility of the nonelectrolyte in pure solvent, S is the solubility of the nonelectrolyte in an electrolyte solution of a given molar concentration C, and k is the salting-out coefficient and is a function of the composition of the system and the temperature. The ratio S_0/S is equal to f, the activity coefficient of the nonelectrolyte in the electrolyte solution. Setschenow plots of the solubility data are shown in Fig. 8 along with the respective slopes or k values for each system. The k values range from about 0.3–0.4 and are higher than those reported for other types of nonelectrolytes such as diacetone alcohol (0.03–0.14) (7), mesityl oxide (0.02–0.18) (7), ethyl acetate (0.02–0.17) (7), and certain barbiturates (0.04–0.21) (8).

The salting-out effect is most apparent in the transition from distilled water to 0.2 M potassium chloride solution. At higher temperatures, however, the effect of added electrolyte is less marked.

Dissolution Rate—Dissolution of triamcinolone acetonide in distilled water at 28° under sink conditions is shown in Fig. 9 as a function of time for various agitation intensities. The data are in accordance with the integrated form of the modified Noyes–Whitney equation (9):

$$\ln \frac{C_s}{C_s - C} = k'At = \frac{DA}{Vh} \cdot t \qquad \text{(Eq. 3)}$$

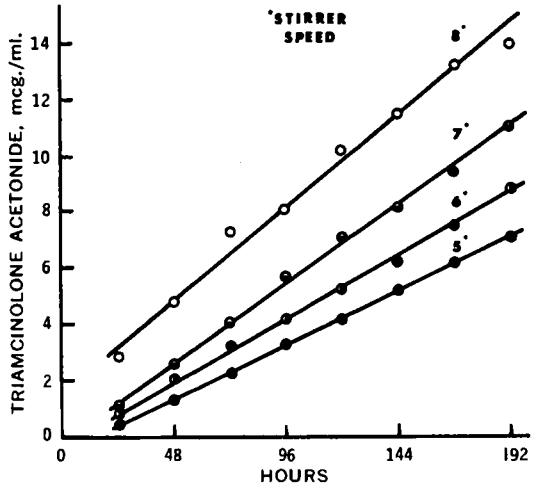

Figure 9—*Triamcinolone acetonide dissolution in distilled water as a function of agitation intensity (stirrer speed 5 = 147 r.p.m., 6 = 248 r.p.m., 7 = 308 r.p.m., and 8 = 398 r.p.m.).*

Table III—Dissolution Rates and Dissolution Rate Constants for Triamcinolone Acetonide in Distilled Water at 28°

Stirrer Speed, r.p.m.	dC/dt, (mcg. $ml.^{-1}$ $hr.^{-1}$) × 10^2	k'^a, ($hr.^{-1}$ $cm.^{-2}$) × 10^3
147	4.01	1.86
248	4.70	2.33
308	5.82	3.15
398	6.63	4.51

[a] Surface area of pellet exposed to dissolution medium was ~1.271 $cm.^2$.

Table IV—Dissolution Rates and Dissolution Rate Constants for Triamcinolone Acetonide in Potassium Chloride Solutions at 28°[a]

Potassium Chloride Solution	dC/dt, (mcg. $ml.^{-1}$ $hr.^{-1}$) × 10^2	k'^b, ($hr.^{-1}$ $cm.^{-2}$) × 10^3
0.2 M	3.61	3.91
0.5 M	1.98	2.37
1.0 M	1.85[c]	3.60[c]

[a] Stirrer speed = 308 r.p.m. [b] Surface area of pellet exposed to dissolution medium was ~1.271 $cm.^2$. [c] For data within the period of 96–192 hr. only.

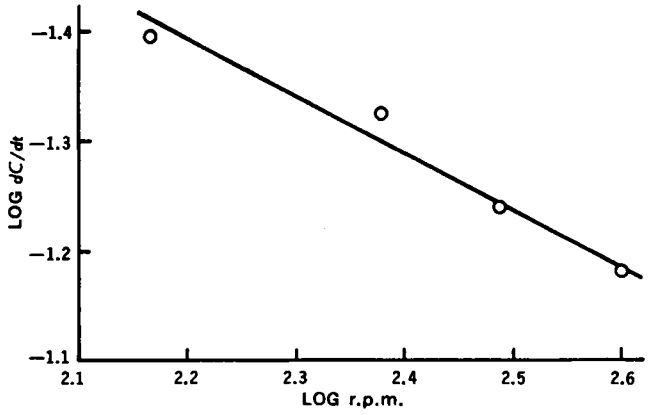

Figure 11—*Log-log plot of triamcinolone acetonide dissolution rate in distilled water* versus *stirrer speed (r.p.m.).*

where C_s and C are the concentrations of a saturated solution of the solute and of a solution of the solute at time t, respectively; k' is the intrinsic dissolution rate constant; A is the surface area of the solid exposed to the dissolution medium; D is the diffusion coefficient of the solute in the dissolution medium; V is the volume of the solution; and h is the diffusion layer thickness. The integrated Noyes–Whitney plot of the dissolution data is shown in Fig. 10. The dissolution rates and dissolution rate constants for triamcinolone acetonide in distilled water at 28° are given in Table III.

The influence of agitation intensity in the unbaffled system employed in this study is quite evident. Cooper and Kingery (10) showed that dissolution from a rotating-disk face is proportional to the square root of angular velocity, ω, *i.e.:*

$$dC/dt = K\omega^{1/2} \qquad \text{(Eq. 4)}$$

where K is a proportionality constant. If the angular velocity is given in revolutions per minute and if Eq. 4 is transformed logarithmically, then:

$$\log (dC/dt) = \log K + {}^1/_2 \log \text{r.p.m.} \qquad \text{(Eq. 5)}$$

A double logarithmic plot of dC/dt as a function of stirrer speed should yield a straight line with a slope of 0.5. Linear regression analysis of the data depicted in Fig. 11 indicates a slope of 0.515, with a correlation coefficient of 0.981.

The evaluation of steroid solubility in potassium chloride solutions as a function of time under sink conditions was only determined at speed 7 (~308 r.p.m.), since vortex formation tended to occur in this system at higher speeds. A plot of the data in accordance with the integrated Noyes–Whitney equation is shown in Fig. 12. The data, however, are not at all indicative of adherence to Eq. 3, since a zero ln $[C_s/(C_s - C)]$ intercept at $t = 0$ is not obtained. Rather, a lag in dissolution is apparent, particularly for dissolution in 1.0 M potassium chloride solution. Dissolution rates and dissolution rate constants for the steroid at speed 7, as a function of potassium chloride concentration, are given in Table IV.

The data for solubility and dissolution appear to be reasonable in view of the most reliable data available to date (3) and in view of the results of linear regression analysis of Beer's plots which yielded correlation coefficients of 0.9985 to 0.9998 for the systems employed. Additional work is underway involving the synthesis of ^{14}C-labeled triamcinolone acetonide. Isotopic methods will be employed to measure its solubility in comparison with the data reported here.

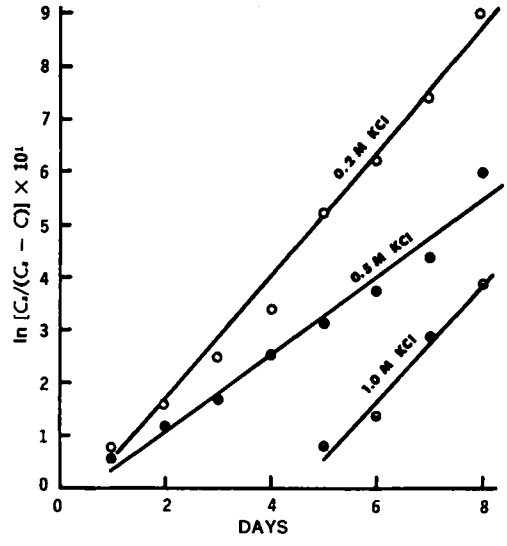

Figure 12—*Triamcinolone acetonide dissolution in potassium chloride solutions at speed 7 (308 r.p.m.) and 28°, plotted in accordance with the integrated form of the modified Noyes–Whitney equation.*

Preformulation Studies I: Molindone Hydrochloride

J. DUDZINSKI, L. LACHMAN, E. SHAMI, and J. TINGSTAD▲

Abstract □ Preformulation studies on molindone hydrochloride, a dihydroindolone tranquilizer, are described. A TLC assay is outlined, degradation products are identified, and results of stability studies are presented. The dissociation constant is estimated using pH determinations.

Keyphrases □ Molindone hydrochloride—preformulation assay development, identification of degradation products, stability, and estimated dissociation constant □ Preformulation assay development, identification of degradation products, stability, and estimated dissociation constant—molindone hydrochloride □ Drug development, preformulation studies—assay development, identification of degradation products, stability, and estimated dissociation constant

This series of articles will present examples of preformulation studies that attain a proper balance between exhaustive quantitative experiments and those that are only semiquantitative. Studies of this type should consider the overall time-economic factors present in new drug development. This paper is concerned with assay development, identification of degradation products, stability studies, and an estimation of the dissociation constant for a dihydroindolone tranquilizer, molindone hydrochloride [3-ethyl-6,7-dihydro-2-methyl-5-(morpholinomethyl)indol-4(5*H*)-one hydrochloride].

EXPERIMENTAL

Selection of Assay—Molindone hydrochloride has UV absorption peaks at 255 and 299 nm., which can be used to determine quantitatively the pure drug substance. However, preliminary studies indicated that obvious chemical degradation (as evidenced by color and precipitate formation) was not accompanied by a concomitant decrease in UV absorption. This showed that degradation products absorb significant amounts of light at these wavelengths and necessitate a separation procedure prior to the determination of UV absorbance. TLC was selected as the separation procedure; the general technique described by Spencer and Beggs (1) was used, with some modifications.

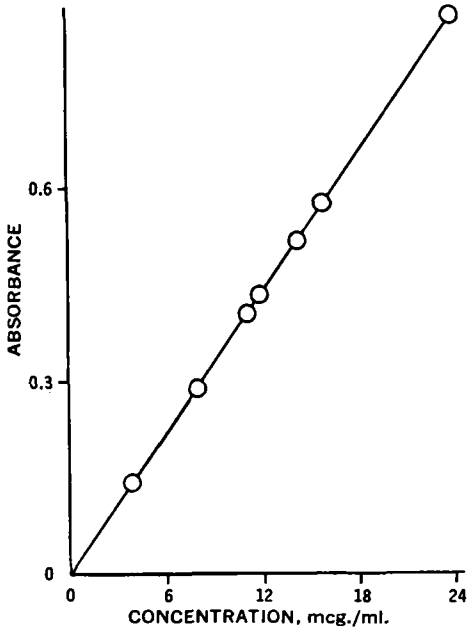

Figure 1—*Standard Beer's law plot for molindone hydrochloride at 255 nm.*

Development of TLC System—Precoated silica gel plates[1] were employed; the developing solvent system was butanol–methanol–1 *N* HCl (85:10:5). Drug solutions (either freshly prepared or degraded by heat[2] or light) were spotted with previously calibrated disposable pipets. The system was then developed for 10 cm. in a sealed glass jar lined with saturated filter paper. Inspection under shortwave UV light provided initial qualitative analysis.

Quantitative TLC Separation and UV Analysis—From 20 to 40 μl. of the solution to be assayed (representing 100–600 mcg. of drug) was applied to the plate and developed as already outlined. The plate was then dried and examined under shortwave UV light; the area containing the drug was removed from the plate with a razor blade and quantitatively transferred to a syringe fitted with a Millipore filter holder containing a 0.22-μ filter. The silica gel was washed in the syringe with four 5-ml. portions of 0.1 *N* HCl; the washings were then filtered directly into a 25-ml. volumetric flask. The solution was brought to volume with 0.1 *N* HCl (also passed through the filter) and read at 255 nm. against 0.1 *N* HCl. A 0.1 *N* HCl blank was subjected to the same treatment.

Preparation of Standard Curve—Because complete recovery of drug from silica gel is seldom accomplished, it was necessary to construct a standard curve. Solutions of molindone hydrochloride were freshly prepared in distilled water at concentrations of 0.5, 0.7, 0.9, and 1.0% and subjected to the described quantitative TLC separation and UV analysis. Each determination was done in quadruplicate.

Determination of Adsorption Isotherm—Results from the standard curve data confirmed that extraction of the drug from silica gel was not complete. Consequently, an adsorption isotherm for this system was constructed to determine whether the amount of drug lost was constant. The average amount of silica gel scraped off the plate (119.5 mg.) was added to standard solutions of molindone hydrochloride (100, 200, 300, 400, and 600 mcg./25 ml.). The flasks were then shaken for 5 min. and filtered through a 0.22-μ filter. The absorbance of each solution was determined at 255 nm. against a silica gel-treated blank. No effort was made to control temperature carefully; this procedure would correspond to the conditions present during the assay.

Identification of Degradation Products—The additional spots from the TLC treatment of degraded solutions were sprayed with test solutions (see *Results and Discussion*) to indicate the chemical nature of the degradation products. In addition, the brown precipitate found in degraded samples was collected and decolorized by dissolving in acetone–methanol (50:50) and treating with activated charcoal. After evaporating the filtered solution to dryness, the residue was recrystallized from methanol. Identification was made by comparison with a known compound and by elemental (C, H, N) analysis.

Stability Studies—The stability of molindone hydrochloride (in solution and in dosage forms) was investigated in the usual manner. Constant-temperature baths were used for studies on the drug substance, while ovens were used for dosage forms.

Determination of Dissociation Constant—The dissociation constant of molindone was estimated by the procedure described by Stern *et al.* (2). Molindone hydrochloride (0.001 or 0.0006 mole) was added to 450 ml. of recently boiled, distilled water. Two milliliters of 0.1 *N* NaOH was added, along with sufficient sodium chloride

[1] Brinkmann HF 254, 250 μ, with fluorescent indicator.
[2] All samples in this report, other than light-degraded ones, were protected from light.

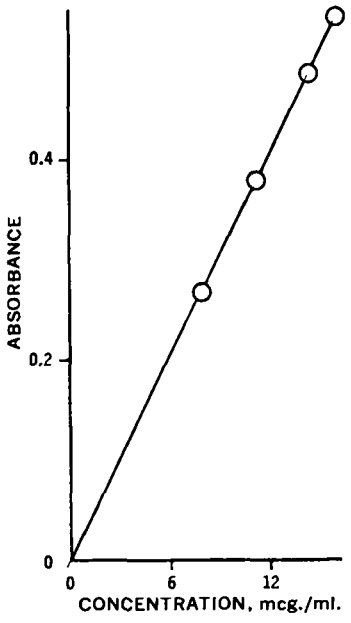

Figure 2—*Standard curve for TLC assay of molindone hydrochloride.*

to bring the ionic strength to 0.2; then the solution was made up to 500 ml. with recently boiled, distilled water. The pH of the solution at 25° was immediately measured using an expanded scale pH meter[3].

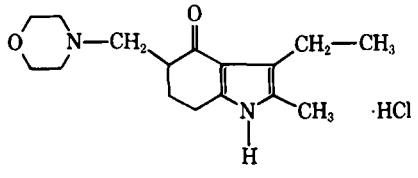
RESULTS AND DISCUSSION

TLC of Freshly Prepared Solutions—Two spots with R_f values of 0 and 0.5 are visible under shortwave UV light. The R_f 0.5 spot stains blue with iodoplatinate reagent (I, specific for heterocyclic nitrogen), stains blue with modified Ehrlich's reagent (II, specific for the indole ring), and exhibits a green fluorescence under longwave UV light after spraying with Prochazka reagent (III, specific for the indole ring); all of these results indicate the presence of molindone. The R_f 0 spot is very faint and does not respond to any of the spray treatments.

TLC of Heat-Degraded Samples—Molindone samples, whether heat degraded in the solid state or in aqueous solution, produce four spots visible under shortwave UV light. The R_f 0 spot does not stain with any of the three reagents. The R_f 0.24 spot (faint) yields a blue color with I and a faint blue color with II, and it produces a faint green fluorescence under longwave UV light in the presence of III. The R_f 0.5 spot produces a blue color with I and a strong blue color with II, and it reacts positively to III. The R_f 0.79 spot does not react with I but yields a faint blue reaction to II and III.

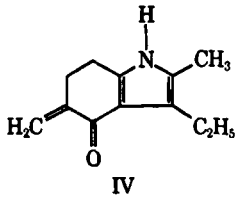
TLC of Light-Degraded Samples—Light-degraded samples of molindone, whether solid or aqueous solutions, show three spots with R_f values of 0, 0.24, and 0.5. These spots react in the same way as the corresponding spots of heat-degraded molindone; however, no R_f 0.79 spot is present in this case.

Quantitative Assay Results—A standard Beer's law plot appears in Fig. 1 (absorptivity with 1-cm. cell = 36.00 ml./mg.). The standard curve for the TLC assay is shown in Fig. 2 (slope = 34.00 ml./mg.). Based upon the slopes of the least-squares lines in Figs. 1 and 2, the average recovery in the standard curve data was 94.5%. To check the validity of the standard curve, nine determinations with known concentrations of drug were performed, reading the calculated concentrations off the standard curve. The average figure



molindone hydrochloride

[3] Corning.



IV

was 98.7% with a standard deviation of 0.23%, indicating that the assay procedure was valid.

Determination of Adsorption Isotherm—The adsorption isotherm for the silica gel–molindone hydrochloride system is shown in Fig. 3. The slope of the line is 33.50 ml./mg., which is in excellent agreement with the 34.00 value obtained for the standard curve. This indicates that a constant percentage of the amount of drug present is recovered from the silica gel; hence, it is valid to use the standard curve in assaying samples (initial and stability) of molindone hydrochloride. It should be mentioned at this point that no drug was adsorbed by the filters used in the assay procedure.

Identification of Degradation Products—Chemically, molindone hydrochloride is 3-ethyl-6,7-dihydro-2-methyl-5-(morpholinomethyl)indol-4(5*H*)-one hydrochloride. From the TLC studies, the R_f 0.5 spot was identified as molindone hydrochloride, staining with Reagent I (specific for heterocyclic nitrogen, *i.e.*, the morpholine substituent) and Reagents II and III (specific for the indole ring). The staining behavior of the R_f 0.79 spot, present in the heat-degraded samples but absent in the light-degraded material, indicated that the indole structure was present (positive II and III) but the morpholine substituent was not (negative I). This suggests an amine elimination reaction similar to that reported by Koshy and Mitchner (3), yielding morpholine and the following compound: 3-ethyl-6,7-dihydro-2-methyl-5-methyleneindol-4(5*H*)-one (IV), used in the synthesis of molindone.

Confirmation that the R_f 0.79 spot is, in fact, Compound IV was accomplished by comparing the recrystallized precipitate from heat-degraded samples with a known sample. The melting points coincided (known 217.5–219° *versus* unknown 218–219°), as did their UV and IR spectra. TLC treatment of the two yielded R_f values of 0.80 and 0.79, and the staining properties were identical with each other and with the aforementioned 0.79 spots. Finally, the elemental analysis of the precipitate yielded the following results.

Anal.—Calc.: C, 76.15; H, 7.99; N, 7.40. Found: C, 76.05; H, 8.12; N, 7.59.

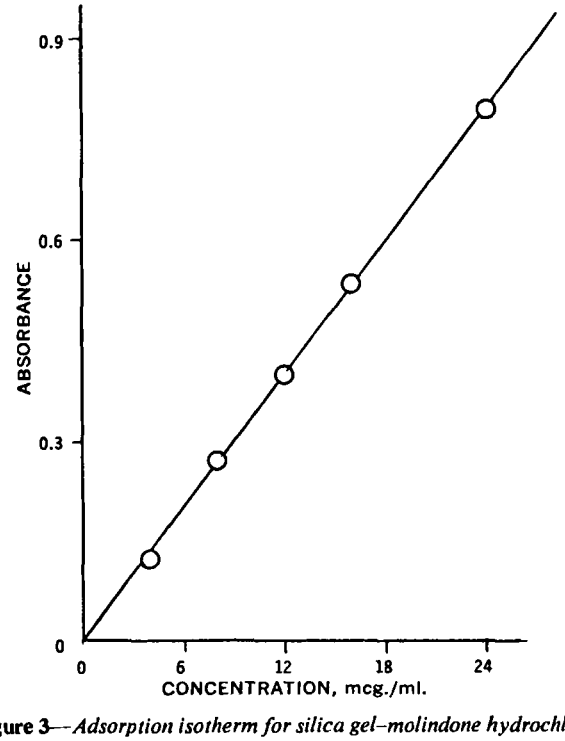


Figure 3—*Adsorption isotherm for silica gel–molindone hydrochloride at room temperature.*

Table I—Pseudo-First-Order Rate Constants and Half-Lives for Molindone Hydrochloride Degradation at Various Temperatures and pH's

pH	Temperature	k, day^{-1}	Half-Life, days
1.24	50°	0.0051	136
1.46	50°	0.0056	124
1.86	50°	0.0044	157
2.24	50°	0.0045	154
1.23	60°	0.0161	43
1.47	60°	0.0140	50
1.86	60°	0.0128	54
2.22	60°	0.0140	50

Trace amounts of this degradation product could be detected on the plates (R_f 0.79) by spraying with 0.5% potassium ferricyanide in a 10% aqueous solution of ferric chloride. While this reagent is not specific (it will react with most substances that are easily oxidized), it is very sensitive and stains the R_f 0.79 spot blue when the amount of the degradation product is too small to be detected by any of the aforementioned methods including UV light.

The R_f 0.24 spot probably represents oxidation products of molindone (4); the morpholine substituent probably hydrolyzes open and is not visible on the developed TLC plates. Because the work on the 0.79 spot indicated the nature of the primary degradation reaction, no definitive experiments were performed on the 0.24 spot.

Stability Studies—While time did not permit a complete investigation of molindone's stability to heat, light, oxygen, and pH, sufficient preformulation studies were conducted to point the way to successful formulation conditions. Fortunately, color development could be used as a semiquantitative end-point to determine the effect of light, oxygen, and pH on the drug in solution. Results from these studies indicated that molindone was susceptible to light degradation and oxidation; these conclusions were confirmed by the TLC studies. Brief semiquantitative experiments indicated that the usual protection from light (amber containers) and oxygen (inclusion of an antioxidant) was sufficient to prevent color formation; subsequent studies concentrated on the effect of pH, buffer species and concentration, and heat.

Because of various formulation restrictions, including solubility, taste (oral liquids), and tissue irritation (injectables), it was desirable to formulate solutions of the drug between pH 3 and 5. When using color formation as a rough indicator, it was found that a pH range of 2.8–3.5 was most desirable from a stability standpoint. With this preliminary information, the following quantitative experiments were performed.

To show the effect of high concentrations of hydrogen ion on stability, four different aqueous solutions (0.1%) of molindone hydrochloride (pH adjusted to 1.2–2.2 with hydrochloric acid and ionic strength held constant with sodium chloride) were stored at 50 and 60° and assayed periodically. The results (Table I) indicated that: (*a*) the reaction (first order) was not particularly sensitive to hydrogen ion, and (*b*) the drug was relatively stable, having a half-life of about 140 days at 50° in this pH range. From these and subsequent experiments, the heat of activation was estimated to be in the "normal" range of about 20 kcal./mole.

To show the effect of buffer species and concentration and to determine whether the pH 3 or 5 area was more desirable, three solutions (A, pH 5.0, 0.167 *M* citrate buffer; B, pH 5.0, 0.333 *M* citrate buffer; and C, pH 3.5, 0.333 *M* citrate buffer, all at constant ionic strength) were stored at 70° and assayed periodically. The results (Fig. 4) confirmed the first-order nature of the reaction and indicated that: (*a*) the drug was about four times more stable at pH 3.5 than at 5.0, and (*b*) the reaction was catalyzed by citrate. No additional spots appeared on the TLC plates, eliminating the possibility of a molindone–citrate reaction as might be suspected from the work of Higuchi and Miki (5). Similar results were obtained with bitartrate and phosphate buffers (still keeping ionic strength constant). Because of these results and because unbuffered solutions of molindone hydrochloride remain at a relatively constant pH with respect to time, no further attempts at buffering solutions of the drug were made.

As a result of these experiments, formulation of solution dosage forms (oral and parenteral) was relatively routine; the stability of the resulting formulations was satisfactory. Preformulation work also included testing the stability of the drug with various tableting excipients. As expected from the pH–stabilty studies in solution, basic materials (*e.g.*, dicalcium phosphate) proved to be unacceptable while acidic components (*e.g.*, calcium sulfate) were acceptable.

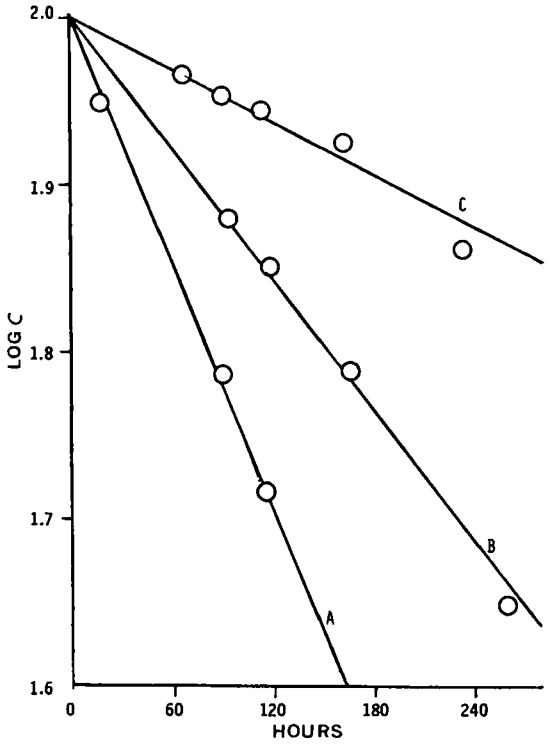

Figure 4—*First-order plot of molindone hydrochloride degradation at 70°. Key: A, pH 5.0, 0.167 M citrate buffer; B, pH 5.0, 0.333 M citrate buffer; and C, pH 3.5, 0.333 M citrate buffer.*

Determination of Dissociation Constant—The pKa of molindone was estimated to be 6.89 (using 0.001 mole of drug) and 6.76 (using 0.0006 mole of drug). As Stern *et al.* (2) pointed out, the values of the dissociation constant obtained with this method are "semi-classical," since the hydrogen ion is expressed in activity units and the other figures in concentration units. The usefulness of this method for estimating dissociation constants is shown by the fact that subsequent determination of pKa by potentiometric titration in water–dioxane mixtures (then extrapolating to zero dioxane concentration), according to the method of Van Uitert and Haas (6), yielded a value of 6.94.

CONCLUSION

The information presented provides a good example of preformulation studies that lead to meaningful semiquantitative and accurate quantitative results useful in product formulation.

Colorimetric Determination of Aromatic Compounds by Hydroxylation

KENNETH S. ALBERT and KENNETH A. CONNORS▲

Abstract □ Aromatic hydroxylation has been developed into a widely applicable analytical method for aromatic compounds. A modified Hamilton hydroxylating system, consisting of hydrogen peroxide, ferric ion, catechol, and glucose, converts aromatic compounds to phenols, which are measured colorimetrically after oxidative coupling with 4-aminoantipyrine. The method is applicable to 10^{-4}–10^{-3} *M* aqueous solutions of many substituted benzene derivatives, linear absorbance–concentration plots being obtained with apparent molar absorptivities in the range of 1–5 × 10^3. The method has been applied to numerous aromatic drugs. Many common tablet excipients do not interfere at normal formulation levels. As one of the few methods available for the detection of the phenyl group, this technique has the advantages and limitations of a general functional group method.

Keyphrases □ Aromatic compounds—hydroxylation, colorimetric determination after oxidative coupling with 4-aminoantipyrine □ Hydroxylation of aromatic compounds—modified Hamilton system (hydrogen peroxide–ferric ion–catechol–glucose), colorimetric determination after coupling with 4-aminoantipyrine □ Phenyl group determination—modified Hamilton hydroxylation, colorimetry after oxidative coupling with 4-aminoantipyrine □ Colorimetry—determination of aromatic compounds, hydroxylation followed by oxidative coupling with 4-aminoantipyrine

A method (Scheme I) for the quantitative determination of aromatic compounds was recently described (1). An aromatic compound is converted to a phenol by the action of the Hamilton hydroxylating system (2–4), consisting of hydrogen peroxide and catalytic amounts of ferric ion and catechol; this system was modified by the incorporation of a cyclodextrin. After hydroxylation, the product phenol is oxidatively coupled with 4-aminoantipyrine for spectrophotometric measurement (5–7). Many benzene derivatives were determined in this manner (1).

Significant improvements have now been made in this aromatic hydroxylation method. The present paper describes the basis for these improvements and the application of the new method to numerous compounds of pharmaceutical interest.

EXPERIMENTAL

Materials—The following chemicals were used as received: ferric perchlorate hexahydrate[1], potassium ferricyanide[2], ethyl acetate[3], acetone[3], chloroform[3], methanol[3], benzene[3], toluene[3], isopropyl alcohol[3], benzoic acid[3], phenol[3], glucose[3], aniline[3], 30% hydrogen peroxide[3], lactose[3], stearic acid[3], benzaldehyde[3], nitrobenzene[3], hydroquinone[3], sorbitol[4], acetonitrile[4], dioxane[4], talc[5], starch[6], 4-aminoantipyrine[7], *N,N*-dimethylformamide[8], Schardinger α- and β-dextrins[9], L-phenylalanine[10], L-tryptophan[11], quinine sulfate[4], *m*-cresol[8], *p*-cresol[8], *m*-chlorophenol[8], *m*-hydroxyacetophenone[8], chloramphenicol[12], benzocaine[13], phenacetin[12], *d,l*-mandelic acid[12], antipyrine[12], *d,l*-ephedrine hydrochloride[8], benzenesulfonamide[7], sulfanilamide[8], atropine sulfate, and chlorpheniramine maleate. Anisole[7] was found to be gas chromatographically pure (10% SE-30, 165°).

Catechol[13] was recrystallized twice from toluene, m.p. 103–104° [lit. (8) m.p. 104°]; hydrocinnamic acid[8] was recrystallized from petroleum ether, m.p. 47–48° [lit. (9) m.p. 47.5–48°]; benzamide[8] was recrystallized from water, m.p. 125.5–127° [lit. (10) m.p. 125–126°]. The three methoxybenzoic acids were recrystallized from water: *o*-methoxybenzoic acid, m.p. 98.5–100° [lit. (10) m.p. 99–101°]; *m*-methoxybenzoic acid, m.p. 104.5–105° [lit. (10) m.p. 104–105°]; and *p*-methoxybenzoic acid, m.p. 183–184° [lit. (11) m.p. 184°].

N-Methylbenzylamine[8] was distilled at reduced pressure, b.p. 71°/2 mm. Hg [lit. (12) b.p. 78°/14 mm. Hg]; methyl benzoate[8] was distilled, b.p. 199.6° [lit. (13) b.p. 200°]; ethylbenzene[8] was distilled, b.p. 135° [lit. (14) b.p. 135°]; benzyl alcohol[8] was distilled at reduced pressure, b.p. 70°/15 mm. Hg [lit. (15) b.p. 104–105°/20 mm. Hg]; *o*-cresol[8] was distilled, b.p. 191–192° [lit. (16) b.p. 192°]; guaiacol[8] was distilled at reduced pressure, m.p. 28° [lit. (17) m.p. 27.4°]; *p*-methoxyphenol[8] was distilled under reduced pressure, m.p. 53° [lit. (18) m.p. 53°]; and salicylaldehyde[8] was distilled at reduced pressure, b.p. 65–66°/2 mm. Hg [lit. (19) b.p. 197°/760 mm. Hg].

Salicylic acid[8] was recrystallized from methanol–water, m.p. 159–160° [lit. (20) m.p. 158°]; *m*-hydroxybenzoic acid[8] was recrystallized from water, m.p. 200° [lit. (21) m.p. 202°]; *p*-hydroxybenzoic acid[8] was recrystallized from xylene–ethanol, m.p. 213–214° [lit. (22) m.p. 212–213°]; *o*-aminophenol was recrystallized from toluene–methanol, m.p. 174.5–176° [lit. (23) m.p. 171°]; *m*-aminophenol was recrystallized from toluene–methanol, m.p. 122–123° [lit. (24) m.p. 123°]; *o*-nitrophenol[8] was recrystallized from ethanol, m.p. 44.5–45° [lit. (25) m.p. 45°]; *m*-nitrophenol[8] was recrystallized from aqueous hydrochloric acid, m.p. 95–96° [lit. tropic acid was recrystallized from benzene, m.p. 116–117° [lit. (34) m.p. 116–117°].

Standard buffers were prepared according to Bates (35). Water was purified by passing once-distilled water through an ion-exchange column[15]. Acetate buffer (pH 4.0), in which hydroxylation reactions were run, was prepared to be 5×10^{-3} *M* in total buffer concentration and 0.1 *M* in ionic strength; ionic strength was adjusted with potassium chloride. Borate buffer, used to quench the hydroxylation reaction and as the color development medium, was prepared to be 0.4 *M* in total boric acid and 0.2 *M* in sodium hydroxide. Hydrogen peroxide (3%) was prepared by dilution of the 30% solution and was standardized by titration with potassium permanganate. Aqueous catechol solutions (3×10^{-3} *M*) were stored in the dark. Ferric perchlorate stock solution (1.5×10^{-2} *M*) was stabilized by adding 1 drop of 60% perchloric acid/50 ml. of solution. Ferric perchlorate reagent solution (1.5×10^{-3} *M*) was prepared by diluting the stock solution.

Apparatus—Spectrophotometric measurements were made in spectrophotometers[16] equipped with thermostatted cell compartments. The pH measurements[17] were made at 25.0°. Reaction temperatures were maintained to ±0.1° with constant-temperature water baths. Thermometers were calibrated against thermometers carrying either an NBS or an ASTM certificate.

Procedures—*Analytical Method*—To a 25-ml. volumetric flask are added 1.0 ml. of 3×10^{-3} *M* aqueous catechol, 1.0 ml. of 1.5×10^{-3} *M* ferric perchlorate, 5.0 ml. of 1.8×10^{-2} *M* glucose, and enough of the aromatic sample compound such that its concentration in the diluted solution is in the range of 10^{-4}–10^{-3} *M*. The solution is diluted to the mark with pH 4.0 acetate buffer, and the pH of the final solution should be in the range of 3.5–4.0.

The flask is placed in a 75° water bath, and reaction is initiated by adding 0.1 ml. of 3% hydrogen peroxide solution. After 10 min., a 5.0-ml. aliquot is pipeted into 5.0 ml. of borate buffer. The color is developed by adding 0.1 ml. of 3% (w/v) aqueous 4-aminoantipyrine followed by 0.1 ml. of 10% (w/v) aqueous potassium ferricyanide. The absorbance is measured immediately at the absorption maximum against a reagent blank carried through the same procedure. A standard curve is prepared by subjecting known concentrations, bracketing the unknown concentration, of the same aromatic compound to the procedure.

Chloroform Extraction Method—To achieve greater sensitivity or to circumvent fading of the color with some compounds (discussed later), substances giving a neutral extractable coupling product can be determined as follows. After hydroxylation is complete, 15.0 ml. of the reaction mixture is transferred to a 60-ml. separator containing 10 ml. of borate buffer. To this is added 0.1 ml. of 3% 4-aminoantipyrine, about 4 ml. of chloroform, and then 0.1 ml. of 10% potassium ferricyanide; the mixture is shaken for about 1 min. The chloroform layer is filtered through glass wool into a 5-ml. volumetric flask. Then the separator is rinsed with an additional 0.75 ml. of chloroform, which is added to the first chloroform extract, and this solution is diluted to volume with chloroform. Its absorbance is measured at the absorption maximum against a reagent blank carried through the same procedure.

Optimization Studies—During the development of the proposed method, many system variables were investigated including time, temperature, pH, concentrations and ratios of concentrations of reactants, other colorimetric finishes, other "stabilizers" (see *Discussion*), and interferences. These studies were carried out in much the same manner as described under *Analytical Method*, with appropriate variation in the feature being studied.

RESULTS

Unmodified Hamilton System—When catechol is subjected to the 4-aminoantipyrine colorimetric method, no significant interference is observed at wavelengths used for monohydric phenols. This lack of interference makes the 4-aminoantipyrine method the finish of choice. It is, therefore, possible to carry out the color development directly in the hydroxylation solution.

Table I—Effect of Reagent Age on Yield in Hydroxylation of Anisole[a]

Age of Hamilton System before Addition of Anisole, min.	A_{500}[b]
0	0.461
5	0.429
10	0.317
15	0.230
30	0.205
60	0.146
120	0.068
120[c]	0.461
180	0.012
180[d]	0.036

[a] 5.36×10^{-4} *M* anisole, 5.90×10^{-5} *M* Fe(III), 1.17×10^{-4} *M* catechol, 1.06×10^{-3} *M* H_2O_2, pH 3.9, 25°, 1-hr. reaction time. [b] 4-Aminoantipyrine finish. [c] Additional catechol (1.17×10^{-4} *M*) and H_2O_2 (1.06×10^{-3} *M*) added at this time. [d] Additional H_2O_2 (1.06×10^{-3} *M*) added at this time.

Dependence of Yield on Peroxide–Substrate Ratio—Typical initial reactant concentrations employed by Hamilton *et al.* (3, 4) were catechol, 1.5×10^{-4} *M*; Fe(III), 4×10^{-5} *M*; hydrogen peroxide, 2×10^{-3} *M*; and substrate, 10^{-2} *M*. The reaction was followed by monitoring the loss of peroxide. As an analytical reagent, however, the hydrogen peroxide in the Hamilton system must be in excess of the aromatic substrate (sample). With these more practical conditions, the yield of phenolic product, as reflected by the absorbance from the 4-aminoantipyrine-coupled product, was markedly dependent upon time of reaction and initial ratio of peroxide to substrate. Moreover, when phenol was substituted for an aromatic substrate in such a system, hydroxylation occurred as shown by the absorbance decrease.

Figure 1 shows the time course for the hydroxylation of anisole. At initial ratios of peroxide–anisole much greater than 2, production and then loss (by further hydroxylation) of monohydroxyanisoles are evident. When this ratio is about 2 or less, stable absorbance values are obtained after 1–2 hr.; however, the yield is sharply dependent upon this ratio, being depressed as the ratio is decreased. In a practical analytical situation, this ratio is not known and cannot be controlled. Under such conditions (namely $[H_2O_2]_0$ is constant and $[\text{anisole}]_0$ is variable), the percent yield of phenolic product depends upon the sample concentration, and a Beer's law plot with curvature is observed. The direction of curvature depends upon the $[H_2O_2]_0$–$[\text{substrate}]_0$ ratio, being negative if this ratio is 2 or less and positive for values greater than 2.

Dependence of Yield on pH, Catechol, and Iron—Initial experiments revealed measurable but small differences in yield between studies carried out under nitrogen and in the presence of air. Most subsequent work was done with an air environment.

Studies of yield (in these, as in other experiments unless otherwise noted, it is to be understood that yields are based upon absorbance values of the 4-aminoantipyrine-coupled products) established optimal conditions for several system variables when $[H_2O_2]_0$–$[\text{anisole}]_0$ was held at about 2 so as to give stable yields. The yield was found to be essentially independent of pH in the range of 3.5–4.2. The optimum concentration of catechol is about 1.2×10^{-4} *M*, and the optimum ratio of Fe(III) to catechol is 0.5, although the yield is not very sensitive to this ratio[18]. These optimum conditions were incorporated into the recommended analytical method.

Aging of Hamilton System—Catechol, which is itself an aromatic, should be hydroxylated, possibly altering its catalytic effectiveness as well as depleting peroxide. This anticipated aging phenomenon is demonstrated in Table I, which shows that the time of addition of substrate to a pre-prepared Hamilton system affects the yield of hydroxylated product. When additional catechol plus peroxide is added, the yield returns to its expected value, but addition of peroxide alone does not restore the yield. These observations were used in designing the analytical method, the reaction being initiated by adding peroxide, that is, by completing the Hamilton hydroxylating system.

[18] Data substantiating these and other findings were reported elsewhere (36).

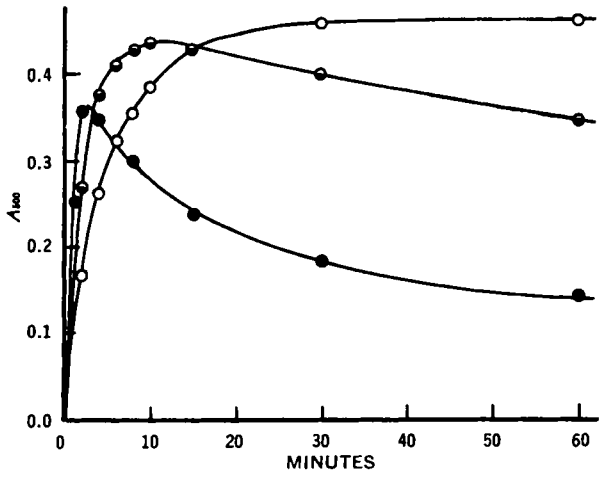

Figure 1—*Change of absorbance with time (4-aminoantipyrine finish) for hydroxylation of anisole at 25° (nitrogen atmosphere). Initial conditions: 5.26 × 10⁻⁴ M anisole, 4.26 × 10⁻⁵ M Fe(III), 1.17 × 10⁻⁴ M catechol, pH 3.9. Key: ○, $[H_2O_2]_0$–$[anisole]_0$ = 2.3; ◒, 4.7; and ●, 23.6.*

Cyclodextrin-Modified Hydroxylating System—Figure 1 shows that under analytical conditions, where the hydrogen peroxide in the Hamilton system is in large excess of the aromatic sample compound, hydroxylation continues beyond the introduction of the first hydroxy group. This phenomenon reduces the attractiveness of the Hamilton system as an analytical reagent.

The hypothesis was conceived that a cyclodextrin (ring compounds of 1,4-linked D-glucose monomers) might have a differential rate effect on the sequential hydroxylation steps as a consequence of its capability of forming inclusion complexes with aromatic compounds (37, 38). Figure 2 shows the time course for the hydroxylation of benzene in the presence and absence of cyclodextrins at an initial peroxide–substrate ratio of 6.75. Evidently the cyclodextrins have a profound stabilizing effect. About 10^{-3} *M* cyclodextrin gives an optimum effect; too high a concentration results in depressed yields. Under the conditions given in Fig. 2, a linear Beer's law plot was obtained for benzene[19] over a concentration range corresponding to initial peroxide–benzene ratios of 3.15–31.5. Incorporation of a cyclodextrin, therefore, provides a satisfactory analytical method.

This method was successfully applied to 15 mono- and disubstituted benzenes, using 1–2-hr. reaction times at 25° (1). Its extension to some drugs and related compounds is shown in Table II. Chlorpheniramine and benzalkonium chloride gave standard curves with marked negative curvature. Benzocaine could not be determined because the product precipitated from solution. The phenobarbital standard plot showed positive curvature. No significant interference (p = 0.05) was observed by tablet excipients in the determination of acetanilid[20]; the mixture contained 35 mg. acetanilid, 100 mg. lactose, 10 mg. starch, 10 mg. talc, and 2 mg. stearic acid.

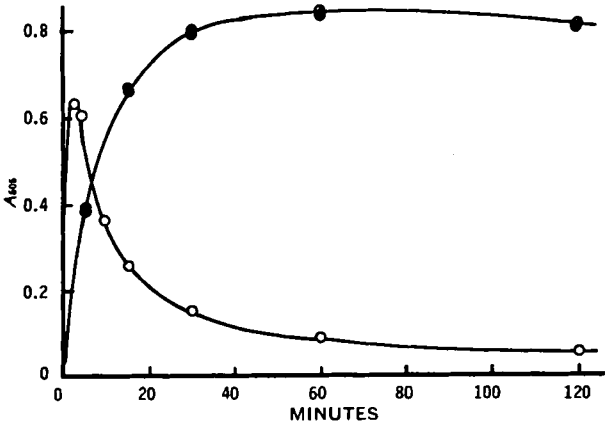

Figure 2—*Change of absorbance with time (4-aminoantipyrine finish) for hydroxylation of benzene at 25°. Initial conditions: 5.38 × 10⁻⁴ M benzene, 1.17 × 10⁻⁴ M catechol, 5.94 × 10⁻⁵ M Fe(III), 3.63 × 10⁻³ M H_2O_2, pH 3.7. Key: ○, no cyclodextrin; ◑, 1.13 × 10⁻³ M β-cyclodextrin; and ●, 1.26 × 10⁻³ M α-cyclodextrin.*

[19] For this substrate, an apparent molar absorptivity of 4.5 × 10^3 is obtained, corresponding to a 37% yield of phenol.

Table II—Aromatic Compounds Determined by the Cyclodextrin-Modified Hydroxylation Method[a]

Compound	Reaction Time, hr.	Analytical Wavelength, nm.[b]	10^{-3} ϵ_{app}[c]
Acetanilid	2	510	3.9
Phenacetin	1.3	490	2.7

Glucose-Modified Hydroxylating System—As a reasonable first step in determining the mechanism of stabilization by cyclodextrins, a time course for hydroxylation was carried out with the incorporation of α-D-glucose instead of cyclodextrin. Figure 3 shows the effect of glucose on the hydroxylation of acetanilid. Evidently, glucose has a stabilizing effect similar to that of cyclodextrin, although higher concentrations of glucose are required. Figure 4 is a Beer's law plot for the hydroxylation of acetanilid, showing that glucose provides a very satisfactory analytical result.

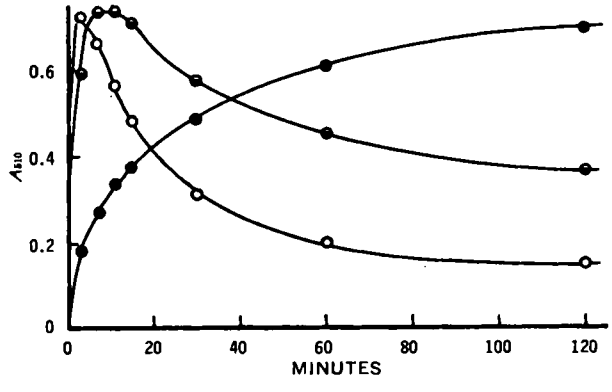

Figure 3—*Time course for hydroxylation of acetanilid (4-aminoantipyrine finish) at 25° in the presence and absence of glucose. Initial conditions: 4.70 × 10⁻⁴ M acetanilid, 1.17 × 10⁻⁴ M catechol, 5.98 × 10⁻⁵ M Fe(III), 4.13 × 10⁻³ M H_2O_2. Key: ○, no glucose; ◒, 1.26 × 10⁻³ M glucose; and ●, 1.26 × 10⁻² M glucose.*

[20] The mixture, contained in a 50-ml. volumetric flask, was shaken with 30 ml. of water for 15 min. After diluting to volume, a 2.0-ml. aliquot of the filtrate was taken for analysis.

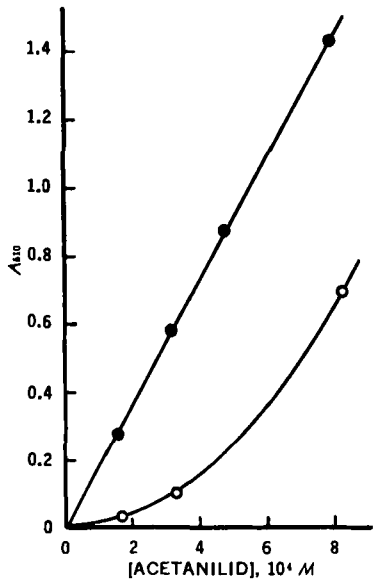

Figure 4—*Concentration–response curves for hydroxylation of acetanilid at 25° in the presence and absence of glucose. Conditions: 1.17 × 10⁻⁴ M catechol, 5.98 × 10⁻⁵ M Fe(III), 4.13 × 10⁻³ M H_2O_2; 2-hr. reaction time. Key: ○, no glucose; and ●, 7 × 10⁻³ M glucose (4-aminoantipyrine finish).*

The effect of temperature on time of hydroxylation is shown in Fig. 5. The hydroxylation reaction reaches a stable yield value after about 10 min. above 70°. At these higher temperatures, yields are slightly lower than at 25°. Moreover, the glucose concentration giving maximum yield, which was established by varying the glucose concentration and measuring the resultant absorbances, is less at higher temperatures and is mildly dependent upon the substrate[18]. At 75° the glucose concentration should be in the range of 2–5 × 10^{-3} *M* for maximal yield and for yields independent of substrate concentration. With such conditions, phenobarbital gave a linear working curve. It was found that yield is independent of catechol concentration in the range of 1–5 × 10^{-4} *M*.

Table III gives analytical results on aromatic compounds subjected to the glucose-modified hydroxylation method as described in the *Experimental* section. Linear working curves were observed for most compounds at concentrations up to 1 × 10^{-3} *M*. Chlorpheniramine showed linear behavior up to 6 × 10^{-4} *M*. Antipyrine gave a standard curve with negative curvature. Many of the Beer's law plots appear to intersect the abscissa close to the origin. This is probably a consequence of the very high peroxide–substrate ratio at low substrate concentration; it is not a serious analytical drawback.

A typical tablet formulation consisting of 65 mg. sodium phenobarbital, 26 mg. lactose, 20 mg. starch, 20 mg. talc, and 0.3 mg. stearic acid gave an average recovery of 98.4 ± 0.6% (four determinations) when compared with a standard phenobarbital solution[21]. When the lactose was increased to 200 mg. in the same formulation, a 10% decrease in response resulted. However, when the phenobarbital was extracted from the tablet formulation prior to hydroxylation, an average recovery of 98.8 ± 1.2% (four determinations) was achieved[22].

Other compounds were found to function effectively as stabilizers, although for analytical purposes they offer no advantages over glucose. The optimum stabilizer concentration depends upon the identity of the stabilizers. These approximate values were observed: lactose, 3 × 10^{-3} *M*; sorbitol, 4 × 10^{-3} *M*; acetonitrile, 0.15 *M*; isopropyl alcohol, 0.01 *M*; dioxane, 10^{-3} *M*; and acetone, 0.1 *M*.

Table III—Aromatic Compounds Determined by the Glucose-Modified Hydroxylation Procedure[a]

Compound	Analytical Wavelength, nm.[b]	$10^{-3}\ \epsilon_{app}$[c]
