Chemical Investigation of *Alhagi pseudalhagi* (Bieb.) Desv.: β-Phenethylamine and Tetrahydroisoquinoline Alkaloids

S. GHOSAL▲ and R. S. SRIVASTAVA

Abstract □ From the stems of *Alhagi pseudalhagi* (Bieb.) Desv. (Leguminosae), five β-phenethylamine and one tetrahydroisoquinoline alkaloids were isolated and characterized. On the basis of chemical transformation and spectral (UV, IR, PMR, and mass) evidence, the alkaloids were identified as β-phenethylamine (I), *N*-methyl-β-phenethylamine (II), hordenine (III), 3,4-dihydroxy-β-phenethyltrimethylammonium hydroxide (IV), *N*-methylmescaline (V), and salsolidine (VI). This is the first time that the occurrence of a 3,4,5-trioxygenated β-phenethylamine such as V has been demonstrated outside the family Cactaceae. The roots of this plant contain essentially the same alkaloids but in poorer yields. Preliminary pharmacological studies of the total alkaloids indicated that some curative properties of the plant extract are due to these entities.

Keyphrases □ *Alhagi pseudalhagi*—isolation, identification of five β-phenethylamine and one tetrahydroisoquinoline alkaloids □ 3,4-Dihydroxy-β-phenethyltrimethylammonium hydroxide—isolation, identification from *Alhagi pseudalhagi* □ Salsolidine—isolation, identification from *Alhagi pseudalhagi* □ Medicinal plants—*Alhagi pseudalhagi*, chemical investigation and pharmacological screening

Alhagi pseudalhagi (Bieb.) Desv. (syn. *A. camelorum* Fisch., *A. maurorum* Baker) (Leguminosae: Lotoidae) is a low erect shrub, widely distributed in the gangetic plains in India. The plant is bitter and acrid with a distinct flavor and finds uses in the indigenous system of medicine for a variety of purposes (1, 2). Pharmacological screening with a 50% alcoholic extract of the whole plant showed (3) antiprotozoal, spasmolytic, cardiotonic, and anticancer (sarcoma 180 in mice) activities. Previous reports (4, 5) indicated only the presence of an alkaloid in this plant. A recent investigation (6) in the authors' laboratory resulted in the isolation of a considerable amount of an alkaloid mixture from its fresh stems. Separation of these alkaloids into individual entities and identification of the major alkaloids have now been achieved.

RESULTS AND DISCUSSION

The stems and roots of *A. pseudalhagi* were separately processed for alkaloids. Gradient pH extraction (7), fractionation into phenolic and nonphenolic bases over a resin[1] column (8), precipitation of the reineckate salts under basic and acidic conditions, and their regeneration over ion-exchange resins (7, 8) resulted in the isolation of five β-phenethylamine and one tetrahydroisoquinoline alkaloids from the stems of *A. pseudalhagi*. The alkaloids are β-phenethylamine (I), *N*-methyl-β-phenethylamine (II), hordenine (III), 3,4-dihydroxy-β-phenethyltrimethylammonium hydroxide (IV), *N*-methylmescaline (V), and salsolidine (VI). This is the first demonstration of the occurrence of a 3,4,5-trioxygenated β-phenethylamine (V) outside the family Cactaceae.

In addition to the mentioned alkaloids, two partially characterized β-phenethylamine bases (one secondary and one quaternary) and a liberal amount of choline were obtained from the stems of this plant. The roots contained essentially the same alkaloids but in poorer yields.

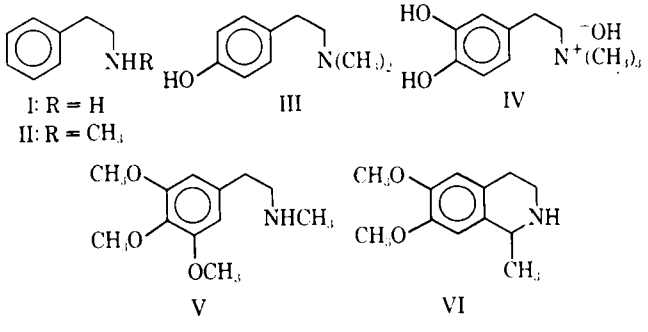
Cooccurrence of aryl-unsubstituted β-phenethylamines (I and II), the oxygenated analogs (III–V), and the cyclized compound (VI) has not been encountered before in nature. In the members of the Cactaceae, which are known to elaborate liberally 3,4,5-trioxygenated β-phenethylamines and their cyclized analogs, occurrence of mono- and dioxygenated compounds is a rare event (9). Also, aryl-unsubstituted compounds (I and II) have not been reported in the Cactaceae. These observations seem to indicate that *A. pseudalhagi* is a phylogenetically complex species, and further studies with related species in this genus are warranted.

Preliminary pharmacological studies with the total alkaloids of *A. pseudalhagi* indicated that the stimulant and expectorant properties of the plant extracts (1, 2) are due to these entities. Details of these findings will be reported soon.

EXPERIMENTAL

Extraction of Alkaloids—The principle of isolation and separation of the alkaloids involved utilization of differential solubility in solvents of graded polarity (petroleum ether, chloroform, and ethanol) in the presence and absence of fat, difference in base strengths, and phenolic and nonphenolic characters. The petroleum ether extract was kept aside for further examination for less basic constituents. The alkaloid mixtures from the ethanol extract were broadly divided into three groups (7): chloroform-soluble acetates, chloroform-soluble strong bases, and water-soluble bases. Subsequently, the alkaloids were separated into phenolic and nonphenolic bases in the usual way (8). The individual alkaloids were obtained by chromatography of the mixtures over neutral alumina[2] and preparative TLC[3] (2-mm. thickness). Monitoring of the column chromatographic runs was accomplished at each stage of purification by TLC. Two solvent systems were used as developers: Solvent 1, chloroform–methanol–concentrated ammonia (80:20:1); and Solvent 2, chloroform–methanol–acetic acid (75:15:10). Dragendorff's, tetrazotized *o*-dianisidine (8), and α-nitroso-β-naphthol–nitrous acid (10) reagents were used for staining. The identity of the homogeneous alkaloids was established by their co-TLC behavior with authentic markers (10–12), by chemical transformation into suitable derivatives where possible, and from correspondence of melting point, optical rotation, and UV, IR, PMR, and mass spectra of the alkaloids with those reported in the literature (9, 13, 14). Satisfactory combustion analyses were obtained for all reported compounds.

In a typical experiment, air-dried and milled stems of *A. pseudal-*



[1] Amberlite IRA-400.

[2] Brockmann, activity grade about III.

[3] Silica gel G, E. Merck.

hagi[4] (10.3 kg.) were processed for alkaloids. The description of the alkaloids is given here in the order of their isolation.

β-Phenethylamine (I)—Column chromatography and preparative TLC (Solvent 2) of the chloroform-soluble acetates afforded (from the upper preparative TLC zone) β-phenethylamine as a pale-brown liquid (0.18 g.) (identified by co-TLC, IR, melting point, and mixed melting point of the picrate).

***N*-Methyl-β-phenethylamine (II)**—The lower zone of the previously mentioned preparative chromatogram gave *N*-methyl-β-phenethylamine as a brown oil (72 mg.) (identified by co-TLC, IR, mass spectrometry, melting point, and mixed melting point of the picrate).

Salsolidine (VI)—Preparative TLC (Solvent 1) of the nonphenolic fraction from the chloroform-soluble strong bases furnished (from the middle zone) salsolidine as a semisolid mass (42 mg.) (identified by co-TLC, UV, IR, mass spectrometry, PMR, melting point, and mixed melting point of the base hydrochloride; $[\alpha]_D^{25}$ 0°.

***N*-Methylmescaline (V)**—From the preparative chromatogram, the lower zone of the nonphenolic alkaloid fraction afforded *N*-methylmescaline as a brown liquid (9 mg.) (identified by co-TLC, UV, and mass spectrometry). No solid derivative could be prepared due to the lack of sample. However, correspondence of spectral data (9, 13) and co-TLC behavior (Solvents 1 and 2) with an authentic synthetic sample, prepared from mescaline by treatment with formaldehyde and reduction of the anil with sodium borohydride in methanol (15), established its identity as *N*-methylmescaline.

Hordenine (III)—Column chromatography and preparative TLC (Solvent 1) of the phenolic alkaloid fraction afforded hordenine as light-brown needles (38 mg.) (identified by melting point, mixed melting point, co-TLC, UV, and melting point and mixed melting point of the methiodide).

3,4-Dihydroxy-β-phenethyltrimethylammonium Chloride/Hydroxide (IV)—The water-soluble bases, after separation of choline in the usual way (7, 16), gave two phenolic quaternary chlorides: R_f 0.11 (major) and 0.20 (minor) (Solvent 2). These were separated by preparative TLC using the same solvent system. The hydroxide of the major component, prepared by passing an alcoholic solution of the chloride through De-Acidite FF (7), readily suffered aerial oxidation. The quaternary chloride (18 mg.) showed UV λ_{max} 218, 230 (sh), and 283 nm., and $\lambda_{max}^{C_2H_5OH-NaOC^1OCH_2\text{-}H_2BO_3}$ 242 and 310 nm., characteristic of *o*-dihydroxy-β-phenethylamine chromophore (14, 17). The PMR spectrum of the quaternary chloride (in D_2O) showed signals at δ 7.1 6.3 (3H, m, unsymmetrical aromatic protons), 3.5–2.7 (4H, m, methylenes), and 3.2 (9H, s, quaternary *N*-methyl) p.p.m., which were consistent with the assigned structure. Co-TLC with an authentic sample of 3,4-dihydroxy-β-phenethyltrimethylammonium chloride, prepared from homoveratrylamine (18), established the correctness of this conclusion.

[4] The identity of the plant material was confirmed by Dr. C. S. P. Rao, Department of Botany, Banaras Hindu University. A voucher specimen has been kept at the Department of Pharmaceutics, Banaras Hindu University.

Glycyrrhetic Acid Derivatives with Modified Ring A

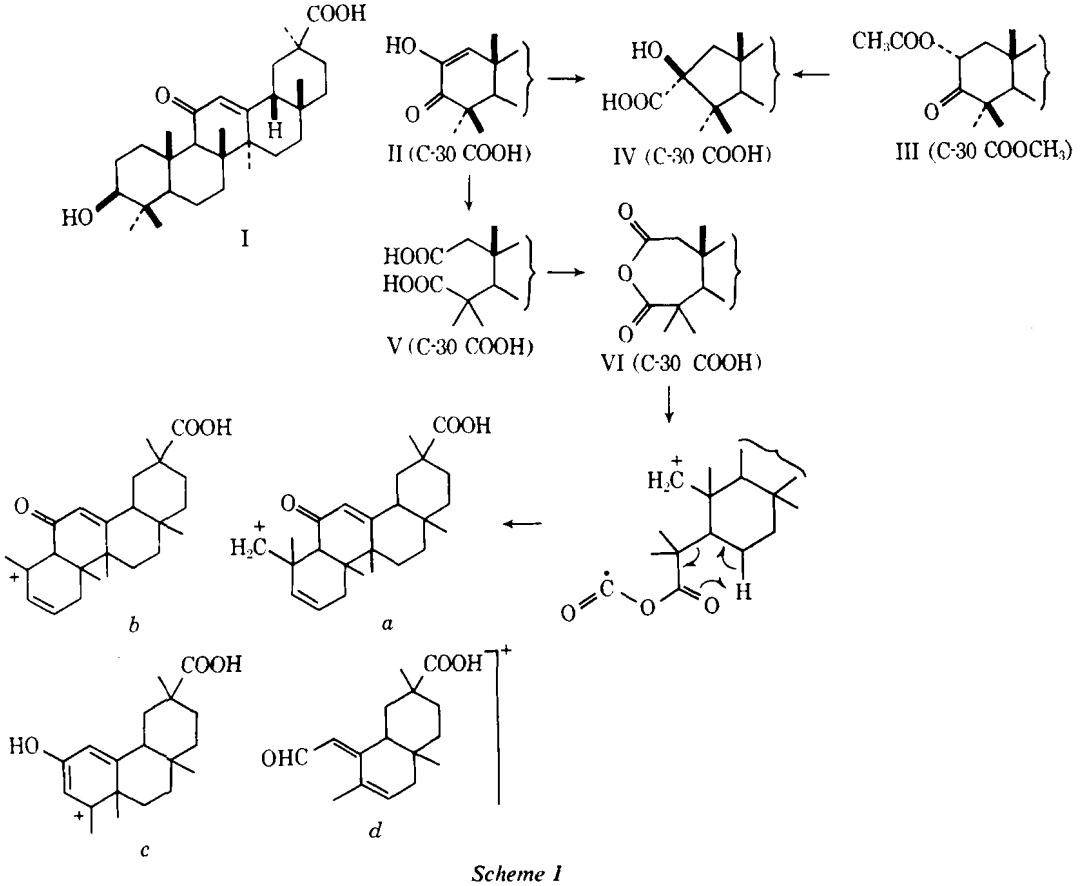
M. H. A. ELGAMAL, B. A. H. EL-TAWIL, and M. B. E. FAYEZ▲

Abstract □ Ring A in glycyrrhetic acid (a therapeutically useful triterpenoid) was modified by contraction to an A-norhydroxy-acid derivative and by cleavage to a *seco*-A-2,3-dicarboxylic acid variant.

Keyphrases □ Glycyrrhetic acid derivatives—modification of ring A □ Triterpenoid aglycones—modification of ring A in glycyrrhetic acid

Glycyrrhetic acid (I), the principal triterpenoid aglycone obtained by acid hydrolysis of licorice (*Glycyrrhiza glabra* L.) root saponins, is perhaps the only triterpenoid with an established therapeutic utility (as an anti-inflammatory agent). Of the numerous studies made to modify this compound's structure, with the object of modifying its activity, very few have been concerned with ring A of the pentacyclic system. During studies in this area, the dicarboxylic and tricarboxylic acids were obtained by ring A contraction and cleavage, respectively, and are described (Scheme I). The first resulted by benzilic acid rearrangement of the diosphenol system in 2-hydroxy-18β-oleana-1,12-dien-3,11-dion-30-oic acid (II) (1) through reaction with boiling alcoholic potassium hydroxide and by a similar treatment of methyl 2α-acetoxy-18β-olean-12-ene-3,11-dion-30-oate (III) (2). The produced A-norhydroxy-acid is tentatively assigned Structure IV, in which the indicated stereochemistry of the ring A oxygen functions follows from the mechanism of the rearrangment where attack by hydroxyl ion at either C-2 or C-3 of the diketone form of II leads to a β-orientation of the resulting hydroxyl group (3).

Oxidative cleavage of ring A between C-2 and C-3 in glycyrrhetic acid, found not to be readily manageable by treatment of the appropriate glycol systems (1) with periodate, was accomplished by reaction of the diosphenol (II) with alkaline hydrogen peroxide. The resulting 2,3-*seco*-2,3,30-tricarboxylic acid (V), giving fitting spectral data, yielded a trimethyl ester and, upon heating in acetic anhydride, the corresponding anhydride (VI). The mass spectrum of V exhibited a very weak M^+ (*m/e* 516), and all fragmentations appear to result from the $M^+ - H_2O$ ion (*m/e* 498, VI) formed as a primary product. These include ions at *m/e* 483, 465, and 437 (losses of CH_3, $H_2O + CH_3$, and $H_2O + CH_3 + CO$, respectively, from the ion *m/e* 498). Collapse of the anhydride ring A with losses of $C_5H_7O_3$ and $C_6H_9O_3$ gives ions (*m/e* 383 and 369, respectively), which may have Structures *a* and *b*, respectively, produced by a mechanism involving transfer of the hydrogen atom on C-6. The base peak of the spectrum (at *m/e* 315) appears to be the product of a dubious reaction type. The



Scheme I

familiar cleavages (4) across ring B (involving a McLafferty transfer of the C-1 hydrogen atom) and across ring C (by a retro-Diels–Alder type of reaction) are both observed giving ions at *m/e* 303 (species *c*) and 262 (species *d*), respectively; the relatively low abundance of the first may be evidence that the original 18β stereochemistry is retained.

EXPERIMENTAL

Melting points are uncorrected. Optical rotations were measured in chloroform unless otherwise stated. UV spectra were taken in ethanol. The R_f values were taken on silica gel G chromatoplates, developed with toluene ethyl acetate–acetic acid (12:4:0.5).

2β-Hydroxy-A-nor-18β-olean-12-en-11-one-2α,30-dicarboxylic Acid (IV)– *Method A*—A solution of methyl 2α-acetoxy-18β-olean-12-ene-3,11-dion-30-oate (III) (2) (100 mg.) in ethanolic potassium hydroxide solution (10%, 5 ml.) was refluxed for 5 hr. After acidification, the precipitated solid matter (shown by TLC to be a mixture of two products, R_f 0.20 and 0.43) was separated by fractional crystallization from acetone–benzene into: (*a*) 2-hydroxy-18β-oleana-1,12-dien-3,11-dion-30-oic acid (II) (1), obtained after purification from ethanol–benzene as needles (20 mg., R_f 0.43), m.p. and mixed m.p. 320–323°; and (*b*) the A-norhydroxy-acid (IV, R_f 0.20) obtained as light-yellowish needles (35 mg., from acetone–hexane), m.p. 250°, $[\alpha]_D$ + 176°, giving one UV maximum at 250 nm. (ϵ = 10,800) and IR (KBr) bands near 3430, 3300, 1720, 1650, and 1630 cm.$^{-1}$.

Anal.—Calc. for $C_{30}H_{44}O_6$: C, 71.97; H, 8.86. Found: C, 71.75; H, 8.83.

Method B—A solution of the free acid of the diosphenol (II, 50 mg.) in ethanolic sodium hydroxide (10%, 5 ml.) was refluxed for 5 hr. followed by the usual workup. The isolated product, m.p. 250°, was shown to be identical (mixed melting point and co-TLC) with the previously described A-norhydroxy-acid (IV).

2,3-*seco*-18β-Olean-12-en-11-one-2,3,30-tricarboxylic Acid (V)– A refluxing solution of the free acid of the diosphenol (II, 1 g.) in ethanol (50 ml.) was treated with hydrogen peroxide solution (100 vol., 110 ml.) and potassium hydroxide solution (10%, 35 ml.), both being added in four equal portions at intervals of 15 min. After acidification, the precipitated product was washed with water and crystallized from *n*-hexane to give hexagonal plates of V (R_f 0.30, 880 mg.), m.p. 205–208°, $[\alpha]_D$ + 172.5° (pyridine). The UV spectrum showed one maximum at 249 nm. (ϵ = 12,700), and the IR spectrum (mineral oil) contained bands near 3510 (broad), 1710, and 1655 cm.$^{-1}$.

Anal. Calc. for $C_{30}H_{44}O_7$: C, 69.74; H, 8.58; mol. wt. 516. Found: C, 69.90; H, 8.64; mol. wt. (by mass spectrometry) 516.

Trimethyl Ester of V—Methylation of V (200 mg.) in chloroform (50 ml.) solution with ethereal diazomethane (from 4 g. *N*-nitrosomethylurea) afforded, after crystallization from chloroform–methanol, 150 mg. of the trimethyl ester (R_f 0.57), m.p. 187–188°; $[\alpha]_D$ +37.6°; UV maximum at 250 nm. (ϵ = 12,800); IR (mineral oil) bands near 1730 and 1650 cm.$^{-1}$.

Anal.—Calc. for $C_{33}H_{50}O_7$: C, 70.93; H, 9.02. Found: C, 70.77; H, 9.11.

Anhydride of V—After refluxing a solution of the triacid (V, 160 mg.) in acetic anhydride for 1 hr., the residue remaining upon evaporation was crystallized from *n*-hexane to give the anhydride (VI) (R_f 0.50, 60 mg.), m.p. 218–220°, $[\alpha]_D$ +180°; UV maximum at 250 nm. (ϵ = 9900); IR (KBr) bands near 3370, 1730, and 1660 cm.$^{-1}$.

Anal.– Calc. for $C_{30}H_{42}O_6$: C, 72.26; H, 8.49. Found: C, 71.86; H, 8.59.

Alkaline Degradation Product of Cephradine

ALLEN I. COHEN▲, PHILLIP T. FUNKE, and MOHINDAR S. PUAR

Abstract □ Cephradine yields an unique alkaline degradation product, which has been identified by proton magnetic resonance, ^{13}C-NMR, and mass spectrometry as 2-[6-(1,4-cyclohexadine-1-yl)-2,5-dioxo-3-piperazinyl]-5,6-dihydro-5-methyl-2*H*-1,3-thiazine-4-carboxylic acid, sodium salt.

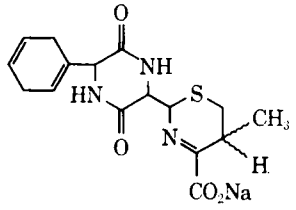
Keyphrases □ Cephradine—structure determination of alkaline degradation product as 2-[6-(1,4-cyclohexadine-1-yl)-2,5-dioxo-3-piperazinyl]-5,6-dihydro-5-methyl-2*H*-1,3-thiazine-4-carboxylic acid, sodium salt □ 2-[6-(1,4-Cyclohexadine-1-yl)-2,5-dioxo-3-piperazinyl]-5,6-dihydro-5-methyl-2*H*-1,3-thiazine-4-carboxylic acid, sodium salt—cephradine alkaline degradation product, structure determination □ Cephem derivatives—structure determination of cephradine alkaline degradation product

The alkaline hydrolysis of penicillins and, more recently, of ampicillin (α-aminobenzylpenicillin) was investigated extensively (1). Similar studies into the aminolysis products of cephalosporins were also reported (2). The structure of the alkaline degradation product of cephradine, a new semisynthetic cephem derived from D-2-(1,4-cyclohexadienyl)glycine and desacetoxy-7-aminocephalosporanic acid (3), is reported here.

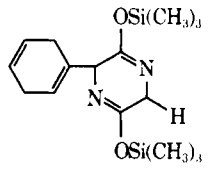
EXPERIMENTAL[1]

Materials—Cephradine[2], 7-[D-2-amino-2-(1,4-cyclohexadien-1-yl)acetamido]-3-methyl-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid hydrate, was prepared by the procedure of Dolfini *et al.* (3). The sample was characterized by NMR and by mass spectrometry as its trimethylsilyl derivative (Fig. 1). Anhydrous sodium carbonate (reagent grade), sodium hydroxide, or 20% sodium deuteroxide in deuterium oxide was used in the degradation studies. Either *N,O*-bis(trimethylsilyl)acetamide[3] or trimethylchlorosilane[3] was employed as the silylating agent.

Preparation of Degradation Product—Cephradine (3.0 g.) and sodium carbonate (9.0 g.) were mixed thoroughly. Then 1.6 g. of the mixture was transferred to a vial, 5 ml. of water was added, and the vial was capped and agitated. The vial was stored at 5° for 1 week. The white precipitate that formed was collected on a sintered-glass funnel. The filter cake was washed with five 2-ml. portions of cold water and then with three 1-ml. portions of 95% ethanol and was dried by suction. The crystals were further dried in a vacuum oven at 40° for 3 hr. The mass spectrum of the trimethylsilyl derivative of the isolated products shows a molecular ion of *m/e* 565.2297, corresponding to the addition of three trimethylsilyl groups, $C_{25}H_{43}N_3O_4SSi_3$ (calc. 565.2280). PMR (dimethyl sulfoxide-d_6 and tetramethylsilane): δ 1.06 (3H, d, J = 7 Hz.), 2.95 (2H, m), 5.05 (1H, m, J = 3 Hz.), 2.6 (5H, m), 4.19 (1H, t, J = 3 Hz.) [which, on deuterium exchange, becomes a doublet (J = 3 Hz.)], 4.93 (1H, $w_{1/2}$ = 3 Hz.) (which has a $w_{1/2}$ = 2 Hz. after deuterium exchange),



I



II: *m/e* 335

5.72 (1H), 5.67 (2H), 8.18 (1H, exchangeable), and 8.10 (1H, d, J = 3 Hz., exchangeable); ^{13}C-NMR (dimethyl sulfoxide-d_6; parts per million from tetramethylsilane, δ = 0): δ 16.8, 23.7, 25.7 (2C), 28.7, 39.6 (dimethyl sulfoxide), 58.8, 59.4, 63.8, 122.6, 123.3, 124.2, 130.2, 166.2, 166.7, and 167.7. There are at least 15 carbon atoms; the formula requires 16.

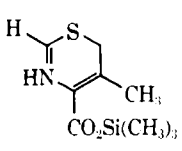
RESULTS AND DISCUSSION

The PMR assignments of the isolated degradation product, dissolved in dimethyl sulfoxide-d_6, are: C-3 methyl δ 1.06 (d, 7 Hz.), vinyl protons δ 5.72 (1H) and δ 5.67 (2H), methylene and C-3 cephem protons δ 2.62 (5H), α-proton of glycyl δ 4.93, and —NH— δ 8.10 and 8.18. The respective chemical shifts of the C-6 and C-7 cephem protons are δ 5.05 (d, 3 Hz.) and 4.19 (t, 3 Hz.); the latter peak becomes a doublet of 3 Hz. coupling on deuterium exchange. The C-2 protons near δ 3 appear as an *ABX* system coupled to the C-3 methine proton. The presence of a methyl doublet and the methine proton at C-3 coupled to the vicinal methylene protons indicates that the double bond has migrated to the C-4,5 position.

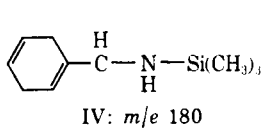
The ^{13}C-NMR spectrum was also used to establish the structure of the degradation product. There are 14 peaks (one has an intensity for two carbons), accounting for 15 of the 16 carbons. Because it is a tertiary carbon of an azomethine group, the 16th carbon occurs as a broad resonance due to a longer relaxation time which results from nuclear quadrupole coupling and π-electron polarization. The pulse interval used in the Fourier experiment did not permit sufficient time for complete relaxation. Additionally, the nitrogen quadrupole coupling can give rise to broadened resonances. The three ^{13}C resonances at δ 166.2, 166.7, and 167.7 clearly demonstrate the presence of three carbonyl groups in the alkaline degradation product (4). The resonances at δ 122–130 account for four of the other five carbon atoms bearing double bonds. The five carbon resonances between δ 16 and 29 are the alkyl carbons bearing two allylic double bonds or one electronegative group, whereas the three resonance lines between δ 59 and 64 account for three carbon atoms bearing two electronegative groups and/or two allylic double bonds.

Structure I for the alkaline degradation product is consistent with the NMR data and the formula derived from the mass spectral data. While the NMR data do not permit assignment of the configuration of the C-3 methyl group, the appearance of a single doublet suggests that one product is formed.

The mass spectrum provides additional support for the structural assignment. Trimethylsilylation with chlorotrimethylsilane resulted in the precipitation of sodium chloride. The molecular ion of *m/e* 565.2297 agrees with the formula $C_{25}H_{43}N_3O_4SSi_3$ (calc. 565.2280) (Fig. 2). The most significant fragment ion is the *m/e* 335 ion, II, which demonstrates the presence of a disilyl moiety resulting from the direct cleavage of the C_6—C_7 bond. Cephradine, on the other



III: *m/e* 230



IV: *m/e* 180

[1] Proton magnetic resonance (PMR) spectra were obtained on a Varian Associates XL-100 spectrometer employing the deuterium field-frequency lock system. The ^{13}C-magnetic resonance (^{13}C-NMR) spectrum was taken on a JEOL PS-100 equipped with a Fourier transform pulser and a Nicolet computer. At 25.1 MHz., the effective sweep range was 5000 Hz. (200 p.p.m.). Low- and high-resolution mass spectra were taken on an AEI MS-902 mass spectrometer. Data were acquired *via* a frequency-modulated analog magnetic tape, which was subsequently processed on a Digital Equipment Corp. PDP-11 computer, employing Squibb programs.

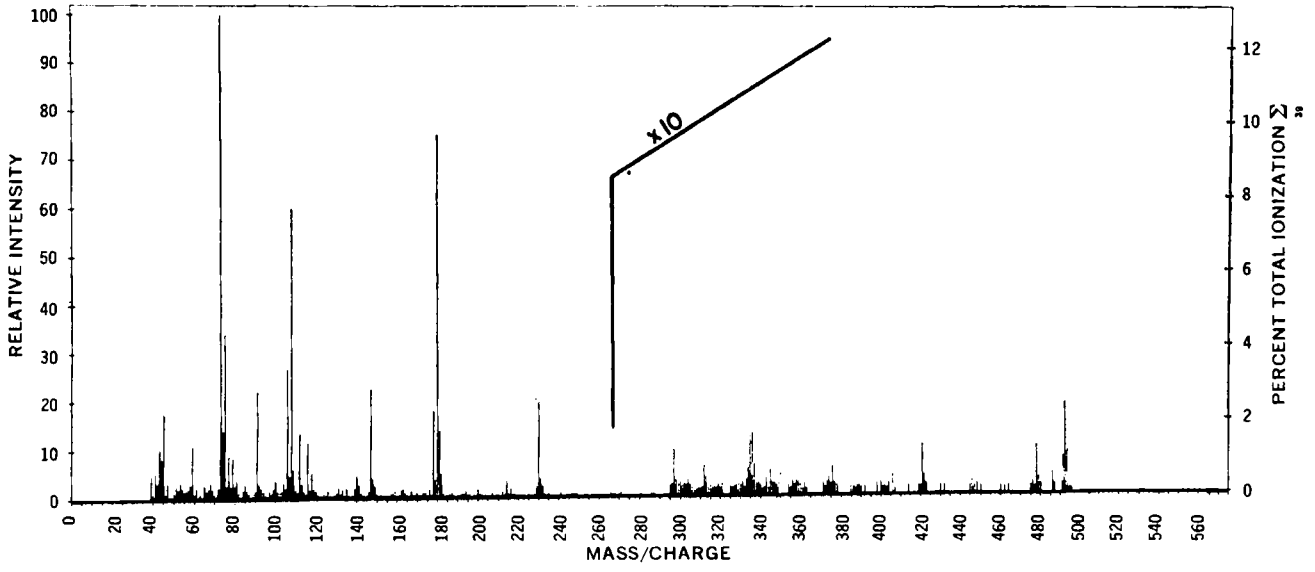

Figure 1—*Low-resolution mass spectrum of the trimethylsilyl derivative of cephradine.*

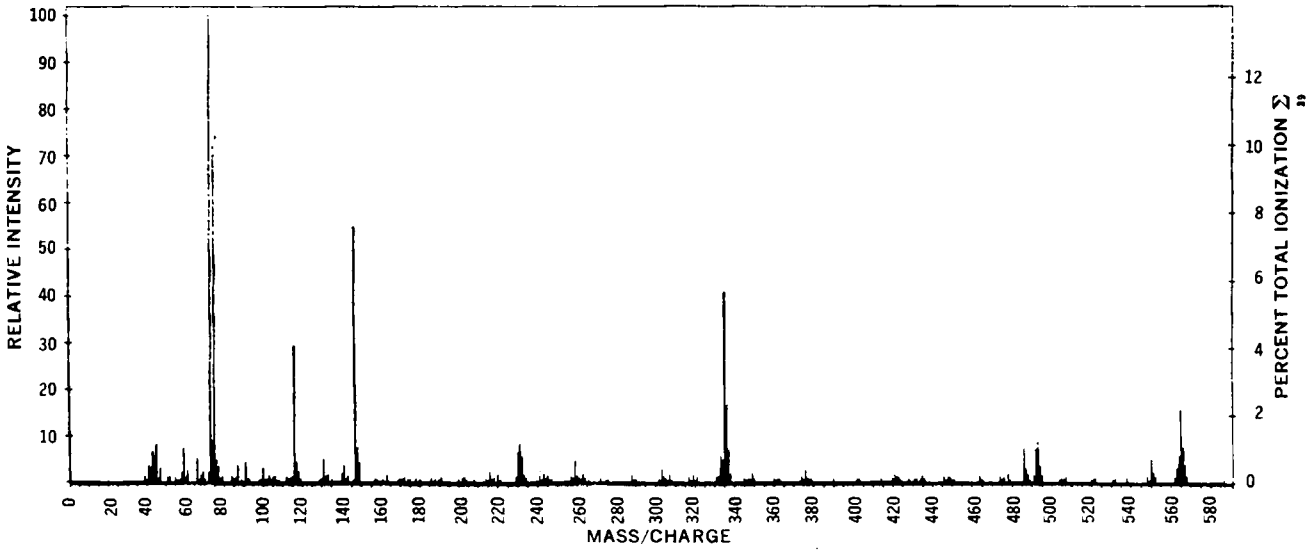

Figure 2—*Low-resolution mass spectrum of the trimethylsilyl derivative of the alkaline degradation product of cephradine.*

hand, was disilylated primarily by *N,O*-bis(trimethylsilyl)acetamide, as demonstrated by the *m/e* 493 ion (Fig. 1), and was also partially trisilylated due to addition to the amide group under the forcing conditions of the trimethylsilylation. Trimethylsilylated cephalosporins yield a *m/e* 230 ion, III, arising through the β-lactam cleavage, proton addition, and cleavage of the C_6—C_7 bond.

The other significant ion in cephradine, at *m/e* 180, produced by the cleavage of the α-carbonyl bond of the trimethylsilylated glycyl portion of the molecule, IV, is absent in the spectrum of the alkaline degradation product. The degradation product exhibits an $M^+ - 79$ ion at *m/e* 486, arising from the cleavage of the dihydrophenyl moiety.

In one continuing program, NMR spectrometry is employed in the determination of stability of drugs in acidic, neutral, and basic aqueous media. The NMR spectrum of a 10-mg./ml. D_2O–NaOD solution of cephradine was determined for 12 hr. at 30° or for 5 hr. at 60°. A progressive decrease in the C-3 methyl proton resonance at δ 1.82 was observed, with the corresponding appearance of a new singlet proton at δ 1.24. When the hydrolysis was performed in water, the methyl proton resonance appeared as a doublet with a coupling constant, *J*, of 7 Hz. That the migration does not occur in the C-2,3 position was demonstrated by the retention of the C-2 methylene proton resonances and, when water was used as the solvent, by the additional vicinal coupling of these protons to the newly introduced methine proton. Thus, double-bond migration to the C-4,5 position occurs with the concurrent introduction, depending on the solvent used, of a proton or of deuterium at C-3 after the cleavage of the β-lactam bond. It appears that the major product[4] of this degradation is identical to the product isolated after treatment with sodium carbonate. A partial tautomerization to the C-3,4 position was demonstrated by redissolving the product isolated from water in D_2O–NaOD and observing the rapid decrease in the C-3 methine proton signal in the PMR spectrum.

The alkaline degradation product represents a unique structure in the penam and cephem series. For example, the glycyl penicillin analog, ampicillin, is reported to yield a penicilloic acid and the decarboxylated derivative (1). Indelicato *et al.* (5) prepared a similar compound, with the retention of the double bond at the C-3,4 position, by refluxing cephalexin in benzene overnight. In a basic aqueous medium, cephradine yields a product that has undergone migration of the double bond to the C-4,5 position and protonation at C-3. Under the same conditions, ampicillin does not yield a cyclic product (1); a cyclic product is not obtained in refluxing benzene either (5). The failure of the cyclization of ampicillin has been attributed to steric effects of the C-2 dimethyl and C-3 methine

[4] Additional studies are being conducted to separate the degradation products formed in acid, neutral, and alkaline media and to elucidate their structures.

groups (5). In cephalosporin studies (2), a double-bond migration was reported only when accompanied by dehydroacetoxylation; otherwise, the double bond remained at the C-3,4 position.

Phytochemical Investigation of *Virola peruviana*, A New Hallucinogenic Plant

A. LAI, M. TIN-WA, E. S. MIKA, G. J. PERSINOS*, and N. R. FARNSWORTH▲

Abstract □ Although *Virola peruviana* has been described in ethnobotanical studies as being used as a hallucinogen, no proof of the presence of chemical agents explaining this activity existed previously. The present study resulted in the isolation of 5-methoxy-*N*,*N*-dimethyltryptamine as well as the identification of *N*,*N*-dimethyltryptamine and 5-methoxytryptamine, thus confirming the hallucinogenic aspect of *V. peruviana*. In addition, myoinositol and the lignans lirioresinol-A dimethyl ether and lirioresinol-B dimethyl ether were isolated and identified. A mixture of *n*-alkanols was isolated and shown to consist of octacosanol, triacontanol, and dotriacontanol, whereas a mixture of sterols was isolated and shown to consist of β-sitosterol, campesterol, and stigmasterol.

Keyphrases □ *Virola peruviana*—phytochemical investigation, hallucinogenic constituents isolated and identified □ Hallucinogens—isolation and identification of hallucinogenic constituents of *Virola peruviana* □ Phytochemistry—isolation and identification of hallucinogenic constituents of *Virola peruviana*

In the Rio Apaporis, Puinave Indians refer to *Virola peruviana* as yá-kee, suggesting its possible utilization in preparing the hallucinogenic snuff by the same name (1). Schultes and Holmstedt (1) suggested that this species may be used as a hallucinogen and determined that it contained alkaloids (1). Other virola species, *i.e.*, *V. theiodora*, *V. rufula*, *V. multinervia*, *V. venosa*, *V. calophylloidea*, *V. calophylla*, and *V. sebifera*, are well documented as hallucinogenic plants, with their active principles being determined as *N*,*N*-dimethyltryptamine, 5-methoxy-*N*,*N*-dimethyltryptamine, and/or *N*-methyltryptamine (2–5).

The purpose of this investigation was to determine whether *V. peruviana* contained chemical constituents that would explain its use as a hallucinogen.

EXPERIMENTAL[1]

Plant Material—The plant material[2] used represented the bark of *Virola peruviana* (A.DC.) Warburg (Myristicaceae), collected near Leticia, Peru, during October 1968.

Extraction and Fractionation—Coarsely milled bark (4.7 kg.) of *V. peruviana* was defatted with 35 l. of petroleum ether (b.p. 30–60°) using a soxhlet apparatus for 24 hr. The combined extracts were filtered and evaporated to dryness to yield 4.0 g. of Fraction A. The defatted plant material was then exhaustively extracted in the soxh-

[1] All chemicals used were of reagent grade quality. Melting points were determined by means of a Thomas-Hoover apparatus or a Kofler hot plate and are uncorrected. Optical rotations were measured in a Carl Zeiss optical polarimeter. The UV spectra were recorded in methanol using a Beckman model DB-G spectrophotometer. IR spectra were taken using a Beckman model IR-18A instrument. Mass spectral analyses were made using the Hitachi Perkin-Elmer model RMD-6D single-focusing mass spectrometer. NMR spectra were taken using a Bruker model HFX-5 magnetic resonance spectrometer. GC analyses were carried out by means of a Perkin-Elmer model 881 linear programmed temperature gas chromatograph, equipped with a hydrogen flame-ionization detector and a Sargent model SR,S-72180-20 1-mv. recorder; a 1-sec. full-scale response was used. A borosilicate coiled glass column, 1.8 m. (6 ft.) × 2.0 mm. (i.d.), was packed with either 3% OV-1 or 5% OV-101 on 100–120-mesh Gas Chrom Q. Silica gel GF_{254} plates were used for monitoring the chromatographic separation of Fraction A; the solvent system used for development of plates was the same as the eluent used to elute the fractions. The same type plates were used for monitoring the chromatographic fractions from Fraction D, but development was with benzene–ethyl acetate–diethylamine (7:2:1). Spots were visualized after spraying the plates with sulfuric acid (70%) or Ehrlich reagent and heating at 110° for 5 min.

[2] A voucher specimen (2245) was authenticated by Dr. J. Wurdack, Smithsonian Institution, Washington, D. C. A specimen has been deposited at that address.

groups (5). In cephalosporin studies (2), a double-bond migration was reported only when accompanied by dehydroacetoxylation; otherwise, the double bond remained at the C-3,4 position.

let apparatus with methanol until the final methanol extract no longer gave a positive alkaloid test with Mayer's reagent. Concentration of the methanol extract *in vacuo* gave 232 g. of a dark-brown syrupy liquid, which was redissolved in 2 l. of boiling methanol and filtered. A nonalkaloidal precipitate (Fraction B), which formed on standing, was removed by filtration (22.7 g.). The filtrate was poured into 6 l. of 2% acetic acid, and the methanol was removed by evaporation *in vacuo*. Suspended impurities were removed by filtration; the filtrate was extracted with chloroform (6 × 2 l.), and, after evaporation *in vacuo*, gave 11 g. of Fraction C.

The aqueous layer was made alkaline with 28% ammonium hydroxide and extracted with chloroform (9 × 2 l.). The combined chloroform extracts were evaporated to dryness *in vacuo* to yield 3.4 g. of Fraction D.

Chromatographic Separation of Fraction A—Fraction A (4.0 g.) was chromatographed over a column (5.5 × 62 cm.) of silica gel PF_{254} (300 g.) and eluted with solvents having increasing polarity (Table I). Each fraction (50 ml.) was monitored by means of TLC, and fractions were combined on the basis of TLC patterns.

Isolation and Identification of *n*-Alkanols—Combined fractions 35–39 from the column, which were eluted with benzene, formed a white precipitate when concentrated *in vacuo*. The precipitate was removed by filtration and crystallized from acetone several times. The IR spectrum of this isolate was typical of that seen with *n*-alkanols. GLC analysis (3% OV-1, 280° isothermal) of this isolate showed it to be a mixture of octacosanol (55%), triacontanol (35%), and dotriacontanol (15%).

Isolation and Identification of Phytosterols—Fractions 65–72 from the column, which were eluted with benzene–acetone (9:1), were combined and evaporated to dryness *in vacuo*. The residue (340 mg.) was crystallized from a benzene hexane mixture to give white plates. GLC analysis (5% OV-101, 250° isothermal) of this material showed it to be a mixture of campesterol (9.9%), stigmasterol (33.9%), and β-sitosterol (57.3%).

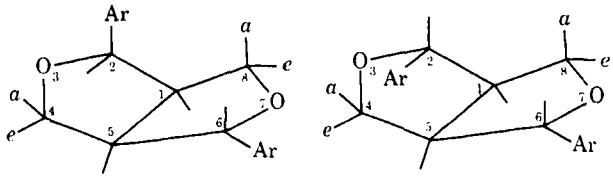
Isolation and Identification of Lirioresinol-A Dimethyl Ether—Concentration of fraction 170 from the column, which was eluted with benzene acetone (6:1), resulted in the formation of crystals. Recrystallization from acetone–hexane yielded 185 mg. of crystals having a melting point of 116° [lit. (6) m.p. 118–120°). The UV spectrum of the isolate showed absorptions at λ_{max} 208 (log ε 4.88) and 271 nm. (log ε 3.48), with a shoulder at 230 nm. (log ε 4.19). IR absorptions were found at 2900, 2800, 1590, 1510, and 810 $cm.^{-1}$. A molecular ion was observed in the mass spectrum at *m/e* 446, in agreement with a formula of $C_{24}H_{30}O_8$. Other prominent peaks were noted at *m/e* 416, 250, 249, 224, 207, 196, and 181, the fragmentation pattern of which is similar with that of lirioresinol-B dimethyl ether (7–9).

Since the presence of six methoxy groups was observed in the NMR spectrum at δ 3.85, the remaining two oxygen atoms were assigned as ether linkages in a lignan of the 3,7-dioxabicyclo[3.3.0]-octane type, considering the lack of hydroxy, phenolic, and carbonyl groups in the IR spectrum. However, the compound was not symmetrical as is the case with lirioresinol-B dimethyl ether. One benzylic hydrogen appeared as a doublet centered at δ 4.89 (J = 3 Hz.), while the other benzylic proton was at δ 4.47 (d, J = 3 Hz.). One methylene proton was seen upfield in the δ 3.38–3.47 region as a multiplet, which corresponded with the axial proton due to the shielding effect of the aryl group; another methylene proton was observed downfield in the δ 4.13–4.24 region, corresponding with the other axial proton affected by the equatorial aryl group. Two additional methylene protons appeared between δ 3.8 and 3.97. Furthermore, two nonequivalent methine protons appeared at δ 2.94 and 3.30, indicating that its NMR spectrum was similar to that reported for lirioresinol-A (10). The identity of this isolate as lirioresinol-A dimethyl ether was confirmed by measurement of the specific rotation $[\alpha]_D^{26}$ + 116 (c 0.65 in $chloroform_3$) [lit. (6) + 119] and preparation of the dibromo derivative (11), m.p. 122° [lit. (6) m.p. 124–126°].

Isolation and Identification of Lirioresinol-B Dimethyl Ether—When the pooled fractions 171–174 were eluted from the column with benzene–acetone (6:1) and concentrated, a crystalline material formed which was removed by filtration. This material was recrystallized from acetone containing a trace of hexane to give 216 mg. of a pure sample, m.p. 118–119° [lit. (6) m.p. 121–123°]. The UV spectrum showed absorption maxima at λ_{max} 208 (log ε 4.88) and 271 nm. (log ε 3.48), with a shoulder at 230 nm. (log ε 4.19). The IR spectrum was very similar to that of the lirioresinol-A dimethyl ether but not identical. The mass spectrum indicated a molecular ion at *m/e* 446, in agreement with a formula of $C_{24}H_{30}O_8$, suggesting that it might be an isomer of lirioresinol-A dimethyl ether. Its fragmentation pattern was in agreement with previously published data for lirioresinol-B dimethyl ether (7–9). This was further supported by the NMR spectrum, which indicated that the isolate was symmetrical; *i.e.*, it gave a proton count of 30 only if the apparent integrals were doubled. The assignments of the signals as indicated below is in agreement with those reported for lirioresinol-B dimethyl ether (9, 10), *i.e*, methine protons at C_1 and C_5 at δ 3.11 (m, 2H), benzylic protons at C_2 and C_6 at δ 4.78 (d, J = 3 Hz., 2H), axial methylene protons at δ 4.24 (m, 2H) and equatorial methylene protons at δ 4.00 (m, 2H), six methoxy protons at δ 3.87 (18H), and four aromatic protons at δ 6.60 (s, 4H).

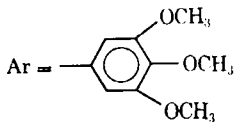
The identity of this compound as lirioresinol-B dimethyl ether was confirmed by measurement of the specific rotation $[\alpha]_D^{26}$ + 49 (0.65 in chloroform) [lit. (6) + 46.2] and preparation of the dibromo derivative (11), m.p. 153° [lit. (6) m.p. 152–155°].

Isolation and Identification of Myoinositol—Fraction B (22.7 g.) was dissolved in 70% ethanol and, on standing, formed crystals which were removed by filtration. Recrystallization from 70% ethanol afforded an analytical sample having a melting point of 220°, which was not depressed on admixture with a reference sample



lirioresinol-A dimethyl ether

lirioresinol-B dimethyl ether



of myoinositol. The IR spectrum of the isolate was identical with that of a reference sample of myoinositol, with $[\alpha]_D^{26} \pm 0$; paper chromatographic comparison of the isolate and myoinositol showed them to be identical (12). The identity of the isolate was further established by preparation and comparison of the acetates, m.p. 216° [lit. (13) m.p. 216°] and the benzoates (14), m.p. 260° [lit. (15) m.p. 258°] of the isolate and reference myoinositol.

Chromatographic Separation of Fraction D—Fraction D (3.0 g.) was chromatographed over a column (2.2 × 27 cm.) of neutral alumina[3] (100 g.), activity grade III. Fractions consisting of 15 ml. each were collected. Initially the column was eluted with petroleum ether (b.p. 30–60°), followed by solvents of increasing polarity (Table II).

Isolation and Identification of 5-Methoxy-*N*,*N*-dimethyltryptamine—Fractions 45–55 from the column were combined and taken to dryness *in vacuo* to yield 50 mg. of residue. This residue was shown by TLC to contain one major component, which gave a pale-yellow fluorescence under UV light and a positive reaction with the Ehrlich reagent. Since the material was resistant to crystallization as the free base, preparative TLC was employed to obtain the base in pure form. The zone at R_f 0.38 was removed from the plates and extracted with chloroform. The combined extracts were dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. A mass spectrum of this residue indicated a molecular ion at *m/e* 218, which corresponded with a molecular formula of $C_{13}H_{18}N_2O$. Other prominent peaks at *m/e* 174, 173, 160, 159, 145, and 58 were all in agreement with published data for 5-methoxy-*N*,*N*-dimethyltryptamine (16). The UV spectrum of the isolate showed absorptions at λ_{max} 224, 277, and 295 nm., which compares favorably with that found in the literature for 5-methoxy-*N*,*N*-dimethyltryptamine (16).

Reaction of the alkaloid residue (40 mg.) with ethanol (10 ml.), 80% sodium hydroxide (2 drops), and 8 ml. of methyl iodide at room temperature for 8 hr. gave the methiodide (17), m.p. 182–183° [lit. (16) m.p. 181–182°]. The IR spectrum was superimposable with that of a synthetic sample of 5-methoxy-*N*,*N*-dimethyltryptamine methiodide, prepared from 5-methoxy-*N*,*N*-dimethyltryptamine as described previously.

Pooled fractions 56–434 (304 mg.) and 435–633 (550 mg.) from the column were processed by the preparation of picrate derivatives. The concentrated residues were dissolved in methanol and mixed with an equimolar solution of picric acid dissolved in methanol. Orange-yellow picrates were obtained and recrystallized from methanol–acetone to give pure samples having melting points of 172° [lit. (16) m.p. 172°]. The IR spectra of these isolates were superimposable with those of a reference sample of 5-methoxy-*N*,*N*-dimethyltryptamine picrate.

Detection of 5-Methoxytryptamine and *N*,*N*-Dimethyltryptamine—GLC (5% OV-101, with a temperature of 150° initially for 2 min. followed by a 10° rise/min. from 150 to 300°) of Fractions C and D indicated the presence of small amounts of 5-methoxytryptamine in Fraction C, while *N*,*N*-dimethyltryptamine, 5-methoxytryptamine, and 5-methoxy-*N*,*N*-dimethyltryptamine were identified in Fraction D.

Specificity of Antibodies Produced by Linear Antigenic Polypeptides of a Known Primary Structure: Synthesis and Use of the Polymers Poly(L-phenylalanyl-L-glutamyl-L-valylglycyl)glycine Methyl Ester and Poly(L-phenylalanyl-L-aspartyl-L-valylglycyl)glycine Methyl Ester

BRIAN J. JOHNSON

Abstract □ The syntheses of the polypeptides poly(L-phenylalanyl-L-glutamyl-L-valylglycyl)glycine methyl ester and poly(L-phenylalanyl-L-aspartyl-L-valylglycyl)glycine methyl ester are described. Using these materials, it was found by cross-reaction and absorption studies that the antibodies to the antigen poly(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-^{14}C ethyl ester show specificities for the phenolic hydroxyl group of the tyrosyl residue and the γ-carboxyl group of the glutamyl residue.

Keyphrases □ Polypeptides, linear—synthesis of poly(L-phenylalanyl-L-glutamyl [and L-aspartyl]-L-valylglycyl)glycine methyl ester, immunochemical properties □ Antibodies, polypeptide produced—specificity, synthesis and testing of poly(L-phenylalanyl-L-glutamyl [and L-aspartyl]-L-valylglycyl)glycine methyl ester □ Immunochemical properties—synthesis and testing of poly(L-phenylalanyl-L-glutamyl [and L-aspartyl]-L-valylglycyl)glycine methyl ester □ Antigenic polypeptides, linear—synthesis and use of poly(L-phenylalanyl-L-glutamyl [and L-aspartyl]-L-valylglycyl)glycine methyl ester

It was previously reported that antibodies produced by rabbits against the polypeptide poly(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-^{14}C ethyl ester (I) (1–3) are most probably dependent upon the conformation of the antigen (4–7). By the use of the polypeptides poly(L-phenylalanyl-L-glutamyl-L-alanylglycyl)glycine (II) (8), poly(L-tyrosyl-L-aspartyl-L-alanylglycyl)glycine (III) (9), and poly(L-tyrosyl-L-glutamyl-L-valylglycyl)-glycine (IV) (10), it was shown that these rabbit antibodies possess specificities for the phenolic hydroxyl group of the tyrosyl residue (8) and the γ-carboxyl group of the glutamyl residue (9). All these specificities were deduced by the use of polymers in which only one amino acid residue was modified at a time. It was, therefore, of interest to investigate the ability of these antibodies to cross-react with polypeptides possessing two or more modified residues. For this purpose, the following polymers were prepared and used: poly(L-phenylalanyl-L-glutamyl-L-valylglycyl)glycine methyl ester (V) and poly(L-phenylalanyl-L-aspartyl-L-valylglycyl)glycine methyl ester (VI).

Table I—Amounts[a] of Protein Nitrogen Precipitated by Homologous and Heterologous Polypeptides

Polypeptide	Protein Nitrogen Precipitated at Equivalence Point, mcg.	Protein Nitrogen Precipitated by I after Absorption, mcg.	Protein Nitrogen Precipitated by Polypeptide, %
(Tyr-Glu-Ala-Gly)$_n$Gly (I)	106	0	100
(Phe-Glu-Ala-Gly)$_n$Gly (II)	61	45	57
(Tyr-Asp-Ala-Gly)$_n$Gly (III)	26	78	25
(Tyr-Glu-Val-Gly)$_n$Gly (IV)	106	0	100
(Phe-Glu-Val-Gly)$_n$Gly (V)	63	43	60
(Phe-Asp-Val-Gly)$_n$Gly (VI)	11	94	10

[a] Per milliliter of anti-poly(Tyr-Glu-Ala-Gly)$_n$Gly-1-^{14}C ethyl ester serum.

DISCUSSION

The syntheses of both polymers, V and VI, were performed as detailed in the *Experimental* section. The respective polymerization units were activated by use of the pentachlorophenyl ester (11). The high dilution procedure of polymerization was employed in both cases, since this method has been shown to produce linear high molecular weight polypeptides (1, 2, 4–10). Each polymer was purified by extensive dialysis and then fractionated by successive diafiltrations through membranes[1] into four different molecular weight fractions: $>5 \times 10^4$, $2\text{–}5 \times 10^4$, $1\text{–}2 \times 10^4$, and $<1 \times 10^4$.

Eight rabbits were immunized against I of molecular weight >50,000, using the previously reported protocol (3). It was found that each serum gave a positive precipitin reaction with the homologous polymer I. The serum from each animal was pooled since it was assumed that each rabbit had responded to the same antigenic determinants in this time interval (12). Using the polypeptides V and VI, each of molecular weight >50,000, incremental amounts of these polymers were added to 1-ml. aliquots of this pooled antiserum; cross-reactions occurred with both polymers. However, neither heterologous polymer precipitated as much antibody as the homologous polypeptide I. To quantitate the amounts of antibody not precipitated by either heterologous polymer, two separate experiments were performed. Quantities equal to the equivalence point amounts of each heterologous polypeptide, V and VI, were reacted with the pooled serums. After removal of the precipitates, 30 mcg. of the homologous polypeptide I was added to the two resulting supernatant liquids. Further precipitation was obtained and quantitated by analysis for nitrogen (Kjeldahl) (Table I).

It has been found that the heterologous polypeptides, V and VI, cross-react with anti-I-serum but precipitate less antibody than the homologous antigen I. It appears from these cross-reactions that the conformations of polymers V and VI are similar to that of the homologous antigen I. A similar situation has been shown to exist for the polypeptides II (8), III (9), and IV (10) (included in Table I for comparative purposes). By using the rationale that the determinants of these heterologous polypeptides are in the same orientation as those of the antigen I, it is suggested that observed differences in the binding abilities of these heterologous polymers are due only to those specifically modified amino acid residues. Comparison of the percentage of protein nitrogen precipitated by polymers I and IV has caused the inference to be made that anti-I-serum does not possess a specificity for the alanyl residue (10). Thus, since the percentages of protein nitrogen precipitated by the polymers II and V are similar, their lower abilities to precipitate with anti-I-serum

[1] Diaflo.

may be due only to their deficiency of phenolic hydroxyl groups. Comparison of the percentage of protein nitrogen precipitated by polymers I and III suggested that antibodies to I have a high affinity for the γ-carboxyl group of the glutamyl residue (9). The small amount of precipitate produced by polymer VI is considered as further evidence that antibodies to I have specificities for the phenolic hydroxyl group of the tyrosyl residue and the γ-carboxyl group of the glutamyl residue.

EXPERIMENTAL[2]

***N*-Benzyloxycarbonyl-γ-*tert*-butyl-L-glutamyl-L-valylglycine Methyl Ester (VII)**—To a solution of 2.05 g. (0.005 mole) of γ-*tert*-butyl-L-glutamyl-L-valylglycyl methyl ester hydrochloride (13) and 0.51 g. (0.005 mole) of triethylamine in 200 ml. of methylene chloride was added 2.74 g. (0.005 mole) of *N*-benzyloxycarbonyl-L-phenylalanine pentachlorophenyl ester. The mixture was stirred overnight at room temperature and concentrated; the product was dissolved in ethyl acetate, washed with 1 *N* HCl and water, and then dried (sodium sulfate). Concentration under reduced pressure gave an oil, which was chromatographed on a column[3] using chloroform–ethyl acetate (1:1) as eluent to give the fully blocked tetrapeptide. Crystallization from ethyl acetate–hexane yielded 3.0 g. (88%), m.p. 158–160°; $[\alpha]_D^{24}$ −21.6° (c 1.50 in dimethylformamide).

Anal.—Calc. for $C_{34}H_{46}N_4O_9$: C, 62.36; H, 7.08; N, 8.56. Found: C, 62.51; H, 6.95, N, 8.28.

***N*-Benzyloxycarbonyl-L-phenylalanyl-γ-*tert*-butyl-L-glutamyl-L-valylglycine (VIII)**—To a solution of 3.0 g. (0.00458 mole) of VII in 200 ml. of methanol was added 4.6 ml. of 1 *N* KOH, and the solution was stirred for 90 min. at room temperature and then concentrated under reduced pressure. The residue was flooded with water, acidified with 10% citric acid solution, and extracted into ethyl acetate. The ethyl acetate solution was dried (sodium sulfate) and concentrated under reduced pressure to give the tetrapeptide free acid. This was crystallized from ethyl acetate–hexane to yield 2.7 g. (95%), m.p. 185–186°; $[\alpha]_D^{24}$ −11.4° (c 1.26 in dimethylformamide).

Anal.—Calc. for $C_{33}H_{44}N_4O_9$: C, 61.84, H, 6.92; N, 8.75. Found: C, 61.63; H, 6.80; N, 8.90.

***N*-Benzyloxycarbonyl-L-phenylalanyl-γ-*tert*-butyl-L-glutamyl-L-valylglycine Pentachlorophenyl Ester (IX)**—To a solution of 2.7 g. (0.00422 mole) of VIII in 200 ml. of methylene chloride were added 1.12 g. (0.00422 mole) of pentachlorophenol and 2.0 g. (0.0047 mole) of 1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide methotoluene-*p*-sulfonate. The mixture was shaken for 2 days at room temperature and then concentrated under reduced pressure to give a solid. This material was washed with water and crystallized from methanol to yield 1.7 g. (45%), m.p. 223°; $[\alpha]_D^{24}$ −19.7° (c 3.04 in dimethylformamide).

Anal.—Calc. for $C_{39}H_{43}Cl_5N_4O_9$: C, 52.69; H, 4.87; N, 6.30. Found: C, 52.43; H, 4.90; N, 6.24.

L-Phenylalanyl-γ-*tert*-butyl-L-glutamyl-L-valylglycine Pentachlorophenyl Ester Hydrochloride (X)—A suspension of 1.7 g. (0.00191 mole) of the tetrapeptide active ester IX and 0.5 g. of 10% palladium-on-carbon in 200 ml. of methanol was treated with 0.07 g. (0.00192 mole) of dry hydrogen chloride in methanol, and the suspension was hydrogenated for 2 hr. The reaction mixture was filtered and the filtrate was concentrated. The residue was crystallized from methanol–ether to give 1.1 g. (73%), m.p. 210–212° dec.; $[\alpha]_D^{24}$ −25° (c 0.60 in dimethylformamide).

Anal.—Calc. for $C_{31}H_{38}Cl_6N_4O_7$: C, 47.03; H, 4.84; N, 7.08. Found: C, 46.83; H, 4.91; N, 7.22.

Poly(L-phenylalanyl-L-glutamyl-L-valylglycyl)glycine Methyl Ester (V)—To a solution of 0.42 g. (0.00415 mole) of triethylamine and 0.5 mg. of glycine methyl ester hydrochloride in 5 ml. of dimethyl sulfoxide was added a solution of 1.1 g. (0.00139 mole) of the polymerizing unit X in 8.3 ml. of dimethyl sulfoxide. The mixture was shaken for 1 week and then centrifuged to yield the fully protected polymer. This material was washed with three 35-ml. portions of water and three 35-ml. portions of ether and dried to give the blocked polymer. Then this material was treated with 30 ml. of 90% trifluoroacetic acid, stirred for 50 min., and concentrated under reduced pressure to yield the crude polypeptide V. This polypeptide was suspended in 15 ml. of water and dissolved by the addition of 1 *N* NaOH to pH 7.5. The solution was dialyzed against distilled water overnight, acidified with 6 *N* HCl to pH 2.5, and dialyzed against distilled water for a day. The precipitated polypeptide V was collected by centrifugation and then lyophilized to yield 0.13 g. (21%); amino acid ratios of an acid hydrolysate were: $Phe_{1.0}$ $Glu_{1.0}$ $Val_{0.9}$ $Gly_{1.0}$.

***N*-Benzyloxycarbonyl-β-*tert*-butyl-L-aspartyl-L-valylglycine Methyl Ester (XI)**—To a solution of 9.0 g. (0.04 mole) of L-valylglycine methyl ester hydrochloride and 4.1 g. (0.04 mole) of triethylamine in 230 ml. of methylene chloride was added 22.8 g. (0.04 mole) of *N*-benzyloxycarbonyl-β-*tert*-butyl-L-aspartic acid pentachlorophenyl ester. The mixture was stirred overnight at room temperature and concentrated, and the product was dissolved in ethyl acetate, washed with 10% citric acid solution and water, and then dried (sodium sulfate). Concentration under reduced pressure yielded an oil, which was chromatographed on a column[3] using chloroform–ethyl acetate (1:1) as eluent. The tripeptide was obtained and crystallized from ethyl acetate–hexane to give 10.0 g. (50%) of the product, m.p. 128°; $[\alpha]_D^{24}$ −25.4° (c 1.18 in dimethylformamide).

Anal.—Calc. for $C_{24}H_{33}N_3O_8$: C, 58.40; H, 7.14; N, 8.51. Found: C, 58.21; H, 7.23; N, 8.50.

***N*-Benzyloxycarbonyl-L-phenylalanyl-β-*tert*-butyl-L-aspartyl-L-valylglycine Methyl Ester (XII)**—A suspension of 6.5 g. (0.0132 mole) of XI and 0.8 g. of 10% palladium-on-carbon in 200 ml. of methanol was treated with 0.482 g. (0.0132 mole) of dry hydrogen chloride in methanol, and the suspension was hydrogenated for 2 hr. The reaction mixture was filtered and the filtrate was concentrated under reduced pressure. The residue was dissolved in 200 ml. of methylene chloride and 1.35 g. (0.0132 mole) of triethylamine, and then 7.2 g. (0.0132 mole) of *N*-benzyloxycarbonyl-L-phenylalanine pentachlorophenyl ester was added. The reaction mixture was stirred overnight at room temperature and concentrated under reduced pressure. The product was dissolved in ethyl acetate, washed with 1 *N* HCl and water, and then dried (sodium sulfate). Concentration under reduced pressure yielded a solid, which was chromatographed on a column[3] using chloroform–ethyl acetate (1:1) as eluent to give the fully blocked tetrapeptide. Crystallization from ethyl acetate–hexane yielded 6.5 g. (76%), m.p. 183°; $[\alpha]_D^{24}$ −30.3° (c 3.80 in dimethylformamide).

Anal.—Calc. for $C_{33}H_{44}N_4O_9$: C, 61.84; H, 6.92; N, 8.74. Found: C, 61.73; H, 7.01; N, 8.82.

***N*-Benzyloxycarbonyl-L-phenylalanyl-β-*tert*-butyl-L-aspartyl-L-valylglycine Pentachlorophenyl Ester (XIII)**—To a solution of 6.0 g. (0.00936 mole) of XII in 250 ml. of methanol was added 9.36 ml. of 1 *N* KOH, and the solution was stirred for 90 min. at room temperature and then concentrated under reduced pressure. The residue was flooded with water, acidified with 10% citric acid solution, and extracted into ethyl acetate. The ethyl acetate solution was dried (sodium sulfate) and concentrated under reduced pressure to give 5.9 g. (100%) of the tetrapeptide free acid. This material was dissolved in 250 ml. of methylene chloride, and then 2.49 g. (0.00936 mole) of pentachlorophenol and 4.4 g. (0.0135 mole) of 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide methotoluene-*p*-sulfonate were added. The mixture was shaken for 3 days at room temperature and then concentrated under reduced pressure to give a solid. This solid was washed with water and crystallized from methanol to yield 3.5 g. (43%) of the product, m.p. 164–166°; $[\alpha]_D^{24}$ −22.2° (c 2.48 in dimethylformamide).

Anal.—Calc. for $C_{38}H_{41}Cl_5N_4O_9$: C, 52.17; H, 4.72; N, 6.41. Found: C, 52.04; H, 4.62; N, 6.36.

Poly(L-phenylalanyl-L-aspartyl-L-valylglycyl)glycine Methyl Ester (VI)—A suspension of 3.5 g. (0.004 mole) of the tetrapeptide active ester XIII and 0.5 g. of 10% palladium-on-carbon in 250 ml. of methanol was treated with 0.146 g. (0.004 mole) of dry hydrogen chloride in methanol, and the suspension was hydrogenated for 2 hr. The reacting mixture was filtered, and the filtrate was concentrated under reduced pressure to yield 3.1 g. (100%) of the tetrapeptide hydrochloride. This material was dissolved in 35 ml. of dimethyl sulfoxide and added to a solution of 1.21 g. (0.012 mole) of triethylamine and 0.7 mg. of glycine methyl ester hydrochloride in 5 ml. of dimethyl sulfoxide. The mixture was shaken for a week and then centrifuged to yield the fully protected polymer. This

[2] Melting points were taken with a Mel-Temp apparatus and are uncorrected.

[3] Silicar CC-7.

material was washed with three 35-ml. portions of water and three 35-ml. portions of ether and then dried to give the blocked polymer. This material was treated with 30 ml. of 90% trifluoroacetic acid, stirred for 50 min., and then concentrated under reduced pressure to yield the crude polypeptide VI. This material was suspended in 30 ml. of water and dissolved by the addition of 1 *N* NaOH to pH 7.5. The solution was dialyzed against distilled water overnight, acidified with 6 *N* HCl to pH 2.5, and then dialyzed against distilled water for a day. The precipitated polypeptide VI was collected by centrifugation and then lyophilized to yield 0.1 g. (6%) of the polymer; amino acid ratios of an acid hydrolysate were: $Phe_{1.0}$-$Asp_{1.0}Val_{1.0}Gly_{1.0}$.

Molecular Weight Determinations—The polypeptide V (0.12 g.) was dissolved in 50 ml. of water by the addition of 1 *N* NaOH to pH 7.4. This solution was separated into four molecular weight ranges by successive diafiltrations through membranes[4]. Each fraction was acidified with 6 *N* HCl, dialyzed, and lyophilized to yield 0.06 g. (mol. wt. >50,000), 0.02 g. (mol. wt. 20,000-50,000), 0.02 g. (mol. wt. 10,000-20,000), and 0.015 g. (mol. wt. <10,000).

A similar process was used to fractionate 0.1 g. of the polypeptide VI, which was comprised of the following: 0.02 g. (mol. wt. >50,000), 0.01 g. (mol. wt. 20,000-50,000), 0.03 g. (mol. wt. 10,000-20,000), and 0.03 g. (mol. wt. <10,000).

Immunochemical Procedures—Eight rabbits were treated with poly(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-^{14}C ethyl ester (I), molecular weight >50,000, at weekly intervals, using the immunization schedule previously described (3); 25 days after the last injection, all rabbits were bled using the standard heart puncture technique. Serum from each rabbit was tested for the precipitin reaction with the homologous antigen I, and serum from each animal gave a positive precipitin reaction. The serum from each animal was pooled, and this combined serum was used for the following experiments. It was assumed that the antibodies produced by each rabbit after the same time interval was directed against the same antigenic determinants of the antigen I.

Quantitative Precipitin Reactions—To 1-ml. aliquots of the pooled rabbit serum were added incremental amounts of the polypeptide I. Each tube was made up to 2 ml. with buffer (0.1 *M* NaCl-0.05 *M* $NaHCO_3$), incubated for 1 hr. at 37°, and then kept at 4° for 48 hr. The tubes were centrifuged in the cold and the precipitates were washed twice with 1 ml. of buffer (0.05 *M* K_2HPO_4-NaOH), pH 7.0. The total amount of protein precipitated was estimated by analysis for nitrogen (Kjeldahl). For V and VI, both of which possessed a molecular weight >50,000, quantitative precipitin reactions were performed using the pooled rabbit serum. These reactions were identical to and run simultaneously with those used for the polypeptide I (Table I).

Absorption Studies—The pooled rabbit serum was treated with the equivalence point amount of the heterologous polypeptides V and VI, each possessing a molecular weight >50,000. The corresponding precipitates were centrifuged out, and the supernatant liquids were poured off into separate tubes. To each supernatant liquid was added 30 mcg. of the homologous antigen, poly(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-^{14}C ethyl ester (I). The tubes were incubated at 37° for 1 hr. and then stored at 4° for 48 hr. The precipitates were collected by centrifugation and washed twice with 1 ml. of buffer solution (0.05 *M* K_2HPO_4-NaOH), pH 7.0. The amount of protein was estimated by analysis for nitrogen (Kjeldahl) (Table I). Controls in which the serum was first absorbed with the homologous antigen I ascertained that the homologous antigen precipitated all of the antibody, since the supernatant liquid gave no further precipitin reaction when 30 mcg. of I was added.

Solubility of Cholesterol and Hormone Drugs in Water

DEVENDRA K. MADAN* and DONALD E. CADWALLADER▲

Abstract □ The aqueous solubilities of cholesterol, testosterone, progesterone, and diethylstilbestrol at 30° were determined using a radioactive assay procedure.

Keyphrases □ Cholesterol—radioactive determination of water solubility □ Testosterone—radioactive determination of water solubility □ Progesterone—radioactive determination of water solubility □ Diethylstilbestrol—radioactive determination of water solubility □ Solubility, water—cholesterol, testosterone, progesterone, diethylstilbestrol, radioactive assay procedure

A search of the literature indicated that solubility values for hormone drugs in water varied considerably and in some cases were not available (1–11). Scattered data reported in the literature for the aqueous solubilities of steroid hormones are presented in Table I. No values were found for diethylstilbestrol. As part of a study on the effects of macromolecules on the solubility of cholesterol and some steroid hormones (12), it was necessary to consider the solution behavior of these compounds.

EXPERIMENTAL

Materials—Progesterone[1], diethylstilbestrol[2], and testosterone[3] were recrystallized from alcohol or diluted alcohol, and their melting points were in good agreement with published values. Cholesterol[4] was purified by recrystallizing from acetic acid. The crystals were dried at 90° in an oven. The sample was then recrystallized from a 70% alcohol–water mixture and dried in a vacuum desiccator. The melting point was found to be 148.5°, and the IR spectrum was in good agreement with reported spectra.

Solubility Experiments—A stock solution of cholesterol in benzene was prepared containing 1.0 mg. of untagged cholesterol and 10 μc. of cholesterol-26-^{14}C[5]. Stock solutions of testosterone and progesterone were prepared to contain 200 mg. of untagged compound and 5 μc. of the labeled compound (testosterone-4-^{14}C and progesterone-4-^{14}C)[5] in 100 ml. of benzene, and a similar stock solution of diethylstilbestrol [using diethylstilbestrol (monoethyl-1-^{14}C)][6] was prepared in methanol. A known amount of a particular stock solution was transferred into a 125-ml. iodine flask, and the solvent was evaporated under a mild stream of nitrogen with constant shaking. A 50-ml. volume of dissolution medium (distilled water or 0.9% saline) kept at 30° was added to the flask. Dissolution studies were carried out at 30 ± 0.5° using a controlled environment unit[6] to maintain the temperature. The solution was stirred at approximately 250–300 r.p.m. using a magnetic stirrer and a 2.7 × 1-cm. Teflon-coated spin bar.

For each dissolution study, the amount of compound used was approximately 10 times in excess of its determined aqueous solubility. At predetermined intervals, 5 ml. of sample was withdrawn from the system and filtered immediately through a filtration assembly[7] containing a 0.45-μ filter. Additional samples containing cholesterol were also filtered through 0.22-μ filters.

Table I—Solubility of Steroids in Water

Compound	Solubility in Water, mcg./ml. This Work (30°)	Literature
Cholesterol	0.09[a]	2600 (20°) (1), 52 (25°) (2)
	0.041[b]	0.025 (30°) (3), 2 (25°) (8), 0.06 (30°) (4)
Progesterone	11.0[c]	9 (25°) (5), 6.6 (25°) (6), 16.8 (37°) (1)
Diethylstilbestrol	25.0[d]	No values found
Testosterone	30.0[e]	24 (25°) (5), 27 (25°) (6), 36 (37°) (6), 29 (25°) (7), 25 (25°) (9–11), 28 (37°) (14), 48 (25°) (2), 125 (37°) (3)

[a] Mean of eight experiments (range 0.07–0.12) using 0.45-μ filter. [b] Mean of eight experiments (range 0.022–0.050) using 0.22-μ filter. [c] Mean of eight experiments (range 8–12). [d] Mean of six experiments (range 21–28). [e] Mean of eight experiments (range 26–33).

Dissolution experiments were carried out in water and 0.9% NaCl solution for cholesterol, testosterone, progesterone, and diethylstilbestrol. A 100-ml. volume of dissolution medium in a 250-ml. iodine flask was used for testosterone studies.

Radioactive Assay Procedure—A 0.20-ml. volume of the particle-free filtrate was pipeted into a liquid scintillation vial. To this was transferred 15 ml. of dioxane–naphthalene scintillation cocktail (13). The scintillation vial was tightly capped and shaken for about 30 sec. to ensure thorough mixing of the experimental solution and the phosphore. At the same time, a blank was prepared in the same manner except that the compound was omitted from the solution. The standard was prepared by pipeting 0.10 ml. of the standard stock solution of the experimental compound into a scintillation vial. After the solvent (benzene or methanol) was evaporated, 0.20 ml. of water and 15 ml. of dioxane–naphthalene scintillation cocktail were added and the vial was shaken. The samples were counted directly using a liquid scintillation system[8]. Sufficient time was allowed for the samples to cool to 4.0° to minimize quenching. The samples were counted for 10 min. and the counts per minute (c.p.m.) were obtained by dividing the 10-min. counts by 10. The solubility values were obtained from the ratio of the counts per minute of the internal standard and the sample.

RESULTS AND DISCUSSION

By using a radioactive assay procedure, the aqueous solubilities of cholesterol, testosterone, progesterone, and diethylstilbestrol were determined at 30° (Table I). Solubilities were also determined in 0.9% NaCl (Table II). Solubilities of hormone compounds were determined as they approached equilibrium and after equilibrium had been established. The solubility values reported in Tables I and II are the solubility values at equilibrium, and the complete solution behavior of these steroids is presented in Figs. 1 and 2.

Variations in water solubility of cholesterol, progesterone, and testosterone were in general accord with the principle that solubility increases with the number of polar groups. As expected, cholesterol

[8] Unilux II, Nuclear Chicago.

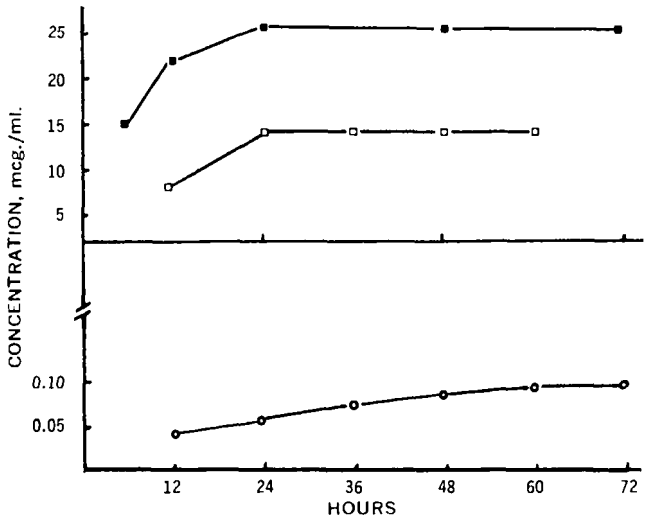

Figure 1—*Aqueous solubility of cholesterol* (○), *progesterone* (□), *and diethylstilbestrol* (■) *at 30°.*

was the least water soluble since it was the most nonpolar and bulkiest of the compounds studied. Testosterone, with one α,β-unsaturated ketone group and a free hydroxyl group, had the highest water solubility of the hormones studied.

Although diethylstilbestrol has a lower molecular weight (268) than testosterone (288), its aqueous solubility was lower; however, its melting point is considerably higher (170°) than testosterone (154°). Therefore, it is quite conceivable that due to its symmetric nature, it may form crystals of high lattice energy as compared to the relatively less symmetrical molecule of testosterone.

Using ^{14}C-labeled cholesterol, Gemant (8) studied the solubilization of cholesterol using a partition chromatographic method. He assumed that, in a solution that solubilized cholesterol, the cholesterol would travel with the moving phase; the stronger the solubilizing action, the farther it would travel. Determination of cholesterol distribution along the paper was accomplished by a radioactive tracer method. ^{14}C-Labeled cholesterol was applied to the paper and, after a suitable time of development, the strip was cut into sections and the activity of each section was measured. He found the solubility of cholesterol to be 0.2 mg./100 ml. of water (= 2 mcg./ml.), more than 20 times the solubility found in the current study.

In more recent work, Saad and Higuchi (3) found the solubility of cholesterol to be 0.025 mcg./ml. in both water and 0.9% NaCl. They equilibrated the cholesterol-water or cholesterol–0.9% NaCl for 30 days and used 0.10- and 0.22-μ filters to clarify the solutions before assay. When 0.45-μ filters were used, significantly higher results (1.5 and 2 times greater) were obtained. The results obtained

Table II—Solubility of Steroids in 0.9% NaCl

Steroid	Solubility, mcg./ml.[a] This Work (30°)	Literature
Cholesterol	0.017	0.025 (30°) (3)
Progesterone	10.0	6.6 (25°) (6)
Diethylstilbestrol	24.5	No values found
Testosterone	29.5	36 (37°) (6), 27 (25°) (6)

[a] Average of two experiments.

in the present study using 0.22-μ filters (0.041 mcg./ml. water and 0.017 mcg./ml. 0.9% NaCl) are in good agreement with the findings (0.025 mcg./ml.) of Saad and Higuchi (3) considering the extremely low solubility levels of cholesterol. When 0.45-μ filters were used in the present study, the aqueous solubility was more than 2 times higher than the solubility data for 0.22-μ filters.

Several experiments were carried out in which sodium chloride was added to saturated solutions of cholesterol (0.09 mcg./ml.) to give a 0.9% salt concentration. The cholesterol solubility values for these solutions decreased to 0.017 mcg./ml. The marked decrease in solubility indicated the possibility that cholesterol crystal nuclei were salted out of solution by the addition of sodium chloride, leaving a true solution of cholesterol. These experiments appear to substantiate that the Coulter counter method used by Saad and Higuchi (3) was able to ascertain the true solubility of cholesterol by detecting crystal nuclei formation.

The solubility values for progesterone, testosterone, and diethylstilbestrol were essentially the same in 0.9% sodium chloride as in water (Tables I and II). There was no significant decrease in hormone concentration when 0.9% sodium chloride was added to saturated solutions of these compounds.

The solution behavior of testosterone is presented in Fig. 2. The equilibrium was approached from supersaturation and not from undersaturation. The decrease in high initial solubility and its subsequent leveling off suggest the conversion of a metastable crystalline form possessing a higher solubility to a form of lower solubility. Thakkar and Hall (9–11) examined the aqueous solution behavior of anhydrous and hydrous testosterone and observed an initial supersaturation with a subsequent leveling for the anhydrous form. The anhydrous form dissolved faster than the hydrous form. They also compared the X-ray diffraction patterns of the original anhydrous form and the residue remaining after the equilibration of the anhydrous form and found that an alteration in the crystalline structure did take place.

In 1954, Bischoff and Stauffer (6) studied the solution behavior of testosterone and found that short equilibration periods gave rise to supersaturated solutions. They also observed that if the solvent was changed after 5 hr. of equilibration, the residue did not produce supersaturated solutions. Heating this residue to slightly below the melting point restored it to the form that produced supersaturated solutions. They hypothesized that this difference in the solution behavior could be due to a difference in the particle sizes of the two samples of testosterone, *i.e.*, one that gave rise to supersaturated solution and one that did not. Actual microscopic examination revealed, however, that there was no difference in the particle size of the two samples. These workers postulated that an explanation of the anomolous solution behavior of testosterone may lie in the existence of polymorphic forms.

Recently, Thakkar and Hall (9–11) attempted to explain the observation of Bischoff and Stauffer (6) by stating that the testosterone sample which produced a supersaturated solution was clearly an anhydrous form whereas the water equilibrated residue which did not was a hydrated form. As might be expected, this hydrate lost its water of hydration and reverted to the anhydrous form when heated to slightly below the melting point. That such a conversion does really occur was shown by the similarity of the X-ray diffraction pattern of the heat-dehydrated hydrate sample to that of the anhydrous form.

Other workers (15, 16) also observed similar solution behavior differences in various solvents for a number of organic compounds including steroids, cholesterol, and fluorohydrocortisone acetate. The decrease in solubility with time once the peak solubility is attained has been explained as being due to nucleation and crystallization of the more stable hydrate.

The peak solubility value displayed during the dissolution of the anhydrous form of testosterone (Fig. 2) may correspond to a short-term steady-state situation involving equal rates of dissolution of the anhydrous form and crystallization of the stable hydrate. On the other hand, the peak solubility could also correspond to the solubility of the anhydrous form. However, the solubilities of both forms of testosterone appear to approach the same value with time (11).

Central Cholinomimetic Actions of 3,3-Dimethyl-1-butanol Carbamate

LYNN WECKER* and C. Y. CHIOU▲

Abstract □ The action of 3,3-dimethyl-1-butanol carbamate on the CNS was studied to determine the mechanism of its convulsant activity. Dimethylbutanol carbamate penetrated into the brain with maximum levels at 15 min. after intraperitoneal injection. The LD_{50} of dimethylbutanol carbamate in mice was 21 mg./kg., and atropine pretreatment protected animals against the toxic effects of dimethylbutanol carbamate, whereas physostigmine enhanced dimethylbutanol carbamate toxicity. Dimethylbutanol carbamate potentiated nicotine-induced convulsions in mice and had no effect on brain cholinesterase activity. Therefore, it appears that dimethylbutanol carbamate is a centrally active agent that produces convulsions *via* a mechanism similar to that postulated for nicotinic agents, although it produces antinicotinic actions peripherally.

Keyphrases □ 3,3-Dimethyl-1-butanol carbamate—mechanism of convulsant activity, central cholinomimetic actions, mice □ Cholinomimetic actions—3,3-dimethyl-1-butanol carbamate, mice □ Convulsant activity—3,3-dimethyl-1-butanol carbamate, mice

3,3-Dimethyl-1-butanol carbamate, a synthetic carbachol analog containing a carbon in place of the quaternary nitrogen atom, is an unusually interesting compound with a potent peripheral antinicotinic effect (1, 2) as well as a central convulsant action in mice, producing tonic-clonic convulsions (3, 4). The effects of this agent on cholinergic-induced drinking behavior in rats have been studied, and it was reported (5) that dimethylbutanol carbamate, when implanted into the lateral hypothalamic region of the rat brain, initiated a response similar to those of acetylcholine and carbachol. These results suggested a central cholinomimetic action of dimethylbutanol carbamate. It has been hypothesized that alterations in brain levels of acetylcholine may be correlated with behavioral changes and that there is a decrease in the acetylcholine content of the brain during convulsions (6–8). When an increase in cortical activity is evident, there is a release of acetylcholine from its storage sites in nerve terminals, resulting in an overall decrease in brain acetylcholine content (6–8).

Dimethylbutanol carbamate was found to cause a significant increase in the release of acetylcholine from the minced guinea pig cerebral cortex (1). Therefore, the present study investigated the possibility that the CNS actions of dimethylbutanol carbamate are due to a direct-releasing action of acetylcholine from storage sites inside nerve endings, a mechanism similar to that reported for the action of nicotinic agents (9). The unusual character of this compound could be used as a tool to elucidate cholinergic mechanisms.

EXPERIMENTAL

ICR Charles River mice, weighing 20–35 g., were used for all studies. To determine the extent of brain penetration of dimethylbutanol carbamate, mice were injected intraperitoneally with 20 mg./kg. ^{14}C-dimethylbutanol carbamate (0.7 μc./mg.). Dimethylbutanol carbamate was synthesized in this laboratory according to the method described previously (1). The animals were sacrificed by cervical dislocation at various times, and their brains were removed, weighed, homogenized (1 ml. water/1 g. tissue), and solubilized[1] at 50° for 12–15 hr. The samples were allowed to cool, and

Keyphrases □ 3,3-Dimethyl-1-butanol carbamate—mechanism of convulsant activity, central cholinomimetic actions, mice □ Cholinomimetic actions—3,3-dimethyl-1-butanol carbamate, mice □ Convulsant activity—3,3-dimethyl-1-butanol carbamate, mice

3,3-Dimethyl-1-butanol carbamate, a synthetic carbachol analog containing a carbon in place of the quaternary nitrogen atom, is an unusually interesting compound with a potent peripheral antinicotinic effect (1, 2) as well as a central convulsant action in mice, producing tonic-clonic convulsions (3, 4). The effects of this agent on cholinergic-induced drinking behavior in rats have been studied, and it was reported (5) that dimethylbutanol carbamate, when implanted into the lateral hypothalamic region of the rat brain, initiated a response similar to those of acetylcholine and carbachol. These results suggested a central cholinomimetic action of dimethylbutanol carbamate. It has been hypothesized that alterations in brain levels of acetylcholine may be correlated with behavioral changes and that there is a decrease in the acetylcholine content of the brain during convulsions (6–8). When an increase in cortical activity is evident, there is a release of acetylcholine from its storage sites in nerve terminals, resulting in an overall decrease in brain acetylcholine content (6–8).

Dimethylbutanol carbamate was found to cause a significant increase in the release of acetylcholine from the minced guinea pig cerebral cortex (1). Therefore, the present study investigated the possibility that the CNS actions of dimethylbutanol carbamate are due to a direct-releasing action of acetylcholine from storage sites inside nerve endings, a mechanism similar to that reported for the action of nicotinic agents (9). The unusual character of this compound could be used as a tool to elucidate cholinergic mechanisms.

EXPERIMENTAL

ICR Charles River mice, weighing 20–35 g., were used for all studies. To determine the extent of brain penetration of dimethylbutanol carbamate, mice were injected intraperitoneally with 20 mg./kg. ^{14}C-dimethylbutanol carbamate (0.7 μc./mg.). Dimethylbutanol carbamate was synthesized in this laboratory according to the method described previously (1). The animals were sacrificed by cervical dislocation at various times, and their brains were removed, weighed, homogenized (1 ml. water/1 g. tissue), and solubilized[1] at 50° for 12–15 hr. The samples were allowed to cool, and

[1] NCS solubilizer, Amersham Searle, Arlington Heights, Ill.

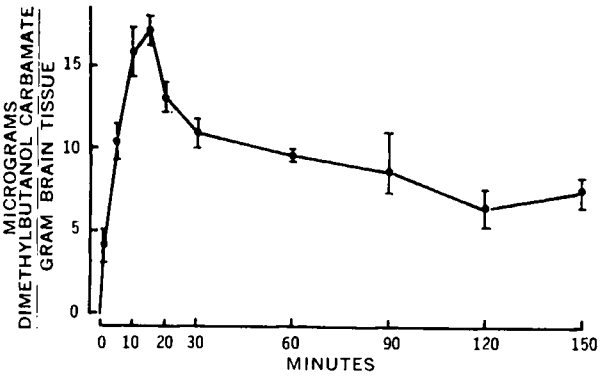

Figure 1—*Uptake of dimethylbutanol carbamate by mouse brain. Mice were injected with 20 mg./kg. ^{14}C-dimethylbutanol carbamate and sacrificed at time intervals shown on the abscissa. The brains were analyzed for radioactivity, and results are expressed as micrograms dimethylbutanol carbamate per gram brain tissue. Each point is a mean of three values, and the bars represent standard errors.*

then 20 ml. scintillation cocktail (6 g. 2,5-diphenyloxazole/l. toluene) was added. The samples were analyzed for radioactivity on a liquid scintillation system[2], with an error of ±1.0%.

The effects of atropine and physostigmine on the toxicity of dimethylbutanol carbamate were determined as follows. Mice were divided into three groups. The LD_{50} of dimethylbutanol carbamate was determined as the control using the first group. The second group of mice was pretreated with atropine (100 mg./kg.) 30 min. prior to dimethylbutanol carbamate administration. It was reported (10) that the effect of this atropine pretreatment is to decrease significantly brain levels of acetylcholine. The third group of mice was pretreated with 0.2 mg./kg. physostigmine 30 min. prior to dimethylbutanol carbamate injection. This physostigmine pretreatment has been found to produce significant behavioral alterations in mice. The LD_{50} and limits at the 95% confidence level for each group were determined by a log dose probit plot (11).

To determine the effects of dimethylbutanol carbamate on nicotine-induced convulsions, mice were divided into two groups. The first group was injected with nicotine intraperitoneally, and the number of animals that developed convulsions was noted. The second group was injected with a subconvulsant dose of dimethylbutanol carbamate (1 mg./kg.) intraperitoneally 30 min. prior to the nicotine injection, and the occurrence of convulsions was once again noted. The dose-response curves were constructed, and the ED_{50}'s to produce convulsant activity and potency ratios were calculated (11).

The effect of dimethylbutanol carbamate on intact brain cholinesterase was determined radioisotopically (12). Mice were sacrificed by cervical dislocation, and their brains were removed immediately, frozen, and weighed. The brains were homogenized for 30 sec. at 10,000 r.p.m.[3], in phosphate buffer (pH 8, 0.1 *M*), yielding a homogenate of 0.1 mg. brain/ml. phosphate buffer. A 0.1-ml. aliquot of the homogenate was added to centrifuge tubes containing phosphate buffer with or without dimethylbutanol carbamate (10^{-4} or 10^{-3} *M*). The tubes were preincubated for 15 min. at 37° before addition of ^{14}C-acetylcholine (1.2×10^{-5} *M*). The reaction mixtures were incubated for various periods, and 500 mg. cation-exchange resin[4] and 5 ml. absolute ethanol were added to stop the reaction. The mixture was shaken for 15 sec. and centrifuged at $1470 \times g$ for 5 min. Aliquots of the supernate (4.0 ml.) were sampled and added to 10 ml. scintillation cocktail (7 g. 2,5-diphenyloxazole and 100 g. naphthalene/l. dioxane). The samples were counted in a liquid scintillation system. Values for autohydrolysis of ^{14}C-acetylcholine were determined from incubation mixtures in the absence of homogenate. Initial rates of hydrolysis were determined during the first 30 min., and the rates were expressed as Δ c.p.m./min. Levels of statistical significance were determined with Student's *t* test at $p \leq 0.05$.

The drugs studied included 3,3-dimethyl-1-butanol carbamate, atropine sulfate, physostigmine sulfate, nicotine tartrate, and acetyl-1-^{14}C-choline iodine (4.53 mc./mmole)[5].

Table I—Effects of Atropine and Physostigmine on the Toxicity of Dimethylbutanol Carbamate in the Mouse

Treatment	Number of Animals	LD_{50} of Dimethylbutanol Carbamate, mg./kg.
Dimethylbutanol carbamate alone	150	21.0 (18.3–24.2)[a]
Atropine plus dimethylbutanol carbamate[b]	80	49.0 (29.7–80.9)[c]
Physostigmine plus dimethylbutanol carbamate[d]	80	17.0 (15.2–19.0)[c]

[a] Limits at the 95% confidence level determined by the method of Litchfield and Wilcoxon (11). [b] Treatment with atropine (100 mg./kg.) 30 min. prior to dimethylbutanol carbamate administration. [c] Significantly different from control at $p \leq 0.05$, determined by the method of Litchfield and Wilcoxon (11). [d] Treatment with physostigmine (0.2 mg./kg.) 30 min. prior to dimethylbutanol carbamate administration.

[2] Beckman liquid scintillation system, model 1650, Beckman Instruments, Fullerton, Calif.

RESULTS

To determine whether dimethylbutanol carbamate penetrated into the CNS, mice were injected intraperitoneally with ^{14}C-dimethylbutanol carbamate. Maximum brain levels were reached at approximately 15 min., and the concentration at that time was 17.1 mcg. dimethylbutanol carbamate/g. wet weight brain tissue (1.3×10^{-4} mole/kg.) (Fig. 1). After 15 min., the concentration of dimethylbutanol carbamate decreased steadily until a fairly constant level was apparent (8.5 mcg. dimethylbutanol carbamate/g. brain tissue) for the following 60 min.

When mice were injected with a lethal dose of dimethylbutanol carbamate, they exhibited initial ataxia followed by hyperactivity leading to tonic-clonic convulsions approximately 30–45 min. after injection. The duration of convulsions was approximately 5 min. before death occurred. At the time of death, the chest cavity of the animal was opened and heart function was inspected. Respiratory paralysis appeared to be the cause of death, but death was probably not due to a peripheral neuromuscular blockade since sciatic nerve gastrocnemius muscle blockade in rabbits was not achieved at doses that produced death. The LD_{50} for the mouse was 21 mg./kg. (Table I). When animals were pretreated with atropine, there was significant protection from dimethylbutanol carbamate toxicity and the LD_{50} was increased to 49 mg./kg. dimethylbutanol carbamate. Conversely, when mice were pretreated with physostigmine, dimethylbutanol carbamate toxicity was enhanced and the LD_{50} was lowered to 17 mg./kg.

The ED_{50} of nicotine to cause convulsion was lowered from 3.8 to 2.7 mg./kg. with dimethylbutanol carbamate pretreatment (Table II). This was a significant potentiation of convulsant activity, with a potency ratio of 1.4. The slopes of the dose-response curves indicate a parallelism with a slope ratio of 1.1.

The effect of dimethylbutanol carbamate on brain cholinesterase was studied to determine whether cholinesterase inhibition was involved with the central actions of dimethylbutanol carbamate. When mouse brain homogenates were incubated with dimethyl butanol carbamate (10^{-4} or 10^{-3} *M*), there was no effect on the rate

of ^{14}C-acetylcholine hydrolysis (Table III), supporting a direct acetylcholine-releasing action by dimethylbutanol carbamate.

DISCUSSION

Dimethylbutanol carbamate has been shown to possess central cholinomimetic effects, although it has cholinolytic actions peripherally (1, 2). This agent has been shown to release acetylcholine from the minced guinea pig cerebral cortex (1) at concentrations that did not affect brain cholinestease activity, suggesting a direct acetylcholine-releasing action. From the studies on dimethylbutanol carbamate toxicity, it has been shown that atropine is able to protect mice from the lethal effects of dimethylbutanol carbamate, while physostigmine potentiates dimethylbutanol carbamate toxicity. Therefore, it appears that dimethylbutanol carbamate toxicity may be due to an increased transmitter release. This idea is supported by the observation that protection of cholinergic actions by atropine is able to decrease dimethylbutanol carbamate toxicity. Although precise action mechanisms of atropine in the CNS are not well established, it is clear that atropine reduces central acetylcholine levels (10), which are probably responsible for the reduction of central cholinergic actions of dimethylbutanol carbamate. Likewise, enhancement of toxicity has been shown to be evident in the presence of a cholinesterase inhibitor.

Dimethylbutanol carbamate was found to enhance nicotine toxicity. It has been shown that nicotine causes the release of acetylcholine in rat cerebral cortex (9), and nicotine-induced convulsions have been postulated to be due to an action on the CNS (13). Thus, it appears that the central actions of dimethylbutanol carbamate and nicotine may be quite similar. It was reported (14) that atropine was the most effective agent against nicotine-induced convulsions. It was also shown that atropine was very effective in protecting animals from dimethylbutanol carbamate toxicity, supporting a similar mechanism for the central actions of dimethylbutanol carbamate and nicotine.

In conclusion, it appears that dimethylbutanol carbamate is a potent central cholinomimetic agent whose action is due to the direct release of endogenous acetylcholine from nerve terminals. This may result in an overall decrease in brain acetylcholine to produce central convulsant activity in animals.

Interaction between DNA and Coralyne Acetosulfate, an Antileukemic Compound

Keyphrases ☐ Coralyne acetosulfate—interaction (complexation) with calf thymus DNA in water ☐ DNA (calf thymus)—interaction (complexation) with coralyne acetosulfate in water

Sir:

The alkaloid coralyne displayed confirmed antileukemic activity against leukemias L-1210 and P-388 in laboratory animals. A practical preparation of the acetosulfate (sulfoacetate) and the chloride salts of coralyne was recently reported (1); the availability of this method has permitted an easy access to this alkaloid, thus permitting unhampered the continuation of biological, pharmacological, and clinical evaluation. Although the exact mode of action of coralyne is not yet understood, a comparative study of UV absorption characteristics revealed an *in vitro* interaction between coralyne and calf thymus DNA in aqueous solution. This phenomenon may be associated with the biological activity of coralyne.

When coralyne acetosulfate (I*a*) was dissolved in water, the UV absorption of the aqueous solution at pH 7 changed rapidly. The major absorption peak of the solution moved from 297 to 262 nm. within 1 hr. This hypsochromic shift was practically complete after 2 days (Fig. 1; the same phenomenon was observed with the less water-soluble chloride salt I*b*). However, when a 1:4 (weight ratio) mixture of I*a* and the sodium salt of calf thymus DNA[1] was dissolved in water at pH 7, the UV spectrum of this complex, which is different from that of either component under the same controlled conditions, showed no change on standing. Even after the solution was allowed to stand at 25° for 4 weeks, the shape of the UV spectrum remained practically unchanged (Fig. 2). Under similar conditions, when the thymus DNA was dissolved in water at pH 7, the UV spectrum showed a single peak at 258 nm. (Fig. 1) which slowly decreased in peak height on standing. A

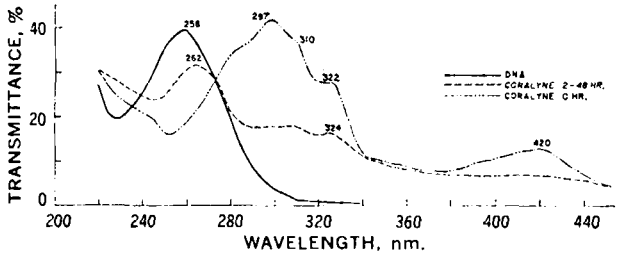

Figure 1—*UV absorption of coralyne and DNA in water at pH 7, 25° [coralyne acetosulfate, 5 mg./l.; and DNA (calf thymus, sodium salt), 20 mg./l.].*

I*b*: X = Cl

precipitate formed after the aqueous DNA solution was stored at 25° for 4 weeks.

Coralyne acetosulfate apparently undergoes a rapid hydration process in aqueous solution. Presumably this is due to multiple bond hydration (2–4) across the C=N region, which results in breaking of the original conjugative system and, hence, alters the electronic transitions. The hydration is reversible; when an aqueous solution containing I*a* was kept at 25° for 2 hr. followed by subsequent lyophilization, the resulting solid showed an identical melting point and IR and UV spectra in methanol (Fig. 3) as the original material, I*a*. Under similar conditions, methanol was not added across the C=N bond, since the UV absorption peak remained unchanged even after long standing.

These results revealed that an interaction between coralyne and thymus DNA in water existed and that the resulting complex blocked the breaking of aromatic conjugation of coralyne by covalent hydration. These observations are significant since complex formation between many biologically active compounds with DNA double helix has been suggested to account for their activity (5–13). Also, a common N—O—O— triangulation feature, which was found among a number of antileukemic compounds including coralyne, has been proposed as a possible pharmacophore, which may contribute to the *in vivo* binding to some biologically pertinent sites (14). Detailed studies on hydration of coralyne as well as certain related problems are being actively performed.

Effect of Formulation on Dissolution of Sodium Warfarin Tablets

Keyphrases □ Sodium warfarin tablets—effect of pregranulation dissolving on dissolution rate □ Dissolution rate, sodium warfarin tablets—effect of dissolving drug prior to granulation

Sir:

Numerous publications have shown that formulation of a solid dosage form can influence dissolution of the active drug. These studies have discussed the effect of binder concentration and tablet hardness (1), types of binders and particle size (2), types of starches (3), lubricants (4), and disintegration agents (5).

Table I—Dissolution Rate Constants (k) of Various Sodium Warfarin Tablet Formulations and Surface Tension of Solutions Used to Granulate

Formulation	k, min.$^{-1}$	Surface Tension[a], γ, dynes/cm.
A. Drug incorporated in dry form	0.060	—
B. Drug and polyvinylpyrrolidone dissolved in alcohol[b]	0.074	26.1
C. Drug dissolved in alcohol[c]	0.113	25.6
D. Drug and polyvinylpyrrolidone dissolved in water[d]	0.154	57.4
E. Drug dissolved in water[e]	0.246	59.4
	Absolute alcohol	24.4
	Water, deionized	74.1

[a] Of solution used to granulate. Measured by a Du Noüy interfacial tensiometer. [b] Solution ratio of drug–polyvinylpyrrolidone–alcohol = 1:1:6. [c] Solution ratio of drug–alcohol = 1:6. [d] Solution ratio of drug–polyvinylpyrrolidone–water = 1:1:4. [e] Solution ratio of drug–water = 1:4.

The purpose of this communication is to report that dissolving sodium warfarin prior to granulating can influence the dissolution rate.

Sodium warfarin was incorporated into a microcrystalline cellulose–lactose (3:1) mixture such that 25 mg. of sodium warfarin was contained/275-mg. tablet. The drug was either added into the formulation in the dry state or dissolved in an aqueous or alcoholic media, with or without an equal ratio of polyvinylpyrrolidone–sodium warfarin. The solutions (Table I) were used to granulate the microcrystalline cellulose–lactose mixture. Magnesium stearate (0.1%) was added to either the powder mixture or the dried, 20-mesh screened granulation. Tablets were compressed on a compressing machine[1]. All tablets disintegrated within 1 min. Dissolution tests were performed in a round-bottom flask, containing 500 ml. of distilled water, maintained at 37°. A half-moon (2.5 cm. in diameter) stirring blade was used at a speed of 50 r.p.m. Assays were performed spectrophotometrically.

The pseudo-first-order rate constants obtained from this study are shown in Table I. As can be seen, the slowest rates are obtained when the drug is in the dry state or is dissolved in an alcoholic polyvinylpyrrolidone solution. Dissolution can be increased when the drug is dissolved in water—with or without polyvinylpyrrolidone—or in alcohol alone prior to granulating.

By dissolving the drug prior to granulating, it is possible to increase the available surface area when this solution is poured onto a powder mixture. This would result in increased dissolution (Table I).

The difference in the rate of solution between Formulations C and E appears to be a function of the surface tension of the solution used to pour onto the lactose–microcrystalline cellulose mixture. It is known that the high surface area of microcrystalline cellulose is due to fissures and crevices found abundantly in the granules. Since the alcoholic solution (Formulation C) has a

By dissolving the drug prior to granulating, it is possible to increase the available surface area when this solution is poured onto a powder mixture. This would result in increased dissolution (Table I).

The difference in the rate of solution between Formulations C and E appears to be a function of the surface tension of the solution used to pour onto the lactose–microcrystalline cellulose mixture. It is known that the high surface area of microcrystalline cellulose is due to fissures and crevices found abundantly in the granules. Since the alcoholic solution (Formulation C) has a

[1] Colton SX, four station.

lower surface tension, it is able to penetrate into fissures and crevices which water cannot readily enter, resulting in a decreased rate of solution.

The addition of polyvinylpyrrolidone into Formulations B and D (Table I) does not alter the surface tension. Therefore, the decrease in dissolution when compared to Formulations C and E, respectively, must be a function of the rate of solution of polyvinylpyrrolidone, causing a decrease in the rate of solution of a rather soluble drug in water.

The results of this study show that the method used to incorporate drug into a solid dosage form can affect the dissolution rate of that drug.

NMR Spectroscopy: Chloro-(tetra-*p*-methylphenylporphinato)indium (III)

Key phrases □ Chloro(tetra-*p*-methylphenylporphinato)indium (III)—NMR spectra □ Porphine complexes with indium—NMR spectra of chloro(tetra-*p*-methylphenylporphinato)indium (III) □ Indium (III), chloro(tetra-*p*-methylphenylporphinato)—NMR spectra □ NMR spectroscopy—identification, chloro(tetra-*p*-methylphenylporphinato)indium (III)

Sir:

Porphine complexes are important biologically and chemically. Structural studies of these complexes may provide information relative to their mechanisms of action. We wish to report NMR studies on the complex chloro(tetra-*p*-methylphenylporphinato)indium (III).

Chloro(tetra-*p*-methylphenylporphinato)indium (III) was prepared and purified as previously reported (1, 2). NMR spectra were obtained using a spectrometer[1] equipped with a variable-temperature probe and operated at power levels below saturation. Temperatures were measured with a thermocouple mounted in the probe; temperature calibration was done with ethylene glycol. Spectra were obtained in 1,1,2,2-tetrachloroethane which had been purified by distillation from phosphorus pentoxide under nitrogen. Spectra were obtained with the spectrometer locked on the solvent resonance, and chemical shifts were reported relative to the solvent.

[1] Varian-HA-100.

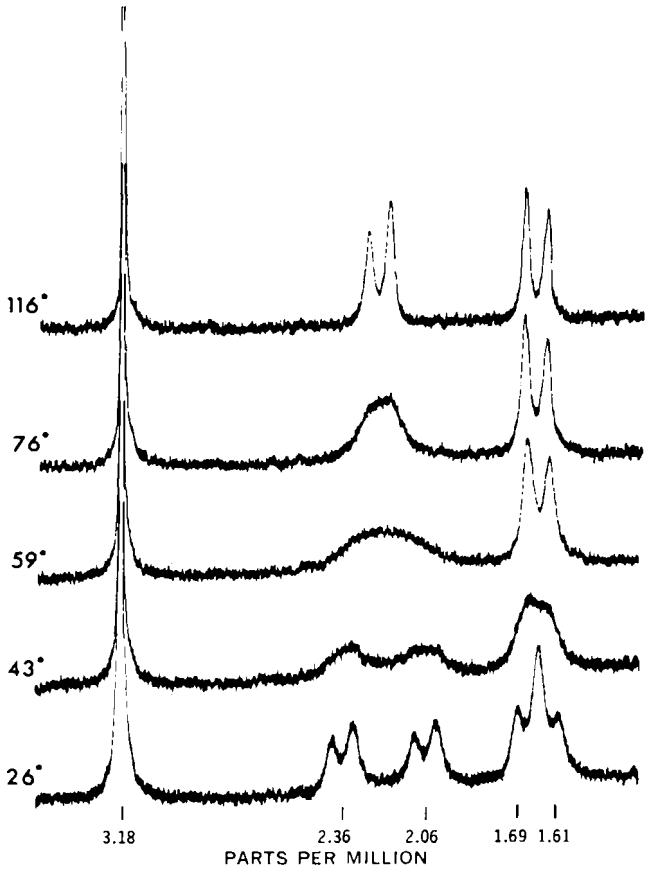

Figure 1—*NMR spectra (100 MHz.) of chloro(tetra-*p*-methylphenylporphinato)indium (III) at various temperatures.*

It has been shown that the NMR spectra of indium–tetraphenylporphine complexes at room temperature exhibit nonequivalence of the phenyl ring protons (2). The NMR spectrum of chloro(tetra-*p*-methylphenylporphinato)indium (III) in Fig. 1 shows that as the temperature rises, the phenyl signals broaden and finally collapse into a pair of doublets at approximately 100°. Spectral changes were reversible with temperature. The resonance at 3.18 p.p.m. resulted from the porphine pyrrole protons. Resonances at 2.06 and 2.36 p.p.m. were assigned to the *ortho*-protons; resonances at 1.61 and 1.69 were assigned to the *meta*-protons (2).

The room temperature spectrum has been assigned an *AA'BB'* pattern in which the two different *ortho*- and *meta*-protons are nonequivalent due to restricted rotation about the *meso*-carbon to phenyl (carbon carbon) bond. As the temperature was elevated, the rotation became fast on the NMR time scale, appearing to yield equivalence of *ortho*- and the *meta*-protons. No attempt was made to obtain accurate kinetic parameters for this highly coupled spin system; the rate of averaging can be estimated (3) as 66/sec. at the coalescence temperature of approximately 60° for the *ortho*-protons: ($\Delta G^{\ddagger}_{333}$ = 16.8 kcal./mole).

The concept of restricted rotation about the carbon-to-carbon bond is strongly supported by X-ray diffraction studies on porphines and porphine complexes (4). Such studies have indicated that the *meso*-phenyl rings are tilted at an angle to the mean plane of the porphine ring (5–7). This angle was found to be approximately

lower surface tension, it is able to penetrate into fissures and crevices which water cannot readily enter, resulting in a decreased rate of solution.

The addition of polyvinylpyrrolidone into Formulations B and D (Table I) does not alter the surface tension. The concept of restricted rotation about the carbon-to-carbon bond is strongly supported by X-ray diffraction studies on porphines and porphine complexes (4). Such studies have indicated that the *meso*-phenyl rings are tilted at an angle to the mean plane of the porphine ring (5–7). This angle was found to be approximately

90° in many metal complexes of tetraphenylporphine (4, 8), although angles as small as 69 (9) and 76° (10) were found in certain metal complexes. Steric interactions between pyrrole hydrogen and phenyl hydrogen atoms have been estimated to require a dihedral angle of 60 (10) or 70° (4).

The sequence of spectral changes given in Fig. 1 is nearly identical to those reported for tetrakis[(*p*-isopropylphenyl)porphinato]ruthenium carbonyl complexes (8, 11). The averaging process for the indium complex occurs at slightly lower temperatures than for the ruthenium complex.

Phenyl ring rotation has been observed in tetra-*o*-hydroxylphenylporphine and its copper complex (12). The rate constant for rotation of the free porphine at 23° in methanol was 1.5×10^{-5}/sec. ($\Delta G^{\neq} = 24$ kcal./mole); rotation was about 10 times slower for the copper complex. Isomers of tetra-*o*-tolylporphine and its nickel complex have also been studied (13). The NMR signals for the methyl resonances of this compound did not appreciably broaden up to 180°, indicating that $\Delta G^{\neq}$ for rotation exceeds 26 kcal./mole (13). The present studies of chloro(tetra-*p*-methylphenylporphinato)indium (III) confirm earlier observations on ruthenium complexes (II); there appears to be a more rapid phenyl group rotation when the *ortho*-substituent is hydrogen than when it is hydroxyl or methyl.

Alternative interpretations of the NMR spectrum for chloro(tetra-*p*-methylphenylporphinato)indium (III) appear less plausible. Since *AA'* and *BB'* coupling was not resolved for indium (III) tetraphenylporphine, it is possible to attribute the room temperature spectra to rapidly rotating phenyl groups in nonequivalent positions with accidental degeneracy of nonequivalent pyrrole and methyl resonances. The temperature dependence of such a spectrum would result from the interchange of nonequivalent phenyl sites. However, it has been demonstrated that phenyl rotation is slow in the ruthenium complexes at room temperature (8, 11); it is not likely that rotation would be fast in the chloro(tetra-*p*-methylphenylporphinato)indium (III) complex at the same temperature. If the chloride in the indium complex were dissociated, ion migration or inversion of a "dished" ring conformation could explain the NMR results; however, there are no data to substantiate such an interpretation.

Specificity of Binding to Human Serum Albumin

Keyphrases ☐ Drug-human serum albumin binding—specificity, lipophilic dependency, equations ☐ Binding, drug-human serum albumin—specificity, lipophilic dependency, equations

Sir:

Whitehouse *et al.* (1) suggested the need for reevaluation of the widely held concept (2, 3) that the fraction of certain acidic drugs bound to plasma protein is pharmacologically inactive. In support of this suggestion, data were presented indicating that a correlation exists between the ability of certain anti-inflammatory agents and uricosuric agents to displace uric acid from its primary binding site on human serum albumin *in vitro* (1) and their ability to reduce uric acid binding capacity *in vivo*. The results of other studies were cited to support this thesis (4, 5). One cited study showed that fatty acids displace warfarin and phenylbutazone from their binding sites on human serum albumin *in vitro* (5).

A relationship was recently shown (6) between the ability of certain acidic drugs to displace albumin-bound uric acid and their affinity for the primary binding site of 5-dimethylaminonaphthalene-1-sulfonamide on human serum albumin. Analysis of these affinity data revealed that for certain members of two classes of nonsteroid anti-inflammatory and uricosuric agents—*viz.*, (*a*) carboxylic acids, and (*b*) benzenesulfonamides and

90° in many metal complexes of tetraphenylporphine (4, 8), although angles as small as 69 (9) and 76° (10) were found in certain metal complexes. Steric interactions between pyrrole hydrogen and phenyl hydrogen atoms have been estimated to require a dihedral angle of 60 (10) or 70° (4).

Specificity of Binding to Human Serum Albumin

Keyphrases ☐ Drug-human serum albumin binding—specificity, lipophilic dependency, equations ☐ Binding, drug-human serum albumin—specificity, lipophilic dependency, equations

Sir:

Whitehouse *et al.* (1) suggested the need for reevaluation of the widely held concept (2, 3) that the fraction of certain acidic drugs bound to plasma protein is pharmacologically inactive. In support of this suggestion, data were presented indicating that a correlation exists between the ability of certain anti-inflammatory agents and uricosuric agents to displace uric acid from its primary binding site on human serum albumin *in vitro* (1) and their ability to reduce uric acid binding capacity *in vivo*. The results of other studies were cited to support this thesis (4, 5). One cited study showed that fatty acids displace warfarin and phenylbutazone from their binding sites on human serum albumin *in vitro* (5).

A relationship was recently shown (6) between the ability of certain acidic drugs to displace albumin-bound uric acid and their affinity for the primary binding site of 5-dimethylaminonaphthalene-1-sulfonamide on human serum albumin. Analysis of these affinity data revealed that for certain members of two classes of nonsteroid anti-inflammatory and uricosuric agents—*viz.*, (*a*) carboxylic acids, and (*b*) benzenesulfonamides and

benzenesulfonylureas, a highly significant relationship exists between the displacing ability of the two structure types and the lipophilicity of these agents as measured by their partition coefficients in the 1-octanol–water system (7). These relationships are given in Eqs. 1 and 2 (7).

50% Displacement of 5-Dimethylaminonaphthalene-1-sulfonamide from Human Serum Albumin by Carboxylic Acids—

$$\log 1/C = 1.06\,(\pm 0.67) + 1.26\,(\pm 0.42)\log P - 0.12\,(\pm 0.06)\log^2 P \quad \text{(Eq. 1)}$$
$$n = 29 \quad R = 0.91 \quad SD = 0.36$$
$$\log P_0 = 5.48\,(4.69\text{–}7.80)$$

50% Displacement of 5-Dimethylaminonaphthalene-1-sulfonamide from Human Serum Albumin by Benzenesulfonamides and Benzenesulfonylureas—

$$\log 1/C = 3.64\,(\pm 0.21) + 0.74\,(\pm 0.28)\log P - 0.34\,(\pm 0.10)\log^2 P \quad \text{(Eq. 2)}$$
$$n = 13 \quad R = 0.91 \quad SD = 0.21$$
$$\log P_0 = 1.10\,(0.89\text{–}1.29)$$

In these equations, C is the concentration (moles/liter) required to displace 50% of 5-dimethylaminonaphthalene-1-sulfonamide from its binding site on human serum albumin, P is the 1-octanol–water partition coefficient, n represents the number of agents in the set, R is the correlation coefficient, SD is the standard deviation of the regression, and P_0 is the partition coefficient associated with optimum affinity for the 5-dimethylaminonaphthalene-1-sulfonamide binding site. The terms in parentheses are the 95% confidence intervals for the appropriate regression coefficients. The analysis of additional data (8) for the displacement of 5-dimethylaminonaphthalene-1-sulfonamide from its primary binding site on human serum albumin by various sulfonamides substantiates the nonlinear relationship between the displacing ability and lipophilicity (Eq. 4).

Percent Decrease in Fluorescence of 5-Dimethylaminonaphthalene-1-sulfonamide–Albumin Complex by Various Sulfonamides—

$$\log \%D = 1.56\,(\pm 0.20) + 0.18\,(\pm 0.14)\log P \quad \text{(Eq. 3)}$$
$$n = 13 \quad SD = 0.27 \quad R = 0.63$$

$$\log \%D = 1.62\,(+0.09) + 0.42\,(\pm 0.10)\log P - 0.13\,(\pm 0.04)\log^2 P \quad \text{(Eq. 4)}$$
$$n = 13 \quad R = 0.94 \quad SD = 0.13$$
$$\log P_0 = 1.60\,(1.32\text{–}2.05)$$

Including the nonlinear term in Eq. 3 is significant at the 99% level of confidence, $F_{1,13} = 43.76$, $F_{1,13,\alpha\,0.01} = 9.07$.

On comparing the analyses of the data for the sulfa drugs (Eqs. 2 and 4), it is significant to note the similarities in log P_0's from the two relationships. The data used to derive Eq. 4 are given in Table I. The agreement is very good considering that the data were obtained from different laboratories. The difference in the two values may be due to the fact that the data used to derive Eq. 2 were obtained at 37° while those used for Eq. 4 were obtained at 24°. The dependence of log P_0 on temperature is not understood, however. The difference in intercepts of Eqs. 2 and 4 may be due to the fact that the dependent variable in the former case is a standard response while that of the latter case is a relative biological response.

Table I—Influence of Various Sulfa Drugs on the Fluorescence of 5-Dimethylaminonaphthalene-1-sulfonamide–Human Serum Albumin Complex

Sulfa Drug	log P	log Percent Decrease in Fluorescence		
		Observed	Calculated[a]	$\lvert\Delta \log \%D\rvert$
Sulfadimethoxine	1.56[b]	1.99	1.96	0.03
Sulfamethoxypyridazine	0.40[b]	1.98	1.77	0.21
Sulfamethazine	0.27[b]	1.91	1.73	0.18
Sulfaphenazole	1.57[b]	1.90	1.96	0.06
Sulfisoxazole	1.15[b]	1.90	1.94	0.04
Sulfadoxine	1.56[c]	1.89	1.96	0.07
Sulfamerazine	0.13[b]	1.71	1.68	0.03
Sulfathiazole	0.35[b]	1.65	1.76	0.11
Sulfamethoxazole	0.54[b]	1.61	1.81	0.20
Sulfanilamide	−0.83[b]	1.22	1.18	0.04
Sulfaguanidine	−1.22[b]	0.84	0.91	0.07
Probenecid	3.21[d]	1.63	1.62	0.01
Tolbutamide	2.34[d]	1.96	1.89	0.07

[a] Equation 4. [b] *Reference 9.* [c] log P estimated to be equivalent to that for sulfadimethoxine. [d] Experimental value, this laboratory.

The parabolic nature of Eqs. 1, 2, and 4 is unusual in that recent studies (10–12) of the dependence of the binding of drugs to serum albumin on lipophilicity led to linear relationships between log P and an appropriate binding parameter. This report is at variance with these studies in that the dependent variable in this case is a measure of the affinity of the displacing agent, relative to that of 5-dimethylaminonaphthalene-1-sulfonamide, for a specific site on human serum albumin. In the cases where linear relationships were found between binding and log P, the binding parameter was an equilibrium binding constant or a related parameter which could give no information about binding specificity.

The nonlinearity found in this and the prior study (7) can be explained by proposing a secondary binding site with an affinity for the displacing agents. As the lipophilicity becomes greater than log P_0 for the series of the displacing agents, affinity for this secondary site increases and the effective concentration of the drug decreases.

There is theoretical justification for the nonlinearity we have found and this lies in the pseudoequilibrium model developed by Higuchi and Davis (13). They found that for systems in equilibrium or quasiequilibrium, nonlinear relationships can result between relative affinities for binding to specific sites or for receptor sites and lipophilicity.

In summary, the findings of this report indicate that drug–human serum albumin interactions can be highly specific and dependent on lipophilicity. It may be possible to take advantage of this specificity and, using Eqs. 1, 2, and 4 as guides in design, synthesize more effective uricosuric agents.

BOOKS

REVIEWS

International Encyclopedia of Pharmacology and Therapeutics—Neuromuscular Blocking and Stimulating Agents, Volumes I and II. Edited by J. CHEYMOL. Pergamon Press, Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. 654 pp. 14.5 × 23 cm. Price $52.50 (two-volume set).

These two comprehensive volumes reviewing the literature on agents which modify neuromuscular transmission represent the joint effort of the following authors: F. Bourillet, D. Bovet, W. C. Bowman, A. S. V. Burgen, C. Chagas, J. Cheymol, R. Couteaux, J. Debecker, J. E. Desmedt, D. Duncalf, Lise Engbaek, F. F. Foldes, G. Genkins, H. Grundfest, J. I. Hubbard, A. R. McIntyre, I. G. Marshall, K. E. Osserman, L. Sollero, G. Suarez-Kurtz, O. Vital-Brazil, G. Vourc'h, S. N. Webb, and P. G. Waser. Both volumes were edited by Professor J. Cheymol.

These two volumes are probably the most comprehensive review of agents that modify neuromuscular transmission that is available. The style of writing and arrangements of the manuscripts are of the highest quality and it is truly a pleasure to read the various chapters. As Professor Cheymol indicates in the Introduction, these volumes are comprehensive and include information that any researcher or clinician must have to understand the basic physiology and pharmacology of transmission. The various sections in the book include an excellent discussion of the anatomy that is involved with the end plate and skeletal muscle. At the physiological level, extensive discussions are included concerning pertinent enzymes, acetylcholine, and the influence of ions on transmission. Most of the volumes are devoted to the pharmacological level of discussion and comprehensive reviews are included covering comparative, chemical, and theoretical aspects of pharmacological actions of neuromuscular blocking agents and stimulants. Detailed discussions of the theoretical receptor as well as basic function of proteins are included. This is followed by discussion of pathological problems involved in neuromuscular transmission and finally the volumes conclude by comprehensive analysis of therapeutic considerations and treatments of various neuromuscular diseases.

Another reason that these are such delightful volumes is that the authors have exercised extreme care in searching the literature. The authors review the printed word all the way from the history of curare to the more recent research on the nerve terminal actions of drugs.

It is a pleasure for this reviewer to recommend these comprehensive volumes and assure any reader that they will be reviewing the most recent published work as well as our important historical heritage that leads to present knowledge. Volume I contains 423 pages and Volume II has 231 pages. Any scientist or clinician who is interested in neuromuscular transmission should have these volumes available as a necessary reference.

Foreign Compound Metabolism in Mammals, Volume 2. By D. E. HATHWAY. The Chemical Society, Burlington House, London, WIV OBN, England, 1972. xv + 513 pp. 14.5 × 22 cm. Price £ 11.00.

The second volume of this series covers the two-year period 1970–1971. It consists of an introduction section, seven chapters, and an author index and a compound index, the latter being a new feature added with this volume.

In the introduction, the editor D. E. Hathway discusses some broad points relative to the book, such as validation in man, biological availability, selection of animals, implications of metabolic studies on determining "no effect" levels, and perspectives in toxicology.

The first chapter on tracers for metabolism includes general considerations, syntheses of various radioisotopes, reactions, and stable isotopes.

The transference of radioactively labeled foreign compounds is covered in the second chapter; it is subdivided into drugs, pesticides, food additives, and other compounds.

Biotransformations, which comprise the third chapter, are discussed by the subdivisions drugs, food additives, carcinogens, lathyrogens, silicon and boron compounds, toxins, rodenticides, insecticides, herbicides, fumigants and fungicides, and other compounds.

Chapter Four includes the mechanisms of biotransformation such as oxidation, reduction, hydrolysis, and conjugation.

The last three chapters cover species, sex, and strain differences in metabolism; drug kinetics; and interactions of drugs and foreign compounds.

Staff Review ■

The Molecular Basis of Antibiotic Action. By E. F. Gale, E. Cundliffe, P. E. Reynolds, M. H. Richmond, and M. J. Waring. Wiley, New York, N.Y., 1972. xviii + 456 pp. 14.5 × 23 cm.

The authors have chosen a topic for this book that is so potentially overwhelming in scope and detail one may justifiably wonder whether a single volume could adequately develop a molecular basis for antibiotic action. Their intent, however, is remarkably well approached. The format established is to classify the antibiotics according to whether they are inhibitors of bacterial cell wall synthesis, nucleic acid synthesis, or ribosome function or whether they affect the function of the cytoplasmic membrane. A clear effort is made to include under each classification examples of each major antibiotic known to function in the specified manner. The unifying thread is a lucid and critical discussion of biochemical or intact cell experiments which point to a particular molecular mechanism of action. Included in certain of the surveys, as well as in a separate chapter, is a fine introduction to the biochemical basis for bacterial resistance to antibiotics.

This is followed by discussion of pathological problems involved in neuromuscular transmission and finally the volumes conclude by comprehensive analysis of therapeutic considerations and treatments of various neuromuscular diseases.

Another reason that these are such delightful volumes is that the authors have exercised extreme care in searching the literature. The authors review the printed word all the way from the history of curare to the more recent research on the nerve terminal actions of drugs.

It is a pleasure for this reviewer to recommend these comprehensive volumes and assure any reader that they will be reviewing the most recent published work as well as our important historical heritage that leads to present knowledge. Volume I contains 423 pages and Volume II has 231 pages. Any scientist or clinician who is interested in neuromuscular transmission should have these volumes available as a necessary reference.

Foreign Compound Metabolism in Mammals, Volume 2. By D. E. HATHWAY. The Chemical Society, Burlington House, London, WIV OBN, England, 1972. xv + 513 pp. 14.5 × 22 cm. Price £ 11.00.

The second volume of this series covers the two-year period 1970–1971. It consists of an introduction section, seven chapters, and an author index and a compound index, the latter being a new feature added with this volume.

In the introduction, the editor D. E. Hathway discusses some broad points relative to the book, such as validation in man, biological availability, selection of animals, implications of metabolic studies on determining "no effect" levels, and perspectives in toxicology.

The first chapter on tracers for metabolism includes general considerations, syntheses of various radioisotopes, reactions, and stable isotopes.

The transference of radioactively labeled foreign compounds is covered in the second chapter; it is subdivided into drugs, pesticides, food additives, and other compounds.

Biotransformations, which comprise the third chapter, are discussed by the subdivisions drugs, food additives, carcinogens, lathyrogens, silicon and boron compounds, toxins, rodenticides, insecticides, herbicides, fumigants and fungicides, and other compounds.

Chapter Four includes the mechanisms of biotransformation such as oxidation, reduction, hydrolysis, and conjugation.

The last three chapters cover species, sex, and strain differences in metabolism; drug kinetics; and interactions of drugs and foreign compounds.

The Molecular Basis of Antibiotic Action. By E. F. Gale, E. Cundliffe, P. E. Reynolds, M. H. Richmond, and M. J. Waring. Wiley, New York, N.Y., 1972. xviii + 456 pp. 14.5 × 23 cm.

The authors have chosen a topic for this book that is so potentially overwhelming in scope and detail one may justifiably wonder whether a single volume could adequately develop a molecular basis for antibiotic action. Their intent, however, is remarkably well approached. The format established is to classify the antibiotics according to whether they are inhibitors of bacterial cell wall synthesis, nucleic acid synthesis, or ribosome function or whether they affect the function of the cytoplasmic membrane. A clear effort is made to include under each classification examples of each major antibiotic known to function in the specified manner. The unifying thread is a lucid and critical discussion of biochemical or intact cell experiments which point to a particular molecular mechanism of action. Included in certain of the surveys, as well as in a separate chapter, is a fine introduction to the biochemical basis for bacterial resistance to antibiotics.

International Encyclopedia of Pharmacology and Therapeutics—Neuromuscular Blocking and Stimulating Agents, Volumes I and II. Edited by J. CHEYMOL. Pergamon Press, Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. 654 pp. 14.5 × 23 cm. Price $52.50 (two-volume set).

These two comprehensive volumes reviewing the literature on agents which modify neuromuscular transmission represent the joint effort of the following authors: F. Bourillet, D. Bovet, W. C. Bowman, A. S. V. Burgen, C. Chagas, J. Cheymol, R. Couteaux, J. Debecker, J. E. Desmedt, D. Duncalf, Lise Engbaek, F. F. Foldes, G. Genkins, H. Grundfest, J. I. Hubbard, A. R. McIntyre, I. G. Marshall, K. E. Osserman, L. Sollero, G. Suarez-Kurtz, O. Vital-Brazil, G. Vourc'h, S. N. Webb, and P. G. Waser. Both volumes were edited by Professor J. Cheymol.

These two volumes are probably the most comprehensive review of agents that modify neuromuscular transmission that is available. The style of writing and arrangements of the manuscripts are of the highest quality and it is truly a pleasure to read the various chapters. As Professor Cheymol indicates in the Introduction, these volumes are comprehensive and include information that any researcher or clinician must have to understand the basic physiology and pharmacology of transmission. The various sections in the book include an excellent discussion of the anatomy that is involved with the end plate and skeletal muscle. At the physiological level, extensive discussions are included concerning pertinent enzymes, acetylcholine, and the influence of ions on transmission. Most of the volumes are devoted to the pharmacological level of discussion and comprehensive reviews are included covering comparative, chemical, and theoretical aspects of pharmacological actions of neuromuscular blocking agents and stimulants. Detailed discussions of the theoretical receptor as well as basic function of proteins are included. This is followed by discussion of pathological problems involved in neuromuscular transmission and finally the volumes conclude by comprehensive analysis of therapeutic considerations and treatments of various neuromuscular diseases.

Another reason that these are such delightful volumes is that the authors have exercised extreme care in searching the literature. The authors review the printed word all the way from the history of curare to the more recent research on the nerve terminal actions of drugs.

It is a pleasure for this reviewer to recommend these comprehensive volumes and assure any reader that they will be reviewing the most recent published work as well as our important historical heritage that leads to present knowledge. The Molecular Basis of Antibiotic Action. By E. F. Gale, E. Cundliffe, P. E. Reynolds, M. H. Richmond, and M. J. Waring. Wiley, New York, N.Y., 1972. xviii + 456 pp. 14.5 × 23 cm.

The authors have chosen a topic for this book that is so potentially overwhelming in scope and detail one may justifiably wonder whether a single volume could adequately develop a molecular basis for antibiotic action. Their intent, however, is remarkably well approached. The format established is to classify the antibiotics according to whether they are inhibitors of bacterial cell wall synthesis, nucleic acid synthesis, or ribosome function or whether they affect the function of the cytoplasmic membrane. A clear effort is made to include under each classification examples of each major antibiotic known to function in the specified manner. The unifying thread is a lucid and critical discussion of biochemical or intact cell experiments which point to a particular molecular mechanism of action. Included in certain of the surveys, as well as in a separate chapter, is a fine introduction to the biochemical basis for bacterial resistance to antibiotics.

Such broad coverage leads necessarily to deficiencies in detail, as in the chapter dealing with inhibitors of protein synthesis, but these are balanced by expanded discussions on antibiotics of more current interest. In the chapter dealing with drugs affecting the cytoplasmic membrane, present membrane models are briefly and critically discussed. The surveys noting the influences of antibiotics on membrane structure and on energy-dependent transport processes are stimulatory and cause one to reflect on how similar effects might be involved more generally in drug transport and other types of drug action. Inhibitors of nucleic acid synthesis, particularly those which function by intercalation, are discussed in considerable detail. In view of the diversity of biological effects manifested by intercalating agents such emphasis is understandable, even though the specificity of action of these compounds is more generally attributable to other factors governing drug action such as differential permeability. A discussion of the genetic basis for antibiotic resistance is incorporated into the chapter terminating the overall development to support earlier descriptions of resistance mechanisms.

There is sufficient content to this book for it to be of interest to students and researchers in nearly all areas of the basic health sciences. This reviewer can recommend it highly.

Fundamentals of Chemotherapy. By WILLIAM B. PRATT. Oxford University Press, 200 Madison Ave., New York, NY 10016, 1973. 332 pp. 14 × 20.5 cm. Price $6.95.

Primarily intended as a textbook, this book's chapters are organized by grouping drugs according to their biochemical site of action. In general, the biochemical process affected by a particular drug is described as is its mechanism of action. Drug resistance and drug interactions are also emphasized. The four major sections are drugs employed in the treatment of bacterial and fungal infection, parasitic disease, viral infection, and neoplastic disease.

Hypersensitivity to Drugs, Volume I. International Encyclopedia of Pharmacology and Therapeutics, Section 75. Edited by M. SAMTER and C. W. PARKER. Pergamon Press. Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. xii + 439 pp. 14.5 × 23 cm. Price $36.00.

It is now recognized that the clinical symptoms which are the result of hypersensitivity to drugs are the final step in a long and often complicated sequence. This volume of the well-regarded *International Encyclopedia of Pharmacology and Therapeutics* series identifies the known conditions which must be met by the drug and by the host before immunological reactions can occur. The wide variety of responses which drugs can induce in organs and systems are covered. Precise definition of the requirements to be met by drug and host will eventually allow prediction of probable hypersensitivity development and will permit the development of measures to prevent it.

Hypersensitivity to Drugs, Volume I. International Encyclopedia of Pharmacology and Therapeutics, Section 75. Edited by M. SAMTER and C. W. PARKER. Pergamon Press. Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. xii + 439 pp. 14.5 × 23 cm. Price $36.00.

It is now recognized that the clinical symptoms which are the result of hypersensitivity to drugs are the final step in a long and often complicated sequence. This volume of the well-regarded *International Encyclopedia of Pharmacology and Therapeutics* series identifies the known conditions which must be met by the drug and by the host before immunological reactions can occur. The wide variety of responses which drugs can induce in organs and systems are covered. Precise definition of the requirements to be met by drug and host will eventually allow prediction of probable hypersensitivity development and will permit the development of measures to prevent it.

Journal of Pharmacokinetics and Biopharmaceutics. Plenum, 227 W. 17th St., New York, NY 10011, 1973. 15 × 23 cm. Price $32.00 (six issues).

Journal of International Research Communication. Published by M. C. S. Buckingham. IRCS, University Park Press, Chamber of Commerce Building, Baltimore, MD 21202, 1973. 20.5 × 29.5 cm. Price $77.00 (monthly).

Such broad coverage leads necessarily to deficiencies in detail, as in the chapter dealing with inhibitors of protein synthesis, but these are balanced by expanded discussions on antibiotics of more current interest. In the chapter dealing with drugs affecting the cytoplasmic membrane, present membrane models are briefly and critically discussed. The surveys noting the influences of antibiotics on membrane structure and on energy-dependent transport processes are stimulatory and cause one to reflect on how similar effects might be involved more generally in drug transport and other types of drug action. Inhibitors of nucleic acid synthesis, particularly those which function by intercalation, are discussed in considerable detail. In view of the diversity of biological effects manifested by intercalating agents such emphasis is understandable, even though the specificity of action of these compounds is more generally attributable to other factors governing drug action such as differential permeability. A discussion of the genetic basis for antibiotic resistance is incorporated into the chapter terminating the overall development to support earlier descriptions of resistance mechanisms.

There is sufficient content to this book for it to be of interest to students and researchers in nearly all areas of the basic health sciences. This reviewer can recommend it highly.

SUMMARY 1588

Interest in the evaluation of the *in vivo* performance of drug dosage forms has increased greatly in the last few years, as an examination of recent volumes of this Journal will readily attest. The pharmacokinetic aspects of dosage form performance have received particular emphasis. In a typical experiment, the dosage form is administered to a group of subjects and blood samples are drawn at various sampling times following administration. Assay of the blood samples for drug content gives a sequence of drug concentrations which may be used to characterize the performance of the formulation. Such questions as how much of the drug does the formulation make available and how rapidly are of obvious interest and importance. When assay methods for blood drug levels are not feasible, an alternative approach consists of collecting and assaying urine specimens.

Methods of statistical analysis are becoming more widely used in the evaluation of such experiments, and there appear to be two main areas of application. The first is in the characterization of the behavior of the formulation in the biological organism by some kind of mathematical model; the second is in the comparison of the behavior of different dosage forms. Both types of application lead naturally to the use of certain statistical techniques. The first leads to estimation problems, particularly those of estimating the various parameters in a mathematical model. The second leads to problems in hypothesis testing, that is, in testing the hypothesis that no difference exists between two formulations. As discussed later in this article, a different approach to the problem of comparison of formulations—*via* confidence intervals—was recently suggested.

Olson and Lee (1) previously reviewed the application of statistical methods to quality control in the pharmaceutical industry. The purpose of the present article is to provide a similar review of the evaluation of *in vivo* performance of dosage forms. No attempt is made to refer to every article in which statistical methods were used. Rather, this article provides a critical review of proposed methods, some of which are now in wide use, with reference to selected papers. The author's opinion is that many statistical techniques have been applied

uncritically, albeit enthusiastically, to this field. The main aim of this review is, therefore, to expose the statistical problems and proposed methods of solution in a critical examination.

CHARACTERIZATION OF A FORMULATION

To examine the *in vivo* behavior of a formulation, one administers the formulation to a subject, draws blood samples at various times following administration, and obtains a sequence of blood concentrations, or blood levels as they are often called. The sequence of blood levels is then used to characterize the formulation. A number of methods of characterization are possible and have been used by various workers. The most popular method, by far, is that of characterizing the formulation by one or more estimated parameters (*e.g.*, an absorption rate constant) obtained from fitting a biologically meaningful mathematical model to the blood level data. In the great majority of cases, compartmental models are employed in which the biological organism is represented as a series of connected compartments (*e.g.*, blood compartment and tissue compartment) and transfers of drug among compartments are usually first order.

A second, purely empirical, method of characterization consists of fitting some mathematical function to the blood levels. In this case, the mathematical function is not intended to be a meaningful model of the biological organisms but only to give a good fit to the observed blood levels. However, the possibility exists—and, indeed, has been utilized—of choosing some parameter of the mathematical function to characterize the formulation. Other methods of characterization of the performance of the formulation, such as choosing some feature of the blood level sequence (*e.g.*, peak blood level or time of peak level) or some computed characteristic of the blood level sequence (*e.g.*, area under the blood level curve as a measure of amount of drug absorbed) are possible and are widely used. The statistical methodology that has been employed in utilizing these methods of characterization will be discussed, and some of the statistical problems will be examined.

Compartmental Models—The overwhelming choice of most workers who are faced with the problem of using a biologically meaningful model to characterize blood levels produced by a drug formulation is the compartmental model with linear transfers. One-, two-, and three-compartment models [see, for example, Chapter 38 of *Reference 2*, Riegelman *et al.* (3), and Nagashima *et al.* (4)] figure prominently in the pharmaceutical literature. Taking the one-compartment open model as an example, one can derive the expression:

$$C(t) = \frac{Dk_a}{V(k_a - k_e)}(e^{-k_e t} - e^{-k_a t}) \qquad \text{(Eq. 1)}$$

for the concentration of drug in the blood at time t. The symbol D represents the amount of drug absorbed, V is an apparent volume of distribution of the blood, and k_a and k_e are absorption and elimination rate constants, respectively. The salient feature of this expression, as it is in all compartmental models, is that it is the sum of a number of exponential terms.

The statistical problem is that of finding the values of the unknown parameters D/V, k_a, and k_e which, in some way, best "fit" the observed data. Again, in the overwhelming majority of cases, the technique of fitting used is that of "least squares," *i.e.*, the estimation of the parameters such that they minimize the sum of squares of differences between observed and predicted blood level values. The method has a number of desirable statistical features but is not the only method possible. Determination of this minimum sum of squares results in three simultaneous equations to be solved for the three parameters. If these equations were linear in the parameters, one could fall back on a well-developed theory for their solution; but in the case of the present example and all compartmental models, the equations are nonlinear in the parameters and little general theory is available for solution of the equations. Therefore, the equations are usually solved by iterative methods. That is, an initial rough estimate of the parameters is obtained and one then proceeds, iteratively, to find a sequence of solutions for which the residual sum of squares becomes progressively smaller. When no further substantial diminution in the sum of squares appears possible, the process is said to have converged to the required least-squares solution.

The initial estimates of the pharmacokinetic parameters are usually obtained by the familiar process of "peeling off" the exponential terms one at a time from a semilogarithmic plot of the blood levels. The technique is frequently mentioned in the pharmaceutical literature; for a systematic approach that has been programmed for a digital computer, reference may be made to Foss (5). Once initial tentative estimates of the pharmacokinetic parameters have been obtained, several techniques of proceeding to the least-squares solution are available. Most of these are based, at least in part, on the so-called Gauss Newton method, which involves linearizing the problem in the neighborhood of the initial estimates and computing by linear least-squares techniques the solution giving the "minimum" sum of squares. One then proceeds, iteratively, from the new solution through further improved solutions until convergence is attained.

Hartley (6) gave a modified version of this technique and Marquardt (7) proposed a method based both on the Gauss Newton method and the method of "steepest descent." Numerous programs based on these methods [*e.g.*, Metzler (8) and Marquardt (9)] are available and are widely used in fitting compartmental models to blood level data. Smith and Shanno (10) produced an improved version of Marquardt's original method, and Ackerman *et al.* (11) proposed a method of solution termed "iterative guessing." However, they gave no reasons for considering their method superior to the other methods already discussed. Lawton and Sylvestre (12) suggested the possibility of taking advantage of any linearities that occur in the functional equations. Since only one term, the D/V introduced earlier, appears linearly in compartmental models, their suggestion would appear to have little utility in the solution of the problems discussed here.

Other methods of fitting sums of exponentials to data are available. Two examples are Cornell's (13) method, which requires equal spacing of the observations in time, and Foss's (14) method, which gives a noniterative

scheme for sums of two or three exponentials not restricted to equal spacing.

An important concern is the reliability of the estimates of the parameters given by the least-squares solution. The usual way of approaching this statistical problem is through the construction of a "confidence region" for the parameter estimates. Briefly, a 95% confidence region, for example, is a region in the parameter space that is so constructed that in repeated trials the true values of the parameter will lie in the confidence region in 95% of the cases. As an example, consider the two-compartment open model in which the five parameters, D/V, k_a, k_{12}, k_{21}, and k_e—or, equivalently, D/V, k_a, k_{21}, α, and β (where $\alpha\beta = k_e k_{21}$ and $\alpha + \beta = k_e + k_{12} + k_{21}$)—are to be estimated. In this case, the confidence region is a five-dimensional ellipsoid and the practical difficulties of interpreting such regions lead, in most programs, to a series of confidence statements for the individual parameter estimates based on the concepts of tangent planes to the ellipsoid. In addition, one can make the straightforward confidence interval statements for each parameter estimate separately, as was done by Maas and Patel (15), but these statements ignore the substantial correlations that usually exist between parameter estimates whenever one is fitting a sum of exponential terms. One result of the strong correlation existing between the parameter estimates is that confidence ellipsoids or, equivalently, the ellipsoids corresponding to the contours of constant residual sum of squares are greatly elongated. In practical terms, this means that one may be able to change the parameter estimates substantially without changing the residual sum of squares or, in other words, that many very different sets of estimates of the pharmacokinetic parameters give about equally good fits of the model to the data.

It should be apparent from this brief discussion that, in most cases in which the equation for blood concentration obtained from a compartmental model is fitted to experimental data, very little faith should be placed in the estimated pharmacokinetic parameters *per se*. The problems inherent in fitting sums of exponential terms to data have been recognized by mathematicians and statisticians for a long time, and the well-known book on numerical analysis by Lanczos (16, chap. IV) contains an excellent discussion of the subject. In view of its great significance to would-be fitters of compartmental models, it is worth spending a little time on the example given by Lanczos.

Lanczos gives a set of 24 data points (accurate to the second decimal place) generated by a function that is the sum of a number of exponentials; the data are error free except for the round-off to the second decimal place. An exact method for estimating the coefficients (amplitudes) of the exponential term and the values of their exponents is used. Lanczos starts tentatively with a three-term exponential model but finds that the series of observations needs only two exponential terms to describe it. He then finds the values of the parameters of the two-exponential term model that best fit the data and is able to generate a near-perfect fit. When the residuals (the differences between the actual data value and the value predicted by the fitted model) are examined, only one of them exceeds 0.005—it is, in fact, 0.006—and the square root of the residual mean square error is 0.0026. One could hardly expect a more perfect fit. Then Lanczos drops his bombshell: not only is the fitted model incorrect, but it does not even have the correct number of terms! In fact the data were generated from an expression that was the sum of *three* exponential terms. Not only was the exponential term with the smallest coefficient lost in the fitting process, but the other two terms of the original function were very different from the two exponentials as actually fitted. Lanczos decides that the result is thus completely unsatisfactory and his brief summation deserves to be quoted in full (p. 279).

> *It would be idle to hope that some other modified mathematical procedure could give better results, since the difficulty lies not with the manner of evaluation but with the extraordinary sensitivity of the exponents and amplitudes to very small changes of the data, which no amount of least square or other form of statistics could remedy. The only remedy would be an increase of accuracy to limits which are far beyond the possibilities of our present measuring devices.*

This quotation might serve as a suitable warning to all who embark on the task of fitting compartmental models to blood level data, especially since the pharmacokineticist is faced with a far more severe problem than that illustrated by Lanczos in his example. Not only is round-off error present, but assay error is also inevitable in determining the blood samples. However, there is worse to follow in view of the fact that no biological organism can be expected to behave as a theoretically perfect compartmental model. One should be prepared to think in terms of another component of error, namely, lack of fit of the actual organism to the theoretical model.

The pharmaceutical literature abounds with examples of blood level data to which the authors have fitted compartmental models by the method of least squares. The foregoing discussion suggests that rather than confining their attention solely to a least-squares solution, authors would be well advised to give confidence limits, alternative solutions with almost equal sums of squares and, additionally, solutions for alternative models having almost equally good fits. Only in this manner would it be possible to form some idea of the validity of the proposed solution from a purely statistical standpoint. Naturally, if extrastatistical arguments (*e.g.*, physiological) can be adduced, the nature of the problem changes.

Methods other than least squares have been proposed for fitting sums of exponentials to blood level data. Gardner *et al.* (17), for example, proposed a method based on Fourier transforms. To date, however, methods other than least squares have not been widely used in the characterization of blood levels by compartmental models. Ackerman *et al.* (11), discussing briefly the problems already raised in this paper and referring to the literature on multicompartment analysis of tracer experiments (18), stated: "Complex transform methods have been attempted but none appear to have proved especially helpful with real biological data."

One aspect of the characterization of a drug formulation by compartmental models that has received little emphasis to date is the possibility of arranging the blood sampling times so as to estimate only certain specified parameters with high precision. For example, the essential characteristic of an orally administered formulation may lie in one parameter only, namely, an absorption rate constant. If one is allowed only a certain number of blood samples from each subject, the best procedure might be to arrange them so as to give the maximum precision in the estimation of this absorption rate constant at the expense of poorer precision for the other parameters. The problem of designing experiments where the underlying model is nonlinear in the model parameter has attracted some attention in the statistical literature but little, as yet, in pharmaceutical applications. Box and Lucas (19) wrote perhaps the first paper on the topic, and since then a number of papers by associates of Box have appeared. The paper by Box (20) extended the theory and also provided useful additional references. A characteristic requirement for the construction of an optimum design in a nonlinear situation is the need for some idea of the magnitude of the parameters that one is attempting to estimate. In practice, pilot studies would normally be carried out from which such rough estimates could be obtained, and this field appears potentially ripe for further investigation.

Normally, one estimates the parameters in a compartmental model by fitting the model to blood level data since this is the only compartment that can be sampled at varying points in time. An interesting possibility is that of obtaining data from other compartments of the model by indirect means. Wagner *et al.* (21) demonstrated that for subjects receiving the drug LSD-25, there appears to be a simple linear relation between the scores obtained by the subjects on arithmetic tests and the predicted concentration of drug in the so-called tissue compartment of a two-compartment open model. Metzler (22) used this idea to fit a two-compartment model to both blood level and test score data simultaneously. In a two-compartment model, there are five parameters (D/V, k_a, k_{12}, k_{21}, and k_e) to be estimated. If the assumption is made that the arithmetic test scores are of the form found in Eq. 2:

$$S(t) = 100 - F_1 C_T(t) \qquad \text{(Eq. 2)}$$

where $S(t)$ is the score at time t, $C_T(t)$ is the tissue concentration at time t, and F_1 is an unknown parameter, then there are six parameters to be estimated but the number of data points available is now the sum of the number of blood levels and the number of test scores. The model is fitted by the usual least-squares techniques, and no new statistical principles are involved. This procedure, when valid, may be viewed as a means of increasing the amount of experimental data available for the fitting process.

In this discussion of compartmental models, attention should be drawn to the paper of Rodda *et al.* (23) which breaks new ground in several aspects of parameter estimation. Their paper dealt, however, only with one of the simplest possible cases, namely, the one-compartment model with oral drug administration. By simulation techniques, they examined the effects of assay error and of random variation in the pharmacokinetic parameters (physiological variation) on the least-squares estimates of the parameters. Their results suggest that the least-squares estimates do, in fact, give unbiassed estimates of the true underlying parameters. However, their estimates of the sampling variance of these parameters are sufficiently different from those obtained by the usual linearization techniques used in most nonlinear least-squares programs to suggest that the confidence intervals given by such programs may be substantially in error. This paper also examined a favorite device of workers in this field, namely, "curve averaging"—the practice of fitting a compartmental model to blood level data that are taken not from one trial but are the mean values of a number of trials. Here, they found, not surprisingly, a distinct tendency for the estimates of the parameters to be biassed.

Finally, the authors (23) discuss an alternative estimation technique which appears to be less sensitive to "outliers" than the usual least-squares estimation. An outlier is an observation subject to considerably greater error than most of the other observations. As should be only too apparent fom the earlier discussion, an outlier in a series of blood level values can have a disastrous effect on the least-squares estimates of the pharmacokinetic parameters. Outright discarding of apparent outliers is open to the objection of arbitrariness and the charge of attempting to make the data fit preconceived theories; the outliers may, in fact, be legitimate observations.

The contents of this paper have been discussed in detail because it is one of the few attempts so far made to examine some of the severe statistical and computational problems that beset the user of compartmental models. However, since it dealt only with one of the simplest possible compartmental models, much statistical examination yet remains to be done to counter the uncritical manner in which workers in this field have embraced compartmental models and nonlinear least-squares programs that fit them to their data. In view of Lanczos's sobering example, an interesting simulation study would be that of fitting two-compartment models to data generated from one-compartment models (and vice versa), with an accompanying examination of the relationship between the true and estimated pharmacokinetic parameters. By using intravenous infusion to mimic known absorption rates, Loo and Riegelman (24) demonstrated that the choice of the wrong model can lead to substantial errors in the estimates of the absorption rate constant. The clear implication is that blood level data must be fitted to the "correct" model for accurate characterization of a dosage form. However, the earlier discussion and, in particular, the example given by Lanczos imply that statistical and mathematical manipulation of the data may provide little guidance in determining this model. To demand that a nonlinear least-squares program decide on the appropriate model and estimate its parameters solely on the basis of statistical criteria is, demonstrably, unrealistic. Moreover, even if nonstatistical criteria (for example, physiological factors) can be adduced to support the validity of a particular model, the severe problems associated with the fitting of the model

parameters to the blood level data remain. The question of the sensitivity of exponential curves to their parameters was discussed in a recent paper by Julius (25).

Empirical Characterization—A feature of the characterization of blood level data by the compartmental model is that the model is intended to represent, however imperfectly and approximately, the biological organism and its handling of the drug. One can, of course, characterize the blood level data in a purely empirical manner by any type of mathematical function that gives a good fit to the data. Westlake (26) suggested that if the characterization is required only to predict future blood levels (*e.g.*, from various regimens), then a simple mathematical representation is adequate. Wold (27) proposed a more elaborate, but still empirical, characterization based on spline functions. Wold used a polynomial spline function to characterize blood levels of a group of subjects receiving various modifications of a semisynthetic penicillin. Briefly, a polynomial spline function is a function that is, piecewise, a polynomial of specified degree. The pieces join each other in points called knots and are subject at the knots to various continuity conditions on the function itself and its derivatives. After a logarithmic transformation of the blood levels, Wold was able to obtain a good fit to blood level data for the 60 subjects in his experiment using a spline function of two pieces, although he encountered numerical difficulties in trying to fit the sum of two exponential terms to the same data sets. Even though the use of spline functions is an empirical approach, Wold suggested taking this idea one step further and using certain features of the function (such as time of peak and final slope) as representative of "meaningful" biological parameters (such as absorption rate and elimination rate). He cited the greater stability of these estimates within subject groups (on the same modification of the drug formulation) in comparison with estimates of the traditional pharmacokinetic parameters as a great advantage. And he considered the disadvantage, namely, the lack of any direct relationship to the parameters of a compartmental model, to be unimportant and mainly a question of the experimenter's familiarization with this new idea.

COMPARISON OF FORMULATIONS

The previous section dealt with the problem of characterizing the *in vivo* performance of a formulation of a drug. In many cases, however, one is less concerned with characterizing a formulation *per se* than with comparing its performance with that of another formulation. This is particularly the case of an abbreviated new drug application (NDA) submitted to the Food and Drug Administration (FDA), where a part of the submission is a comparative blood level trial in which the new formulation is compared with an already approved "standard" formulation. The general problem is that of comparing the *in vivo* behavior of two or more formulations of the same drug by conducting trials in which the formulations are administered to subjects and blood samples (or urine samples) are taken at various times following administration.

A major problem in comparing the performance of the formulations is deciding which characteristics of the blood level sequence should be compared. The following list of possibilities is suggested:

1. Comparison of the formulations with respect to estimated parameters (*e.g.*, an absorption rate constant or area under the curve as a measure of the amount of drug absorbed) in a biologically meaningful model, such as a compartmental model.

2. Comparison of the formulations with respect to some empirical, but presumably meaningful, characteristic of the blood level sequence (*e.g.*, peak blood level achieved or time of peak blood level).

3. Comparison of the formulations solely with respect to the sequences of blood levels that they generate. Essentially, the comparison of formulations is treated as a "repeated-measurements" experiment (the statistical terminology for a sequence of observations—in this case, blood levels at various sampling times—on each item in the trial). The essential feature of such a method of analysis is that one does not pick out any "meaningful" feature of the blood level sequence for special treatment.

Trials in which the *in vivo* performance of formulations are compared have come to be known as (comparative) bioavailability trials. The term bioavailability denotes different things to different workers. For a limited definition as "relative absorption efficiency," see *Reference 2* (chap. 25). Metzler (28) suggested that, in its broadest use, "the term includes the study of the factors which influence and determine the amount of active drug which gets from the administered dose to the site of pharmacologic action as well as the rate at which it gets there." Metzler gave an excellent, brief summary of the statistical problems arising in comparative bioavailability trials. Underlying all comparative studies of the *in vivo* performance of different formulations lies a question that is of the utmost importance: If statistical analysis detects "significant" differences between formulations, are these differences of any clinical or therapeutic importance? Without an adequate answer to the question of what differences in blood level characteristics or estimated pharmacokinetic parameters correspond to significant clinical or therapeutic differences, all comparative blood level trials must, to a certain extent, be academic exercises.

Design of Comparative Blood Level Trials—The design of comparative blood level trials is based, at least in its statistical aspects, on the well-established principles laid out by Cochran and Cox (29), for example. Designs may employ parallel groups in which each subject of a group receives a given formulation, or they may be of the crossover type in which each subject receives all formulations, in some sequence, with a suitable wash-out period between administrations of the different formulations. The crossover design has achieved almost universal acceptance because, as in much biological experimentation, subject-to-subject variation is considerable. Use of the crossover design, as contrasted with the design in parallel groups, for example, enables one to eliminate subject-to-subject variation in the analysis, thereby achieving a more sensitive test of the formulations. The various ways of laying out the assignment of formulations to subjects were reviewed by Westlake (30). Briefly, one can assign all formulations to

each subject in a random sequence (randomized blocks), or the administration of formulation to subjects can be made in sequences that form a series of Latin squares. A further possibility, not widely used to date, is that of assigning formulations in a balanced incomplete block design. In this case, each subject does not receive all of the formulations (if more than two are involved in the study) but receives at least two of them. The analysis is only slightly more complicated than the more usual Latin-square design, and the crossover concept, which enables one to isolate the subject-to-subject variation, is preserved.

Once the appropriate design has been selected, the remaining problem is determining the appropriate number of subjects for the trial. Again, there is a standard statistical methodology for achieving this end. (See, for example, chap. II, *Reference 29.*) One needs: (*a*) an estimate of the minimum difference between two formulations with respect to some characteristic that one wishes to detect, (*b*) a probability of detecting this difference should it occur, (*c*) a significance level (commonly 0.05) at which the test of the null hypothesis of no difference between the formulations is to be made, and (*d*) an estimate of the residual error standard deviation, which is a measure of the inherent variability in the data. Usually, such an estimate will be available from preliminary work or from a pilot experiment. An elementary discussion of the problem of determining the number of subjects required in the trial was given by Westlake (30).

Analysis of Variance in Comparative Blood Level Trials—The basic method of analyzing a crossover trial in a Latin-square design is an analysis of variance (ANOVA). For example, suppose that it is desired to analyze a characteristic for which there is one value per administration of a formulation to a subject. Examples are an estimated pharmacokinetic parameter, an area under the blood level curve, and a peak blood level. Then the basic ANOVA partitions the total sum of squares of the observations about their mean into a component due to the subjects, a component due to the different days of administration, a component due to the formulations, and a component termed residual error. The formulation sum of squares is tested against the residual error sum of squares to check for differences among formulations, and, of course, similar tests are available to test for differences between individual pairs of formulations.

Variations on the basic ANOVA are possible and correspond to various factors in the assignment of subjects to the respective sequences of formulations that they receive. Cochran and Cox (29, chap. IV) summarized the variations on the basic crossover design and its analysis. Wagner (31) mentioned three of these variations in connection with blood level trials. The variation that he designated as Type I is the same as that discussed above with a further component, due to sequence of administration, extracted from the sum of squares due to subjects. Type II, on the other hand, contains one essential point of difference from the basic design. Subjects are assigned to Latin-squares in a nonrandom manner; for example, one might split them up into fairly homogeneous groups with respect to weight and assign each group to a Latin-square. One can then extract from the subjects' sum of squares a component due to Latin-squares which enables one to test whether the weight of the subjects was a factor of importance. One feature of the analysis is that instead of extracting one overall "day of administration" effect, a day effect for each Latin-square is generated. This has the effect of reducing the number of degrees of freedom available for the error term and it might be questioned whether one would really expect the day effect, if present, to vary from square to square. If the day effects are collapsed into one overall day effect, Type II becomes essentially the same as Type I. The Type III crossover design can be analyzed as in Type I, but it can also be subjected to a much more elaborate form of analysis which adjusts for potential "residual effects," that is, the possible carryover from one administration to the following administration. This type of design has potential application in certain clinical trials, but for blood level trials there is already a very direct check on residual effects, namely, the zero-hour blood level, which is customarily taken at the time of administration of the formulation.

Another variation based on an analysis given in Lindquist (32) was used by MacLeod *et al.* (33) in their study of the bioavailability of three brands of ampicillin. Their analysis extracts from the error term a component that can only be described as a "within subject interaction between formulations and days." One would not, perhaps, be greatly interested in testing this component, but its removal from the error term could possibly affect the test on formulations, since the error term would now be different. This component can only be obtained if the number of formulations compared in the Latin-square design is greater than two. The "among subjects interaction between formulations and days," which the authors extracted from the subjects' sum of squares, is the same thing as the sequence component referred to earlier. Finally, the analysis of a crossover trial arranged as a balanced incomplete block design was given by Westlake (30).

Validity of Analysis of Variance and Transformations—Although the basic analysis of the crossover design has been discussed, the question now arises of whether the data should be transformed in some manner before analysis. To answer this question, an understanding of the underlying structure implicit in the analysis is necessary, namely, that any observation is made up of the sum of an overall mean, a component due to the particular subject, a component due to the day, a component due to the formulation, and a random error term. The error terms for the various administrations are assumed independent and normally distributed with zero mean and uniform variance. A characteristic that is often analyzed in a crossover trial is an estimated pharmacokinetic parameter (*e.g.*, an absorption rate constant), the object being to determine if the formulations differ with respect to this parameter. In numerous examples in the literature, the analyses were carried out in terms of the basic ANOVA. If each experiment yielded an observed value of the parameter, the analysis might be appropriate since it could reasonably be assumed that the observed value was equal to the true value for that subject–week–formulation combination plus a random

error term. In actual practice, of course, the parameter has not been observed but estimated from data; consequently, a second error term applies to the estimated parameter. This can be expressed as: estimated parameter value equals true mean parameter value plus e_1 plus e_2, where e_1 is the error term expressing random fluctuation of the parameter value about its mean value for that subject–day–formulation combination, and e_2 is a sampling error term which is dependent on the goodness-of-fit of the model to the data. An estimate of the variance of e_2 can be obtained directly when the parameter is estimated, and frequently this variance is far from uniform.

The foregoing discussion suggests that the use of ANOVA may not be appropriate and that a better course of action lies in analyzing the data with a test that does not require the assumption of uniform variance. A number of nonparametric tests are possible candidates. Westlake (30) suggested that, in a crossover trial, the simple sign test would be suitable for testing estimated pharmacokinetic parameters. Bernard *et al.* (34), in comparing half-lives and peak serum concentrations of minocycline in different groups of patients, used another nonparametric test, the Mann–Whitney U-test. An elementary reference to these and several other nonparametric tests is Siegel (35). An interesting possibility[1], which does not yet appear to have been studied, is that of comparing formulations with respect to the variance of some estimated pharmacokinetic parameter—not with respect to the mean value of the parameter as is usually done. A formulation that provided a much more variable value of the absorption rate constant, k_a, for example, might well be regarded as an inferior, because more variable, product.

The area under the blood level curve from zero to infinity is one of the most frequently analyzed characteristics of the blood level curve. Under the assumptions that elimination of the drug occurs only from the blood compartment and that the elimination is first order, Eq. 3 can be readily demonstrated:

$$\text{area} = FD/k_eV \qquad \text{(Eq. 3)}$$

where F is the proportion of the dose D of drug absorbed, while k_e and V are the elimination rate constant and apparent volume of distribution, respectively. Wagner (2, chap. 25) discussed several ways of transforming the areas prior to analysis. He suggested that, in a crossover design, one can obtain the ratio of the proportions of drug absorbed by taking the ratios of the areas. In this case, D cancels out of the ratio, as does the product k_eV if this is assumed constant for a given subject. However, the ensuing analysis must then ignore the "day effect," since this was absorbed into the ratio. An alternative approach, suggested by Westlake (30), is to take the logarithms of the areas which gives the relation found in Eq. 4:

$$\log \text{area} = \log F + \log D - \log (k_eV) \qquad \text{(Eq. 4)}$$

The log of the area may now be analyzed by the standard ANOVA, since the term $\log (k_eV)$ can be treated as an additive effect due to the subject. It is not essential that k_eV remains exactly constant for a given subject but only that it be distributed around a mean value for that subject with either a relatively small variance or with a standard deviation proportional to the mean.

Wagner (2) suggested performing the analysis of the data after a transformation which involves correction for the volume of distribution and elimination rate constant. My understanding of this method is as follows. The area is multiplied by the product of W (body weight) and the decay constant, as estimated from the final exponential decay of the blood levels, and then divided by the dose. For a one-compartment model, this transformation results in Eq. 5:

$$\frac{(\text{area})(Wk_e)}{D} = \frac{(FD/Vk_e)(Wk_e)}{D} = \frac{F}{V/W} \qquad \text{(Eq. 5)}$$

Thus, on the assumption that V/W is constant and k_e has been correctly estimated, the transformed area can be analyzed as a measure of fraction of dose absorbed. However, if the behavior of the subject is more closely modeled by a two-compartment model, one sees that the transformation gives not $F/(V/W)$ but $F/(V/W)$ multiplied by k_{21}/α or, equivalently, by β/k_e. The approximate constancy of the mean value of the factor k_{21}/α in the group of subjects does not, of course, imply that this factor therefore cancels out in the analysis since it is multiplicative and not additive. In fact, the situation seems quite similar to the analysis of unadjusted areas proposed first. In the former case, one is analyzing FD/k_eV; with a logarithmic transformation and the assumption that k_eV for a given subject is approximately constant or distributed with relatively small variance, one can proceed to the standard ANOVA. In the case where areas are adjusted in the manner just described, one is analyzing $[F/(V/W)](k_{21}/\alpha)$ and, again, a logarithmic transformation and the assumption that both V/W and k_{21}/α are distributed with a relatively small variance about a mean value allow one to proceed to the ANOVA. It is thus difficult to see, on statistical grounds, what the adjustment of areas has achieved, especially since one is also making the assumption that β (the final exponential decay constant) has been adequately estimated from the data. However, the adjustment of areas might be an appropriate procedure if it could be demonstrated that the product k_eV were considerably more variable in a given subject than the quotient of the pharmacokinetic parameters k_{21}/α.

Analysis of the area under the blood level curve, when feasible, is likely to be of major importance in any comparative blood level trial in view of its direct relation to the amount of drug absorbed. Other parameters that are not dependent on any model of the drug distribution, such as peak blood level and time at which it occurs, are sometimes studied since they characterize the performance of the drug formulation. One either picks the peak blood level occurring among the samples or attempts to interpolate it in the sequence of sample values. Little appears to have been written on the problems associated with interpolation of maximum blood levels, although the spline-function approach, suggested by Wold (27), should be of value in this regard.

In addition, the question can be asked: Should such

[1] Suggested by Dr. K. R. Heimlich, personal communication.

data be transformed before subjecting them to an analysis of variance? Again, little seems to have been done on this subject, although Westlake (30) tentatively suggested that *any* concentration data can be regarded as possible candidates for a logarithmic transformation. The reason put forward is that for any pharmacokinetic model the apparent volume of distribution will appear in the denominator of the expression for drug concentration in the blood. Thus, if volume of distribution is roughly constant for a subject and is to be treated as an additive effect in the ANOVA, then the data cannot be expected to conform to the ANOVA model without some prior transformation. Logarithmic transformation will certainly have the effect of bringing the volume of distribution into the model additively, as required, but the question is a complicated one and no completely satisfactory answer appears forthcoming.

Analysis of Comparative Blood Level Trials as "Repeated-Measurements" Experiments—In the final type of analysis of blood level data to be considered, no particular features of the sequence of blood levels are picked out for special treatment. For each subject–day–formulation combination—in other words, for each administration of the drug—one is simply faced with a sequence of blood levels taken at various sampling times. The statistical term for such an experiment is a repeated-measurements experiment, the repeated measurements, of course, being the sequence of blood levels taken at repeated times. Numerous methods of statistical analysis are available and are based on no assumptions (implicit or otherwise) concerning the nature of the biological organism or the relative importance of features of the blood level sequence. Such methods have a certain appeal, particularly inasmuch as it usually is not clear which features of the blood level sequence are important or have a direct bearing on the therapeutic effect of the drug formulation.

The method most often used is that of performing the basic ANOVA at each sampling time, that is, a series of n ANOVA's where n is typically in the 6–12 range. Countless literature references could be given so that there is little point in singling out any one as an example. The problem, statistically speaking, is that one is forced to adjust the significance level to make this series of tests meaningful. For example, to test a null hypothesis (the hypothesis of no difference between formulations) at the 0.05 level means that one is accepting a 0.05 probability of deciding that the formulations are different when they are, in fact, the same. However, if there are, say, 10 sampling times, then it can be shown that if one rejects the null hypothesis on the grounds that any individual ANOVA shows a significant difference between the formulations at the 0.05 level, the probability of rejecting the null hypothesis even when true is about 0.40 (assuming independence of sampling times). The reason is, of course, that there are 10 opportunities to reject the null hypothesis; thus, to make sense of the series of tests, one must scale the significance level for individual tests down to a very much lower level. This procedure also has some unsatisfactory features, and the problem was discussed at length by Westlake (30).

A method of analyzing comparative blood level trials, which is in many ways more satisfactory, consists of viewing the trial as a "split-plot" design or, more accurately stated, as a "strip-plot" design. Details of the analysis of variance of a repeated-measurements design treated in this way were given by Winer (36). Briefly, the ANOVA comprises two sections, each with its appropriate error term for testing the various effects. The so-called "main plot" part of the analysis is, essentially, an analysis of mean blood levels (the mean being taken over all sampling times) and has the same structure as that given earlier for the basic ANOVA, namely a partitioning into components due to days, subjects, formulations, and residual. The so-called "subplot" is comprised of a partitioning into components due to sampling times and the interactions of sampling times with days, subjects, and formulations, respectively, and a subplot error term. Two tests, one in the main plot and one in the subplot, are of particular interest in the comparison of formulations. The test on the formulation mean square in the main plot tests whether there are differences among formulations with respect to their mean blood levels over the sampling times. The test on the (sampling times × formulations) interaction in the subplot tests whether there are differences among formulations with respect to the *patterns* of blood levels to which they give rise. Tests for difference between mean blood levels and patterns of blood levels for any given pair of the formulations studied in the design can also be made.

This method of analysis has a number of advantages, not least of which is that it produces one simple test on the mean blood levels and one test on the blood level patterns over time. Another advantage is that the concepts of mean blood level and blood level pattern are readily grasped by the nonstatistical scientists who must make the final decision concerning equivalency. There is an important restriction in that the method of analysis is only valid if the variance–covariance matrix of residuals has a particular form known as "uniform" (that is, the variances at the different sampling times are equal and all covariances between different sampling times are equal). A practical consequence of this is that the correlation between blood levels at different sampling times must be independent of the distance in time between the samples. In his book, Winer (36) gave details of a test, first devised by Box (37), to be carried out to determine whether the assumption of uniform variance–covariance holds. The author's experience (see *Reference 38*) with many orally administered drugs—in which samples are usually taken at intervals approximately an hour apart—is that the assumption is often valid, especially when a transformation of the data is made to ensure equal variances. This paper (38) also gives an extension of the analysis, including Box's test, to the case of comparative blood level trials arranged as balanced incomplete block designs. For the case where the uniform variance–covariance matrix requirement is not satisfied, Greenhouse and Geisser (39) gave an approximate test which could be useful in blood level trials.

Other more complex methods of analysis are, of course, available. Cole and Grizzle (40) discussed an example in which the effects of intravenous morphine sulfate and intravenous trimethaphan on blood hista-

mine levels of dogs were studied. Sampling times were at 0, 1, 3, and 5 min. and, perhaps not surprisingly with samples taken so close together in time, the uniform variance–covariance assumption was not valid. They discussed the application of a more complex method of multivariate analysis, namely the multivariate analysis of variance (MANOVA). Apart from their example, few applications of these techniques to blood level data appear to have been published in the literature. One drawback to routine application of MANOVA to typical blood level trials in which formulations are to be compared is the difficulty of interpreting these more sophisticated concepts so that they are meaningful to the nonstatistical scientists who must make the decisions based on the analysis.

Another possible method of analysis, described by Church (41), is based on principal components. The sequence of, say, n blood levels over the sampling times is treated as a vector of n observations. One then seeks a linear transformation of these n variables into a new set of n orthogonal (uncorrelated) variables such that the first variable accounts for the maximum amount of variability in the data, the second component for the maximum amount of the remaining variability, and so on. The advantage is that the new variables are uncorrelated and can be ranked in order of importance in accounting for the variability of the data. The dimension of the vector may also be effectively reduced if it is found that fewer than n principal components account for the bulk of the variability. Redman (42) discussed the application of principal components to blood level experiments. Snee (43) proposed a modification of Church's method in which the variation of the data is partitioned into two parts, the first connected with the mean of the blood levels and the second with the pattern of the blood levels. Principal components are then used to analyze the pattern component. A possible problem with the use of methods based on principal components is, as with MANOVA, the potential difficulties of conveying the statistical ideas to a nonstatistical user of the results. A second problem is that, instead of one simple test for pattern difference among formulations, there are a number of tests dependent on how many principal components are thought to be sufficient to account for the variation of the data. Thus, there is a greater likelihood that some difference among patterns will be detected as statistically significant, even though it may not have any meaningful relation to clinical or therapeutic significance. So at the end of this discussion of possible methods of analysis, one returns to the problem that plagues the whole subject of comparative bioavailability, namely, the relationship, if any, of differences between the blood level characteristics of the formulations to differences in their therapeutic effects. Until much more is known about this fundamental aspect of *in vivo* testing, unsatisfactory features will be connected with most statistical analysis.

Use of Confidence Intervals—All of the methods of analysis discussed so far have been formulated in terms of the statistical theory of hypothesis testing. To illustrate the simplest possible case, suppose that a crossover trial is conducted in which two formulations are to be compared with respect to some single parameter, such as area under the blood level curve as a measure of drug absorbed. If the basic ANOVA is used to analyze the data, one is essentially testing the null hypothesis that $\mu_1 = \mu_2$, where μ_1 denotes the mean amount of drug absorbed when the first formulation is administered to an essentially infinite population of subjects and μ_2 has the same meaning for the second formulation. Now it appears reasonable to assert that, in actual fact, μ_1 and μ_2 will never be equal since there will always be some differences, however slight, in the composition and methods of manufacture of the formulations. Consequently, if a sufficiently large number of subjects is employed in the crossover trial, one should be able to detect a statistically significant difference between any pair of formulations. This observation suggests that the idea of testing a simple null hypothesis of the type $\mu_1 = \mu_2$ may not be a very realistic approach to testing whether two formulations provide equivalent amounts of drug absorbed. The key lies in the word "equivalent" which, in a practical situation, means therapeutically or clinically equivalent. This might mean, for example, that the second formulation could be considered equivalent to the first if it resulted in an area under the blood level curve (taken to be a measure of absorption) that was within $n\%$ of that achieved with the first formulation. How small n must be to indicate therapeutic equivalence is, of course, a decision for the clinician to make; and as Levy (44) pointed out, the nature of n depends on the particular drug under consideration.

Suppose that for a given drug the value of n is taken to be 20; that is, the mean area under the blood level curve for the second formulation must be within 20% of the mean area for the first formulation in order to be judged "practically" equivalent. Then a suitable null hypothesis to test would be $(0.80\ \mu_1 \leq \mu_2 \leq 1.20\ \mu_1)$ rather than simply $\mu_1 = \mu_2$. However, construction of a test poses considerable problems and an alternative approach is to abandon hypothesis testing methods completely and replace them with the concept of confidence intervals. A 95% confidence interval statement, for example, resulting from the analysis of the example under discussion would be of the type $(\mu_1 - k_1 \leq \mu_2 \leq \mu_1 + k_2)$. Note that this gives an indication of where μ_2 is located in relation to μ_1; when the result of the analysis is stated in this form, it gives the physician or clinical pharmacologist information in a form from which he or she can make a judgment as to the practical equivalence of the formulations. Metzler (28) discussed the use of confidence intervals as a means of summarizing a comparative bioavailability trial and gave a number of examples, for each of which various criteria of acceptance are proposed based on a confidence interval approach. He then showed how certain formulations meet the acceptance criteria while some do not. Some that meet the acceptance criteria would be rejected as being statistically significantly different from the standard formulation against which comparison was made; some that would pass the hypothesis testing do not meet the acceptance criteria based on confidence intervals.

Many instructive examples can be constructed to

show how the confidence interval approach, which can be made the basis of a decision by the physician or clinical pharmacologist, leads to quite different results from the hypothesis testing approach, which is based only on the statistician's more-or-less arbitrary selection of significance levels. Defenders of the hypothesis testing approach will probably reply that, in planning the trial, the number of subjects is selected to allow detection of a certain minimum difference between the bioavailability of the formulations based on the error variance (estimated from pilot studies), significance level of the test, and required probability of detecting the minimum difference. This is true, but much of this careful planning may be negated if the variability turns out to be different from that estimated from the pilot experiments. In this case, the trial may be either incapable of detecting the minimum difference as statistically significant or, on the other hand, may show supposedly unimportant differences to be statistically significant. The confidence interval approach thus appears to provide a more satisfactory answer.

One disadvantage of constructing conventional confidence intervals, which are symmetrical about the difference of the population means of the two formulations, is that when expressed in the form given earlier, $(\mu_1 - k_1 \leq \mu_2 \leq \mu_1 + k_2)$, they are *not* symmetrical; that is, k_1 and k_2 are not equal. Many clinical pharmacologists would, however, make their equivalence statements in a symmetrical form, for example: the second formulation is clinically equivalent to the first if its bioavailability is within 20% of that of the first formulation. This implies that k_1 and k_2 are equal in a confidence statement of the type just given. Westlake (45) suggested that the traditional method of constructing confidence intervals could be modified so as to ensure a symmetrical statement in which k_1 and k_2 are equal, and he gave a method for carrying out this procedure.

The author's opinion is that confidence intervals currently afford the best means of summarizing the results of a comparative bioavailability trial since, unlike hypothesis tests, they portray the information in a manner that can form the basis for an informed judgment by a physician or clinical pharmacologist. Unfortunately, this only seems to be true when one is discussing a simple quantity such as amount of drug absorbed or mean blood level over time. More complex concepts, such as the difference between the blood level patterns over time, would not seem to be amenable to a confidence interval treatment at present. Theoretically, there is no difficulty; the problem lies in the practical interpretation of confidence interval statements concerning more complex functions of blood levels.

SUMMARY

The discussion of the statistical methods used in the evaluation of *in vivo* performance of dosage forms has covered the characterization of dosage forms by biologically meaningful models and purely empirical means and the comparison of formulations. The subject seems to have resulted in very few novel developments in statistical theory and, by and large, existing statistical methods seem more than adequate to cope with the problems that arise in this particular field. It seems questionable whether new statistical techniques could improve matters in the estimation of pharmacokinetic parameters in compartmental models. Rather, as Lanczos (16) so elegantly demonstrated, only an immense refinement in measuring techniques can improve the estimation of parameters in a function that is the sum of exponential terms. Even if this were possible, one would still face the fact that any compartmental model is a grossly simplified model of the biological reality. For the comparison of dosage forms or formulations, numerous methods of analysis are available but it has been suggested that a confidence interval approach, rather than the more usual hypothesis testing, may offer more hope for a realistic appraisal of comparative dosage form performance. Eventually, it seems that the major problem in the use of statistical methods is a nonstatistical one. That problem is the elucidation of the relationship of blood level characteristics to therapeutic use of the drug. It is only with improved knowledge in this area that we can hope to determine accurately those blood level characteristics which are of really critical importance. Statisticians can perform many types of analyses on blood level sequences; some of them are of considerable sophistication and complexity. But the value and significance of such analyses can hardly be assessed until a clear idea of the relation between blood levels and therapeutic use of the drug is available.

Conformation of Sodium Cromolyn in Aqueous Solution Using Light Scattering and Magnetic Birefringence

J. V. CHAMPION and G. H. MEETEN▲

Abstract □ The conformation of the sodium cromolyn (disodium cromoglycate) molecule is possibly relevant to its pharmacological activity in the treatment of bronchial asthma. Two optical techniques, depolarized light scattering and magnetic birefringence, were used to study the molecular conformation in dilute solutions (<1 g./100 ml.) of unassociated molecules. Both techniques confirm that the molecule in dilute solution has a planar conformation as found in the crystal.

Keyphrases □ Sodium cromolyn (disodium cromoglycate)—molecular conformation in aqueous solution, light-scattering and magnetic birefringence techniques □ Molecular conformation, sodium cromolyn—determination in aqueous solution, light-scattering and magnetic birefringence techniques □ Light-scattering techniques—determination of sodium cromolyn conformation in aqueous solution □ Magnetic birefringence techniques—determination of sodium cromolyn conformation in aqueous solution

The conformation of the molecule of sodium cromolyn[1] (disodium cromoglycate) is of particular interest because the compound has been used as a new pharmacological approach to the treatment of bronchial asthma. The solid-state chemistry of sodium cromolyn was recently described (1), and the lattice parameters of the crystalline solid solution at high (90%) relative humidity indicate that the molecule is in a planar conformation. In the concentrated solution state, the formation of liquid crystals occurs.

The aim of this study was to determine the conformation of the molecule in aqueous solution. This may be important in assessing the activity and specificity of biological action at a membrane surface.

The chemical structure of sodium cromolyn in the planar conformation is shown here (I), and the molecule may be approximated to a pair of rigid chromones joined by a glycerol bridge [—O—CH_2—CH(OH)—CH_2—O—], the hydroxy, carbonyl, and ether groups giving many possibilities of hydrogen bonding, especially in the presence of water molecules. Simple molecular model building shows that numerous different conformations are possible by rotation about the bonds of the glycerol bridge, many of these having a small

Conformation of Sodium Cromolyn in Aqueous Solution Using Light Scattering and Magnetic Birefringence

J. V. CHAMPION and G. H. MEETEN▲

Abstract □ The conformation of the sodium cromolyn (disodium cromoglycate) molecule is possibly relevant to its pharmacological activity in the treatment of bronchial asthma. Two optical techniques, depolarized light scattering and magnetic birefringence, were used to study the molecular conformation in dilute solutions (<1 g./100 ml.) of unassociated molecules. Both techniques confirm that the molecule in dilute solution has a planar conformation as found in the crystal.

Keyphrases □ Sodium cromolyn (disodium cromoglycate)—molecular conformation in aqueous solution, light-scattering and magnetic birefringence techniques □ Molecular conformation, sodium cromolyn—determination in aqueous solution, light-scattering and magnetic birefringence techniques □ Light-scattering techniques—determination of sodium cromolyn conformation in aqueous solution □ Magnetic birefringence techniques—determination of sodium cromolyn conformation in aqueous solution

The conformation of the molecule of sodium cromolyn[1] (disodium cromoglycate) is of particular interest because the compound has been used as a new pharmacological approach to the treatment of bronchial asthma. The solid-state chemistry of sodium cromolyn was recently described (1), and the lattice parameters of the crystalline solid solution at high (90%) relative humidity indicate that the molecule is in a planar conformation. In the concentrated solution state, the formation of liquid crystals occurs.

The aim of this study was to determine the conformation of the molecule in aqueous solution. This may be important in assessing the activity and specificity of biological action at a membrane surface.

The chemical structure of sodium cromolyn in the planar conformation is shown here (I), and the molecule may be approximated to a pair of rigid chromones joined by a glycerol bridge [—O—CH_2—CH(OH)—CH_2—O—], the hydroxy, carbonyl, and ether groups giving many possibilities of hydrogen bonding, especially in the presence of water molecules. Simple molecular model building shows that numerous different conformations are possible by rotation about the bonds of the glycerol bridge, many of these having a small

energy barrier. Hence, in dilute aqueous solution, the molecule may exist in a form in which the two chromone structures either are randomly oriented with respect to each other or are in a fixed orientation due to intramolecular or intermolecular hydrogen bonding.

Precursory measurements, using viscometric and light-scattering techniques whereby the hydrodynamic volume was determined, showed that aggregation or strong solute–solute interaction occurred at concentrations greater than 0.5 g./100 ml. in aqueous solution. Above 0.8 g./100 ml., the aggregation was time dependent.

The conformation of the molecule can be related to the molecular optical and magnetic anisotropy, which can be measured using depolarized light scattering and magnetic birefringence, respectively. The necessity of using very dilute aqueous (conducting) solutions of relatively low molecular weight material (516) limits the techniques available for observing molecular anisotropy to the two described here.

OPTICAL AND DIAMAGNETIC ANISOTROPY

It will be shown in the following section that the optical and diamagnetic anisotropies of the sodium cromolyn molecule are sensitive functions of its conformation, hence the use of light-scattering depolarization and magnetic birefringence techniques.

Calculation of the sodium cromolyn molecule optical anisotropy was made using bond polarizability tensor additivity (2). In this calculation, each bond is assigned a polarizability tensor α. For single bonds, α is diagonal in coordinates x, y, and z, where x is along the bond and y and z are perpendicular to it. Thus:

$$\alpha = \begin{pmatrix} \alpha_x & 0 & 0 \\ 0 & \alpha_y & 0 \\ 0 & 0 & \alpha_y \end{pmatrix}$$

For double bonds:

$$\alpha = \begin{pmatrix} \alpha_x & 0 & 0 \\ 0 & \alpha_y & 0 \\ 0 & 0 & \alpha_z \end{pmatrix}$$

where the x axis lies along the bond and the y axis is perpendicular to the π-electron plane.

The polarizability of a molecule with many bonds is then calculated by choosing axes 1, 2, and 3 fixed to the molecule and calculating the molecular polarizability tensor:

$$\begin{pmatrix} \alpha_{11} & \alpha_{12} & \alpha_{13} \\ \alpha_{21} & \alpha_{22} & \alpha_{23} \\ \alpha_{31} & \alpha_{32} & \alpha_{33} \end{pmatrix} = \alpha_m$$

The components are:

$$\alpha_{jk} = \alpha_{kj} = \sum_b \sum_u \alpha_u \gamma_{uj} \gamma_{uk} \qquad u = x, y, z \qquad \text{(Eq. 1)}$$

where γ_{uj} is the direction cosine of the angle between the u ($u = x$, y, or z) and the j axes, and j and k take value 1, 2, or 3. The Σ_b denotes a summation over all bond types in the molecule. In this scheme, benzene rings are considered as bonds having x axes perpendicular to the ring plane.

Calculation of the molecule diamagnetic susceptibility tensor χ_m was made in an exactly similar way as for the optical polarizability tensor, with bond susceptibilities χ_x, χ_y, and χ_z replacing α_x, α_y, and α_z.

Two conformations for sodium cromolyn were chosen as representing extreme examples of its conformation: (*a*) the planar conformation, as suggested by X-ray measurements on the crystal (1); and (*b*) the perpendicular conformation, obtained when the benzene rings of the molecule lie in perpendicular planes. This perpendicular conformation is possible due to internal rotation around O—C and C—C bonds in the O—C_3—O bridge connecting the rings. Experiments on a Courtalds space-filling molecular model showed no steric hindrance to a perpendicular conformation. Light-scattering and magnetic birefringence theories require principal polarizabilities such that:

$$\alpha_m = \begin{pmatrix} \alpha_1 & 0 & 0 \\ 0 & \alpha_2 & 0 \\ 0 & 0 & \alpha_3 \end{pmatrix} \quad \text{and} \quad \chi_m = \begin{pmatrix} \chi_1 & 0 & 0 \\ 0 & \chi_2 & 0 \\ 0 & 0 & \chi_3 \end{pmatrix}$$

Since $\alpha_{jk} = \chi_{jk} = 0$ for molecular axes of symmetry, these are also the principal polarizability or susceptibility axes. For the planar conformation, the 1 axis is coplanar with the benzene rings and parallel to a line joining their centers, the 2 axis is perpendicular to the benzene ring planes, and the 3 axis lies in the plane containing the planes of the benzene rings.

The perpendicular conformation is the result of rotation about the 1 axis of each of the molecular halves such that the 2 axis of one-half of the molecule becomes parallel to the 3 axis of the other half. A large number of —OC_3O— bridge conformations may attend this rotation, and the average —OC_3O— bridge conformation is unknown. However, the optical and diamagnetic anisotropies of the —OC_3O— bridge are small compared with the whole molecule since most anisotropy arises from the ring structures. Thus, to a good approximation:

$$\alpha_1(\text{perpendicular}) = \alpha_1(\text{planar}) \qquad \text{(Eq. 2)}$$

$$\chi_1(\text{perpendicular}) = \chi_1(\text{planar}) \qquad \text{(Eq. 3)}$$

$$\alpha_2(\text{perpendicular}) = \alpha_3(\text{perpendicular}) = {}^1/_2\alpha_2(\text{planar}) + {}^1/_2\alpha_3(\text{planar}) \qquad \text{(Eq. 4)}$$

$$\chi_2(\text{perpendicular}) = \chi_3(\text{perpendicular}) = {}^1/_2\chi_2(\text{planar}) + {}^1/_2\chi_3(\text{planar}) \qquad \text{(Eq. 5)}$$

Vuks' (3) comprehensive and well-tested set of bond polarizabilities was used; relevant values are listed in Table I. The benzene ring value in Table I was derived from light-scattering measurements on gaseous benzene, using Vuks' values for the CH bond polarizabilities. Since further data were lacking, no distinction was made between aliphatic and aromatic carbon atoms, the latter denoted by C′. Thus, C′X and CX are assumed to have the same optical anisotropy.

Bond diamagnetic susceptibility anisotropy data for CC, CH, C′H, and CO in Table I are taken from Bothner-By and Pople (4). The other values in Table I were calculated by the present authors from the measured molecular susceptibility anisotropies of benzene (4), hexamethylbenzene (4), resorcinal (4), and formaldehyde (5).

Models of sodium cromolyn molecules in the planar and perpendicular conformation were constructed using stick models, and the bond angles were measured relative to the symmetry axes. The molecular anisotropies (Table II) were calculated.

Mean values of optical molecular polarizability $\bar{\alpha}$ were calculated from the sum of mean bond values over the molecule. Tables of bond average polarizabilities were published by several workers for commonly encountered bonds, and there is close agreement on values between tables. No O—Na bond mean polarizability has been reported. Its value was estimated for present purposes by plotting $\bar{\alpha}^{0-z}$ against the atomic weight of element X, where X was C, H, P, and As as given by LeFevre (6) and Vuks (3), and interpolating for

X = Na. Table III shows Denbigh's (2) and Vuks' (3) values with $\bar{\alpha}^{0-Na}$ inserted as estimated previously. The mean molecular polarizabilities according to the table do not differ significantly from 44 Å, and this value was adopted for future calculation. Estimates of mean molecular polarizability may also be made from the crystalline refractive indexes 1.488, 1.66, and 1.705 measured (1) at 40% relative humidity (16.2% water by weight). Assuming additivity of molar refractivities for sodium cromolyn and water in the crystal gives 44.7 Å³. The Vuks (7) modification to the molar refractivity scheme gives 44.9 Å³. In both cases, a water molecule mean polarizability of 1.59 Å³ was used (8).

LIGHT SCATTERING

The scattering of light by a transparent medium arises from the inhomogeneities of the medium and may be used to characterize them. In a liquid or solution, the scattering is due to the local statistical fluctuations in the polarizability of the medium, arising from density and concentration fluctuations and, for anisotropic molecules, orientational fluctuations. The total scattering power of such a medium is usually expressed in terms of its Rayleigh ratio, $R(\theta)$, defined as the intensity of light, I_θ, scattered in a direction θ with respect to the incident beam, per unit solid angle per unit scattering volume, divided by the incident light intensity, I_0.

The total Rayleigh ratio can be separated into an isotropic part and an anisotropic part:

$$R = R_{is} + R_{an} \qquad \text{(Eq. 6}a\text{)}$$

and:

$$R = KI_\theta \qquad \text{(Eq. 6}b\text{)}$$

for a given scattering system with I_0 constant and with the angular dependence omitted if I_θ is in a direction perpendicular to I_0. The scattered light contributing to R_{is} is polarized perpendicularly to the plane determined by the direction of I_0 and the direction of observation of I_θ and is termed vertically polarized. The anisotropically scattered light has a horizontally (H) as well as a vertically (V) polarized component. Hence, Eqs. 6*a* and *b* become:

$$R = R_{is,V} + R_{an,V} + R_{an,H} = R_V + R_H \qquad \text{(Eq. 7)}$$

and the depolarization of the scattered light for unpolarized incident light is given by:

$$\rho_u = R_H/R_V = I_H/I_V \qquad \text{(Eq. 8)}$$

where $I_H + I_V = I_\theta$.

It has been shown at liquid densities that the isotropic scattering per molecule is strongly reduced (to 5–10%) in comparison with its vapor due to pronounced positional correlations and has a much larger influence on the isotropic than on the anisotropic part of the scattering. The latter, due to orientational correlations, is largely independent of density or concentration fluctuations. Therefore, observations of the anisotropic scattering can lead to information regarding the optical anisotropy of the molecules.

Experimental—A light-scattering photometer, developed for depolarization measurements, was used, whereby the sensitivity and signal/noise ratio were maximized by using a 5.08-cm. (2-in.) o.d. low noise photomultiplier tube[2]; the output was fed to a low noise, high gain d.c. amplifier. The amplifier output was averaged with a time constant of 10 sec. and then recorded on a chart. The source was a 250-w. compact arc mercury lamp, giving an output brightness of 20,000 stilb. The smallest signal, the scattered intensity of the horizontally polarized component of pure water (I_H^w), had a signal/noise ratio of 8:1, and the presence of dust could be readily detected by an increase in signal/noise ratio and the occurrence of large spurious peaks in the recorder trace. A high quality polarizing prism[3] was mounted in front of the photomultiplier entrance pupil, enabling I_V and I_H to be separately determined.

A rectangular Pyrex glass scattering cell was used. The length of the cell was 25 times the length of the observed scattering volume, removing the scattering volume as far as possible from the exit and entrance windows of the incident beam and thus considerably reducing the intensity of the spurious multiple reflections along the cell walls seen by the detector.

The distilled water was prepared by double distillation over potassium permanganate to remove dust and organic matter. The pure water or solution was then centrifuged at 80,000×g for 1 hr. and transferred to the scattering cell *via* a 50-nm. filter[4] under dust-free atmospheric conditions.

All scattered intensities were measured at the mercury green (5461 Å) and mercury blue (4358 Å) wavelengths using narrow band isolating filters.

All concentrations of sodium cromolyn solutions used were corrected for water content of the solid by weighing at known humidity and using the data of Cox *et al.* (1).

Theory and Results—It has been shown (9) that for a system of independent scatters in the liquid state, assuming a Lorentz internal field:

$$R_{is} = \left(\frac{8\pi^4 kTN^2\beta_T\bar{\alpha}^2}{\lambda^4}\right)\left(\frac{n^2+2}{3}\right)^4 \qquad \text{(Eq. 9)}$$

and:

$$R_{an} = \left(\frac{8\pi^4 N\gamma^2}{\lambda^4}\right)\left(\frac{13}{90}\right)\left(\frac{n^2+2}{3}\right)^2 \qquad \text{(Eq. 10)}$$

where k is Boltzmann's constant, T is the absolute temperature, N is the number of scatterers per milliliter, β_T is the isothermal compressibility, λ is the wavelength *in vacuo*, n is the refractive index, and $\bar{\alpha} = (\alpha_1 + \alpha_2 + \alpha_3)/3$ (the mean polarizability of the particle), and $\gamma^2 = (\alpha_1 - \alpha_2)^2 + (\alpha_2 - \alpha_3)^2 + (\alpha_3 - \alpha_1)^2$ (the optical anisotropy of the particle).

The apparatus is calibrated for the distilled water–sodium cromolyn scattering system from Eq. 7, whereby $R^w = k$; $I_s = k(I_H^w + I_V^w) = 0.87 \times 10^{-6}$ cm.$^{-1}$ at λ = 5461 Å and $R^w = 2.32 \times 10^{-6}$ cm.$^{-1}$ at λ = 4360 Å, as given by Cohen and Eisenberg (10). Thus, k can be determined in terms of the instrumental values of $(I_H^w + I_V^w)$. The superscripts w, s, and d represent pure water, solution of sodium cromolyn-water, sodium cromolyn, respectively.

For dilute solutions, the excess horizontally polarized anisotropic scattering of sodium cromolyn molecules is:

$$R_{an,H}^d = k(I_H^s - I_H^w) \qquad \text{(Eq. 11)}$$

Table III—Mean Bond and Molecular Polarizabilities

Bond	Number of Bonds per Sodium Cromolyn Molecular	Å³ per Bond, Denbigh (2)	Å³ per Bond, Vuks (3)

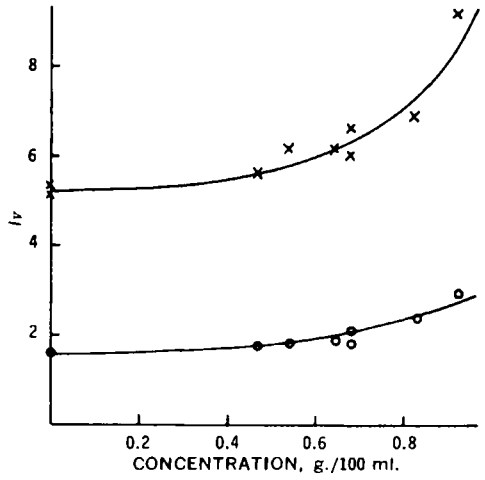

Figure 1—*Vertically polarized scattered intensities as a function of sodium cromolyn concentration and wavelength. Key:* O, *5461 Å; and* ×, *4358 Å.*

giving $R^d_{an} = R^d_{an,V} + R^d_{an,H} = K13/6\ (I_H^s - I_H^w)$ making use of the result $R_{an,V}/R_{an,H} = 7/6$ obtainable from the Cabbannes (11) depolarization factors. By using Eqs. 10 and 11 then:

$$I_H^s - I_H^w = \left(\frac{8\pi^4\gamma^2(I_H^w + I_V^w)}{15\lambda^4 R^w}\right)\left(\frac{n^2+2}{3}\right)^2\left(\frac{N_0}{M}\right)c \quad \text{(Eq. 12)}$$

where N_0 is Avogadro's number, M is the molecular weight of sodium cromolyn, c is the concentration in grams per milliliter, and n is the refractive index of the medium surrounding the sodium cromolyn molecules (*i.e.*, water).

It was found from the experiment that I_H^s and I_V^s were time dependent. For concentrations below 1.0 g./100 ml., this time dependence was relatively slow. No change was observable within the first few hours of making up a solution, while 50% changes were found after several days. Also I_H^s was markedly less sensitive to time than I_V^s. Hence, all the observations reported here were made within 3 hr. of making up the solutions, and low (<1 g./100 ml.) concentrations were used.

The scattered intensities I_H and I_V and the depolarization ratio ρ_u^s as a function of concentration are shown in Figs. 1–4. The scattered intensities (I's) are in arbitrary instrument units, calibration being obtained from the known scattering power of water (10) as described previously. A graph of $I_H^s - I_H^w$ as a function of concentration is shown in Fig. 5. From the slopes of these curves and Eq. 12, values of γ^2 at the two wavelengths are $\gamma^2_{5461} = 1390$ Å^6 and $\gamma^2_{4360} = 1430$ Å^6, using a molecular weight of 516 for sodium cromolyn. The refractive index correction $[(n^2+2)/3]^2$ in Eq. 12 converts the independent particle (gas) value of γ^2 to the value appropriate to the molecule being surrounded by water. These values of γ^2 are directly comparable to those derived from the polarizability anisotropy tensor additivity scheme.

An alternative approach is to obtain the depolarization ratio

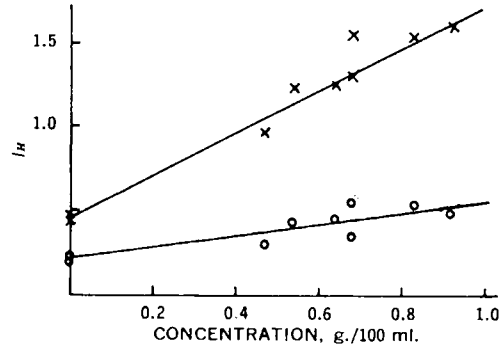

Figure 2—*Horizontally polarized scattered intensities as a function of sodium cromolyn concentration and wavelength. Key:* O, *5461 Å; and* ×, *4358 Å.*

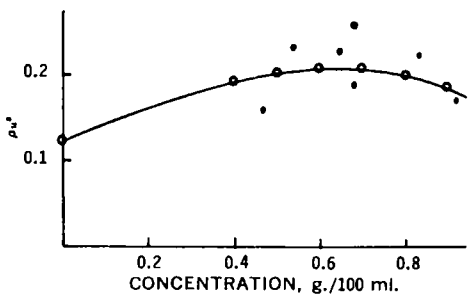

Figure 3—*Depolarization ratio as a function of sodium cromolyn concentration at 5461 Å. Key:* O, *interpolated points from Figs. 1 and 2.*

(ρ_u^d) of the sodium cromolyn molecule. According to Sicotte and Rinfret (12) and using Eq. 8:

$$\frac{I_s^s\rho_u^s}{I_s^w(1+\rho_u^s)} = \rho_u^d\left(\frac{I_s^s}{I_s^w(1+\rho_u^s)}\right) - \left(\frac{\rho_u^d - \rho_u^w}{1+\rho_u^w}\right)\phi_w \quad \text{(Eq. 13)}$$

where ϕ_w is the volume fraction of water in the solution. For dilute solutions in the concentration range 0 → 1.0 g./100 ml., ϕ_w varies from 1.00 to 0.99 and may be assumed constant, the variables being ρ_u^s and I_s^s ($= I_H^s + I_V^s$). Figure 6 shows a plot of $\{(I_s^s/I_s^w)[\rho_u^s/(1+\rho_u^s)]\}$ *versus* $[I_s^s/I_s^w(1+\rho_u^s)]$. The slope of the linear part of the curve, below concentrations of 0.6 g./100 ml., gives a value of $\rho_u^d = 0.31$. It is expected that values for both wavelengths should fall on the same curve due to the negligibly small variation of polarizability with wavelength.

It was shown (10) that the depolarization ratio of a particle in a surrounding medium (sodium cromolyn in water) is given by:

$$\rho_u^d = \frac{6\left(\frac{n^2+2}{3}\right)^2\gamma^2}{\frac{90N_0kT\beta_T d}{M_w}\left(\frac{n^2+2}{3}\right)^4\bar{\alpha}^2 + 7\left(\frac{n^2+2}{3}\right)^2\gamma^2} \quad \text{(Eq. 14)}$$

where the density d, β_T, M_w, and n relate to the medium surrounding the sodium cromolyn molecule. The terms containing these quantities convert the independent particle value of optical anisotropy γ^2 and the average polarizability $\bar{\alpha}$ to a value appropriate to the molecule in a surrounding medium.

Using the values $\beta_T = 4.5 \times 10^{-11}$ cm.^{2}/dyne (10), $d = 1.0$ g./ml., $M_w = 18$, $n = 1.33$, and $\bar{\alpha} = 44$ Å^3 with $\rho_u^d = 0.31$, one gets $\gamma^2 = 1100$ Å^6.

From the bond polarizability data in the preceding section, $\gamma^2_{planar} = 1060$/Å^6 and $\gamma^2_{perpendicular} = 365$ Å^6. The average experimental value is 16% higher than that calculated for the planar conformation and 300% higher than the calculated perpendicular conformation of the sodium cromolyn molecule. With the large (20%) error in individual experimental observations, this must give very strong evidence for the existence of the planar conformation in very dilute solutions.

MAGNETIC BIREFRINGENCE

The Cotton–Mouton constant C is defined as $\Delta n/\lambda B^2$, where Δn is the birefringence induced in a specimen by a magnetic field B, measured using light of wavelength λ. The effect is due to the small

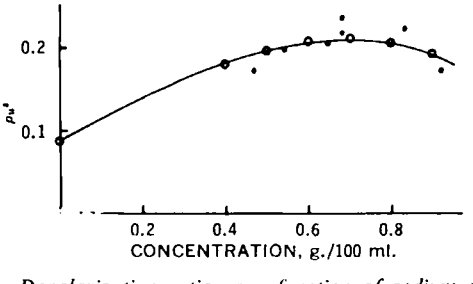

Figure 4—*Depolarization ratio as a function of sodium cromolyn concentration at 4358 Å. Key:* O, *interpolated points from Figs. 1 and 2.*

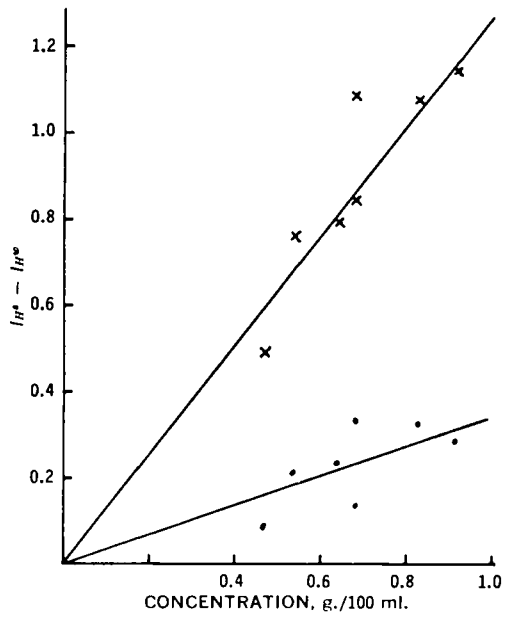

Figure 5—*Horizontally polarized excess scattering of sodium cromolyn solution. Key:* ×, *4358 Å; and* ○, *5461 Å.*

degree of nonrandom alignment of molecular optic axes caused by interaction between the magnetic field and the anisotropy of molecular diamagnetism.

In the measurement of C, it is necessary to pass a beam of monochromatic linearly polarized light through length L of the specimen and traverse to a known field B. The birefringence $\Delta n = C\lambda B^2$ produces ellipticity in the emergent beam. This ellipticity is a maximum when the incident beam polarization azimuth is $\pm 45°$ to B, the phase difference δ between the principal vibration components being $(2\pi/\lambda)L\,\Delta n$.

Experimental—The apparatus was constructed around an electromagnet[5] having a maximum field of about 23 kOe. The solution was contained in standard 20-cm., fused quartz polarimeter tubes with the glass windows replaced by spectrosil fused quartz. Practically monochromatic light was produced by a 250-w. mercury arc lamp, and a filter[6] was used to isolate the 5461 Å green line. Light from the lamp, after being collimated by means of a pinhole and two lenses, passed through a polarizer[7]. After traversing the specimen, the emergent beam's ellipticity was analyzed using a quarter-wave plate specially constructed to be free from optical strain and another polarizer[8] as an analyzer. Intensity minima were observed using a telescope focused for infinity on the pinhole and a filter[9] fitted to the eyepiece to remove a small amount of red light not removed by the other filter[6]. The whole apparatus was used in a dark room at ambient temperatures between 21 and 25°.

Since the field was not constant over the optical path length in the solution, the average value of B^2 (denoted by $\bar{B}^2$) is necessary to calculate C. This was measured for various magnet currents using nitrobenzene, which has $C = 262 \times 10^{-13}$ Oe.$^{-2}$ cm.$^{-1}$ (13) at 5461 Å and 23°. Point-to-point measurement of B along the optical path using a gaussmeter and calculation of:

$$\bar{B}^2 = \frac{1}{L}\int_0^L \beta^2(dL) \qquad \text{(Eq. 15)}$$

agreed to within ±1% with the calibration using nitrobenzene.

The experimental procedure was thus to rotate the quarter-wave plate and analyzer for an intensity minimum with the specimen between the magnet pole-pieces, the polarizer azimuth having been previously set at ±45° to the direction of B. Energizing the magnet then produced a weak illumination in the field of view. The intensity minimum could be restored by adjusting the analyzer azimuth by a rotation $\Delta\theta$, whereupon $\delta = \pm 2(\Delta\theta)$.

Sources of error were Faraday rotation in the specimen and residual birefringence in the polarimeter tube windows. These were reduced to negligible proportions by accurate alignment and selection of low strain windows, respectively.

The solutions were prepared by shaking the sodium cromolyn powder with distilled water and using 50- or 100-nm. filters[10] before making the measurements. Weighing tests had shown that these filters did not remove any of the dissolved sodium cromolyn. No glass was allowed to contact the solutions at any stage. Aged or unfiltered solutions often showed a nonlinearity of Δn with $\bar{B}^2$. This dependence of C upon B is typical of solutions of very large particles or liquid crystals. Solutions exceeding about 2% concentration invariably showed this behavior, which varied with time in a nonreproducible manner. Accordingly, all measurements were made immediately after filtering at less than 1.5% concentration. Any result showing a field dependence of C was rejected. Figure 7 shows a typical graph of Δn *versus* $\bar{B}^2$. Each point is the average of between 3 and 10 analyzer readings for each value of $\bar{B}^2$. The concentration dependence of C is shown in Fig. 8, where the intercept on the C axis (pure water) was taken from the Landolt-Bornstein

Table IV—Summary of Experimental Results

Technique	Parameter	Value of Parameter: Experiment	Planar (Calculated)	Perpendicular (Calculated)
Depolarized light scattering	$\gamma^2/Å^6$	1100	1060	365
Magnetic birefringence	$10^{12}(dC/dc)/$ Oe.$^{-2}$ cm.$^{-1}$ g.$^{-1}$ ml.	3.6	2.26 4.2 (relative method)	0.71 1.3 (relative method)

tables. Errors in C, judged from the scatter of experimental Δn values, are shown as vertical bars in Fig. 8. The error in concentration C is negligible. The line through the points in Fig. 8 is a line of best fit, assuming the value of C for water to have zero error. This was done since the value of C for water is of higher precision than the values of C for the measured solutions.

Values of incremental refractive index dn/dc and density $d\rho/dc$ were measured using a high precision Abbé refractometer and weighing bottle, respectively. The values at 23°, 5461 Å, were found to be $dn/dc = 0.233 \pm 0.005$ ml. g.$^{-1}$ and $d\rho/dc = 0.49 \pm 0.02$.

A relative method, not requiring absolute values of α and χ, is to measure the Cotton-Mouton constant for a compound similar to sodium cromolyn but having a known conformation. Such a compound is 9C in which the —O—C_3—O— bridge connecting the benzene rings in sodium cromolyn is replaced by a —O—C_9—O— bridge. Due to the increased bridge length (therefore more possibilities for internal rotation about C—C bonds), the bridge is thought to be flexible. Additional evidence for flexibility comes from Raman spectra of linear carbon chains in *n*-alkanes. The spectra show (16) that there are no rigid all-*trans*-isomers present when the chain exceeds nine carbon atoms in length. Thus, the orientation of one end of the 9C molecule by the applied magnetic field may take place without affecting the other end. When neglecting the flexible bridge, which has a low optical and diamagnetic anisotropy, this lack of correlation between the molecule ends means that each 9C molecule contributes to the Cotton-Mouton constant as though it were two free halves of a sodium cromolyn molecule.

Theory and Results—Bottcher (14) gave an expression for the refractive index of a mixture in terms of the number densities N and effective polarizabilities α^* of each component:

$$\frac{(n^2 - 1)(2n^2 + 1)}{12\pi n^2} = N_1\alpha_1^* + N_2\alpha_2^* \qquad \text{(Eq. 16)}$$

where $\alpha_i^* = \bar{\alpha}_i/(1 - f_i\bar{\alpha}_i)$, and $f_i = (1/a_i^3)[(2n^2 - 2)/(2n^2 + 1)]$; a_i is the effective radius of the particles of the ith sort and $\bar{\alpha}_i$ is their mean polarizability. According to the Langevin theory (15) of the Cotton-Mouton effect of diamagnetic molecules, an applied field B in the x direction produces an average polarizability difference:

$$\bar{\alpha}_x - \bar{\alpha}_y = \frac{3}{2}\theta_1 B^2 \qquad \text{(Eq. 17)}$$

where $\theta_1 = (1/45kT)[(\alpha_1 - \alpha_2)/(\chi_1 - \chi_2) + (\alpha_2 - \alpha_3)(\chi_2 - \chi_3) + (\alpha_3 - \alpha_1)(\chi_3 - \chi_1)]$. Differentiating Bottcher's equation for small changes in α^* of both components and in the limit of low concentrations of Component 1 gives:

$$\Delta n = \frac{(18n^2\pi N_1)(\Delta\bar{\alpha}_1)}{(2n^2 + 1)^2(1 - f_1\bar{\alpha}_1)^2} + \Delta n_2 \qquad \text{(Eq. 18)}$$

where $\Delta\alpha_1 = 3/2\theta_1 B^2$ using Langevin's theory. Bottcher's equation may also be used to calculate dn/dc, if low concentrations are again assumed:

$$\frac{dn}{dc} = \frac{18\pi n^3 N_0}{(2n^2 + 1)^2}\left[\frac{\alpha_1^*}{M_1} - \frac{\alpha_2^*}{M_2}\left(1 - \frac{d\rho}{dc}\right)\right] \qquad \text{(Eq. 19)}$$

where N_0 is Avogadro's number. By assuming, as $c \to 0$, that $\alpha_2^* = \alpha_{water}^*$, then:

$$\alpha_1^* = \frac{M_1(2n^2 + 1)}{36\pi n^3 N_0}\left[2(2n^2 + 1)\frac{dn}{dc} + 3n(n^2 - 1)\left(1 - \frac{d\rho}{dc}\right)\right] \qquad \text{(Eq. 20)}$$

Thus $(1 - f_1\bar{\alpha}_1) = \bar{\alpha}_1/\alpha_1^* = 0.815$, using the bond polarizability value of 44 Å^3 for $\bar{\alpha}_1$, and measured values of dn/dc and $d\rho/dc$.

Putting $M_1 = 516$ for sodium cromolyn and $n = 1.335$ gives absolute dC/dc values as follows:

$$\left(\frac{dC}{dc}\right)_{abs} = 2.26 \times 10^{-12} \text{ Oe.}^{-2} \text{ cm.}^{-1} \text{ g.}^{-1} \text{ ml.}$$

(planar conformation) (Eq. 21)

$$\left(\frac{dC}{dc}\right)_{abs} = 0.71 \times 10^{-12} \text{ Oe.}^{-2} \text{ cm.}^{-1} \text{ g.}^{-1} \text{ ml.}$$

(perpendicular conformation) (Eq. 22)

Neglecting the optical and diamagnetic anisotropy of the 9C flexible bridge and assuming complete flexibility give θ_1 (planar sodium cromolyn) $= 2\theta_1$(9C). Bond polarizability calculations predict a ratio of 3.3 between the values of $\theta_{1\,\text{sodium cromolyn}}$ in the planar and perpendicular conformation; thus, it may be assumed that:

$$\theta_1(\text{perpendicular sodium cromolyn}) = \frac{2}{3.3}\theta_1(9C) = 0.61\theta_1(9C) \qquad \text{(Eq. 23)}$$

Only a small quantity of 9C was available, and two experiments were made on one solution of concentration 0.625%. These gave 0.66×10^{-14} and 0.85×10^{-14} Oe.$^{-2}$ cm.$^{-1}$ for the Cotton-Mouton constant (Fig. 9). Adopting $(0.75 \pm 0.1) \times 10^{-14}$Oe.$^{-2}$ cm.$^{-1}$ as a mean value and using the Landolt-Bornstein value of C for water allow an estimate of dC/dc for the two sodium cromolyn conformations after allowing for the molecular weight difference between sodium cromolyn (516) and 9C (600). This gives, for sodium cromolyn:

$$\left(\frac{dC}{dc}\right)_{rel} = 4.2 \times 10^{-12} \text{ Oe.}^{-2} \text{ cm.}^{-1} \text{ g.}^{-1} \text{ ml.} \quad \text{(planar)} \qquad \text{(Eq. 24)}$$

$$\left(\frac{dC}{dc}\right)_{rel} = 1.3 \times 10^{-12} \text{ Oe.}^{-2} \text{ cm.}^{-1} \text{ g.}^{-1} \text{ ml.} \quad \text{(perpendicular)}$$

(Eq. 25)

Comparing the dC/dc values, both absolute and relative, with the

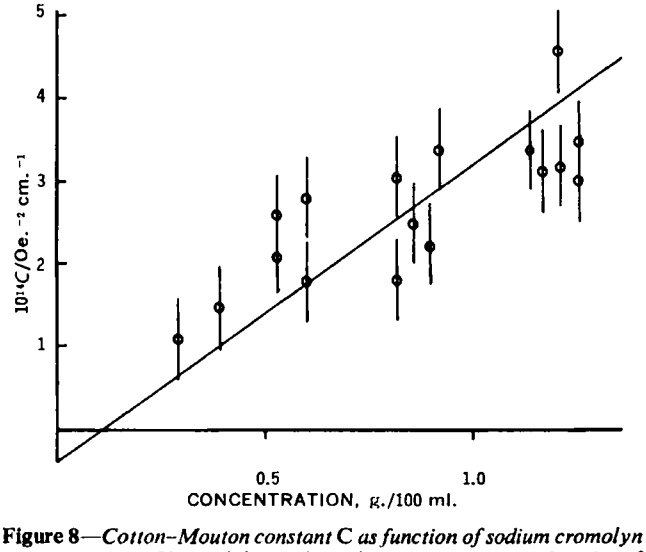

Figure 8—*Cotton-Mouton constant C as function of sodium cromolyn concentration. Vertical lines through points represent domain of measurement error.*

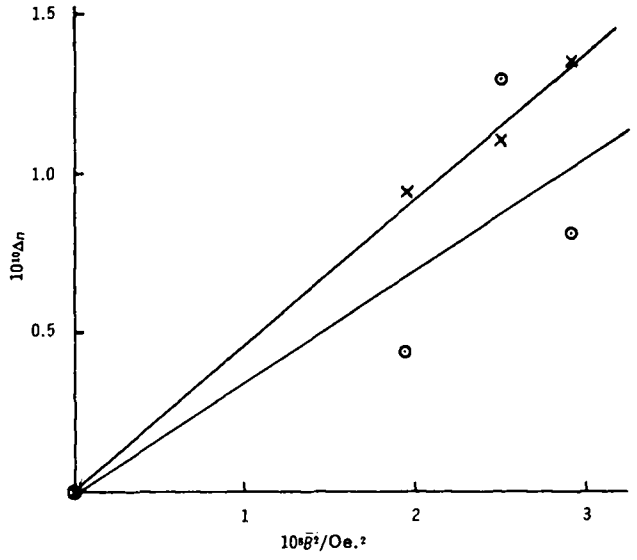

Figure 9—*Birefringence* Δn *of 0.625 g./100 ml. 9C solution. Key:* O, *lower line, first experiment; and* ×, *upper line, second experiment. Both lines are least-square fits to the experimental points.*

experimental value of 3.6×10^{-12} Oe.$^{-2}$ cm.$^{-1}$ g.$^{-1}$ ml. from Fig. 8 shows that the planar conformation is favored.

CONCLUSION

The summary of experimental and calculated data relating to the conformation is shown in Table IV. Both techniques show conclusively that the planar rather than the perpendicular or random conformation exists in very dilute solution within the estimates of error discussed in the text. The larger errors apparent in the magnetic birefringence comparisons are thought to arise from uncertainties in some of the bond magnetic anisotropy values.

Due to flexibility in the —O—C_3—O— bridge between the two identical halves of the sodium cromolyn molecule, a planar conformation of the isolated molecule is unexpected. The molecule's affinity for water (1) provides an explanation in terms of water molecules bridging the chromone groups by hydrogen bonding and thus forming a rigid structure. Experiments using scale space-filling molecular models show that several water molecules can be accommodated to form this bridge. Due to their low optical and diamagnetic anisotropy, the water molecules would not greatly affect the values of γ^2 and dC/dc and thus not show up in the experimental measurements.

Both techniques are sensitive indicators of molecular association or liquid crystal formation, and the time-dependent and nonlinear behavior found at about > 1g./100 ml. shows that these phenomena are occurring at much lower concentrations than previously thought (1).

Embryonic-Fetal Toxicity and Teratogenic Effects of Adipic Acid Esters in Rats

A. R. SINGH, W. H. LAWRENCE, and J. AUTIAN▲

Abstract □ Seven adipates (dimethyl, diethyl, dipropyl, diisobutyl, di-*n*-butyl, di-2-ethylhexyl, and dicyclohexyl) were evaluated for their embryonic-fetal toxicity and teratogenic effects in rats, and the results were compared to those of a previous study with phthalate esters. The data suggest that the adipates are less teratogenic than the comparable phthalates when administered during gestation in equivalent fractions of the respective LD_{50} doses.

Keyphrases □ Adipic acid esters—embryonic fetal toxicity and teratogenic effects in rats □ Embryonic fetal toxicity and teratogenic effects—adipic acid esters, rats □ Teratogenicity and embryonic fetal toxicity—adipic acid esters, rats □ Plasticizers, adipic acid esters—embryonic-fetal toxicity and teratogenic effects, rats

Adipates, esters of adipic acid and various alcohols, are employed as plasticizers for polyvinyl chloride, particularly for low temperature applications. Although no teratological information is available on these materials, there are some reports concerning their acute and subacute toxicities. Data on the acute oral toxicity of some of these adipates have been reported (1–3). A subacute study was conducted on di-2-ethylhexyl adipate, in which rats were fed a diet containing 0.5, 2.0, and 5.0% of the adipate, representing approximately 0.25, 1.0, and 2.5 g./kg./day, respectively. The only abnormality observed was a retardation of growth at the 5.0% level (1). Furthermore, dogs were given 2 g./kg./day of the compound, and only a transient loss of appetite was noted (1). In another study (2), di-2-ethylhexyl adipate was fed to rats; no adverse effect was noted at dietary levels equivalent to 0.16 g./kg./day, but an increased mortality was seen in those receiving 4.74 g./kg./day.

The metabolism and toxicity of adipic acid have also been studied, showing that this compound is oxidized *in vitro* by isolated rat liver mitochondria. However, its *in vivo* metabolism is incomplete, as evidenced by the presence of varying amounts of unchanged acid in the urine (4). When using ^{14}C-labeled adipic acid, it was found that 70% of the radioactivity in a 50-mg. dose administered to rats appeared in the expired carbon dioxide within 24 hr.; such carbon dioxide was produced more rapidly from acid labeled in the first rather than in the second carbon position (5). Low residual activity was confined mainly to the kidneys and liver, and ^{14}C-labeled urea, as well as glutamic, lactic, adipic, β-ketoadipic, and citric acids, was identified in the urine. Further studies showed that the urea and citric acid were not direct metabolites of adipic acid but were formed from the radioactive carbon dioxide. Demonstration that the ^{14}C-label of adipic acid can be incorporated into glycogen, with acetic and succinic acids as intermediates, and the identification of β-ketoadipic acid in the urine indicate that the metabolism of adipic acid is by β-oxidation (5).

Table I—Acute Toxicity of Adipic Acid Esters in Rats

Compound	Acute LD_{50}, ml./kg.	95% Confidence Limits, ml./kg.	Slope (b)[a]
Dimethyl adipate	1.8086	1.5735–2.0789	16.24
Diethyl adipate	2.5119	2.1859–2.8871	16.24
Dipropyl adipate	3.7858	3.3279–4.2087	19.55
Diisobutyl adipate	5.9500	4.6903–7.5482	4.69
Di-*n*-butyl adipate	5.2441	4.9023–5.6096	39.41
Di-2-ethylhexyl adipate	>50	-	—
Dicyclohexyl adipate	5.1007[b]	4.7038–5.5313	16.24

[a] Probit slope (b) = probits/log of dose. [b] Compound warmed to 37–38° to liquefy it for injection.

The acute LD_{50} of adipic acid in mice was found to be 1900 mg./kg. p.o. and 680 mg./kg. i.v. In rats, the intraperitoneal LD_{50} was 275 mg./kg. (6). These workers also fed adipic acid at dietary levels of 0.1–5.0% (representing an intake of 50–2500 mg./kg./day) to rats for 2 years, and the only abnormality they detected was reduced growth at levels of 3.0% (1500 mg./kg./day) or more. In another study, increased mortality, diarrhea, and reduced growth were noted in rats given a dietary level equivalent to 16 or 11.4 g./kg./day for 5 or 33 weeks, respectively (7). These effects were observed during the first 2 weeks, after which surviving animals recovered but histological changes in the liver, kidneys, and intestine were reported. However, none of these effects was evident at a dose level of 5.7 g./kg./day (7)[1].

Gaunt *et al.* (9) reported acute toxicity studies of dialkyl 79 adipate (adipate esters in which alcoholic portions contained seven–nine carbon atoms) in mice and rats and short-term feeding studies in rats. They found it to be most toxic to mice by the oral route (LD_{50} = 8–12 g./kg.), while rats tolerated 20 g./kg. without any mortalities. There were no deaths in either mice or rats at intraperitoneal doses up to 20 g./kg. These doses of dialkyl 79 adipate produced piloerection and diarrhea in both species along with reduced spontaneous activity; the diarrhea was more pronounced in the animals receiving the compound orally. In 98-day feeding studies with rats, they found the "no-effect" level to be 0.25% in the diet, representing approximately 125 mg. adipate/kg. rat/day. Some alterations in values obtained for nonlethal parameters (*e.g.*, weight gain, hemoglobin concentration, and relative kidney weight) were noted when the diet contained 0.5 or 1.0% dialkyl 79 adipate; however, no deaths were attributed to the adipate.

As the adipates comprise an important group of

[1] The Joint FAO/WHO Expert Committee on Food Additives allocated a conditional acceptable daily intake for man of 0–5.0 mg./kg. for adipic acid (8).

[a] Five pregnant female rats were injected in each group on Days 5, 10, and 15 of pregnancy. [b] Numbers represent the average values (grams) ± the standard error of the mean for each group. *$p \leq 0.05$, **$p \leq 0.01$, significantly different from blunt needle-injected controls.

plasticizers, it was decided to initiate embryonic-fetal toxicity and teratogenic tests in rats with seven adipic acid esters. A parallel study (10) on some phthalic acid esters provided data with which to make a comparison between certain members of the two series.

EXPERIMENTAL

Materials—The adipates included in this study were: dimethyl[2], diisobutyl[2], diethyl[3], dipropyl[3], di-2-ethylhexyl[3], di-*n*-butyl[3], and dicyclohexyl[3]. Test animals were adult, virgin female, Sprague-Dawley rats[4], weighing 175–225 g. Adult, male rats of this strain were utilized as the "stud pool."

Procedure—Acute toxicity of the adipate esters was determined by administering graded doses of these specific samples by intraperitoneal injection to rats and observing the animals for mortality for 7 days. Acute LD_{50} values, 95% confidence limits, and slopes were calculated by Cornfield and Mantel's modification of Karber's method (11).

Female rats were selected for experimentation only after observation of at least two complete 4- or 5-day estrus cycles. Occurrence of estrus was determined by daily vaginal smears, obtained by introducing 0.2 ml. of fresh, clean tap water into the vagina with a smooth, clean, sterile medicine dropper, withdrawing a part of the liquid, and transferring it to a clean slide. The slide was examined microscopically while fresh, and the stage of estrus (proestrus, estrus, or diestrus) was determined according to cell types found in the vaginal smear.

Five female rats were housed with one male in a large cage at room temperature (22–27°) with food[5] and fresh tap water provided *ad libitum*. The onset of gestation was established by the presence of sperm in the vaginal smear and was designated as Day 0, with the following day being Day 1 of the gestation period. At this time, the female rats were moved to individual cages, where they were kept undisturbed except for specified injections. There were 31 groups, each composed of five female rats.

All treatments were administered by intraperitoneal injection on the 5th, 10th, and 15th days of gestation. The six more toxic adipates were injected intraperitoneally at four dosage levels: one-thirtieth, one-tenth, one-fifth, and one-third of their acute LD_{50} values in each injection. Di-2-ethylhexyl adipate was administered at three dosage levels of 1, 5, and 10 ml./kg. Distilled water, normal saline, and cottonseed oil were used at a dose of 10 ml./kg., corresponding to the largest volume of adipate injected (di-2-ethylhexyl adipate), although no diluent was used with the adipates. A "blunt-needle-injected" group[6] was also included for comparative purposes.

On the 20th day of gestation, 1 day prior to expected parturition, the rats were sacrificed by ether inhalation. The uterine horns and ovaries were surgically exposed to permit counting and recording of the numbers of corpora lutea, resorption sites, and viable and dead fetuses. Fetuses were removed, blotted dry, and weighed[7] to the nearest tenth of a milligram. All fetuses, both viable and nonviable, were examined for gross abnormalities. A randomly selected number (usually 50% of the total, excluding whenever possible those showing gross evidence of deformities) were prepared as transparent specimens to permit skeletal visualization for evaluating malformations. In a few instances, in which the incidence of resorption was very high, all fetuses were included. Skeletal visualization was accomplished by the procedure of Staples and Schnell (12). The remaining fetuses were examined for visceral abnormalities.

[a] Percent resorptions are based on total number of resorptions and dead and live fetuses. [b] Percent gross abnormalities are based on total number of fetuses. [c] Percent skeletal abnormalities are based on total number of stained fetuses (50% of total fetuses). [d] Percent visceral abnormalities are based on total number of unstained fetuses. [e] Values greater than the 95% confidence interval of the "pooled volume control."

The following parameters of adverse effects were investigated: (*a*) embryonic–fetal toxicity, as evidenced by resorptions and stillbirths, (*b*) gross (external) malformations of fetuses, (*c*) skeletal malformations, (*d*) visceral abnormalities, and (*e*) fetal size (weight). In all evaluations, both viable and nonviable fetuses were considered.

RESULTS

The observed number of corpora lutea ranged from 52 to 72 per group, with a mean of 62.5. Of the 1938 corpora lutea observed in this study, 1840 or 94.9% were accounted for as live fetuses, dead fetuses, or resorption sites.

The acute intraperitoneal LD_{50} values and the 95% confidence limits for the adipate esters are presented in Table I. As shown, LD_{50} values were obtained for six of the adipates used in this study, but the sample of di-2-ethylhexyl adipate used failed to produce 50% mortality at doses considerably in excess of 50 ml./kg. Dimethyl adipate is the most acutely toxic, while the other adipate esters showed a decreased toxicity, generally as the size of the alcoholic portion increased.

Compound-dependent and dose-related effects upon embryonic and fetal growth and development were generally observed with these adipates. The results of developmental changes are presented in Tables II and III for the distilled water, normal saline, cottonseed oil, blunt-needle-injected, and all experimental groups. Table II presents data concerning the number of corpora lutea, resorption sites, dead fetuses, live fetuses, and fetal weights according to treatment groups. Table III shows a comparison of the number and percent of resorptions and gross, skeletal, and visceral abnormalities.

Resorptions—All control and treatment groups exhibited one or more resorptions. These ranged from 1.6% for one-tenth of the acute LD_{50} of diisobutyl adipate to 20.0% for one-third of the LD_{50} dose level of dicyclohexyl and dipropyl adipates. The highest incidences were seen with the four dose levels of dicyclohexyl adipate (20.0, 19.4, 19.6, and 14.5%), and the highest dose of dipropyl adipate (20.0%). The lowest incidences of resorptions occurred in the groups treated with one-tenth of the LD_{50} of diisobutyl adipate (1.6%), one-fifth of the LD_{50} of dimethyl adipate (1.8%), and one-thirtieth of the LD_{50} of diethyl adipate (1.9%). Only one resorption site was observed in each of these last three experimental groups.

Fetal Deaths—Fetal deaths were observed with much less frequency and in smaller numbers than the other criteria considered. Although most experimental groups revealed some resorption sites, dead fetuses were found only in groups treated with four of the compounds: diisobutyl, diethyl, di-*n*-butyl, and dicyclohexyl adipates. The two high doses of diisobutyl adipate produced one dead fetus (1.6%) for each dose level; two dead fetuses (3.6%) were found in the group receiving the high dose of diethyl adipate; and two (3.1%) dead fetuses and one (1.4%) dead fetus were found in groups treated with one-third and one-fifth of the acute LD_{50} dose levels of di-*n*-butyl adipate, respectively. Dicyclohexyl adipate produced fetal toxicity at all four dose levels employed. It revealed the largest number of fetal deaths in this study. Two (3.2%), one (2.0%), two (3.2%), and five (7.7%) fetal deaths were noted with one-thirtieth, one-tenth, one-fifth, and one-third of the acute LD_{50} dose, respectively.

Teratogenicity—*Gross Abnormalities*—A significant number of malformations were observed throughout the treatment groups, and these tended to show a dose-related incidence when considered as percentage of malformations. No gross abnormalities were seen in the blunt-needle (without injection) or distilled water control groups; neither were there any with one-thirtieth of the acute LD_{50} dose of any adipates employed nor with 1 ml./kg. of the di-2-ethylhexyl adipate. One malformed fetus was seen in each group treated with normal saline, cottonseed oil, dimethyl adipate (0.1809 ml./kg.), diethyl adipate (0.5024 and 0.2512 ml./kg.), di-*n*-butyl adipate (0.5244 ml./kg.), diisobutyl adipate (1.1900 ml./kg.), dipropyl adipate (0.3786 ml./kg.), and di-2-ethylhexyl adipate (5 ml./kg.), representing from 1.6 to 2.0% of the fetuses within the various groups. The greatest number of gross malformations seen was five per group, which occurred with the high dose of diisobutyl adipate; this represented 8.3% of the total fetuses. A complete tabulation of the

number and percentage of fetuses in which gross abnormalities were noted is presented in Table III.

The most common gross abnormalities observed were hemangiomas on various parts of the fetus, twisted hindlegs, and compact head and neck (some were monsters). One-fifth the acute LD_{50} of dimethyl and dipropyl adipates produced one fetus each without a tail. Most adipates studied produced a number of poorly developed and very small fetuses.

Skeletal Abnormalities—The number of skeletal abnormalities observed for each group and its percentage of visualized fetuses are presented in Table III. The abnormalities most often seen were elongated anterior ribs, often fused to the sternebrae, as well as elongated and fused posterior ribs (bilateral or unilateral); less frequently, one or two ribs were missing.

The incidences of skeletal abnormalities ranged from 0% for the distilled water, the lowest dose of dimethyl and diisobutyl adipates, the two lower doses of diethyl and dicyclohexyl adipates, and the three lower doses of di-*n*-butyl and dipropyl adipates up to a high of 19.2% for the high dose of dimethyl adipate.

Visceral Abnormalities—Visceral abnormalities were observed with much less frequency and in smaller numbers than were the gross and skeletal abnormalities. No visceral abnormalities were seen in the blunt-needle control group, cottonseed oil group, or any groups treated with dipropyl and dicyclohexyl adipates. The highest incidence of visceral abnormalities seen was two per group, which occurred with the high dose of dimethyl adipate. The most common visceral abnormalities observed were umbilical hernia, angulated anal opening, and absence of one kidney.

Fetal Size—Fetuses from most of the treated groups of rats were smaller, based upon weight, than those from the blunt needle-injected control group. However, these differences were not statistically significant except with the two higher dose levels of diisobutyl, the two higher dose levels of di-2-ethylhexyl, the one-fifth LD_{50} dose levels of dipropyl and di-*n*-butyl, and the highest dose level of dicyclohexyl adipates. The control fetuses averaged 3.91 g. each, while those from the adipate ester-treated rats had a mean fetal weight from 3.06 to 4.12 g. (Table II).

DISCUSSION

Administration of these adipate esters to pregnant rats on the 5th, 10th, and 15th days of gestation generally produced a compound-dependent and dose-related increase in resorptions and gross and skeletal abnormalities and a reduction in fetal weight at birth. The types of abnormalities found with these compounds were quite similar to those reported by Singh *et al.* (10) for a group of phthalate esters; however, the incidences of abnormalities were less in the adipate-treated animals. Although visceral abnormalities were observed less frequently than other types, when they occurred they were generally in the groups receiving the highest dose or doses. The two exceptions seen were with 0.2512 ml./kg. of diethyl adipate and 0.5244 ml./kg. of di-*n*-butyl adipate. In the former group, one fetus had an umbilical hernia and, in the latter group, one fetus exhibited an incomplete vascular development, particularly in the area of the shoulders.

As shown in Tables II and III, the blunt-needle-injected rats produced no dead fetuses or gross or visceral abnormalities, and there were only four (6%) resorption sites, one (3%) skeletal abnormality, and 63 (94%) live fetuses from 69 corpora lutea. Thus, if these findings are used as the baseline, most treatments produced an effect in one or more of the parameters studied except the lowest dose level, one-thirtieth of the acute LD_{50} of each adipate ester.

A more conservative evaluation could be made between the effects produced by the adipic acid esters when compared to the results of a "volume control" to compensate for any effects resulting from the physical or mechanical trauma of injection and handling. Since no diluent was used when these compounds were injected and the injected volume ranged from 0.0603 to 10.00 ml./kg., it was decided to employ distilled water, normal saline, and cottonseed oil in a quantity equivalent to the largest dose of the test compound (10.00 ml./kg.). Since the results obtained from these three "controls" were not uniform and there was no justification for selecting one of these in preference to the others, the data were combined to calculate a 95% confidence interval (13) for the "pooled volume control" in regard to resorptions and gross and skeletal abnormalities. The confidence intervals thus obtained were as follows: resorptions, 3.7–12.3%; gross abnormalities, 0.7–3.1%; and skeletal malformations, 1.0–12.6%. A significant increase in resorptions was observed for the 0.1809-ml./kg. level of dimethyl adipate, for 1.2619 ml./kg. of dipropyl adipate, and for all four dose levels of dicyclohexyl adipate. The incidence of gross abnormalities was increased significantly in groups receiving the following treatments: 0.3617 and 0.6028 ml./kg. of dimethyl adipate, 0.8373 ml./kg. of diethyl adipate, 0.7572 and 1.2619 ml./kg. of dipropyl adipate, 0.5950 and 1.9833 ml./kg. of diisobutyl adipate, 1.7480 ml./kg. of di-*n*-butyl adipate, the high dose (10.00 ml./kg.) of di-2-ethylhexyl adipate, and the three highest doses of dicyclohexyl adipate. Concerning skeletal malformations, only the two highest dose levels of dimethyl adipate showed an incidence greater than the 95% confidence interval (Table III).

Dicyclohexyl adipate was interesting due to the marked effect this compound had upon the developing embryo and fetus. Quite a number of fertilized ova were detected only as resorption sites in all four dose levels, indicative of an early embryotoxic effect; dead fetuses were found with all four dose levels employed, indicating a later toxic action as well. In spite of its embryonic-fetal toxicity, a number of gross abnormalities were noted in the three higher dose groups. Most abnormalities produced by this compound were hemangiomas of different parts of the body, and twisted hindlegs were often observed. After visualizing and staining the skeleton, one of the 25 visualized fetuses of the high dose level had two ribs less than normal; one of the 26 in the next highest dose group had elongated and fused posterior ribs, while those in the two lower dose groups did not show any skeletal malformation. No visceral abnormalities were seen in the groups receiving this adipate.

Another compound, dimethyl adipate, produced considerable embryotoxic and teratogenic effects. In the high dose group, one fetus had hemangiomas of the neck, one on the shoulder, one of the foreleg, and one on the right thigh. Skeletal examinations of this group revealed five of 26 fetuses had elongated frontal ribs fused to the sternebrae. This group also contained two visceral abnormalities: one fetus did not have the left kidney and one fetus had an angulated anal opening. In the second highest dose group, one fetus did not have a tail; two of the 29 stained fetuses had a few elongated and fused posterior ribs, and two fetuses had elongated anterior ribs fused to the sternebrae. The 0.1809-ml./kg. dose level of this compound produced only one fetus with hemangiomas of the right hindquarter, while two of the 27 stained fetuses had elongated anterior ribs fused to the sternebrae. The lowest dose level did not produce any gross, skeletal, or visceral abnormalities.

Diisobutyl adipate produced a number of gross and skeletal abnormalities in offspring of treated rats; however, only one fetus demonstrated a visceral abnormality (perforated anal opening) in the high dose group. Also within this group, one fetus had a hemangioma of the chin and another had one on the back; three had twisted hindlegs. Skeletal examinations of this group revealed three of 31 fetuses had elongated and fused posterior ribs. In the second highest dose group, one fetus had a hemangioma of the chin; two of 30 stained fetuses had elongated and fused posterior ribs, and one fetus had elongated anterior ribs fused to the sternebrae. In the group receiving 0.5950 ml./kg., one fetus had a hemangioma of the shoulder, and another fetus had a hemangioma of the neck. One of 32 stained fetuses had elongated and fused posterior ribs, and one had elongated anterior ribs fused to the sternebrae. The lowest dose group of this compound did not show any gross, skeletal, or visceral abnormalities.

Diethyl, dipropyl, di-*n*-butyl, and di-2-ethylhexyl adipates produced few gross, skeletal, or visceral abnormalities, and these occurred mainly at the higher dose levels. In very few of these groups were the incidences greater than the pooled volume control. Two dead fetuses were found in the high dose group of diethyl adipate, and two dead fetuses were observed in the high dose group and one dead fetus in the second highest dose group of di-*n*-butyl adipate.

One-thirtieth of the acute LD_{50} dose of the six adipic acid esters used in this study for which there was an acute LD_{50} (dimethyl, diethyl, dipropyl, diisobutyl, di-*n*-butyl, and dicyclohexyl adipates) were completely tolerated by rat fetuses after intraperitoneal administration on the 5th, 10th, and 15th days of pregnancy, since this dose level of each compound did not produce any gross, skeletal, or visceral abnormalities. Therefore, these compounds may be considered not teratogenic under these conditions at this dose level. Therefore, from the data obtained, it would appear that the "no effect" level for these adipates under the conditions of this test would be equal to or greater than one-thirtieth but less than one-tenth

Table IV—Comparison of Embryonic–Fetal Toxicity and Teratogenicity of Adipates and Phthalates[a]

[a] Phthalate ester data taken from Singh *et al.* (10).

of their respective acute LD_{50} values. Di-2-ethylhexyl adipate, which failed to produce 50% mortality at doses in excess of 50 ml./kg. i.p., did not produce gross or visceral abnormalities at the 1-ml./kg. dose level; only one skeletal abnormality was noted in this group.

A previous study with phthalic acid esters (10) indicated a range of embryonic–fetal toxicity from 0 to 98.2% in rats treated with one-tenth, one-fifth, and one-third of the acute LD_{50} doses of the phthalates, whereas similar dose levels of adipates resulted in an embryonic fetal toxicity of 1.6–27.7%. It would appear, therefore, that the adipic acid esters possess a lower degree of toxicity to the developing embryo and fetus than was seen with the phthalic acid esters.

Fetal malformations varied from 0 to 100%, both for gross and skeletal abnormalities, with skeletal defects generally being more common with phthalate ester-treated rats; fetal malformations in adipate-treated rats ranged from 1.6 to 10% for gross abnormalities and from 0 to 19.2% for skeletal deformities. Thus, the comparison suggests the phthalates exert a more potent teratogenic effect than that noted for the adipates.

Three adipates included in this study were comparable analogs to phthalates reported earlier (10). When comparable doses, based upon the fraction of an acute LD_{50} dose of each compound, were administered to rats at the same time intervals, marked differences were noted in the abnormalities seen. Examination of Table IV reveals differences between the esters; in general, the phthalates tended to produce the greatest effect. This is especially noticeable for skeletal abnormalities.

The mean fetal weight on the 20th day of gestation ranged from 1.75 to 4.0 g. in rats treated with phthalic acid esters; in those treated with adipic acid esters, the mean fetal weight was 3.06–4.12 g. This indicates that adipic acid esters exert less growth-retarding effect than the phthalic acid esters. Overall, the data suggest that the embryonic–fetal toxicity and teratogenic effects of adipic acid esters were less than those produced by comparable doses of the phthalic acid esters.

SUMMARY AND CONCLUSIONS

All of the adipic acid esters studied exerted some degree of deleterious effect upon the developing embryo and fetus. At one or more of the dose levels employed, each compound produced some or all of the following effects: resorptions; gross, skeletal, and visceral abnormalities; fetal death; and decreased fetal size. Blunt-needle-injected animals were used as controls to determine the "normal" fetal size and a baseline of normal values; within this group there were no gross or visceral abnormalities or fetal deaths, and only 6% resorptions and one (3%) skeletal deformity were observed. However, seven experimental groups contained fetuses of significantly lighter weights than these controls. A secondary comparison was made using a 95% confidence interval obtained by pooling data from volume controls of distilled water, normal saline, and cottonseed oil. When a comparison was made using the 95% confidence limits of the pooled volume controls, 12 of the adipate-treated groups showed a significant incidence of gross abnormalities, six groups had a significant increase in resorptions, and two showed a definite increase in skeletal malformations.

Although this regimen of adipic acid ester administration did not elicit as great an effect as did the phthalates upon embryonic and fetal development, the incidences of adverse effects noted were generally dose related and compound dependent, perhaps with the more soluble compounds tending to be more active. The "no effect" level established in this study for adipic acid esters was approximately one-thirtieth of the acute LD_{50} dose.

Constituents of *Cannabis sativa* L. IV: Stability of Cannabinoids in Stored Plant Material

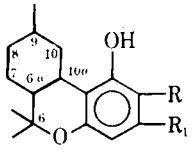
CARLTON E. TURNER▲, KATHY W. HADLEY, PATRICIA S. FETTERMAN, NORMAN J. DOORENBOS, MAYNARD W. QUIMBY, and COY WALLER

Abstract □ The (−)-Δ^9-*trans*-tetrahydrocannabinol content of *Cannabis sativa* L. stored at −18, 4, and 22 ± 1° decomposed at a rate of 3.83, 5.38, and 6.92%, respectively, per year, whereas the material stored at 37 and 50° showed considerable decomposition. *C. sativa* L. stored in the absence of direct light at −18, 4, and 22 ± 1° was more stable than cannabis stored under nitrogen. These data indicate that for normal research use, storage under nitrogen at 0° is not mandatory. Cannabinol is not the only decomposition product of (−)-Δ^9-*trans*-tetrahydrocannabinol. Tentative evidence supports the possible formation of hexahydrocannabinol as a decomposition product in stored *C. sativa* L.

Keyphrases □ *Cannabis sativa* L.—stability of cannabinoid constituents in stored plant material □ Cannabinoids—stability in stored *Cannabis sativa* plant material □ GLC—analysis, cannabinoid content in stored *Cannabis sativa* plant material

Eckler and Miller (1), using the dog ataxia assay, reported that certain preparations[1] of *Cannabis sativa* retained their biological activity after 5 years, whereas dry storage for the same period resulted in loss of biological activity. Moreover, it was reported (2) that a 43-year-old sample of cannabis fluidextract showed the presence of cannabidiol (II), (−)-Δ^9-*trans*-tetrahydrocannabinol (V), and cannabinol (VII) when analyzed by TLC and GLC. These two reports on fluidextracts are important but insufficient, since most cannabis currently used for research is stored dry under a myriad of conditions. Therefore, the limited data available on the effects of dry storage on a well-defined sample of *C. sativa* L. plant material prompted an investigation of II, V, and VII in stored plant material. GLC was employed as the principal analytical tool.

To duplicate as nearly as possible those conditions normally used by researchers for storage of cannabis and to determine the percent decomposition of V to VII or other products, the Mexican[2] variant normally supplied to researchers by the National Institute of Mental Health (NIMH) was selected. The study began in 1970 and terminated in 1972 after 104 weeks.



Number	Cannabinoid	Other	R	R_1
I	(−)-Δ^9-*trans*-tetrahydrocannabivarin	$\Delta^{9,10}$	H	C_3H_7
IV	(−)-Δ^8-*trans*-tetrahydrocannabinol	$\Delta^{8,9}$	H	C_5H_{11}
V	(−)-Δ^9-*trans*-tetrahydrocannabinol	$\Delta^{9,10}$	H	C_5H_{11}
VII	cannabinol	$\Delta^{8,9}$; $\Delta^{10,10a}$ $\Delta^{6a,7}$	H	C_5H_{11}
XI	(−)-Δ^9-*trans*-tetrahydrocannabinolic acid	$\Delta^{9,10}$	COOH	C_5H_{11}
XIII	hexahydrocannabinol		H	C_5H_{11}

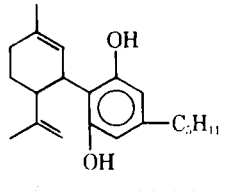
[1] Fluidextracts and granulated drug moistened with alcohol.

METHODS

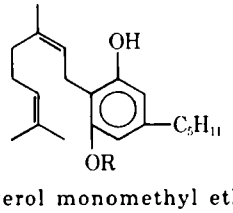
Mexican *C. sativa* L. grown from seed stock ME-A[3] was utilized. The plant material was grown in the Mississippi Delta in 1969 and was harvested at flowering[4]. Female plants were dried for 2 days at ambient temperature and humidity and subsequently manicured[5]; the plant material then was weighed and stored in 1-g. amber, large-mouth bottles. Each bottle was sealed with an aluminum cap containing an inserted paper lining, but the seal was not absolutely airtight. No sample was stored under nitrogen as proposed by Liskow (3). Five storage conditions were employed: (*a*) freezer at −18°; (*b*) refrigerator at 4°; (*c*) ambient temperature 22 ± 1°, with limited exposure to light; (*d*) oven at 37°; and (*e*) oven at 50°. Analyses were performed at 10-week intervals. Major cannabinoids were graphed as percent cannabinoids *versus* their neutral phenol and trimethylsilyl ethers or trimethylsilyl ester-ether derivatives.

GLC Analysis—The extraction procedure is basically that described by Lerner (4) and modified by Fetterman *et al.* (5) and Turner and Hadley (6). Two 1-g. samples were extracted simultaneously with 40 ml. of spectrograde chloroform. The resulting solutions were refrigerated at 4° and shaken for approximately 30 sec. at 10–12-min. intervals for 1 hr.

The plant material was removed by filtration, and the mother liquor was concentrated *in vacuo* at ambient temperature to a greenish paste void of solvent. This concentrate was dissolved in approximately 1 ml. of 95% ethanol. The ethanolic solution was subjected to continuous vibration from an ultrasonic vibrator until



II: cannabidiol



III: cannabigerol monomethyl ether, R = CH_3
VI: cannabigerol, R = H

[2] Seed Code ME-A.
[3] Origin: Acapulco, Guerrero, Mexico, 1968. Obtained through NIMH.
[4] Herbarium specimens of Mexican *C. sativa* L. are stored in the Herbarium, Department of Pharmacognosy, School of Pharmacy, University of Mississippi, University, MS 38677
[5] Manicured material is devoid of fruits and large stems. This was accomplished by passing the material through a 14-mesh sieve.

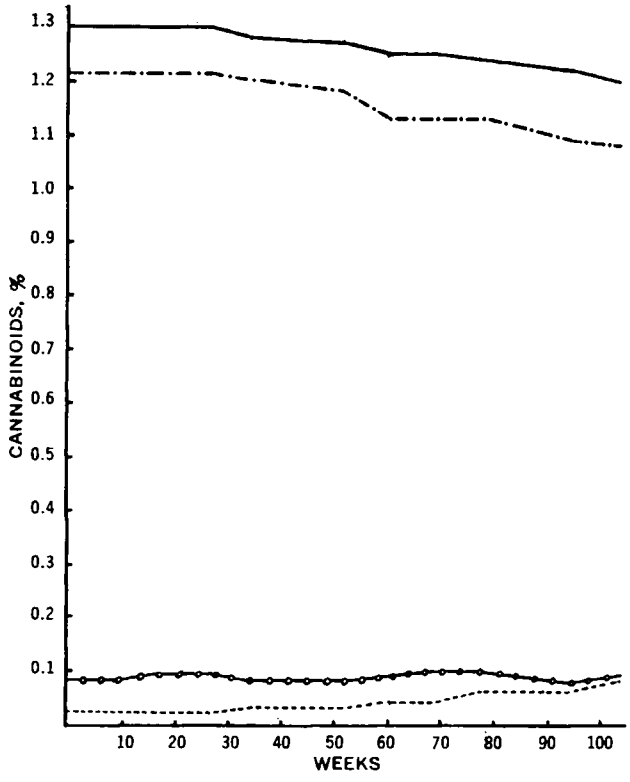


Figure 1—C. sativa *L. plant material stored at −18°. Key:* ——, (−)-Δ^9-trans-*tetrahydrocannabinol;* -·-, (−)-Δ^9-trans-*tetrahydrocannabinolic acid;* -O-, *cannabidiol; and* - - -, *cannabinol.*

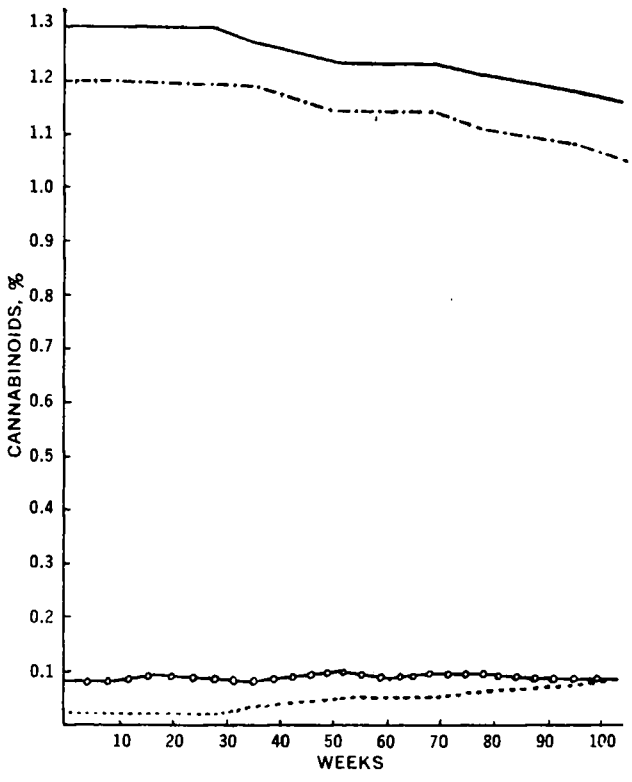

Figure 2—C. sativa *L. plant material stored at 4°. Key:* ——, (−)-Δ^9-trans-*tetrahydrocannabinol;* -·-, (−)-Δ^9-trans-*tetrahydrocannabinolic acid;* -O-, *cannabidiol; and* - - -, *cannabinol.*

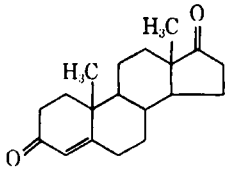
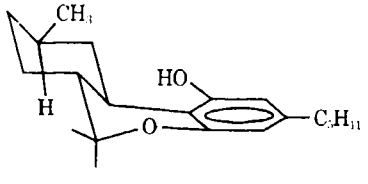
all resin was in solution. At this point, an additional 0.5 ml. of an ethanolic solution containing a known concentration of 4-androstene-3,17-dione (VIII) as the internal standard was added. The concentration of VIII varies depending upon the plant sample. Usually from 0.05 to 0.5 μl. of this solution is injected into the chromatograph.

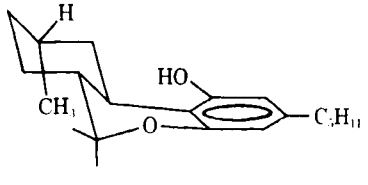
Analyses were performed using gas chromatographs[6] equipped with hydrogen flame-ionization detectors and operated isothermally at 210°. The inlet temperature was 240°, and the detector temperature was 260°. Glass and stainless steel columns [0.63 cm. (0.25 in.) o.d.; 2 mm. i.d. × 2.43 m. (8 ft.)] were packed[7] with 2% OV-17[8] on 100–120-mesh Chromosorb WHP or Gas Chrom Q. Nitrogen was used as the carrier gas at a flow rate of 10–30 ml./min., depending on the instrument used. Peak area measurements were made using the method of peak height times width at half height. Peak area of each cannabinoid was compared with the peak area of the internal standard and, using the appropriate relative response factors, the cannabinoid concentration was determined. Synthetic cannabinoids used in determining the relative response factors were obtained through NIMH.



VIII: 4-androstene-3,17-dione



XIV: C-9 equatorial hexahydrocannabinol



XV: C-9 axial hexahydrocannabinol

Silylation of Plant Extract—A 1-g. sample was extracted with 40 ml. of spectrograde chloroform. The resulting solution was refrigerated at 4° and shaken for approximately 30 sec. at 10-min. intervals for 1 hr. Then the plant material was removed by filtration, and the mother liquor was concentrated *in vacuo* at ambient temperature to a greenish paste void of solvent.

Anhydrous pyridine, 0.5 ml., was added followed by continuous vibration from an ultrasonic vibrator until all resin was in solution. The internal standard in a 10:1 pyridine to steroid solution was then added. The amount of internal standard varies with different plant samples. At this point, 0.5 ml. of *N,O*-bis(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane was added[9]. The resulting reaction mixture was then heated, using a heating mantle, for 10–12 min. at 80°, and 0.1 μl. was injected into the gas chromatograph.

RESULTS AND DISCUSSION

Lerner (4) reported that V converted to VII at the rate of approximately 5%/month. However, as Lerner pointed out, this was only an indication since no quantitative analysis was available of the original sample. Schou and Nielsen (7) reported that one sample of cannabis was examined twice with an interval of 4 years. The content of V had dropped to less than one-fourth of the original,

but the contents of II and VII were relatively unchanged. This sample was stored under nitrogen at room temperature. This study indicated that V is not necessarily oxidized to VII under storage as previously proposed by Levine (8). Turk *et al.* (9) reported that a sample of 100% synthetic V decomposed to VII in the ratio of 97.1 : 2.9%, indicating that V is converted only to VII. Additionally, Razdan *et al.* (10) reported that synthetic V oxidized to VII at the rate of 10%/month at 25°. Thus, these reports seem to indicate that V in stored plant material probably decomposes by a different route than does stored synthetic V.

The Mexican variant chosen for this study contained 1.30% V, 0.02% VII, and 0.08% II. The percent of (−)-Δ^9-*trans*-tetrahydrocannabinolic acid (XI) as its trimethylsilyl ester–ether derivative (11) was 95%.

At the end of this study (104 weeks), the samples stored at 4 and −18° contained 1.16 and 1.20% of V, respectively; 0.08 and 0.07% of VII, respectively; 0.08 and 0.08% of II, respectively; and 91 and 90% of XI, respectively (Figs. 1 and 2). Although II was 0.08% at the start and 0.09% after 104 weeks in the material stored at −18°, this change is within experimental error for concentrations of such small percentages.

Figure 3 is a graph of plant material stored at 22 ± 1°. Percentages of the cannabinoids in the beginning were the same as those reported for 4 and −18°. However, after the end of 2 years, V was 1.12% and XI was 76%. The content of VII and II was 0.10 and 0.09%, respectively. These data do not correlate with data obtained previously (4, 7). However, it is obvious that conditions greatly determine the stability of cannabinoids in stored plant material. Under the conditions set forth in this experiment, the decomposition of V was 6.92%/year when stored at 22 ± 1°; material stored at −18 and 4° decomposed at 3.83 and 5.38%, respectively.

Plant material stored at 36° showed a steady decline in V and XI through Week 60 (Fig. 4). Between Weeks 60 and 70, there was a marked decrease in V from 1.03 to 0.29%. The increase of VII was from 0.40 to 0.50%. From Week 70, there was a steady decline in V and a steady rise in VII. At the termination date, the composition of V and VII was 0.08 and 0.67%, respectively. Thus, there was a material balance deficit of 0.57% between these two cannabinoids (1.30 + 0.02 = 1.32% at the start and 0.08 + 0.67 = 0.75% at termination).

The material deficit and decomposition rate between V and VII were more pronounced when the material was stored at 50°. Pars

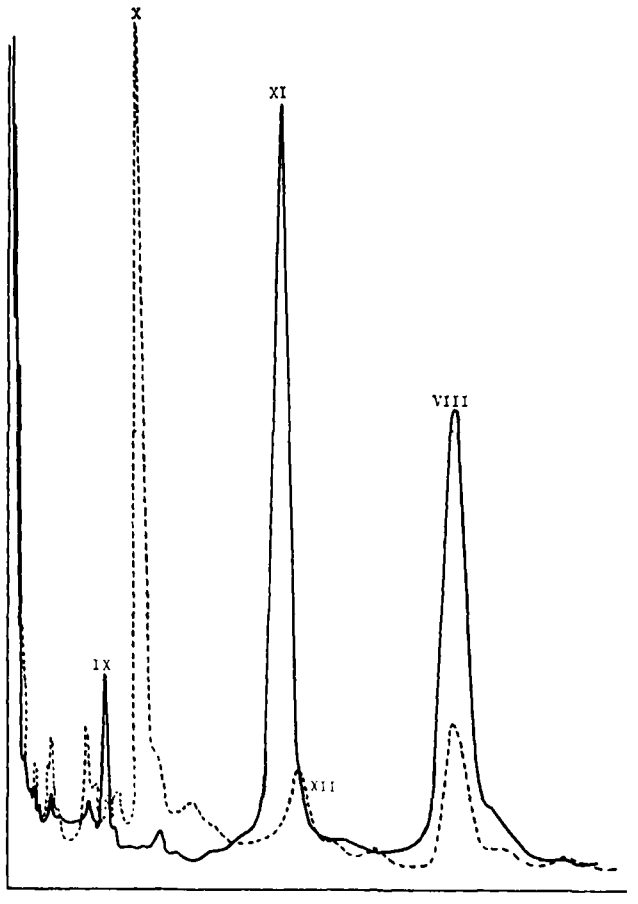

Figure 7—*Overlay of original plant material silylated* (——) *and silylated plant material stored at 37° for 2 years* (- - -). *Key: IX,* (−)-Δ⁹-trans-*tetrahydrocannabinol trimethylsilyl ether; X, cannabinol trimethylsilyl ether; XI,* (−)-Δ⁹-trans-*tetrahydrocannabinolic acid trimethyl ester-ether; XII, cannabinolic acid trimethylsilyl ester-ether; and VIII, 4-androstene-3,17-dione.*

and Razdan (12) observed that synthetic V heated at 80° for 7 days disappeared with concomitant formation of VII, whereas IV showed no change in composition. Data in Fig. 5 indicate that V in stored plant material under thermal conditions did not decompose entirely to VII as was observed with synthetic V. Moreover, the concentration of VII decreased after 50 weeks. The deterioration of V in plant material stored at 37 and 50° could possibly be initiated by an autocatalytic state.

Since V possesses a benzylic proton which is also allylic, the formation of a radical stabilized by resonance would be highly possible under thermal conditions; however, a radical formation would not be as stabilized by delocalization in IV. Thus, the concentration of IV would be expected to remain fairly constant even under thermal conditions, but the concentration of V would decrease precipitously (Fig. 6).

If, indeed, a radical is formed at carbon-10*a* in V, a disproportionation reaction would be possible. It is known that certain heterocyclic systems readily undergo disproportionation, with three molecules giving one hexahydro and two aromatic levels (13). The relative retention time for the aromatic cannabinoid level (VII) is well documented, but no relative retention time is available for hexahydrocannabinol (XIII) using VIII as the internal standard. Thus, XIII was prepared by catalytic hydrogenation of V as described by Archer *et al.* (14). GLC analysis of the reaction mixture produced one peak having a relative retention time of 0.37. This is close to cannabigerol monomethyl ether (III), which has a relative retention time of 0.38. Although the concentration of III increased slightly on storage (Fig. 6), it was impossible to determine if this increase was due exclusively to the formation of hexahydrocannabinol since the amount of plant material allocated for this study was limited. This will be the subject of a future article.

Since, to the authors' knowledge, no GLC data are available in the literature on the trimethylsilyl ether of XIII, this derivative was produced. Silylation of XIII followed by GLC analysis yielded relative retention times of 0.17 and 0.22, respectively. Two peaks were expected since there existed the possibility of a mixture of C-9 equatorial (XIV) and axial (XV) methyl isomers (Fig. 7). (See Fig. 7 for silylated plant material.)

Archer *et al.* (14) reported an axial-to-equatorial ratio of 3:1 as determined by PMR analysis. In these laboratories, the ratio was 3:2 as determined by GLC analysis of the trimethylsilyl ethers. Therefore, since the C-9 methyl axial isomer was the major product, it was assigned the relative retention time of 0.17; the equatorial isomer was assigned the relative retention time of 0.22.

Decomposition of V in *C. sativa* L. produces many products not yet identified; some are probably polymerization products. Moreover, biological data obtained on *C. sativa* L. will remain contradictory due to variations in chemical constituents. Although the cannabinol content of cannabis does, indeed, increase with storage, the suggestion that V plus VII would approximate the V content, irrespective of degradative changes (5), must be revised.

The cannabidiol content of all stored material remained relatively constant with no detectable decomposition. Additionally, a sample of *C. sativa* L. plant material of 1930 vintage[10] was analyzed in 1970 and 1972. The content of II (0.28%) was constant over this period, whereas V and VII changed from 0.05 and 0.65 to 0.04 and 0.66, respectively.

Kinetics and Mechanisms of Monolayer Interactions II: Effect of Chain Length of Alkyl Ionic Surfactants on Their Interaction with Dipalmitoyl Glycerol, Dipalmitoyl Phosphatidylethanolamine, and Dipalmitoyl Lecithin

FEDERICO A. VILALLONGA▲ and EDWARD R. GARRETT

Abstract □ The energies of activation of the interaction of alkyl trimethylammonium surfactants with dipalmitoyl glycerol, dipalmitoyl phosphatidylethanolamine, and dipalmitoyl lecithin monolayers spread at the air–water interface were estimated from the increase of the surface pressure with the concentration of the injected surfactant. The energies of activation are a linear function of the chain length of the injected surfactant for the six-, eight-, 12-, and 16-carbon chains studied. The ionic groups of the polar hydrophilic moiety of dipalmitoyl lecithin were not equivalent in the perturbation that an attached surfactant ion produces in the surface pressure of the monolayer. The energies of activation per methylene group of the hydrocarbon chain and per polar ionic head of the injected surfactant were calculated and were compared with those that correspond to the energies of adsorption of these groups at hydrocarbon–water and air–water interfaces.

Keyphrases □ Alkyl sulfates and alkyl trimethylammonium ions—interactions with dipalmitoyl glycerol, dipalmitoyl phosphatidylethanolamine, and dipalmitoyl lecithin monolayers, kinetics, mechanisms □ Monolayers, dipalmitoyl glycerol, dipalmitoyl phosphatidylethanolamine, and dipalmitoyl glycerol—interactions with alkyl sulfate and alkyl trimethylammonium ions, kinetics, mechanisms □ Phospholipid monolayers—interactions with long-chain surfactants, kinetics, mechanisms □ Surfactants, long chain—interaction with phospholipid monolayers, kinetics, mechanisms □ Chain length effect—interaction of alkyl surfactants with phospholipid monolayers

The energies of interaction of cetyl sulfate and cetrimonium ions with dipalmitoyl glycerol and dipalmitoyl lecithin monolayers spread at the air–water interface were estimated recently (1) from the variation of the equilibrium surface pressure with varying concentrations of subphase-injected surfactants on the premise that the entropy factor calculated on the basis of collision theory was constant for all species.

The energies of adsorption at the oil–water and air–water interfaces of homologous series of alkyl surfactants are provided in the literature (2–11). These data permit the estimation of the contributions of the hydrocarbon moiety per methylene group and that of the polar head to the total energy of adsorption at a "clean" interface. A clean interface is defined here as a liquid–liquid or air–liquid interface without any spread monolayer.

These studies were designed to determine the dependence of the maximum obtainable changes in surface pressure and energies of interaction of monolayers of dipalmitoyl glycerol, dipalmitoyl phosphatidylethanolamine, and dipalmitoyl lecithin with subphase-injected surfactants on the numbers of methylene groups and on the nature of the charged polar head in the injected surfactant.

	$C_{n(2n+1)}\cdot N^+(CH_3)_3$	−4.7	−5.9	−10.6	−12.0	−0.78	—	−0.1	78

[a] Calculated on the premise that 1 kcal. mole^{-1} is the energy of interaction per pair of methylene groups in close contact (4.2 Å).

described previously (1). Dipalmitoyl phosphatidylethanolamine[1] was chromatographically homogeneous by TLC (12). Sodium lauryl sulfate[2], sodium octyl sulfate[1], sodium hexyl sulfate[1], and dodecyltrimethylammonium bromide[3] gave no minima in the curves of surface tension against the logarithm of the concentration. The octyltrimethylammonium and hexyltrimethylammonium bromides were prepared[4] by the reaction of *n*-dimethyloctylamine with methyl bromide and *n*-hexyl bromide with trimethylamine and were chromatographically homogeneous by TLC (13). The hexanes[2,5] used to prepare the lipidic spreading solutions and the distilled water used as subphase fulfilled the requirements described previously (1).

Instruments and Methods—Surface tension was measured with a Wilhelmi platinum plate attached to an electrobalance[6]. Surface potential was measured with an americium-241 air electrode and an electrometer[7]. The output of the electrobalance and the electrometer were fed into a dual-pen recorder[8].

The experimental assembly and the methods for the measurement of the increase of the surface pressure after the injection of the alkyl surfactant ion were described previously (1). The concentration of the surfactant solution to be injected was kept below the critical micelle concentration (CMC) in all cases. The average values of three different experiments for each of three different final concentrations of injected surfactant ions were used for the estimation of the slope of the plot of the reciprocal of the change of the surface pressure at equilibrium ($1/\Delta\pi_{eq}$) against the reciprocal of the number of surfactant ions per cubic centimeter ($1/n$) (1). The reproducibility of the changes of the surface pressure was within ±0.5 dyne cm.$^{-1}$. All experiments were performed at an initial surface pressure of the lipidic monolayer of 5 dynes cm.$^{-1}$ (±0.1 dyne cm.$^{-1}$) and at 22° (±1°).

RESULTS

The values of the maximum change of the surface pressure ($\Delta\pi_m$) were calculated from the intercept, $1/\Delta\pi_m$, of the plot of the reciprocal of the surface pressure change at equilibrium ($1/\Delta\pi_{eq}$) against the reciprocal of the number of subphase surfactant ions per cubic centimeter ($1/n$) on the assumption of the continuity of the straight-line relationship for surfactant concentrations above those used in the experiments in accordance with the equation: $1/\Delta\pi_{eq} = 1/\Delta\pi_m + B/\Delta_m \cdot 1/n$. They are plotted in Fig. 1 for dipalmitoyl glycerol, dipalmitoyl phosphatidylethanolamine, and dipalmitoyl lecithin monolayers against the chain length of the injected alkyl sulfate anions and alkyl trimethylammonium cations.

The maximum change of the surface pressure ($\Delta\pi_m$) is not a linear function of the chain length of the injected surfactant ion. The plots present distinct *maxima* in $\Delta\pi_m$ at the eight-carbon atom chain for the observed cases of the interaction of the positively charged alkyl trimethylammonium cations with the monolayers. The plots present *minima* at this same chain length for the interaction of the negatively charged alkyl sulfates with dipalmitoyl glycerol and dipalmitoyl lecithin monolayers. The minimum may be at 12-carbon atoms with dipalmitoyl phosphatidylethanolamine monolayers.

The energies of activation (ψ) were calculated on the premise of a collision model and a constant entropy factor (1) for the interace tion of the subphase-injected surfactant ion with the moleculer that form the monolayer at the air-water interface. They ahe plotted in Fig. 2*a* for dipalmitoyl glycerol monolayers against ts-chain length of the injected alkyl sulfate anions and alkyl trimethylammonium cations. The calculated energy of activation for a given chain length of the injected surfactant was independent of the

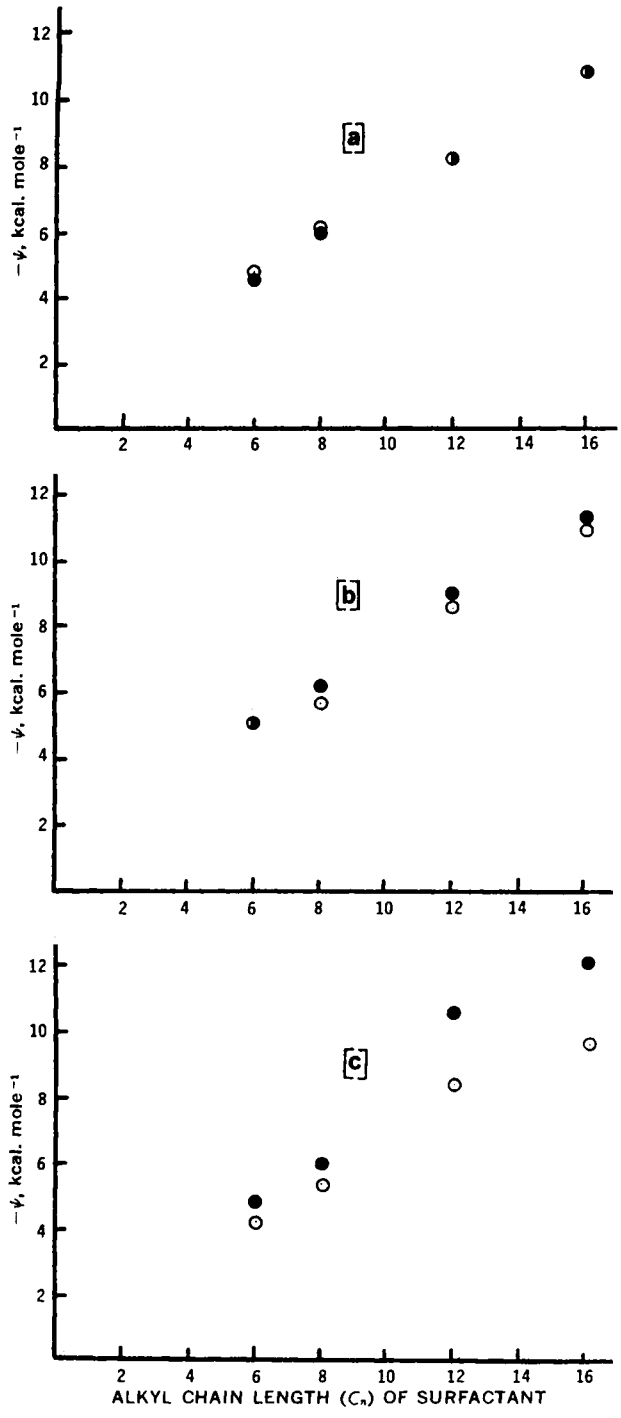

Figure 2—*Effect of chain length of alkyl sulfate* (○) *and alkyl trimethylammonium* (●) *surfactants on the energy of activation of their interactions with: (a) dipalmitoyl glycerol, (b) dipalmitoyl phosphatidylethanolamine, and (c) dipalmitoyl lecithin monolayers.*

nature of their polar heads within the limits of experimental error (±0.1 kcal. mole^{-1}) and was a linear function of the chain length between the studied six- and 16-carbon atoms.

The energies of activation (ψ) for the interaction of dipalmitoyl phosphatidylethanolamine monolayers were plotted against the chain lengths of the same series of alkyl sulfate and alkyl trimethylammonium ions in Fig. 2*b*, and the results were similar.

The energies of activation (ψ) for the interaction of dipalmitoyl lecithin monolayers with both series of surfactant ions are given in Fig. 2*c*. In these cases, there was a difference between the energy of activation of the interaction with the surfactant with the positively charged polar head compared with the interaction with the surfactant with the negatively charged head at a given chain length. This was more pronounced at the higher chain lengths. The same general increase in the energy of activation with the number of carbon atoms in the alkyl chain of the injected surfactant ion was observed as with the two other monolayers.

The energy of activation (Table I) per methylene group of the surfactant hydrocarbon chain was calculated from the regression coefficient of the best straight lines through the experimental points of Fig. 2. The energies of activation for the sulfate or trimethylammonium groups were calculated from the intercept on the assumption that the extrapolation of the straight line to $C_n = 0$ (C_n represents alkyl chain length of surfactant) gives a numerical value related to the energy of activation of the polar head group of the surfactant ion. The values of the energy of activation per methylene group were in the range of from −0.56 to −0.77 kcal. mole^{-1}, with an overall average value of −0.63 kcal. mole^{-1}. The values of the energy of activation per polar head of the injected surfactant ion were in the range of from −0.10 to −1.4 kcal. mole^{-1}.

DISCUSSION

Interfacial Phase—It has been suggested (1, 14) that the molecules that form these lipidic monolayers at a surface pressure of 5 dynes cm.$^{-1}$ are oriented with the long hydrocarbon chains perpendicular to the plane of the air-water interface. The total length of the dipalmitoyl glycerol molecule is roughly 26 Å measured from space-filling models. The length of dipalmitoyl phosphatidylethanolamine and dipalmitoyl lecithin molecules, assuming a configuration of the phosphatidylethanolamine polar group parallel to the interface (see Fig. 9, *Reference 1*), is roughly 30 Å. If the molecules are completely submerged in the water phase, the volume of the interfacial phase is determined by the length of the molecule times the total surface area of the air-water interface, which was 42.54 cm.^{2} in all of the experiments. The concentrations (in moles per liter) in this thin crust of water were calculated (Table II) for each lipid on this basis, since the total number of molecules necessary to form the monolayer was known.

The percentage of water in this interfacial phase (Table II) can be estimated from the total volume of the interfacial phase and from the volume occupied by the lipidic molecules calculated from the length of the molecule, the cross-sectional area of two hydrocarbon chains, and the total number of lipidic molecules. According to the values of Table II, the interfacial phase can be considered to be predominantly hydrocarbon.

Surfactant-Ion Hydrocarbon Chain—Van der Waals' forces between methylene groups of neighboring hydrocarbon chains can be calculated from Salem's equation (15):

$$W_{disp} = A\left(\frac{9.42}{8 \times l}\right)\left(\frac{n}{d^6}\right) \qquad \text{(Eq. 1)}$$

where W_{disp} is the energy of interaction in kcal. mole^{-1} for each pair of methylene groups of neighboring chains, A is a constant (−1.340 kcal. mole^{-1}), l is the effective distance between carbon atoms along a chain (1.253 Å), n is the number of methylene pairs, and d is the distance between the central axes of the hydrocarbon chains. The equation is valid for $d \geq 4.0$ Å. The energy of interaction becomes appreciable when d is less than 7 Å and increases exponentially with shorter distances as the hydrocarbon chains approach each other.

The minimum possible distance between the central axes of two neighboring hydrocarbon chains is 4.2 Å. From Eq. 1, the energy of interaction per pair of methylene groups will be 1.0 kcal. mole^{-1} for that distance.

The contribution to the total energy of activation that corresponds to the hydrocarbon chain for the interaction of the surfactant ions with the lipidic monolayers can be estimated by subtracting the contribution that corresponds to the polar ionic head from the total energy of activation (Table I). On the assumption that each methylene group of the surfactant ion that interacts with a methylene group of the hydrocarbon chains of the molecules that form the monolayer is in close contact (*i.e.*, at 4.2 Å with 1.0 kcal. mole^{-1} per pair of methylene groups), these values would numerically approximate the number of methylene groups of the surfactant ion that interacts with the hydrophobic moiety of the monolayer.

It was suggested (1) that the first step of the interaction process was the attachment of the polar charged head of the injected surfactant ion to the polar or the ionic attraction centers of the hydro-

philic moiety of the molecules that form the monolayer. The subsequent increase of the surface pressure could then be rationalized as reflecting the subsequent interactions of the hydrocarbon chains with the hydrophobic moiety.

The hydrophilic region of the dipalmitoyl glycerol molecule does not have an ionic charge. However, the two fatty acid ester linkages and an alcoholic group give a high electronic density to this region. It can be assumed that the positively charged or negatively charged surfactant-ion polar head tends to be attached by ion-dipole interactions to this region. It is noted that the percentage of methylene groups in close contact with the hydrophobic region of the monolayer apparently is independent of the charge of the surfactant ion (64 and 58%) (Table I).

The hydrophilic zwitterionic group of dipalmitoyl phosphatidylethanolamine is fully charged at the experimental conditions (pH 6.0–6.5). Its coplanarity with the plane of the interface (18–21) produces an attractive potential between vicinal molecules which keeps the monolayer closely packed (Table II). The strong P^-–N^+ electrostatic interaction jointly with the attractive potential between neighboring molecules should produce a rigid structuring of the monolayer in this case where any net charge is essentially negligible. Thus, it is understood that the calculated percentage of methylene groups in close contact with the hydrophobic region of this monolayer is similar to that of the nonionic dipalmitoyl glycerol (Table II).

The hydrophilic zwitterionic group of dipalmitoyl lecithin is similarly charged in the experimental conditions and should show a similar rigid structure. [The studies on the conformation of this group have resulted in much disagreement. The zwitterion has been considered oriented with its axis parallel to the plane of the interface (1, 14, 16–19), perpendicular (19, 20), or at some unlocalized intermediate position (23). On the basis of the apparent dipole moment measured (1, 14) on monolayers spread at the air–water interface, it will be assumed in the following discussion that the zwitterionic group of dipalmitoyl lecithin is oriented with its axis *parallel* to the plane of the interface.]

However, it can be argued that the dipalmitoyl lecithin monolayer would be less closely packed at the air–water interface than that of dipalmitoyl phosphatidylethanolamine (Table II) because of the shielding effect of the positively charged amino group by the three methyl groups that decreases the attractive potential between neighboring molecules or because of the lack of hydrogens that would promote hydrogen bonding. Accordingly, a less rigid structural organization of this monolayer can be expected as compared with the dipalmitoyl phosphatidylethanolamine and has been shown experimentally as indicated by the comparison of the Å^2 molecule^{-1} in Table II.

The calculated percentage of methylene groups of the surfactant hydrocarbon chain supposedly in close contact with the hydrophobic region of the dipalmitoyl lecithin monolayer differs markedly with the nature of the charge of the surfactant polar head. This contrasts with the other two monolayers. It can be assumed that the first step of the interaction involves the attachment of the negatively charged polar head of the surfactant to the positively charged trimethylammonium group of the P–N ionic dipole. Such an attachment could produce a change in the dipole orientation toward the perpendicular position that would displace the trimethylammonium group of the phosphatidylcholine moiety 5 Å farther below the hydrophobic region of the dipalmitoyl lecithin molecules.

The phosphate group of the P–N dipole constitutes the hinge for this change or orientation (Fig. 9 of *Reference 1*). Consequently the attachment of a positively charged polar head to the hinge should not readily produce rotation about the hinge. However, the attachment of a negatively charged polar head to the extreme end of the lever could readily cause rotation about the hinge to 5 Å below the hydrophobic portion of the dipalmitoyl lecithin molecule. The greater rigidity of the dipalmitoyl phosphatidylethanolamine molecule and its greater affinity for its neighboring molecules in the monolayer, as already stated, could rationalize the greater resistance to such a change in the steric position of its P–N axis. The fact that space-filling models show that a 5-Å lowering of the trimethylammonium group subtracts two to three pairs of methylene groups of an attached surfactant hydrocarbon chain from the hydrophobic region of the dipalmitoyl lecithin molecule is consistent with this explanation.

These phenomena strongly suggest that entropic factors associated with the configuration of the molecules that form the monolayer *do* contribute to the energies of interaction. Thus, the simplified assumption of a common entropy factor for such interactions based on collision theory on which the calculations of energies of activation were based (1) is most probably an oversimplification of a complex process.

Surfactant-Ion Polar Head—The contribution of the sulfate group to the total energy of adsorption of an alkyl sulfate surfactant has been estimated to be −1.8 kcal. mole^{-1} at a "clean" hydrocarbon–surfactant solution interface (8) and 2.4 kcal. mole^{-1} at a "clean" air–surfactant solution interface (11). The positive value for the latter interface has been attributed to the strongly hydrophilic nature of the sulfate group (11).

The values estimated for the contribution of the sulfate group to the total energy of activation of the interaction of alkyl sulfates with the three lipidic monolayers studied in this work are negative in all cases (Table I), which seems to indicate that the interaction of this group takes place at a hydrocarbon environment.

The contribution of the trimethylammonium group to the total energy of adsorption of an alkyl trimethylammonium surfactant has been estimated to be −0.95 kcal. mole^{-1} at a clean hydrocarbon–surfactant solution interface (8). From literature data (9, 10), a value of 2.9 kcal. mole^{-1} for the adsorption at a clean air–surfactant solution interface can be calculated. Again the negative estimated values of the contribution of the trimethylammonium group to the total energy of activation of the interaction of alkyl trimethylammonium surfactants suggest the interaction of this group with a hydrocarbon environment.

The adsorption of the polar heads of the surfactant ions to a hydrocarbon–water interface would be in accord with the postulated hydrocarbon nature of the interfacial phase (Table II). However, there is a discrepancy in regard to the hydrocarbon chains of the surfactant ion. The free energy of adsorption per methylene group of a hydrocarbon chain that adsorbs at a clean hydrocarbon–surfactant solution interface has been estimated to be between −0.80 and −0.82 kcal. mole^{-1} (6–8). At a clean air–surfactant solution interface, the estimated value is between −0.600 and −0.625 kcal. mole^{-1} (2, 8, 9, 11). With the exception of the value that corresponds to the alkyl trimethylammonium–dipalmitoyl lecithin

interaction (−0.77), the energy of activation per methylene group in all cases (Table I) has been found to be much closer to that which corresponds to the adsorption of the methylene group to an air-water interface.

Absorption of Chlormadinone Acetate and Norethindrone from *In Situ* Rat Gut

KATHLEEN S. PELZMANN

Abstract □ The GI absorption of chlormadinone acetate and norethindrone was studied in a rat *in situ* preparation. The data evaluated with respect to the absorption half-life in the ligated stomach and intestine suggest that chlormadinone acetate is absorbed slightly more rapidly than norethindrone and that both steroids are absorbed to a greater extent in the intestine. The effects of bile duct cannulation, ethanol, and exogenous bile salts were investigated. The presence of bile significantly altered the absorption and metabolism of chlormadinone acetate. Ethanol, which was used as the drug vehicle, did not improve or depress the absorption of either steroid. Tissue accumulation experiments indicated that the jejunum of the intestine and the pyloric and cardiac area of the stomach accumulate the steroids to a greater extent than other GI tissues. Both compounds exhibited biexponential absorption with significant membrane accumulation.

Keyphrases □ Chlormadinone acetate and norethindrone—absorption from *in situ* rat gut □ Norethindrone and chlormadinone acetate—absorption from *in situ* rat gut □ Absorption, GI—norethindrone and chlormadinone acetate, *in situ* rat gut

Although the oral administration of steroids is common today, relatively little is known about their GI absorption characteristics. Most published studies measure absorption indirectly by plasma or urine levels of a steroid and its metabolites. The present investigations were undertaken to study the GI absorption of two progestins, chlormadinone acetate and norethindrone, and to develop an animal model for these studies.

Some investigators have used the *in vitro* rat intestine preparation (1, 2) or the everted intestinal sac method (3, 4). The absorption rates measured in these experiments are not influenced by blood and blood pressures, lymph, nerves, and GI secretions. Levine *et al.* (5) reported the loss of structural integrity and cellular death occurring in the intestinal mucosa within 10–15 min. after the preparation of an everted intestine. Consequently, the only observation that can be made is the movement of drug across a semiviable membrane.

Searching for a less traumatic intestinal preparation, Schanker *et al.* (6) used *in situ* perfusion techniques consisting of a single pass or a recycling of the drug solution through the cannulated intestine. Doluisio *et al.* (7) described an *in situ* technique with duodenal and ileal ends of the intestine cannulated with L-shaped cannulas. Stopcocks and syringes were attached to both cannulas for instilling and sampling the drug solution. Although Doluisio *et al.* reported very reproducible results, this preparation was found cumbersome by the present author.

Only a few experiments involving steroid intestinal absorption in animals have been published. Symchowicz

interaction (−0.77), the energy of activation per methylene group in all cases (Table I) has been found to be much closer to that which corresponds to the adsorption of the methylene group to an air-water interface.

Doluisio *et al.* (7) described an *in situ* technique with duodenal and ileal ends of the intestine cannulated with L-shaped cannulas. Stopcocks and syringes were attached to both cannulas for instilling and sampling the drug solution. Although Doluisio *et al.* reported very reproducible results, this preparation was found cumbersome by the present author.

Only a few experiments involving steroid intestinal absorption in animals have been published. Symchowicz

et al. (8), using in-dwelling intestinal cannulas, studied the absorption of betamethasone in various sections of the dog gut. Meli *et al.* (9) studied the possible active transport of estrogens by the rat small intestine, and Collins and Forist (10) inferred the absorption properties of hydrocortisone in the dog from plasma levels. The most comprehensive study was reported by Schedl and Clifton (11) on the absorption of 22 androgens, estrogens, and corticosteroids. Their data were obtained with the rat gut intestinal perfusion technique; the percentage of absorbed steroid was independent of concentration over a wide range. It was concluded that steroids seem to be absorbed by passive diffusion.

In this paper, the absorption characteristics of chlormadinone acetate and norethindrone from the GI tract are presented in detail. The animal preparation described is a simple and an improved *in situ* method. Intestinal and gastric absorption rates can be described by sampling the lumen contents as well as the bile and plasma with a minimum of apparatus and trauma to the animal.

EXPERIMENTAL

Animal Preparation—Sprague–Dawley female rats, weighing 200–250 g., were fasted 16–18 hr. with water *ad libitum* prior to surgery. They were housed in false-bottom cages to prevent coprophagy. The animals were anesthetized with pentobarbital, 50 mg./kg. i.p., and the viscera were exposed by midline abdominal incision. To prevent enterohepatic circulation, the bile duct was cannulated with 11 cm. of polyethylene tubing[1]. The portal vein was cannulated to permit blood sampling (12), and the pylorus was closed with clamps or sutures. In some experiments, the jejuno-ileal junction was ligated. In experiments in which the jejunum was not restricted, 10 ml. of the drug solution was instilled into the duodenum with a 23-gauge needle and a disposable syringe at the rate of 5 ml./min. In experiments that were restricted to certain ligated sections, the amount of solution varied, depending on the volume required to fill, but not distend, the intestinal section, usually 3–5 ml. The gut was not rinsed previous to the instillation. To sample the intestinal contents, a 27-gauge needle was inserted through the intestinal wall along the ligated section, and at each time point a 0.1-ml. sample was withdrawn into a tuberculin syringe. Intralumenal bleeding was not a problem, because care was taken not to sample in the vascular lateral regions of the intestine. The bile samples, approximately 0.1 ml., were an accumulation of flow over 5-min. intervals. Blood samples of 0.3 ml. were taken from the portal vein at specific times, and 0.1 ml. of plasma was used for the drug assay.

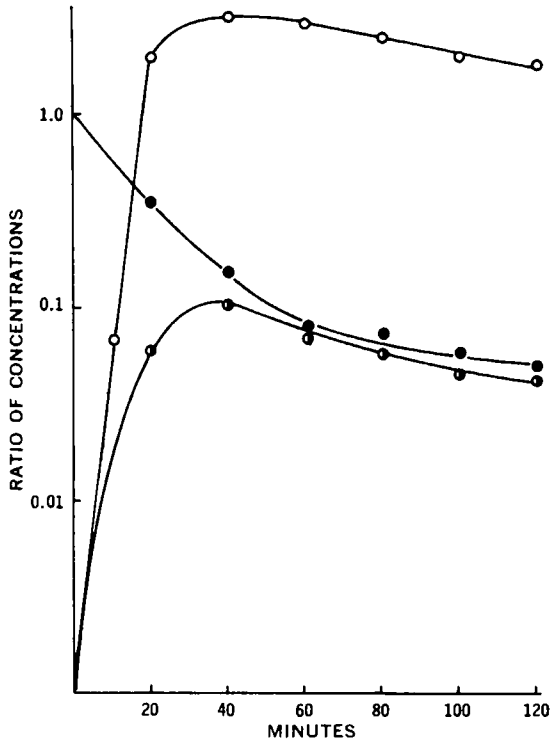

Figure 1—*Time course of norethindrone absorption in the intestine* (●) *and its appearance in the plasma* (◑) *and the bile* (○). *Ratio of concentrations is calculated in terms of* (*drug at* t_n/*0.1 ml. sample*)/(*drug at* t_0/*0.1 ml. sample*). *Norethindrone is highly concentrated by the liver and, consequently, the rise above 1.0 is not unreasonable.*

For gastric absorption studies, the stomach was exposed. The muscular area was made ready for fistulation by purse string sutures in the least vascular pyloric area. An incision was made through the muscle, and a polyethylene cannula was inserted and secured by purse string sutures. The pylorus was clamped securely, the animal's head was raised slightly, and 2.5 ml. of the drug solution was instilled through the cannula into the stomach. Samples of 0.1 ml. were taken through the cannula at regular intervals. Throughout the experiments, the viscera were kept warm with a high-intensity lamp and moist with gauze and saline.

Drug Solutions—The compounds studied were the tritiated progestogens, norethindrone (I) and chlormadinone acetate (II). Tritiated steroid was coprecipitated with unlabeled steroid in cold acetone and water to make a specific activity of 4 mc./mmole. The dose per rat was 0.4 mg./kg., approximately 30 times the normal human dose. Because of the low aqueous solubility of these steroids, the 100-mcg. dose was dissolved in 1 ml. absolute ethanol. Just prior to the experiment, the alcohol solution was diluted with 9 ml. of Sørensen's buffer, pH 6.3, or 9 ml. of Clark and Lub's potassium chloride–hydrochloric acid buffer, pH 1.6, and made isotonic.

Water diffusion out of the intestine has a considerable effect after 45–60 min. Phenol red was used as a standard to correct for changes in steroid concentration resulting from water absorption (13).

The intestinal drug solution volume was 10 ml., although solutions of 8, 5, and 3 ml. were also used depending on the length of the intestinal section studied. The final ethanol concentration was 10%. In gastric studies, 2.5-ml. solutions of varying ethanol concentration were used. A double-tracer experiment was used to follow the absorption of ^{14}C-ethanol and ^{3}H-steroid simultaneously.

All samples of lumen contents, bile, and plasma were added to Bray's solution (14) and counted on a scintillation counter[2]. Several bile samples were pooled and extracted with ether. The drug remaining in the water phase was considered to be metabolite. No further determination of the metabolites was made. All data reported are total radioactivity. To account for quenching, a "spike" of ^{3}H-toluene was added to each vial and the vial was recounted. The

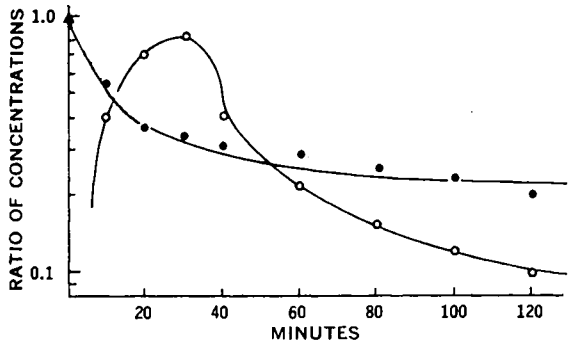

Figure 2—*Time course of norethindrone in the stomach* (●) *and its appearance in the bile* (○).

disintegrations per minute and amount of drug recovered from each sample were calculated and used to determine the percent dose remaining in the gut or entering the bile.

Site of Accumulation—Experiments were done to determine if steroids are absorbed uniformly in all sections of the GI tract. Drug solutions (25 mcg./2.5 ml. or 100 mcg./5 ml.) were instilled into the stomach or the ligated duodenum, jejunum, or ileum. The solutions remained in the stomach 30 min. before the rat was sacrificed. The stomach was removed, washed, and divided into four parts: cardiac, pyloric, and two fundus portions. In the intestinal experiments, the animals were sacrificed 1 hr. after the drug solution was instilled into the ligated section. The intestine was excised, washed with saline, and cleaned of mesentery and fat. The intestinal sections were divided into 1-cm. pieces.

All tissue sections were dried overnight at 60° and combusted using a tissue oxidizer[3]. The samples were assayed for tritium by scintillation counting.

Bile Effect—The intestinal absorption of each steroid was studied with and without bile duct cannulation. To investigate the effects that bile might have in drug absorption, 1 ml. of the exogenous bile salt, sodium dehydrocholate (100 m*M*), was used to stimulate bile flow in uncannulated animals. The bile salt was administered by placing the solution in the exposed peritoneal cavity beneath the portal vein immediately prior to injecting the drug solution. Drug was then instilled into the duodenum; bile and lumen samples were taken as previously described.

To extend the bile study, dual bile duct cannulation experiments were devised. Two rats were prepared as described in the previous section and both bile ducts were cannulated. Rat 1 supplied fresh bile to Rat 2 by placing the first cannula into the duodenum of Rat 2. In the first experiment, drug solutions were instilled into the duodenum of Rat 2 with bile samples collected from Rat 2. In the second experiment, drug solutions were placed in the duodenum of Rat 1 with a few bile samples from Rat 1 and continuous bile sampling from Rat 2.

Binding Affinities of Steroids to Gastric Juices—Human gastric juice and gastric mucin[4] were used to determine the possible effect of steroid binding on absorption characteristics. Human gastric juice (pH 1.6) was obtained from hospital patients undergoing surgery for other than GI ailments. Simulated gastric fluid was made from 2.6 g./l. mucin, 2.0 g./l. NaCl, and 80 ml./l. concentrated HCl. The final pH was 1.3. By using a microequilibrium dialysis apparatus, 100 μl. of drug solution in Sørensen's buffer was placed in one well-half and 100 μl. of binding substance was placed in the other, separated by cellulose dialysis membrane. The drug solutions ranged from 10^{-10} to 10^{-6} *M*.

The dialysis apparatus was shaken for 24 hr. at 37°. Samples of 50 μl. were taken from each well-half with a syringe[5]. The samples were placed in Bray's solution for scintillation counting. The binding constants and bound-to-free ratios were determined by a computer program written from Scatchard's original binding calculations (15). Human serum albumin was used as a standard.

Partition Coefficient—The partition coefficients of ^{3}H-chlormadinone acetate and ^{3}H-norethindrone were determined in a two-phase system of 10% ethanol–Sørensen's buffer at pH 6.3 and isopropyl myristate. The phases were first equilibrated at 37° to ensure saturation of each phase with the other. The drug solution (0.1 μc. in 1 μl. ethanol) was added to the ethanol–buffer solution. The phases were shaken 5 min. and stored overnight at 37°. Duplicate 1-ml. samples were taken from each phase and assayed by scintillation counting. Four separate determinations were made.

logical conditions. The absorption curves showed that the absorption of these progestins was not described by simple first-order kinetics but was biexponential in all sections of the gut. This absorption was not only dependent on the concentration of drug in any one tissue compartment but was also regulated by the membrane structure, apical and basal; by the mesentery blood flow, pressure, and volume; and by tonicity of the instilled solution.

Chlormadinone acetate and norethindrone were readily absorbed from both the intestine and the stomach, as measured by the appearance in the plasma and bile and by the disappearance from lumen and gastric contents. Both steroids showed biexponential disappearance from the gut.

As shown in Fig. 1, when 0.1 mg. norethindrone in 10% ethanol-buffer solution was instilled into the intestinal lumen, the time to reach the apparent second phase of absorption was approximately 20–25 min. The maximum concentration of drug in the bile was also found within this time range. The time required for the original drug concentration to decrease to half in the lumen ($t_{1/2}L$) was less than 10 min.; 8–10 min. was required for one-half the original drug concentration to appear in the bile ($t_{1/2}B$). These data were corroborated by experiments conducted in another laboratory using the Doluisio technique[6]. The $t_{1/2}L$ was 10 min. in those intestinal absorption experiments.

In the stomach, the absorption of norethindrone was not as rapid or as complete as from the intestine (Fig. 2); $t_{1/2}L$ ranged from 10 to 13 min., and $t_{1/2}B$ was about 15 min. The time to reach the apparent second phase of lumenal absorption was 20–30 min., and the peak drug concentration in the bile appeared at 30–40 min.

Chlormadinone acetate was absorbed slightly more rapidly than norethindrone (Figs. 3 and 4). In the intestine, the $t_{1/2}L$ was less than 5 min. and the time to reach the apparent second phase was 10–15 min. The bile concentration peaked at 15–20 min., with one-half the original drug concentration appearing in the bile from 9 to 12 min. Chlormadinone acetate absorption from the stomach was considerably less than from the intestine. The $t_{1/2}L$ ranged from 6 to 16 min. The drug concentration in the bile reached a maximum value at 50–60 min., but the biliary concentration did not reach one-half the original lumen concentration. This low response of the liver to the clearance of chlormadinone acetate from the blood is quite remarkable when compared to the rapid $t_{1/2}B$ reported for norethindrone. Table I is a summary of the absorption data.

From the lumenal and plasma data, rate constants were determined. The feathering method was used to determine the rate constants from graphical estimations as shown in Fig. 5.

There is apparently no unique site of absorption for these steroids

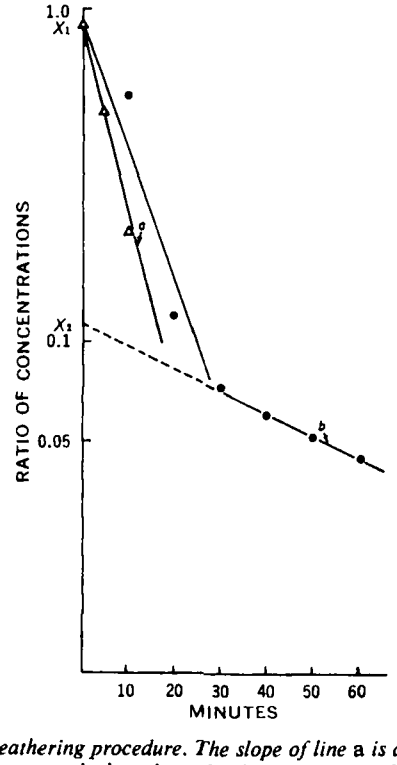

Figure 5—*Feathering procedure. The slope of line* a *is determined by extending the second phase* b *and subtracting second phase values from the first phase values.*

in the stomach or in the intestine, but there is a possibility that the stomach is more selective. Compared to the fundus sections, the pyloric and cardiac regions of the stomach exhibited considerable affinity to norethindrone and chlormadinone acetate. The large amount of drug absorbed by the pyloric region is easily understood because of the ample supply of blood and the binding properties of both drugs to the gastric fluids produced there. This does not explain the high accumulation observed in the less vascular area of the cardiac region. In the intestine, the duodenum showed greater affinity for the steroids than did the jejunum, and the ileum absorbed drugs to the least extent. Along with the tissue combustion data and the biexponential disappearance of the steroids from the lumen, these results led to the conclusion that accumulation or storage of the drugs in the intestinal or gastric membranes was occurring. This can account for the rapid distribution of drugs from the lumen solution into the membrane, with a slower appearance of the drug into the plasma (Table II).

The binding studies (Table III) were designed to show any correlation between absorption rates and affinities of steroids to gastric juice and gastric mucin. It is obvious from these data that chlormadinone acetate bound much more to the gastric mucin and natural gastric juice than did norethindrone. Binding of norethindrone appears to occur mainly with gastric mucin, whereas the binding of chlormadinone acetate is only partially accounted for by mucin. Chlormadinone acetate possibly binds to other components of

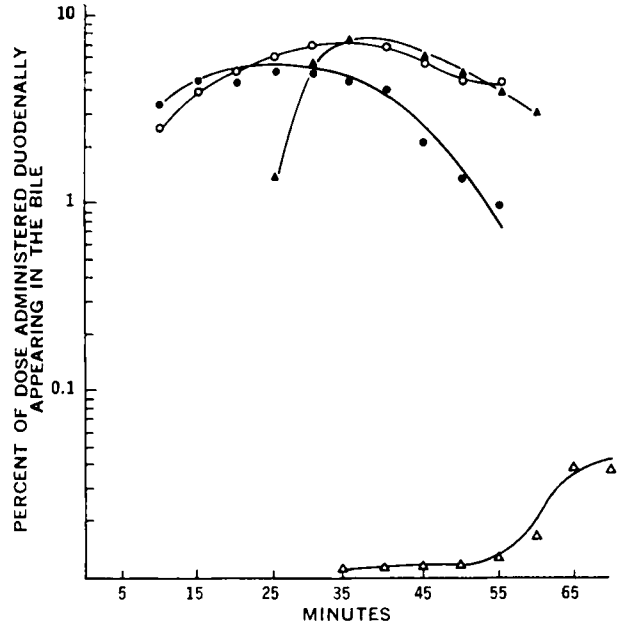

Figure 6—*Metabolite appearance in the bile. No change was seen in metabolite output when norethindrone was instilled into the duodenum with and without bile (●, dual cannulation; ▲, bile cannulation). When chlormadinone acetate was instilled in the presence of bile, the drug was metabolized to a great extent (○, dual cannulation; △, bile cannulation).*

Table III—*In Vitro* Binding Properties of Chlormadinone Acetate and Norethindrone

		0.42	29.4

natural gastric juice such as chondroitin sulfate or other low molecular weight mucoproteins which serve as the "intrinsic factor."

Extending the *in vitro* comparison of chlormadinone acetate and norethindrone in GI absorption, the partition coefficients of the two steroids were found to be 65 for chlormadinone acetate and 48 for norethindrone. The partition coefficient data support results previously given in this paper which imply that chlormadinone acetate is absorbed to a greater extent and at a faster rate than norethindrone in gastric preparations. The *in vivo* absorption rates did not indicate such a large difference as might be expected by the differences in the partition coefficients and binding affinities. Consequently, the estimation of *in vivo* absorption rates from the partition coefficient and other *in vitro* methods should be made with caution.

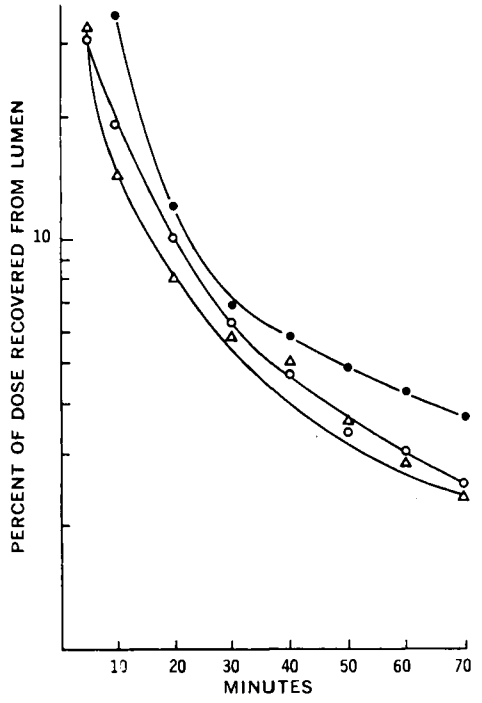

Figure 7—*Intestinal absorption of norethindrone under various conditions. Key: ○, no bile cannulation or stimulation; ●, animals with bile duct cannulation; and △, animals with exogenous sodium dehydrocholate stimulation. The intestinal absorption is affected only slightly.*

It is recognized that bile salts play an important role in the intestinal absorption of lipids and other substances and that they themselves are absorbed by active transport in the ileum. Because of the bile cannulation in the preparations, absorption was unaided by bile salts in most experiments. However, several experiments were devised to ascertain the effects of bile on chlormadinone acetate and norethindrone absorption. The bile appeared to have a significant effect on the absorption and metabolism of chlormadinone acetate, but it did not appear to influence norethindrone. As seen in Fig. 6, bile greatly enhanced the output of chlormadinone acetate or its metabolite from the liver. In cannulated animals, less than 1% radioactivity was recovered in the bile as compared to 40% recovered after the intestine received fresh bile from the donor rat. Rates of lumenal absorption were not altered significantly by the presence or absence of bile. Bile flow stimulation through the use of exogenous sodium dehydrocholate did have an effect on the lumenal absorption rates of chlormadinone acetate and norethindrone, but the enhanced absorption was not significant (Fig. 7).

These results are in contrast with data obtained previously (16) using sulfadiazine, which showed the exogenous stimulation greatly increased the bile acidity and consequently the solubility of sulfadiazine. This result possibly increased the absorption of the drug. Kakemi *et al.* (17) found from perfusion experiments that unionized and poorly absorbed drugs are hardly affected by bile salts. This is consistent with the findings on the two progestins. Kakemi *et al.* also suggested that any enhanced absorption of poorly absorbed drugs may be due to the bile salt action on the mucosal membrane and not to the direct drug–bile salt interaction.

Because the steroids were administered in an alcoholic solution, experiments were conducted to determine the effect of the vehicle. The percent of ethanol in the drug solutions was varied, and simultaneous ^{14}C-ethanol–^{3}H-drug solution absorption curves were plotted. In the gastric preparations, the variation of ethanol in the drug solutions did not have an effect on the drug absorption; the "solubilizing function" proposed by Tappeiner (18) in 1880 was ruled out. In some instances, however, there appeared to be a delay in the appearance of metabolites in the bile. Ethanol is known to cause irritation to organic tissue. In concentrations exceeding 15% in the stomach, the solution was so strong that marked congestion and ulceration often occurred. It is possible, therefore, that the delay in metabolite appearance was the result of ethanolic irritation of the liver and interaction with drug metabolism as well. In the few experiments done, no evidence was found to indicate any difference whatsoever in the intestinal absorption of chlormadinone acetate and norethindrone using ethanol concentrations of 0–15%. Magnussen (19) reported that ethanol aids gastric absorption of only a few drugs, these drugs being already well absorbed without ethanol.

The absorption of the drugs is not affected by the presence or absence of ethanol or bile. Chlormadinone acetate does show greater binding properties, with higher partition coefficient values and greater general intestinal absorption, than norethindrone. According to Schedl and Clifton (20), the absorption is predictable from the chemical structure: the less polar the steroid, the greater is the absorption rate. The wall of the intestinal wall is lipoidal and substances that are lipid soluble pass into the wall more readily than do some hydrophilic compounds. The structures of norethindrone and chlormadinone acetate are so similar that this comparison is difficult to make. However, chlormadinone acetate is slightly more hydrophobic, resulting in the small differences seen in the GI absorption of the two steroids.

The data from the intestinal absorption experiments show a biexponential profile which suggests that the drug is rapidly distributed between the gut lumen and the intestinal wall, followed by a slower release of the drug from the membranes into the blood. The initial absorption of the drugs into the intestinal membranes and the consequent distribution into the blood is not simple first-order kinetics. The absorption did appear to be *via* diffusion without an energy requirement or the mediation of an enzyme system.

Determination of Bioavailability of Digitoxin Using the Radioimmunoassay Procedure

R. G. STOLL*, M. S. CHRISTENSEN, E. SAKMAR, D. BLAIR†, and J. G. WAGNER▲

Abstract □ A commercial digitoxin radioimmunoassay procedure, normally used to evaluate equilibrium-state plasma levels, was modified such that the sensitivity was increased 20-fold. Due to the extensive metabolism of digitoxin in man, the specificity of the assay procedure for digitoxin was determined against several known metabolites. These studies indicated that the assay procedure was more sensitive to digoxin and the monodigitoxoside and bisdigitoxoside of digitoxigenin than to digitoxin itself. It also had a lesser degree of sensitivity to the aglycone digitoxigenin. For the bioavailability study, single 0.1-mg. doses of digitoxin were administered orally, as one of two commercial brands of tablets, to a panel of eight subjects in a crossover study with 56 days separating the two doses. Plasma levels were measured for 15 days following dosing. Significant differences in the plasma levels between brands, as determined by analysis of variance, were found at 0.5, 1, 72, and 240 hr. The peak plasma levels were found to differ significantly. No statistical difference in the relative bioavailability, as measured by the area under the plasma level curve, was found between the two tablets tested.

Keyphrases □ Digitoxin plasma levels—radioimmunoassay determination, two commercial tablets, man □ Bioavailability, two commercial digitoxin tablets—determination of plasma levels, man □ Radioimmunoassay technique—determination, digitoxin plasma levels, two commercial tablets, man

During the past few years, this laboratory has been involved in a continuing effort to study the generic equivalence or inequivalence of marketed drug products. Past studies have included ephedrine (1), warfarin (2), and propoxyphene (3).

The importance of uniform dosage and bioavailability is perhaps epitomized by the cardiac glycosides as with no other series of therapeutic agents, because these agents produce such a strong inotropic effect on the heart and frequently represent the difference between life and death for many patients suffering from congestive heart failure. Since digitoxin is known to have a long half-life, it is particularly important that uniform dosage and bioavailability limits are maintained. These difficulties are further complicated by the fact that a fairly low dose of the cardiac glycoside is used to achieve the desired therapeutic results, and manufacturing tablets with uniform drug content apparently is difficult when such low levels of medication are required. The manufacturing difficulties are evidenced by the number of tablets of various cardiac glycosides that have been recalled during a 1-year period. As determined from the "Drug Recall" section of the *Journal of the American Pharmaceutical Association* during the period of June 18, 1970, to June 16, 1971, approximately 25 million tablets containing cardiac glycosides were recalled by the Food and Drug Administration (FDA).

Assay methodology to perform adequate bioavailability studies on digitoxin tablets was lacking, since assay sensitivity was usually not sufficient to follow plasma levels long enough to measure bioavailability. With the advent of the red blood cell ^{86}Rb-uptake assay (4) and the Na,K-ATPase inhibition procedure (5), new levels of assay sensitivity for digitoxin were achieved. Nonetheless, both procedures are too impractical for routine assays as are needed for a bioavailability study. The development of the radioimmunoassay procedure for digitoxin (6) unquestionably provided the researcher with an assay technique that could be made sufficiently sensitive to measure the levels of drug for an adequate length of time to determine the bioavailability of a single dose of digitoxin.

This report is the first in a series on the bioavailability of digitoxin and digoxin commercial tablets. The commercial radioimmunoassay[1] procedure, normally used to determine equilibrium-state plasma levels for patients receiving the medication chronically, was modified and the sensitivity was increased at least 20-fold to achieve the necessary assay sensitivity for a single-dose bioavailability study. Thus, a reproducible sensitivity of 0.2 ng./ml. was achieved. In the study reported here, plasma levels of digitoxin and its metabolites were measured in eight normal volunteers in a crossover study for 15 days following the administration of a 0.1-mg. dose of the drug. The innovators' product was compared to one other commercial digitoxin tablet USP.

EXPERIMENTAL

The radiotracer, antiserum, standard digitoxin solution, and buffer components used for this radioimmunoassay procedure were all obtained from the radioimmunoassay kit[1]. The dextran-coated charcoal[2] suspension was prepared from laboratory materials. The assay samples were counted in a liquid scintillation spectrometer[3], using a liquid scintillation cocktail[4]. The reference standard used for preparation of a quench curve was standard tritiated water[5], and the most suitable quenching agent for the scintillation cocktail was found to be chloroform. All other chemicals used were reagent grade and were used as received.

Study Conditions and Subjects—Both brands of tablets used conformed to the USP XVIII requirements with respect to identity, disintegration time, content, content uniformity, and other digitoxosides. Individual tablets of Treatment A[6] were assayed by FDA and were found to contain an average of 101.3% of label, with a range of 98.6–104.9%. Treatment B[7] tablets were also assayed at FDA laboratories and were found to contain an average of 96.5% of label, with a range of 89.7–103.5%.

The screening method used for this study was previously reported by Wagner *et al.* (2). The subjects selected were eight normal males from 22 to 30 years of age. The subjects were arranged into two groups of four as follows: Group I, Subjects 1–4, weight 54.4–78 kg., age 22–29 years; and Group II, Subjects 5–8, weight 81.2–93 kg., age 24–30 years.

[2] Dextran T70, Pharmacia, Uppsala, Sweden; and Norit A charcoal, Sigma Chemical Co., St. Louis, Mo.

[3] Packard Tri-Carb, model 3320.

[4] Unogel, Schwarz/Mann, Orangeburg, N. Y.

[5] New England Nuclear, Boston, Mass.

[6] Treatment A was one tablet of Purodigin, 0.1 mg., Wyeth, Lot 1693870.

[7] Treatment B was one tablet of digitoxin USP, 0.1 mg., Squibb, Lot 9L695.

The protocol was as previously reported by Wagner *et al.* (2) with some modifications. The changes in protocol were related to the changes in medication, sampling times, and period of treatments. First, samples of whole blood were taken from a forearm vein at time zero, 0.5, 1, 2, 4, 6, 12, 24, 72, 120, 240, and 360 hr. after dosing. The two doses administered in the crossover study were separated by 56 days or approximately 9–10 half-lives of elimination.

During Phase I of the study, Subjects 1–4 received a dosage form designated as Treatment A[6], while Subjects 5–8 received Treatment B[7]. Fifty-six days later, Subjects 1–4 received Treatment B and Subjects 5–8 received Treatment A.

***In Vitro* Dissolution Studies**—The dissolution of individual tablets was conducted in a 1-l. three-necked flask containing 500 ml. of distilled water maintained at 37°. A single-bladed, Teflon stirrer was rotated at 50 r.p.m., and 10-ml. samples were removed at predetermined time periods with immediate replacement with fresh solvent. At least four dissolution trials were conducted for each brand of tablets.

The samples were analyzed by the fluorometric method of Wells *et al.* (7) in a spectrophotofluorometer[8], using an activation wavelength of 395 nm. and an emission wavelength of 570 nm. The procedure was used to analyze quantitatively aqueous solutions containing 0.01–0.25 mcg./ml. of digitoxin. With different sets of reagents, the slope varied slightly; therefore, a separate calibration curve (0.2–8.0 ng./ml.) was run with each individual dissolution trial. All assays were carried out at least in duplicate.

Radioimmunoassay—The procedure used for the analysis of total digitoxin derivatives in plasma was a modification of the one described in the commercially available digitoxin radioimmunoassay kit[1]. The commercial procedure essentially was that reported earlier by Smith (6).

Whole blood, obtained by venipuncture, was collected from patients in vacutainers containing sodium citrate as an anticoagulant. The plasma samples were stored in capped polystyrene test tubes at −15° for up to 2 weeks prior to assay. It had been previously determined that these storage conditions did not adversely affect the assay of digitoxin.

Two significant changes were made in the recommended procedure. The modifications involved changing the ratio of the tracer to antiserum to obtain the necessary assay sensitivity in the concentration range of 0.2–8.0 ng./ml. Yalow and Berson (8) discussed the factors involved in the antigen–antibody binding process and gave an excellent background discussion for the radioimmunoassay procedure. Also, since it was necessary to change the quantity of plasma used in the assay procedure to 1 ml., the concentration of charcoal in the dextran-coated charcoal suspension had to be changed. The factors that determine the amount and type of adsorbent used in radioimmunoassay procedures were discussed by Herbert *et al.* (9). The charcoal suspension used in the experiment described in this paper consisted of 250 mg. dextran and 10 g. charcoal in 100 ml. of pH 7.4 phosphate-buffered saline. The phosphate-buffered saline was prepared from the kit material, and the pH was adjusted as described in the commercial kit.

The assay procedure involved the following steps. To 1 ml. of patient plasma or plasma spiked with digitoxin standard solution, 10 μl. of antiserum and 5 μl. of tracer were added. To the blank plasma sample, only 5 μl. of tracer was added. Calibrated Lang Levy constriction pipets[9] were used to measure all microliter quantities, because automatic pipeting devices were found to be too inaccurate. The material was then gently mixed on a vortexer and allowed to incubate at ambient temperature for 30 min. Following the incubation, 0.5 ml. of the dextran-coated charcoal suspension was rapidly added to each sample, the material was vortexed gently, and after 5 min. the material was centrifuged at 1500×*g* for 20 min. The clear supernate was then decanted into 15 ml. of liquid scintillation-solubilizer fluid and counted in a liquid scintillation counter.

A quench correction for all samples was made through use of an automatic external standard, and a standard curve was prepared from reference standard tritiated water[5]. The data obtained were then corrected to disintegrations per minute, and the percent of tritiated digitoxin bound to the antiserum could be calculated. The percent bound was then plotted against the concentration of unlabeled digitoxin in solution to obtain the standard curve shown in Fig. 1. In addition to the patient samples and the standards determined with each assay group, it was also necessary to determine the appropriate blanks (consisting of all components except antiserum), total counts for the tracer added (consisting of adding 5 μl. of the tracer directly to the liquid scintillation flask), and the total amount of tracer bound by the antiserum in the absence of unlabeled drug, which in this case was 30–35%. The total count value was used as a control for the number of counts added to each sample, and the blanks were used as a background value for correction of all counts obtained for the assayed samples.

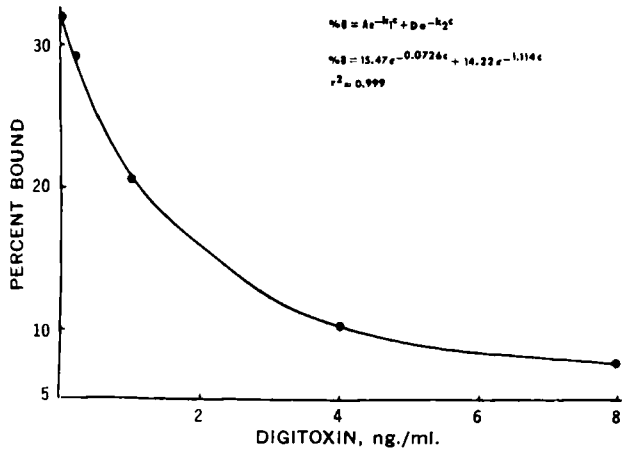

Figure 1 – *Example of typical calibration curve determined for each set of samples analyzed.*

An example of a typical calibration curve is shown in Fig. 1. Each curve was fitted to a biexponential equation using the program NONLIN[10] on a computer[11]. In all cases, the fits were essentially perfect, giving a coefficient of determination[12] of at least 0.999. An example of the equation used for the calibration curves and the parameter estimates for the sample calibration curve shown are found inset in Fig. 1. Since all samples were assayed in duplicate, it was possible to calculate a mean normalized difference between duplicates in terms of percentages. In all, 352 samples (not including calibration curves) were analyzed. The mean normalized difference between duplicates was 12.3% with a standard deviation of 14.1%. This value represents the actual differences found from day to day for all patient samples and at all concentrations levels.

Cross-Reactivity Studies Since it has been noted that digitoxin is extensively metabolized in man and other species (10–13), it was deemed necessary to evaluate the binding of the major digitoxin metabolites with the antiserum under the assay conditions. Thus, the degree of binding of digoxin[1], the bisdigitoxoside[13] and the monodigitoxoside[13] of digitoxigenin, and digitoxigenin[13] with the antiserum was studied. Since these compounds interact with the antiserum on a molecular basis, the comparison of their reactivity with the antiserum was made on a molar basis. Previous studies (6, 14) showed that most endogenous steroid compounds produce virtually no interference with the digitoxin antiserum. Usually, levels of 1000 10,000 ng./ml. of progesterone or testosterone were necessary to inhibit antibody binding of tritiated digitoxin. In the present studies, approximately 20% of the blank serum samples produced small false-positive responses. The "apparent" concentration of drug in the blanks was usually calculated to be less than 0.1–0.2 ng./ml. For those subjects where such apparent positive blank values occurred, the percent tritiated digitoxin bound was corrected or normalized for all samples.

RESULTS

The scheme for the metabolism of digitoxin (Scheme I) was proposed by Lauterbach and Repke (15) following *in vitro* and *in vivo* studies with rats. A similar pattern for the metabolism of digitoxin

in man has evolved primarily through the works of Okita and coworkers (12, 13), Ashley *et al.* (11), Hermann and Repke (16), and Repke (17). Therefore, the effects of these various metabolites on the analysis of digitoxin in plasma were determined.

Figure 2 shows the results of the studies comparing the effect of nonradiolabeled digitoxin and digoxin on the binding of ^{3}H-digitoxin with the antiserum. It is apparent that, on an equimolar basis, digoxin displaces the tracer from the antiserum to a larger extent than digitoxin itself. This was not too surprising since the antiserum used was prepared by challenging rabbits with a digoxin-albumin conjugate; thus, such cross-reactivity was anticipated. Although the relative proportions of digitoxin to digoxin necessary to produce the same percent of tracer bound to antiserum are variable, for most of the curve it takes approximately four times as much digitoxin as digoxin to produce the same decrease in the percent tracer bound.

A separate study was undertaken to determine the sensitivity of the radioimmunoassay to the various digitoxigenin derivatives of digitoxin, and all of the metabolites interacted to a varying degree with the antiserum (Fig. 3).

Figure 4 is a plot of the *in vitro* dissolution data for the two brands of tablets used in the *in vivo* studies. The curves for each brand were obtained from the average data of four dissolution trials. The vertical bars represent 1 standard deviation on either side of the mean. The results of the analysis of variance for the dissolution of the two dosage forms are shown in Table I.

Table II presents the average plasma levels of digitoxin and its metabolites obtained at each indicated time period. The values reported are the mean plasma levels of the eight subjects. Also shown are the average peak plasma concentrations and the average elimination half-lives. The area under the plasma level–time curve, shown

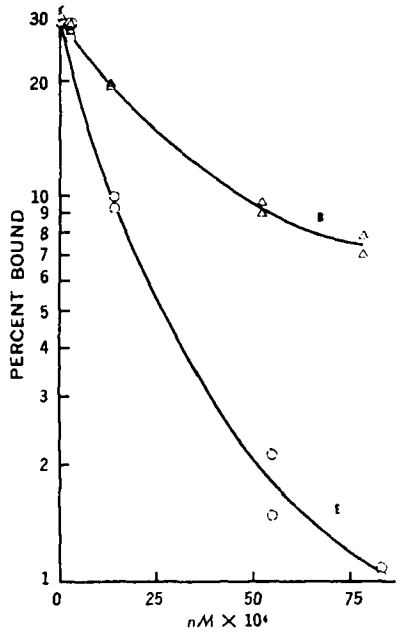

Figure 2—*Effect of digoxin on digitoxin radioimmunoassay. Key: B, △, digitoxin; and E, ○, digoxin.*

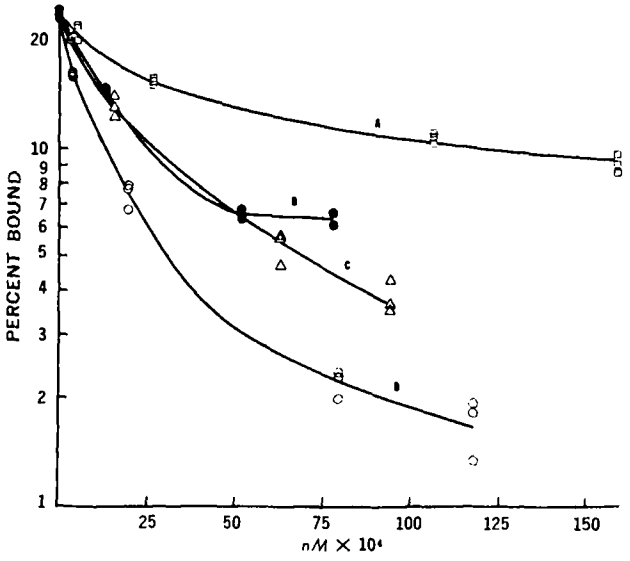

Figure 3—*Affinity of various digitoxigenin metabolites of digitoxin for antiserum in commercial radioimmunoassay procedure. Key: A, □, digitoxigenin; B, ●, digitoxin; C, △, bisdigitoxoside of digitoxigenin; and D, ○, monodigitoxoside of digitoxigenin.*

as average area in this table, is an indication of the relative availability of each dosage form. Data for the 0–360-hr. period and the estimated area from zero to time infinity are also reported.

DISCUSSION

The metabolic pathway shown in Scheme I was developed primarily from urinary excretion data. Very little information is available on the blood levels of these various metabolites, primarily because of the extremely low levels of drug and metabolites obtained following normal doses of digitoxin. This problem has not been satisfactorily resolved to date. However, urinary excretion studies have indicated that digitoxin is extensively metabolized in man and, as reported by Okita (12), only approximately 8% of an administered dose of ^{14}C-digitoxin was recovered as unchanged drug in the urine over a 3-week period; approximately 70% of the dose was recovered as metabolic products over the same time interval (12). A major component of the metabolic products was determined to be digoxin (12).

Since the kit[1] used in this study had an antiserum that was prepared by challenging rabbits with a digoxin albumin conjugate, it was apparent that some cross-reactivity would exist between digitoxin and its metabolite digoxin. Since all of the other metabolites shown in Scheme I have also been detected in urine, the possibility of their existence in the blood should be considered. As shown in Fig. 2, the antiserum exhibited a much greater affinity for digoxin than for digitoxin.

On an equimolar basis, the ability of each of the digitoxigenin derivatives to interfere with the ^{3}H-digitoxin antiserum binding process was found to be the monodigitoxoside of digitoxigenin > the bisdigitoxoside of digitoxigenin ≃ digitoxin > digitoxigenin (Fig. 3). Thus, all metabolites of digitoxin tested so far would in a very real sense interfere with the analysis of digitoxin, depending on the relative proportions of each in the blood. It would appear that the level of digitoxigenin would be extremely small since it has been reported that this material is rapidly conjugated and excreted. Also, since this compound has the least affinity for the antiserum, it would contribute very little in the analysis of digitoxin in plasma. However, both the monodigitoxoside and bisdigitoxoside of digitoxigenin would markedly affect the radioimmunoassay of digitoxin in plasma. The digoxigenin derivatives (Scheme I) were not studied in this experiment. However, recent studies in these laboratories with the digoxin radioimmunoassay procedure indicated that these derivatives have essentially the same affinity for the antiserum as digoxin itself. Thus, again depending upon their plasma levels in man, these components could potentially interfere with the analysis of digitoxin. Having verified that many of these substances have at least the same or greater affinity for the antiserum as digitoxin itself, it can be concluded that the digitoxin radioimmunoassay procedure used in this study was not specific for just digitoxin and most likely was actually a measure of total drug and metabolites in the plasma.

It is felt that this information in no way detracts from the clinical usefulness of the radioimmunoassay procedure. It is still the most sensitive, convenient, and economical procedure available at present for measuring cardiac glycosides in the blood. It has been shown (18) that all of the metabolites are cardioactive to varying degrees in both the guinea pig and the cat. Digitoxin and the monodigitoxoside and bisdigitoxoside of digoxigenin were approximately equipotent. Digitoxigenin itself was only about one-half as potent as digitoxin. The same is true for digoxin and the monodigitoxoside and bisdigitoxoside of digoxigenin, which have about the same potency, with digoxigenin having only approximately one-tenth the activity of digoxin. Nonetheless, all important metabolites of digitoxin ap-

Average estimated area, zero to infinity	467.0	446.0	41.5	N.S. ($p > 0.25$)
Average elimination $t_{1/2}$, days	8.03	9.85	32.9	N.S. ($p > 0.25$)

[a] Coefficient of variation (%) = $\frac{\sqrt{\text{residual mean square}}}{\text{grand average}} \times 100$. [b] Sig. = significant, and N.S. = not significant.

pear to be cardioactive and thus the assay procedure is a measure of the active drug in the blood following any given dose of digitoxin. However, pharmacokinetic analysis of digitoxin data cannot be carried out using this assay procedure unless the metabolites are separated from the parent compounds prior to analysis.

Tablets of two different manufacturers were subjected to *in vitro* dissolution tests to determine which tablets would be used for the *in vivo* bioavailability studies. The dissolution rate curves for the two tablets used in the studies are shown in Fig. 4. The dissolution of the Treatment B tablet was significantly slower than that of the Treatment A tablet, but in all cases dissolution was found to be complete within 2 hr. Table I shows the data for the average time required to dissolve 25, 50, and 75% of the digitoxin from the two tablet forms studied. As determined by analysis of variance, the differences between the average dissolution time at 25, 50, and 75% dissolved were highly significant.

Table II presents the average plasma levels of digitoxin and its metabolites obtained at each indicated time period. The differences between the average plasma levels of digitoxin during the first two sampling times of 0.5 and 1.0 hr. were highly significant. This finding correlates with the significant differences in the *in vitro* dissolution rate of the two tablets. Also, the average peak plasma concentration for the two tablets was found to be significantly different by analysis of variance for crossover design. However, the difference between the average areas under the plasma level curve following the two tablets was not statistically significant for either the 0–360-hr. period or the estimated area from zero to infinite time.

The data indicate that the differences in *in vivo* dissolution rates for the two tablets were not of sufficient magnitude to depress the relative bioavailability of the tablet that dissolves more slowly *in vitro*. The slower absorption rate and the consequent lower peak level, as noted in these studies, correlated well with the *in vitro* results.

As indicated in Table II, the average half-life, estimated from terminal plasma concentrations, was found to be 8.03 days for Treatment A. The range in half-lives for this dosage form for all eight patients varied between 6.5 and 9.9 days. In the case of Treatment B, the mean half-life was 9.84 days with a range of 5.0–13.7 days. Again, since the assay is nonspecific, this value is a measure of the total drug in the plasma. These values should, therefore, be comparable to the half-life of digitoxin determined with radiolabeled digitoxin, a procedure that also is nonspecific. Okita and coworkers (13, 19), measuring the urinary excretion of digitoxin and its metabolites, found the half-life to be 9.0 days for both a 1.2- and a 0.5-mg. dose of ^{14}C-digitoxin. Caldwell *et al.* (20) measured the levels of radioactivity in the blood following a 1.2-mg. oral dose of ^{3}H-digitoxin in hydroalcoholic solution. In their study, the mean half-life was 11.5 ± 2.3 days. However, in subjects who received a 4-g. dose of cholestyramine 4 hr. after dosing with digitoxin, there was a significant change in the mean plasma half-life to 6.6 ± 1.9 days. The apparent drop in the plasma half-life of the drug following treatment with cholestyramine, a compound that binds digitoxin, was due to the interruption of the enterohepatic circulation of the drug. Okita (21) showed that, in man and several other species, digitoxin and its metabolites are excreted in bile into the small intestine and subsequently reabsorbed. Okita also was able to relate the species differences in the half-life of digitoxin to differences in the enterohepatic circulation. There is little doubt that enterohepatic circulation plays an important role in regulating the time course of digitoxin and its metabolites in the body. It is also quite apparent that this effect can cause considerable variability in the apparent half-life of digitoxin from one subject to another or conceivably within the same subject. This would be expected since the compounds excreted in the bile are concentrated in the gallbladder and gallbladder emptying is dependent upon the time at which food or fatty materials are consumed. Nevertheless, the half-life values obtained in this study generally agree well with the reported literature values.

In summary, one main problem associated with the determination of digitoxin plasma levels in a single-dose study is sensitivity. The only procedures available with the required sensitivity are the radioimmunoassay, the ^{86}Rb-uptake assay, and the Na,K-ATPase

inhibition procedures. All of these procedures are plagued with the same lack of specificity and, as stated earlier, in our opinion the radioimmunoassay is the most convenient and readily available procedure of these three.

For bioavailability studies, when unlabeled drug must by necessity be used, a separation of unchanged digitoxin and its metabolites by a chromatographic procedure is virtually impossible. This is because of: (*a*) the extremely low plasma levels of drug following a single oral dose, and (*b*) the number of samples that must be processed for a bioavailability study. Furthermore, the problem of assay specificity is in reality more involved than just separating the drug from its metabolites. Studies have shown that the metabolites of digitoxin also are cardioactive in animals. Since this is the case, metabolism in the intestinal wall and in the GI tract should be considered. Furthermore, studies should be undertaken to determine the cardioactivity of these compounds in man. Only if these factors are known would it be possible to determine the availability of active drug from a given dosage form of digitoxin. It is presently thought that all of the metabolites except the aglycone of digitoxigenin and digoxigenin are cardioactive in man, but this has not been quantitatively nor qualitatively reported in the literature. If the various metabolites are all cardioactive, as is believed, then to some measure the radioimmunoassay would be a measure of total active drug. To this extent in carefully controlled crossover studies, the radioimmunoassay is presently the best method for bioavailability studies.

The results of the human bioavailability study reported herein should not be construed as suggesting that all digitoxin tablets made by different manufacturers are equally bioavailable. Only two manufacturers' tablets were studied, and the results should not be extrapolated to any other manufacturer's products.

NMR Spectroscopy: Antibiotic Interactions with Phospholipids

JOHN M. PADFIELD▲ and I. W. KELLAWAY

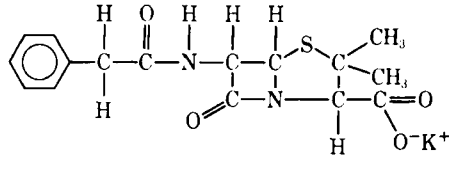
Abstract □ Sonicated dispersions of phosphatidylcholine, lysophosphatidylcholine, phosphatidylinositol, and phosphatidylserine in deuterium oxide were studied by NMR, and the changes in spectra produced on addition of penicillin G and ampicillin to the dispersions were observed. The antibiotics appeared to reduce the configurational freedom and kinetic motion of the phospholipid hydrocarbon chains due to hydrophobic interaction between the hydrocarbon chains and the phenyl portion of the antibiotic side chain. Penicillin G interacted with the phospholipid systems to a greater degree than ampicillin, while the phospholipids interacted in the order phosphatidylserine > phosphatidylcholine > phosphatidylinositol > lysophosphatidylcholine.

Keyphrases □ Antibiotic interactions with phospholipids—studied using NMR spectroscopy □ Phospholipids, interactions with penicillin G and ampicillin—studied using NMR spectroscopy □ Penicillin G and ampicillin interactions with phospholipids—studied using NMR spectroscopy □ Ampicillin and penicillin G interactions with phospholipids—studied using NMR spectroscopy □ NMR spectroscopy—used to study antibiotic interactions with phospholipids

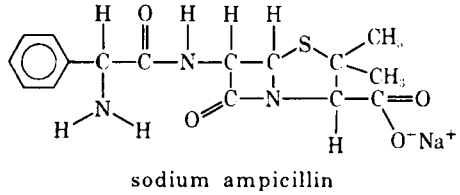
This work is part of a physical study (1) designed to investigate the reported differences in *in vivo* activity (2) of penicillin G (I) and ampicillin (II) by attempting to correlate these differences with the relative penicillin affinity for binding with phospholipids (III*a*, III*b*, III*c*, and III*d*). Previous work examined the effects of interactions on the rheology of phospholipid systems (3, 4), on diffusion of the antibiotics through phospholipid dispersions, and on gel filtration (5). The significance of such interactions was also discussed (5).

NMR spectroscopy is a useful method of investigating the relationships between lipids and other molecules because it often allows a single component to be studied in a heterogeneous environment (6, 7). Furthermore, Jardetzky (8) showed that NMR is invaluable in assessing the extent to which various functional groups on small drug molecules participate in drug–macromolecule interactions.

NMR spectroscopy has been used to study lipids (9–11) and lipid–water systems (12, 13), primarily by broad-line measurements. Sonication of the systems enabled a high resolution spectrum to be obtained (13–16) similar to that observed when the phospholipid was dissolved in a solvent such as deuterochloroform (17). Most workers indicated that the lamellar state is retained after sonication, *i.e.*, no phase change occurs, although this is not universally accepted (18).



potassium penicillin G
I



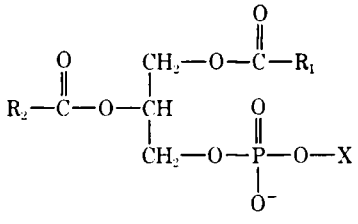
sodium ampicillin
II

These studies provide the basis for investigating the interaction of phospholipids with cholesterol (19, 20), acetylcholine (21), and polypeptide antibiotics (22, 23). The observed broadening of the lipid hydrocarbon chain proton signal has been interpreted as a reduction in the configurational freedom and kinetic motions of the hydrocarbon chains (19, 24). Further studies indicated binding of phospholipids to anesthetic molecules (25) and epinephrine (26).

NMR studies on penicillin G and ampicillin have not been widely reported. The demonstration of binding of penicillin G to serum albumin (27, 28) and guanosine (29) indicated the use of selective changes in relaxation times in assessing which portion of the penicillin molecule was involved in binding.

EXPERIMENTAL

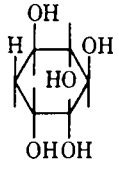
Materials[1]—Egg phosphatidylcholine (III*a*) was prepared as previously described (5). Highly purified lysophosphatidylcholine (III*b*), phosphatidylinositol (III*c*), and phosphatidylserine (III*d*)



III*a*: phosphatidylcholine, $X = -CH_2-CH_2-\overset{+}{N}(CH_3)_3$,
R_1 and R_2 = fatty acid chains (C_{13}-C_{23})

III*b*: lysophosphatidylcholine, $X = -CH_2-CH_2-\overset{+}{N}(CH_3)_3$,
R_1 = fatty acid chain (C_{13}-C_{17}, saturated), R_2 = H

III*c*: phosphatidylinositol, X =



R_1 and R_2 = fatty acid chains (C_{14}-C_{20})

III*d*: phosphatidylserine, $X = -CH_2-CH(NH_2)-COOH$,
R_1 and R_2 = fatty acid chains (C_{12}-C_{18})

[1] Potassium penicillin G was the gift of Glaxo Research Limited, Greenford, England, and sodium ampicillin was the gift of Beecham Research Laboratories, Betchworth, England; both materials were laboratory reference grade.

[a] Key: PC = phosphatidylcholine, LPC = lysophosphatidylcholine, PI = phosphatidylinositol, and PS = phosphatidylserine. [b] X = H in penicillin G, and X = NH_2 in ampicillin. [c] s = singlet and d = doublet. [d] Values given are peaks of very broad signals. No signals observed for other groups. [e] Not observable under deuterium oxide signal.

were obtained commercially[2]. The phospholipids were stored with a desiccant at −5°, and their purity was confirmed by TLC on kieselguhr G plates[3]. Deuterium oxide (D_2O), 99.95%, and tetramethylsilane were also used[4].

Preparation of Dispersions—The antibiotic solutions and phospholipid sols were 2% w/v unless otherwise stated. The phospholipid sols were prepared by adding deuterium oxide directly to the weighed amount of phospholipid in a flask. The dispersions were sonicated at 20 KHz. for 10 min. in nitrogen atmosphere (23, 25).

Phospholipid–antibiotic mixtures were prepared by adding 0.5 ml. of the sonicated phospholipid sol to the requisite amount of antibiotic; the mixtures were shaken to dissolve the antibiotic, and the spectra were obtained after 18 hr. (1).

NMR Measurements—The spectra were obtained at 31° using a spectrometer[5], operating in a field-sweep mode. The spectra of the phospholipids were accumulated on a computer of average transients[6]; 15 scans were normally sufficient. Tetramethylsilane provided a lock signal for the instrument and an external reference signal for measuring chemical shifts.

RESULTS

Table I gives the chemical shifts for the antibiotics in the 100-MHz. spectra; signal assignments are based on those of Fischer and Jardetzky (27) and Green *et al.* (30). Although a doublet was observed for each proton of the β-lactam ring in penicillin G, only one singlet was observed for both protons in ampicillin.

Figure 1 illustrates the high-resolution NMR spectrum of III*d* and its interaction products; the computer of average transients spectrum is shown in Fig. 2. Peak assignments are based on those of Chapman and Morrison (17). Table II indicates the chemical shifts observed for the phospholipids. The primary peaks observed in all spectra were those due to the hydrocarbon chain, $(CH_2)_n$, protons and the chain terminal, CH_3, protons; in addition, a strong signal was observed for the terminal choline, $^+N(CH_3)_3$, protons in III*a* and III*b*. These signals are only observed in sonicated dispersions, the fine structure being absent in unsonicated material (15, 16, 20). The $(CH_2)_n$ peaks, composed of more than 30 protons, are broader in appearance. Broad peaks are also characteristic of aggregate forms in dispersion.

The effect of the addition of penicillin G and ampicillin to sonicated dispersions of phosphatidylserine is indicated in Figs. 1*b*, 1*c*, 2*b*, and 2*c*. Differential line broadening and line shifts are observed for some peaks (Tables I and II). The penicillin G peaks most affected are those due to the aromatic and α-CH_2 groups, while the gem-dimethyl and C-3 proton peaks of ampicillin are also implicated.

The computer of average transients spectra indicate that the phospholipid peaks most affected are those due to the $(CH_2)_n$ and CH_3 groups. The line broadening observed is so marked in some cases (phosphatidylcholine–penicillin G and phosphatidylserine–penicillin G) that the signals are lost in the baseline.

Tables III and IV illustrate T_2 relaxation times for the antibiotic and phospholipid protons; they were determined by measuring the line width at half maximum peak height (31).

DISCUSSION

The following discussion has been limited to data relevant to penicillin–phospholipid interactions and does not attempt to discuss the previously documented details of the relaxation processes of proton lipid spectra previously referenced.

Previous work (9–26) showed that both the solid phospholipids and dispersions in water give NMR lines that are intermediate between solids and liquids at normal temperatures. A gradual narrowing of the lines is observed with rising temperature, and a "liquid" state can be observed in highly unsaturated phospholipids at temperatures normally found in biological systems. Sonication gives rise to a liquid signal from the hydrocarbon chain protons even when this is not present in the bulk material, indicating a substantial increase in chain mobility. The addition of substances like cholesterol and alamethicin removes the hydrocarbon chain signal, whereas other substances like procaine hydrochloride and epinephrine affect the hydrophilic parts of the phospholipids.

The antibiotics' spectra are relatively sharp, the chemical shifts being in accordance with published work (27, 30). The coupling constants (J) for the β-lactam doublets of penicillin G (Table I) are identical to those of Green *et al.* (30).

Comparison of the β-lactam signal for penicillin and ampicillin indicates that the two doublets in penicillin G collapse to give one singlet in ampicillin. The presence of an electron-attracting group such as an amino group may transfer its effect to the β-lactam ring to produce the observed differences. Pek *et al.* (32) found that substituents in the side chain affect the chemical shifts of the methyl protons remote from them. Recently, Kan *et al.* (29), using a 220-MHz. NMR spectrometer, reported that the phenyl signal and the —CH_2— signal of penicillin G are present as a multiplet and an *AB* quartet (J = 15 Hz.), respectively, whereas both appear as singlets at 60 and 100 MHz. Similarly, these workers reported two doublets for the β-lactam protons in dimethyl sulfoxide and that the —CH_A—CH_B—NH_X signals represent an *ABX* system with $J_{AX} = 0$, J_{AB} = 4 Hz., and J_{BX} = 9 Hz. The T_2 relaxation times for antibiotic protons have not been widely reported; however, the present findings (Table III) are of the same order as those of Fischer and Jardetzky (27).

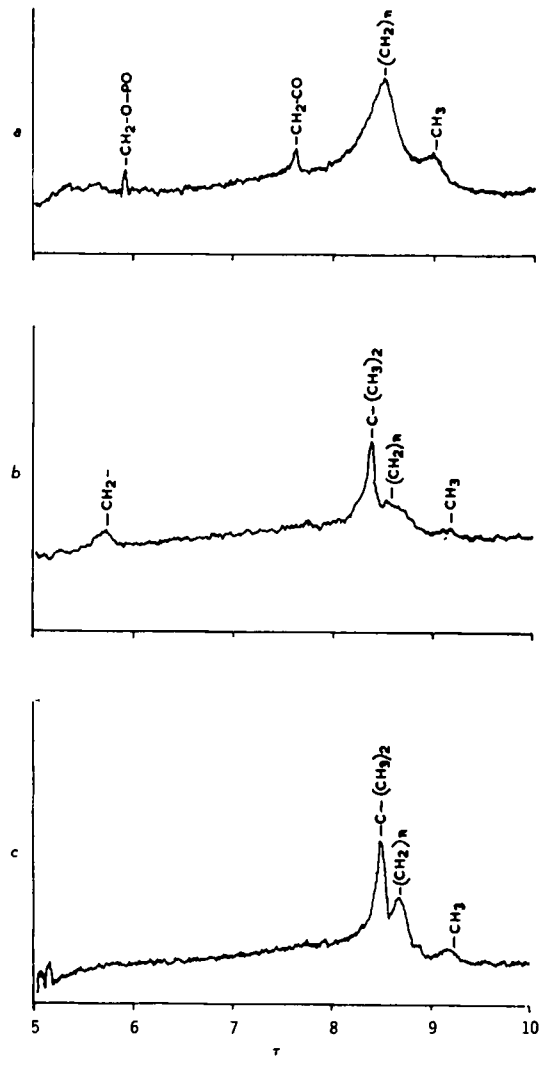

Figure 2—*The 100-MHz. NMR computer of average transients spectrum (15 scans) of 2% phosphatidylserine in deuterium oxide in the presence and absence of the antibiotics (2%). Key:* a, *phosphatidylserine;* b, *phosphatidylserine + penicillin G; and* c, *phosphatidylserine + ampicillin.*

The signals observed for the phospholipids (Table II) are in accordance with those of other workers. Sheard (18) indicated that only 88 ± 5% of the $^{+}N(CH_3)_3$ protons of III*a* contributed to the spectrum, behavior paralleled by the $(CH_2)_n$ protons. He also reported that this latter signal was more field dependent than the $^{+}N(CH_3)_3$ or CH_3 signals and proposed that each broad signal is a superimposition of many narrower signals.

The T_2 relaxation times for phospholipid protons have not been widely reported, but T_1 measurements (33) indicated a single relaxation time above and below the transition temperature, suggesting that a single relaxation mechanism exists for the bulk of the phosphatidylcholine molecule. The T_2 relaxation times found in this study are shown in Table IV.

Addition of the antibiotics to phospholipids indicates effects similar to those observed on addition of cholesterol (20, 24). Reduction in the motion of the fatty acid chain protons is so marked in some cases (penicillin G–phosphatidylcholine and penicillin G–phosphatidylserine) that the $(CH_2)_n$ and CH_3 signals are lost in the baseline (Table II).

In general, differential downfield line shifts are observed for the antibiotic protons, although those of penicillin G are more susceptible than those of ampicillin; the phospholipids, in contrast, experience an upfield shift. Downfield shifts indicate a deshielding effect, whereas shielding is implicated by upfield shifts. If the relative motion of the hydrocarbon chains is reduced by hydrophobic interaction with penicillin G, increased shielding of the protons is suggested and upfield shifts would be expected; examination of the spectra indicates this to be the case. It has been suggested (20) that the ends of the hydrocarbon chains are relatively more mobile than the rest of the chain, because the terminal CH_3 signal is broadened to a lesser extent than that representing the majority of the $(CH_2)_n$ protons.

More specifically, the phenyl and α-CH_2 protons of the antibiotics are shifted to a greater degree than other protons in the molecule, the effect being more pronounced for mixtures containing penicillin G. The phenyl and methylene protons become deshielded, possibly due to changes in the rotation of the side chain in the presence of phospholipids.

The greatest shifts of phospholipid protons observed are those present in the hydrocarbon chain, *i.e.*, $(CH_2)_n$ and CH_3. In mixtures of penicillin G–phosphatidylcholine and penicillin G–phosphatidylserine, these signals are lost in the baseline. However, due to the broad nature of these signals in the absence of the antibiotics, precise chemical shifts are not possible; a similar conclusion was reached by Hammes and Tallman (26).

The loss of the four peaks from the penicillin G spectra on addition of phosphatidylserine is interpreted as a case of extreme line broadening. In view of the observed changes in the phospholipid spectra, it is difficult to envisage any form of interaction other than of a hydrophobic nature, which would thus implicate the aromatic ring and α-CH_2 group of the antibiotic. Confirmation of this view was provided by substituting phosphatidylcholine for phosphatidyl-

serine when line shifts of 24 and 26 Hz. were recorded for the aromatic ring and α-CH_2 group, respectively (Table I). Ampicillin, being less hydrophobic than penicillin G (35), would be bound to a lesser extent; thus smaller changes were noted in the NMR spectra (Tables I and II). Rheological studies (3, 5) using hydrophobic bond breakers, such as urea and guanidine hydrochloride, indicated the hydrophobic nature of the antibiotic-phospholipid interaction.

Changes in T_2 relaxation times are more indicative of molecular changes than line shifts. Tables III and IV further implicate the parts of the antibiotic and phospholipid molecules already described. Some workers (26, 27) reported that a reduction in T_2 is indicative of restricted rotational freedom of certain groups stabilized by the interaction. However, where line broadening occurs, one may observe an increased value of T_2, suggesting greater freedom; this occurs because the line becomes so broad that the area under the peak is the same as or greater than the peak area of the signal before interaction.

Complex formation can often be detected by observing the changes in chemical shift or relaxation time of a signal; the former is due to changes in charge density at a given proton resulting from interaction. However, line broadening may result even though no change in charge density is observed.

Line broadening may be due to magnetic inhomogeneity, viscosity changes, self-association, or intermolecular complex formation. Viscosity can be disregarded because a 2% solution of phosphatidylcholine has a low viscosity (1.0260×10^{-2} poise at 30°). Sharp resonance lines, although broadened, were observed for the antibiotic protons, thus ruling out magnetic inhomogeneity. Self-association of penicillin G has been reported (34); but since line broadening of some phospholipid signals is also observed, self-association

of the antibiotic is unlikely to be the only mechanism, if it occurs at all (5).

The experimental evidence indicates rapid exchange of penicillin G between the free and unbound forms; if the exchange was slow, sharp lines due to the free species would be superimposed on the broad lines.

Thus, a complex appears to be formed between the antibiotics and phospholipids. This may involve the side chain of the antibiotics and fatty acid chains of the phospholipids. The change in peak size of the $(CH_2)_n$ and CH_3 protons indicates changes in the relative mobility of the hydrocarbon chains. In all phospholipid dispersions examined, penicillin G was observed to interact to a greater degree than ampicillin, while the phospholipids interacted in the order phosphatidylserine > phosphatidylcholine > phosphatidylinositol > lysophosphatidylcholine. The significance of the results in relation to the differences in activity of these antibiotics was discussed elsewhere (1, 5).

Morphine-Induced Fetal Malformations III: Possible Mechanisms of Action

PETER A. ARCURI* and RONALD F. GAUTIERI▲

Abstract □ The teratogenic effects exerted by morphine sulfate in CF-1 mice on Days 8 and 9 appear, from indirect evidence, not to be attributable to cholinesterase inhibition. The anticholinergic drug, atropine, when used in combination with morphine, resulted in the potentiation of morphine-induced defects, exencephaly and axial skeletal fusions. In addition, both atropine and morphine, either alone or in combination, produced constriction of the placental vessels. Morphine administration on Days 8 and 9 resulted in an increase in blood sugar regardless of the dose employed. Previously reported similarities produced by atropine and morphine on the placental vessels, the knowledge that both drugs decrease oxygen tension, the resemblance of hypoxic-induced malformations to the defects observed in this study, the effects of hypoxia on carbohydrate metabolism, and the reported involvement of carbohydrate metabolism in the morphogenesis of the embryonic neural tube all suggest that the malformations observed following morphine administration are related to the reduced oxygen concentration as well as the hyperglycemia produced subsequent to its administration in gravid mice.

Keyphrases □ Morphine-induced fetal malformations—possible mechanisms of action □ Exencephaly, morphine induced—possible mechanisms of malformation □ Teratogenicity, morphine—possible mechanisms of morphine-induced fetal malformations □ Fetal malformations—possible mechanisms of morphine-induced exencephaly

Exencephaly, an anomaly characterized by the extensive exterior protrusion of cerebral tissue due to the absence of skin and bones of the cranial vault, has been shown to be caused by a variety of inducers. The causative agents include genetic mutations (1), irradiation (2), nutrition (3), hypoxia (4), and a number of chemical agents (5) including morphine sulfate (6).

Having established the fact that high subcutaneous doses of morphine sulfate (200, 300, and 400 mg./kg.) are teratogenic (6), the subsequent investigation of a mechanism of action was undertaken in this laboratory. Among the problems encountered in trying to define a mechanism of teratogenicity for morphine are the enigmatic pharmacological reactions produced by it—histamine release (7), food retardation (8), cholinesterase inhibition (9), vasoconstriction of placental vessels (10), and hyperglycemia (11)—plus the knowledge that teratogenic insult may occur at any of three different loci: the mother, the placenta, and the embryo.

The involvement of histamine release and food retardation as the underlying factors causing the malformations observed following morphine administration were negated by Iuliucci and Gautieri (12) and Harpel and Gautieri (6), respectively. Consequently, the objectives of this investigation were to: (*a*) reconfirm the teratogenic potential of high subcutaneously administered doses of morphine in CF-1 mice; (*b*) evaluate the possibility of cholinesterase inhibition by morphine as a causative factor in the production of fetal anomalies, determined by increasing the defects with the prior administration of physostigmine or decreasing them with the prior administration of atropine; (*c*) ascertain whether an effect exerted by morphine, atropine, and physostigmine on the placental vasculature *in vivo*, utilizing ^{22}Na transport, is involved in the production of the abnormalities; and, finally, (*d*) assess the involvement of the hyperglycemic component in the teratogenicity induced by morphine.

EXPERIMENTAL

CF-1 albino mice[1], weighing between 25 and 30 g., were employed in all experimental procedures and subjected to treatment and breeding procedures as reported previously (6, 12).

Injectable solutions of morphine sulfate[2] (40.0 mg./ml.), physostigmine sulfate[3] (0.025 mg./ml.), atropine sulfate[4] (5 mg./ml.), sodium sulfate[5] (10 mg./ml.), and sodium chloride (9 mg./ml.) were prepared fresh weekly by dissolving the drugs in distilled water.

The pregnant female mice were assigned at random to one of 35 experimental categories, with each category being treated on either Day 8 or 9 of gestation as designated in Tables I–IV. Iuliucci and Gautieri (12) described termination of pregnancy, removal of fetuses, gross inspection, and preparation of the excised fetuses for both skeletal (13) and soft tissue examination (14).

A second aspect of this study involved the actions of certain drugs upon the placental vasculature as determined by transport of ^{22}Na according to the procedure described by Robson and Sullivan (15), who employed it to study placental transport *in vivo*.

Five minutes after the subcutaneous administration of the respective drug(s), the isotope, 0.1 ml. delivering 3 μc., was injected intravenously into a tail vein of the mouse. By reporting the activity of the samples as a percentage of the concentration of isotope in maternal blood, each animal served as its own control.

A third aspect of this study involved an evaluation of the effects exerted by morphine (200, 300, and 400 mg./kg.) on the maternal blood sugar of 8- and 9-day pregnant CF-1 mice.

Each animal was initially bled by inserting a fine glass pipet into the medial canthus and removing 0.1 ml. of blood from the veins of the retro-orbital plexus (16). This was followed by the subcutaneous administration of designated test agent and dose. Twenty minutes later, a second 0.1-ml. sample was withdrawn from the mouse. Both samples were then subjected to the Folin–Malmros (17) micromethod for blood glucose determination. By withdrawing two samples, one prior to and one following drug administration, each animal served as its own control.

RESULTS

Maternal Effects of Test Drugs—The subcutaneous administration of 50 mg./kg. atropine sulfate did not produce readily observable effects, except an apparent increased heart rate and a coldness of the tail. When administered in combination with morphine, no Straub tail was detected at first; when it did appear some 30 min. later, it lasted for only 5 min. as compared with several hours following the injection of morphine alone. Next came a period of depression and labored breathing, followed by a hyperactive period. Atropine sulfate failed to produce any deaths when used alone. However, com-

binations of atropine, followed in 15 min. by varying doses of morphine, resulted in a definite increase in the number of maternal deaths. The higher the morphine dose following the atropine injection, the greater the incidence of maternal death, the greatest incidence (100%) being observed with the 400-mg./kg. dose of morphine.

Treatment with 0.005 mg. physostigmine produced a generalized lethargy in the animals. Salivation and Straub tail were noted, along with hyperpnea that lasted for approximately 1 hr.; at the end of this time, the mice became hyperactive. Unlike atropine pretreatment, which antagonized morphine-induced Straub tail, the prior administration of physostigmine not only did not alter the Straub tail produced following the administration of morphine but actually stimulated a Straub tail itself. Atropine injection before physostigmine resulted in effects quite similar to those noticed following the administration of atropine alone—no Straub tail. The single injection of 0.005 mg. physostigmine sulfate caused no deaths. Conversely, when administered 15 min. prior to morphine, physostigmine produced a substantial increase in the death rate, especially at the higher doses of the latter; 100% fatality, regardless of the day, resulted from the combination of 0.005 mg. physostigmine and 400 mg./kg. morphine.

It was also observed that the injection of saline 15 min. prior to morphine administration did not result in any noteworthy change in the normal maternal symptoms produced by the narcotic.

Tables I–IV, which contain the cumulative mean values for each experimental group, give the results obtained from the various categories employed in the teratological aspect of this study.

Exencephaly (Herniated Brain)—The observed fetal and litter incidences of offspring manifesting herniated brains are tabulated in Tables V–VIII, and Fig. 1 contains representative specimens exhibiting this anomaly.

By referring to these tables, it can be seen that of all the agents and combinations tested, only 300 mg./kg. morphine and 300 mg./kg. morphine preceded by 50 mg./kg. atropine administered on Day 8 produced a significant incidence of exencephaly when compared with saline controls. The combination of atropine and 300 mg./kg. morphine on Day 8, although insignificant when compared with 300 mg./kg. morphine on Day 8 on a litter basis, was significant when compared on a fetal basis. This combination resulted in the greatest incidence of exencephaly, in which five out of six litters, totaling 13 exencephalic fetuses, exhibited this abnormality.

A significant decrease in the number of litters displaying exencephaly when compared with the respective dose and day of morphine administration was observed only in the group receiving the combination of 0.005 mg. physostigmine and 300 mg./kg. morphine on Day 8. The administration of physostigmine alone on Day 8 produced exencephalies in two litters, which borders on being significant.

The occurrence of this anomaly was not apparently influenced by either uterine horn (right *versus* left) or position, because the defect was evenly divided between the horns and no particular position was favored irrespective of the treatment employed. Furthermore, this defect did not appear to be sex related, since a predominance of the malformation was not observed in either sex. Many of the exencephalic fetuses also had open eyes, a condition not observed even in untreated fetuses at regular parturition.

Other Soft Tissue Defects—In addition to exencephaly and its related defects, retardation of testicular descent (cryptorchid testes) (Fig. 2) was the only other soft tissue anomaly that occurred at a significant degree. The results of the various test agents upon testicular descent are depicted in Tables V–VIII.

Some other soft tissue malformations observed in this study are as follows: At least one fetus exhibiting hydronephrosis was observed in groups administered saline; 200, 300, and 400 mg./kg. morphine; and physostigmine and 200 mg./kg. morphine on Day 8.

Table III—Mean Values of Test Groups Receiving Combination Treatments[a] on Day 8

[a] With 15-min. interval between injections. [b] S = starting weight and T = terminal weight. [c] Statistically significant in comparison with saline control, $p < 0.05$. [d] Statistically significant in comparison with single injections of the respective dose of morphine, $p < 0.05$.

Bloody hemispheres (internal hemorrhage) were a common observance in the physostigmine groups on either Day 8 or 9. The 50 mg./kg. atropine and 300 mg./kg. morphine combination produced the greatest array of soft tissue anomalies (Fig. 3), including sirenomelus, exencephaly, cryptorchid testes, cranioschisis, gastroschisis, facial abnormality involving the snout and jaw, and ophthalomodisgenesis.

Skeletal Abnormalities—Tables I–IV show the high incidence of skeletal malformations that resulted from treatment on either Day 8 or 9 with various agents. Among the most common of these observed defects were delayed ossification in the phalanges, sternebrae, and skull, especially the supraoccipital bone, and rib and vertebral fusions (Tables V–VIII).

Results of Radio-Sodium Experiment—The 12 mice comprising the control group were injected with 0.3 ml. normal saline 5 min. prior to the intravenous administration of the radio-sodium isotope. Three animals then were sacrificed at 5-, 10-, 15-, and 20-min. intervals each.

The mean values generated for the placentas and fetuses at the various time periods following drug pretreatment were then compared with the mean values obtained for saline; significance was determined by Student's t test (Table IX). Only morphine at the 5- and 15-min. intervals exhibited a significant difference when the placental values were compared ($t > 2.77$, $p < 0.05$). Comparison of the fetal values resulted in significant differences being observed for both atropine and morphine at 5 min. and for the atropine-morphine combination at 10 min. ($t > 2.77$, $p < 0.05$).

Results of Blood Sugar Experiment—Two blood samples were withdrawn from each of the six mice constituting one of 10 experimental groups, with the second sample being taken 20 min. after the designated treatment of the respective animal. The mean change per group in either Day 8 or 9 is delineated in Table X.

The increases in blood sugar observed with the 200- and 300-mg./kg. doses of morphine administered on Day 8, when compared with saline controls, resulted in significant differences. All three doses of morphine employed on Day 9 were significantly different. An interdose comparison of morphine, however, resulted in no significant differences being observed on either Day 8 or 9.

DISCUSSION

The most profound effect exerted upon the maternal mouse following the injections of morphine, atropine, physostigmine, and various combinations thereof was death, resulting from acute toxicity. Single injections of the doses employed proved nonlethal

except in mice receiving 400 mg./kg. morphine on either Day 8 or 9. Both 0.005 mg. physostigmine and 50 mg./kg. atropine, administered 15 min. prior to this dose of morphine, resulted in the deaths of all animals so challenged. Consequently, combinations of 400 mg./kg. morphine with other test agents were deleted from the remainder of the study. Atropine or physostigmine administered 15 min. before the 200- and 300-mg./kg. doses of morphine also increased the mortality rate, with the greatest enhancement occurring on Day 8; 81%, 27 out of 33, succumbed following the 50 mg./kg. atropine and 300 mg./kg. morphine combination. The incidence of deaths observed in the various groups should be borne in mind when considering the anomalies produced by different combinations, because defects can be obscured by the production of maternal or fetal death (18). Furthermore, death may actually be secondary to the malformation (18), for the insult may be of such severity that the fetus may not survive.

The combination of 50 mg./kg. atropine followed in 15 min. by 0.005 mg. physostigmine proved to be nontoxic on Days 8 and 9, attesting to the relative innocuousness of this combination in the doses employed when compared with their lethal actions when used in combination with morphine. Another interesting observation was the increase in acute toxicity following the saline and 300 mg./kg. morphine injections. Evidently, the mere trauma of an injection preceding morphine administration is substantial enough to cause death.

The present study demonstrated that more exencephalic fetuses were observed when the gravid animal was treated with 300 mg./kg. morphine on Day 8, while treatment on Day 9 with morphine (all three doses) resulted in a greater number of fetuses displaying axial skeletal fusions. This combination of defects, *i.e.*, exencephaly and axial skeletal fusions, is not unusual. On the contrary, Book and Rayner (19) contend that deficiencies in skeletal and muscle development are secondary to a primary anomaly of the central nervous system (CNS).

Pretreatment with saline 15 min. prior to the morphine injection produced no significant defects compared with morphine alone, thereby negating the possibility that trauma of injection is involved in the subsequent induction of anomalies when a drug is administered before morphine. Therefore, the observance of a significant difference in the incidence of anomalies, *i.e.*, exencephaly and axial skeletal fusions, following pretreatment of morphine administration with a drug must be interpreted as an interaction between the agent and morphine.

Another soft tissue anomaly found in significant numbers was cryptorchid testes, which was generally observed to be associated with a decreased mean fetal weight. Although the importance of

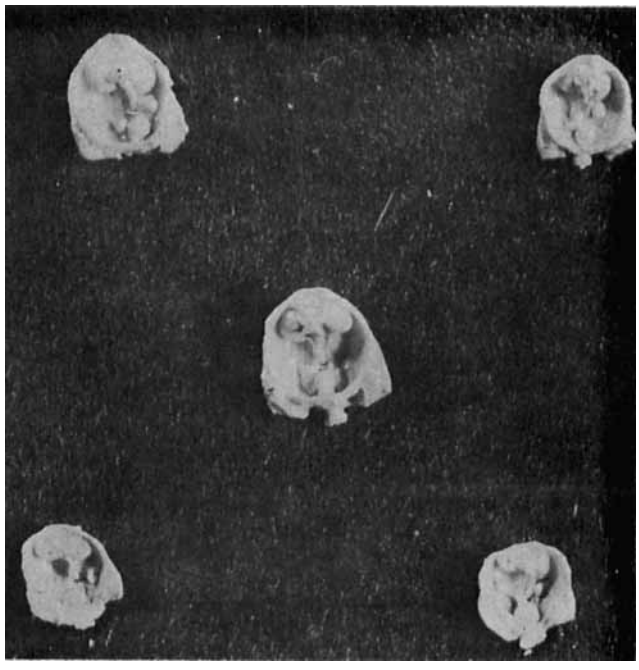

Figure 2—*Specimens exhibiting cryptorchidism. Orientation of section: spinal cord and kidneys at top; bladder and testes on each side, in center at bottom. Upper left and right and lower left: right unilateral cryptorchidism. Middle: normal section. Lower right: bilateral cryptorchidism.*

retarded testicular descent is not clear at this time, conceivably as growth continues the normal descent of the testes may occur. Zondek and Zondek (20) also reported that failure of testicular descent and anencephaly occur concomitantly.

The reversible anticholinesterase agent, physostigmine, when used alone, produced a total of two exencephalic fetuses (one in each of two different litters), significant retardation of testicular descent, and no axial skeletal fusions. The cryptorchid testes and the ob-

Physostigmine, 0.005 mg., and morphine, 300 mg./kg.	6	0	57	0	2	4	18	1	6	0	28	0

[a] Significant $(X)^2 > 3.84$ = significantly different from single morphine injection.

servable skeletal defects were, in all cases, associated with the inhibition of fetal growth. The administration of physostigmine 15 min. prior to morphine did not increase the incidence of exencephaly or axial skeletal fusions. However, on the contrary, a significant decrease in the number of exencephalic fetuses resulted from the combination of physostigmine and 300 mg./kg. morphine administered on Day 8. Also, the combination of physostigmine and 200 mg./kg. morphine administered on Day 8 resulted in a significant reduction in the resorption ratio as compared with morphine, while the same combination on Day 9 resulted in a significant increase in the incidence of cryptorchid testes. Therefore, although apparently not involved in the production of the two major anomalies observed following morphine administration, the effect of growth retardation exerted by physostigmine possibly is responsible for the augmented number of fetuses exhibiting cryptorchid testes.

Atropine injection alone resulted in the production of no significant anomalies. Only one exencephalic fetus and one fetus exhibiting axial skeletal fusions were induced following 50 mg./kg. atropine on Days 8 and 9, respectively.

The results obtained from the combination studies with atropine and morphine clearly indicate a potentiation of the teratogenic capability of morphine to induce both exencephaly and axial skeletal fusions. This is evident from the increased incidence of exencephalic fetuses: five out of six litters, totaling 13 fetuses, following the 50-mg./kg. atropine and 300-mg./kg. morphine combination on Day 8. Most combinations of atropine and morphine on both Days 8 and 9 resulted in greater numbers of axial skeletal fusions than with morphine alone. Although atropine has been used as an antidote in morphine poisoning (21) and has been shown to antagonize the Straub tail reactions produced by morphine (22), recent investigations conducted elsewhere indicate an "additive synergism" between atropine and morphine in producing death in mice (23). Hence, the enhancement of acute toxicity by atropine pretreatment of morphine-injected mice observed in the present study is in agreement with the latter study.

The fact that morphine has been shown to exert an effect upon the placental vasculature (10), plus the awareness that atropine has been reported to abolish certain actions produced by acetylcholine upon this structure (24), provided the impetus for this segment of the investigation. The importance of the placenta in the exchange occurring between the maternal and fetal organisms with respect to agents such as oxygen, nutrients, and glucose cannot be overemphasized.

Table VIII—Occurrence of Exencephaly, Axial Skeletal Fusions, and Cryptorchid Testes with Treatment on Day 9 (Compared with Morphine, 200 or 300 mg./kg.)

Treatment	Exencephaly				Cryptorchid Testes				Axial Skeletal Fusions			
	Litters		Fetuses		Litters		Fetuses		Litters		Fetuses	
	Normal	Abnormal	Normal	Abnormal	Normal	Abnormal	Normal	Abnormal	Normal	Abnormal	Normal	Abnormal
Saline, 0.3 ml., and morphine, 200 mg./kg.	6	0	59	0	5	1	13	1	6	0	28	0
Saline, 0.3 ml., and morphine, 300 mg./kg.	5	1	48	1	1	5	9	6	3	3	16	6
Atropine, 50 mg./kg., and morphine, 200 mg./kg.	5	1	62	1	4	2	12	2	0	6[a]	18	14[a]
Atropine, 50 mg./kg., and morphine, 300 mg./kg.	5	1	60	1	5	1	11	1	2	4	23	7
Physostigmine, 0.005 mg., and morphine, 200 mg./kg.	4	2	44	2	2	4[a]	7	5[a]	3	3	17	6
Physostigmine, 0.005 mg., and morphine, 300 mg./kg.	6	0	61	0	1	5	17	8	1	5	23	7

[a] Significant $(X)^2 > 3.84$ = significantly different from single morphine injection.

Consequently, the possibility exists that interference in the transport of any or all of the above by the action of an agent on the placental vessels, on either the maternal or fetal side, could have detrimental effects on the conceptus.

The results of the radioisotope study (Table IX) demonstrated that, following morphine administration, constriction of the maternal placental vessels occurred at the 5-min. interval, followed by vasodilation at the 15-min. interval. Comparison of the effects of the drugs upon the fetal side showed that both atropine and morphine produced constriction at the 5-min. interval, while the combination of atropine and morphine still caused constriction after 10 min.

The initial vasoconstriction of the placental vasculature by morphine *in vivo* is similar to that observed in the perfused human placenta (10). This action conceivably could precipitate a reduction in the amount of oxygen accessible to the fetus, with the subsequent production of congenital malformations or even death. Therefore, the fact that atropine prolonged morphine vasoconstriction of the placental vessels, plus the increased incidence of anomalies following the administration of this combination, leads to a good cause-and-effect relationship. Further substantiation of this possibility has been provided by others who clamped the uterine vessels in the rodent, which resulted in both severe malformations and death of the fetus (25). In addition, atropine has been reported to cause a fall in mean arterial oxygen tension (26), a condition not unlike that produced by morphine (27), which also reduces the extraction of oxygen from the blood circulating through the brain. Also, morphine has been reported to decrease fetal brain oxygen for at least 50 min. (28). Furthermore, an overdose of morphine early in gestation has resulted in the birth of a malformed child (29), attributed to the acute anoxia caused by morphine.

Ingalls *et al.* (4) induced anencephaly, cryptorchid testes, and rib fusions by exposing mice to decreased oxygen concentrations. These anomalies were the most prominent defects observed in the present study. Moreover, hydramnios, also observed in this study in association with every case of exencephaly, was present where anencephalic fetuses were found in the above study (4). Also, Ingalls and Curley (30), in another investigation, found cranioschisis, rib and vertebral malformations, and open eye in mice rendered hypoxic. Again, these abnormalities were also observed in the present study. In addition, Grabowski (31), utilizing chicks, noted "tremendous edema," blisters, hematomas, and the ultimate defects of "exocephaly," defective eyelids, and short upper beaks following exposure to reduced oxygen concentrations.

Table IX—Mean Percent of ^{22}Na Activity in Placentas and Fetuses of Selected Test Groups Compared with Saline

Group	Time Elapsed after Isotope Administration, min.	Mean Percent of ^{22}Na in Placenta	*SD*	Mean Percent of ^{22}Na in Fetus	*SD*

Table X—Observed Change in Blood Sugar on Either Day 8 or 9

Treatment	$\bar{X}$ Blood Sugar Change, mg./100	*SE*	p^a
Untreated control—Day 8	0.9	±0.95	0.20
Saline control—Day 8	8.0	±4.13	—
Morphine, 200 mg./kg.—Day 8	57.9[a]	±10.04	0.001
Morphine, 300 mg./kg.—Day 8	42.2[a]	±10.30	0.02
Morphine, 400 mg./kg.—Day 8	33.7	±12.05	0.10
Untreated control—Day 9	4.5	±0.89	0.80
Saline control—Day 9	5.2	±1.38	—
Morphine, 200 mg./kg.—Day 9	50.7[a]	±15.35	0.02
Morphine, 300 mg./kg.—Day 9	49.1[a]	±6.85	0.001
Morphine, 400 mg./kg.—Day 9	34.6[a]	±3.07	0.001

[a] Significant $t > 2.776 = p < 0.05$ calculated from Student's t test = significant increase in glycemic response compared with saline control.

The fact that hypoxia produces various biochemical changes, *e.g.*, an increased utilization of glycogen stores with a subsequent increase in blood glucose and lactic acid (32), plus the knowledge that hyperglycemia in mice precipitates a decrease in brain glycogen concentration (33) stimulated the third aspect of this particular study. All three doses of morphine employed on both Days 8 and 9 produced increases in blood glucose when compared with controls (Table X), with the greatest increase occurring at the lowest dose and the smallest increase occurring at the highest dose, respectively. This phenomenon can possibly be explained by the term "autointeraction" (34), in which a drug noncompetitively antagonizes its initial effect, as the concentration is increased, by becoming attached to a second receptor. Besides, it has been reported that high maternal blood sugars are accompanied by high fetal blood sugars (35). The acceptance of these facts enables one to assume that the aforementioned decrease in brain glycogen (33) precipitated by glucose administration also occurred in this study in response to the morphine-induced hyperglycemia. Since Runner (3) hypothesized that carbohydrate metabolism may be selectively critical for the morphogenesis of the embryonic neural tube, the above-mentioned hyperglycemia and resultant effects produced by anoxia upon carbohydrate metabolism cannot be completely excluded as possible factors contributing to morphine-induced congenital malformations.

Residual Ethylene Oxide in Gas-Sterilized Medical-Grade Silicones

J. D. WHITE*▲ and T. J. BRADLEY†

Abstract □ Residual gas was extracted from ethylene oxide-treated silicone sheets by high vacuum distillation, and the residue subsequently was analyzed by GLC. To indicate the necessary aeration time of the materials before they can be considered safe to use, the desorption characteristics of ethylene oxide in three types of the silicone polymer were studied. Very rapid desorption of the gas to low residual levels was observed in the two nonreinforced silicone rubbers examined: medical-grade silicone sheeting and a medical-grade elastomer. The third material, Dacron-reinforced silicone sheeting, lost the gas at a considerably slower rate, after an initial rapid drop, due to retention by the Dacron reinforcement.

Keyphrases □ Silicone sheets, medical grade—absorption and diffusion of ethylene oxide after gas sterilization □ Ethylene oxide gas sterilization—absorption and diffusion from medical-grade silicone sheets □ Sterilization with ethylene oxide—absorption and diffusion from medical-grade silicone sheets

During the last couple of decades, there has been an ever increasing trend to utilize synthetic rubber and plastics in medical instruments and equipment as well as in permanent or semipermanent implants and prostheses. Because many synthetic materials are heat labile, conventional dry heat or autoclaving processes have been substituted by low temperature sterilization methods.

One such method is ethylene oxide gaseous sterilization, and its relative merits have already been well documented. However, one serious disadvantage of sterilization with this gas is that ethylene oxide remains in the material, and its presence in a polymeric device can present potential toxicological problems if the gas is released to tissue. Only in recent years, with the increasing use of GLC, has it been discovered that various types of polymeric materials may contain reaction products of ethylene oxide other than ethylene glycol, such as the highly toxic ethylene chlorohydrin (2-chloroethanol) which is formed in the presence of chloride ions (1, 2).

Medical-grade silicones are widely used in tissue implants and can be successfully sterilized both by conventional methods and by ethylene oxide. With the latter method, there is uncertainty concerning the retention time of the gas, together with the possibility of cytotoxic reaction products. These considerations prompted this study.

THEORY

If there is a uniform distribution of a dissolved gas in a thin slab of material and the surfaces are suddenly exposed to zero partial pressure of the gas and maintained at that, the gas begins to clear from the material. It can be shown (3) that, after an initial period during which the mean gas concentration in the medium decreases by 10–20%, the concentration at all points decreases exponentially with the same half-time:

$$T_{1/2} = \frac{2.77\left(\frac{L}{2}\right)^2}{\pi^2 D} \qquad \text{(Eq. 1)}$$

where:

$T_{1/2}$ = half-time (sec.)
L = thickness of material (cm.)
D = diffusion coefficient (cm.^{2} sec.$^{-1}$) —constant for a given gas, temperature, and material

Thus, if the total amount of dissolved gas can be calculated as a function of time, the diffusion coefficient can be deduced from the slope of the exponential (which indicates the time taken for the concentration of dissolved gas to decrease by half) and the thickness of the medium; repeating the experiment with a different thickness of the material provides a check on the value.

The $T_{1/2}$ of Eq. 1 is also a measure of the rate of diffusion *into* the material.

Table I shows the diffusion coefficient of ethylene oxide in several plastics at 23°. Knowledge of the diffusion coefficient of ethylene oxide in a particular material at room temperature should permit

some predictions to be made concerning the minimum aeration time necessary to achieve sterile, nontoxic medical devices manufactured from that material.

EXPERIMENTAL

Materials—Medical-grade silicone sheeting[1], reinforced and nonreinforced, and a room temperature vulcanizing medical-grade silicone elastomer (Silastic 382)[1] were used.

GLC—A dual flame-ionization gas chromatograph[2] was used. The columns were of glass tubing, 4 mm. i.d. and 1.5 m. (5 ft.) in length. The packing consisted of 80–100-mesh Porapak Q[3] for the estimation of ethylene oxide and of polyethylene glycol 20,000, 10% w/w, on 100–120-mesh Diatomite C[3] for the estimation of ethylene chlorohydrin. Nitrogen was used as the carrier gas at a flow rate of 45 ml. min.$^{-1}$ with a column oven temperature of 125°, an injection temperature of 175°, and a detector oven temperature of 200°. The injection solvent was distilled water. Peak areas were obtained from the product of the peak height and the width at half the peak height.

IR Determinations—A double-beam grating IR spectrophotometer[4] was employed. Standard gas cells (150-ml. capacity) were used to follow the uptake of ethylene oxide by the silicone, with measurements being made at 11.5 μ. Internal reflection spectroscopy was carried out using a KRS-5 crystal (thallous-bromide-iodide complex)[3] and a beam incidence angle of 60°.

Exposure to Ethylene Oxide—Uniformly thin sheets of the three types of silicone were cut into strips (each measuring approximately 20 × 76 mm.), which were freely suspended from a glass rod by metal clips. The strips of the different materials were then exposed in turn to pure ethylene oxide (1200 mg. l.$^{-1}$) at 23° and 60% relative humidity in the gas sterilizer[5] for a sufficient time to ensure equilibration (24 hr.). Three manual evacuation cycles were then carried out to empty the sterilizer chamber of the toxic ethylene oxide, and the strips were removed from the sterilizer. This procedure was followed by aeration at 23° under a gentle stream of air, the samples being taken at accurately timed intervals for extraction and analysis.

Extraction of Residual Ethylene Oxide—Vacuum extraction techniques for residual ethylene oxide and its reaction products have already been used successfully (5–7). The method employed here was based on distillation under high vacuum, with a distillate trap cooled in liquid nitrogen. The extracted sterilant residues were then dissolved in a small volume of distilled water for quantitative determination by GLC.

Diffusion Cell—A small, stainless steel diffusion cell was set up using a filter[6], with the silicone as a membrane to form the two compartments of the cell (Fig. 1). A 50-ml. gas syringe full of pure ethylene oxide was attached to one side while an empty syringe, equipped with a sampling device, was fitted to the other compartment; the pistons of the syringes allowed the contained gases to remain at atmospheric pressure at all times. The system was tested underwater for leaks and found to be gas tight. Samples were withdrawn at timed intervals from the receiver compartment and estimated on the gas chromatograph.

RESULTS AND DISCUSSION

The results obtained for the uptake of ethylene oxide by the heat vulcanized silicone using the IR spectroscopy method and measuring the decrease in absorbance at 11.5 μ are displayed in Fig. 2. It can be seen that equilibration occurs within a short time.

By plotting the logarithm of residual ethylene oxide *versus* desorption time, the predicted straight-line graphs of Fig. 3 are obtained; these plots permit ready calculation of the diffusion coefficient of ethylene oxide in the elastomer, a room temperature vulcanized silicone rubber.

The desorption curves of ethylene oxide from heat vulcanized silicone sheeting, nonreinforced and Dacron reinforced (Figs. 4 and 5, respectively), suggest a two-stage desorption mechanism and require further investigation. An examination of Fig. 4 showed that it was possible that a compressed film of ethylene oxide had built up on the surface of the heat vulcanized silicone without gas penetration into its interior. Removal from the sterilizer would produce rapid loss of this surface film until only a relatively strongly held monolayer of adsorbed ethylene oxide remained. (This would correspond to the almost horizontal part of the curves and the amount agrees closely with calculation of monolayer capacity.)

This possibility was investigated in two ways:

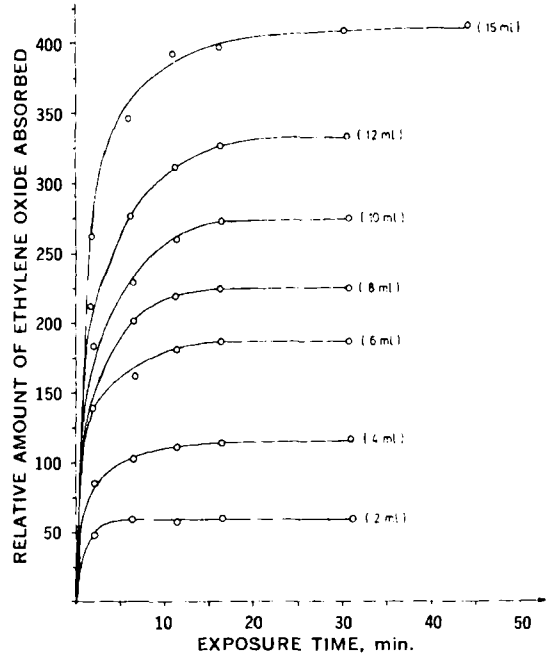

Figure 2—*Plot of amount of ethylene oxide absorbed in 1.0-mm. thick, heat vulcanized silicone rubber* versus *time exposed to the gas. The volume of ethylene oxide admitted to the gas cell is shown in parentheses beside each curve.*

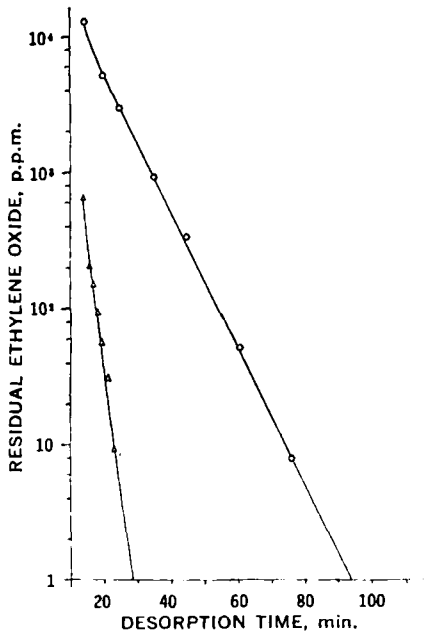

Figure 3—*Plot of log residual ethylene oxide in room temperature vulcanized silicone elastomer* versus *desorption time. Key:* O, *2.0-mm. thick sheet; and* Δ, *1.0-mm. thick sheet.*

1. By internal reflection spectroscopy, an IR technique used essentially to study surface phenomena. This technique was employed in an effort to detect the existence of a thin film of adsorbed ethylene oxide on the silicone immediately after removal from the sterilizer. No ethylene oxide was detected; however, this does not exclude the possibility of a monomolecular surface layer because the sensitivity of the method is low.

2. By determining the diffusion of ethylene oxide through a membrane of the silicone in the diffusion cell. The results (Fig. 6) indicate that ethylene oxide is, in fact, absorbed by heat vulcanized silicone and diffuses very rapidly through it. With this knowledge, the shape of the desorption curves of Fig. 5 can be explained by the relatively slow release of absorbed ethylene oxide from the Dacron tricot weave reinforcement in the middle of the sheet of heat vulcanized silicone.

Since it had been confirmed that absorption and diffusion do occur, the diffusion coefficient of ethylene oxide in the two non-

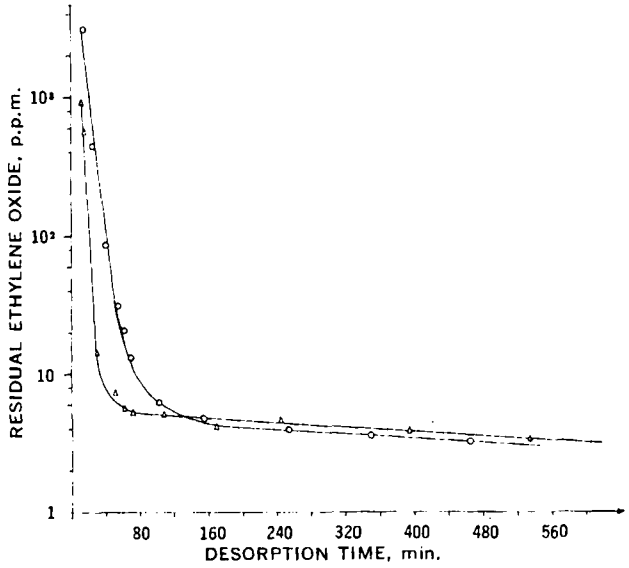

Figure 4—*Plot of log residual ethylene oxide in heat vulcanized silicone rubber* versus *desorption time. Key:* O, *1.6-mm. thick sheet; and* Δ, *1.0-mm. thick sheet.*

reinforced materials was calculated using Eq. 1; the results are shown in Table II.

Since Fig. 5 indicates that it is the Dacron reinforcement and not the silicone that governs the desorption of ethylene oxide, it was not possible to obtain a value for the diffusion coefficient of the gas in the reinforced material. However, it was noted that during the first 45 min. after removal from the sterilizer the ethylene oxide level dropped to approximately 10% of its equilibrium value; thereafter, the half-time (*i.e.*, the time for the concentration of dissolved ethylene oxide to decrease by half) was observed to be about 100 min., which would seem to imply that reinforced silicone sheeting is completely safe to use after 24 hr. aeration.

Although the vacuum process is known to extract reaction products of ethylene oxide when these are present (and has been successfully used for this purpose by the authors), none was detected in any silicone sheeting.

An incontinence implant was used as the test piece in the final

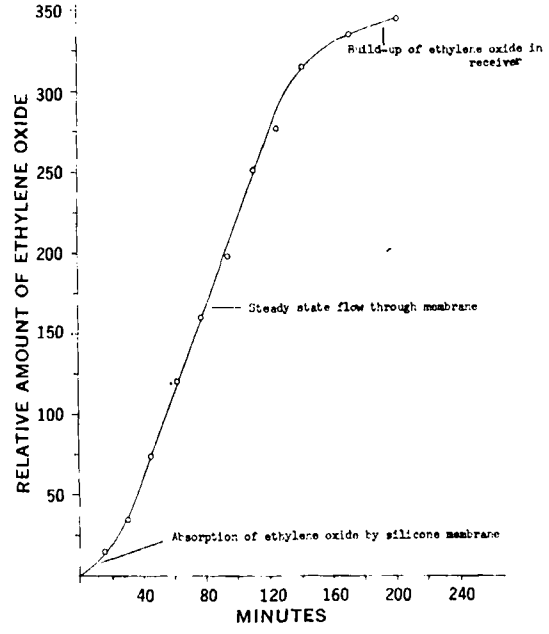

Figure 6—*Plot of amount of ethylene oxide which has diffused through a 1.0-mm. thick membrane of heat vulcanized silicone rubber* versus *time.*

Table II—Diffusion Coefficient of Ethylene Oxide in Silicone Sheeting at 23°

Material	Mean Thickness, mm.	Diffusion Coefficient, $cm.^2\ sec.^{-1}$
Room temperature vulcanized silicone	1.0	7.7×10^{-6}
	2.0	8.0×10^{-6}
Heat vulcanized silicone sheeting	1.0	4.3×10^{-6}
	1.6	4.2×10^{-6}

study to predict minimum aeration time using the diffusion coefficient. The body of the device, comprising the electronic components enclosed in room temperature vulcanized silicone, measured 38 mm. in diameter and was 10.8 mm. deep. Attached to it were two 23 mm. long wire leads, surrounded by heat vulcanized silicone approximately 0.7 mm. thick.

Two assumptions were made in working out the theoretical aeration time for the level of residual ethylene oxide to fall to a low value: (*a*) the body of the device could be considered as being composed entirely of room temperature vulcanized silicone, and (*b*) the silicone would contain a maximum of 13,000 p.p.m. ethylene oxide after sterilization. (This value comes from the previous experiments on this material.)

The first assumption is not entirely unjustified since any void areas in the center of the electronics compartment will have attained the equilibrium concentration of ethylene oxide throughout the surrounding silicone. Since the half-time for this thickness of silicone is approximately 170 min. at 23°, after sterilization at 50° for 1 hr. a uniform equilibrium concentration of absorbed ethylene oxide (13,000 p.p.m.) will probably not have been achieved.

Ignoring losses from the sides of the body, the time necessary to fall to 10 p.p.m. ethylene oxide was calculated using Eq. 1 and the experimental value of the diffusion coefficient of ethylene oxide in room temperature vulcanized silicone at 23°; the time was found to be about 27 hr.

This value was tested using the implant device described. The article, wrapped in the routine paper-polypropylene pack which presents no barrier to the passage of ethylene oxide gas, was subjected to the normal sterilizing procedure, *i.e.*, exposure to 1200 mg. ethylene oxide/l. for 1 hr. at 50°, followed by seven automatic evacuation cycles of the chamber. Aeration at the ambient temperature (23°) was for 24 hr., after which the analysis was carried out; 4 p.p.m. ethylene oxide was detected.

CONCLUSIONS

This study shows that the diffusion of ethylene oxide in nonreinforced medical-grade silicone (heat or room temperature vulcanized) is extremely rapid and that in the case of relatively simple shapes the minimum aeration time required to eliminate ethylene oxide can be obtained from Eq. 1.

Dacron-reinforced silicone sheeting loses the gas at a considerably slower rate due to retention by the Dacron reinforcement, and it is recommended that a minimum aeration of 24 hr. be adopted for this material.

Comparison of Degree of Susceptibility of Hyperthyroid and Euthyroid Animals to Cardiac Glycoside-Induced Arrhythmias

EMMANUEL B. THOMPSON

Abstract □ The present studies were performed to determine the arrhythmogenic dose of ouabain in euthyroid and hyperthyroid guinea pigs and rabbits. The animals were made hyperthyroid by daily injection of thyroxine 100 mcg./kg. i.p. for 10–14 days. Cardiovascular responses, including heart rate from limb lead II electrocardiogram and arterial blood pressure, were monitored. By the method of analysis of variance, no significant difference was shown between the arrhythmogenic dose of ouabain in euthyroid and hyperthyroid guinea pigs. However, this difference was statistically significant in rabbits. An increase in extracellular serum calcium-ion concentration did not change the responsiveness of the myocardium to ouabain toxicity in either the euthyroid or the hyperthyroid animal. In addition, the β-adrenergic receptor blocking drug practolol (10 mg./kg.) was ineffective in completely abolishing the resting tachycardia in hyperthyroid rabbits. These studies do not support the idea of decreased responsiveness to cardiac glycosides due to the hyperthyroid state.

Keyphrases □ Ouabain-induced arrhythmias in hyperthyroid and euthyroid guinea pigs and rabbits—species differences, effect of extracellular calcium and practolol □ Cardiac glycoside-induced arrhythmias in hyperthyroid and euthyroid guinea pigs and rabbits—species differences, effect of extracellular calcium and practolol □ Arrhythmogenic response to ouabain—comparison between euthyroid and hyperthyroid guinea pigs and rabbits □ Hyperthyroid and euthyroid guinea pigs and rabbits—degree of susceptibility to ouabain-induced arrhythmias compared

There is now abundant evidence (1, 2) that the hyperthyroid state is usually associated with increased sensitivity of the myocardium to various drugs. In addition to sympathomimetic amines, these drugs include histamine, cocaine, endotoxin, monoamine oxidase (MAO) inhibitors, and barbiturates (3). Evidence also exists that thyroid hormones influence the excitability of the myocardial conducting system. For instance, feeding rabbits with thyroid extract made the rabbit hearts more susceptible to epinephrine arrhythmias, such as atrial fibrillation and ventricular tachycardia (4). Other studies (5–7) showed that hyperthyroidism is a common cause of atrial fibrillation and other supraventricular arrhythmias, whereas irregularities of cardiac rhythm are rare in myxedema.

However, the findings of other investigators do not support this view of increased sensitivity of the myocardium in hyperthyroid conditions to certain drugs. In experimentally induced hyperthyroidism in dogs, hyperthyroid animals were more resistant to the development of ouabain-induced ventricular arrhythmias than were hypothyroid and euthyroid dogs (8) and no significant difference was found, between the arrhythmogenic doses of ouabain in hypothyroid and euthyroid animals.

The difference in response to digitalis glycosides demonstrated in experimental animals (8, 9) and clinically (1, 10) has made the question of why the thyroid state modifies the effectiveness of digitalis glycoside action an increasingly important one from the standpoint of both therapy and the potential susceptibility of the myocardium to cardiac glycoside-induced arrhythmias. The action of thyroxine in sensitizing the myocardium to biogenic amines and other drugs has been described (3) as being nonspecific.

Although it has been implied (11, 12) that intact catecholamine stores are necessary for the increased sympathetic activity and sometimes the arrhythmias observed in hyperthyroid animals, it is still equivocal whether the increased sympathetic activity seen in conditions of hyperthyroidism plays a role in the arrhythmogenic toxicity of cardiac glycosides. If such arrhythmias were dependent upon increased levels of sympathetic activity brought about by the hyperthyroid state, then these arrhythmias would occur much more readily and at lower dose levels of the cardiac glycoside in the experimentally induced hyperthyroid state than in the euthyroid state. Furthermore, this would imply an increased rather than a decreased sensitivity to the cardiac glycoside as suggested by earlier investigators (8, 9). Since digitalis toxicity is associated with myocardial potassium loss, it is also postulated (13–15) that ionic imbalance such as the acute loss of potassium from myocardial cells caused by rapid digitalization or an increase in calcium plasma levels will cause the precipitation of cardiac arrhythmias in hyperthyroid states sooner than in euthyroid conditions.

The aims of this study were: (*a*) to elucidate further the influence of excessive thyroxine on ouabain-induced changes of spontaneous heart rate and arterial blood pressure in hyperthyroid and euthyroid guinea pigs and rabbits, and (*b*) to determine if there is a difference in the arrhythmogenic dose of ouabain under such conditions.

EXPERIMENTAL

Albino guinea pigs, weighing 200–300 g., and New Zealand White rabbits, weighing 2.5–3.5 kg., of either sex, fed on a standard diet[1] and water *ad libitum* were used in these experiments. A condition of hyperthyroidism was induced by daily injection of 100 mcg./kg. i.p. of sodium levothyroxine[2] for 10–14 days. Euthyroid animals were given a daily intraperitoneal injection of normal saline in amounts equivalent to the volume of the thyroxine dose employed. Prior to each experiment, each animal was anesthetized with sodium pentobarbital[3]; the guinea pigs received 25 mg./kg. i.p. and the rabbits received an identical dose intravenously. Supplemental doses of 0.2–0.5 ml. were given as needed.

The trachea of each animal was cannulated to ensure uninterrupted respiration. A jugular vein was exposed and cannulated for

intravenous administration of drugs, and a cannulated common carotid artery was connected by means of a polyethylene catheter to a pressure transducer[4] for monitoring arterial blood pressure. Heparinized saline (sodium heparin, 10 mg./ml.) was used routinely for flushing both arterial and venous catheters. Heart rate was measured from an electrocardiogram (ECG) obtained with limb lead II needle electrodes inserted under the skin. ECG changes as well as arterial blood pressure were recorded on an ink-writing oscillograph[5]. In those experiments in which a 2 m*M* concentration of calcium chloride was administered, the solution was infused by means of an infusion pump[6] at the rate of 5.5 ml./hr. After the surgical procedure, 15–20 min. was allowed for stabilization before baseline heart rate and blood pressure were measured. Control readings were taken prior to any drug administration.

The following drugs were used: sodium levothyroxine (100 mg./ml.), sodium pentobarbital (50 mg./ml.), reserpine (25 mg./ml.), ouabain (0.5 g./ml.), calcium chloride (2 m*M* solution), and practolol (10 mg./ml.).

The values obtained from these experiments were expressed as the mean ± *SE* of six or more observations. Statistical analyses of the data were performed using conventional formulas; differences between means were tested with the Student *t* test and analysis of variance described in Goldstein (16).

Control Experiments with Hyperthyroid and Euthyroid Animals—The guinea pigs and rabbits used in this study were divided into groups of euthyroids and hyperthyroids. These animals received daily injections of normal saline and thyroxine, respectively, for a total of 14 days. Heart rate, determined from limb lead II ECG's, and arterial blood pressure were monitored every 10 min.

Following stabilization of the monitored variables, a loading dose of 25 mcg./kg. i.v. of ouabain was administered followed by 15 mcg./kg. 15 min. later and a maintenance dose of 10 mcg./kg. given every 10 min. therafter until the first signs of rhythm disturbance occurred. The end-point was taken as the appearance of three or more premature ventricular contractions or extrasystoles. The total dose of ouabain was then noted, and the means of the values for the total number of animals in the series for both euthyroid and hyperthyroid animals were compared for significance.

Experiments with Reserpine-Treated Animals—Euthyroid and hyperthyroid guinea pigs and rabbits were pretreated with 0.5–1.0 mg./kg. i.p. of reserpine for 2 consecutive days prior to the day of challenge with ouabain.

Heart rate, arterial blood pressure, and ECG changes were monitored in all animals. The total amount of intravenously administered ouabain that evoked arrhythmia was noted for each animal.

Experiments Involving Calcium Infusion—Both hyperthyroid and euthyroid rabbits and guinea pigs received calcium chloride by infusion. Prior to the ouabain administration, a continuous infusion of a 2 m*M* solution of calcium chloride *via* the cannulated jugular vein was commenced at the rate of 5.5 ml./hr. Infusion was continued for 10–20 min. before the initial dose of ouabain. The calcium chloride infusion was continued until the first signs of cardiac irregularities appeared; it was then stopped and the total amount of ouabain evoking the arrhythmias was noted.

Experiments with β-Adrenergic Receptor Blocking Drugs—The β-adrenergic receptor blocking agent practolol[7], reported (17) to have a selective cardiac blocking action, was used to determine the effect of adrenergic blockade on the increased sympathetic activity in hyperthyroid rabbits. Anesthetized animals breathing room air spontaneously were used. Doses of 1, 2, 5, and 10 mg./kg. i.v. of the blocking drug were administered on a cumulative basis at 10-min. intervals. Control readings were taken in all instances prior to practolol administration.

RESULTS

Control Experiments with Euthyroid and Hyperthyroid Animals—*Guinea Pigs*—The apparent difference in the arrhythmogenic dose of ouabain in the euthyroid and hyperthyroid states was not statistically significant (Table I). In eight animals, prior to ouabain administration the mean heart rate response was found to be 248 ± 7 beats/min. in the euthyroid state as compared to 318 ± 12 beats/min. in the hyperthyroid state (Table II). However, serial administration of ouabain intravenously produced a progressive increase in spontaneous heart rate. The arterial blood pressure responses in the resting state and during ouabain administration in the guinea pigs (Table III) were higher in hyperthyroid than in euthyroid states. Injection of ouabain caused a progressive rise in both systolic and diastolic pressures in the hyperthyroid state, while euthyroid animals demonstrated a nonuniform response.

Rabbits—With rabbits not pretreated with either reserpine or calcium, the average resting heart rate values for six animals prior to ouabain injection were 372 ± 19 beats/min. in hyperthyroid rabbits and 297 ± 8 beats/min. in euthyroid rabbits. This difference in spontaneous heart rate values between hyperthyroid and euthyroid states was statistically significant ($p < 0.01$). Unlike guinea pigs, spontaneous heart rate in euthyroid and hyperthyroid rabbits did not increase following ouabain administration.

The average total dose of ouabain evoking arrhythmias (Table I) in these two groups of rabbits was significantly different ($p < 0.025$) in both euthyroid and hyperthyroid rabbits. Arterial blood pressure values at the start of the experiment were 230 ± 8/206 ± 6 mm. Hg in hyperthyroid and 193 ± 9/173 ± 11 mm. Hg in euthyroid rabbits. Ouabain administration resulted in a slight but progressive increase in the systolic pressure of euthyroid animals. In hyperthyroid rabbits, both systolic and diastolic pressures decreased with time (Table III).

Reserpine-Treated Animals—*Guinea Pigs*—Reserpinization of guinea pigs for 2 days caused a reduction in the resting spontaneous heart rate in both euthyroid and hyperthyroid animals. These values were 204 ± 9 beats/min. and 227 ± 13 beats/min., respectively. There was an observed difference in the average values of the resting spontaneous heart rate of nonreserpinized and reserpinized euthyroid guinea pigs. Heart rate was higher in the nonreserpine-pretreated animals (248 ± 7 beats/min.) than in the pretreated group of animals (204 ± 9 beats/min.) (Table II). Similarly, the resting spontaneous heart rate value was higher in nonreserpinized hyperthyroid guinea pigs (318 ± 12 beats/min.) than in the reserpinized hyperthyroid group (227 ± 13 beats/min.). The reduction in heart rate seen in hyperthyroid guinea pigs due to reserpine pretreatment was significantly different from that of the nonreserpinized hyperthyroid animals ($p < 0.01$ analysis of variance).

The initial arterial blood pressure of 121 ± 6/96 ± 6 mm. Hg in euthyroid reserpinized guinea pigs was low compared with 151 ± 14/119 ± 19 mm. Hg pressure in the nonreserpinized animals. In hyperthyroid guinea pigs, the increased diastolic blood pressure response to ouabain injection was much more gradual than the systolic component (Table II). Although there was an apparent difference in the total dose of ouabain evoking arrhythmias in euthyroid and hyperthyroid guinea pigs, this difference was not statistically significant (Table I).

Table II—Spontaneous Heart Rate in Guinea Pigs and Rabbits following Ouabain Administration[a]

Calcium-infused rabbits	Euthyroid	283 ± 8 (6)	283 ± 12 (6)	260 ± 10 (6)	278 ± 20 (5)	300 ± 1 (1)	300 ± 1 (1)
	Hyperthyroid	342 ± 26 (6)	326 ± 23 (6)	292 ± 25 (6)	292 ± 22 (5)	320 ± 26 (3)	—

[a] Numbers in parentheses refer to number of animals tested in each group. [b] Heart rate values (mean ± *SE*). [c] p significant at 0.01% level. [d] p significant at 0.05% level.

Rabbits—Pretreatment of rabbits with reserpine also caused a reduction in the resting spontaneous heart rate in both euthyroid and hyperthyroid animals. The heart rate values were 231 ± 9 beats/min. and 280 ± 31 beats/min., respectively (Table II). Serial administration of ouabain did not change these values substantially; however, only a slight progressive increase in spontaneous heart rate occurred with time in the reserpinized hyperthyroid rabbits. The difference in the arrhythmogenic dose of ouabain between the reserpinized euthyroid rabbits and the reserpinized hyperthyroid rabbits was highly significant (Table I).

In reserpinized euthyroid rabbits, both systolic and diastolic arterial pressures declined progressively with time following ouabain administration (Table IV). However, reserpinized hyperthyroid rabbits showed an apparently consistent level of both systolic and diastolic arterial pressures.

Calcium Chloride Infusion in Animals—*Guinea Pigs*—The infusion of calcium chloride solution into euthyroid and hyperthyroid guinea pigs did not seem to affect either the spontaneous heart rate or the arrhythmogenic dose of ouabain. A comparison of the data of noncalcium-treated and calcium-treated euthyroid guinea pigs shows that there was no significant difference in the resting heart rate ($p > 0.1$). The spontaneous heart rate values were 248 ± 7 beats/min. and 242 ± 5 beats/min. in the untreated and treated animals, respectively. There was no appreciable difference in the time of onset of arrhythmia, and the arrhythmogenic doses of ouabain were numerically identical.

In both the euthyroid and hyperthyroid states, diastolic blood pressure responses were severely suppressed. This effect was more pronounced in the hyperthyroid state. The levels of arterial pressure of both calcium-infused euthyroid and hyperthyroid guinea pigs 90 min. following ouabain injection were 135 ± 10/92 ± 7 mm. Hg and 123 ± 8/75 ± 1 mm. Hg, respectively (Table II).

Rabbits—Infusion of calcium chloride in euthyroid and hyperthyroid rabbits did not appreciably increase the spontaneous heart rate response over 90 min. following ouabain injection. However, a comparison of these data with those of noncalcium-treated euthyroid and hyperthyroid rabbits (Table II) indicates only a slight increase in spontaneous heart rate due to ouabain injection. The heart rates were 318 ± 12 beats/min. in noncalcium-treated hyperthyroid compared to 342 ± 26 beats/min. in calcium-treated hyperthyroid animals ($p > 0.1$).

Calcium chloride (2 m*M* solution) infusion shortened the time required for the onset of ouabain-induced arrhythmias in euthyroid rabbits. Ventricular extrasystoles appeared early following repeated injections of ouabain in four out of six euthyroid rabbits tested. These extrasystoles occurred 20 min. later in five out of six hyperthyroid rabbits.

In both calcium-treated euthyroid and calcium-treated hyperthyroid animals, systolic blood pressure remained nearly constant whereas diastolic pressure showed a progressive decline.

Effects of β-Adrenergic Receptor Blockade in Hyperthyroid Rabbits—The resulting changes in heart rate and arterial blood pressure caused by administration of cumulative doses of practolol, a β-adrenergic receptor blocking agent, are depicted graphically in Fig. 1. Practolol produced a progressive reduction of spontaneous heart rate. However, the resting tachycardia resulting from the hyperthyroid state was decreased, but not abolished, by β-adrenergic blockade. The spontaneous heart rate prior to administration of 1 mg./kg. practolol was 363 ± 28 beats/min., and it was 299 ± 29 beats/min. after a total cumulative dose of 10 mg./kg. This reduction in heart rate was not statistically significant ($p > 0.05$).

DISCUSSION

These studies indicate that there was a varying degree of sensitivity to the arrhythmogenic dose of ouabain between the euthyroid group and hyperthyroid group of animals tested. In rabbits, the arrhythmia-evoking doses of ouabain were found to be significantly different between euthyroid and hyperthyroid groups of animals not premedicated with either reserpine or calcium as well as the reserpine-pretreated animals. However, in both calcium-treated euthyroid and hyperthyroid rabbits, this dose of ouabain was identical (Table I). Therefore, these findings suggest that the level of sensitivity to ouabain toxicity had not been altered in the guinea pig by the experimentally induced hyperthyroid state but was significantly modified in rabbits. It further suggests that experimental hyperthyroidism may modify the tolerance level to cardiac glycosides in one species of animal without significant effects in others. This modification usually results in an increase in the amount of glycoside required to attain the arrhythmia end-point. The present findings are to the contrary.

Although observations in laboratory animals suggested a relationship between many of the manifestations of thyroxine-induced hyperthyroidism and the activity of the sympathetic nervous system, the existence of such a relationship is still equivocal. The data from this study do not wholly support the assumption that intact catecholamine stores are necessary for some of the toxic effects of cardiac glycosides on the heart in hyperthyroid states. The mean arrhythmogenic dose of ouabain was slightly higher in the reserpinized guinea

pigs in the hyperthyroid state than in the reserpinized euthyroid condition. This suggests a change in responsiveness due partly to a depletion of catecholamine stores and partly to a predominance of parasympathetic activity produced by reserpine. This view is in agreement with that expressed by Cairoli and Crout (18), who found that the rate-normalizing effect of reserpine as seen by induced bradycardia in both euthyroid and thyroxine-treated unanesthetized rats could be blocked with atropine.

In rabbits, the arrhythmogenic dose of ouabain was significantly lower in the reserpinized hyperthyroid animals than in the reserpinized euthyroid animals. This observation, however, does not support those of Roberts *et al.* (19), who reported that reserpine pretreatment increased the amount of acetylstrophanthidin required to induce ventricular arrhythmias in the dog. This difference in response to ouabain in both reserpinized rabbits and guinea pigs in the hyperthyroid state still leaves an equivocal answer to the question of the role of sympathetic activity in cardiac glycoside toxicity in experimental hyperthyroidism. The present data imply that intact catecholamine stores are essential as mediators of the toxic manifestation of glycosides in hyperthyroidism in certain animal species but not in others.

Although it is known that cardiac glycosides can cause a loss of potassium ions from myocardial cells, thereby rendering the heart sensitive to increased concentrations of serum calcium, the present study shows that an increase of extracellular calcium ions, induced by an infusion of a 2 m*M* solution of calcium chloride, did not seem to make a difference in the degree of sensitivity of the heart to the arrhythmogenic dose of ouabain in either euthyroid or hyperthyroid animals.

The β-adrenergic receptor blocking agent practolol, which is known to possess a selective blocking action on the heart, failed to abolish the resting tachycardia of hyperthyroidism. This observation is explained partly on the basis of the fact that the many manifestations of hyperthyroidism are not mediated entirely by increased sympathetic activity and partly because practolol lacks a depressant activity on the myocardium. As a β-blocker, it is less potent than its congener propranolol, which had been used in the treatment of tachycardia in thyrotoxic patients (20–22). The reduction of the resting tachycardia from control values by different doses of practolol was not statistically significant at all dose levels ($p > 0.05$). These observations suggest either that the blockade was incomplete or that nonadrenergic factors continue to sustain cardiac hyperactivity in the hyperthyroid state.

SUMMARY AND CONCLUSIONS

The present investigation permitted the further elucidation of the relationship of the thyroid state and increased sympathetic activity and their contribution to any altered sensitivity of the myocardium to cardiac glycosides. Of particular interest was the finding that an increase in extracellular serum calcium ions did not change the responsiveness of the myocardium to ouabain toxicity in either euthyroid or hyperthyroid animals.

Furthermore, euthyroid and hyperthyroid guinea pigs responded differently from rabbits in certain drug treatments. This observation may partly explain the contrasting findings of Goodkind *et al.* (23), who found that myocardial norepinephrine concentration in guinea pig ventricles increased in hyperthyroidism, and those of Kurland *et al.* (24), who showed that the norepinephrine concentration in rabbit ventricles was decreased in hyperthyroidism and increased in hypothyroidism.

The β-adrenergic receptor blocking drug practolol was ineffective in normalizing resting tachycardia in hyperthyroid rabbits at the dose levels used in these studies. Although these studies have pointed out definite differences in some cardiovascular responses in the euthyroid and hyperthyroid states, the findings with regard to the arrhythmia threshold in euthyroid and hyperthyroid animals, in reserpinized animals as well as in calcium-treated animals, only help to confirm further the observations of earlier investigators and to point out that the factor or factors responsible for this change in myocardial response to cardiac glycosides in hyperthyroidism are still unknown.

The answers to these questions will most likely be found in the elucidation of other mechanisms at the molecular level since the direct effects of excessive blood level of thyroxine on myocardial cells are still obscure.

Coumarins XII: Synthesis of (±)-*cis*- and *trans*-3′,4′-Dihydroxy-3′,4′-dihydroxanthyletin and Their Diesters

SAMIR M. EL-ANTABLY* and T. O. SOINE▲

Abstract □ (±)-*cis*-3′,4′-Dihydroxy-3′,4′-dihydroxanthyletin was synthesized from xanthyletin by the use of osmium tetroxide. It was also obtained, unexpectedly, by acid or base hydrolysis of (±)-*trans*-3′-acetoxy-4′-(*m*-chlorobenzoyloxy)-3′,4′-dihydroxanthyletin and, spontaneously, by recrystallization of the product from epoxidation of xanthyletin with trifluoroperacetic acid. (±)-*trans*-3′,4′-Dihydroxy-3′,4′-dihydroxanthyletin was obtained together with the (±)-*trans*-3′-hydroxy-4′-acetoxy derivative by peracetic acid treatment of xanthyletin. The diacetates, dipropionates, and di-*n*-butyrates of both the *cis*- and *trans*-diols were prepared together with the *trans*-3′-propionoxy-4′-acetoxy- and 3′-*n*-butyroxy-4′-acetoxy-3′,4′-dihydroxanthyletins. NMR studies of the diols and the diesters were carried out to establish chemical shifts of specific groups, with special emphasis on the 2′-gem-dimethyls together with the *J* values for the 3′- and 4′-protons as diagnostic features for the *cis*- or *trans*-configuration.

Keyphrases □ Xanthyletin derivatives—synthesis and structure determination of (±)-*cis*- and *trans*-3′,4′-dihydroxy-3′,4′-dihydroxanthyletin and diesters □ Dihydroxy-3′,4′-dihydroxanthyletin, (±)-*cis* and *trans*, and diesters—synthesis and structure determination □ Coumarin derivatives—synthesis and structure determination of (±)-*cis*- and *trans*-3′,4′-dihydroxy-3′,4′-dihydroxanthyletin and diesters

Naturally occurring pyranocoumarins, also known as chromeno-α-pyrones, have been known since the initial isolation of xanthoxyletin (I*b*) by Staples (1) in 1829, although its structure was not established until 1936 (2). Subsequent isolations and structural studies revealed three different basic ring fusions which may be said to be derived from xanthyletin (I*a*), alloxanthyletin (II*a*), and seselin (III*a*). The xanthyletin type is comprised of xanthyletin (I*a*), xanthoxyletin (I*b*), and luvangetin (I*c*). In the alloxanthyletin series, the known compounds are alloxanthoxyletin (II*b*), calophyllolide (II*c*), and inophyllolide (II*d*). Only two representatives of the seselin type are presently known: seselin (III*a*) and braylin (III*b*).

It was not until 1957 that the now well-known 3′,4′-diesters derived from 3′,4′-dihydroseselin were isolated and structurally characterized by Bencze *et al.* (3) when they described samidin (IV*a*) and visnadin (IV*b*). Their work was quickly followed by that of Smith *et al.* (4) who, in addition, characterized dihydrosamidin (IV*c*). Since then, a number of these diesters have been isolated and structurally elucidated (*e.g.*, 5–7) and their widespread presence in umbelliferous plants has been established. In addition, following the isolation and structural elucidation of lomatin (3′-hydroxy-3′,4′-dihydroseselin) (IV*d*) (8), esters of this coumarinic alcohol were reported (9, 10).

With respect to the corresponding esters related to the linear dihydro-I*a*, the first discoveries were the 3′-monoesters, namely, decursin (V*a*) (11) and the corresponding angelate (V*b*) (12). The present work was initiated in the hope that, eventually, the 3′,4′-diesters derived from 3′,4′-dihydroxy-3′,4′-dihydroxanthyletin would be isolated and that knowledge gained from the synthesis of known derivatives would be useful for characterization of such compounds. Indeed, during these studies the first such compound, xanthalin (V*c*), was reported from *Xanthogalum purpurascens* Lall. by Sokolova *et al.* (13) and provided an excellent corroboration of other findings (14). Since then Zheleva and coworkers (15–17) assigned similar structures to the coumarins of *Peucedanum arenarium*, and configurational assignments (17) have relied on the present work.

DISCUSSION

Xanthyletin (I*a*) was utilized as the starting point in the present work. This material is readily obtainable in a relatively pure form through the petroleum ether extraction procedure of King *et al.* (18) from the heartwood of East Indian satinwood, *Chloroxylon swietenia*. Recrystallization from warm methanol according to the procedure of Lemmich *et al.* (12) provided a means of separating xanthyletin from the accompanying xanthoxyletin in a form sufficiently pure for synthetic work. The xanthyletin thus obtained, when subjected to TLC on silica gel, showed only traces of xanthoxyletin when examined in the dark under UV light, both being highly fluorescent. The identity of xanthyletin was established by direct

comparison with an authentic sample[1], and it was also identical in all respects to the same compound reported by Alpin and Page (19).

The objective was to utilize Ia to prepare both the *cis*- and *trans*-3′,4′-dihydroxy-3′,4′-dihydroxanthyletins (VIa and VIIa, respectively). It was anticipated that physical data on a number of diester derivatives could be obtained suitable for future structural studies since, aside from optical activity and melting-point differences, these would be useful models related to their natural counterparts.

Compound VIa was prepared by the action of osmium tetroxide on Ia. The diol so obtained showed a strong IR hydroxyl absorption band at 3450 cm.$^{-1}$, and the NMR spectrum (Table I) showed a coupling constant for the 3′- and 4′-protons of 4 Hz. as well as

two singlets for the gem-dimethyl groups at 1.29 and 1.42 p.p.m. Compound VIa was converted to the diacetate (VIb), m.p. 172–173°, and it was also obtained in an attempt to prepare 3′,4′-epoxyxanthyletin by treating Ia with *m*-chloroperbenzoic acid. The oily product showed a hydroxyl absorption band at 3400 cm.$^{-1}$. The crude product was treated with sulfuric acid in dimethyl sulfoxide so that any epoxide present would be hydrolyzed to the diol. The product was a glass and showed an identical IR pattern to the untreated oily material, indicating that the epoxide ring opening had probably occurred in the original reaction mixture to generate a *trans*-hemiester of the diol in a manner similar to that previously reported (12). Acetylation of the crude product afforded *trans*-3′-acetoxy-4′-(*m*-chlorobenzoyloxy)-3′,4′-dihydroxanthyletin (VIIb). The IR spectrum did not show hydroxyl absorption, and the NMR spectrum (Table I) revealed a considerable difference in the chemical shifts of the gem-dimethyl protons and $J_{3',4'} = 6$ Hz.

Compound VIIb was subjected to both acid and base hydrolysis in an effort to obtain the *trans*-diol (VIIa), but only the *cis*-diol (VIa) was obtained. The products obtained in both cases showed identical IR and NMR spectra to those of VIa, and TLC failed to show detectable amounts of VIIa. Acetylation of these products gave diacetoxy derivatives, each identical to VIb as determined by melting point, mixed melting point, and IR and NMR spectra. Another surprising route to the *cis*-diol (VIa) was encountered during an attempted epoxidation of Ia with trifluoroperacetic acid (20). The product, m.p. 144–145°, when recrystallized from methanol, showed a large change in melting point which corresponded to that of the *cis*-diol (VIa). The identity of the product was confirmed by IR and NMR spectral properties and by acetylation to

[a] The solvent in these cases was dimethyl sulfoxide-d_6.

VI*b*. *cis*-3′,4′-Diacetoxy-3′,4′-dihydroseselin (IV*e*) was prepared to compare its NMR spectrum with that of VI*b*. Compound IV*e* did not differ greatly from VI*b* (Table I) in that it showed (in $CDCl_3$) 1.40 [6H, 2s, $C_{2'}$—$(CH_3)_2$], 2.04 and 2.09 (6H, 2s, 2-$OCOCH_3$), 5.20 (1H, d, $C_{3'}$—H), and 6.38 (1H, d, $C_{4'}$—H) p.p.m. with $J_{3',4'}$ = 5 Hz.

The reason for the virtually exclusive formation of the *cis*-diol (VI*a*) over the *trans*-diol (VII*a*) in these hydrolytic procedures is not readily apparent, since mixtures of the *cis*- and *trans*-diols occur routinely from alkaline saponification of 3′,4′-diacyloxy-3′,4′-dihydroseselins (3). Although speculative, this might be ascribed to the hydrogen-bonding stability in both the *cis*- and *trans*-diols derived from the seselin series in which the 4′-hydroxy group can hydrogen bond with the lactone ether oxygen, a situation that cannot possibly take place in the series derived from xanthyletin. The behavior of VII*b* on treatment with methanolic potassium hydroxide may have bearing on the possibility of hydrogen bonding of the hydroxyl groups being influential in the virtually exclusive formation of the *cis*-diol (VI*a*). Because a methoxyl group would now occupy the 4′-position, the possibility of hydrogen bonding would be minimized. Ordinarily, as in the seselin-derived series, based on the suggested enone mechanism (4), a mixture of *cis*- and *trans*-isomers should result. In the present case, however, the IR and NMR spectra (Table I) were completely compatible with the assignment of a *trans*-structure. This compound (VII*c*) was acetylated to provide *trans*-3′-acetoxy-4′-methoxy-3′,4′-dihydroxanthyletin (VII*d*) which, by IR, showed no hydroxyl absorption; the NMR showed (in dimethyl sulfoxide-d_6) the presence of the methyl ether singlet at 3.58 p.p.m. in VII*c* and at 3.52 p.p.m. in VII*d* as well as a singlet for acetoxymethyl at 2.12 p.p.m. A *trans*-assignment for the 3′,4′-substituents was tentatively made on the basis of the substantial separation of the gem-dimethyl singlets and the variable $J_{3',4'}$ for VII*c* and VII*d*.

The *cis*-dipropionoxy and *cis*-di-*n*-butyroxy esters (VI*c* and VI*d*) were prepared in addition to VI*b*. The IR spectra of the prepared esters showed no hydroxyl absorption, and they all possessed virtually the same NMR pattern (Table I) except for differences in the acid moieties. The differences in chemical shifts of the gem-dimethyl singlets (1.29 and 1.42 p.p.m.) noted in the diol was eliminated in the diesters (1.45 p.p.m.). Previously (12), *cis*-3′,4′-dihydroxy-3′,4′-dihydroseselin (*i.e.*, *cis*-khellactone, IV*f*) showed only a small difference in the chemical shifts of the gem-dimethyl groups (1.41 and 1.44 p.p.m.) with $J_{3',4'}$ = 5 Hz. This same diol was prepared in the present study. No difference was found in the chemical shifts of the gem-dimethyl groups with only a singlet at 1.42 p.p.m. It was also reported (12) that *trans*-3′,4′-dihydroxy-3′,4′-dihydroseselin (*i.e.*, *trans*-khellactone) showed 1.31 and 1.51 p.p.m. for the gem-dimethyl groups and $J_{3',4'}$ = 6.9 Hz. In the present study, *trans*-khellactone (3) and its diacetate were prepared, and the NMR spectra were found to be identical to those reported (12).

The preparation of the *trans*-diol (VII*a*) was finally achieved while attempting to prepare 3′,4′-epoxyxanthyletin using 40% peracetic acid in acetic acid. Epoxidation of xanthyletin with peracetic acid resulted, as previously observed with *m*-chloroperbenzoic acid (12), in spontaneous opening of the epoxide by acetate anion. Workup of the reaction mixture first provided *trans*-3′-hydroxy-4′-acetoxy-3′,4′-dihydroxanthyletin (VII*e*), the IR of which showed hydroxyl absorption at 3400 $cm.^{-1}$; the NMR spectrum (Table I) possessed two widely separated signals for the gem-dimethyls (*i.e.*, 1.35 and 1.51 p.p.m.) and $J_{3',4'}$ = 7 Hz. The mother liquor, upon concentration, yielded a crystalline diol which had a different melting point than VI*a* and depressed its melting point on admixture. The IR of the diol exhibited a strong hydroxyl band at 3400 $cm.^{-1}$, and the NMR spectrum (Table I) showed two singlets for the gem-dimethyls at 1.22 and 1.47 p.p.m. and $J_{3',4'}$ = 9 Hz. Acetylation of the diol and VII*e* resulted in the same diacetoxy derivative (VII*f*) as evidenced from the melting point, mixed melting point, and IR and NMR spectra. VII*f* possessed different physical constants and spectra from those of the *cis*-diacetoxy derivative (VI*a*). Additional evidence for the *trans*-structure was obtained from the preparation of *trans*-dipropionoxy-, *trans*-di-*n*-butyroxy-, *trans*-3′-acetoxy-4′-propionoxy-, and *trans*-3′-acetoxy-4′-*n*-butyroxy-3′,4′-dihydroxanthyletins (VII*g*, VII*h*, VII*i*, and VII*j*, respectively). Each *trans*-diester (VII*g* and VII*h*) possessed a different melting point from that of the corresponding *cis*-diester (*i.e.*, VI*c* and VI*d*). All of the *trans*-diesters prepared had nearly identical NMR spectra except for differences due to the acyloxy groups, and they showed $J_{3',4'}$ = 6 Hz. and widely separated signals for the gem-dimethyl groups at 1.38 and 1.45 p.p.m. They were significantly different from the *cis*-diesters, which showed $J_{3',4'}$ = 4 Hz. and only one signal for the gem-dimethyl groups at 1.45 p.p.m.

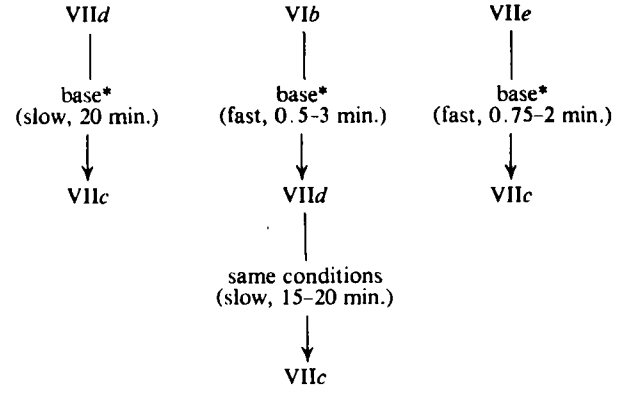
It was hoped that mild acid hydrolysis of VII*e* would result in the *trans*-diol (VII*a*) but, unfortunately, the NMR spectrum of the diol obtained showed that the hydrolysis resulted in a mixture of *cis*- and *trans*-diols; characteristic signals for each were observed in the spectrum of the product. Presumably, the milder conditions in this hydrolysis did not result in complete conversion of VII*e* to the *cis*-diol as was the case in the acid hydrolysis of VII*b* where VI*a* appeared to be virtually the exclusive product. On the basis of these experimental findings, together with the NMR data, it appears very probable that the product isolated from the mother liquor of the peracetic acid epoxidation reaction was the *trans*-diol (VII*a*). Therefore, the identity and physical characteristics of the *cis*- and *trans*-diols (VI*a* and VII*a*, respectively) are established.

As a result ot this study, it has been possible to draw conclusions regarding the NMR spectra of the 3′,4′-diols and diesters derived from 3′,4′-dihydroxanthyletin, as well as to establish the relationships between these compounds and those of the isomeric series derived from seselin.

With the *cis*-diol and its diesters, $J_{3',4'}$ was invariably 4 Hz. regardless of the substituent, a situation quite similar to that obtained with naturally occurring 3′,4′-dihydroseselin diesters where $J_{3',4'}$ was invariably 5 Hz. The *trans*-diol and its diesters prepared in this study showed a variability of $J_{3',4'}$ from 6 to 9 Hz., together with well-separated singlets for the gem-dimethyl group ranging from 1.22 to 1.51 p.p.m. If only xanthyletin *trans*-diesters are considered, however, $J_{3',4'}$ was consistently 6 Hz., combined with a well-defined spread ranging from 1.38 to 1.45 p.p.m. for the gem-dimethyl singlets. The generalization of Lemmich *et al.* (12) seems to hold with respect to the diagnostic requirement that well-separated gem-

dimethyl signals are indicative of the *trans*-arrangement and that little or no separation of these signals suggests the *cis*-arrangement. However, within the limited spectra of the diesters prepared in this study, the variability of $J_{3',4'}$ noted in the seselin-derived *trans*-compounds (12) has not been observed, with the single exception of the parent diol (VII*a*) itself[2].

Although there seemed to be little question concerning the assignments of the respective locations (*i.e.*, 3′ and 4′) of the acetoxy moieties in VII*d* and VII*e*, it was desirable to substantiate them independently. A relatively simple experiment was carried out by taking advantage of the greatly differing rates of hydrolysis of 3′- and 4′-acyloxy substituents in these compounds. The 3′-ester groups are subject to a normal basic hydrolysis whereas the 4′-ester groups are much more labile on the basis of the special mechanism referred to earlier (4). Therefore, by carrying out the reaction of methanolic potassium hydroxide on VII*d*, VII*e*, and VI*b*, it appeared possible to follow the rates of change by means of TLC and, thereby, to show that in VII*d* the rate of saponification is relatively slow whereas in VII*e* the rate of generation of the deacylated compound is comparatively much more rapid. The experience with VI*b* was in complete accord with the expected fast loss of 4′-acetate and the slower loss of the remaining 3′-acetate group. The data recorded in Scheme I summarize the results, which clearly substantiate the positions assigned to the acetoxy moieties in VII*d* and VII*e*.



*Scheme I—Base (*0.01 N methanolic potassium hydroxide) hydrolysis of VII*d, *VII*e, *and VI*b *at room temperature*

EXPERIMENTAL[3]

Extraction of Xanthyletin (I*a*)—Fine wood shavings (600 g.) of *Chloroxylon swietenia* were exhaustively extracted[4] for 5 days with petroleum ether (b.p. 30–60°) in a soxhlet apparatus. The solvent was removed by distillation, and the yellow crystalline material remaining was recrystallized from warm methanol to obtain colorless needles of xanthyletin, m.p. 128–130° [lit. (18) m.p. 126–127°]. TLC, in comparison with an authentic specimen[1], indicated the identity of the two samples. TLC was carried out on silica gel impregnated with formamide and developed with either dibutyl ether or *n*-hexane[5]-cyclohexane (1:1); a mixed melting-point comparison was also made.

***cis*-3′,4′-Dihydroxy-3′,4′-dihydroxanthyletin (VI*a*)**—A solution of I*a* (1.45 g., 0.0063 mole) in dioxane (50 ml.) was added to a solution of osmium tetroxide (2 g., 0.0079 mole) in dioxane (50 ml.), and the mixture was kept in the dark at room temperature for 4 days. Ethyl acetate (50 ml.) was added, and a stream of hydrogen sulfide was bubbled into the reaction mixture for 2 hr. The black precipitate was removed by filtration, and the filtrate was evaporated to dryness to obtain a white crystalline material (1 g., 60.5%) which was recrystallized several times from methanol to obtain a product, m.p. 234–236°, shown to be VI*a*.

Anal.—Calc. for $C_{14}H_{14}O_5$: C, 64.11; H, 5.38. Found: C, 64.09; H, 5.52.

***cis*-3′,4′-Diacetoxy-3′,4′-dihydroxanthyletin (VI*b*)**—A mixture of VI*a* (0.2 g., 0.0008 mole), acetic anhydride (4 ml.), and anhydrous sodium acetate (0.25 g.) was refluxed for 2 hr. The hot solution was poured into ice-cold water, filtered, washed with water, and recrystallized from methanol to give 0.22 g. (85%) of VI*b*, m.p. 172–173°.

Anal.—Calc. for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24. Found: C, 62.46; H, 5.45.

***trans*-3′-Acetoxy-4′-(*m*-chlorobenzoyloxy)-3′,4′-dihydroxanthyletin (VII*b*)**—To an ice-cold solution of xanthyletin (0.6 g., 0.0026 mole) in chloroform (50 ml.) was added dropwise an ice-cold solution of *m*-chloroperbenzoic acid (80%, 0.56 g.) in chloroform (75 ml.), and the mixture was stirred at room temperature in the dark for 24 hr. The reaction mixture was successively washed with 100 ml. each of 10% sodium bicarbonate, 5% sodium iodide, 5% sodium sulfite, and, finally, water. The dried (sodium sulfate) chloroformic solution was evaporated to dryness, and the residue was dissolved in dimethyl sulfoxide (75%, 40 ml.) containing sulfuric acid (1 ml.). The mixture was stirred at room temperature for 16 hr. and then diluted with water until precipitation ceased. The white solid which separated was filtered, washed with water, and dried. The crude product was refluxed for 2 hr. with acetic anhydride (15 ml.) and anhydrous sodium acetate (1 g.), the mixture was poured into ice-cold water and filtered, and the white crystalline material obtained was recrystallized from methanol to yield 0.6 g. (54.5%) of white prisms, m.p. 165–167°.

Anal.—Calc. for $C_{23}H_{19}ClO_7$: C, 62.38; H, 4.32. Found: C, 62.34; H, 4.04.

Acid Hydrolysis of VII*b*—A solution of VII*b* (0.45 g., 0.001 mole) in a mixture of ethanol (8 ml.) and sulfuric acid (0.8 ml.) was refluxed for 3 hr. The cooled reaction mixture was diluted with water (38 ml.), and the alcohol was removed under reduced pressure. After standing for 30 min. at room temperature, the crystalline precipitate was filtered and recrystallized from methanol to obtain 0.20 g. (75%) of colorless prisms, m.p. 188–191°. In spite of the broad range of the melting point, the IR and NMR spectra were largely identical to those of VI*a*. The product was then acetylated in the same manner as for the preparation of VI*b* to yield a diacetate identical to VI*b* in melting point, mixed melting point, TLC behavior, and IR and NMR spectra. These data suggest that VI*a* obtained in this way is a dimorphic form of the higher melting product.

Base Hydrolysis of VII*b*—A mixture of VII*b* (0.6 g., 0.0014 mole) in dioxane (5 ml.) and 1 *N* aqueous potassium hydroxide (15 ml.) was allowed to stand overnight at room temperature. The mixture was then diluted with water (1000 ml.), acidified with 20% sulfuric acid, and allowed to stand for 1 hr. at room temperature. The reaction mixture was brought to pH 8 with aqueous sodium carbonate and then extracted with chloroform. The chloroformic extract was washed with water, dried (sodium sulfate), and evaporated to dryness to obtain a crystalline residue, which was crystallized from methanol to yield 0.3 g. (84.3%) of colorless crystals, m.p. 234–

[2] Lemmich *et al.* (12) discussed the relative $J_{3',4'}$ values of the *cis*- and *trans*-3′,4′-disubstituted-3′,4′-dihydroseselins in connection with their similarity to 3,4-flavandiols and their derivatives. The latter are almost frozen conformers with the 2-aryl substituent equatorial. In the above seselin derivatives and, presumably, with the corresponding xanthyletin derivatives discussed here, the observed *J* values correspond to time averages of the two possible conformations. They note that the dihedral angles of the two *trans*-conformers vary considerably whereas those of the *cis*-form are virtually the same; therefore, the conformational equilibria determine the resultant *J* values, with those for the *cis*-derivatives being relatively constant and those for the *trans*-derivatives being potentially variable depending on the substituents.

[3] Melting points were determined in capillary tubes in a Thomas-Hoover melting-point apparatus and are uncorrected. IR (KBr pellet) and UV (95% ethanol) spectra were determined on a Perkin-Elmer 237B grating IR spectrophotomer and a Cary model 14, respectively. The observed absorption bands, in each case, were in accord with the assigned structures and only values with a diagnostic function were mentioned in the previous discussion. NMR spectra were obtained on a Varian A-60D instrument using tetramethylsilane as an internal standard; the observed values, together with the solvents used, are recorded in Table I. TLC was performed on Eastman silica gel Chromagram sheets (No. 6060) unless otherwise specified as with the plates employing silica gel impregnated with formamide. In this case, a mixture of silica gel G (E. Merck AG) (30 g.), formamide (30 ml.), and distilled water (60 ml.) was shaken for 45 sec., spread over 20 glass plates 5.08 × 20.32 cm. (2 × 8 in.), and left to dry at room temperature overnight. Preparative TLC plates refer to alumina or silica gel plates (F_{254}, Brinkmann, 20 × 20 cm., 2000 μ thick). The *Chloroxylon swietenia* (Rutaceae) wood was obtained from Craftsman Wood Service Co., Chicago, Ill., and was authenticated by Mr. A. Stamm, Forest Products Laboratory, Madison, Wis. It was reduced to fine shavings with a mechanical planer prior to extraction. Other reagent chemicals were obtained from reputable sources. Analyses were performed by the Microanalytical Laboratory, University of Minnesota, and Schwartzkopf Microanalytical Laboratory, Woodside, N. Y.

[4] Skellysolve F.

[5] Skellysolve B.

236°. The product was identical to VI*a*, and acetylation in the usual manner afforded a diacetate identical to VI*b*.

***trans*-3′-Hydroxy-4′-methoxy-3′,4′-dihydroxanthyletin (VII*c*)**—A mixture of VII*b* (3g., 0.0067 mole) in methanol (120 ml.) and 1 *N* methanolic sodium hydroxide (12 ml.) was refluxed for 45 min. The cooled reaction mixture was diluted with water (60 ml.), and the alcohol was removed under reduced pressure. The aqueous layer was further diluted with water (1000 ml.), acidified with 20% sulfuric acid, and allowed to stand for 30 min. at room temperature. The pH of the mixture was adjusted to 8 with sodium carbonate solution, and the mixture was extracted thoroughly with chloroform. The extract was washed with water, dried (sodium sulfate), and stripped of solvent to yield 1.08 g. (57.7%) of a yellow crystalline material, m.p. 180–182°. The crude product was purified on 12 alumina plates which were developed in a benzene–ether (4:1) mixture. The blue fluorescent band was removed and the material was extracted with a warm methanol–acetone (1:1) mixture. The solvents were removed by evaporation, and the residue was recrystallized several times from methanol to yield 0.84 g. (44.9%) of white prisms, m.p. 185–186°.

Anal.—Calc. for $C_{15}H_{16}O_5$: C, 65.21; H, 5.48. Found: C, 65.20; H, 5.63.

The preceding compound (VII*c*) (0.1 g., 0.00036 mole) was refluxed for 2 hr. with acetic anhydride (5 ml.) and anhydrous sodium acetate (0.25 g.). The hot solution was poured into ice-cold water, and the precipitated crystalline material was filtered and washed with water. Recrystallization from methanol–water provided 0.09 g. (80%) of a colorless acetate, m.p. 134–135°.

Anal.—Calc. for $C_{17}H_{18}O_6$: C, 64.14; H, 5.69. Found: C, 64.34; H, 5.70.

***trans*-3′-Hydroxy-4′-acetoxy-3′,4′-dihydroxanthyletin (VII*e*) and *trans*-3′,4′-Dihydroxy-3′,4′-dihydroxanthyletin (VII*a*)**—A mixture of I*a* (2.85 g., 0.0125 mole), sodium acetate trihydrate (2.5 g.), and chloroform (50 ml.) was stirred in an ice bath. Peracetic acid in acetic acid (40%, 7.5 ml., ~ 0.04 mole) was added dropwise, and the reaction mixture was stirred in an ice bath for 2 hr. and then at room temperature for a total of 14 hr. The mixture was successively washed with water, 5% sodium bicarbonate, and water. The extract was dried (sodium sulfate) and stripped of solvent to obtain a colorless glass, which crystallized on treatment with benzene–hexane[5] (1:1) and was recrystallized from methanol to give VII*e* (1.8 g., 47.3%), m.p. 166–168°, as colorless prisms.

Anal.—Calc. for $C_{16}H_{16}O_6$: C, 63.15; H, 5.30. Found: C, 63.13; H, 5.38.

The combined mother liquors were evaporated to dryness, and the crude residue was purified by chromatography on six preparative silica gel plates. The plates were developed with a chloroform–methanol mixture (39:1) and air dried, and the two blue fluorescent bands which formed were removed from the plates. Each band was eluted with warm methanol–acetone (1:1) and, when the solvents were evaporated, the component with the higher R_f value (0.2 g.) was found to be identical to VII*e* (total yield 2 g., 52.6%). The second component was crystallized several times from methanol–water to obtain colorless crystals (0.98 g., 30%) of VII*a*, m.p. 194–196°.

Anal.—Calc. for $C_{14}H_{14}O_5$: C, 64.11; H, 5.38. Found: C, 63.97; H, 5.60.

Acetylation of VII*a* and VII*e* in the usual manner afforded, in each case, a virtually quantitative yield of *trans*-3′,4′-diacetoxy-3′,4′-dihydroxanthyletin (VII*f*) as colorless crystals from methanol, m.p. 189–191°.

Anal.—Calc. for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24. Found: C, 62.21; H, 5.32.

Acid Hydrolysis of VII*e*—A mixture of VII*e* (0.18 g., 0.00058 mole) in 5% hydrochloric acid (3 ml.) was stirred on a steam bath for 45 min. and poured into water (50 ml.); the resulting mixture was extracted with ether (4 × 100 ml.). The ethereal extract was washed once with 5% sodium bicarbonate (100 ml.) and then water, dried (sodium sulfate), and stripped of solvent. The crystalline residue was recrystallized from dilute methanol to yield colorless crystals (0.11 g., 73.3%), m.p. 181–183°. Its NMR spectrum indicated that it was a mixture of VI*a* and VII*a* and, because of the small amount of material, separation into its components was not attempted.

Epoxidation of Xanthyletin with Trifluoroperacetic Acid—An ice-cold stirred suspension of hydrogen peroxide (90%, 0.6 ml., 0.02 mole) in methylene chloride (5 ml.) was treated with trifluoroacetic anhydride (3.7 ml., 0.026 mole); the mixture was stirred for 10 min. and then transferred to a dropping funnel. The mixture was added dropwise (20 min.) to a stirred ice-cold solution of I*a* (4.56 g., 0.02 mole) and triethylammonium trifluoroacetate (2.14 g., 0.01 mole) in methylene chloride (25 ml.), and the mixture was stirred at room temperature for 17.5 hr. according to the method of Emmons *et al.* (20). The volatile solvents were removed under reduced pressure, and the brown residual oil was dissolved in benzene (200 ml.) and then washed with water (2 × 75 ml.), dried (sodium sulfate), and stripped of solvent. The brownish residue was crystallized from benzene–*n*-hexane[5] to give 3.39 g. (70%) of pale-yellow crystals, m.p. 144–145°[6]. Recrystallization from warm methanol, however, afforded colorless crystals, m.p. 226–228°. These, when acetylated in the usual fashion with anhydrous sodium acetate and acetic anhydride, gave a crystalline diacetate, m.p. 172–173°, identical to VI*b*.

***cis*-3′,4′-Dipropionoxy-3′,4′-dihydroxanthyletin (VI*c*)**—A mixture of VI*a* (0.1 g., 0.0004 mole), propionic anhydride (1.5 ml., 0.012 mole), and pyridine (0.5 ml.) was refluxed for 4 hr. and poured into an excess of ice-cold water. The brown oil which separated was extracted with ether (4 × 100 ml.), and the extract was then successively washed with 100-ml. portions of 5% hydrochloric acid, 5% sodium bicarbonate, and water. The extract was dried (sodium sulfate) and filtered, and the ether was evaporated to obtain a brown semisolid residue (1.25 g.). This residue was chromatographed on 10 preparative silica gel plates with a mixture of benzene–ethyl acetate (7:3). The blue fluorescent band (visualized under UV light) was removed and extracted with a warm mixture of acetone–methanol (1:1). The solvents were evaporated, and the residue was recrystallized several times from methanol–water to give colorless crystals of VI*c* (0.9 g., 60%), m.p. 115–116°.

Anal.—Calc. for $C_{20}H_{22}O_7$: C, 64.16; H, 5.92. Found: C, 63.87; H, 5.93.

***cis*-3′,4′-Di-*n*-butyroxy-3′,4′-dihydroxanthyletin (VI*d*)**—This was prepared in a manner similar to that for VI*c* from VI*a* using *n*-butyric anhydride and pyridine. The product, m.p. 80–81°, was obtained in 80% yield.

Anal.—Calc. for $C_{22}H_{26}O_7$: C, 65.65; H, 6.51. Found: C, 65.59; H, 6.32.

***trans*-3′-Propionoxy-4′-acetoxy-3′,4′-dihydroxanthyletin (VII*i*)**—This was prepared as for VI*c* from VII*e*, using propionic anhydride and pyridine, in 76% yield, m.p. 108–109°.

Anal.—Calc. for $C_{19}H_{20}O_7$: C, 63.33; H, 5.59. Found: C, 63.44; H, 5.61.

***trans*-3′-*n*-Butyroxy-4′-acetoxy-3′,4′-dihydroxanthyletin (VII*j*)**—This was prepared as for VI*c* from VII*e*, using *n*-butyric anhydride and pyridine, in 80% yield, m.p. 131–132°.

Anal.—Calc. for $C_{20}H_{22}O_7$: C, 64.14; H, 5.92. Found: C, 64.41; H, 5.94.

***trans*-3′,4′-Dipropionoxy- and *trans*-3′,4′-Di-*n*-butyroxy-3′,4′-dihydroxanthyletins (VII*g* and VII*h*)**—These compounds were prepared from VII*a* and the corresponding anhydride as described previously for VI*c* to obtain crystalline derivatives in 62% yield, m.p. 122–124°, and 69% yield, m.p. 76–77°, respectively.

Anal.—Calc. for VII*g*, $C_{20}H_{22}O_7$: C, 64.14; H, 5.92. Found: C, 64.45; H, 6.17.

Anal.—Calc. for VII*h*, $C_{22}H_{26}O_7$: C, 65.65; H, 6.51. Found: C, 65.59; H, 6.73.

Action of Methanolic Potassium Hydroxide on VII*d*, VI*b*, and VII*e*—To a solution of VII*d* (0.1 g.) in methanol (4 ml.) was added dropwise at room temperature a solution of 0.1 *N* methanolic potassium hydroxide until the mixture became alkaline to litmus paper. Portions of the solution were withdrawn at intervals, acidified with 2% hydrochloric acid, spotted on silica gel plates, developed with benzene–methanol (9:1), and examined in the dark under UV light. The starting material remained unaffected for the first 20 min. and then slowly disappeared as two spots with lower mobility appeared corresponding to VII*c* and VI*a*. The same experiment was repeated

[6] The identity of this product, unfortunately, was not determined unambiguously before it was recrystallized from methanol, during which process it increased markedly in melting point. Although speculative, it is possible that it could have been *trans*-3′-hydroxy-4′-trifluoroacetoxy-3′,4′-dihydroxanthyletin, obtained in much the same way as the 3′-hydroxy precursor to VII*b* described elsewhere in this paper. Hydrolysis during the heating with methanol could conceivably have then produced the higher melting VI*a*.

using VI*b*. TLC analysis after 30 sec. indicated only a very faint fluorescent spot of VI*b* remaining and a strongly fluorescent spot corresponding to VII*d*. The starting material disappeared completely in 3 min. After 15 min., two additional spots appeared corresponding to VII*c* and VI*a*. Finally, VII*e* was treated in the same manner as VII*d* and VI*b*. TLC analysis after 45 sec. revealed two spots, a faint one corresponding to VII*e* and a stronger spot corresponding to VII*c*. After 2 min., the starting material had disappeared and an additional spot corresponding to VI*a* appeared.

Altered Bioavailability of Drugs in the Eye Due to Drug-Protein Interaction

THOMAS J. MIKKELSON*, SUKHBIR S. CHRAI, and JOSEPH R. ROBINSON▲

Abstract □ The biological activity of a number of ophthalmic drugs is influenced by drug-protein interaction in tissues and fluids of the eye. High concentration of protein in lacrimal fluid, in both normal and pathological states, coupled with a relatively rapid turnover of this fluid, which moves drug solution away from the eye, leads to a considerable loss in drug activity for drugs that bind to protein. High levels of protein, as occur in some pathological states, and a slower, but substantial, turnover rate of aqueous humor can also lead to significant drug loss and a decrease in drug activity for compounds that complex with proteins. The present study, utilizing both *in vitro* and *in vivo* experiments, shows that drug-protein interaction in tissues and fluids of the eye occurs and that this interaction has an enormous influence on drug bioavailability. Equilibrium dialysis experiments, using pilocarpine nitrate, sulfisoxazole, and methylprednisolone, demonstrated that extensive binding to proteins in tears, cornea, and aqueous humor does occur. In addition, pupillary diameter experiments, using pilocarpine nitrate as the test agent, illustrated the influence of drug-protein interaction on drug bioavailability. A discussion of drug binding in combination with tear and instilled fluid dynamics is presented. It is suggested that this phenomenon can be responsible, partly or wholly, for some reported anomalous observations associated with drug therapy in the eye.

Keyphrases □ Ophthalmic bioavailability—effects of drug-protein binding, equilibrium dialysis, pupillary diameter experiments in rabbits □ Drug-protein binding—effect on bioavailability of ophthalmic drugs, equilibrium dialysis and pupillary diameter experiments

Binding of drugs to proteins can greatly affect drug activity. When this interaction occurs in tissues and fluids that are turned over at appreciable rates, and from which drug absorption must occur, the problem becomes even more severe, since both free drug and its reservoir of bound drug are being lost. Lacrimal fluid in both normal and pathological states contains appreciable quantities of protein and is turned over at rapid rates, while aqueous humor in some pathological conditions also contains large amounts of protein and is turned over at a slower but still significant rate. One could expect then that drug protein interaction in eye tissues and fluids would reduce the amount of free drug to either act locally or reach the anterior chamber

using VI*b*. TLC analysis after 30 sec. indicated only a very faint fluorescent spot of VI*b* remaining and a strongly fluorescent spot corresponding to VII*d*. The starting material disappeared completely in 3 min. After 15 min., two additional spots appeared corresponding to VII*c* and VI*a*. Finally, VII*e* was treated in the same manner as VII*d* and VI*b*. TLC analysis after 45 sec. revealed two spots, a faint one corresponding to VII*e* and a stronger spot corresponding to VII*c*. After 2 min., the starting material had disappeared and an additional spot corresponding to VI*a* appeared.

Altered Bioavailability of Drugs in the Eye Due to Drug-Protein Interaction

THOMAS J. MIKKELSON*, SUKHBIR S. CHRAI, and JOSEPH R. ROBINSON▲

Abstract □ The biological activity of a number of ophthalmic drugs is influenced by drug-protein interaction in tissues and fluids of the eye. High concentration of protein in lacrimal fluid, in both normal and pathological states, coupled with a relatively rapid turnover of this fluid, which moves drug solution away from the eye, leads to a considerable loss in drug activity for drugs that bind to protein. High levels of protein, as occur in some pathological states, and a slower, but substantial, turnover rate of aqueous humor can also lead to significant drug loss and a decrease in drug activity for compounds that complex with proteins. The present study, utilizing both *in vitro* and *in vivo* experiments, shows that drug-protein interaction in tissues and fluids of the eye occurs and that this interaction has an enormous influence on drug bioavailability. Equilibrium dialysis experiments, using pilocarpine nitrate, sulfisoxazole, and methylprednisolone, demonstrated that extensive binding to proteins in tears, cornea, and aqueous humor does occur. In addition, pupillary diameter experiments, using pilocarpine nitrate as the test agent, illustrated the influence of drug-protein interaction on drug bioavailability. A discussion of drug binding in combination with tear and instilled fluid dynamics is presented. It is suggested that this phenomenon can be responsible, partly or wholly, for some reported anomalous observations associated with drug therapy in the eye.

Keyphrases □ Ophthalmic bioavailability—effects of drug-protein binding, equilibrium dialysis, pupillary diameter experiments in rabbits □ Drug-protein binding—effect on bioavailability of ophthalmic drugs, equilibrium dialysis and pupillary diameter experiments

Binding of drugs to proteins can greatly affect drug activity. When this interaction occurs in tissues and fluids that are turned over at appreciable rates, and from which drug absorption must occur, the problem becomes even more severe, since both free drug and its reservoir of bound drug are being lost. Lacrimal fluid in both normal and pathological states contains appreciable quantities of protein and is turned over at rapid rates, while aqueous humor in some pathological conditions also contains large amounts of protein and is turned over at a slower but still significant rate. One could expect then that drug protein interaction in eye tissues and fluids would reduce the amount of free drug to either act locally or reach the anterior chamber

of the eye and potentially to alter the amount of free drug in the anterior chamber, thus decreasing the apparent biological drug activity.

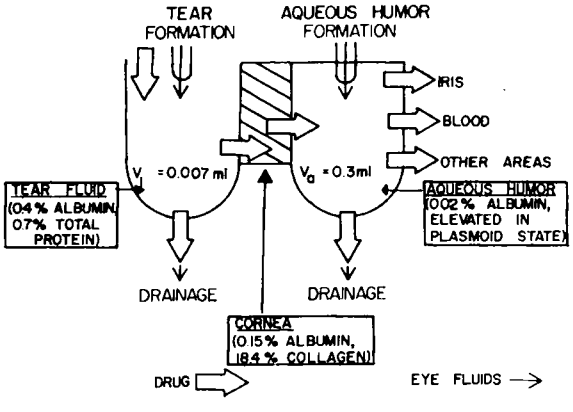
The purpose of this report is to show that protein binding of drugs to fluids and tissues of the eye can have an enormous influence on the biological activity of these drugs. It is our contention that many apparently anomalous, unexplained observations associated with drug utilization in the eye, including the difficulty in treating some disease states with conventional drugs, are explained partly or wholly by protein binding. For example, the relative unresponsiveness of uveitis conditions to steroid therapy may be due to drug–protein interaction since large amounts of protein are present in this disease state. In addition, this effect can play an important role in the total biological activity of some drugs used in ophthalmology.

Upon instillation of a drug into the eye, the drug mixes with lacrimal fluid and then is transported across several membranes until it reaches the target area. If the target area is assumed to lie posterior to aqueous humor, the drug, after mixing with tears, must cross the cornea and enter the anterior chamber, where it mixes with aqueous humor and is then transported to the target area. Scheme I illustrates the major fluid and tissue boundaries, in terms of protein content and turnover rate, that the drug contacts during its transport and distribution.

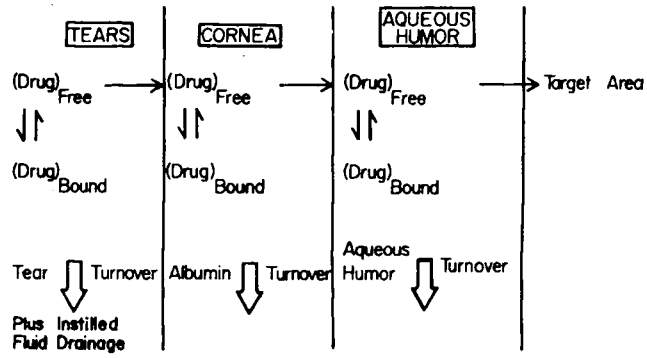
BACKGROUND

Lacrimal Fluid—The normal volume of tears present in the eye is approximately 7–10 μl. (1) in humans and about 7 μl. in rabbits (2). The turnover rate of tears in humans is about 16%/min. (1) under normal circumstances, whereas in rabbits it is 7.1%/min. (2). These turnover rates apply when the volume of fluid in the precorneal area of the eye is the normal volume. Upon instillation of fluid into the eye, the drainage of instilled solution proceeds at a rapid rate (2) until the volume is back to normal.

A significant feature of the tear composition is the presence of a relatively high concentration of protein. The total protein present in lacrimal fluid varies qualitatively and quantitatively depending upon the method of analysis, the method of obtaining tear samples, and the species of animal. A relatively conservative estimate (3) lists the albumin content of tears to be 0.4% for humans with a total protein content of approximately 0.7%, whereas for rabbits it is 0.3% albumin with a total protein content of 0.5% (4). Emotional stress, irritation, and other factors greatly influence the protein content.



Scheme I—Pictorial representation of drug and fluid movement in a portion of the human eye. Protein concentrations in tears, cornea, and aqueous humor are listed together with the normal volume of tears and aqueous humor. Large arrows depict potential drug movement, and small arrows depict eye fluid movement.



Scheme II—Potential rates and equilibria associated with drug movement through a portion of the eye

Cornea—The cornea is made up of about 80% water; the solid material present in the greatest amount is 18.4% collagen along with 0.15% albumin and globulin (5). Albumin diffuses from the peripheral capillaries toward the center of the cornea and is lost at the corneal surface to tears and aqueous humor. A transfer constant describing this turnover of albumin in humans was found to be 10–20%/day (6). Since the literature does not report this information for rabbits, their turnover rate was assumed to be similar.

Aqueous Humor—The volume of aqueous humor in humans is approximately 300 μl. with a turnover rate of approximately 1%/min. (7, 8). These figures are comparable in rabbits (9, 10).

Aqueous humor is a much more dilute fluid than blood serum under normal circumstances. The most significant difference in solid content between aqueous humor and serum is the paucity of protein found in aqueous humor. Human serum contains approximately 7.0% total protein (2.8–4.5% albumin) (11), but the aqueous humor contains only 0.01–0.02% total protein (12). The blood serum of the rabbit contains 5.6% total protein of which 4.4% is albumin, whereas rabbit aqueous humor contains approximately 0.05% total protein of which 0.025% is albumin (12).

Aqueous humor composition, particularly the protein content, is a function of the integrity of the intraocular blood vessels, *i.e.*, the blood-aqueous barrier. Various causative agents (*e.g.*, mechanical means, responses to drugs, and certain disease states) may result in partial or complete breakdown of the blood-aqueous barrier. The most striking feature of this breakdown is the concomitant increase in protein concentration of aqueous humor. The fluid that develops, termed plasmoid aqueous humor of secondary composition, can, at the extreme, possess a similar protein composition to that of plasma, representing increases from 0.02 to 7% in man and from 0.05 to 5.6% in rabbits.

From the previous description, the binding of drugs to proteins was expected with subsequent loss due to turnover in the tears, cornea, and aqueous humor as well as other tissues. The relative importance of each tissue and fluid to drug loss is a function of the type of protein, protein concentration, drug concentration and affinity for the protein, and turnover rate of fluid and tissue.

The various equilibria that occur when a drug is instilled into the eye are shown in Scheme II. Upon instillation, the drug is diluted with the lacrimal fluid and enters into a rapid equilibrium with the proteins. Only the free form of the drug is transported into the cornea. Drainage of the instilled solution plus lacrimal fluid turnover results in removal of both free and bound forms of the drug. When the drug enters the cornea, it also enters into a rapid equilibrium with the proteins. However, the turnover rate of albumin in the cornea is small enough so that removal does not present a problem unless the binding constant is very large or drug transport is very slow. Due to binding in the cornea, it would be expected that a lag time will exist before drug enters the anterior chamber and that the duration of the lag time will be proportional to the binding constant, concentration and diffusivity of drug, and thickness of the cornea. After entrance into the anterior chamber, the extent of protein binding in aqueous humor depends upon the condition of the eye and, therefore, the protein composition and content in the aqueous humor. Turnover of aqueous humor, which

is considerably slower than that of lacrimal fluid, results in drug loss. Naturally, the drug in these various fluids after parenteral administration is also subject to binding and loss.

EXPERIMENTAL

Adult, male, albino rabbits[1] were used as the experimental animals. No special pretreatment methods or diets were incorporated into the *in vivo* procedures.

Cellulose dialysis tubing[2] and crystalline rabbit serum albumin[3] were obtained from commercial sources.

Methylprednisolone[4], sulfisoxazole[5], tritiated pilocarpine nitrate[6], and *N*-1-naphthylethylenediamine dihydrochloride[7] were used; all chemicals were either USP or reagent grade.

Equilibrium Dialysis

Cells and Procedures—Two different sets of dialysis cells were utilized, depending upon the type of solution under investigation. Dialysis cells of identical half-cell chamber size of 10-ml. capacity were employed in studies to determine the binding capabilities of rabbit serum albumin. Unequal half-cell capacity cells were used for the tears, cornea, and aqueous humor studies. In the unequal half-cell experiments, the drug volume side was 5 ml. and the protein or tissue side was 1 ml.; cell thicknesses were adjusted so that differing volumes produced equivalent levels in the cells.

Protein solution or the tissue sample was placed in one half-cell chamber and drug solution was placed on the opposite side. The contents of the dialysis cells were equilibrated for 24 hr. at 25 ± 1.0° on a shaker[8]. Twenty-four hours under these conditions was sufficient for reaching equilibrium.

The equilibrium concentration of free drug in the protein-free dialysate was determined following equilibration. Assays were performed immediately after removal of the protein-free dialysate to avoid potential microbial growth which can occur upon standing. From measurement of the free drug concentration and after suitable blank corrections, the fraction of drug bound was determined.

Dialysis Membrane Preparation—Dialysis tubing was cut into strips and purified extensively prior to use (13).

Drug Solution Preparation—All drug solutions were prepared using Sørenson phosphate buffer, pH 7.38 (14). The buffer is isotonic, giving the solutions a sufficiently high ionic strength so that any discrepancies in distribution due to the Donnan effect should be minimal. Isotonic solutions include the drug solutions that were applied locally to the rabbit eye in the *in vivo* studies as well as the drug and rabbit albumin solutions employed in the *in vitro* dialysis studies.

Dialysis Solution—Crystalline rabbit serum albumin solutions, 2.89×10^{-5} *M*, were prepared in Sørenson phosphate buffer, pH 7.38.

Eight milliliters of protein solution was placed in one half-cell and 8 ml. of drug solution was placed in the opposite half of the dialysis chamber.

Corneal Tissue—The corneal tissues employed in the equilibrium dialysis binding studies were obtained from rabbits and were used fresh.

Dialysis studies on the cornea were initiated immediately following removal of the tissue, utilizing the entire intact cornea (without pulverization). The corneas were placed in the dialysis chamber with a small volume of buffer. Two corneas were placed in one-half of the dialysis chamber together with 0.5 ml. buffer solution, and 3 ml. drug solution was placed in the other half. The height of the liquids on both sides was the same. The corneas occupied an average volume of 0.092 ml. and had an average dry weight of 0.096 g. Calculation of the fraction of drug bound was carried out in the usual manner and included the unequal volumes in the half-cells, which were 3 ml. on the drug side and 0.592 ml. on the corneal side.

Aqueous Humor—The primary aqueous humor samples were obtained by making a single puncture into the anterior chamber of the rabbit eye. Depending upon the size of the rabbit, a volume of 0.2–0.3 ml. was obtained from each eye.

Pooled primary aqueous humor was used for dialysis studies. A volume of 0.2 ml. of aqueous humor together with 0.2 ml. of buffer was placed in one half-cell, and 1 ml. of drug solution was placed in the other half-cell. The height of the liquids was the same. Fraction of drug bound was calculated and included corrections for the unequal volumes as well as blank corrections.

Secondary or plasmoid aqueous humor was obtained by carefully removing primary aqueous humor and then removing the secondary at either a 1- or 4-hr. interval. Generally, the volume of the plasmoid aqueous humor obtained was in the range of 75 µl./eye.

Lacrimal Fluid—The lacrimal fluid employed in the equilibrium dialysis studies was collected from two adult, male human subjects. The lacrimal fluid from one subject was obtained by mechanically irritating the eye through placement of a thin strip of filter paper in the lower cul-de-sac. An overflow of tears was produced, which was collected as drops rolling from the lid. The majority of the tear samples came from the second subject where overflow lacrimal fluid was obtained without mechanical stimulation. The overflow tears were collected by the subject during late hours of the day as an accompanying phenomenon to yawning. Again, the lacrimal fluid in the form of drops was collected rolling from the eyelids. All lacrimal fluid samples were pooled and stored at 5° until used.

The volume and methods of dialysis, as well as the calculation, were the same as in the aqueous humor study.

Assays[9]—*Methylprednisolone*—Determination of methylprednisolone concentration was accomplished by direct spectrophotometric measurement. The compound was found to follow Beer's law in the concentration range studied, at an absorbance maximum of 248.5 nm. Methylprednisolone exhibits a molar absorptivity of 1.46×10^4 M^{-1} cm.$^{-1}$ at this wavelength in pH 7.38 aqueous Sørenson buffer.

Pilocarpine—The quantitative determination of pilocarpine nitrate was accomplished by utilizing its reactivity with hydroxylamine to form a hydroxamic acid that is subsequently complexed with ferric ion as previously described (15). The formed complex shows an absorbance maximum at 500 nm. and a molar absorptivity of 2.26×10^2 M^{-1} cm.$^{-1}$ at this wavelength.

Radioactive pilocarpine nitrate was assayed by liquid scintillation detection[10].

Sulfonamides—Quantitative determination of sulfisoxazole was accomplished by utilizing the primary aromatic amine character of the drug molecule. Diazotization of the primary aromatic amine, followed by coupling with Bratton–Marshall reagent (*N*-1-naphthylethylenediamine), yields a product that displays an absorbance maximum in the visible region (16). Sulfisoxazole exhibited an absorbance maximum at 546 nm. with a molar absorptivity of 2.52×10^3 M^{-1} cm.$^{-1}$ at this wavelength and obeyed Beer's law in the concentration range studied.

Miosis–Time Studies

Procedure—Anesthetized animals were used in these experiments. After onset of anesthesia, the test animals were placed in restraining boxes with the head elevated in such a manner that the lid line, upon closure, was approximately horizontal. This position, which is not the natural posture for the rabbit, was chosen to facilitate pupillary diameter measurements. Experimental testing of this animal position as compared to the normal position showed no difference in drug response, so the elevated position was used.

Lighting and temperature in the test room were constant throughout the study. The entire test room was as isolated as conditions would permit to keep audiovisual stimuli to the test animal to a minimum.

The observer was hidden from the test animal by a cardboard shield containing a vertical slit through which measurements of pupillary diameter could be made. The observer, once inside the room, was not allowed movement in or out of the room until the experiment was complete. These precautions were found necessary for obtaining reproducible results.

[9] All spectral measurements were carried out on a Cary 16 spectrophotometer.
[10] Packard Illinois, model 2002.

Measurement of pupillary diameter (with an accuracy of ±0.1 mm.) was made with a cathetometer[11], positioned approximately 50 cm. from the test animal.

After positioning the animal in the restraining box, in line with the cathetometer and prior to drug instillation, pupillary diameter readings were made at 100-sec. intervals. This procedure was continued until the test animal had adapted to its environment as judged by the constancy of pupillary diameter (±0.1 mm. for 10 min.). The adaptation period varied from 15 to 30 min., and the initial diameter ranged from 6.0 to 7.8 mm.

Pipets[12] with blowout delivery were used to instill the drug solution and were checked for accuracy of delivery prior to use by weighing the delivered solutions.

Drug solutions were instilled onto the cornea so that they collected in the lower cul-de-sac. To prevent loss of solution during instillation, the lower eyelid was pulled slightly away from the globe of the eye to form a pocket. This particular form of solution instillation was followed at all times.

After instillation of drug solution, the lower lid was lifted back and forth over the cornea to mix the drug solution with lacrimal fluid. At no time was the lid ever massaged against the cornea so that only movement of the drug solution over the cornea occurred. To exert some degree of control in this method, the eyelid was lifted over the cornea exactly four times, during about 5 sec., in all cases. All procedures were performed in precisely the same manner and with the same time intervals.

After instillation of the drug solution, pupillary diameter was measured as a function of time. The other eye of the test animal served as a control. One hundred-second intervals were used for the first 50 min. of the experiment, 300-sec. intervals were used from 50 to 80 min., and 600-sec. intervals were used thereafter. Measurements were terminated when the measured diameter reached a constant value close to the initial value.

No experimental animal was used more than once, and each experiment was repeated at least four times.

Solution Preparation —*Pilocarpine Nitrate Solutions*—These solutions were prepared fresh and were discarded immediately after the experiment. The solutions were prepared by addition of pilocarpine nitrate to Sørenson phosphate buffer, pH 7.38. Solution pH was checked and adjusted where necessary[13]. The pH meter and electrode system were standardized against phosphate buffer as described previously (17). No attempt was made to sterilize the solutions. Isotonicity of solutions was maintained by addition of sodium chloride.

Anesthetic Solutions – Solutions containing sodium pentobarbital, 50 mg./ml., or sodium phenobarbital, 100 mg./ml., in a vehicle containing 20% (v/v) propylene glycol and 10% (v/v) ethanol were prepared. Both solutions were refrigerated between uses and were never kept for more than 2 weeks.

Anesthesia—It was found that a dose of 33 mg./kg. i.p. sodium pentobarbital and 100 mg./kg. i.p. sodium phenobarbital was sufficient in most cases to anesthetize the rabbits for 8–12 hr.

Miosis Study following Paracentesis—Anterior chamber paracentesis was accomplished by making a puncture incision at the limbus through the cornea into the anterior chamber and aspirating the aqueous humor. Extreme care was taken upon removal of the needle from the deflated anterior chamber to minimize damage to the surfaces exposed to the needle. After waiting for either 1 or 4 hr., the drug solution was instilled into the eye and the change in pupillary diameter was monitored as a function of time.

RESULTS

Demonstration of *In Vitro* Drug–Protein Interaction—The fact that many drugs are bound to proteins is well known (18). A demonstration of this interaction, using rabbit serum albumin as the protein and sulfisoxazole as the drug, is presented in Fig. 1. This particular form of data presentation, namely fraction of drug bound *versus* drug concentration, is generally used when the concentration and nature of the protein are unknown (13). Since an analysis of the various eye fluids and tissue used in this study, as to their types and concentration of protein components, as well as their binding potential was not performed, the *in vitro* data are presented as a fraction of drug bound. Studies are currently underway to characterize these proteins and may be reported later.

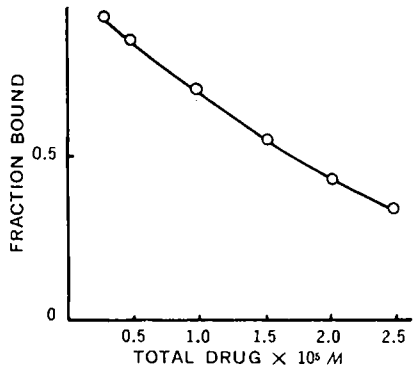

Figure 1—*Equilibrium dialysis experiment on the extent of sulfisoxazole binding to 0.2% (w/v) rabbit serum albumin. Data points are mean values from four separate determinations, and standard deviations are within ±5% of the mean values.*

Although drug binding to blood proteins is well known, what is apparently not as well appreciated is that many other tissues and fluids of the body, such as eye tissues and fluids, also bind drugs and can greatly influence drug bioavailability. This influence is particularly important when the tissue or fluid is turned over at a rapid rate as is the case with tears. Figure 2 demonstrates the interaction of sulfisoxazole and methylprednisolone with the components of human tears, and it is clear that these drugs are extensively bound to the components at the drug concentrations tested. The ramifications of this binding to drug therapy can be appreciated by realizing that instillation of 50 µl. of 1% methylprednisolone solution, which is equal to about 0.5 mg. of drug, followed by dilution of the solution and removal through drainage and turnover, rapidly converts the drug concentration to levels equal to or below that indicated in Fig. 2.

It is important to recognize that the tears used in this study were obtained from healthy eyes by stimulation and, therefore, were low in protein content (19) as compared with tears obtained without stimulation or from inflamed eyes. Thus, binding of these drugs to "normal" tears or tears in an inflamed eye would be expected to be much greater than is indicated in Fig. 2.

In addition to tears as a potential site of drug–protein binding, due to their relatively high protein content, corneal tissue and plasmoid aqueous humor are also potential sites due to a rich supply of protein. *In vitro* dialysis studies of methylprednisolone and sulfisoxazole binding to corneal tissue, in the concentration range of $1-5 \times 10^{-6}$ *M*, show very high drug binding. This is not at all surprising considering the high total protein content of corneal tissue. Likewise, binding of these drugs to plasmoid aqueous humor was also very extensive. It was earlier indicated that primary aqueous humor is low in protein content; as might be expected, the binding of sulfisoxazole and methylprednisolone to this fluid was negligibly small in the concentration range of $1-5 \times 10^{-5}$ *M*. On

[13] All pH measurements and adjustments were made on an Orion model 801 digital pH meter, using a Beckman E3, wide range, glass electrode.

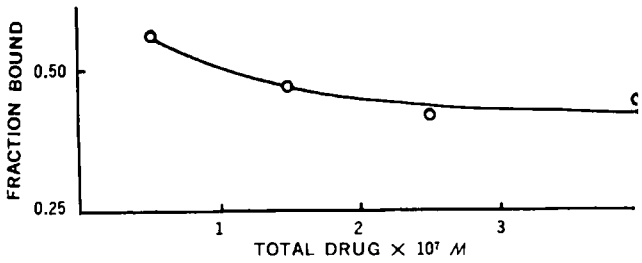

Figure 3—*Equilibrium dialysis studies of tritiated pilocarpine nitrate and plasmoid aqueous humor. Data points represent the mean values from two determinations.*

the other hand, plasmoid aqueous humor is extremely rich in protein; equilibrium dialysis studies with sulfisoxazole and methylprednisolone to this fluid showed almost complete binding in this same concentration range.

Since both sulfisoxazole and methylprednisolone are intermediate in their binding capabilities to albumin [sulfisoxazole is 5×10^3 M^{-1} (20) and methylprednisolone is approximately 10^4 M^{-1} (13)], an additional drug with a low binding constant was chosen to demonstrate the extent of drug binding to plasmoid aqueous humor. Pilocarpine nitrate is a miotic drug used extensively in ophthalmology. It has a binding constant of less than 100 to rabbit serum albumin[14] (21).

Figure 3 shows a fraction bound *versus* concentration plot for pilocarpine nitrate and plasmoid aqueous humor. At low drug concentration and presumed high protein concentration, there is considerable binding of the drug. Note that the drug concentration used in this study is considerably lower than with studies involving sulfisoxazole; this is a reflection of the smaller binding constant of pilocarpine nitrate to the protein. There is, of course, the possibility that pilocarpine nitrate is very highly bound to a specific protein that is present at low concentration, but this cannot be resolved until studies are completed on protein types, concentration, and drug affinity in plasmoid aqueous humor.

These *in vitro* results, using drugs that represent a range of binding affinities from 10^2 to 10^4 M^{-1}, show that there is extensive drug binding to the components of tears, cornea, and plasmoid aqueous humor. This binding can have a large or small influence on drug bioavailability, depending on the extent of binding and rates of turnover or removal of these drugs containing fluids and tissue.

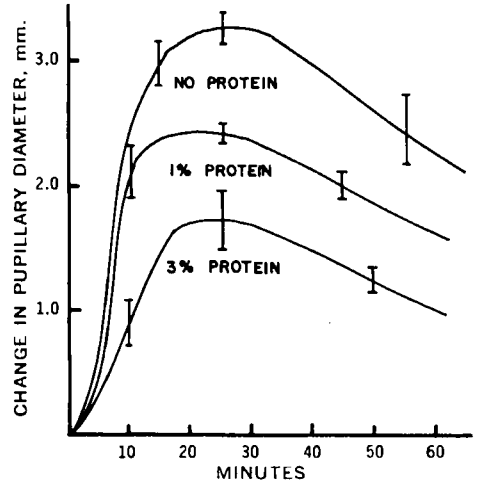

Figure 4—*Miotic activity of 50 μl. of 2.5 × 10^{-2} M pilocarpine nitrate in the presence and absence of added rabbit serum albumin. Each experiment was conducted at least three times, and the vertical bars show the standard deviation at random times. Each line was drawn on the basis of approximately 30 experimental points.*

[14] As determined by ultracentrifugation and by equilibrium dialysis studies using tritiated pilocarpine nitrate. These results will be the subject of a separate publication.

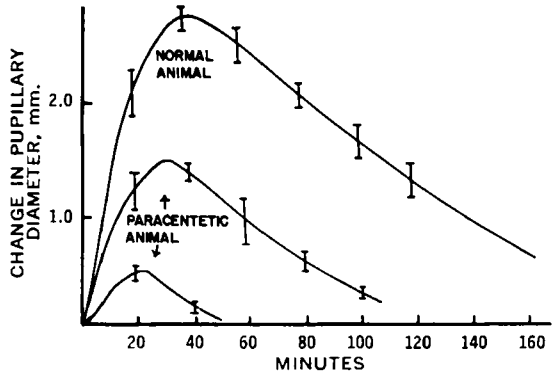

Figure 5—*Effect of plasmoid aqueous humor on the miotic response to pilocarpine nitrate as compared to normal aqueous humor. Fifty microliters of 1 × 10^{-2} M drug was instilled into the eye, and each line represents the mean of at least three determinations. The bottom line represents addition of drug 1 hr. after paracentesis, and the middle line corresponds to drug addition 4 hr. after paracentesis. Vertical bars are standard deviations at random points on the curve, and each curve was drawn on the basis of 15–40 experimental points.*

Demonstration of Drug–Protein Binding Influence on Drug Bioavailability—Pupillary diameter studies were used to assess the influence of protein binding on drug bioavailability. Pilocarpine nitrate was used as the test agent, and the change in pupillary diameter as a function of time and drug concentration was used as an index of drug activity.

The *in vitro* dialysis experiments using tears and various drugs showed that extensive binding of drug occurred. If drug binding to proteins in tears is responsible for a loss in drug, it should be possible to increase this loss by further addition of the proper protein to tears. Addition of protein to tears is difficult, but the same results should be obtained by placing the protein in the drug solution prior to administration into the eye. Rabbit serum albumin was added to the drug solution, and the resultant effect on drug bioavailability, as judged by response to the drug, is shown in Fig. 4. When lower drug concentrations were used in this experiment, the entire miotic activity of the drug could be suppressed by addition of rabbit serum albumin to the drug solution. This diminished response bears out the expectation that drug binding influences bioavailability through drug loss. Albumin was selected as the protein only for convenience. It is possible that other proteins normally present in tears would have a larger affinity for the drug and yield more dramatic results.

Albumin, by itself, was found not to have any effect on pupillary diameter, although it does have surface activity and this property might have two additional effects that should be considered in evaluating the results. The first effect might be to promote drug transport, since a number of surface-active agents are known to have this effect in the eye (22, 23). This would cause an *increase* in drug bioavailability due to a faster penetration of the drug through the corneal tissue; if this was a factor in the present study, it was clearly swamped out, as judged by the *decrease* in biological response. A second effect, which might account for a decreased response, would be a lowering of the surface tension of the instilled solution and hence an increase in the rate of solution drainage. Data from this laboratory on drainage rate studies (2), as well as the fact that many of the tested surface-active agents are without effect in influencing corneal absorption of drugs[15] (22, 23), suggest that a reduction in surface tension of the instilled solution and a corresponding increase in drainage rate are not the mechanisms for the decreased drug response when albumin is added to the drug solution. Thus, the result from this experiment is attributed principally to drug–protein interaction and its concomitant effect on drug loss.

The magnitude of the drug-response change (Fig. 4) is considerable. From dose-response curves generated for pilocarpine nitrate (13), the addition of 3% protein to the drug solution is equivalent to a 75–100-fold reduction in drug concentration, as judged by

[15] Additional studies from this laboratory that are part of another report (13).

biological response in the absence of added protein. Considering the relatively small binding constant for pilocarpine nitrate to albumin, as compared with some antibiotics and steroids, the potential effect of this interaction with other drugs becomes apparent.

If it is possible to depress the bioavailability of drugs by addition of protein, it should be possible to increase the biological activity by competitively inhibiting the interaction. Addition of appropriate substrates to inhibit drug-protein binding can increase the free-drug concentration and, hence, the drug bioavailability. In the case of pilocarpine nitrate solutions, it is possible to increase miotic activity in healthy albino rabbits by more than a factor of 10 through addition of suitable substrates (13). Furthermore, the influence of added protein in depressing the miotic activity of pilocarpine, described earlier, was fully reversible in the presence of a competitive inhibitor. A full account of this work is given in a separate paper[15], but mention is made here to further support the contention of drug-protein binding in eye fluids and tissues as an influencing factor in drug bioavailability.

It was also of interest to determine if the presence of higher concentrations of protein in aqueous humor could be responsible for a decrease in drug activity. Paracentesis was carried out on several animals to form a protein-rich secondary aqueous humor, and the activity of pilocarpine nitrate was determined in these animals (Fig. 5). Instillation of pilocarpine nitrate solution 4 hr. after paracentesis caused a significant drop in the biological response to pilocarpine nitrate, and an even further reduction in activity occurred if the drug was instilled 1 hr. after paracentesis. At the 4-hr. point, the aqueous humor is returning to its normal state and is not as rich in protein as at the 1-hr. point.

The dramatic decrease in drug response, shown in the paracentesis experiment, could be largely attributed to trauma incurred by withdrawing aqueous humor. If trauma to the iris or any portion of the tissue responsible for pupillary activity occurred, it returned to normal within 12 hr. but nevertheless could account for a portion of the results in this experiment. When the result of the *in vivo* paracentesis experiment is evaluated together with the results from the *in vitro* dialysis experiment, using plasmoid aqueous humor and pilocarpine nitrate, it seems reasonable to assume that a sizable portion of the loss in drug activity in the paracentetic animal was due to drug-protein interaction and not trauma.

DISCUSSION

An important facet of drug binding influence on ophthalmic drug bioavailability is the turnover rate of eye fluids and tissues, as well as drainage of instilled solutions when these are used as the delivery system. Chrai *et al.* (2) showed that instilled solutions are very rapidly drained from the eyes of rabbits. For example, approximately 50% of a 50-μl. instilled drop will drain from the eye of a rabbit within 30 sec. postinstillation and better than 84% will be lost within 3–4 min. These values are even larger in humans and, according to Maurice[16], most instilled solution in humans is lost within 1–2 min. In addition to drainage of instilled solution, one must also be concerned with turnover of tears, since this results in both dilution and removal of the drug.

The smaller turnover rate of albumin in the cornea suggests that drug binding to this tissue would have less of an influence on total drug availability, although it can influence the rate of transport and the time lag before drug appears in the anterior chamber. Aqueous humor also has a smaller turnover rate than tears but can nevertheless influence drug bioavailability if the binding constant is large or if protein content is large.

Other portions of the eye such as the sclera and conjunctiva can and probably do bind drugs and are responsible for a decrease in drug bioavailability. The present study was concerned principally with components of the eye that are constantly being turned over and are at the same time rich in protein.

Partial Purification of Antigen E from Mixed Stems and Leaves of Short Ragweed Plant

A. SHAFIEE, E. J. STABA▲, and Y. J. ABUL-HAJJ

Abstract □ Short ragweed leaves-stems, roots, and seeds were examined for the presence of the most potent pollen allergen, antigen E. Soluble proteins were precipitated by ammonium sulfate and partially purified by a combination of dialysis and anion exchange and gel filtration chromatography. Immunodiffusion, disk electrophoresis, and skin testing of short ragweed pollen-sensitive individuals indicated that antigen E was present in leaves-stems portion of this plant as well as the pollen.

Keyphrases □ Ragweed leaves-stems, roots, and seeds—distribution and isolation of antigen E □ Antigen E, short ragweed—distribution in leaves-stems, roots, and seeds, isolation from leaves-stems □ Allergen distribution—antigen E in short ragweed leaves-stems, roots, and seeds

Wind-borne plant particles other than pollen can cause allergic symptoms in persons showing pollen hypersensitivity (1). Rebhun *et al.* (2), by direct skin testing of ragweed-sensitive patients, demonstrated that reagin reacting antigens were present in all parts of the giant ragweed plant. Other researchers reported the purification of antigens E and K (3–5), of Ra. 3 (6), and of a basic protein from short ragweed pollen (7). The distribution of short ragweed pollen antigen E in other portions of this plant was investigated in this study.

EXPERIMENTAL

Plant Materials and Antigen E Source—In 1971, short ragweed plants[1] (*Ambrosia elatior* L.) were grown and collected shortly before pollination in the medicinal plant garden and were also received from a commercial source[2]. The collected plant materials were air dried, milled, and stored in an airtight container at room temperature. Plant materials used for extraction did not contain pollen when examined microscopically both before and after staining with Calberla's solution (8).

Antigen E from short ragweed pollen[3] was prepared according to a reported procedure (3, 4). The prepared antigen E (Sephadex G-100, Fraction IV) had a similar disk electrophoresis pattern (Fig. 1), and a complete line of identity with National Institutes of Health (NIH) antigen E (NIH antigen E) when evaluated with antiantigen E and antipollen crude extract serums by the Ouchterlony immunodiffusion test.

Allergen Isolation Procedure—A modification of the literature procedure (3, 4) was used to isolate the allergens from short ragweed leaves-stems, roots, and seeds.

Leaves-Stems—Plant samples collected from the medicinal plant garden and from the commercial source (100 g. leaves-stems) were separately defatted and depigmented with peroxide-free ether for 24 hr. in a soxhlet apparatus. The defatted, air-dried plant material was extracted with 800 ml. of 0.005 *M* iced phosphate buffer (pH 7.4) in a 2-l. erlenmeyer flask on a gyrotory shaker[4] at 200 r.p.m. for 24 hr. at 22°. The extract was filtered through glass wool at 4°[5], and the filtrate (500 ml., pH 6.5) was adjusted to pH 7.4 with 3 *N* ammonium hydroxide. The filtrate was further clarified by centrifugation at 1230×*g* for 20 min. in a centrifuge[6]. The precipitate was washed with extracting buffer until the wash buffer reacted negatively against antipollen crude extract rabbit serum in the immunodiffusion test. The combined filtrate (510 ml., pH 7.2) was concentrated to approximately 51 ml. with an ultrafiltration cell[7] equipped with a membrane[8] and adjusted to 0.9 saturation with 31.7 g. ammonium sulfate[9].

The resulting suspension was stirred overnight at 4° and centrifuged at 14,350×*g* for 40 min. The precipitate was then dissolved in 25 ml. of 0.1 *M* tromethamine-hydrochloric acid buffer (pH 7.9) to form a dark-brown solution. This solution was desalted and further depigmented on an anionic exchange column[10] (50 × 4 cm.), which was equilibrated and eluted with 0.025 *M* tromethamine-hydrochloric acid buffer (pH 7.9). The flow rate was adjusted to 60 ml./hr., and 15-ml. fractions were collected at 22° and monitored by their absorption at 280 nm. The first peak, Fraction A, was concentrated to 20 ml. at a pressure differential of 700 mm. Hg using size 8 dialysis tubing[11]. Since loss of allergen through dialysis tubing was detected, the dialysate was concentrated in the ultrafiltration cell as before and combined with the dialysis tubing retentate. The second peak, Fraction B, containing the pigments and ammonium salt was discarded. The combined concentrate Fraction A (22 ml., 6 mg. dry wt./ml.) was exhaustively dialyzed against 0.025 *M* tromethamine hydrochloric acid (pH 7.9) and applied on diethylaminoethyl-cellulose (medium mesh, 0.88 meq./g.) column[12] (25 × 2.7 cm.) previously equilibrated and eluted with the 0.025 *M* tromethamine-hydrochloric acid buffer (pH 7.9). The flow rate was adjusted to 180 ml./hr., and 13-ml. fractions were collected and monitored as previously described. The first diethylaminoethyl-cellulose peak, Fraction C, was collected. The column was then eluted with 0.05 *M* tromethamine-hydrochloric acid–0.2 *M* NaCl buffer (pH 7.9) to obtain a second peak, Fraction D. Fraction D was concentrated to 1.5 ml. and contained 0.8 mg. protein/ml. Protein was determined by the method of Lowry *et al.* (9) with crystalline bovine albumin as standard.

Roots and Seeds—Short ragweed roots were extracted and partially purified for antigen E as described for plant leaves-stems. However, the allergen isolation procedure for the seeds was slightly different from that already described. Seed samples (100 g.) were ground into fine pieces with a mortar and pestle and were defatted. The defatted seed was extracted with 500 ml. of 0.005 *M* phosphate buffer (pH 7.4), and the resulting suspension was expressed through four layers of muslin cloth. The residue was mixed with enough buffer to form a uniform suspension and sonified[13] for 2 min. with the power source set at 90 w. The sonified suspension was also expressed through four layers of muslin cloth, and the filtrates of the two extracts were mixed. Seed Fraction D was obtained as previously described for leaves-stems. Seed Fraction D was concentrated to 10 ml. by use of the ultrafiltration cell. The concentrated Fraction D (10 mg. protein/ml.) was chromatographed on a resin column[14] (195 × 2.5 cm.). Prior to the application of the sample to the column, the concentrate was equilibrated by dialysis with the column buffer [0.1 *M* tromethamine-hydrochloric acid–0.2 *M* ammonium sulfate (pH 7.9)]. The flow rate was adjusted to 20 ml./hr., and 6.2-ml. fractions were collected and monitored as previously described.

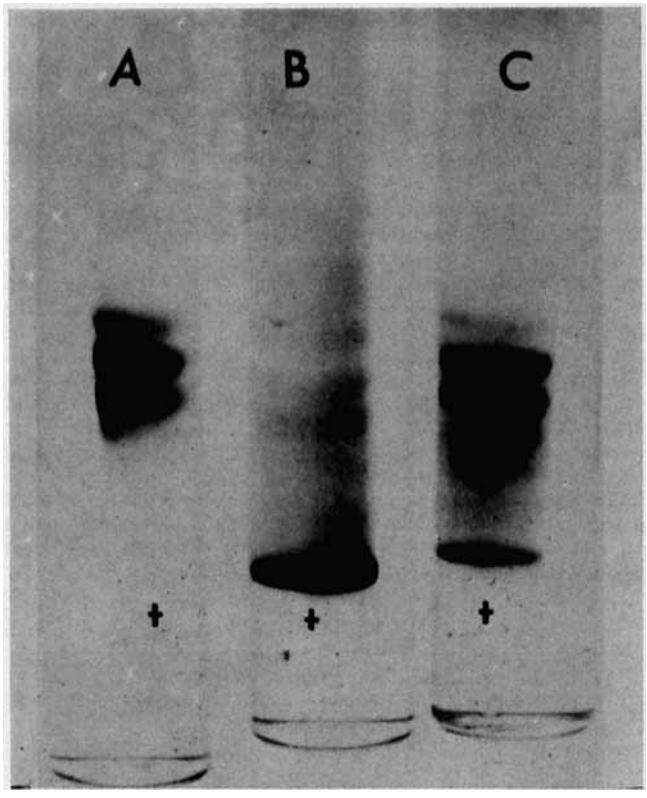

Figure 1—*Polyacrylamide gel electrophoresis patterns at pH 8.9. Key: A, NIH antigen E; B, leaves–stems Fraction D; and C, pollen antigen E (Sephadex G-100, Fraction IV). The fastest moving anodic band in B and C is bromphenol blue marker dye and it is barely seen in A.*

Rabbit Antiserum Preparation—Antipollen crude extract serum was prepared by injecting male rabbits (New Zealand White) at four weekly intervals subcutaneously with an emulsion of 0.5 ml. of 0.1 *M* tromethamine–hydrochloric acid (pH 7.9) buffer solution of 0.9 saturation ammonium sulfate precipitate (81 mg./ml. dry weight) and 0.5 ml. of complete Freund's adjuvant[15] (6). The animals were bled from the marginal ear vein 10 days after the last injection. The serum from each animal was separately tested against pollen crude extract and NIH antigen E by the Ouchterlony immunodiffusion test (10). Positively reacting serum was pooled and stored at −10° in 1-ml. portions until used.

Antiantigen E serum was prepared by injecting each rabbit subcutaneously at four different sites on the back and neck areas at weekly intervals with an emulsion of 0.5 ml. (0.52 mg. protein/ml.) antigen E (Sephadex G-100, Fraction IV) and 1 ml. of complete Freund's adjuvant. The antiantigen E serum was tested and stored as described for antipollen crude extract serum.

Disk Electrophoresis—The reagents and apparatus used for disk electrophoresis were purchased[16]. Disk electrophoresis of Fraction D (leaves–stems), pollen antigen E (Sephadex G-100, Fraction IV), and NIH antigen E was performed at a running gel pH of 9.5 with the discontinuous buffer system of Davis and Ornstein (11). A sample load [0.1–0.2 mg. in 0.2 ml. of 0.025 *M* tromethamine–hydrochloric acid (pH 7.0)] was added to the top of the spacer gel, and larger pore solution was added to fill the electrophoresis tube. Bromphenol blue was used as a marker dye. The gels were stained[17] after being run at 4-mamp./tube current for 45 min.

Immunological Studies—Ouchterlony immunodiffusion tests were carried out in 60-mm. plastic petri dishes containing 5 ml. of 1% Noble agar[18] and 0.1% sodium azide (10). The antiserum was placed in the center well and antigens were placed in the outer wells (3-mm. diameter). After 48–72 hr., the precipitin line positions were observed and photographed. Antigen E concentrations in leaves–stems were estimated by the double-diffusion technique with antipollen crude extract serum (12). The standard curve was established by using purified antigen E in a concentration range of 0.125–0.015 mg./ml. The precipitin line positions on negative films were measured with a shadow graph[19].

[17] Amido Schwarz.
[18] Difco.

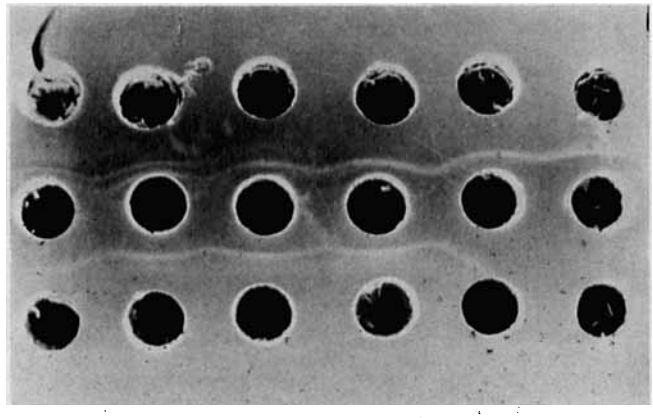

Figure 2—*Antigen E quantitative immunodiffusion analysis. The center wells were filled with antipollen crude extract serum. The upper wells were filled with NIH antigen E (left to right: 0.5, 0.25, 0.125, 0.062, 0.031, and 0.015 mg. protein/ml.), and the lower wells were filled with leaves–stems Fraction D (left to right: 0.1, 0.2, 0.4, and 0.8 mg. protein/ml.). The lower last two wells were filled with buffer and are controls.*

Unstained electrophoresis gels loaded with Fraction D (leaves–stems) were aligned with stained pollen antigen E and gel cuts made in the region of the pollen antigen E. The gel cuts were eluted with 1 ml. of 0.025 *M* tromethamine–hydrochloric acid buffer (pH 7.9) at 4° overnight. The eluate was lyophilized, and the appropriate concentration was made by redissolving the lyophilized eluate in the buffer prior to the Ouchterlony immunodiffusion test.

Allergenic activity of column fractions and NIH antigen E was determined by direct skin testing on patients with known short ragweed pollen sensitivity. Solutions were sterilized by filtration[20] (0.22-μ pore size). Serial 10-fold dilutions of the sterilized solutions were made immediately prior to the injections with sterile phosphate-buffered saline[21]. Intradermal injections (0.02 ml.) were made into the forearm of the patients, and the wheal and flare reactions were read within 20 min. Nonallergic individuals served as controls and were injected with high concentrations of column fractions and NIH antigen E solutions. As suggested by Berrens (13), the allergenic activities of leaves–stems Fraction D and pollen antigen E are reported in terms of specific activity (units per milligram protein). In this system, one unit of activity represents the minimum quantity of the fraction (milligrams protein) eliciting a minimum reaction in specifically sensitive patients.

RESULTS AND DISCUSSION

The literature procedure (3, 4) was successfully used to isolate antigen E (Sephadex G-100, Fraction IV) from short ragweed pollen (1.3 mg. protein/g. pollen). Leaves–stems Fraction D (0.1–0.8 mg. protein/ml.) extracted from commercially supplied plants and NIH antigen E (0.015–0.125 mg. protein/ml.) gave a single precipitin line against antipollen crude extract serum (Fig. 2) and antiantigen E serum. However, when high concentrations of NIH antigen E (>0.125 mg. protein/ml.) were used, a contaminating antigen was detected (Fig. 2, first three upper wells from left). To prevent any nonspecific precipitin line formation, 0.062 mg. protein/ml. of NIH antigen E was used in all comparative immunodiffusion studies shown in Fig. 3.

Figure 3A illustrates the formation of lines of identity when NIH antigen E (Well 2) and leaves–stems Fraction D (Well 3) were placed in adjacent wells against antiantigen E serum. The material eluted from the unstained polyacrylamide cut gels in the region of standard antigen E (Fig. 3B, Wells 3 and 5) formed a common line

(A) Leaves-stems Fraction D and NIH antigen E against antiantigen E serum: 1, antiantigen E serum; 2, NIH antigen E (0.062 mg./ml.); 3, leaves-stems Fraction D (0.8 mg./ml.); 4, buffer control; and 5, leaves-stems Fraction D (0.2 mg./ml.). (B) Leaves-stems Fraction D polyacrylamide gel eluate and NIH antigen E against antipollen crude extract serum: 1, antipollen crude extract serum; 2, 4, NIH antigen E (0.062 mg./ml.); and 3, 5, leaves-stems polyacrylamide gel eluate. (C) Root Fraction D and NIH antigen E against antiantigen E serum: 1, antiantigen E serum; 2, NIH antigen E (0.062 mg./ml.); and 3, 4, 5, root Fraction D (1.6, 0.8, and 0.4 mg./ml., respectively). (D) Root Fraction D and NIH antigen E against antipollen crude extract serum: 1, antipollen crude extract serum; 2, 3, root Fraction D (1.6 and 0.4 mg./ml., respectively); 4, buffer control; and 5, NIH antigen E (0.062 mg./ml.).*

of identity with NIH antigen E (Fig. 3B, Wells 2 and 4) against antipollen crude extract serum. Similar results were obtained when antiantigen E serum was used in place of antipollen crude extract serum. Further evidence for the presence of antigen E in short ragweed leaves-stems was obtained by disk electrophoresis and direct skin testing of sensitive individuals. Disk electrophoresis of NIH antigen E, leaves-stems Fraction D, and pollen antigen E (Sephadex G-100, Fraction IV) shows a similar pattern (Fig. 1). However, purified NIH antigen E had a slower anodic movement, which possibly resulted from the 50% glycerol present as a stabilizer. Leaves-stems Fraction D was tested on the skin of two short ragweed pollen-sensitive individuals. The specific activity of this fraction was established to be 10^7 (units/mg. protein) as compared to 10^9 (units/mg. protein) for NIH antigen E on the same patients.

The protein content of the commercially supplied leaves-stems in Fraction D was found to be 0.012 mg./g. while the antigen E content was estimated to be 0.0022 mg. protein/g. when quantitated from the standard curve of the logarithm of the NIH antigen E concentrations *versus* precipitin line positions (Fig. 2). Twice as much protein was obtained from leaves-stems that had been collected from the medicinal plant garden.

Figures 3C and 3D illustrate the reaction of root Fraction D and NIH antigen E against antiantigen E and antipollen crude extract serums, respectively. Precipitin lines between various concentrations of root Fraction D and antiantigen E serum did not appear (Fig. 3C, Wells 3, 4, and 5). A complete line of nonidentity developed between NIH antigen E, root Fraction D (Fig. 3D, Wells 2 and 5), and antipollen crude extract serum. Short ragweed seed Fraction D was obtained in a similar manner as that for pollen antigen E and was further fractionated by chromatography[14]. Five peaks eluted from the column were separately subjected to immunodiffusion and disk electrophoresis testing as described for leaves-stems; none contained antigen E.

In conclusion, immunodiffusion, disk electrophoresis, and skin testing evidence showed that the allergen, antigen E, is present in leaves-stems of short ragweed plant. Although the results of immunodiffusion and disk electrophoretic analysis indicated that antigen E was absent from roots and seeds of short ragweed, the possibility that other pollen allergens or their modification may be present in other parts of this plant cannot be excluded. In fact, this assumption is supported by immunofluorescent antibody studies substantiating that surface materials of ragweed pollen (exine and intine) are derived from the diploid tapetum and not from the haploid pollen (14). Results also suggest that the antigen E present in short ragweed leaves-stems may have been a major cause of hay fever symptoms, as recently suggested (1) for wind-borne plant particles. It is also concluded that short ragweed leaves-stems might serve as a source of antigen E, although the concentration present is much less than that of the pollen.

Metabolism of Clindamycin II: Urinary Excretion Products of Clindamycin in Rat and Dog

F. F. SUN

Abstract □ The urinary excretion products of clindamycin metabolism in rats and dogs were isolated and characterized. Of the radioactive materials excreted in rat urine, 53% was identified as unchanged clindamycin, 31% as clindamycin sulfoxide, and 15% as *N*-demethylclindamycin. In dog urine, 36% of the radioactivity excreted was identified as unchanged drug, 28% as the sulfoxide, 28% as clindamycin glucuronide, and 9.16% as *N*-demethylclindamycin. No glucuronide conjugate was found in the rat urine. Thus, based on the metabolic patterns found in the urine of the two species, sulfoxidation and *N*-demethylation were the predominant metabolic routes in the rat, while conjugation with glucuronic acid and sulfoxidation were the major pathways in the dog.

Keyphrases □ Clindamycin metabolism—urinary excretion products in rats and dogs □ Excretion, urinary—identification of clindamycin metabolites, rats, dogs

In the first paper of this series (1), studies on the absorption and excretion of a new antibiotic, clindamycin[1], in experimental animals were described. In continuation of the study of clindamycin metabolism, effort was directed to the elucidation of the metabolic pathways for clindamycin in mammals. This report describes the isolation and characterization of urinary excretion products in the rat and the dog.

Studies of Brodasky *et al.* (2) on the characterization of human urinary excretion products of clindamycin suggested that *N*-demethylclindamycin was the major metabolite. These authors also observed two other drug-related substances with chromatographic behavior similar to clindamycin sulfoxide and clinimycose (the 1-hydroxy derivative). The trace amounts of these two components precluded their isolation and characterization. Clindamycin sulfoxide and *N*-demethylclindamycin (3) have been isolated and identified as the metabolic products of clindamycin in microorganisms.

EXPERIMENTAL[2]

Dosage and Collection of Samples—Twelve female Sprague–Dawley rats (Upjohn strain) were given 100-mg./kg. oral doses of clindamycin hydrochloride through a stomach tube every day for a month. Tritium-labeled drug (6.0 μc.) was given on the first and the last days to check for possible adaptation or stimulation of metabolism and to provide labeled metabolites for isolation. Urine specimens were collected once a day through stainless steel metabolism cages and frozen immediately until used. The rats were maintained on powdered food[3] and deionized water. Food was given during the daytime only to provide empty stomachs before dosing every morning. Water was provided at all times.

Three male beagle dogs, weighing 8.2, 8.9, and 11.7 kg., respectively, each received single daily oral doses of 500 mg. clindamycin hydrochloride (in hard-filled capsules) for 7 days. Urine samples were collected once a day through stainless steel metabolism cages. Food[4] was given once a day and deionized water was allowed freely. Urine samples containing radioactive clindamycin and metabolites from the previous experiment (1) were added to the pooled urine to monitor the separation.

Preparation of Extract—The polystyrene resin was thoroughly washed successively with acetone, methanol, and distilled water before being packed into a 38 × 300-mm. glass column. A pooled urine sample, spiked with radioactive urine (total volume 2 l.), was filtered through glass wool and adjusted to pH 8.5. The filtered urine was passed through the column. The column was subsequently washed with 6 l. of distilled water and eluted with: (*a*) 2 l. of a methyl ethyl ketone–water mixture (95:5), and (*b*) 2 l. of methanol. The spent urine and aqueous wash were discarded. The ketone and methanol eluents were pooled and evaporated to dryness. Recovery of radioactivity was greater than 90%.

The drug-related components in the urine extracts were examined by TLC. The separation procedure is presented in Scheme I.

Isolation of Clindamycin and Metabolites from Rat Urine Extract—*Countercurrent Distribution*—The dried material from rat urine was dissolved in 20 ml. of anhydrous methanol and acidified with methanolic hydrochloric acid. Twenty milliliters of acetone and 400 ml. of anhydrous ether were added, and the mixture was cooled to 0°. A large amount of precipitate, containing essentially all of the radioactivity, separated out and was collected by filtration. The precipitate was dissolved in 30 ml. of water-saturated *n*-butanol and loaded into the first three tubes of a 500-tube, all-glass countercurrent distribution separator with 10 ml. of *n*-butanol as the upper phase and 10 ml. of water as the lower phase. After 500 transfers were completed, aliquots were withdrawn from every 10th tube and analyzed for radioactivity. The locations of radioactivity (Fig. 1) were then determined, and the rest of the tubes were emptied and combined into two fractions. The two layers in each fraction were separated. The pH of the aqueous layer was adjusted to 10 with 1 *N* NaOH before being extracted three times with equal volumes of *n*-butanol. The extracts were combined with each corresponding fraction, and the pooled butanol solution was evaporated to dryness. Extracted aqueous layers were checked for radioactivity losses before being discarded. The losses of radioactivity in aqueous layers were negligible. Drug-related components in each fraction were examined by TLC.

Purification of Clindamycin Sulfoxide—The fraction containing clindamycin sulfoxide (Fraction I-CCD) was dissolved in 1 ml. of methanol, and the entire fraction was streaked on a 2-mm. thick preparative thin-layer silica gel G_{254} plate. The plate was developed in the methyl ethyl ketone–acetone–water (93:26:10) solvent. Standard clindamycin sulfoxide was spotted and run along with the streak to identify the desired band. After the solvent front reached the top, the band corresponding to the clindamycin sulfoxide was scraped off and homogenized in 100 ml. of absolute methanol. The silica gel was then filtered out and washed twice with 50-ml. aliquots of methanol. The combined methanol solution was evaporated to dryness, and the residue was leached twice with 5-ml. aliquots of chloroform–methanol (4:1). Traces of silica gel at this point could be removed by centrifugation. The chloroform–methanol solution was concentrated and the entire preparative TLC procedure was repeated once with the same solvent and once with chloroform–methanol (6:1) as the developing solvent. The final product, showing

[1] Cleocin, The Upjohn Co.

[2] Amberlite XAD-2 polystyrene resin was purchased from Rohm and Haas Co. Silica gel (0.05–0.2 mm.) and preparative silica gel G precoated thin-layer plates were obtained from Brinkmann Instruments. Dicalate, an amorphous diatomaceous silica filter aid, was obtained from Grefco Inc., Los Angeles, Calif. Precoated analytical silica gel thin-layer plates were obtained from Analtech, Inc. Tritium-labeled clindamycin was synthesized as previously described with the specific activity of 2.386 mc./mg. (1). Clindamycin sulfoxide and *N*-demethylclindamycin standards were provided by Mr. R. D. Birkenmeyer, Infectious Diseases Research, The Upjohn Co.

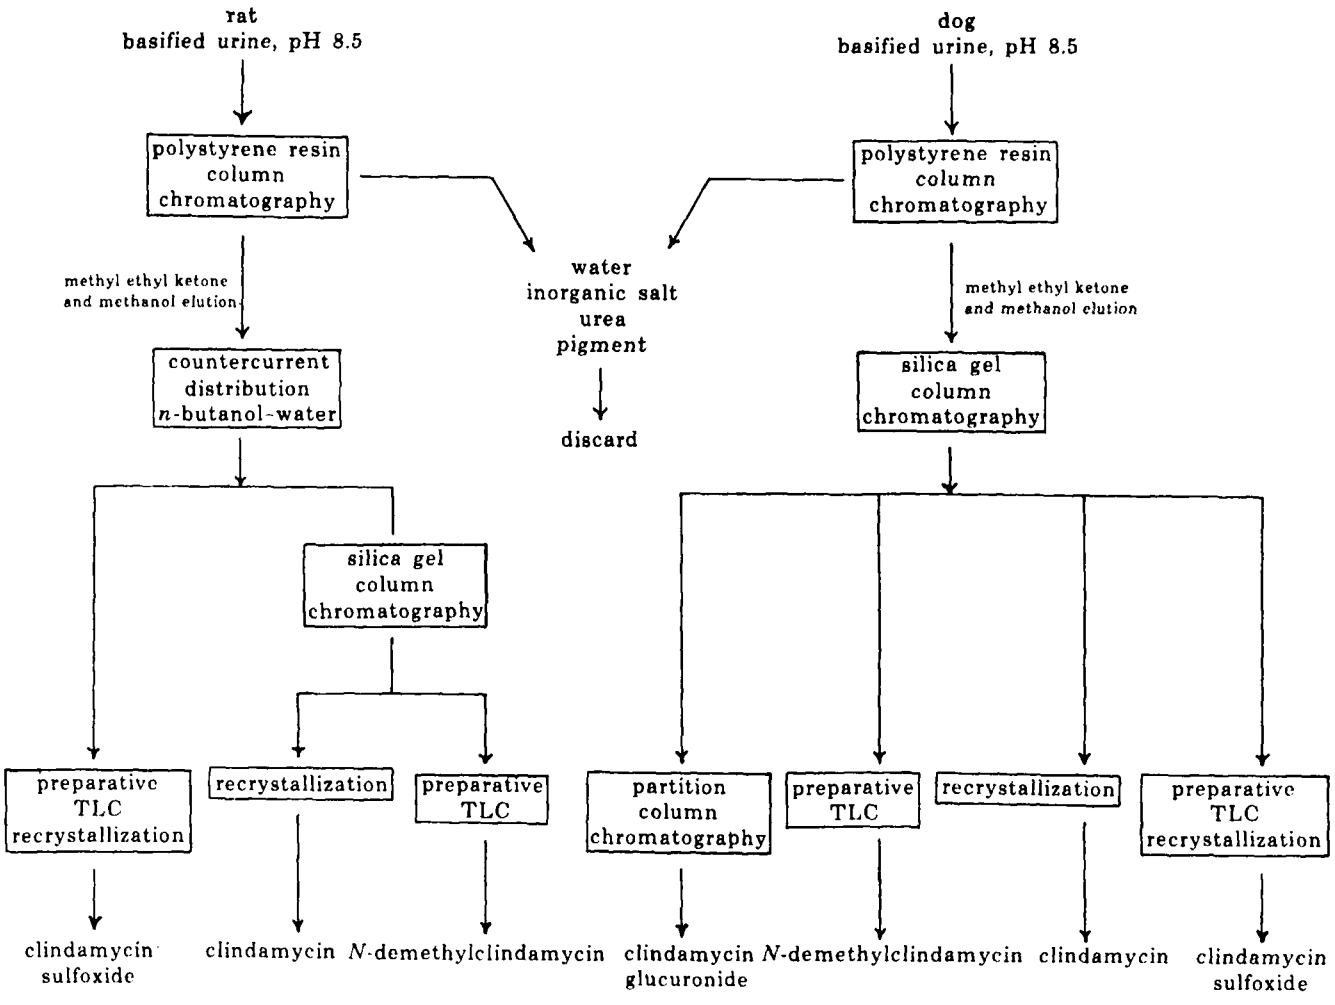
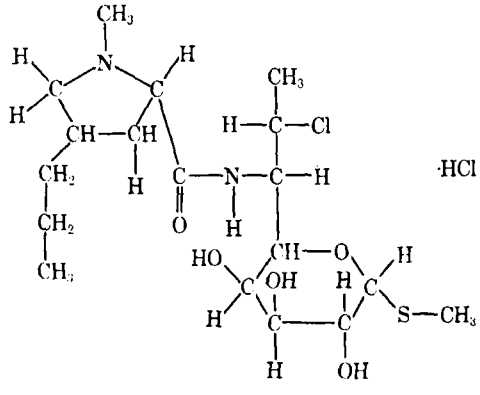


Scheme I—Sequential experimental steps for the separation of clindamycin and metabolites from rat and dog urine

only one spot on the thin-layer plate, was crystallized from ethanol and ethyl acetate.

Purification of Clindamycin and N-Demethylclindamycin—The fractions from countercurrent distribution (tubes in Fraction II-CCD) containing these two components were pooled, evaporated to dryness, and redissolved (or suspended) in 20 ml. of chloroform–methanol (10:1). This solution was placed on the top of a silica gel (0.02–0.5 mm.) column packed in the same solvent (26 × 240 mm.). Elution was carried out first with 250 ml. of chloroform–methanol (10:1), then with 400 ml. of chloroform–methanol (5:1), and finally with 250 ml. of chloroform–methanol (2:1). Eluates were collected in 10-ml. fractions, and aliquots were withdrawn from every other tube for radioactivity counting. The desired fractions were combined, concentrated, and analyzed by TLC.



clindamycin hydrochloride

Fractions containing clindamycin were evaporated to dryness and redissolved in 1 ml. of methanol. The drug was converted to the hydrochloride salt and precipitated by adding 1 ml. of acetone and 20 ml. of ether. The precipitate was crystallized from 2 ml. of ethanol and 7 ml. of ethyl acetate. The final product appeared to be free from contaminants and was analyzed by NMR, IR, mass spectrometry, and TLC.

Fractions containing *N*-demethylclindamycin were concentrated and purified by preparative TLC according to the procedure used for clindamycin sulfoxide. The final product was evaporated to dryness and analyzed without crystallization.

Isolation of Clindamycin and Metabolites from Dog Urine Extract—In the dog study, since there was one radioactive zone located near the origin on the thin-layer chromatogram (Fig. 2), it was separated first by silica gel column chromatography. The dried material, obtained from polystyrene resin chromatography, was homogenized in a solvent mixture of chloroform–methanol (95:5) and loaded on a silica gel column (38 × 360 mm.) packed in the same solvent. Elution was carried out successively with the following solvent mixtures: (*a*) 700 ml. chloroform–methanol (20:1), (*b*) 500 ml. chloroform–methanol (10:1), (*c*) 500 ml. chloroform–methanol (8:1), (*d*) 500 ml. chloroform–methanol (5:1), (*e*) 1000 ml. chloroform–methanol (1:3), (*f*) 600 ml. methanol, and (*g*) 500 ml. methanol–water (1:1). The eluates were collected in 10-ml. fractions. An aliquot from every third fraction was analyzed for radioactivity. Eight radioactivity fractions were separated (Table I) (Fig. 3), concentrated, and analyzed by TLC.

Purification of Unchanged Clindamycin and Clindamycin Sulfoxide—The purification of intact clindamycin (Fraction I) and clindamycin sulfoxide (Fraction II) was carried out by preparative TLC according to the methods described in the previous section. Clindamycin was recrystallized as the hydrochloride salt from a mixture

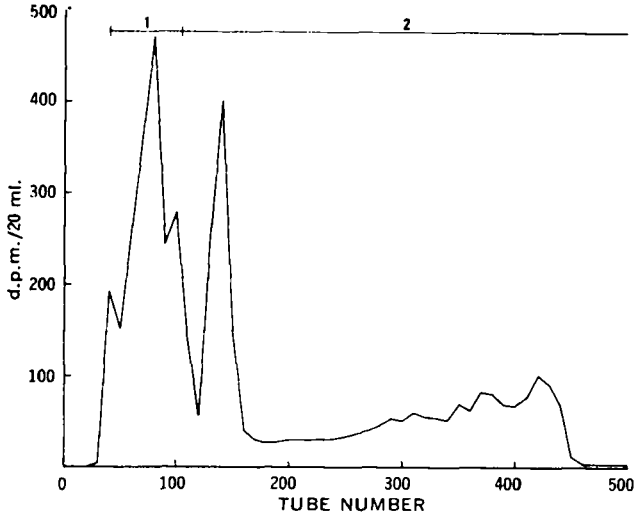


Figure 1—*Countercurrent distribution of rat urine extract.*

of ethyl acetate–ethanol (7:2). Clindamycin sulfoxide was isolated as the free base. Both compounds were identified by NMR, IR, and mass spectrometry.

Purification of Clindamycin Glucuronide—When eluted from the silica gel column, fractions 4 and 5 (Fig. 3) were contaminated with large amounts of a yellow urinary pigment. These fractions were further purified by liquid–liquid partition chromatography. A solvent mixture of 300 ml. of *n*-butanol, 700 ml. of ethyl acetate, and 400 ml. of water was mixed by shaking and allowed to settle. The upper phase and lower phase were separated. Twenty grams of an amorphous diatomaceous silica filter aid[5] were mixed with 200 ml. of the upper phase. The lower phase (8 ml.) was added dropwise with vigorous stirring. The mixture was poured into a column and allowed to settle. The fraction to be purified was: (*a*) dissolved in 2 ml. of the lower phase, (*b*) mixed with 4 g. of Hyflo Super Cel, and (*c*) diluted with 10 ml. of the upper phase; the eluate was collected in 10-ml. fractions. Aliquots from every other tube were counted for radioactivity. The radioactive zone was pooled and evaporated to dryness.

The same procedure was repeated twice to obtain about 500 mg. of white fluffy material. TLC analyses showed that a single zone was present. The material was used for spectroscopic analyses.

Additional clindamycin glucuronide was purified by countercurrent distribution, using a solvent system of *n*-butanol–water. Based upon TLC, the clindamycin glucuronides purified by countercurrent distribution and partition chromatography were identical.

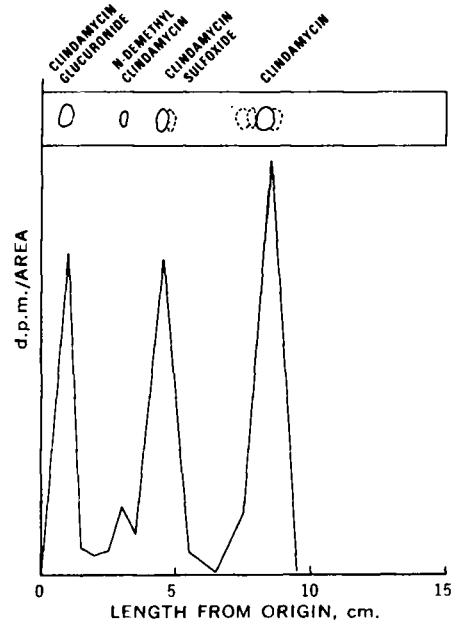

Figure 2—*Quantitative thin-layer chromatogram of pooled dog urine extract (unhydrolyzed). The solvent system was ethyl acetate–acetone–water (8:5:1).*

[5] Dicalate.

Table I—Recovery of Radioactivity after Silica Gel Chromatography of Dog Urine Extract[a]

Fraction	Microcuries	Recovery, %	Identification
1	3.28	23.39	Clindamycin
2	5.64	40.22	Clindamycin sulfoxide
3	0.95	6.73	*N*-Demethylclindamycin
4	0.486	3.46	Clindamycin glucuronide
5	3.161	22.54	Clindamycin glucuronide
6	0.142	1.01	—
7	0.153	1.09	—
8	0.068	0.49	—

[a] Total microcuries added = 14.022 μc. Total percentage recovery = 98.93%.

Analytical Methods[6]—*TLC*—TLC, used for monitoring the separation procedure, was carried out on 2.5 × 20-cm. glass plates precoated with 0.25 mm. of silica gel G_{254}. The following solvent systems were used: (*a*) methyl ethyl ketone–acetone–water (93:26:10), (*b*) chloroform–methanol–water (8:4:0.4), (*c*) chloroform–methanol (6:1), (*d*) *n*-butanol–water (5:1), (*e*) ethyl acetate–acetone–water (8:5:1), and (*f*) acetone–chloroform (3:1). Since clindamycin glucuronide remained near the origin when chromatographed in these solvent mixtures, three additional systems were required. They were: (*g*) methyl ethyl ketone–acetone–water (1:3:1), (*h*) ethyl acetate–acetone–water (2:6:1), and (*i*) chloroform–methanol (1:3).

Spraying reagents used to locate the desired spots were as follows:

Spraying Reagent	Reaction
8.0 g. $NaIO_4$; 10 g. K_2CO_3; 1.0 g. $KMnO_4$ in 500 ml. of distilled water (4)	sugar moieties
2% 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in benzene (5)	sulfides, sulfoxides, sulfones
0.5% ninhydrin in acetone	secondary amine in *N*-demethylclindamycin

Radioactive zones were located by scanning in a glass plate scanner[7].

Quantitative TLC was used to measure the relative amount of each component in the urine. Twenty-milliliter aliquots of urine

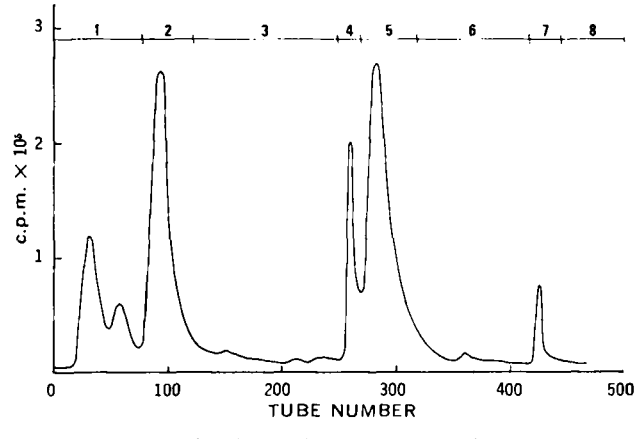

Figure 3—*Silica gel column chromatography of crude dog urine extract.*

[6] NMR spectra were obtained on a Varian model A60 spectrometer. Mass spectra were obtained on either an Atlas CH-4 mass spectrometer or a Consolidated Electrodynamics 21-110B high-resolution mass spectrometer. IR spectra were obtained on a Perkin-Elmer 421 grating spectrometer.

[7] Vanguard 885.

Table II—Relative Amounts of Clindamycin and Metabolites Excreted in Rat Urine[a]

	Relative Amounts in Total Urine, % of Urinary Radioactivity							
	Radioactive Urine Collected the 1st Day				Radioactive Urine Collected the Last Day			
	1[b]	2[b]	3[c]	Mean	1[b]	2[b]	Mean	Average
Unchanged clindamycin	54.59	52.47	50.07	52.38	52.11	57.58	54.85	53.36 ± 2.55
Clindamycin sulfoxide	30.41	30.54	36.34	32.43	31.56	28.20	29.88	31.41 ± 2.7
N-Demethyl-clindamycin	14.95	16.97	13.50	15.14	16.2	13.82	15.04	15.10 ± 1.35

[a] Radioactive urine samples are collected from 0 to 48 hr. postadministration. [b] The solvent system used was chloroform–methanol (6:1). [c] The solvent system used was ethyl acetate–acetone–water (8:5:1).

samples collected from the clindamycin-treated rats or dogs were concentrated to 0.5 ml. The pH was adjusted to approximately 10 before 20 μl. of each was streaked on a 2.5 × 18-cm. thin-layer plate (250 μ thick), and the plate was developed with the TLC Solvent Systems *c* and *e*. After the development was completed, the silica gel was scraped in 1-cm. sections into 18 scintillation counting vials containing 0.5 ml. of water and 15 ml. of counting solvent[8] (1). The radioactivity was counted in a liquid scintillation counter[9]. Quenching losses were corrected by adding 0.05 ml. of tritiated toluene and counting again.

Enzymatic Analysis (Identification of Clindamycin Glucuronide)—The identity of clindamycin glucuronide was established by treatment with β-glucuronidase. Clindamycin glucuronide (20 mg.) was dissolved in 10 ml. of 0.1 *M* sodium acetate buffer (pH 5.0) and mixed with 0.1 ml. of concentrated β-glucuronidase aryl sulfatase solution[10]. The mixture was incubated in a 37° water bath for 24 hr. After the incubation period, the mixture was adjusted to pH 10.0 with 3.6 *N* potassium hydroxide and passed through a small (10 × 100 mm.) polystyrene resin column. The acetate buffer was washed off with 500 ml. of water. The clindamycin and clindamycin glucuronide were eluted with 200 ml. of 95% aqueous acetone and 200 ml. of methanol. The solvent eluates were pooled and concentrated under reduced pressure. Intact clindamycin (hydrolysis product) was isolated from the extract by preparative TLC in a solvent system composed of ethyl acetate–acetone–water (8:5:1). Identification of the hydrolytic product as intact clindamycin was based upon TLC behavior and mass spectrometry. As a control, another 20-mg. sample of clindamycin glucuronide was carried through the entire procedure but without the addition of enzyme. The glucuronide was recovered unaltered.

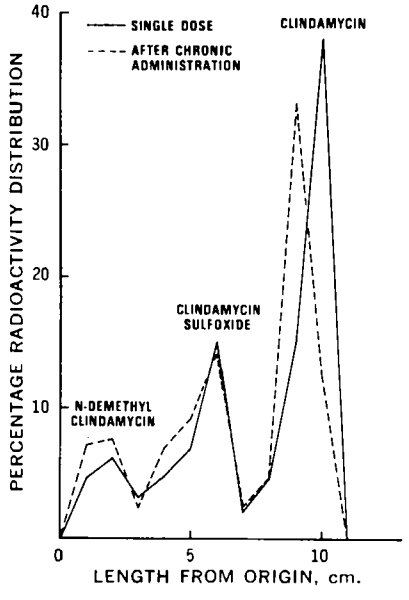

Figure 4—*Quantitative thin-layer chromatogram of lyophilized pooled rat urine. The solvent system was chloroform–methanol (6:1).*

For use as a chromatographic standard, authentic clindamycin glucuronide was synthesized enzymatically by reacting clindamycin with uridine diphosphoglucuronic acid (ammonium salt) in the presence of freshly prepared dog liver microsomes. The reaction product was separated from the unreacted clindamycin by polystyrene resin and silica gel chromatography.

Isolation of *In Vitro* Metabolites of Clindamycin—Preliminary experiments were conducted to study the metabolism of clindamycin under *in vitro* conditions. Livers from eight Sprague–Dawley rats (four male and four female), with the average body weight of 200 g., and from two male beagle dogs were used. The rats were sacrificed by cervical dislocation, and the dogs were sacrificed by electrocution. Microsomes were prepared by the differential centrifugation procedure of Allmann *et al.* (6), except 0.25 *M* sucrose–0.01 *M* tromethamine hydrochloride solution was used for suspension instead of sucrose–mannitol A.

N-Demethylation and sulfoxidation reactions of clindamycin were carried out in open 25-ml. erlenmeyer flasks at 38° in a metabolic shaker[11]. The complete reaction medium contained per each milliliter: potassium phosphate buffer (pH 7.5), 100 μmoles; magnesium chloride, 5 μmoles; nicotinamide-adenine dinucleotide phosphate (NADP), 1 μmole; nicotinamide-adenine dinucleotide (NAD), 1 μmole; sodium isocitrate, 5 μmoles; isocitrate dehydrogenase, 0.1 mg.; microsomes, 3–5 mg.; and clindamycin, 5 μmoles. The mixture was incubated for 1 hr. under air.

Glucuronic acid conjugation of clindamycin was carried out in a 25-ml. erlenmeyer flask at 38° under nitrogen atmosphere. The reaction mixture consisted of the following components per each milliliter: tromethamine hydrochloride, 100 μmoles; uridine diphosphate glucose (UDPG), 133 μmoles; magnesium chloride, 4 μmoles; clindamycin, 2 μmoles; and microsomes, 2–4 mg. The mixture was incubated for 1 hr. before extraction.

After the incubation was complete, the reaction was terminated by addition of 0.05 ml. of 3 *M* trichloroacetic acid/ml. of the reaction mixture. The excess acid was immediately neutralized by the addition of 3 *M* KOH. The denatured protein was removed by centrifugation. The clear supernate was adjusted to pH 8.5 with 3 *M* KOH and loaded into a small polystyrene resin column (10 × 100 mm.). The column was washed with 200 ml. of distilled water. Clindamycin and its metabolites were eluted with 200 ml. of 95% aqueous acetone and 200 ml. of methanol. The solvents were pooled and concentrated under reduced pressure. Drug-related compounds in the extract were isolated by preparative TLC and identified as described previously.

RESULTS AND DISCUSSION

Rats—Figure 4 shows the thin-layer chromatograms of two crude rat urine extracts from polystyrene resin column chromatography. The solid line shows the distribution pattern of urinary radioactivity from rats that received a single dose of clindamycin hydrochloride, and the dotted line shows the same pattern from rats after chronic administration of the drug for a month. In both cases, three radioactive spots were observed. After further separation with countercurrent distribution and silica gel column chromatography, the three compounds were characterized as follows: Zone 1,

[8] Diotol.
[9] Packard Tri-Carb 314EX.
[10] Sigma Type H-2 β-glucuronidase, No. G-0876, 143,000 units/ml.
[11] Dubnoff.

unchanged clindamycin; Zone 2, clindamycin sulfoxide; and Zone 3, *N*-demethylclindamycin.

Appreciable quantities of both intact drug and clindamycin sulfoxide were isolated for an unequivocal identification. For the intact drug, results from all three spectroscopies and TLC were consistent with the authentic material.

For the clindamycin sulfoxide, mass spectrometry showed peaks (*m/e*) at 440 and 442, corresponding to the molecular ion; 377 and 379, due to the M − S(=O)CH_3 ion; 275 and 277, due to the M − methylthiogalactose ion; and 126, due to the propylhygric acid ion.

NMR spectroscopy showed that the protons of the S-methyl group were shifted downfield, which is consistent with the sulfoxide structure. IR (micro KBr pellet) and TLC results were identical to those for the reference material. Thus, the identity was established.

Since these spectra were presented elsewhere (3), they are not reproduced in this report.

The identity of *N*-demethylclindamycin was established mainly by TLC and mass spectrometry. The amount of isolated material was insufficient for a positive identification by NMR. This compound showed mass spectral peaks (*m/e*) at 410 and 412, corresponding to the molecular ion; 373 and 375, due to the M − SCH_3 ion; 261 and 263, due to the M − methylthiogalactose ion; and 112, due to the *N*-demethylpropylhygric acid ion. This was consistent with the assigned structure. Furthermore, the isolated material showed identical R_f values with an authentic sample of *N*-demethylclindamycin in all six TLC solvent systems tested. Both samples developed a purple color after spraying with ninhydrin reagent, which indicates the free secondary amine group. These results are all consistent with the identification of the unknown compound as *N*-demethylclindamycin.

Quantitative determination of the percentage of each component in rat urine was carried out with TLC (Fig. 4 and Table II). Similar results were obtained from five separate determinations of two pooled urine samples from rats given single or chronic doses of clindamycin with two different developing systems. In all cases, it was found that approximately one-half of the radioactivity in rat urine was unchanged clindamycin (53.36 ± 2.70%) and *N*-demethylclindamycin (15.10 ± 1.35%). These determinations were carried out on pooled urine samples, so the standard deviation represented only the variation of the TLC assays.

To determine whether chronic administration of clindamycin to rats would stimulate or inhibit its own metabolism, radioactive drug was given to these rats on the first and the last days of the 1-month dosing period, with unlabeled drug in between. The percentage of each major component in the two radioactive urine samples was measured and compared. The results (Table II) clearly revealed that the percentage of metabolites and unchanged drug did not change after chronic administration, which ruled out the possibility that clindamycin modified its own metabolism.

Dogs—Typical thin-layer chromatograms (Fig. 2) of the urine extracted from polystyrene resin column chromatography show three major radioactive zones plus one minor zone. Resolution of the same extract by silica gel column chromatography yielded eight fractions (Fig. 3 and Table I). Each fraction was characterized as follows.

Fraction 1—The materials under the two peaks were identical based upon TLC in three solvent systems. After purification by preparative TLC, this fraction yielded unchanged clindamycin as established by TLC, mass spectroscopy, and IR spectroscopy.

Fraction 2—This fraction was purified and identified as clindamycin sulfoxide by TLC and mass spectrometry.

Fraction 3—This fraction contained one radioactive compound, which appeared in the same R_f region as *N*-demethylclindamycin on the thin-layer chromatogram and also showed a positive ninhydrin reaction. It was tentatively identified as *N*-demethylclindamycin. Further confirmation was not possible since the quantity was too small.

Fractions 4 and 5—Both fractions were identical based upon TLC or countercurrent distribution. The isolated material was identified as clindamycin glucuronide by the following criteria:

1. Mass Spectroscopy—Low-resolution mass spectroscopy showed neither molecular ion nor any ion that contained a chlorine atom. Peaks were observed at *m/e* 388 (clindamycin free base − HCl), 345 (clindamycin free base − HCl − SCH_3), and 126 (hygric acid portion). It appeared that the compound lost hydrogen chloride readily upon electron impact.

High-resolution mass spectroscopy of the trimethylsilyl ether derivative showed peaks at *m/e* 1032 (molecular ion) which was consistent with the hexa(trimethylsilyl) clindamycin monoglucuronide. Peaks were also seen at *m/e* 1017 (M − 15); 966 (M − HCl); 989 (M − SCH_3); 375, due to the silylated sugar portion; and 126, due to the propylhygric acid portion of the molecule.

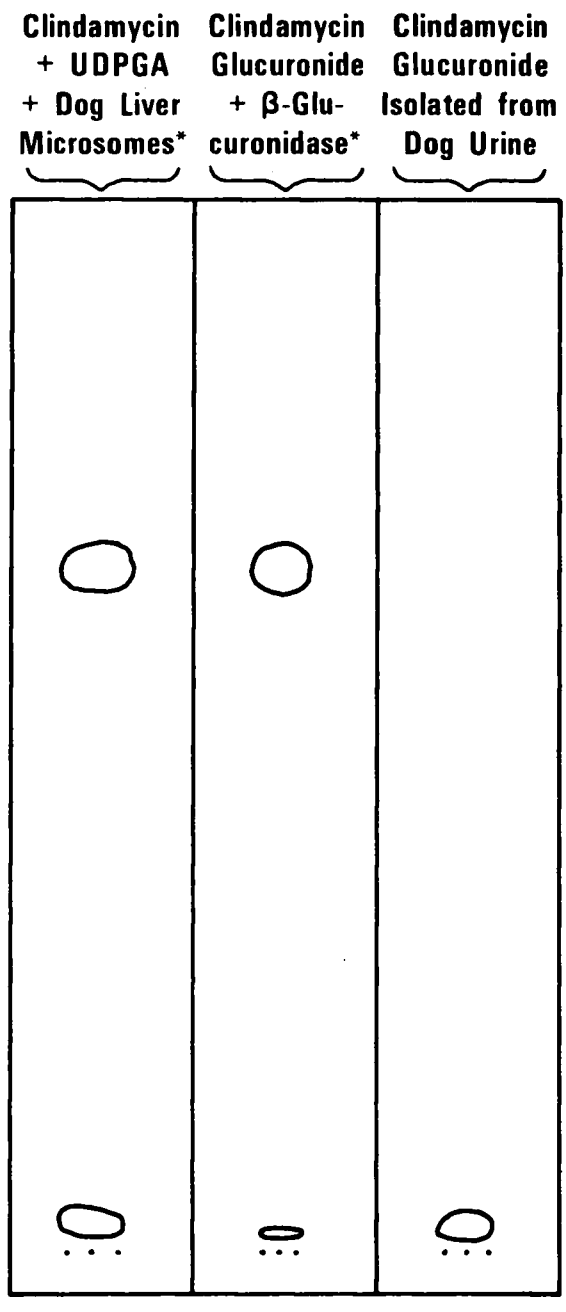

Figure 5—*Thin-layer chromatogram of three clindamycin glucuronide preparations. The solvent system was ethyl acetate–acetone–water (8:5:1). (* Extracts from polystyrene resin column chromatography.)*

2. IR Spectroscopy—The IR spectrum (micro KBr) was consistent with a glucuronic acid derivative of clindamycin with an ether linkage.

3. NMR Spectroscopy—The spectrum was too complex for a detailed analysis. It was not possible to locate which hydroxyl group was conjugated with glucuronic acid on the *S*-methylthiogalactose.

4. Glucuronidase Treatment—After treatment with β-glucuronidase, the glucuronic acid was removed and unchanged clindamycin was regenerated. The reaction product was identified by both TLC and mass spectroscopy.

5. TLC—The thin-layer chromatograms of clindamycin glucuronide isolated from dog urine compared to authentic clindamycin

Table III—Metabolites Produced by Incubating Liver Microsomes with Clindamycin-^{3}H in the Presence of NADPH and O_2 for 30 min.

Enzyme Source	Clindamycin Sulfoxide Produced, mole^{-9}/mg.	Formaldehyde Produced, mole ^{9}/mg.	*N*-Demethylclindamycin Produced, mole^{-9}/mg.
Rat liver microsomes	28.25	45.81	6.15
Boiled rat liver microsomes	1.82	—	—
Dog liver microsomes	21.24	22.50	Not detectable
Boiled dog liver microsomes	2.97	-	—

glucuronide are shown in Fig. 5. The identical R_f values serve as further confirmation of their identity.

Fractions 7 and 8—The two fractions contained less than 2% of the total radioactivity placed on the column. TLC showed that both fractions were heavily contaminated by known drug-related components, *i.e.*, unchanged clindamycin, clindamycin sulfoxide, and clindamycin glucuronide. These compounds were probably the sources of radioactivity. Both fractions were discarded.

Quantitative determination of the percentage of each component in dog urine was carried out by TLC. An average of 35.69% of the total radioactivity excreted in urine was unchanged drug. The remaining consisted of 27.57% clindamycin sulfoxide, 27.58% clindamycin glucuronide, and 9.16% *N*-demethylclindamycin.

Metabolism of Clindamycin-^{3}H *In Vitro*—Preliminary evidence was obtained that liver microsomes from both species are capable of catalyzing the bioconversion of clindamycin to its metabolites (Table III). When radioactive clindamycin was incubated with freshly isolated rat or dog liver microsomes in the presence of NADPH and oxygen, the predominant product was clindamycin sulfoxide. A small but detectable amount of *N*-demethylclindamycin could also be observed. However, if semicarbazide was added to the reaction mixture, the *N*-demethylation reaction could be readily demonstrated by following the formaldehyde generated with Nash's (7) reagent. Both metabolic activities were abolished when boiled microsomes were used or NADPH was deleted from the reaction mixture.

Glucuronic acid conjugation could also be demonstrated, under *in vitro* conditions, by the liver microsomes from both species. Radioactive clindamycin was incubated with microsomes in the presence of uridine diphosphoglucuronic acid and magnesium salt at 37° for 1 hr. The reaction mixture was deproteinized and passed through a polystyrene resin column. Clindamycin glucuronide in very small quantity was isolated from the extract by preparative TLC. It had the same spectral and chromatographic properties as the material isolated from urine and could be converted back to clindamycin by treatment with β-glucuronidase. Since the conditions of the reaction have not been optimized, the results cannot be expressed quantitatively at present.

The study described here has established that clindamycin is metabolized by the rat through two well-known mechanisms: *S*-oxygenation and *N*-demethylation. On the other hand, *S*-oxygenation and glucuronic acid conjugation are the major metabolic routes in the dog. However, since the major excretion route of clindamycin in both species is the feces (60–70%) rather than the urine, it would be risky to assume that the urinary composition of drug and metabolites reflects the overall picture.

The bioactivities of both clindamycin sulfoxide and *N*-demethylclindamycin have been determined in the past (3). *N*-Demethylclindamycin was approximately four times as effective as clindamycin in the antibacterial tests, whereas clindamycin sulfoxide has only one-quarter the activity of the parent drug.

The bioactivity of clindamycin glucuronide was determined[12], and the conjugate had practically no antibacterial activity (less than 0.02% of the antibacterial activity of clindamycin).

The species difference in glucuronic acid conjugation of clindamycin between rat and dog was quite interesting. The difference was probably partially due to a relative deficiency of uridine diphosphate-glucuronyltransferase in the rats used for this study. Investigation of the uridine diphosphate-glucuronyltransferase system in rat and dog liver showed that dog liver possessed five times more glucuronide synthesis activity than the rat liver using *p*-nitrophenol as substrate. A survey of the literature also indicated that rats possess the least glucuronide synthesis activity of the six species studied, *i.e.*, rabbit, guinea pig, mouse, sheep, and dog (8–10). However, since the metabolite profile of clindamycin in the feces was not known and the bioconversion of clindamycin to clindamycin glucuronide by rat liver microsomes could not be demonstrated, other factors, such as excretion through the bile, could be the cause for the failure to detect clindamycin glucuronide in rat urine.

Cactus Alkaloids XXI: β-Phenethylamines from *Dolichothele sphaerica*

J. J. DINGERDISSEN and J. L. McLAUGHLIN▲

Abstract □ Studies concerning the isolation and biosynthesis of an imidazole alkaloid, dolichotheline (*N*-isovalerylhistamine), in the cactus *Dolichothele sphaerica* (Dietr.) Br. and R. were previously reported. In the current investigation, chromatographic analysis (TLC) detected additional alkaloids; however, these compounds were β-phenethylamines rather than imidazoles. Preparative TLC aided in the crystallization of five of these compounds: *N*-methylphenethylamine hydrochloride, *N*-methyltyramine hydrochloride, synephrine hydrochloride, β-*O*-methylsynephrine hydrochloride, and β-*O*-ethylsynephrine hydrochloride. The last compound was shown to be an extraction artifact of synephrine. This is the first report of the isolation of *N*-methylphenethylamine from the Cactaceae, but the other natural compounds were all previously isolated from other cactus species.

Keyphrases □ Cactus alkaloids—isolation, identification of five β-phenethylamines from *Dolichothele sphaerica* □ *Dolichothele sphaerica* (Dietr.) Br. and R.—isolation, identification of five β-phenethylamines □ β-Phenethylamine alkaloids—isolation, identification from *Dolichothele sphaerica*

The known cactus alkaloids are generally either β-phenethylamines or the related tetrahydroisoquinolines. An exception is the imidazole alkaloid dolichotheline, 4(5)-[2-*N*-isovalerylaminoethyl]imidazole or *N*-isovalerylhistamine. This compound was isolated (1, 2) from *Dolichothele sphaerica* (Dietr.) Br. and R., a small cactus indigenous to southern Texas and northern Mexico. The biosynthesis of this unusual alkaloid was demonstrated (3, 4) to involve amide formation between histamine and isovaleric acid, with the latter compound likely arising naturally from leucine catabolism. Recently, this plant was also found (5) to produce aberrant imidazole alkaloids, such as *N*-isocaproylhistamine and 4(5)-[*N*-isovalerylaminomethyl]imidazole, when administered the proper exogenous precursors.

Earlier reports referred to the presence of "toxic" alkaloids in this species (6) and to ethnobotanical relationships of *Dolichothele* species with *Lophophora* through the common name of "peyote" (7–9). The present phytochemical studies with *D. sphaerica* were undertaken to isolate and identify additional unusual alkaloids that might have medicinal or psychotropic potential.

EXPERIMENTAL

Plant Material—Specimens of the cactus were purchased[1], and identification was made by comparison with a literature description[2] (10). Since the genus *Dolichothele* is not universally recognized, the botanical synonym, *Mammillaria longimamma* DC. var. *sphaerica* K. Brandegee as described by Benson (11), was included in the identification. The cacti were sliced, frozen, freeze dried (87% moisture) at temperatures not exceeding 30°, and ground to a powder using a 2-mm. sieve on a Fitzpatrick mill.

Preparation of Crude Alkaloid Fractions—The powdered plant material (617 g.) was defatted, basified, and extracted *via* chloroform percolation (12, 13). Condensing the filtered chloroform extract on a flash evaporator[3] and then under rotary vacuum evaporation produced a thick syrup, which was extracted with six successive 200-ml. portions of 1 *N* hydrochloric acid. The aqueous extracts were filtered, combined, and extracted six times with 1-l. portions of both chloroform and ether. These organic extracts were combined, dried over anhydrous sodium sulfate, and condensed under rotary vacuum to a residue containing primarily nonalkaloidal material (Fraction B).

Following basification of the aqueous solution to pH 8.5 with sodium hydroxide, the solution was extracted with 3 l. each of chloroform and ether (in 1-l. portions). Repeated extractions at pH 9.5 and 10.5 resulted in combined extracts totaling 18 l., which were condensed with the flash and rotary vacuum evaporators to a volume of 5 ml. containing the bulk of the alkaloids (Fraction A).

Traces of organic solvents were removed from the aqueous solution by placing it under rotary vacuum evaporation at 40° for 30 min.; then it was freeze dried. The remaining salt residue was extracted with portions of 10% ethanol in chloroform until the eluates were colorless. The combined eluates were filtered and condensed under rotary vacuum evaporation to yield the water-soluble alkaloids (Fraction C).

Analysis of crude alkaloid Fractions A, B, and C with analytical TLC detected dolichotheline and four unknown alkaloids in Fractions A and C; Fraction B contained traces of dolichotheline mixed with nonalkaloidal material. Fractions A and C were combined, and the resulting ethanolic solution was separated into phenolic and nonphenolic portions using a basic ion-exchange column[4] as previously described (12).

TLC—Previously utilized TLC methods were used analytically to provide a tentative identification of alkaloids in the extracts and preparatively to separate the components (12–15). Analytical TLC plates were purchased[5], and preparative plates were prepared with a 1-mm. layer of silica gel PF_{254}[6].

Analytical separations were achieved by the use of the following solvent systems: Solvent A, ethyl acetate–methanol–28% ammonium hydroxide (17:2:1); Solvent B, chloroform–ethanol–28% ammonium hydroxide (15:20:1); Solvent C, chloroform–methanol–28% ammonium hydroxide (18:1:1); Solvent D, chloroform–acetone–diethylamine (5:4:1); Solvent E, ether–acetone–methanol–28% ammonium hydroxide (9:8:2:1); Solvent F, ether–methanol–28% ammonium hydroxide (17:2:1); Solvent G, chloroform–acetone–28% ammonium hydroxide (10:8:1); and Solvent H, methyl ethyl ketone–dimethylformamide–28% ammonium hydroxide (80:12:1).

Preparative separations were achieved using Solvent F with repeated developments for maximal separations as monitored under shortwave UV light. Analytically, the alkaloids were detected using sprays of dansyl chloride (12), tetrazotized benzidine (12), and a modified Pauly's reagent to react with imidazoles (16).

Resolution of Nonphenolic Alkaloids—Analytical TLC revealed that this fraction contained dolichotheline, a major unknown al-

kaloid which fluoresced with dansyl chloride and produced a white chromophore with tetrazotized benzidine, and traces of five possible imidazoles that produced red chromophores with Pauly's reagent and gave R_f values in Solvent F at 0.29, 0.34, 0.43, 0.48, and 0.55. Ten milliliters from a 30-ml. ethanolic solution containing the total nonphenolic extract was condensed to a residue and, after four crystallizations from acetone–benzene (1:1), yielded a total of 1.338 g. of dolichotheline, melting point and mixed melting point 129–131° [lit. (1) m.p. 130–131°].

The mother liquor remaining from the dolichotheline crystallization was resolved *via* preparative TLC on 43 plates (20 × 20 cm.). The major unknown was eluted from the combined similar bands with ammoniacal ethanol (15). Analytical TLC of the condensed filtrates indicated chromatographic purity, and the hydrochloride was prepared by acidifying with anhydrous hydrogen chloride in absolute ethanol (5% w/w) and inducing crystallization by the dropwise addition of ether (yield 92.5 mg.).

Identification of Unknown Nonphenolic Alkaloid—A lime-green fluorescent dansyl conjugate of this alkaloid indicated a primary or secondary amine function (12). The IR spectrum[7] of the hydrochloride showed major bands at ν_{max}^{KBr} 2940, 2760 (broad, aromatic, and aliphatic C—H and salts), 1600, 1501, 1480 (aromatic C=C), 1315, 1080, 1055, 1020, 945, 890, 780, 740, and 690 cm.$^{-1}$. NMR spectra[8] showed peaks in deuterochloroform at δ 2.7 (singlet, 3H, CH_3—N), 3.2 (singlet, 4H, CH_2—CH_2), 7.3 (singlet, 5H, aromatic), and 9.8 (singlet, 1H, N—H). The low-resolution mass spectrum[9] showed a parent ion peak at *m/e* 135 (0.2%, $C_9H_{13}N$) and major fragmentation peaks at 91 (16.6%, C_7H_7), 65 (14.8%, C_5H_5), 44 (100%, CH_2NHCH_3), and 28 (14.2%, C_2H_4) consistent with those expected for phenethylamines.

Interpretation of these data suggested that the unknown alkaloid was simply *N*-methylphenethylamine hydrochloride. A reference sample of *N*-methylphenethylamine hydrochloride was synthesized from phenethylamine (17). Spectral data (IR, NMR, and mass spectrometry) obtained with the synthetic compound were essentially identical to those obtained with the isolated alkaloid hydrochloride. The melting points[10] and mixed melting points of the isolated and reference *N*-methylphenethylamine hydrochloride were the same (164–165°). Cochromatography of the isolate with the reference in five TLC systems (A, B, C, F, and G) substantiated this identification.

Resolution of Phenolic Alkaloids—Analytical TLC of this fraction revealed the presence of three major alkaloids and one minor alkaloid. Nine milliliters of a 26-ml. (total) ethanolic solution of this fraction was resolved *via* preparative TLC on 64 plates (20 × 20 cm.). The bands, after detection under UV light or by spraying the edge of the plate with tetrazotized benzidine, were removed and eluted. Further TLC analysis of the condensed eluates allowed a tentative identification of three alkaloids as *N*-methyltyramine, *β-O*-methylsynephrine, and synephrine. Crystalline hydrochlorides for the first two were then prepared as described previously.

Identification of Phenolic Alkaloids—Cochromatography with reference racemic *β-O*-methylsynephrine hydrochloride in five solvent systems (A, C, F, G, and H) tentatively identified this compound as one of the crystallized phenolic alkaloids. Melting points and mixed melting points were similar (186–189°). IR spectral data were comparable between the isolated and reference racemic *β-O*-methylsynephrine hydrochloride; however, slight shifts and different intensities of a few bands in the IR spectrum of the isolate when compared to that of the racemic reference suggested that the isolate was likely (−)-*β-O*-methylsynephrine hydrochloride (15, 18). Determination of the optical rotation was not attempted due to the low yield (13.5 mg.). The NMR spectra of the two compounds in deuterated methanol compared identically, with peaks at δ 2.6 (singlet, 3H, CH_3—N), 3.2 (multiplet, 5H, containing a singlet, 3H, CH_3—O, and a doublet, 2H, CH_2—C—H), 4.3 (weak multiplet, 1H, benzylic), and 7.0 (quartet, 4H, *para*-substituted aromatic). Mass spectral analysis showed parent ion peaks at *m/e* 181 and the expected fragmentation.

Reference *N*-methyltyramine hydrochloride and the second crystalline hydrochloride consistently cochromatographed (Solvents A, B, C, F, and G). The melting point of the isolate (146–148°) and mixed melting point (147–150°) with reference *N*-methyltyramine hydrochloride proved to be similar. The IR spectra were essentially identical, and both showed bands at ν_{max}^{KBr} 3260 (phenolic OH), 2890, 2810 (broad, aromatic and aliphatic C—H, secondary amine salt), 1620, 1600, 1530 (aromatic C=C), 1220 (C—O), and 820 cm.$^{-1}$. The NMR spectra showed peaks in deuterium oxide at δ 2.8 (singlet, 3H, N—CH_3), 3.1 (multiplet, 4H, containing two overlapping triplets, CH_2—CH_2), and 7.1 (quartet, 4H, *para*-substituted aromatic). Mass spectral analysis of the isolate showed a parent ion peak at *m/e* 151 and major fragmentation peaks corresponding to the fragmentation observed with reference *N*-methyltyramine hydrochloride.

The eluates containing synephrine were further separated *via* preparative TLC on eight plates (20 × 20 cm.) to yield synephrine and an unknown alkaloid which cochromatographed with the unknown minor phenolic alkaloid previously mentioned. These latter eluates were combined, and the hydrochlorides of these compounds were then successfully crystallized.

Cochromatography of the isolated synephrine hydrochloride and reference synephrine hydrochloride in Solvents A, B, C, F, and G substantiated the identification of the isolate as synephrine. Melting points and mixed melting points of the isolate and reference racemic synephrine hydrochloride were similar (153–155°). The IR spectra of the isolate and reference racemic material were similar but exhibited some differences (15, 18); however, the IR spectrum of the isolate and that of natural (−)-synephrine hydrochloride (15) were essentially identical, and the isolate is assumed to be (−)-synephrine hydrochloride. The NMR spectrum in deuterium oxide showed peaks at δ 2.6 (singlet, 3H, N—CH_3), 3.2 (doublet, 2H, CH_2—C—H), 4.9 (multiplet overlapping D_2O peak, 1H, benzylic), and 7.1 (quartet, 4H, *para*-substituted aromatic). Mass spectral analysis showed a parent ion peak at *m/e* 167 and major fragmentation peaks consistent with those observed for reference synephrine hydrochloride.

The IR spectrum of the unknown phenolic alkaloid showed bands at ν_{max}^{KBr} 3240, 2980 (broad, aromatic and aliphatic C—H, secondary amine salts), 1620, 1610, 1600, (aromatic C=C), 1300, and 1110 (ether, aryl C—O) cm.$^{-1}$. Due to the small amount of material isolated (8.8 mg.), an NMR spectrum was not obtained. Analysis of high-[11] and low-resolution mass spectral data allowed the assignment of *m/e* 195 (2.3%, $C_{11}H_{17}NO_2$) as the parent ion. The major fragmentation peaks that aided in the structural assignment were at 151 (100%, $C_9H_{11}O_2$), 150 (18.6%, $C_9H_{12}NO$), 123 (82.5%, $C_7H_7O_2$), and 77 (24.4%, C_6H_5). The UV spectrum[12] showed two peaks at 225.5 and 275 nm., with $E_{1\,cm.}^{1\%}$ values equal to 450 and 75, respectively; in base these peaks showed a bathochromic shift typical of *para*-hydroxyphenols. Interpretation of these data suggested that the unknown was *β-O*-ethylsynephrine.

Synthesis of Reference *β-O*-Ethylsynephrine—A modification of the procedure of Stewart and Wheaton (18) was used. One gram of synephrine base[13] was added to an excess (15 g.) of thionyl chloride under nitrogen. After a few minutes, the precipitate was washed with benzene and again with ether. Ten milliliters of ethanol was added, and the mixture was refluxed in a water bath for 1 hr. The resulting solution was condensed to a small volume, and the addition of acetone induced crystallization. Treatment with activated charcoal and recrystallization from ethanol and ether yielded 512 mg. (51% yield) of synthetic (±)-*β-O*-ethylsynephrine hydrochloride (m.p. 169–171°). IR, NMR, and mass spectral data identified the material as the desired synthetic product.

Identification of Unknown Phenolic Alkaloid as *β-O*-Ethylsynephrine—TLC comparison of the synthetic *β-O*-ethylsynephrine hydrochloride with the isolated unknown alkaloid resulted in cochromatography (Solvent F) and identical chromophore formation with tetrazotized benzidine. Melting points of the isolated alkaloid (167–169°) and mixed melting points (170–173°) further supported this identification. IR and mass spectral data were likewise confirmatory.

To substantiate the natural occurrence of this compound in the plant, a new extraction of a 20-g. sample of *D. sphaerica* was made using methanol in place of ethanol and deleting ether in the original

Table I—Quantities of Alkaloids Isolated from *D. sphaerica*

Alkaloid	Yield, mg.	Concentration in Cactus, % w/w
Dolichotheline	1338.0	0.6500
N-Methylphenethylamine hydrochloride	92.5	0.0411
β-*O*-Methylsynephrine hydrochloride	13.5	0.0060
N-Methyltyramine hydrochloride	26.0	0.0115
Synephrine hydrochloride	7.5	0.0033
β-*O*-Ethylsynephrine	8.8	0.0038

extraction procedure. Following this new extraction, analytical TLC (Solvent F) of Fractions A and C showed the complete absence of this alkaloid in the extracts. Apparently, since several steps in the usual extraction procedure utilize acid and ethanol, there was an ethylation of some natural synephrine to produce β-*O*-ethylsynephrine as an artifact.

DISCUSSION

As summarized in Table I, six alkaloids were isolated as their hydrochlorides from alkaloid extracts of *D. sphaerica*. Identifications of the compounds were achieved by comparing data (IR, NMR, and mass spectral), TLC behavior, and melting points with those of reference alkaloids. The isolated alkaloids were dolichotheline, as expected from previous reports (1, 2), *N*-methylphenethylamine hydrochloride, *N*-methyltyramine hydrochloride, synephrine hydrochloride, β-*O*-methylsynephrine hydrochloride, and β-*O*-ethylsynephrine hydrochloride. Since ethyl groups are rare in nature, reextraction of additional plant material, taking care to eliminate any contact with ethyl-containing compounds, was performed; TLC analysis then failed to detect β-*O*-ethylsynephrine in the new extracts. Apparently, this compound was isolated as an extraction artifact of synephrine; similar *O*-alkylation of synephrine while extracting it from tangerine leaves was reported (18).

N-Methylphenethylamine, the major new alkaloid isolated, has never before been isolated from the Cactaceae. This compound was first isolated in 1939 from *Arthrophytum leptocladum* Popov in the Chenopodiaceae (19, 20) and has since been isolated from several *Acacia* species (Leguminosae) (21–26). Of particular interest is its isolation from *Acacia berlandieri* Benth. as a major toxic constituent (26); goats and sheep in west Texas eat this shrub in large amounts during prolonged drought and suffer from a condition known as "Limberleg" or "Guajillo Wobbles." However, the acute action of *N*-methylphenethylamine as a pressor agent has been shown to occur experimentally with low toxicity (27, 28). Logical biosynthetic precursors for this alkaloid would be phenylalanine and methionine, following a similar two-step pathway as in the formation of *N*-methyltyramine from tyrosine in *Hordeum* (29).

N-Methyltyramine was first isolated from *Hordeum* in 1950 (17) and has previously been identified in several cactus species as well as other plant families (12, 13, 15, 30–33). It possesses weak sympathomimetic activity (34, 35).

β-*O*-Methylsynephrine has been isolated twice previously from the Cactaceae (15, 36) and from citrus leaf extracts as an artifact of synephrine (18). Comparison of IR spectra of the isolated and racemic reference β-*O*-methylsynephrine hydrochloride suggested that the isolate is the (−)-isomer. If this compound were made from synephrine during the extraction procedure, the racemic mixture would have been isolated. No reported studies concerning the pharmacological action of β-*O*-methylsynephrine were found; however, a similar compound, β-*O*-methylepinephrine, produces considerable central nervous system stimulation (37).

Synephrine was previously isolated and detected in *Citrus* (38), and it was detected in three other plant families (33) as well as in human urine (39). Recently, it was detected and isolated in several cacti (15, 36, 40, 41). Synephrine is a well-known sympathomimetic agent (42).

While the pharmacological action of the most abundant alkaloid, dolichotheline, remains unknown, the presence of these sympathomimetic β-phenethylamine alkaloids confers explainable physiological activity on this cactus and, perhaps, helps to explain its folkloric connections with *Lophophora*.

Kinetics and Mechanisms of Drug Action on Microorganisms XVII: Bactericidal Effects of Penicillin, Kanamycin, and Rifampin with and without Organism Pretreatment with Bacteriostatic Chloramphenicol, Tetracycline, and Novobiocin

EDWARD R. GARRETT▲ and CHONG MIN WON

Abstract □ *Escherichia coli* (ATCC 12407), generating in the logarithmic growth phase, was killed by penicillin, kanamycin, and rifampin. The logarithm of number of viables of the drug-treated culture decreased linearly with time after a certain lag period and above a minimum drug concentration. The slopes of these plots were characteristic of kill rate constants and were linearly dependent on drug concentrations. The microorganisms developed resistance against the cidal action of the antibiotics. The lower the penicillin concentration and the rate of kill, the greater is the number of resistant organisms, most probably formed by generation in the presence of penicillin. Penicillin was inactivated with time in the culture of organisms, and the resistant individuals eventually grew and were shown to be insensitive to penicillin. When organisms were exposed to the cidal action of kanamycin or rifampin, the appearance of resistant individuals was ascertained. Penicillin yielded debris and ghost cells of *E. coli*. No such apparent lysis was observed with kanamycin or rifampin. The activity of kanamycin increased with the pH of the medium, so activity can be assigned to the uncharged or lesser charged fraction of the drug concentration. The addition of penicillin or kanamycin to the organisms treated with tetracycline, chloramphenicol, or novobiocin did not show any significant difference in killing rate from organisms not previously treated with such bacteriostatic agents. However, the combination of a bactericidal and a bacteriostatic antibiotic depressed the resistant mutant formation of resistant individuals over that of the bactericidal drug alone. When rifampin was added to organisms pretreated with tetracycline or chloramphenicol, the cidal action of rifampin was significantly reduced.

Keyphrases □ Bactericidal activity, kinetics and mechanisms—penicillin, kanamycin, and rifampin with and without *E. coli* pretreatment with chloramphenicol, tetracycline, or novobiocin □ Antibiotics, kinetics and mechanisms of bactericidal activity—penicillin, kanamycin, and rifampin with and without *E. coli* pretreatment with chloramphenicol, tetracycline, or novobiocin □ Bacteriostatic *E. coli* pretreatment with chloramphenicol, tetracycline, or novobiocin—effect on bactericidal activity of penicillin, kanamycin, and rifampin

Antibacterial agents have two possible modes of action: inhibition of microbial generation and/or "kill" superimposed on generation. They can be differentiated by concomitantly monitoring the microorganism concentration of the nutrient medium containing the agent by viable (colony) counts and total (Coulter) counts as a function of time. It was shown (1) that the total counts and colony counts are coincident for the bacteriostatic tetracyclines, chloramphenicol, sulfonamides, macrolides, lincosaminides, *etc.*, in the concentration ranges below the amount resulting in complete inhibition of microbial generation.

The bactericidal action of drugs in defined concentration ranges must be kinetically defined by the time-consuming and laborious colony count method. This article reports on studies designed to quantify systematically the effects on microbial generation of several bactericidal antibiotics: penicillin, kanamycin, and rifampin.

The primary action of penicillin is in the inhibition of the production of cell wall material, specifically in the biosynthesis of murein (2). Presumably by interacting with the acceptor site of the ribosome, kanamycin may cause significant conformational changes in ribosomes which induce ambiguity in the readout of mRNA. (2). Rifampin was shown (2) to inhibit DNA-dependent RNA synthesis by specifically interfering with the function of the RNA polymerase by forming a stable rifampin–polymerase complex.

EXPERIMENTAL

Microorganism—Replicate slants of *Escherichia coli* (ATCC 12407) were used in all experiments.

Culture Media—Bacto Antibiotic Medium 3[1], rehydrated (pH 7.05) according to the specifications of the manufacturer to Medium 3 USP, was used. The culture medium was filtered through a 0.45-μ filter[2] and autoclaved at 120° for 15 min. To obtain media in the pH range of 6.30–7.55, various amounts of concentrated hydrochloric acid and sodium hydroxide solution were added aseptically to the culture media.

Antibiotic—The assayed samples of sodium penicillin G[3] (1625

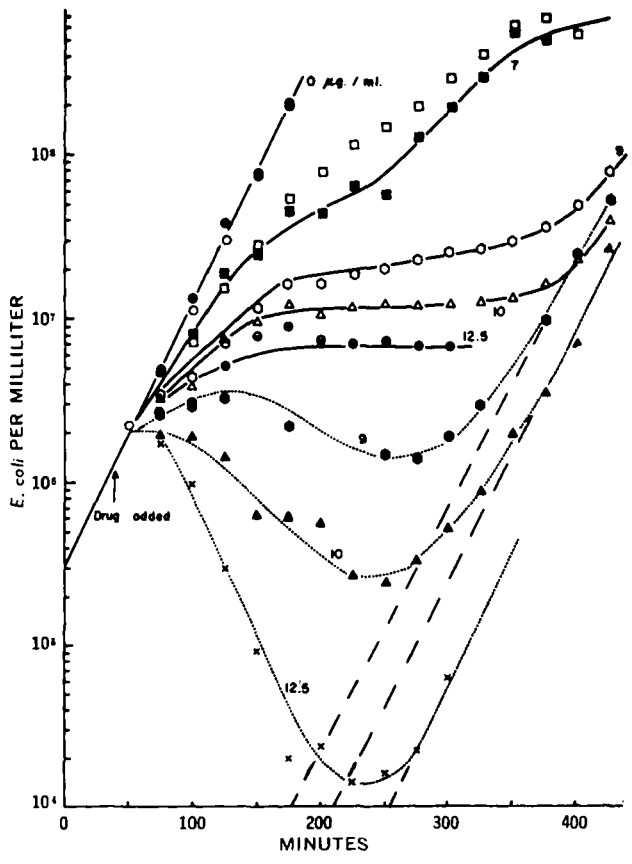

Figure 1—*Typical generation curves of* E. coli *in Medium 3 USP at pH 7.05 and 37.5° in the absence and presence of various concentrations of sodium penicillin G, obtained by total (solid lines) and viable (dashed lines) counts. The curves are labeled with the sodium penicillin G concentration in micrograms per milliliter. The short dashed lines represent the logarithmic growth of the emergent resistant organisms.*

units/mg.), kanamycin sulfate[4] (795 mcg./mg.), and rifampin[5] (981 mcg./ml.) were used.

Bacterial Culture—An aliquot (5 ml.) of culture medium was inoculated from a fresh slant, and the culture was allowed to generate for 15 hr. at 37.5° in an incubator. An aliquot (0.5 ml.) was then diluted into 49.5 ml. of fresh culture medium. The generation of the culture was followed up to 2×10^7 *E. coli*/ml. An aliquot of this culture was added to bulk broth medium so that the organism population was diluted 100-fold. The inoculated bulk solution was shaken and kept in an incubator at 37.5° for 15 min. Aliquots (49.5 ml.) of the inoculated broth medium were then aseptically transferred into replicate, 125-ml., loosely capped conical flasks through a delivery head. The temperature of the cultures was maintained at 37.5 ± 0.01° in a constant-temperature water bath equipped with a shaker.

Total Count Method—Aliquots (1.00 or 0.50 ml.) of cultures were withdrawn at 25-min. intervals and added to an appropriate amount of diluent. The diluent was a 0.45-µ filtered[2] aqueous solution of 0.85% sodium chloride and 1% formaldehyde. This number of organisms in a 50-µl. sample was counted on the Coulter counter[6] equipped with a 30-µ orifice. The total counts were corrected for the background counts of the particular batch of medium used, which was diluted in the same way as the sample. The coincidence corrections were made by a program on a calculator[7] in accordance with the coincidence correction chart supplied by the manufacturer's manual for the Coulter counter.

Viable Count Method—Aliquots (0.50 ml.) of the drug-affected culture were withdrawn and appropriately diluted into sterilized 0.85% saline solution according to a preplanned dilution scheme. Aliquots (1.00 ml.) from those dilutions were pipeted onto each of three replicate agar plates. The plates were incubated for 48 hr. at 37.5°, and colonies were counted on a colony counter[8].

Effect of Bactericidal Antibiotics on Generation Rates—Fresh solutions of sodium penicillin G, kanamycin sulfate, and rifampin were aseptically prepared for each experiment. They were sufficiently diluted so that aliquots of 0.50 ml. added to 49.5 ml. culture yielded the desired graded drug concentrations. The antibiotic solutions were added to the cultures generating at 37.5° in the logarithmic phase at predetermined organism populations. Samples were withdrawn every 25 min. and counted by the total count method as well as by the viable method. One culture without drug was studied in each experiment as a control. The plots of the logarithm of the total and viable numbers of *E. coli* per milliliter against time yielded generation curves for penicillin-, kanamycin-, and rifampin-affected cultures (Figs. 1–3).

Irreversibility of Kanamycin Action—Aliquots (5.0 and 0.5 ml.) of a drug-free culture generating in the logarithmic phase with an inoculum size of 1.7×10^7 *E. coli*/ml. (curve A in Fig. 4) were added to 45.0 and 49.5 ml. of fresh broth so that the organism population was diluted 10-fold (curve B) and 100-fold (curve C), respectively. A 49.5-ml. volume of broth containing 2.2×10^6 *E. coli*/ml. in the logarithmic generation phase was treated with 0.5 ml. of kanamycin sulfate solution to achieve a final concentration of 5 mcg./ml. (curve D). Twenty-five minutes after the drug addition, aliquots of curve D culture were diluted 10-fold into broth containing enough kanamycin sulfate so that the drug concentrations were adjusted to 1.7 (curve E), 2.2, and 3.3 mcg./ml. At 205 min., after the total counts of the culture of curve D reached a plateau of 1.5×10^7 *E. coli*/ml., aliquots of 5.0 and 0.5 ml. were added to 45.0 and 49.5 ml. fresh broth so that both organism and drug concentrations were diluted 10-fold (curve E) and 100-fold (curve F), respectively. At the same time, aliquots of the culture of curve D were diluted 10-fold (curve E) and 100-fold (curve F) in broths containing enough kanamycin sulfate so that the drug concentration was restored to 5 mcg./ml.

Cell Size Analyses—The size distribution of cells of *E. coli* in the

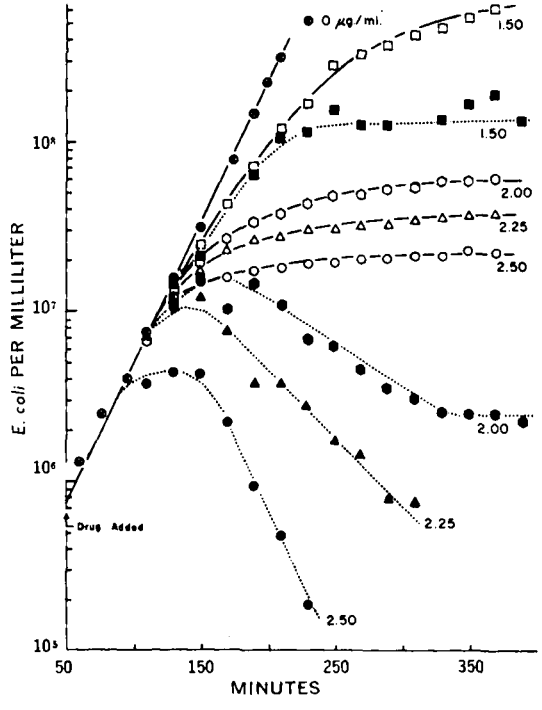

Figure 2—*Typical generation curves of* E. coli *in Medium 3 USP at pH 7.05 and 37.5° in the absence and presence of various concentrations of kanamycin sulfate, obtained by total (solid lines) and viable (dashed lines) counts. The curves are labeled with the kanamycin sulfate concentration in micrograms per milliliter.*

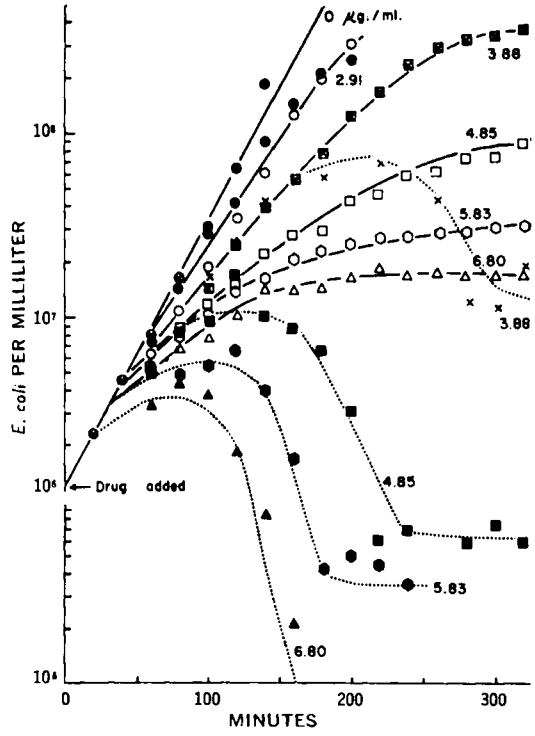

Figure 3—*Typical generation curves of* E. coli *in Medium 3 USP at pH 7.05 and 37.5° in the absence and presence of various concentrations of rifampin, obtained by total (solid lines) and viable (dashed lines) counts. The curves are labeled with the rifampin concentration in micrograms per milliliter.*

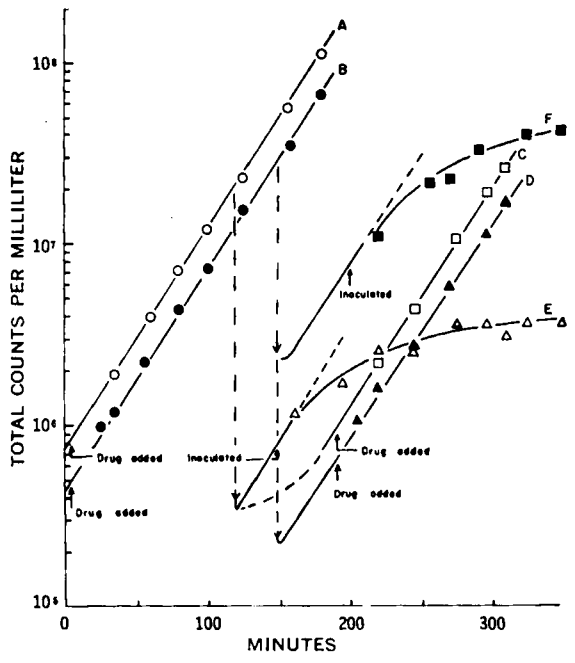

Figure 5—*Proof of development of rifampin- and kanamycin-resistant* E. coli. *Curves A and B are the generation curves for the cultures of rifampin- and kanamycin-resistant* E. coli *treated with 8.7 and 4.0 mcg./ml. rifampin and kanamycin, respectively. Curves C and D result when the filtered organisms of the cultures of curves A and B, in fresh medium, are treated with 8.7 and 4.0 mcg./ml. rifampin and kanamycin, respectively. Curves E and F result when the filtrates of the cultures of curves A and B, respectively, are inoculated with fresh* E. coli.

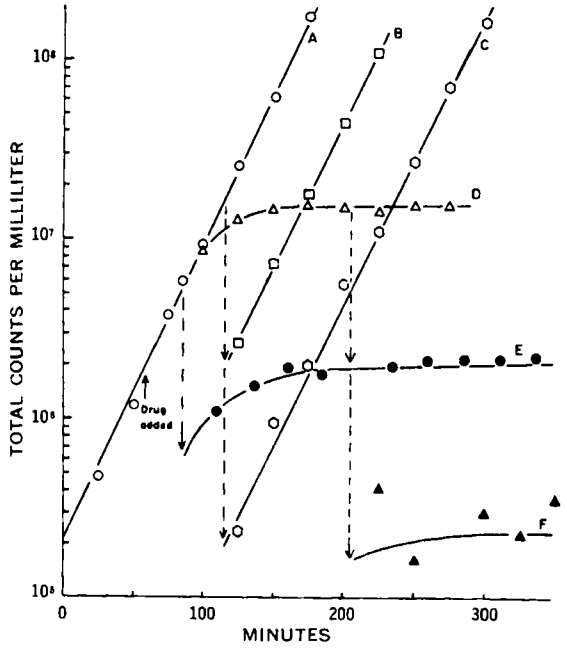

Figure 4—*Irreversibility of kanamycin sulfate-inhibited generation of* E. coli. *Curve A is for the drug-free culture. Curves B and C result after 1:10 and 1:100 dilutions, respectively, of the curve A culture with fresh broth. Curve D results after the addition of kanamycin sulfate to achieve a final concentration of 5 mcg./ml. Curve E results after the 1:10 dilution of curve D at 25 min. with broth containing kanamycin sulfate at a final concentration of 1.7 mcg./ml. Curve E also results after 1:10 dilution of curve D at 205 min. with final concentrations of 0.5 and 5 mcg./ml. of kanamycin sulfate. Curve F results after 1:100 dilution of curve D and with final concentrations of 0.05 and 5 mcg./ml. of kanamycin sulfate.*

presence or absence of penicillin, kanamycin, and rifampin was studied using the Coulter counter in conjunction with a Channelyzer and plotter[9]. The instruments were calibrated with polyvinyl toluene latex beads of 1.305-μ mean diameter. Replicate 49.5-ml. samples of culture generating in the logarithmic phase were treated with penicillin, kanamycin, and rifampin stock solutions to achieve final concentrations of 24.0, 4.0, and 8.7 mcg./ml., respectively. Samples were taken every 25 min., and cell size distribution was obtained. A culture generated in the absence of drug was studied as a control.

Bacterial Resistance to Penicillin Action—Aliquots (0.5 ml.) of sodium penicillin G solutions were added to cultures generating in the logarithmic phase to achieve final concentrations of 7.0 (Culture A), 9.0 (Culture B), and 12.5 (Culture C) mcg./ml. The drug-affected cultures of A, B, and C were allowed to generate for 15 hr. at 37.5° in an incubator. An aliquot (0.5 ml.) was then diluted into 49.5 ml. of fresh culture medium, brought up to the logarithmic growth phase, and diluted 100-fold again with fresh medium so that the original penicillin concentrations were diluted 10,000-fold. (See section on *Bacterial Culture.*) Aliquots of this solution were treated with various amounts of penicillin. The microorganisms generated from Culture A were treated with drug concentrations of 7.0, 10.0, 20.0, 39.6, and 77.7 mcg./ml.; those generated from Culture B were treated with 9.0, 20.0, 39.6, 77.7, and 114 mcg./ml.; and those generated from Culture C were treated with 12.5, 20.0, 39.6, 77.7, and 114 mcg./ml. Coulter counts were obtained every 25 min. for all drug-affected generations. The microorganisms generated from Culture C and treated with 12.5 mcg./ml. of sodium penicillin G were aseptically filtered 55 min. after the drug addition. The filtrate was inoculated with fresh organisms in the logarithmic generation phase.

A fresh broth was inoculated with the filtered organisms and treated with fresh drug solution to give a final concentration of 12.5 mcg./ml. of sodium penicillin G.

Bacterial Resistance to Kanamycin and Rifampin—Aliquots (0.5 ml.) of kanamycin and rifampin solutions were added to cul-

[9] Coulter Electronics, Inc.

Curve G results when kanamycin sulfate (2.50 mcg./ml.) is added to the culture of curve B, and curve H results when rifampin (6.00 mcg./ml.) is added to the culture of curve B.* (c) *Curve B results from the generation of culture in the presence of 90.0 mcg./ml. of novobiocin. Curve F results when sodium penicillin G (10.0 mcg./ml.) is added to the novobiocin-affected culture of curve B. Curve G results when kanamycin sulfate (2.50 mcg./ml.) is added to the culture of curve B, and curve H results when rifampin (6.00 mcg./ml.) is added to the culture of curve B.*

tures in the logarithmic growth phase to achieve final concentrations of 4.0 mcg./ml. of kanamycin and 8.7 mcg./ml. of rifampin. The drug-treated cultures were allowed to generate in an incubator for 15 hr. at 37.5°. An aliquot (0.5 ml.) was then diluted into 49.5 ml. of fresh culture medium, brought up to the logarithmic growth phase, and diluted 100-fold again so that the original drug concentrations were diluted 10,000-fold. (See section on *Bacterial Culture.*) Aliquots were treated with various amounts of the respective antibiotics.

The cultures of rifampin- and kanamycin-treated *E. coli* were again challenged with rifampin (curve A in Fig. 5) or kanamycin (curve B) to achieve final concentrations of 8.7 and 4.0 mcg./ml., respectively. One hundred fifteen minutes after rifampin addition and 145 min. after kanamycin addition, the cultures of curves A and B were filtered and the filtered organisms were allowed to generate in fresh broth medium. Aliquots of the cultures of the filtered organisms were diluted into fresh medium and treated with rifampin (curve C) or kanamycin (curve D) to give final concentrations of 8.7 and 4.0 mcg./ml., respectively. The filtrates of cultures of curves A and B were inoculated with aliquots of fresh *E. coli* generating in the logarithmic growth phase and gave curves E and F, respectively.

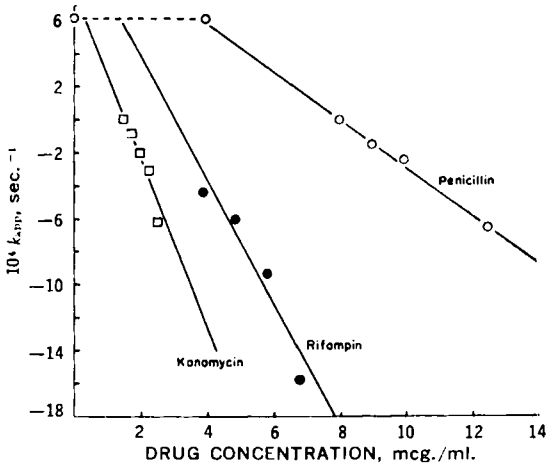

Figure 7—*Dependence of the apparent generation rate constant, k_{app}, for* E. coli *in Medium 3 USP on sodium penicillin G, kanamycin sulfate, and rifampin concentrations. The curves are constructed from two separate experiments.*

Effect of pH on Kanamycin-Affected Generation Rates—Six replicate 49.5-ml. volumes of medium, each buffered at a different pH value, were inoculated with an *E. coli* culture in the logarithmic generation phase. Drug solutions were added to the aliquots of these replicate cultures to achieve desired concentrations of kanamycin. Coulter counts were obtained for samples withdrawn every 25 min.

Potentiometric Determination of pKa Values of Kanamycin—Ninety-four milligrams of kanamycin sulfate was dissolved in 2.5 ml. of 0.2 *N* NaOH solution. A direct-reading pH meter[10] with a combination pH electrode[11] was used for pH measurements. The titrant was 1 *N* HCl solution and was delivered by a microburet[12] having a total capacity of 2 ml. and reading to 0.001 ml. on a microgauge. A magnetic stirrer kept the solution agitated. The procedure was repeated for a blank titration of a solution prepared like the sample solution with only the drug omitted.

Action of Penicillin, Kanamycin, and Rifampin in Combination with Bacteriostatic Antibiotics Tetracycline, Chloramphenicol, and Novobiocin—Replicate 49.5-ml. volumes of a culture containing 4×10^5 *E. coli*/ml. generating in the logarithmic phase (curve A in Fig. 6*a*) were treated with tetracycline (curve B), penicillin (curve C), kanamycin (curve D), and rifampin (curve E) to give final concentrations of 0.30 mcg./ml. of tetracycline hydrochloride, 10.0 mcg./ml. of sodium penicillin G, 2.50 mcg./ml. of kanamycin sulfate, and 6.00 mcg./ml. of rifampin, respectively. Twenty-five minutes after the addition of the first drug, replicate samples of the tetracycline-treated culture of curve B were treated with penicillin (curve F), kanamycin (curve G), or rifampin (curve H) to achieve final concentrations of 10.0 mcg./ml. of sodium penicillin G, 2.50 mcg./ml. of kanamycin sulfate, and 6.00 mcg./ml. of rifampin, respectively, with each containing the 0.30 mcg./ml. of tetracycline. Samples were taken every 25 min. Coulter counts were obtained for the drug-free culture (curve A) and tetracycline-treated culture (curve B), and viable counts were obtained for penicillin-, kanamycin-, or rifampin-treated cultures (curves C–H).

The experiment was reported for the combined action of penicillin, kanamycin, and rifampin with 1.90 mcg./ml. of chloramphenicol (Fig. 6*b*) and 90 mcg./ml. of novobiocin (Fig. 6*c*).

RESULTS AND DISCUSSION

Effects of Drugs on Microbial Generation—The numbers of *E. coli* as a function of time as affected by various concentrations of penicillin, kanamycin, and rifampin are plotted semilogarithmically in Figs. 1, 2, and 3, respectively. Certain general features of these curves are common to all three drugs. Subsequent to drug inoculation of the medium, the apparent generation rates of viables, as monitored by colony counts, decrease until the number of viables reach a maximum. These maxima are lower and occur faster with time the greater the drug concentration. Subsequent to these maxima and at the higher drug concentrations, the numbers of variables decrease and approach a first-order decay as manifested by a linear plot of the logarithm of viables against time. At the lowest concentration of drugs studied (7.0 mcg./ml. of sodium penicillin G, 1.5 mcg./ml. of kanamycin sulfate, and 3.88 mcg./ml. of rifampin), the generation rate was slowed until a relatively constant value of viables was achieved.

Subsequent to drug inoculation of the medium, the generation rate of total organisms, as monitored by Coulter counts, diminished and approached a constant value of plateau that persisted with time. These plateau values were lower with increasing concentrations of the drug.

The significant decreases in the numbers of *E. coli* per milliliter obtained by viable counts as a function of time compared to the total numbers obtained by the Coulter counter show that penicillin, kanamycin, and rifampin kill organisms at all of the studied concentrations (Figs. 1–3).

There were definite lag periods (Figs. 1–3) after drug addition before the slopes of the plots of logarithms of viable numbers against time decreased, and the effect was most pronounced with respect to kanamycin (Fig. 2). There were periods of slowed generation rates before the semilogarithmic plots decreased linearly with time. These intervals can be assigned to the time dependence of the drug partitioning process into the bacterial membrane, and their durations were apparent functions of drug concentrations.

The rate of loss of viables after these lag and induction periods may be expressed as the difference between the rate of generation and that of killing, where the latter is a function of drug concentration, *D* (1). If the kill rate is proportional to the first power of drug concentration:

$$dN/dt = (k_0 - k_D D)N \qquad \text{(Eq. 1}a\text{)}$$

$$dN/dt = k_{app}N \qquad \text{(Eq. 1}b\text{)}$$

where k_0 in the generation rate constant in the absence of drug, k_D is the kill rate constant, and N is the number of viable microorganisms. The apparent first-order generation rate constant, k_{app}, can be obtained from the slopes of the linear portions of semilogarithmic plots of number of viable counts against time in the drug-affected steady state prior to the appearance of possible resistant organisms, which may explain the terminal increase in microbial generation as manifested in Fig. 1.

The plot of k_{app} values against drug concentration demonstrates a linear dependence of k_{app} on drug concentration in accordance with the expectations of Eqs. 1*a* and 1*b* (Fig. 7). However, the actual function is:

$$k_{app} = k_0 - k_D(D - D^*) \qquad \text{(Eq. 2)}$$

A definite concentration of antibiotic must be exceeded before antibacterial activity is manifested. This minimum concentration, D^*, possibly may be assigned to the binding or removal of effective antibiotic concentration by the components of the medium (1). A maximum killing rate probably cannot be exceeded at very high concentrations of the antibiotics.

When the numbers of viables are negligible with respect to the numbers of dead organisms, the total numbers approach plateau values (Figs. 1–3). The plateau number, N_p, is some function of drug concentration and thus should be a function of the k_{app} value. Plots of k_{app} values against the logarithms of the ratio of the plateau number to the number at the time of drug addition, N_0, are shown in Fig. 8 for penicillin, kanamycin, and rifampin. Once the empirical relationship between $\log (N_p/N_0)$ and k_{app} is established, the k_{app} values can be estimated by Coulter counts only. This method has been applied to the studies of bacterial resistance to penicillin (Fig. 9) and of the effect of pH on kanamycin action (Fig. 10).

Effect of pH on Kanamycin Action—The k_{app} values may be estimated from the plateau numbers of total organisms from the correlations of Fig. 8. The estimated k_{app} values for cultures maintained at various pH values (6.30–7.50) are plotted against kanamycin sulfate concentrations in Fig. 10. The drug-free generation rate constants are independent of pH in this range (1), while the drug-affected apparent generation rate constants decrease with increasing pH at comparable drug concentrations. The slopes of the plots of Fig. 10 are representative of the killing constants, k_D, in Eq. 2 and

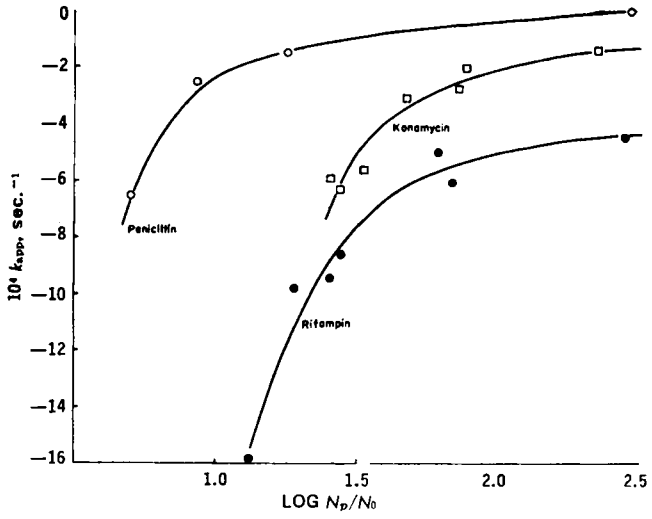

Figure 8—*Empirical relationship between the apparent generation rate constant, k_{app}, and the logarithm of the ratio of total counts at plateau (N_p) to the counts at the time of drug addition (N_0) for penicillin, kanamycin, and rifampin in Medium 3 USP.*

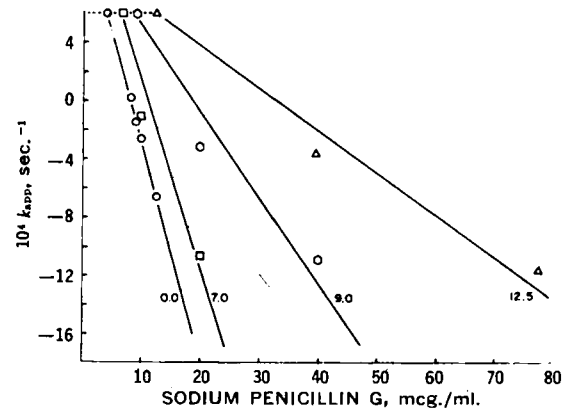

Figure 9—*Demonstration of the development of penicillin-resistant organisms on exposure to drug. Dependence of the apparent generation rate constant, k_{app}, for the generation of* E. coli *that has been exposed to penicillin on the sodium penicillin G concentration. The lines are labeled according to the sodium penicillin G concentrations, in micrograms per milliliter, to which the microorganisms were exposed for 15 hr. at 37.5° before these penicillin concentrations were diluted 10,000-fold and the concentrations of penicillin stated on the abscissa were added. The k_{app} values for viables were estimated from established correlations between rates of viable decay and plateau final values of total counts as given in Fig. 8.*

vary as a function of pH (Fig. 11). Potentiometric titration showed that kanamycin has four overlapping pKa values ranging from 6.5 to 9.7 (pKa_1 = 9.7, pKa_2 = 8.6, pKa_3 = 7.5, and pKa_4 = 6.5). The fact that the data in Fig. 12 are reasonably linear indicates that the less protonated or the unprotonated fraction of total kanamycin concentration is most probably the active species.

The minimum concentration, D^*, necessary for manifestation of antibacterial activity also decreases with increasing pH (Fig. 10) and implies that the inactivated species, possibly bound to components of the medium, is probably the more highly protonated.

Possible Development of Resistant Organisms to Drug Actions—Although there were indications from the terminal viable counts of the drug-affected organisms in the kanamycin and rifampin cases (Figs. 2 and 3) that some organisms remained that were resistant to the cidal action of these drugs but would not generate in their presence, it was clearly shown in the case of penicillin (Fig. 1) that there was either a population of organisms that did multiply in the presence of this drug or that the drug action had ceased after a time interval. This was manifested in the curves 200 min. after drug addition when the rate of decay of viables increased and eventually approached a typical first-order process of generation where the logarithmic number of viables was linear with time. The apparent parallelism of these terminal segments of the plots with that of a similar plot for *E. coli* generation in the absence of penicillin was indicative of negligible drug action.

Development of Penicillin-Resistant Organisms and Penicillin Inactivation—This phenomenon could be attributed to the consumption or degradation of the drugs, to the production of an inhibitor or inactivator of antibiotic action, and/or to the presence of bacteria able to resist the drug action. These bacteria could be present from the time of the microbial inoculation or could have arisen by mutation or adaptation processes occurring during the organisms' drug exposure. The cultures of *E. coli* were exposed to sodium penicillin G at concentrations of 7.0, 9.0, and 12.5 mcg./ml. for 15 hr., a time when the harvested organisms should be representative of a resistant strain if it exists (Fig. 1). When the original concentrations of penicillin were diluted 10,000-fold and the exposed organisms were challenged with the same concentrations of sodium penicillin G, they showed the same rates of generation as organisms in the absence of drug (Fig. 9). This is conclusive evidence that the subsequent increase in generation of viables of a culture exposed to penicillin was due to the presence of resistant organisms. The higher the drug concentration to which the organisms have been exposed, the greater is the drug concentration needed to kill organisms at the same rate (Fig. 9).

When the organisms that had been exposed to penicillin were filtered and used to inoculate fresh broth medium and were then challenged with penicillin, the generation rates of the filtered organisms were the same as the untreated *E. coli* in the absence of drug. When the filtrate was inoculated with naive organisms and challenged with penicillin, the generation rates were also the same as untreated *E. coli* in the absence of drug. These facts indicate that not only is the organism made resistant on exposure to penicillin but that the drug is degraded or inactivated in the culture. Thus, this drug degradation is a fast process and/or a penicillin antagonist is formed readily in the medium. The fact that penicillin is destroyed by β-lactamase produced by penicillin-resistant organisms (3) is consistent with this result.

The terminal data of the semilogarithmic plots of viables against time for various penicillin concentrations show an eventual increase in viables. The positive slopes of the plots of these terminal data appear to be parallel but have different intercepts (Fig. 1). Since the inoculum size for each study was the same, these penicillin-resistant organisms that manifest themselves are not the sole result of a small and constant fraction of the original inoculum that was penicillin resistant. Resistance must arise primarily during the time

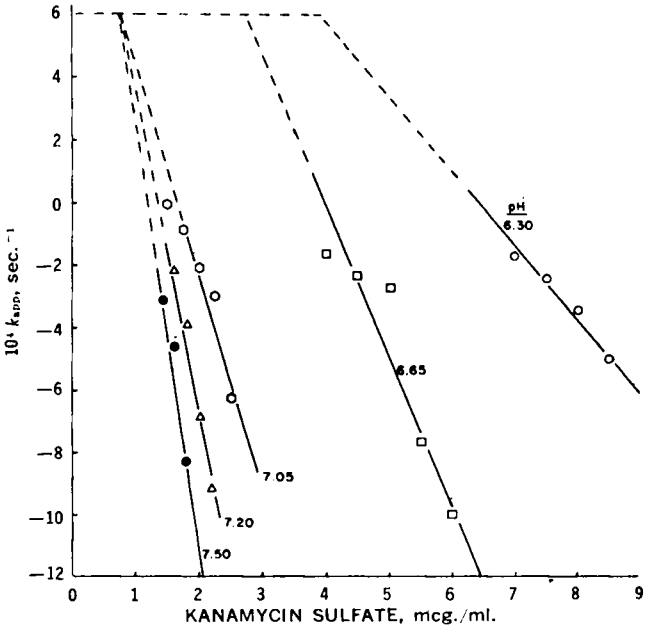

Figure 10—*Dependence of the apparent generation rate constant, k_{app}, for* E. coli *in Medium 3 USP on kanamycin sulfate concentration at various pH values.*

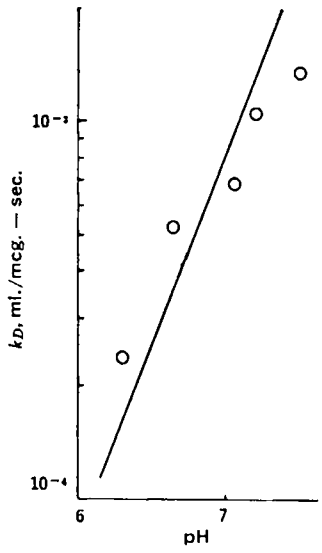

Figure 11—*Dependence of the killing constant, k_D, for the action of kanamycin on* E. coli *generation in Medium 3 USP on the pH value.*

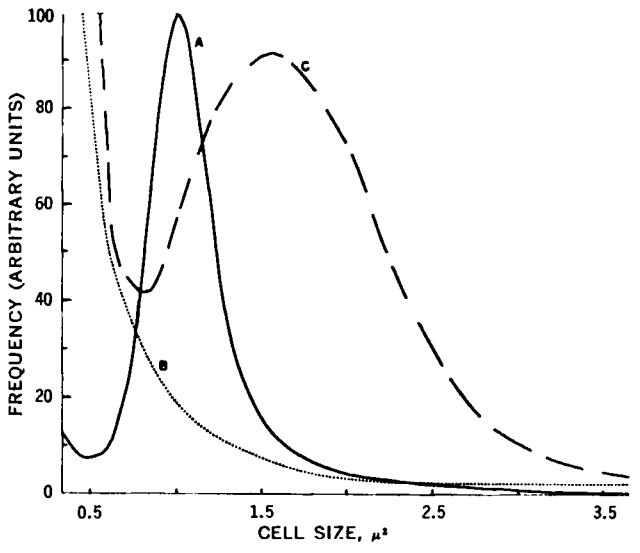

Figure 12—*Size-frequency distribution of the control organisms and (A) organisms treated with 4.0 mcg./ml. of kanamycin sulfate, (B) organisms treated with 24 mcg./ml. of sodium penicillin G 25 min. after drug addition, and (C) organisms treated with 8.7 mcg./ml. of rifampin 75 min. after drug addition.*

interval that the organisms are exposed to penicillin. The higher intercepts at lower penicillin concentrations imply the development of higher numbers of penicillin-resistant organisms at these concentrations for the same time after drug addition. Thus, the generation and production of resistants may be favored in the presence of lowered penicillin concentrations where some generation may still proceed.

Development of Rifampin- and Kanamycin-Resistant Organisms—When rifampin- and kanamycin-resistant organisms were filtered and the filtered organisms were tested in fresh medium against fresh drugs, the organisms were resistant to drug action (curves C and D in Fig. 5), whereas the filtrates showed drug activity when they were tested against fresh organisms (curves E and F). In these cases, therefore, the premise that the drugs are primarily destroyed or an antagonist is secreted can be ruled out, even though enzymatic drug inactivation was reported (4) to explain developed resistance to kanamycin and dihydrostreptomycin. This is consistent with the claim (5) that the resistance to rifampin is primarily due to the formation of a modified RNA polymerase insensitive to the action of rifampin. Analogously, streptomycin resistance was reported (6, 7) to be the result of modifications in the structure of the ribosomes that affect their affinity for streptomycin.

The studies of Fig. 4 clearly indicate the bactericidal action of kanamycin prior to the appearance of significant numbers of drug-resistant bacteria. The drug-affected bacteria did not generate significantly on dilution into media with lower drug concentrations or into fresh medium.

The size distribution studies (Fig. 12) show that kanamycin has no significant effect on cell size, whereas the cell size of rifampin-affected microorganisms gradually increases up to 75 min. after drug addition, at which time the cell size remains constant (curve C). In the case of *E. coli* killed by penicillin, no peak was apparent (curve B) shortly after drug addition. This result may be assigned to cells disintegrating into debris by the inhibition of cell wall synthesis so that cellular contents are dispersed and/or the cell membranes are devoid of contents and occupy lessened volumes. The fact that total counts (Fig. 1) achieved a plateau is indicative of this latter fact.

Combined Action of Penicillin, Kanamycin, and Rifampin with Tetracycline, Chloramphenicol, and Novobiocin—It has been claimed that various bacteriostatic drugs may interfere with the action of bactericidal antibiotics. The proposed explanation is that most bactericidal drugs only kill multiplying bacteria; when multiplication is inhibited by bacteriostatic drugs, killing cannot occur (8–11). For example, the early rate of bactericidal action of penicillin on several types of microorganisms was retarded by chloramphenicol *in vitro* (9–11) as well as *in vivo* (11–13) and by chlortetracycline or oxytetracycline *in vitro* (10, 14) and *in vivo* (13, 15). In many of these papers, the *number* of organisms killed by the bactericidal drug in the presence of the bacteriostatic eventually exceeded that in the presence of the bactericidal alone. Chloramphenicol, chlortetracycline, and oxytetracycline also interfered with the action of streptomycin (16) *in vitro* and in experimental infections of mice. However, reports of the combined action of the bacteriostatic sulfonamides and penicillin are conflicting; some state that these drugs are synergistic (17 26) and others that they are antagonistic (27–29). The conflicting reports may be due to differences in techniques, methods of measurement, and definitions of synergism and antagonism (29). If a bacteriostatic drug does interfere with the action of penicillin by inhibiting the multiplication of organisms, the stated cases of combinations with sulfonamides are difficult to reconcile with this premise.

An argument presented to rationalize an indifferent effect of sulfonamides on the initial action of penicillin is that sulfonamide has delayed action on microbial generation (30) and the penicillin activity may be exercised within that lag interval before the manifestation of sulfonamide inhibition of bacterial multiplication.

The premise that bacteriostatic drugs antagonize bactericidal drugs *in vitro* when the former are administered prior to or simultaneously with the latter has been based primarily on studies when the inocula of various organisms were in the stationary phase and were introduced at relatively large inoculum sizes (about 10^6–10^8 organisms/ml.) into the culture medium containing the drug combinations (9–11, 14, 16). The stationary phase occurred at 10^7–10^9 organisms/ml., so normally only a 10-fold increase in concentrations of organisms was possible. Thus, the actions of such drug combinations have been evaluated against microorganisms that were not in steady-state balanced generation, *i.e.*, the logarithmic phase, but were undoubtedly in the initial early lag phase where rates of generation are low and slowly accelerating and where the main process is an increase in size of the microorganisms.

Figure 6 shows that the prior addition of the bacteriostatics tetracycline and novobiocin do not interfere with the bactericidal actions of penicillin and kanamycin on balanced growth cultures in the logarithmic growth phase when the number of *E. coli* was 10^6/ml. for the addition of the latter antibiotic. The rates of decrease of viable counts of curves C and D are not significantly different from that of curves F and G, which contrast with the observations of Jawetz and coworkers (9–16) for large inocula of organisms introduced in the lag phase to a medium containing the antibacterial combination.

In most cases, the pretreatment of organisms with bacteriostatic antibiotics (curves F and G) has an advantageous effect on the more complete action of bactericidal drugs. This may be attributed to the fact that there is an interval between penicillin and kanamycin addition and their cidal action wherein microbial generation continues. In this interval of penicillin and kanamycin contact with rapidly generating organisms, mutants or adaptations resistant to these antibiotics may arise that are not possible with a prior action of the bacteriostatic drugs.

The prior addition of novobiocin had no significant effect on the

bactericidal action of rifampin in the present studies (Fig. 6c). However, when tetracycline or chloramphenicol was added before rifampin, the combined action of tetracycline (curve H in Fig. 6a) or chloramphenicol (curve H in Fig. 6b) with rifampin was dramatically less than that of rifampin alone (curve E).

The postulate that penicillin, kanamycin, or possibly other bactericidal agents will not be active on organisms in the stationary growth state (30) or in the early lag phase affected by bacteriostatic agents cannot be generalized automatically to bacteriostatically affected organisms from balanced cultures and in the logarithmic generation phase. The physiology of resting bacteria may be completely different than that of organisms whose generation is inhibited by bacteriostatic agents in the logarithmic generation phase. It appears that microbial kinetics affected by bactericidal agents alone and in combination with bacteriostatic and other bactericidal drugs need reevaluation using balanced cultures at lower inoculum sizes.

Pattern of Phenylbutazone Degradation

D. V. C. AWANG▲, A. VINCENT, and F. MATSUI

Abstract □ Phenylbutazone and phenylbutazone–antacid formulations were examined by TLC for the presence of decomposition products. A procedure was developed for minimizing on-plate oxidation of phenylbutazone during TLC analysis, and preparative TLC was utilized for isolation of the major products of decomposition. Unequivocal identification of the major products of degradation was made by NMR and mass spectrometric determination of isolated material. Official phenylbutazone tablets underwent only trace oxidation whereas phenylbutazone–antacid preparations gave evidence of significant levels of oxidation and hydrolysis products. An accelerated decomposition study of the bulk drug and its products of degradation was also conducted.

Keyphrases □ Phenylbutazone and phenylbutazone–antacid formulations—isolation and identification of degradation products □ TLC—isolation, degradation products in phenylbutazone and phenylbutazone–antacid formulations

Two publications have appeared dealing with an evaluation of the integrity of phenylbutazone formulations: Beckstead *et al.* (1) examined both *official* and *alka*[1] preparations in the form of tablets and capsules, while Pawelczyk and Wachowiak (2) were concerned with aqueous injection solutions of sodium phenylbutazone and suppositories.

The former publication outlined an assay procedure for phenylbutazone employing acid–base extraction and determination by UV spectrophotometry. It also described a TLC system to facilitate identification and

Two publications have appeared dealing with an evaluation of the integrity of phenylbutazone formulations: Beckstead *et al.* (1) examined both *official* and *alka*[1] preparations in the form of tablets and capsules, while Pawelczyk and Wachowiak (2) were concerned with aqueous injection solutions of sodium phenylbutazone and suppositories.

The former publication outlined an assay procedure for phenylbutazone employing acid–base extraction and determination by UV spectrophotometry. It also described a TLC system to facilitate identification and

[1] The term "alka" was used to designate preparations containing aluminum hydroxide and magnesium oxide or carbonate.

semiquantitative estimation of decomposition products. Pawelczyk and Wachowiak (2) employed column chromatography and preparative TLC for isolation of decomposition products, identification being made by comparison with standards mainly on the basis of melting point and R_f values. A qualitative assessment and rationale of the pattern of phenylbutazone decomposition were presented for the two types of formulation examined.

In view of the extensive use of phenylbutazone as an antiarthritic and analgesic, coupled with its alleged numerous attendant side effects (4), the claim that appreciable deterioration was observed in the majority of its alka formulations warranted a closer examination of the chemistry of the drug and its degradation products. It was felt that the results of such a study would allow a more reliable assessment of the integrity of these formulations. In addition, careful examination of the literature raised some doubts as to the rigor of the published methods of characterization of the decomposition products.

Sixty-six samples of phenylbutazone tablets (representing 35 manufacturers) and 15 samples of phenylbutazone–antacid formulations, in the form of capsules and tablets (representing four manufacturers), were subjected to careful examination. In addition, the degradation of phenylbutazone bulk drug was observed under conditions of accelerated hydrolytic and oxidative decomposition, and the transformations of the derived carboxylic acids were examined under pyrolytic conditions.

Identification of phenylbutazone and its decomposition products was generally made by TLC comparison with standard reference samples. Short wavelength UV light and various spray reagents were utilized for detection. In the case of the major decomposition products, preparative TLC was utilized for isolating sufficient quantities of material from decomposed formulations to allow confirmation of identity by NMR spectroscopy and/or mass spectrometry.

EXPERIMENTAL[2]

Samples of the reference compounds were used as obtained[3], with periodic checks by TLC being made to ascertain their integrity. All compounds were found to be stable when stored in tightly closed dark bottles under normal laboratory conditions.

TLC[4]—*Preparation of Layers*—Five plates (20 × 20 cm. glass) of about 250-μ layer thickness were obtained by application of a slurry, prepared by mixing 20 g. each of silica gel GF_{254}[5] and MN-kieselguhr[6] with 95 ml. of McIlvaine buffer (pH 6), using standard layer-spreading equipment. Two hundred milliliters of buffer is produced by mixing 74 ml. of 0.1 *M* citric acid[7] and 126 ml. of 0.2 *M* disodium phosphate[7].

Solvent System—The following was used: cyclohexane (saturated with McIlvaine buffer, pH 6)–chloroform–methanol (60:30:5), all reagent grade. Five milliliters of acetic acid was added to 95 ml. of a mixture of these solvents in the same ratio (buffer excluded) when developing plates coated with silica gel only.

Detecting Agents—The following were used: (*a*) short wavelength UV light, and (*b*) 0.5% w/v potassium dichromate (analytical reagent) in 20% v/v sulfuric acid (ACS), followed by concentrated sulfuric acid.

Standards—The standard solution of phenylbutazone was prepared by dissolving 20 mg. of the bulk drug in 1 ml. of ethyl acetate (analytical reagent). Standard solutions of the decomposition products were prepared by dissolution of 2 mg. of sample in 10 ml. of the same solvent.

Detection of On-Plate Air Oxidation—Ten 20-μl. samples of the standard solution of phenylbutazone were spotted at 15-min. intervals on a single silica gel TLC plate prepared as described previously (1). The procedure was repeated, each plate being developed immediately after application of the final spot[8]. The experiment was repeated on silica gel–kieselguhr plates buffered at pH 6, prepared as already outlined.

Preparation of Sample from Formulation—An amount of powdered tablet or contents of capsule equivalent to 100 mg. of phenylbutazone was placed in a 25-ml. culture tube, 2 ml. of 0.1 *N* sodium hydroxide was added, and the mixture was swirled to a wet powder mass. Then 5 drops of concentrated hydrochloric acid and 10 ml. of ethyl acetate (analytical reagent) were added; the tube was rotated[9] for 15 min. and then centrifuged. The supernate was applied to the chromatoplate.

Procedure for Assessment of Decomposition in Formulations—A preliminary screening of each formulation was conducted by spotting 10 μl. of the standard phenylbutazone solution against a mixture made up of 5 μl. (representing 1% of the label claim for phenylbutazone) of each standard solution of decomposition product. Only those decomposition products present in amounts greater than 1% were subjected to further evaluation.

Decomposition products present in excess of 1% (as determined by the preliminary screening) were assessed on separate chromatoplates by spotting 10 μl. of sample solution against 5-, 10-, 15-, and 20-μl. applications (corresponding to 1, 2, 3, and 4%, respectively, of the label claim for phenylbutazone) of the particular decomposition product.

On all plates, 5 μl. of the standard phenylbutazone solution was applied as the initial and final spots on the chromatoplate. The extent of on-plate oxidation was then reflected in the difference in amount of oxidation product observed in these two samples; for decomposed formulations, only amounts of oxidation product greater than what was seen in the first-applied standard were considered to be indicative of the existence of oxidation products prior to application to the chromatoplate.

Alkaline Hydrolysis of Phenylbutazone—Phenylbutazone, 1.00 g. (0.003 mole), was dissolved in 12 ml. of 10% sodium hydroxide (0.030 mole), and the solution was refluxed[10] for 24 hr. At this point, reflux was halted and the reaction flask was allowed to cool to room temperature. The condenser, in which was deposited a considerable amount of sublimate[11], was washed out with chloroform and the solvent was evaporated under reduced pressure. A yellow solid, 154 mg., was thus obtained; TLC and spectral analysis indicated that this was almost pure hydrazobenzene contaminated

[2] NMR spectra were obtained with a Varian A-60A spectrophotometer, and mass spectra were obtained with a Hitachi Perkin-Elmer RMU-6 L spectrophotometer.

[3] Geigy Pharmaceuticals, Basel, Switzerland.

[4] The TLC procedures for preliminary identification, as well as semiquantitative assessment of the components of formulations and degraded bulk drug, are similar to those employed by Beckstead *et al.* (1). Most modifications were introduced to minimize oxidation on the TLC plate, the only degradative process that occurs to any detectable degree during analysis.

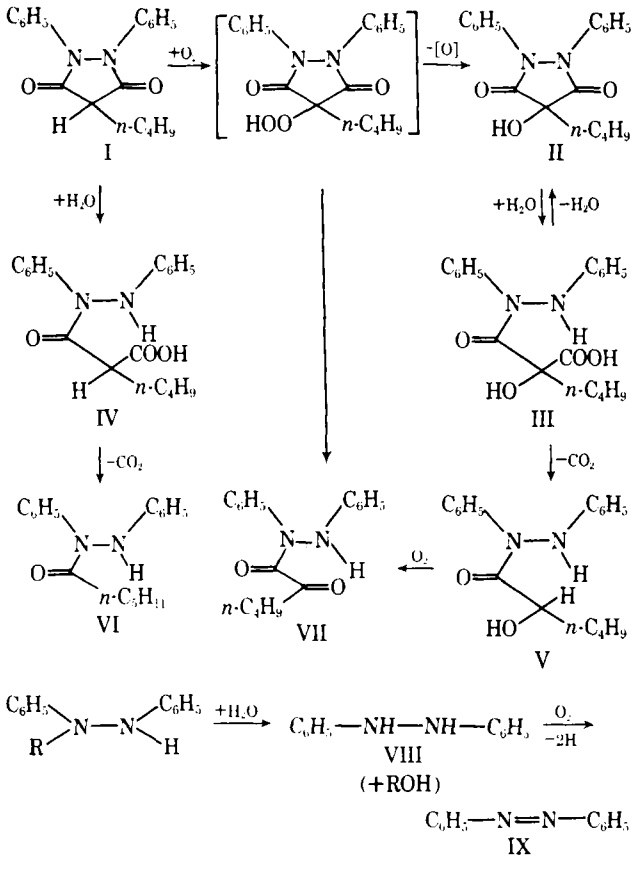
[8] There was unmistakably a direct relationship between the duration of residence of the phenylbutazone sample on the unbuffered silica gel plate and the amount of contaminant observed. Only trace contamination could be perceived in samples run on buffered silica gel–kieselguhr plates. Semiquantitative assessment indicated that 2–3% hydroxyphenylbutazone was formed after 1 hr. exposure to the atmosphere on unbuffered silica gel plates.

[9] Multipurpose rotator, model 150 V, Scientific Industries, Springfield, Mass.

[10] A duplicate experiment was conducted simultaneously, and this reaction was sampled hourly (aliquots of approximately 0.25-ml. volume). At the end of 6 hr. of refluxing, both reactions were sampled to check their agreement. There was no apparent difference in the appearance of chromatograms of parallel samples, and all indicated only a slight degree of hydrolysis of I to IV (Scheme I). Five milliliters of the solution from the duplicate experiment was neutralized with 0.1 *N* hydrochloric acid, extracted with chloroform, and dried over anhydrous sodium sulfate. The off-white solid obtained upon evaporation of solvent from the dried filtrate was semiquantitatively analyzed and shown to be phenylbutazone containing less than 4% of IV.

[11] This sublimate was essentially white, but flecks of orange, undoubtedly due to azobenzene, could be easily perceived.



Scheme I

with a trace of azobenzene. The white solid floating on the surface of the solution in the cooled reaction flask was filtered off using suction, washed with water, and allowed to dry in the open air; the yield of essentially pure hydrazobenzene was 385 mg. The filtrate was worked up in the manner described in *Footnote 10* and yielded 82 mg. of phenylbutazone contaminated with less than 4% of the hydrolysis product IV[12]. The merest trace of a contaminant of R_f corresponding to VI also could be detected. The total weight of hydrazobenzene, coupled with the amount of phenylbutazone recovered, corresponded to close to 90% hydrolysis of phenylbutazone.

RESULTS AND DISCUSSION

Preliminary—The likely products of decomposition of phenylbutazone (1,2-diphenyl-4-*n*-butylpyrazolidine-3,5-dione, I) under the relatively mild conditions of normal storage can be predicted from an assessment of the characteristic chemistry of its structural components. Scheme I outlines the salient features and a detailed analysis follows.

Air oxidation at the tertiary C-4 position could be expected to be particularly facile in view of the potential stabilizing effect of two α-carbonyl groups on development of radical or anionic character at that site. Such oxidation[13], probably *via* an unstable hydroperoxide intermediate (5)[14], would give rise to 1,2-diphenyl-4-*n*-butyl-4-hydroxypyrazolidine-3,5-dione (II). This compound has been identified as the major product of phenylbutazone degradation in suppositories (2).

Hydrolysis of II with cleavage of one C—N amide bond would lead to formation of *n*-butyltartronic acid mono-(*N,N'*-diphenyl)-hydrazide (III). Indeed, Compound II is so readily hydrolyzed that it cannot normally[15] be detected in the product of phenylbutazone oxidation in alkaline hydroxylic solution (7-11). The survival of II in suppositories (2) was undoubtedly related to the hydrophobic nature of the bases with which phenylbutazone was compounded in the formulations examined. Similar hydrolysis of I would lead to *n*-butylmalonic acid mono-(*N,N'*-diphenyl)hydrazide (IV); not surprisingly, the latter compound has been observed to be the major product of phenylbutazone degradation in aqueous solutions of its sodium salt (2, 3).

Decarboxylation of III and IV appears a likely further degradative pathway in view of the well-known facilitation of decarboxylation of carboxylic acids by a β-keto group (12). Loss of carbon dioxide from III and IV would then lead to formation of *N*-(α-hydroxycaproyl)hydrazobenzene (V) and *N*-caproylhydrazobenzene (VI), respectively.

Oxidation of IV to III and dehydrogenation of V to *N*-(α-ketocaproyl)hydrazobenzene (VII) also appear feasible.

Hydrolytic cleavage of the second C—N amide bond in all of the ring-opened hydrazobenzene derivatives would result in formation of hydrazobenzene (VIII), which is readily oxidized to azobenzene (IX).

Interpretation of Results—Application of the procedure recommended for TLC identification of phenylbutazone decomposition products (1) revealed some inconsistencies in the published data as well as shortcomings which could vitiate both qualitative and semiquantitative assessments of deteriorated formulations.

Table I lists the R_f values relative to that of phenylbutazone (I) (assigned a value of 1) calculated for the decomposition products considered in the present study. For comparison, corresponding "relative" R_f values calculated from the published (1) data[16] are also listed. The glaring discrepancy in the values for Compound V is somewhat enigmatic. In our experience, the R_f values for Compounds II and V are so similar under the TLC conditions employed that they can only be differentiated on the basis of their reaction to oxidizing spray reagents: the open-chain, more readily oxidizable hydrazo compounds such as V give rise to much more intense and rapid color development than Compounds I and II, where tertiary aromatic nitrogen atoms are involved in a closed-ring system. Upon treatment with 0.5% potassium dichromate in 20% (v/v) sulfuric acid, Compounds III, IV, V, and VI give almost instantaneously violet-colored spots, while VII affords a yellow to pink coloration. Compounds I and II show up as yellow to orange spots only upon the succeeding application of concentrated sulfuric acid, which also intensifies the other spots.

Hydrazobenzene (VIII) gives R_f values identical with those of phenylbutazone (I) under all conditions employed in the present study. Compound VIII is easily detected in mixtures with I, however, since it gives an instantaneous yellow-brown coloration with the dichromate-sulfuric acid spray reagent. Compound VIII was not detected in any formulation examined but was produced when I was refluxed in aqueous sodium hydroxide. The fact that VIII was not observed in decomposed aqueous injection solutions of

Table I—Relative R_f Values for Phenylbutazone Derivatives

Compound	R_f Silica Gel GF—Earlier Study	R_f Silica Gel GF—Present Study	R_f Silica Gel GF–Kieselguhr (1:1)
II	0.51	0.55	0.66
III	0.27	0.25	0.12
IV	0.37	0.39	0.30
V	0.72[a]	0.55	0.66
VI	0.80	0.75	0.91
VII	—	0.70	0.85

[a] It seems probable that Compound VII, which was not considered in the earlier study, was mistaken for V.

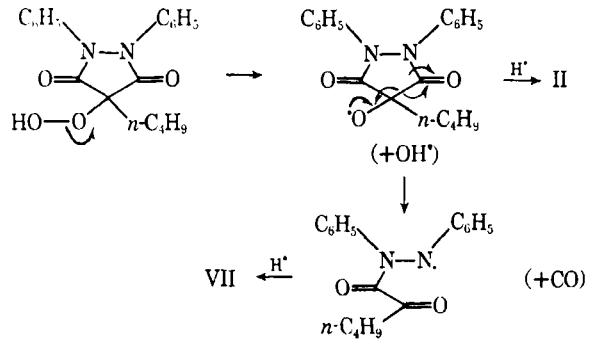
[12] No attempt was made to isolate *n*-butylmalonic acid, but its presence was indicated when a TLC plate was developed in iodine vapor.

[13] This process is probably the major cause of difficulties encountered in attempts at TLC and paper chromatographic assays of substances of the pyrazolone class (6).

[14] Hydrazobenzene catalysis, which takes place in alkaline ethanolic solution (7), is obviously not involved in the mechanism of solid-state or near-neutral air oxidation. No azobenzene, which would be formed in concomitant oxidation, was observed in those instances of appreciable C-4 oxidation in capsules or tablets or on TLC plates.

[15] Awe and Kienert (8) reported recovery of a 10% yield of II from such an oxidation, but we have not been able to duplicate this. Likewise, Veibel *et al.* (7) have not been successful in detecting II upon repetition of the procedure of Sokolova and Magidson (9) which was claimed to allow its isolation.

[16] These relative R_f values are much less variable than absolute R_f values.



Scheme II

sodium phenylbutazone (2), which contained its oxidation product azobenzene (IX)[17], is probably due to the rate of oxidation of VIII being greater than its rate of formation under normal storage conditions. A mixture of I and VIII was separated by preparative TLC from the product of a hydrolysis experiment and was characterized by comparison with authentic material using NMR spectroscopy.

It has been confirmed that air oxidation of phenylbutazone is a remarkably facile process (see earlier discussion) which readily occurs on the TLC plate unless special precautions are taken to obviate it. Two products of on-plate oxidation were observed. The major product was indicated to be 4-hydroxyphenylbutazone (II) by comparison of its R_f value and its reaction to spray reagents with those of an authentic sample. In addition, enough material was isolated by preparative TLC of partially oxidized phenylbutazone to allow its identity to be confirmed by mass spectrometry. The minor product of oxidation was not present in sufficient quantity to allow convenient isolation (and thereby unequivocal identification), but it was almost certainly *N*-(α-ketocaproyl)hydrazobenzene (VII). Its R_f value and reaction to various spray reagents were identical with those of an authentic sample. The complete absence of carboxylic acids III and IV in the oxidized product renders unlikely the involvement of hydrolysis and decarboxylation in the sequence leading to VII (Scheme I); also, Compounds IV and V do not suffer any observable on-plate oxidation. The most plausible mechanism of formation of VII appears to be that outlined in Scheme II.

The formation of II and VII by on-plate oxidation was effectively suppressed by utilizing a 1:1 mixture of kieselguhr–silica gel (instead of silica gel alone) and by impregnating the TLC support with McIlvaine buffer (pH 6).

The absence of II in formulations, concomitant with the presence of trace amounts of VII and appreciable quantities of III and IV (Table II), is consistent with facile hydrolysis of II, formed by air oxidation of the formulations examined. Observation of III in formulations that showed no evidence of IV also attests to the fact that the rate of hydrolysis of II is considerably greater than that of I.

No products of decarboxylation were observed in the formulations examined, but slight formation of *N*-caproylhydrazobenzene (VI) was observed after prolonged refluxing of phenylbutazone in aqueous sodium hydroxide. As noted earlier, there was attendant formation of hydrazobenzene (as well as trace quantities of azobenzene), a result of more extensive hydrolysis. Evidently, the rate of hydrolysis of IV is comparable with its rate of formation.

An interesting situation, probably reflective of the complexity of conformation and association involved in the case of the two carboxylic acids III and IV, concerns their behavior under thermolytic and mass spectrometric conditions. Whereas pyrolysis of solid IV gives an almost quantitative yield of the product of *decarboxylation*, VI, similar pyrolysis of III is a most efficient method of preparation of the product of *dehydration*, II[18] (10). On the other hand,

[17] This compound shows up as a bright-yellow spot having an R_f value greater than that of I, and it was undoubtedly mistakenly designated as "hydroazobenzene" by Beckstead *et al.* (1).

[18] This result is particularly surprising since incorporation of electron-withdrawing groups normally facilitates decarboxylation (12). The preference for dehydration is so overwhelming that refluxing of a suspension of III in water resulted in the exclusive formation of II. No indication of V was detected when the dichromate–sulfuric acid spray was applied. The sodium salt of III, when subjected to the same conditions, showed no sign of degradation.

Table II—Assessment of Impurities in Phenylbutazone–Antacid[a] Formulations by TLC

Formulation	Percent Decomposition Product III	IV	VII
Capsule			
1	1	1	—
2	1.5	1.5	Trace
3	2	2.5	Trace
4	1	>0.5<1	—

12	<0.5	—	—
13	<0.5	—	—
14	0.5	0.5	—
15	<0.5	0.5	—

[a] Only two of the 66 samples of phenylbutazone tablets showed more than trace amounts of any impurity. The major contaminant in both cases constituted less than 0.5% impurity and appeared to be Compound II on the basis of R_f value and reaction to spray reagents.

the mass spectrum of IV was identical with that of I, the highest mass peak appearing at *m/e* 308 (M − 18) and indicating facile loss of water from the parent molecule of IV. However, no peak corresponding to its molecular ion or to loss of water, carbon dioxide, or both from its parent molecule could be perceived in the mass spectrum of III, the highest mass peak being found at *m/e* 205[19].

[19] The remarkable differences observed in the thermal degradative behavior of Compounds III and IV in the solid and liquid states, as well as under varying conditions of temperature and concentration in different solvents, will be reported and interpreted (as will be their mass spectral fragmentation) in a forthcoming article.

Primary Local Anesthetic Testing and Acute Toxicity of *N,N'*-Disubstituted 2,3-Diamino-2',6'-propionoxylidides

H. JACK ADAMS▲, GEORGE H. KRONBERG, and BERTIL H. TAKMAN

Abstract □ Eight *N,N'*-disubstituted 2,3-diamino-2',6'-propionoxylidides and 1-*tert*-butyl-2-aziridinecarboxy-2',6'-xylidide were prepared and tested for local anesthetic activity in the rat sciatic nerve block and in the guinea pig wheal. The durations in the rat sciatic blocks fell between those for lidocaine and tetracaine, but none of them possessed the long duration of tetracaine in the guinea pig wheal. All compounds were more toxic than tetracaine intraperitoneally in the mouse but, except for the aziridine compound, were less irritating than tetracaine in the rabbit intradermal wheal.

Keyphrases □ 2,3-Diamino-2',6'-propionoxylidides, *N,N'*-disubstituted—local anesthetic activity and acute toxicity, compared to lidocaine and tetracaine □ 1-*tert*-Butyl-2-aziridinecarboxy-2',6'-xylidide—local anesthetic activity and acute toxicity, compared to lidocaine and tetracaine □ Anesthetic activity, local—*N,N'*-disubstituted 2,3-diamino-2',6'-propionoxylidides and 1-*tert*-butyl-2-aziridinecarboxy-2',6'-xylidide □ 2,6-Xylidine derivatives—*N,N'*-disubstituted 2,3-diamino-2',6'-propionoxylidides and 1-*tert*-butyl-2-aziridinecarboxy-2',6'-xylidide, local anesthetic activity and acute toxicity

2,3-Bis(mono- and dialkyl) aminopropionanilides have been studied as local anesthetics (1–3). Except for 2,3-bis(diethylamino)-2',6'-propionoxylidide (IX), no other derivative of 2,6-xylidine has been reported previously (1). Because of the rather long duration of anesthesia observed for this substance, several related compounds (Table I) were synthesized and investigated pharmacologically.

EXPERIMENTAL

Chemistry[1]—2,3-Dibromopropionyl chloride (4, 5) was allowed to react with 2,6-xylidine to give 2,3-dibromo-2',6'-propionoxylidide (X) (1). When X was refluxed with secondary amines, the bistertiary amines were obtained. In several cases where X was allowed to react with propylamine or *tert*-butylamine under the same conditions, the expected bis(monoalkyl) aminopropionoxylidides were not formed.

Only the reaction with *tert*-butylamine was studied in some detail. The main portion of the basic products obtained was found to be 1-*tert*-butyl-2-aziridinecarboxy-2',6'-xylidide (XI). The fact that no similar compound was obtained from the reaction of propylamine and X indicates a stabilizing effect on the aziridine system by the presence of the bulky *tert*-butyl group.

The formation of aziridine derivatives from amines and 2,3-halogenopropionyl derivatives was reported previously (6, 7) but under exceedingly milder temperature conditions (liquid ammonia). Some aziridinecarboxanilides also were prepared previously, although by quite different routes (8).

Intermediates—2,3-Dibromo-2',6'-propionoxylidide (X) (1) was obtained from 2,3-dibromopropionyl chloride (5) and 2,6-xylidine in an acetate buffer system (1).

[1] Melting points were taken on the Thomas–Hoover capillary melting-point apparatus and are uncorrected. Analyses were performed by Alfred Bernhardt Microanalytical Laboratory, Elbach über Engelskirchen, West Germany, and Schwarzkopf Microanalytical Laboratory, Woodside, N. Y. IR spectra were recorded on a Perkin-Elmer 257 spectrophotometer; NMR spectra were recorded on a Varian A60 with tetramethylsilane as internal standard. The IR spectra were as expected.

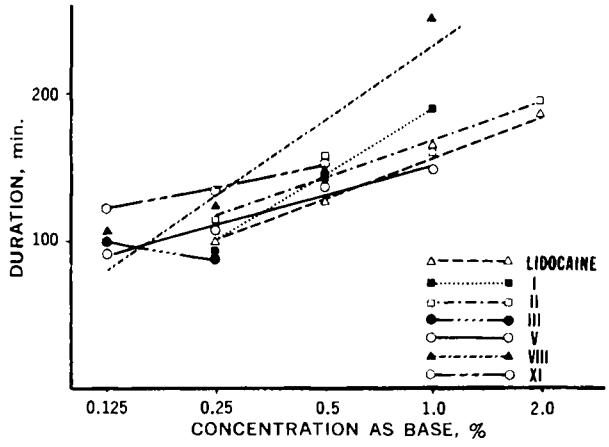

Figure 1—*Rat sciatic nerve blocks.*

Compounds of Table I—To a cool stirred solution of the secondary amine (4.5 moles) in dry benzene was added X (1 mole) in portions. After brief stirring at room temperature, the mixture was allowed to reflux for 5–6 hr. When cool, the reaction mixture was filtered, the volatiles were stripped off under reduced pressure at 50–60°, and the residue was taken up in dilute hydrochloric acid. The aqueous acid solution was washed several times with ether and then alkalinized (pH 10–11) and extracted with ether to obtain the base. The product was further purified either by direct recrystallization or through salt formation and subsequent recrystallization (*cf.*, Tables I and II).

(±)-1-tert-*Butyl-2-aziridinecarboxy-2',6'-xylidide* (*XI*)—In a glass-lined pressure vessel, X (43 g., 0.128 mole), *tert*-butylamine (73.1 g., 1.00 mole), and benzene (400 ml.) were heated for 16 hr. at 100°. After cooling, a white precipitate of *tert*-butylammonium bromide (91% yield) was filtered off. The amber filtrate was evaporated, and the waxy residue was dissolved in 200 ml. 1 *M* HCl. The solution was washed with ether, made alkaline under cooling with 7 *M* NaOH, and immediately extracted exhaustively with ether. After

Table I Physical and Chemical Data

Number	R	R_1	Compound Form	Yield, %	Melting Point	Recrystallization Solvent
I	CH_3	CH_3	Base	55	150.5–151.5°	Cyclohexane
II	CH_3	C_2H_5	Base	55	113.5–114.5°	—[a]
III	CH_3	n-C_3H_7	Base	58	57.5–59.5°	—[b]
IIIa			Monooxalate		126.5°	Acetonitrile
IV	CH_3	iso-C_3H_7	Base	57	97–98°	Cyclohexane; n-hexane
V	CH_3	CH_2=$CHCH_2$	Base	48	88–89.5°	Aqueous ethanol
VI	CH_3	CH≡CCH_2	Base	52	101–103°	95% ethanol
VII	CH_3	$CH_3OCH_2CH_2$	Diperchlorate	40	124–125°	95% ethanol
VIII	NRR_1 = pyrrolidino		Base	43	163.5–165.5°	Benzene–cyclohexane

[a] The base was obtained from an oxalate, m.p. 130.5–131°, which was not analyzed. [b] Not recrystallized; obtained from IIIa.

drying (sodium sulfate) and evaporation, a light-brown powder (29.9 g.) was obtained. Repeated recrystallizations from petroleum ether (b.p. 60–110°) gave colorless crystals (12.5 g., 0.0508 mole, 40%), m.p. 112.5–113°. Approximately another 2.5 g. of XI could be isolated from the mother liquors with the help of chromatographic purification of a benzene solution on aluminum oxide. The total yield of XI was thus approximately 48%; NMR ($CDCl_3$): 1.08 [s, 9H, $(CH_3)_3C$], 1.84–2.04 (m, 2H, CH_2), 2.20 (s, 6H, 2 CH_3—C_6H_5), 2.36–2.52 (m, 1H, CH), 7.07 (s, 3H, C_6H_5), and 8.18 (s, 1H, NH).

Anal.—Calc. for $C_{15}H_{22}N_2O$: C, 73.1; H, 9.00; N, 11.37. Found: C, 73.0; H, 8.97; N, 11.50.

Pharmacology and Toxicology—*Rat Sciatic Nerve Blocks*—This technique was described by Camougis and Takman (9). Each compound was tested at three to five concentrations. For this primary evaluation, all solutions contained 1:100,000 epinephrine. Precisely 0.2 ml. drug solution was injected into the midthigh region so that it was deposited around the sciatic nerve trunk. Five animals were used at each concentration, and both thighs were injected on each animal. After being injected, animals were examined at frequent intervals for onset, depth, and duration of motor block. Linear regression lines were fitted to the dose–duration data[2] for the rat sciatic nerve blocks and the guinea pig wheals.

Guinea Pig Intradermal Wheals—A modification of the method described by Bülbring and Wajda (10) was used. Each wheal was made by injecting 0.1 ml. of drug solution or vehicle intradermally on the shaved back. Six wheals were made per animal, and eight to 12 wheals were made at each concentration. All solutions contained 1:100,000 epinephrine. Presence or absence of anesthesia was determined at frequent intervals by means of pinpricks.

Irritation Studies—This method was described by Camougis and Takman (9). The backs of rabbits were shaved, and a series of eight wheals per animal was made by injecting 0.1 ml. of drug solution or vehicle intradermally at each site. Twenty-four hours later the wheals were graded for degree of erythema, degree of edema, and presence or absence of necrosis. Grading was done on a numerical scale, and mean scores were obtained for all wheals at each concentration of test compound.

Acute Toxicity—The LD_{50}'s were determined in female CRCD mice, weighing about 20–25 g. Test compounds were dissolved in isotonic saline or distilled water and administered intraperitoneally. Three to five dose levels were used for each LD_{50}, and there were 10 animals at each dose level. Control groups received vehicle at a dose volume comparable to the highest dose volume of test compound. The LD_{50}'s and 95% confidence limits were calculated by the minimum logit chi-square method (11).

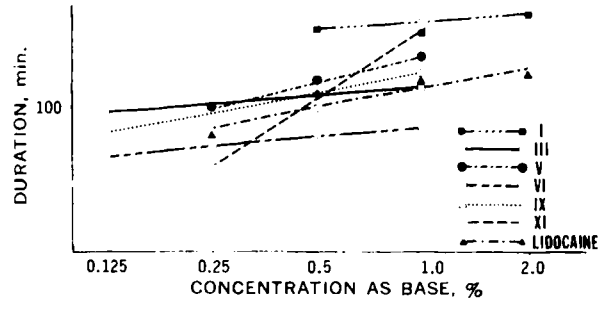

Figure 3—*Guinea pig intradermal wheals.*

[2] Using a Hewlett-Packard 9100B calculator, a 9125B plotter, and a linear regression program No. Stat-Pac X-7.

RESULTS

Rat Sciatic Nerve Blocks—Compounds I, II, III, V, and XI had dose–duration curves similar to that of lidocaine (Fig. 1). Only two points were obtained with III because 100% fatalities occurred at all concentrations above 0.25%. The dose–duration curve for VIII indicates somewhat longer durations than for the other compounds, chiefly due to the long blocks at the 1.0% concentration. Compounds IV and VI (Fig. 2) had durations greater than that of lidocaine but less than that of tetracaine; the dose–duration curves for VII and IX were comparable to that of tetracaine (Fig. 2).

Table III—Acute Intraperitoneal Toxicity in Female Mice

Compound	LD_{50} and 95% Confidence Limits, mg./kg. as Base
I	44 (26–58)
II	17 (14–22)
III	16 (14–21)
IV	9 (6–13)
VII	7 (5–9)
VIII	16 (14–22)
IX	14 (11–16)
Lidocaine hydrochloride	133 (121–150)
Tetracaine hydrochloride	55 (44–69)

Frequency of block was 70% or greater at the lowest concentration tested for all compounds except VI and IX; frequency was 70% or greater at concentrations above 0.25% with these two compounds.

Guinea Pig Intradermal Wheals—The dose–duration curves for lidocaine and for Compounds I, III, V, VI, IX, and XI are shown in Fig. 3. Except for XI, these compounds exhibit flat dose–duration curves in this preparation and, in general, their curves lie close to that obtained with lidocaine. The curves for tetracaine and for Compounds II, IV, VII, and VIII are shown in Fig. 4. Although durations with these test compounds tended to be greater than those obtained with lidocaine, none of them was comparable to tetracaine in this test procedure. Because of the toxicity of VII, only two points were obtained with that compound.

In the rat sciatic nerve block experiments, Compounds VII and IX exhibited the longest durations of any test compounds; in the guinea pig wheal, VII was one of the two test compounds with the longest duration of action. However, this pattern is not consistent throughout. For example, Compound VIII was short acting in the rat sciatic but long acting in the guinea pig wheal. Such apparent inconsistencies can probably be accounted for by: (*a*) marked physiological differences between the two sites of drug application, and (*b*) differences in the physicochemical and pharmacological properties of the test compounds (12).

Irritation Studies—Because of differences in toxicity, all compounds were not tested at the same three concentrations. Lidocaine, tetracaine, and Compounds I, II, V, VI, and VIII were tested at 0.5, 1.0, and 2.0%. The others were tested at 0.25, 0.5, and 1.0%. Therefore, data are available at 0.5 and 1.0% for all compounds except VII, which was lethal at 1%. The rank order of the compounds for which irritation indexes were obtained at 0.5 and 1.0% is: least irritating = lidocaine < V < I < II < IV < III < VI < VIII < tetracaine < XI = most irritating.

Acute Toxicity—Because insufficient quantities remained after the other tests had been performed, acute toxicity determinations were not done with V, VI, and XI. The LD_{50}'s for the other test compounds and for lidocaine and tetracaine are shown in Table III. All of the compounds tested are more toxic than lidocaine, and all but I are significantly more toxic than tetracaine.

CONCLUSIONS

All of the test compounds exhibit short latency and excellent frequency of local anesthetic block. Durations are, in general, intermediate between those of lidocaine and tetracaine. All but one of the compounds are more irritating than lidocaine but less irritating than tetracaine; except for one compound, all are more toxic than tetracaine. Further synthetic efforts along these lines should obviously be aimed at retaining the excellent local anesthetic activity while attempting to reduce the toxicity.

Physicochemical Properties of Prostaglandin $F_{2\alpha}$ (Tromethamine Salt): Solubility Behavior, Surface Properties, and Ionization Constants

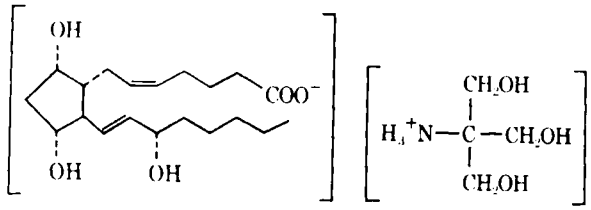
T. J. ROSEMAN▲ and S. H. YALKOWSKY

Abstract □ The pH-solubility profile of the tromethamine salt of $PGF_{2\alpha}$ was determined. The intrinsic solubility of the free acid is 0.0042 *M* at 25° and, as expected for a carboxylic acid, the solubility increased as a function of pH. However, at a pH value just above 5, there is a marked increase in solubility, which is significantly greater than would be expected from the ionization constant of the acid. This type of behavior is attributed to the formation of micelles that solubilize the drug once a critical concentration and pH are reached. Independent determination of the critical micellar concentration (CMC) by drop volume or potentiometric techniques demonstrated that $PGF_{2\alpha}$ tromethamine does form micelles. The CMC increased with the degree of ionization and, therefore, is a function of pH. The pKa of $PGF_{2\alpha}$ was determined by titration in aqueous media to be 4.90 ± 0.02. The pKa increased above the CMC as a function of concentration to a maximum value of 5.6. When a plot of concentration *versus* pKa is made, the point of deviation from the true value of 4.90 is in good agreement with the CMC reported by the drop volume technique. The interrelationship between the potentiometric, solubility, and surface properties of $PGF_{2\alpha}$ tromethamine are presented. Interestingly, these properties are qualitatively similar to those reported for certain bile acids that have similar functional groups present on the parent cholanic acid nucleus.

Keyphrases □ Prostaglandin $F_{2\alpha}$, tromethamine salt—solubility behavior, surface properties, and ionization constants □ pH-solubility profiles—prostaglandin $F_{2\alpha}$ tromethamine salt, micelle formation □ Micelle formation—factor in solubilization of prostaglandin $F_{2\alpha}$ tromethamine salt

Prostaglandins are a class of biologically active lipids found in various animal and human tissues. In recent years, the scientific literature of many disciplines has virtually exploded with publications on prostaglandin research. Several reviews (1–3) summarized prostaglandin research in the areas of chemical synthesis, biosynthesis and metabolism, analytical methods, biology, and clinical applications. From a clinical point of view, $PGF_{2\alpha}$ and PGE_2 have been the most widely tested prostaglandins; their use in induction of labor and in therapeutic abortion is well documented (4).

Prostaglandins have been administered to patients as parenteral and vaginal solutions, vaginal tablets, and suppositories. Yet, studies on their physicochemical properties have been limited. Although Johnson and Saunders (5) reported that $PGF_{2\beta}$ and PGE_1 do not form micelles, their studies did not cover a sufficiently wide concentration range. Data are presented which demonstrate that $PGF_{2\alpha}$ (as the tromethamine salt) does indeed form micelles. The present article describes an in-depth study on certain physicochemical properties of $PGF_{2\alpha}$. These properties are characterized with regard to solubility behavior, surface properties, and ionization constants, and the interrelationships among them are demonstrated. In this respect, these findings are consistent with the studies of Ekwall *et al.* (6) using bile salts. They showed that



I

micelle formation affects other physicochemical properties such as ionization and solubility behavior. A knowledge of these properties will provide not only a rational basis for the design of formulations but also an insight into other areas of prostaglandin research. For example, structure–activity relationships based upon partition coefficient data can be influenced by micelle formation since the presence of micelles may alter partition values. Micelle formation and ionization behavior can also influence the absorption pattern of the drug molecule.

EXPERIMENTAL

Prostaglandin $F_{2\alpha}$ was used as its tromethamine salt (1). This salt was selected because it is crystalline and could be obtained in high purity. The free acid exists as a wax-like material and is not only difficult to purify but also is subject to weighing errors when small quantities are needed. As the tromethamine salt, $PGF_{2\alpha}$ was 99.2% pure by GLC and showed one major spot using TLC. The melting point was 100.3–101.3°. All solutions were prepared with compression distilled water, and reagent grade chemicals were used.

Solubility Determinations—Appropriate quantities of $PGF_{2\alpha}$ (tromethamine) were placed into 20-ml. glass screw-capped vials containing distilled water. The solution was then adjusted to the desired pH with 0.1 *N* HCl. The final solutions were examined visually to be sure that excess drug was present. The vials were then sealed with a wax film[1] and rotated end-over-end in a thermostated water bath at 25 ± 0.1°. After equilibration, the pH was again measured and this equilibrium value was used in reporting the data. Samples were rotated for at least 48 hr., which was previously shown to be sufficient for establishing equilibrium. At pH values ≤3, some drug decomposition was noted at 48 hr.

After equilibration, samples were centrifuged for approximately 15 min. and then filtered through a 13-mm., 0.22-μ filter[2]. The resulting clear solutions were analyzed for their $PGF_{2\alpha}$ content by GLC. One milliliter was extracted with 3 × 10 ml. of chloroform after the addition of 2 ml. of 0.2 *M* pH 3 citrate buffer. Previous studies demonstrated that this procedure yields quantitative recovery of $PGF_{2\alpha}$. The chloroform was evaporated to dryness at 37° with a stream of nitrogen. The residue was then dissolved in 0.1 ml. of pyridine and silylated with a 4:1 mixture of *N,O*-bis(trimethylsilyl)acetamide[3]–trimethylchlorosilane[3] containing 3 mg./ml. of cholesteryl acetate as the internal standard. The volume of silylating reagent varied depending upon the amount of $PGF_{2\alpha}$ present. The reagent was swirled in the flask to ensure that all $PGF_{2\alpha}$ was silylated. After al-

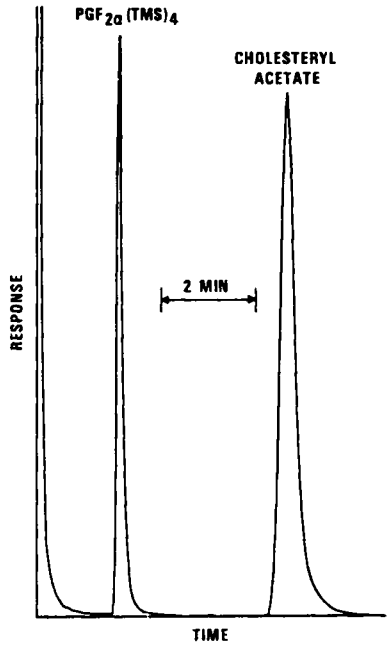

Figure 1—*GLC chromatogram of silylated $PGF_{2\alpha}$ and internal standard (cholesteryl acetate).*

lowing the solution to stand 15 min., a 1-μl. sample was injected into a chromatograph[4] under the following conditions: glass column, 1.2 m. × 0.63 cm. (4 ft. × 0.25 in.) 1% SE-52 on Gas Chrom Q (80–100 mesh); column temperature, 215°; detector temperature, 265°; and flash heater temperature, off. The helium gas flow was 60 ml./min.; air and hydrogen were adjusted to give maximum response.

Two references were prepared at each assay time. Exactly 1 mg. of $PGF_{2\alpha}$ tromethamine was weighed on an electrobalance[5] and dissolved in 0.1 ml. pyridine. It was then silylated in an identical manner as the samples. A typical chromatogram is shown in Fig. 1. The $PGF_{2\alpha}$ concentration, C, in milligrams per milliliter was calculated from the following expression:

$$C = \frac{R}{R_1} C_1 \frac{V_1}{V_{12}} \qquad \text{(Eq. 1)}$$

where:

R = ratio of sample peak area to internal standard peak area
R_1 = ratio of standard peak area to internal standard peak area
C_1 = concentration of standard
V_1 = volume of sample reagent
V_{12} = volume of solution extracted

CMC Determinations—Solutions of $PGF_{2\alpha}$ tromethamine were prepared by dissolving the drug in distilled water and adjusting the pH with 0.001–0.1 *N* HCl or 0.001–0.1 *N* NaOH. Solutions were then transferred to a 2- or 10-ml. syringe[6] equipped with a Teflon plunger. The syringe was mounted on an infusion pump[7] adjusted to deliver 0.08 ml./min. The surface tension (γ) of the solution was calculated from the average volume of 10 drops at ambient temperatures (25 ± 2°). The apparatus and calculations were reported previously (7).

pKa Determinations—The pKa values were determined by titrating aqueous solutions of different concentrations of $PGF_{2\alpha}$ tromethamine with 1.0 *N* HCl. The hydrochloric acid normality was chosen to minimize volume changes during the titration. The solutions were decarbonated by bubbling with purified nitrogen for 15 min. Titrations were carried out in a nitrogen atmosphere. A digital pH meter[8] equipped with a combination electrode[9] was used to measure pH.

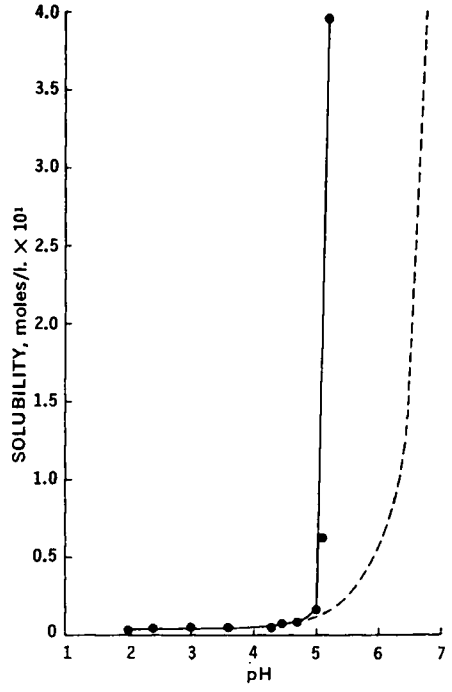

Figure 2—*pH-solubility profile of $PGF_{2\alpha}$ tromethamine. Key: ●, experimental value; and – –, predicted based upon pKa = 4.9.*

The hydrochloric acid was added using a syringe[6] calibrated to deliver 0.01 ml. Titrations of small volumes (2–4 ml.) were accomplished by using a cone-shaped container and a microstirring bar. After the addition of each increment of hydrochloric acid, the solution was allowed to equilibrate to a constant pH before the pH was recorded. The pKa at different percents of drug neutralized was calculated from the titration curve according to the method of Albert and Serjeant (8), and the pKa values were calculated from the following expression:

$$\text{pKa} = \text{pH} + \log \frac{C_T(\beta) - H_3O^+}{C_T(1-\beta) + H_3O^+} + \frac{0.505\sqrt{I}}{1 + 1.6\sqrt{I}} \qquad \text{(Eq. 2)}$$

where C_T is the total concentration of prostaglandin present (P^- + PH) and β is the degree of neutralization, *i.e.*, PH/(P^- + PH). The ionic strength contribution to the pKa was negligible below the CMC. At concentrations below the CMC, the reported pKa is an average of nine values from the titration curve.

RESULTS AND DISCUSSION

Solubility—The intrinsic solubility of the free acid of $PGF_{2\alpha}$ is 1.5 mg./ml. (0.0042 mole/l.). As shown in Fig. 2, the solubility of $PGF_{2\alpha}$ as the tromethamine salt increases with pH. The sharp (35-fold) increase in solubility with pH between 5.0 and 5.2 is far greater than would be expected on the basis of normal ionization

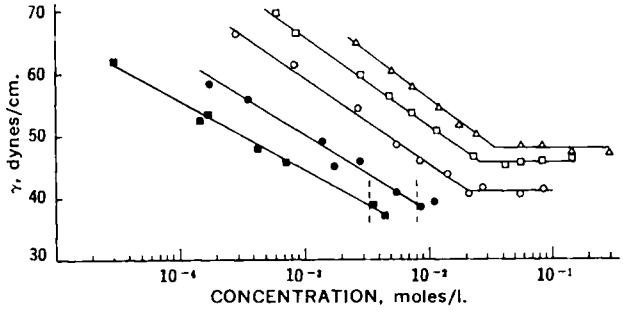

Figure 3—*Effect of pH on the surface tension plots of $PGF_{2\alpha}$ tromethamine in water. Solutions to the right of the vertical lines were colloidal for pH 3.0 and 5.0. Key: ■, pH 3.0; ●, pH 5.0; ○, pH 6.0; □, pH 8.0; and △, pH 10.0.*

Table I—CMC (Moles per Liter) of $PGF_{2\alpha}$ Tromethamine

pH	Medium	CMC Method—Titration	CMC Method—Surface Tension
10.0	Water	—	0.033
8.0	Water	—	0.026
6.0	Water	0.022	0.021

5.0	Water	—[a]	—[a]
3.0	Water	—[a]	—[a]
6.0	0.2 *M* Tromethamine	—	0.018
6.0	0.2 *M* NaCl	—	0.022
3.0	0.2 *M* Tromethamine	—	—[a]

[a] Since micelle formation could not be distinguished from precipitation, no value is reported.

of the acid. For purposes of comparison, the solubility that would be predicted on the basis of the following equation (9) is also shown:

$$S = S_0\left(1 + \frac{K_a}{H_3O^+}\right) \qquad \text{(Eq. 3)}$$

where S_0 is the intrinsic solubility of the acid and $K_a = 1.26 \times 10^{-5}$. This theoretical plot assumes that the solubility of the salt is much greater than the free acid. Although the exact solubility of the salt could not be determined, it is at least 500 mg./ml.

Micelle Formation—The unusual solubility behavior suggested that some type of molecular association, such as micelle formation, occurs above pH 5. Therefore, surface tension experiments were initiated to determine whether or not micelle formation occurs and to evaluate the CMC as a function of pH. Figure 3 shows the surface tension *versus* concentration plots for $PGF_{2\alpha}$ tromethamine at several pH values. At pH 3 and 5, surface tension lowering is evident, but the limited solubility of the drug precluded the distinction between micelle formation and precipitation. At the higher pH values, a well-defined plateau region is present, and the CMC is readily determined from the point of intersection of the two straight lines. These values are tabulated in Table I along with values calculated from the titration data. It was reported previously that, based on surface tension data, prostaglandins $F_{1\beta}$ and E_1 (5) do not form micelles. The discrepancy between that report and the present data could lie in the fact that the earlier study was not extended to sufficiently high concentrations to detect micelles.

The dependence of the CMC on pH is shown in Fig. 4. The points at the lower pH values represent the total solubility of the monomeric material, and it was not possible to measure a true CMC. From the data in Fig. 4, it can be seen that in the neutral pH range the micelles formed are likely to be mixed micelles composed of unionized and ionized $PGF_{2\alpha}$. This type of behavior is in agreement with results of similar studies using other surfactants (10, 11). Figure 5 shows the effect of salt on the surface tension–concentration plots at pH 3 and 6. Neither the slopes (discussed later) nor the CMC values (Table I) appear to be very dependent upon the presence of salt. Independent determination of exact CMC values utilizing the dye

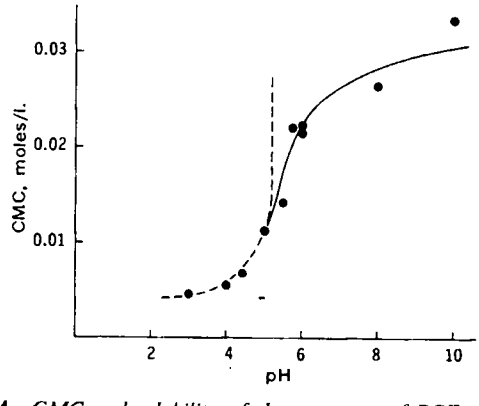

Figure 4—*CMC and solubility of the monomer of $PGF_{2\alpha}$ tromethamine as a function of pH. Key: - - -, solubility of the monomer; and —, CMC.*

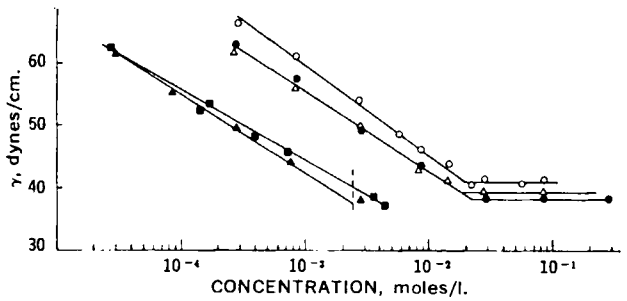

Figure 5—*Effect of salt on surface tension plots of $PGF_{2\alpha}$ tromethamine at pH 3.0 and 6.0. Solutions to the right of the vertical line were colloidal for pH 3.0. Key: ▲, pH 3.0, 0.2 M tromethamine; ■, pH 3.0, water; △, pH 6.0, 0.2 M tromethamine; ●, pH 6.0, 0.2 M NaCl; and ○, pH 6.0, water.*

solubilization method was unsuccessful due to assay interference by $PGF_{2\alpha}$. However, an increase in solubility of the dye (anthracene) was noted at approximately the CMC value. The CMC value calculated from titration data was in agreement with the value from surface tension measurements.

Micelle formation describes an association of several molecules showing a change in slope of a physical property at a critical concentration. Certain molecules may show this type of behavior and yet aggregate according to a stacking-type arrangement (12). This type of association can be characterized for rigid molecules where cooperative interaction of hydrophobic portions of the molecules is limited. Estimates of thermodynamic constants from CMC data may be misleading when this occurs (12). In the case of $PGF_{2\alpha}$, sufficient data are not available to determine the specific nature of the association process. However, space-filling molecular models show that $PGF_{2\alpha}$ has flexible hydrophobic chains (upper and lower) which could interact in a cooperative manner and probably form micelles in the classical sense.

Titration Curves—The titration curves in Fig. 6 are plots of pH *versus* fraction of total titrant added, β, obtained at various concen-

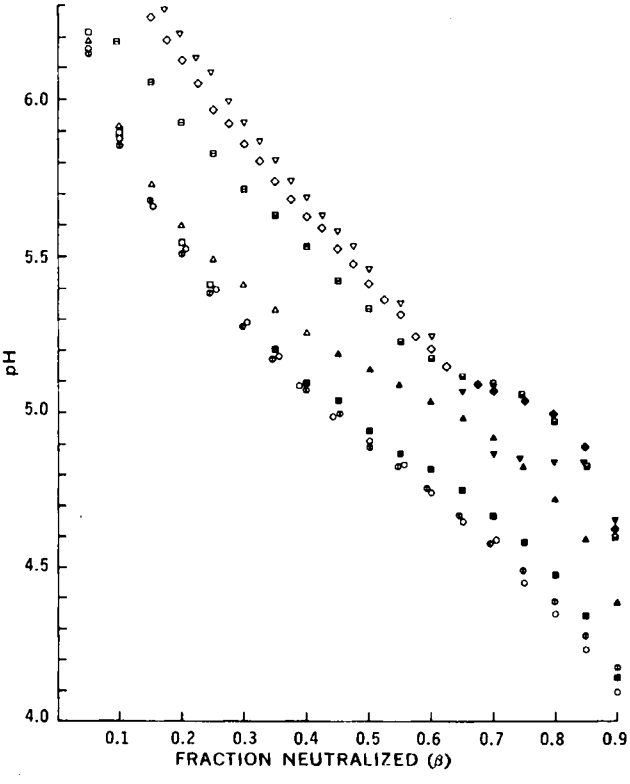

Figure 6—*Representative titration curves for $PGF_{2\alpha}$ tromethamine for various concentrations. Shaded symbols indicate precipitation. Key: ⊕, 0.001 M; ○, 0.002 M; □, 0.01 M; △, 0.02 M; ⊟, 0.05 M; ◇, 0.10 M; and ▽, 0.50 M.*

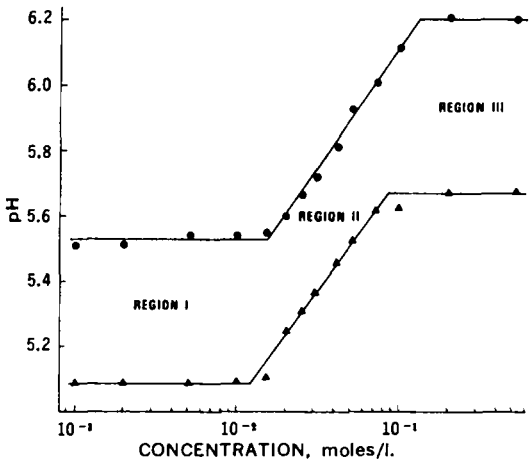

Figure 7—*pH-concentration profile for $PGF_{2\alpha}$ tromethamine. Key: ●, $\beta = 0.2$; and ▲, $\beta = 0.4$.*

trations. The fraction of total titrant is also referred to as the degree of neutralization of the system. The curves are independent of drug concentration at low concentrations, but they are displaced toward higher pH values as the concentration is increased and again become nearly superimposable at high drug concentrations. The shaded symbols indicate the regions where the system is colloidal, and these occur at $PGF_{2\alpha}$ tromethamine concentrations equal to or greater than 0.01 *M* and below a pH of about 5.1. These points were found to be less reproducible and more time dependent than those obtained for the true solutions, because equilibrium within the oil droplets could not be reached rapidly and with certainty. These points are indicated only to show the behavior of the titration curves in the situation where oiling out occurs. The slow dissolution of the oil droplets would explain why precipitation occurs in some cases at higher pH values than noted in the solubility profile. Only the values obtained for true solutions were used in calculating the data for the next section.

When pH is plotted against drug concentration at a constant β value, three distinct regions are noted, as in Fig. 7 for $\beta = 0.2$ and 0.4. At concentrations within the first region (I), only the monomeric species is present and a constant value for pH results. Above the CMC, the curves deviate from ideality. In this region (II), the pH changes with concentration due to the contribution of two species, monomer and micelle. Above 0.1 *M* (Region III), the pH again becomes constant since the micellar species predominates and the fraction of monomers becomes negligible.

The titration curves in Fig. 6 were also used to determine the CMC of $PGF_{2\alpha}$ as a function of pH. By plotting the drug concentration at which each curve crosses a particular pH, two curves are obtained which intersect at the CMC. When only monomers are present, as in Fig. 7, β is independent of concentration; however, it begins to deviate from the monomer value at the CMC (Fig. 8). This procedure for determining the CMC is equivalent to the pH-stat method described by Wood *et al.* (13). The CMC at pH 6.0 was in good agreement with the value determined from surface tension measurements (Table I and Fig. 3).

Ionization Constants—The pKa of $PGF_{2\alpha}$ tromethamine was

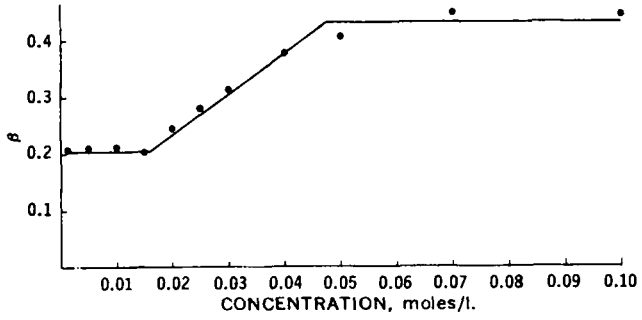

Figure 8—*Degree of neutralization (β) of $PGF_{2\alpha}$ tromethamine as a function of concentration at pH 5.5.*

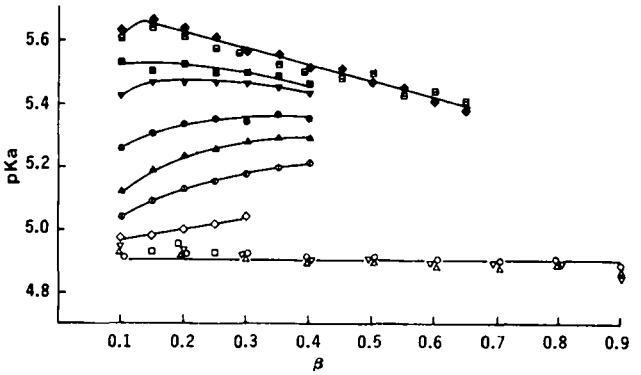

Figure 9—*pKa of $PGF_{2\alpha}$ tromethamine as a function of β at different concentrations. Key: △, 0.001 M; ○, 0.002 M; ▽, 0.005 M; □, 0.01 M; ◇, 0.02 M; ⊕, 0.03 M; ▲, 0.04 M; ●, 0.05 M; ▼, 0.07 M; ■, 0.1 M; ◆, 0.2 M; and ⊟, 0.5 M.*

calculated for each point in the raw titration curves (Fig. 6) as described in the *Experimental* section. The plots in Fig. 6 consider three variables (solute concentration, pH, and β), which are interrelated as shown in Eq. 2. The resultant pKa values as a function of β for different drug concentrations are shown in Fig. 9. At concentrations below 0.01 *M*, the pKa is equal to 4.90, as would be expected for an aliphatic carboxylic acid, and is independent of β and prostaglandin concentration. As the drug concentration is increased above the CMC, the pKa becomes dependent upon both β and prostaglandin concentration. In all cases, the apparent pKa increases as a function of the fraction of micelles present. This is shown graphically in Fig. 10A, where the plots are made for constant β values. Again, three regions are present which correspond to those described in Fig. 7. This type of behavior has been noted for other surfactant systems (14–16).

The higher pKa of the micellar $PGF_{2\alpha}$ compared to the monomer results from the fact that the negative carboxyl groups in the micelle are closer to one another than they are in free solution. In this respect, they resemble titratable groups of a polyelectrolyte (17–21). The accumulation of negative charges on the micellar surface places each individual carboxylate in a negatively charged environment. As a result, there are more protons in the vicinity of each carboxyl

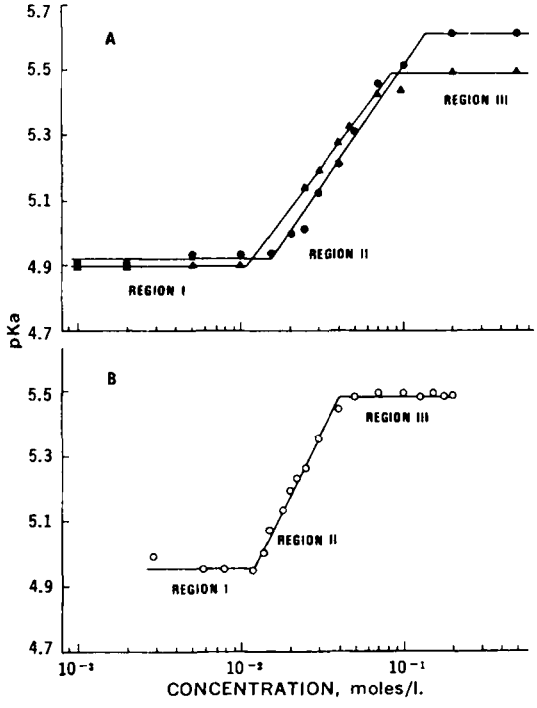

Figure 10—*(A) pKa as a function of concentration at different values of β for $PGF_{2\alpha}$ tromethamine. Key: ▲, $\beta = 0.4$; and ●, $\beta = 0.2$. (B) pKa as a function of concentration for cholic acid at 20° (14).*

group. Thus, deprotonation of each group is inhibited and the observed pKa increases. The magnitude of the increase in pKa is related to the number and closeness of the negative charges on the surface of the micelle. Therefore, the pKa of the ionized micelle ($\beta \rightarrow 0$) is greater than that of the more neutral micelle ($\beta \rightarrow 1.0$), and a negative slope would be expected for a pKa *versus* β plot. Ideally, the pKa of micelles at $\beta = 1.0$, where all of the carboxyl groups are in their neutral protonated form, should be equal to about 4.9 (the intrinsic value of a free aliphatic carboxyl group). When this is the case, the surface potential of the micelle at any value of β can be determined from the difference between the pK observed at that value of β and the intrinsic pK of the titratable group (17–21). The surface potential could be used to calculate the size of the micelle (21). However, other factors such as hydrogen bonding and changes in micelle size and shape tend to complicate the situation, especially for polyfunctional structures such as the prostaglandins.

The maximum surface potential of the micelle was calculated to be −41 mv. This value is less than the values reported for dimethyldodecylamine oxide (22) and long-chain acylcarnitines (21) and suggests that $PGF_{2\alpha}$ forms a loosely packed micelle.

At concentrations slightly above the CMC, the pK *versus* β plots (Fig. 9) have a positive slope. As mentioned earlier, a negative slope would be expected for micelles or a fixed mixture of monomers and micelles. This apparent discrepancy is explained by the fact that as β increases, the CMC decreases and, therefore, the fraction of micelles increases. This causes an increase in the observed pKa, which overcompensates for the decrease due to the neutralization of the surface charge as β increases. The following equation expresses this dependence in mathematical terms (11):

$$\text{pKa(observed)} = \text{pH} + \log\left[\frac{\beta - (C_0\beta_m/C_T)}{(1 - C_0/C_T) - (\beta - C_0\beta_m/C_T)}\right] \quad \text{(Eq. 4)}$$

where β_m is the degree of neutralization of the monomers, C_T is the total concentration of prostaglandin, and C_0 is the CMC.

The dependence of the CMC upon β is evidenced by the difference in concentration at which the breaks occur between Regions I and II (Fig. 10A). At 0.015 *M*, the curve at $\beta = 0.2$ represents only monomer. At higher values of β, the systems are a mixture of monomers and micelles.

Influence of Micelles on Solubility Profile—Returning now to the solubility–pH behavior of $PGF_{2\alpha}$ tromethamine, it is apparent that the rapid increase in solubility just above pH 5 is related to micelle formation. Figure 4 shows that the solubility of the monomeric acid and salt differs by less than a factor of 8. This does not, then, account for the observed solubility profile. Based upon Fig. 3 (see pH 3 and 5 runs), either the unionized acid of $PGF_{2\alpha}$ does not form micelles or the micelles are not very soluble. Hence, the observed solubility behavior (pH > 5) is due to the contribution of ionized drug, because it forms micelles that are extremely soluble. In the pH range of 3–8, the micelles are mixed due to the presence of both ionized and unionized species. The exact ratio of salt to acid is governed by the pH of the system, as described by the Henderson–Hasselbalch equation (23). There appears to be a critical ratio that is necessary for the rapid increase in solubility. Above pH 5.10, the ratio[10] of salt to acid is greater than 2:1; below this pH, there are less than two salt molecules for each acid molecule. Not surprisingly, as β approaches a value of 0.6 (Figs. 6 and 9), precipitation is noted for concentrations well above the CMC. This observation is consistent with the requirement that a critical ratio of salt to acid of near 2.0 be exceeded.

It is not clear why at least two molecules of salt are required to solubilize one molecule of acid. However, this type of behavior is not unusual in pharmaceutical systems. If the acid and salt are thought of as two distinct species whose relative concentrations are controlled by the pH of the solution, these observations are strikingly similar to those of Higuchi and Lach (24–26) for complexes of definite stoichiometry such as benzocaine–caffeine (1:1) and barbital–caffeine (2:1). Furthermore, some bile salts and their corresponding acids were shown by Ekwall *et al.* (6) and Ekwall (27) to exhibit a marked increase in solubility when the pH, and thus the acid–salt ratio, reaches a critical value.

[10] This ratio is based upon the pKa of the micelle being 5.38 at pH 5.10.

Table II—Area (Å²) per Molecule of $PGF_{2\alpha}$ Tromethamine at the Air–Water Interface

pH	Medium	Area per Molecule
3.0	Water	85.9
5.0	Water	75.5
6.0	Water	67.5
8.0	Water	64.1
10.0	Water	63.9
6.0	0.2 *M* Tromethamine	74.0
6.0	0.2 *M* NaCl	72.5
3.0	0.2 *M* Tromethamine	74.2

The similarity between $PGF_{2\alpha}$ and bile salts, *e.g.*, cholic acid, goes beyond the solubility–pH behavior mentioned previously. The CMC values of certain bile salts (28) fall in the same high concentration range as those of $PGF_{2\alpha}$, and their ionization constants (14) show a similar dependence on concentration (Fig. 10B). There is also an obvious similarity between the functional groups on cholic acid and $PGF_{2\alpha}$ (one carboxyl and three hydroxyl groups in each case). Moreover, in spite of its greater molecular weight, the molecular volume of cholic acid (28) is close to the value calculated for $PGF_{2\alpha}$ from its group contributions (29).

Area per Molecule—The area per molecule of $PGF_{2\alpha}$ was calculated from Eq. 5, the Gibbs adsorption equation (30):

$$\Gamma = \left(\frac{1}{kT}\right)\left(\frac{d\gamma}{d \ln C}\right) \quad \text{(Eq. 5)}$$

where Γ is surface excess of material adsorbed (moles/cm.²), k is the Boltzmann constant, T is absolute temperature, and $d\gamma/d \ln C$ is 1/2.303 times the slope of surface tension–log concentration curves in Figs. 3 and 5. Wherever applicable, activity coefficient corrections were made for variation in ionic strength. In the case of the $PGF_{2\alpha}$ tromethamine salt at low ionic strength, no correction was made for the adsorption of counterions at the interface (30, 31). The apparent lack of need for the full correction factor of 2.0 is evident in Table II. The areas calculated for pH 8 and 10 in the absence of added electrolyte differ by 17% from those obtained when a correction factor is not appropriate, *i.e.*, in swamping electrolyte or when only free acid is present. This might indicate that $PGF_{2\alpha}$ is adsorbed as an ion-pair rather than as free ions. The areas per molecule of the free acid or of the anion in swamping electrolyte (for which Eq. 5 is valid) average 77 Å². It is possible to construct space-filling molecular models, oriented with all of the polar groups on one side of the molecule, that have areas of about 85 Å². This orientation is reasonable since it would be expected that the polar groups would orient toward the polar aqueous phase. In this respect, prostaglandin $F_{2\alpha}$ again resembles the cholic acid molecule which contains three α-hydroxyl groups and a carboxylic acid moiety which are oriented toward the water at an air–water interface (28).

CONCLUSION

The pKa of $PGF_{2\alpha}$ was found to depend upon the concentration of drug titrated. The pKa increased from 4.9 for the monomer to 5.6 for the micellar state. This increase in pKa is consistent with the presence of a net negative charge at the surface of the micelle. The presence of these negatively charged micelles have been shown to account for the unusual solubility behavior observed for $PGF_{2\alpha}$ tromethamine salt. The existence of molecular aggregates was confirmed by surface tension measurements as well as the titration behavior.

Determination of CMC and Partial Specific Volume of Polysorbates 20, 60, and 80 from Densities of Their Aqueous Solutions

BAHRAM FARHADIEH

Abstract □ The CMC of the surfactants was determined by measuring the density of their aqueous solutions at 24.88° with a new instrument which can measure accurately the change in natural frequency of a hollow oscillator of constant volume when it is filled with a solution of unknown density. The frequency change is transformed into density by calibrating the instrument with liquids of known densities. The CMC values obtained were 12×10^{-3} wt.% for polysorbate 20, 9×10^{-3} wt.% for polysorbate 60, and 6.2×10^{-3} wt.% for polysorbate 80. By applying the intercept method, partial specific volumes of water and the surfactant were obtained from the density of each surfactant solution. These partial quantities indicated that the formation of micelles is associated with an increase in the partial specific volume of the surfactant and a concomitant decrease in that of water.

Keyphrases □ Polysorbates 20, 60, and 80—determination of CMC's and partial specific volumes from densities of their aqueous solutions □ CMC and partial specific volume, polysorbates 20, 60, and 80—determination from density of aqueous solution □ Density measurements, polysorbates 20, 60, and 80—used to determine CMC and partial specific volume

Various methods have been used in the determination of the critical micelle concentration (CMC) of ionic and nonionic surfactants. In general, these methods rely on the abrupt change that occurs in a number of physicochemical properties of the surfactant solutions as the CMC is approached (1–3). Partial volume quantities are a direct measure of the changes occurring in the body of the solutions but have rarely been used in the study of aggregation (4–8). The limited use of this method has been due mainly to difficulties involved in obtaining accurate measurements at constant temperatures and at low concentrations of the associating solute (6, 7). The availability of new instrumentation has greatly reduced such measurement difficulties.

The study reported here deals with the determination of densities of the aqueous solutions of polysorbates 20, 60, and 80 using a digital precision density meter[1]. The CMC for each surfactant and the partial specific volumes of the components of each surfactant solution are obtained from the corresponding density data. The results are used to describe changes that occurred in these solutions during aggregation.

EXPERIMENTAL

Chemicals—The nonionic surfactants examined were a group of three commercial products of pharmaceutical interest: polysorbate 20[2] [polyoxyethylene (20) sorbitan monolaurate], polysorbate 60[3] [polyoxyethylene (20) sorbitan monostearate], and polysorbate 80[4] [polyoxyethylene (20) sorbitan monooleate]. These surfactants

By applying the intercept method, partial specific volumes of water and the surfactant were obtained from the density of each surfactant solution. These partial quantities indicated that the formation of micelles is associated with an increase in the partial specific volume of the surfactant and a concomitant decrease in that of water.

Keyphrases □ Polysorbates 20, 60, and 80—determination of CMC's and partial specific volumes from densities of their aqueous solutions □ CMC and partial specific volume, polysorbates 20, 60, and 80—determination from density of aqueous solution □ Density measurements, polysorbates 20, 60, and 80—used to determine CMC and partial specific volume

Various methods have been used in the determination of the critical micelle concentration (CMC) of ionic and nonionic surfactants. In general, these methods rely on the abrupt change that occurs in a number of physicochemical properties of the surfactant solutions as the CMC is approached (1–3). Partial volume quantities are a direct measure of the changes occurring in the body of the solutions but have rarely been used in the study of aggregation (4–8). The limited use of this method has been due mainly to difficulties involved in obtaining accurate measurements at constant temperatures and at low concentrations of the associating solute (6, 7). The availability of new instrumentation has greatly reduced such measurement difficulties.

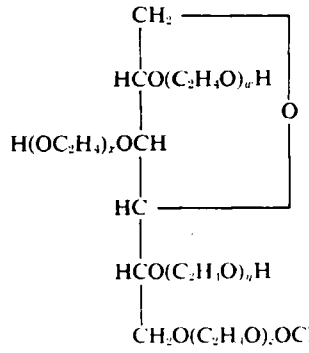
The study reported here deals with the determination of densities of the aqueous solutions of polysorbates 20, 60, and 80 using a digital precision density meter[1]. The CMC for each surfactant and the partial specific volumes of the components of each surfactant solution are obtained from the corresponding density data. The results are used to describe changes that occurred in these solutions during aggregation.

EXPERIMENTAL

Chemicals—The nonionic surfactants examined were a group of three commercial products of pharmaceutical interest: polysorbate 20[2] [polyoxyethylene (20) sorbitan monolaurate], polysorbate 60[3] [polyoxyethylene (20) sorbitan monostearate], and polysorbate 80[4] [polyoxyethylene (20) sorbitan monooleate]. These surfactants

[1] Model DMA 02/C, Anton Paar Kg., A-8054, Graz, Austria.
[2] Lot 1337, Tween 20, Atlas Chemical Industries Inc., Wilmington, Del.
[3] Lot 854, Tween 60, Atlas Chemical Industries, Inc.
[4] Lot 1147, Tween 80, Atlas Chemical Industries, Inc.

have the following general chemical formula:



where the RCO- group represents the fatty acid moiety and $n = w + x + y + z$ is the number of ethylene oxide units, which is equal to 20 for the surfactants considered (9). In this study, samples from these commercially available lots were analyzed as received. Further refining was not attempted because methods available (10) can effect only partial removal of the impurities. All solutions were prepared in distilled water on a weight-to-weight basis.

Density Measuring Apparatus—The system consisted of a digital precision density meter[1], circulator[5], and a digital thermistor thermometer[6]. The precision density meter consisted of a readout unit and a sample compartment. The sample compartment contained a hollow, V-shaped oscillator made of glass. The oscillator had a fixed volume (V), and it was filled and emptied through two ports located on the outside of the sample compartment. The oscillator could be excited to an undamped oscillation by a magnetic rod which was activated electronically. The readout unit measured the frequency of the oscillation (f) and displayed it as the oscillation period (T), where $T = 1/f$. The circulator was connected with short rubber tubing to the sample compartment. When in operation, it could maintain the temperature of the sample compartment to within ±0.02°. The temperature of the sample compartment was monitored during each run with the digital thermistor thermometer.

Instrument Theory The digital precision density meter can be represented by an equivalent system consisting of a hollow body of mass (M) and of volume (V) suspended from a spring with a spring constant (C). When the hollow body is filled with a liquid of density d and is set into motion, the oscillation period for the system is given by the following expression (11):

$$T = 1/f = 2\pi\sqrt{(dV + M)/C} \qquad \text{(Eq. 1)}$$

According to this relationship, which is general for any liquid, the oscillation period is only a function of the density of the liquid used. Expansion of Eq. 1 and further transformation yield:

$$T^2 = Ad + B \qquad \text{(Eq. 2)}$$

where A and B are the instrument's constants and are defined by $(A = 4\pi^2V/C)$ and $(B = 4\pi^2M/C)$.

[a] Average of four determinations.

For two liquids of differing densities, it readily follows that the difference in their densities is given by the equation:

$$(d_1 - d_2) = \frac{1}{A}(T_1^2 - T_2^2) \qquad \text{(Eq. 3)}$$

In this expression, A has the same definition as before and therefore represents the calibration constant for the instrument; T_1 and T_2 are the oscillation periods when the oscillator is filled with liquids of densities d_1 and d_2, respectively.

Density Measurement Procedure—Generally, the instrument was started 1 hr. prior to any density measurements to assure temperature equilibration. The hollow oscillator was washed by injecting distilled water through the injection port and emptying it by forced air several times. Next, the instrument was calibrated by obtaining the oscillation period for distilled water (T_1) and for anhydrous ethanol (T_2). These two liquids were used because their respective densities at various temperatures are reported in the literature (12). The densities of the aqueous solutions of the polysorbates were measured against distilled water as the reference.

All measurements were done at 24.88 ± 0.02°. It was necessary to wait for 15 min. between each sample injection for the temperature to reequilibrate. The accuracy of the measurements was investigated with distilled water. It was determined to be $\pm 3.0 \times 10^{-6}$ g./cm.³ of the reported value (12). Accuracy of this order of magnitude is easily obtainable since the instrument determines the density through precise measurement of frequency rather than determination of weight and volume.

RESULTS AND DISCUSSION

The densities of aqueous solutions of the three surfactants used in this study are reported in Table I. Each reported density is the mean of four separate determinations. In Fig. 1, the densities of the aqueous solutions of each surfactant are plotted against their re-

0.0600	1.002901	1.002911	1.002918

spective concentration. Each curve consists of two linear segments of different slopes. The abrupt change in slope occurs at the CMC of the surfactant (1–8). The CMC values for polysorbate 80, polysorbate 60, and polysorbate 20 were 6.2×10^{-3}, 9.0×10^{-3}, and 12×10^{-3} g./100 g., respectively. Bjaastad *et al.* (10) obtained CMC's of 6.0×10^{-3} and 4.5×10^{-3} g./100 ml. for partially purified polysorbate 80 and polysorbate 60, respectively, at room temperature. The higher value obtained for polysorbate 60 by the method employed in this investigation is probably due to impurities in the commercial sample used.

The volume (V) of a solution composed of n_1 moles of constituent x_1 and n_2 moles of constituent x_2 is related at constant temperature and pressure to n_1 and n_2 by the relationship (13):

$$V = n_1\bar{V}_1 + n_2\bar{V}_2 \qquad \text{(Eq. 4)}$$

where $\bar{V}_1$ and $\bar{V}_2$ are the partial molal volumes of the constituents x_1 and x_2, respectively, and are defined by the following expressions:

$$\bar{V}_1 = (\partial V/\partial n_1)_{T,P,n_2} \qquad \text{(Eq. 5)}$$

$$\bar{V}_2 = (\partial V/\partial n_2)_{T,P,n} \qquad \text{(Eq. 6)}$$

The subscripts T, P, n_1, and n_2 refer to the constant temperature and pressure conditions at constant amount of component one or two, respectively. If grams is chosen instead of moles as the concentration unit, Eqs. 4–6 are valid for partial specific volumes. These multiplied by their respective molal weights give the corresponding partial molal volumes.

The commercial polysorbates used in this study are impure and their exact molal weights cannot be used for such conversions without introducing some errors in the values of their partial molal

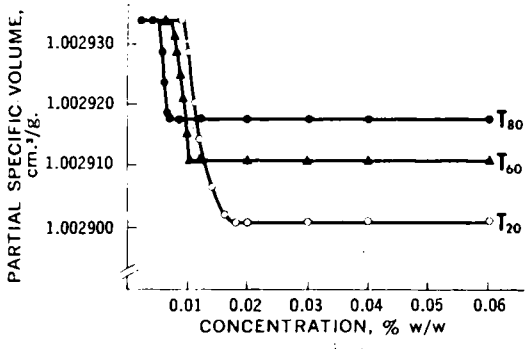

Figure 3—*Partial specific volume of water in aqueous solutions of polysorbate 20* (T_{20}), *polysorbate 60* (T_{60}), *and polysorbate 80* (T_{80}).

volumes. Thus, the densities of each polysorbate solution were used to calculate the partial specific volumes of the surfactants ($\bar{v}_2$) and that of the water ($\bar{v}_1$) rather than their respective partial molal volumes. The method of intercepts (13) was used in these calculations. In this method, the specific volume (1/density) of each of the solutions was plotted *versus* the surfactant concentration (weight percent). A smooth curve was fitted through the points. If a tangent is drawn to the curve of such a plot at any one point, the intercept of this tangent upon the ordinate representing 100% water is equal to $\bar{v}_1$. Similarly, the intercept upon the 100% surfactant ordinate is equal to $\bar{v}_2$. Figure 2 is such a plot for polysorbate 80 solutions. The broken line is a tangent drawn to the point on the curve corresponding to a solution containing 0.0065 g. of surfactant/100 g. of solution. The partial specific volumes of the water in aqueous solutions of each surfactant were determined graphically. For the surfactants, however, graphical extrapolation of the tangents to the 100% surfactant ordinate was not practical. Therefore, all values for $\bar{v}_2$ were obtained by determining the straight-line equations fitting the tangent lines. From these equations, the intercepts upon the ordinate representing 100% surfactant were calculated.

The values of $\bar{v}_1$ and $\bar{v}_2$ at several concentrations were obtained for the three surfactant solutions (Tables II and III) and are plotted *versus* concentration of the polysorbates in Figs. 3 and 4, respectively. An inspection of Figs. 3 and 4 shows that below the CMC the values of $\bar{v}_1$ and $\bar{v}_2$ are constant, indicating that the surfactants behave as normal undissociable solutes at these concentrations. Depending on the magnitude of change in the slope of specific volume *versus* concentration plot, the values of $\bar{v}_1$ and $\bar{v}_2$

undergo a sharp change near or at the CMC of each surfactant, which continues over a narrow concentration range beyond the CMC. This type of behavior has been observed for potassium *n*-octoate (5) and for potassium laurate and lauryl sulfonic acid (8). The concentration dependency of $\bar{v}_1$ and $\bar{v}_2$ is due to the changing ratio of monomeric to micellar surfactant (14, 15). After this transition region, $\bar{v}_1$ and $\bar{v}_2$ begin to become constant again due to the diminishing ratio of the monomeric surfactant to the micellar surfactant.

It also has been suggested (16) that the decrease in the partial specific volume of water with a concomitant rise in that of the surfactant is due to change of water structure upon micelle formation. Below the CMC where the surfactant molecules exist in their monomeric form, the hydrophobic portions of these molecules are tightly surrounded by water molecules (17, 18). Thus, these monomers are subjected to high compression by the strong cohesive field of water molecules. At the same time, by their interposition between water molecules, these monomers effectively reduce the attraction of water molecules for each other which results in less compression on water. Upon aggregation, the area of contact between water and the hydrophobic portions of the surfactant is greatly reduced on account of the large size of the micelle as compared to single molecules. This reduction of the contact area releases most of the water molecules that were originally bound to the surfactant molecules and were the cause of their compression. For these reasons, micelle formation is accompanied by a reduced compression of the surfactant molecules (larger partial specific volume) and by an increased compression of the water molecules (smaller partial specific volume).

Effect of Wavelength on Production of Previtamin D_2

ELIANE ABILLON[▲] and RENÉ MERMET-BOUVIER

Abstract □ On the basis of a previously established reaction scheme, the formation rate of various isomers produced by UV irradiation of ergosterol at low temperature was calculated for wavelengths between 240 and 320 nm. Particular attention was given to previtamin D_2, the precursor of vitamin D_2; the production optimum and the time required to obtain it were investigated in relation to the irradiation wavelength.

Keyphrases □ Previtamin D_2 photochemical formation from ergosterol—effect of irradiation wavelengths □ Ergosterol photochemical conversion to previtamin D_2—effect of irradiation wavelength □ UV irradiation of ergosterol—conversion to previtamin D_2, effect of various wavelengths

Much work has been done on the photoisomerization of ergosterol (1–3), and various reaction schemes have been proposed (4–6). Only the thermal transformation of previtamin D_2 to vitamin D_2 was reported (2) and is insignificant if the temperature of the irradiated medium is under 10°.

The production of vitamin D_2 is achieved in two steps:

1. UV irradiation of ergosterol (I) at a low temperature, which results in the formation of the following isomers: previtamin D_2 (II), tachysterol$_2$ (III), lumisterol$_2$ (IV), and toxisterols.
2. Separation of previtamin D_2, which becomes vitamin D_2 (V) through thermal transformation.

The purpose of this work was to determine the effect of the irradiation wavelength on the percentage of the previtamin formed. The absorption properties were investigated as a function of wavelength for the isomers concerned in accordance with a recently determined reaction scheme representing the different photochemical transformations.

PHOTOCHEMICAL REACTION SCHEME OF ERGOSTEROL AT LOW TEMPERATURE: CORRESPONDING KINETICS

The reaction scheme (7, 8) used in this study is shown in Scheme I. The quanta transformation yield values are indicated and are ex-

undergo a sharp change near or at the CMC of each surfactant, which continues over a narrow concentration range beyond the CMC. Effect of Wavelength on Production of Previtamin D_2

ELIANE ABILLON[▲] and RENÉ MERMET-BOUVIER

Abstract □ On the basis of a previously established reaction scheme, the formation rate of various isomers produced by UV irradiation of ergosterol at low temperature was calculated for wavelengths between 240 and 320 nm. Particular attention was given to previtamin D_2, the precursor of vitamin D_2; the production optimum and the time required to obtain it were investigated in relation to the irradiation wavelength.

Keyphrases □ Previtamin D_2 photochemical formation from ergosterol—effect of irradiation wavelengths □ Ergosterol photochemical conversion to previtamin D_2—effect of irradiation wavelength □ UV irradiation of ergosterol—conversion to previtamin D_2, effect of various wavelengths

Much work has been done on the photoisomerization of ergosterol (1–3), and various reaction schemes have been proposed (4–6). Only the thermal transformation of previtamin D_2 to vitamin D_2 was reported (2) and is insignificant if the temperature of the irradiated medium is under 10°.

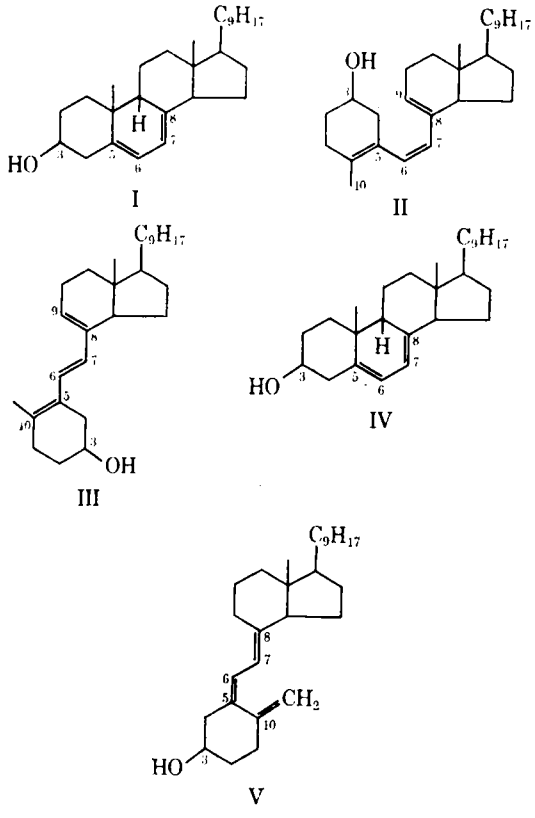
The production of vitamin D_2 is achieved in two steps:

1. UV irradiation of ergosterol (I) at a low temperature, which results in the formation of the following isomers: previtamin D_2 (II), tachysterol$_2$ (III), lumisterol$_2$ (IV), and toxisterols.
2. Separation of previtamin D_2, which becomes vitamin D_2 (V) through thermal transformation.

The purpose of this work was to determine the effect of the irradiation wavelength on the percentage of the previtamin formed. The absorption properties were investigated as a function of wavelength for the isomers concerned in accordance with a recently determined reaction scheme representing the different photochemical transformations.

PHOTOCHEMICAL REACTION SCHEME OF ERGOSTEROL AT LOW TEMPERATURE: CORRESPONDING KINETICS

The reaction scheme (7, 8) used in this study is shown in Scheme I. The quanta transformation yield values are indicated and are ex-



pressed in number of molecules per photon absorbed by the starting isomer.

The kinetic reaction of the various isomers (9) was studied. The isomer system investigated corresponds to the interaction graph in Scheme II. This is a true exotropic graph (10) in which: (*a*) summits ①, ②, ③, and ④ represent the classes of ergosterol, previtamin D_2, tachysterol$_2$, and lumisterol$_2$ molecules, respectively; (*b*) the f_{kj} functions represent the probabilities, per unit of time, of transforming the isomer (*j*) into the isomer (*k*); and (*c*) the f_{2e} function represents the probability, per unit of time, of the exit of previtamin D_2 molecule from the system concerned.

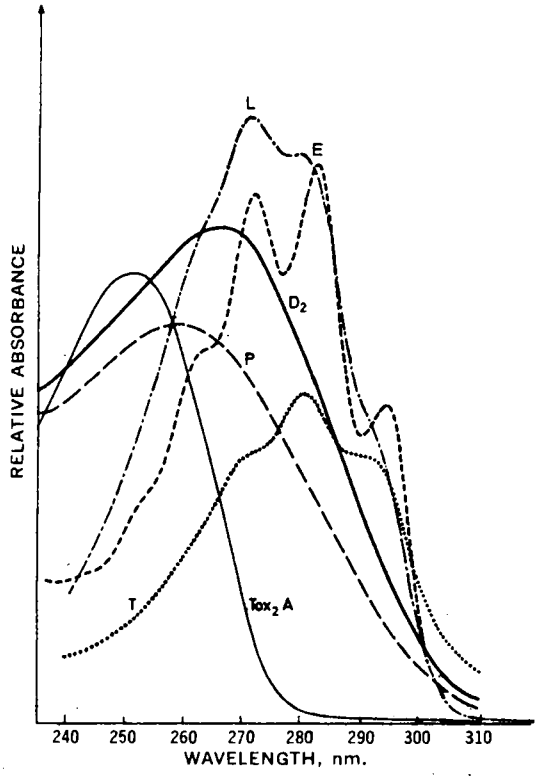


Figure 1—*UV absorption graphs. Key: E, ergosterol; L, lumisterol$_2$; P, previtamin D_2; T, tachysterol$_2$; D, vitamin D_2; and Tox$_2$A, toxisterol$_2$A.*

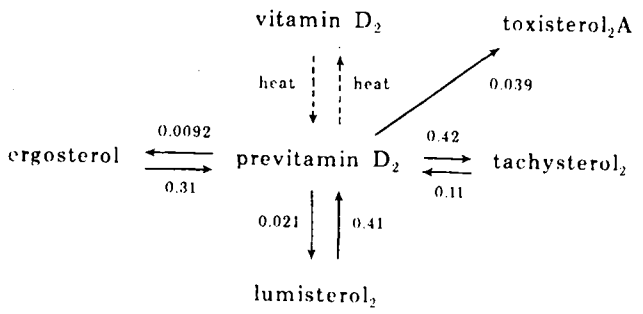


Scheme I—Reaction scheme of ergosterol photoisomerization at low temperature

Let $N_j(t)$ be the number of molecules in isomer (*j*) at time *t*. The equations governing the change in the system are:

$$\frac{dN_1(t)}{dt} = f_{12}N_2(t) - f_{21}N_1(t) \qquad \text{(Eq. 1)}$$

$$\frac{dN_2(t)}{dt} = f_{21}N_1(t) + f_{23}N_3(t) + f_{24}N_4(t) - (f_{12} + f_{32} + f_{42} + f_{2e})N_2(t) \qquad \text{(Eq. 2)}$$

$$\frac{dN_3(t)}{dt} = f_{32}N_2(t) - f_{23}N_3(t) \qquad \text{(Eq. 3)}$$

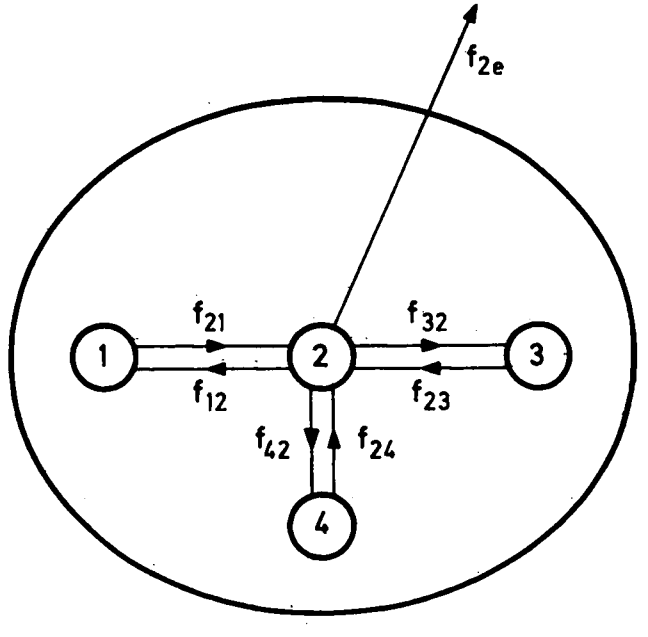
$$\frac{dN_4(t)}{dt} = f_{42}N_2(t) - f_{24}N_4(t) \qquad \text{(Eq. 4)}$$

The expression of the transfer function (in sec.$^{-1}$) is (11):

$$f_{kj} = 0.38 \times 10^{-20}\,\Phi_0 \cdot \varphi_{kj} \cdot \epsilon_j(\lambda) \qquad \text{(Eq. 5)}$$

where Φ_0 is the incident photon flux, expressed in photons/cm.^{2} sec.; φ_{kj} is the quantum transformation yield of the isomer (*j*) into the isomer (*k*), expressed in molecules per absorbed photon; and $\epsilon_j(\lambda)$ is the molar absorptivity of isomer (*j*) at wavelength λ.

The differential system (Eqs. 1–4) is valid for a thin-layer irradiation. It has been shown (11) that this system also holds for thick-



Scheme II—True exotropic graph of the ergosterol photochemical system at low temperature. (A true exotropic graph is a maximum strongly connected component to which are added boundary functions that are all divergent.)

layer irradiation—the medium being kept homogeneous—providing that the time t variable is replaced by the variable:

$$\tau = \int_0^t \frac{\bar{\Phi}_{(t)}}{\Phi_0}\, dt \qquad \text{(Eq. 6)}$$

where $\Phi_{(t)}$ is the mean photon flux in the irradiated medium at time t.

EXPERIMENTAL

Data Used—The differential system (Eqs. 1–4) was solved by computer with the following data.

1. The incident photon flux Φ_0 was assumed to be equal to 10^{18} photons/cm.^{2} sec.
2. The quanta yields φ_{kj} used are indicated in Scheme I.
3. The initial conditions required that only the ergosterol was present at the beginning and the number of molecules $N_1 (t = 0) = 1$.
4. Two series of molar absorptivities, $\epsilon_j(\lambda)$, were used. The first series was taken from the data of Havinga and coworkers (12, 13) and is given in Table I. The second series was obtained from UV spectra determinations as explained in the *Procedures* section. The absorption curves were obtained in relative values (Fig. 1), and it was necessary to normalize them to obtain the molar absorptivities in absolute values. To make this normalization, the values given by Havinga and coworkers at the wavelength of 253.7 nm. were retained and yielded:

$$\underset{\text{absolute value}}{\epsilon_j(\lambda)} = \underset{\text{relative value}}{\epsilon_j(\lambda)} \times \left(\frac{\epsilon_j\,(253.7)_{\text{Havinga}}}{\epsilon_j\,(253.7)_{\text{relative value}}} \right) \qquad \text{(Eq. 7)}$$

Procedures—The various isomers were obtained by irradiating an ergosterol solution in ether (10 g./l.) at 5° with two UV sources:

1. A germicide lamp[1] which, with its 253.7-nm wavelength emission, furthered the production of tachysterol$_2$.
2. A high pressure mercury vapor lamp[2] fitted with two filters. One filter consisted of a quartz tank filled with distilled water to reduce the intensity of IR radiation, and the other was a filter[3] that absorbed the short wavelength UV radiation, thereby producing lumisterol$_2$.

These isomers were separated by column chromatography (14). The column (60 × 1 cm.) was filled with a mixture of silica gel (88%) and alumina (12%). The elution was made with the same solvent (ether) used in the UV irradiation medium of ergosterol. With this method, five isomers could be separated and the eluted fractions corresponding to each isomer were analyzed by UV spectrometry. The UV spectra for these isomers are shown in Fig. 1.

RESULTS

Previtamin D_2 Production—During irradiation, the formation of previtamin D_2 began, rose to a maximum, and then decreased to zero.

[1] Mazda TG-16 Lampe Mazda, Paris 8e, France.
[2] Bausch & Lomb, Rochester, N. Y.
[3] MTO-J280a, MTO filter, Massy, France.

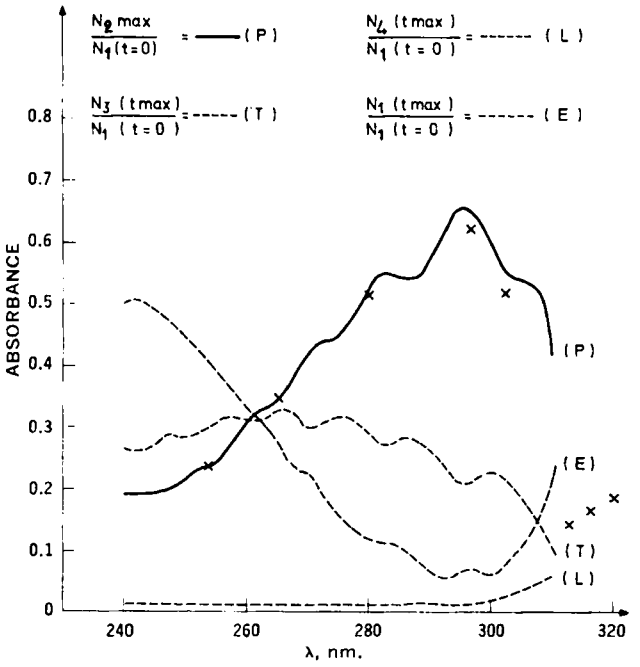

Figure 2—*Effect of wavelength on the maximum previtamin D_2 production and the simultaneous production of isomers. Key: (P), maximum previtamin D_2 production; (E), simultaneous ergosterol production; (T), simultaneous tachysterol$_2$ production; (L), simultaneous lumisterol$_2$ production; and ×, maximum previtamin D_2 production obtained with molecular extinction coefficients (12, 13).*

If the maximum number of previtamin molecules formed is called N_2 max and the number of ergosterol molecules before the irradiation is called $N_1(t = 0)$, the variation in the maximum number N_2 max/$[N_1(t = 0)]$ of previtamin D_2 molecules formed, brought down to an initial ergosterol molecule, according to the wavelength, is given in Fig. 2. The results obtained with the data of Havinga and coworkers (12, 13) (Table I) are indicated by ×'s. This graph (Fig. 2), plotted point by point every 2.5 nm., shows that maximum previtamin D_2 production occurs at the 295-nm. wavelength for which the percentage of ergosterol molecules transformed into previtamin D_2 is:

$$\frac{N_2 \text{ max}}{N_1(t = 0)} = 65\% \qquad \text{(Eq. 8)}$$

This result disagrees with Deribere (15) who recommended UV radiation at approximately 280 nm. corresponding to the maximum absorption of ergosterol and tachysterol$_2$. At this wavelength there is, in fact, a percentage of:

$$\frac{N_2 \text{ max}}{N_1(t = 0)} = 52.5\% \qquad \text{(Eq. 9)}$$

The t_{max} irradiation times required to obtain the maximum previtamin D_2, according to the wavelength, are given in Fig. 3. These times correspond to an incident photon flux $\Phi_0 = 10^{18}$ photons/cm.^{2} sec. For a different Φ_0' flux, the interaction functions become equal to:

$$f_{kj}' = \frac{\Phi_0'}{\Phi_0} f_{kj} \qquad \text{(Eq. 10)}$$

The differential system (Eqs. 1–4) remains the same if:

$$t' = \frac{\Phi_0}{\Phi_0'} t \qquad \text{(Eq. 11)}$$

is submitted. The yield values are therefore identical and only the time required to obtain them varies.

Formation of Other Isomers—When investigating the production of previtamin D_2, it is important to know the evolution of the other photochemical isomers: ergosterol, lumisterol$_2$, and tachysterol$_2$.

The concentrations $N_1(t_{max})$, $N_4(t_{max})$, and $N_3(t_{max})$ of these

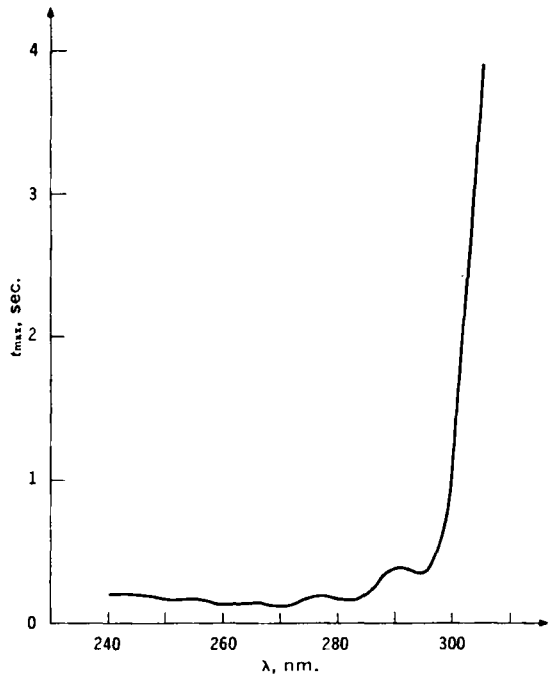

Figure 3—*Time needed to reach maximum previtamin D_2 production, with intensity of irradiation $\theta_0 = 10^{18}$ photons/cm.^{2} sec.*

isomers, when the previtamin has reached its maximum, are shown in Fig. 2. For the maximum of previtamin D_2 at the 295-nm. wavelength, there is a minimum of the three other isomers. The $N_2(t_{max})/N_3(t_{max})$, $N_2(t_{max})/N_1(t_{max})$, and $N_2(t_{max})/N_4(t_{max})$ ratios are, respectively, equal to 3.1, 10.2, and 47.5 at the 295-nm. wavelength and 1.8, 4.4, and 38.8 at the 280-nm. wavelength. This is an additional argument for seeking an irradiation source as rich as possible in UV radiation near to 295 nm.

Quantitative Determination of Thebaine in Poppy Plants Using High Speed Liquid Chromatography

DAVID W. SMITH▲, THOMAS H. BEASLEY, Sr., RICHARD L. CHARLES*, and HOWARD W. ZIEGLER

Abstract □ A method for the quantitative determination of thebaine in poppy plants using high speed liquid chromatography is described. A nonionic polymeric adsorbent resin column cleanup of the sample is used to eliminate interferences from nonalkaloidal plant components. The separation is effected on a high efficiency adsorption column using *n*-hexane–chloroform–methanol–diethylamine (900:75:25:0.1) as the mobile phase. The column effluent is continuously monitored with a UV photometric detector (254 nm.). The thebaine fraction is well resolved from the isothebaine and orientalidine fractions. With 1-g. poppy samples, 0.01% thebaine is readily determined (detection limit of less than 25 ng.).

Keyphrases □ Poppy plants—analysis of thebaine using high speed liquid chromatography □ *Papaver bracteatum*—analysis of thebaine using high speed liquid chromatography □ Thebaine in poppy plants—analysis, high speed liquid chromatography □ Liquid chromatography, high speed—analysis, thebaine in poppy plants

A sensitive and rapid method was sought for the analysis of thebaine in small samples of poppy plants and parts thereof. The classical procedures of solvent extraction or column chromatography combined with gravimetric or titrimetric estimation of the isolated alkaloids were precluded (1, 2). Extraction methods for isolating the alkaloids from poppy plants and their subsequent separation for biosynthetic studies were previously described (3, 4). isomers, when the previtamin has reached its maximum, are shown in Fig. 2. For the maximum of previtamin D_2 at the 295-nm. wavelength, there is a minimum of the three other isomers. The $N_2(t_{max})/N_3(t_{max})$, $N_2(t_{max})/N_1(t_{max})$, and $N_2(t_{max})/N_4(t_{max})$ ratios are, respectively, equal to 3.1, 10.2, and 47.5 at the 295-nm. wavelength and 1.8, 4.4, and 38.8 at the 280-nm. wavelength. This is an additional argument for seeking an irradiation source as rich as possible in UV radiation near to 295 nm.

kieselguhr columns was used in the quantitative determination of the "secondary alkaloids" in opium (2). TLC on silica gel, followed by spectrophotometric measurement of the resolved alkaloids, was also used (5, 6). GLC was employed for the separation and quantification of opium alkaloids (7, 8), but problems due to adsorptive effects were encountered with GLC determination of the alkaloids (8). Other procedures include an ion-exchange separation (9) and an IR spectrophotometric determination (10). The latter procedure allows the simultaneous determination of narcotine, thebaine, and papaverine in opium by examining the IR spectrum of a carbon tetrachloride solution of the dried chloroform residue from an extraction of an acetic acid–water solution.

EXPERIMENTAL

Reagents—All reagents were analytical reagent grade, except diethylamine which was organic reagent grade. The nonionic polymeric adsorbent resin[1] (20–50 mesh) was washed before use with two, two, and four column volumes of acetone, methanol, and water, respectively. The strong cationic-exchange resin in the hydrogen form[2] (20–50 mesh), high efficiency adsorption packing[3] (37–50 μm.), TLC plates[4], and silicic acid[5] were used as received. A mixed solvent (Reagent A) consisting of chloroform–methanol (3:1) was used throughout the procedure.

Standards—Three thebaine standard solutions in the concentration range of 0.1–0.4 mg./ml. were prepared by dissolving thebaine alkaloid in Reagent A. The thebaine alkaloid was purified by classical purification procedures in these laboratories. It was shown to be single-component material by TLC, GLC, and high speed liquid chromatography (HSLC) and was found to be 99+% pure by nonaqueous acid–base titration. The standard solutions were freshly prepared each week and were stable when protected from light and solvent evaporation.

Equipment—A laboratory mill[6] was used to mill dried samples. A 1.4-cm. i.d. × 30-cm. glass column fitted with a Teflon stopcock was used for column chromatography in the cleanup procedure. A cotton plug was used for a bed support.

HSLC System—The system consisted of a mobile phase reservoir, a liquid metering pump[7], a pressure relief valve[8], a pulse dampening system, a 5-μl. sample injector valve[9], a 2.8-mm. i.d. × 300-mm. glass analytical column[10] containing a suitable packing[3], a UV (254-nm. wavelength) photometric detector[11], a recorder, various connectors and fittings, and 0.79-mm. (0.031-in.) i.d. Teflon tubing[10] arranged as shown in Fig. 1. The pulse dampening system was constructed from two 0–42.2-kg./cm.^{2} (0–600 p.s.i.) gauges[12] and a 2.8-mm. i.d. × 75-mm. column[10] packed with silicic acid. A 25-cm. coil of Teflon tubing was used to connect the second gauge to the fluid stream. At the beginning of each day, the coil was opened, drained, and reconnected to the system. The air column trapped in the coil served as an effective pulse suppressor to allow the detector to be operated at its most sensitive setting. The air slowly dissolved in the mobile phase, thus requiring its daily replacement.

Procedures—*Sampling and Extraction*—Fresh or frozen poppy roots, leaves, and/or stems were subdivided by chopping into about 0.5-cm. cubes (squares, if leaves). Dried roots, stems, leaves, capsules, or bracts were milled to approximately 1-mm. diameter particles. The subdivided sample was mixed to obtain a representative sample. Two portions of approximately 1 g. each were accurately weighed. A loss on drying at 105° (overnight) was determined on the first portion. The second portion was placed in a 250-ml. (8-oz.) blender jar, 100 ml. of water was added, and the pH was adjusted to 2 ± 0.2 with 10% (v/v) phosphoric acid solution. The sample was blended 4 × 30 sec. at high speed. Then the cutter blades were removed and the jar was placed in an ultrasonic bath. Filter pulp was added and the mixture was sonically agitated and simultaneously stirred with a motor-driven plastic paddle for 5 min. The slurry was filtered through paper with the aid of reduced pressure, and the filter cake was quantitatively washed with approximately 0.01 *N* phosphoric acid. The filter cake was saved and tested for thebaine content. The filtrate and washes were collected in a 400-ml. beaker, and the pH was adjusted to 9–10 with approximately 1 *N* sodium hydroxide.

Column Chromatography– A 10-ml. portion of prepared nonionic resin[1] was placed in the 1.4 × 30-cm. column. The sample was al-

lowed to pass through the column, adjusted to a flow rate of approximately 2 ml./min. The inside wall of the column was rinsed once with water, and then an additional 40 ml. of water was passed through the resin bed. The aqueous effluent was saved and checked for thebaine. A 200-ml. ⅋ 24/40 round-bottom flask was placed under the column. The inside wall of the column was washed with a few milliliters of methanol, and the alkaloids were eluted with 50 ml. of methanol. After approximately one-half of the methanol had gone through the column, the flow was stopped and the solvent voids were removed by running a stiff wire in and out of the resin bed. A cotton plug, to prevent the resin from floating, was placed on top of the bed; then the elution with the remainder of the methanol was resumed. Finally, 75 ml. of Reagent A was passed through the column. The resin bed was saved and checked for thebaine.

Sample Preparation for HSLC—The sample solution was evaporated to dryness using a rotary vacuum evaporator at 40–60°. Five milliliters of Reagent A was added to the sample residue in the flask. The flask was sealed with a polypropylene stopper and placed in an ultrasonic bath to extract the alkaloids from any insoluble residue. The solution was filtered through a medium-porosity, sintered-glass filter into a 25-ml. volumetric flask. The round-bottom flask was rinsed three times with 3-ml. portions of Reagent A, and each portion was filtered. Finally, the filter was washed twice with 3 ml. of Reagent A. Filtration was facilitated by positive pressure developed with a rubber squeeze bulb fitted on top of the filter funnel. The sample solution and washes were diluted to volume with Reagent A.

HSLC—The operating conditions for the analysis were as follows: (*a*) mobile phase composition, *n*-hexane–chloroform–methanol–diethylamine (900:75:25:0.1 v/v); (*b*) mobile phase flow rate, 1 ml./min. [approximate column head pressure of 2.8 kg./cm.^{2} (40 p.s.i.) was developed]; and (*c*) detector setting, 0.08 absorbance unit full scale (AUFS) for usual operation. The sample or standard solution was transferred to the sampling valve by means of a 1-ml. tuberculin syringe. Five microliters was then injected onto the column by manually actuating the sample injector valve. Peak heights of the thebaine peaks from sample and standard chromatograms were measured manually from the extrapolated baselines. Three standards were run each day to prepare a calibration curve. The thebaine concentrations of the samples were found from the calibration curve. A shared-time computer was used for constructing the calibration curve by finding the best slope (m) for a line of the equation $y = mx$, where y is the absorbance and x is micrograms of thebaine. Analytical results were calculated on the dried basis from the sample weights and loss on drying values.

TLC Procedure for Checking for Alkaloid Losses—*Filter Cakes*—The filter cake was placed in a beaker, about 50 ml. of water was added, and the pH was adjusted to approximately 3 with 10% (v/v) phosphoric acid solution. Five milliliters of cation-exchange resin[2] was added to the beaker. The mixture was then ultrasonically agitated and mechanically stirred for 5 min. The beaker was removed from the ultrasonic cleaner, and distilled water was added to fill the beaker. After the resin was allowed to settle, the supernate and suspended pulp were decanted. The water addition and decanting

Table I—Thebaine Assay Values of Several Iranian Poppy Plant Samples

Sample Number	Description	Weight Percent Thebaine (Dried Basis)
16B	Mature capsules	1.50, 1.41, 1.62, 1.42, 1.48
16C	Green stems	1.87, 1.83
16D	Bracts	1.42, 1.37
16E	Green capsules	1.23, 1.25
45B	Mature capsules	1.40, 1.48, 1.42

step was repeated at least three times. Most of the water was poured off, and then 25 ml. 1 *N* ammonium hydroxide in 70% methanol was added (11). The mixture was ultrasonically agitated 5 min. and then filtered through a cotton plug, fitted in a powder funnel, into a 100-ml. ⅋ 24/40 round-bottom flask. The resin was washed in the funnel three times with 5 ml. of 70% methanol. The filtrate and washes were evaporated to dryness on a rotary vacuum evaporator. The residue in the flask was extracted in 5 ml. of Reagent A with the aid of ultrasonic agitation, and 100 μl. was spotted (in 10-μl. increments) on a TLC plate.

The TLC conditions were as follows: (*a*) mobile phase, benzene–ethanol–ammonium hydroxide (90:15:1); (*b*) development, 10 cm., ascending; and (*c*) visualization, UV (254 nm.) and iodoplatinic acid spray reagent. Five microliters of a 1% thebaine solution was spotted adjacent to the sample spot for reference. The plate was developed and any thebaine found was noted. Any thebaine loss detected was cause to repeat the sample work-up using less sample.

Aqueous Effluents—The pH of the solution was adjusted to about 3 and treated as described previously beginning with the addition of the ion-exchange resin.

Posteluates—Alkaloid losses on the nonionic resin[1] were checked by passing another 50 ml. of Reagent A through the resin bed. The effluent was collected in a 100-ml. ⅋ 24/40 round-bottom flask and then evaporated to dryness on the evaporator. Five milliliters of Reagent A was added to the flask, and 100 μl. of the resulting solution was spotted (in 10-μl. increments) on a TLC plate.

RESULTS AND DISCUSSION

Figure 2 shows a chromatogram of a synthetic mixture of orientalidine, isothebaine, and thebaine. These three alkaloids are reported to occur in *Papaver bracteatum* and *P. orientale* (12, 13).

Figure 3 shows a plot of peak height *versus* micrograms of thebaine from chromatograms of thebaine standard solutions. For assay work, the system was calibrated each day because some variation in the thebaine retention volume was occasionally noted from day to day. Recalibration was also required when fresh mobile phase was used. Fresh mobile phase was prepared at least every 3 days because some loss in resolution was noted with 1-week-old mobile phase. However, the system was stable within a particular day. The peak heights for replicate injections of a standard sample throughout a 5-hr. period would nominally have an average variation of less than ±1% relative standard deviation (*RSD*).

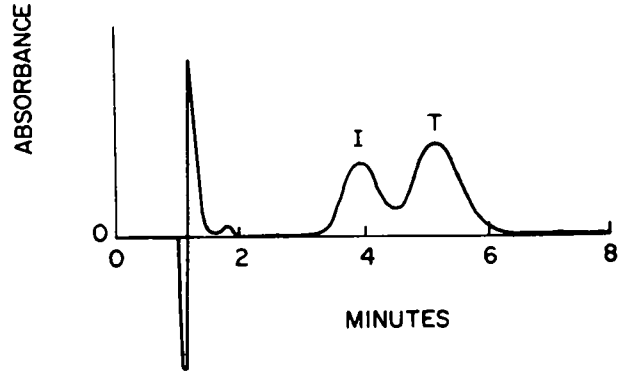

Figure 4—*Typical chromatogram of a poppy plant sample. Key: I, isothebaine; and T, thebaine.*

A chromatogram of a typical poppy plant sample is shown in Fig. 4. The retention volumes for the alkaloids are noted to be greater here than in Fig. 2. The chromatogram in Fig. 4 was run 2 months before the one in Fig. 2. The sample was 0.55 g. of capsules and assayed 0.39% thebaine on the dried basis (6.64% loss on drying).

Table I shows assay values for several Iranian poppy samples[13], tentatively identified as *P. bracteatum*. The coefficient of variation for the method was 5.7% with Sample 16B. It was felt that the precision obtained on this sample was limited by sampling error, since these data were obtained on a rather coarse (hand-ground) grind of the capsules. Duplicate assays on other samples ground finer by milling appeared to be in closer agreement.

TLC was used to check for thebaine losses as noted in the procedure. The sensitivity of a single TLC test was 1 mcg. of thebaine alkaloid (absolute). The cumulative thebaine loss from three TLC checks per sample could, therefore, not exceed 1.5%.

A procedure using a cation-exchange resin[2] (11) was tried and then abandoned. The resin is an efficient extractant for the alkaloids from the plant matrix. However, the resin extracted other plant matter, particularly from green stems and capsules, which eluted with the alkaloid fraction (1 *N* ammonia in 70% methanol was used to elute the alkaloids from the resin). Upon evaporation of the eluant, a large amount of residue remained from which the thebaine could not be quantitatively recovered. For such samples, the extraneous material was effectively removed with a postcolumn of a strong anionic-exchange resin in the chloride form[14]. For certain sample types, a gummy mass formed when the methanol–water phase was added to the cation-exchange resin[2] which hopelessly plugged the columns. However, the nonionic resin[1] procedure gave the least amount of extraneous residue and worked well with all sample types.

The nonionic polymeric adsorbent resin[1] system, as described here, has a capacity to handle about 50 mg. of thebaine. Losses due to incomplete extraction by, or elution from, the resin do occur with larger sample loads. The TLC monitoring of the sample cleanup procedure for different sample types easily determines if losses are occurring. The monitoring can be discontinued once an analyst determines the proper sample size to use.

Detection of Ampicillin Contamination in Nitrofurantoin Preparations by High Pressure Liquid Chromatography

ALFRED BRACEY

Abstract □ Ampicillin as a contaminant in nitrofurantoin capsules and tablets was determined by high pressure liquid chromatography. The method uses a strong anion-exchange column, 0.01 *M* KH_2PO_4 buffer, and an ampicillin working standard as reference. Identity of ampicillin was verified by assaying spiked samples of nitrofurantoin. The method is quantitative over the range 1–10 mcg. of ampicillin.

Keyphrases □ Nitrofurantoin tablets and capsules—analysis of ampicillin contamination, high pressure liquid chromatography □ Ampicillin contamination in nitrofurantoin tablets and capsules—analysis, high pressure liquid chromatography □ High pressure liquid chromatography—analysis, ampicillin contamination in nitrofurantoin capsules and tablets

Ampicillin, 6-[D(−)-α-aminophenylacetamido]penicillanic acid, is a semisynthetic penicillin, first prepared by Doyle *et al.* (1). The anhydrous and trihydrate forms and the sodium salt are widely used therapeutically. It has been shown to be inhibitory at low concentrations against a wide variety of both Gram-negative and Gram-positive bacteria (2–4). Because it is manufactured and formulated into dosage forms by many drug companies that also produce other drugs, cross-contamination is a possibility. This situation causes concern, particularly since small quantities of penicillin derivatives may cause allergic reactions (5–7). As part of its antibiotic certification program, the Food and Drug Administration (FDA) has developed and used tests (8) to check cross-contamination of penicillin in other pharmaceuticals, but these tests do not detect ampicillin.

A test to determine ampicillin contamination of nitrofurantoin became necessary when it was suspected as a contaminant in samples submitted to the National Center for Antibiotic Analysis for analysis. Attempts to recover ampicillin added to nitrofurantoin by the standard procedures (8) were unsuccessful because ampicillin, being amphoteric, could not be extracted into amyl acetate from an acid solution. A test based on liquid chromatography was developed.

A strong anion-exchange column was selected because ampicillin has an anion-exchangeable carboxylic group and is water soluble. Of various buffers and solvent systems tried, 0.01 *M* KH_2PO_4 (pH 6.5) buffer was optimal. This mobile phase separated nitrofurantoin and ampicillin and simultaneously was used to identify and quantitate ampicillin. The reliability of the method was verified by assaying spiked samples of nitrofurantoin capsules and tablets.

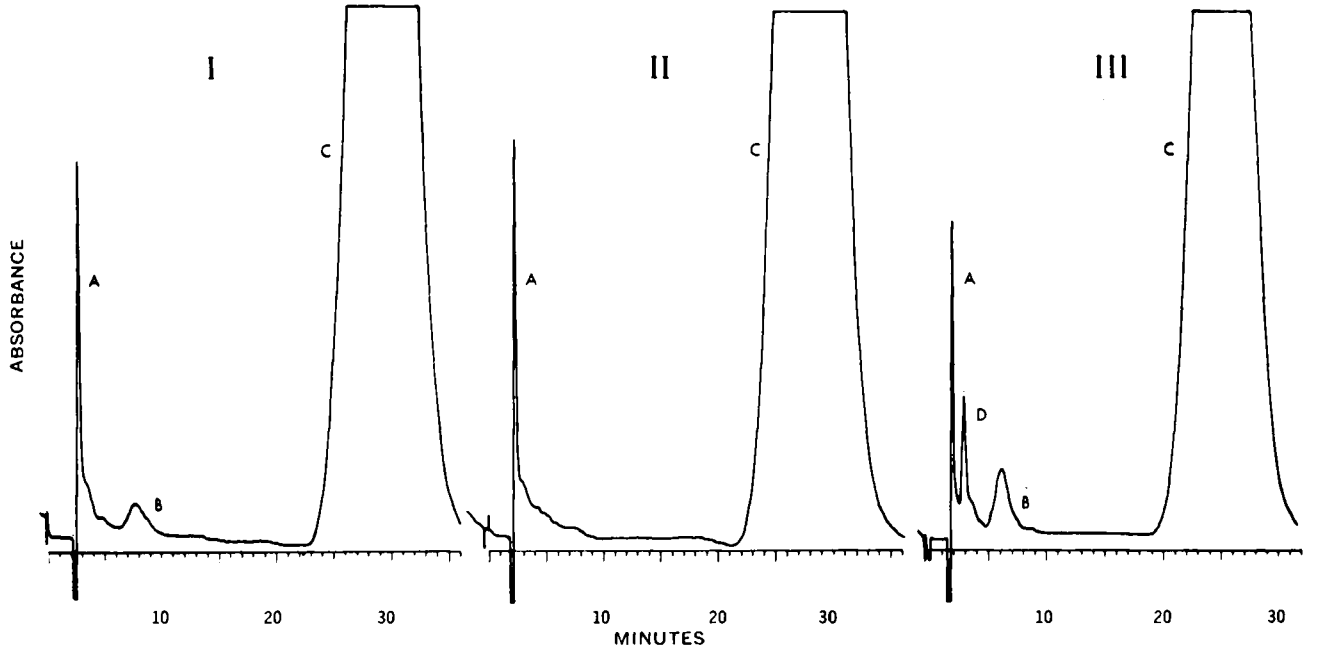

Figure 1—*Chromatogram of (I) nitrofurantoin capsules spiked with 0.1 mg. of ampicillin per dose, (II) uncontaminated nitrofurantoin capsules, and (III) commercial nitrofurantoin capsules contaminated with ampicillin. Key: A, solvent; B, ampicillin; C, nitrofurantoin; and D, unidentified impurity.*

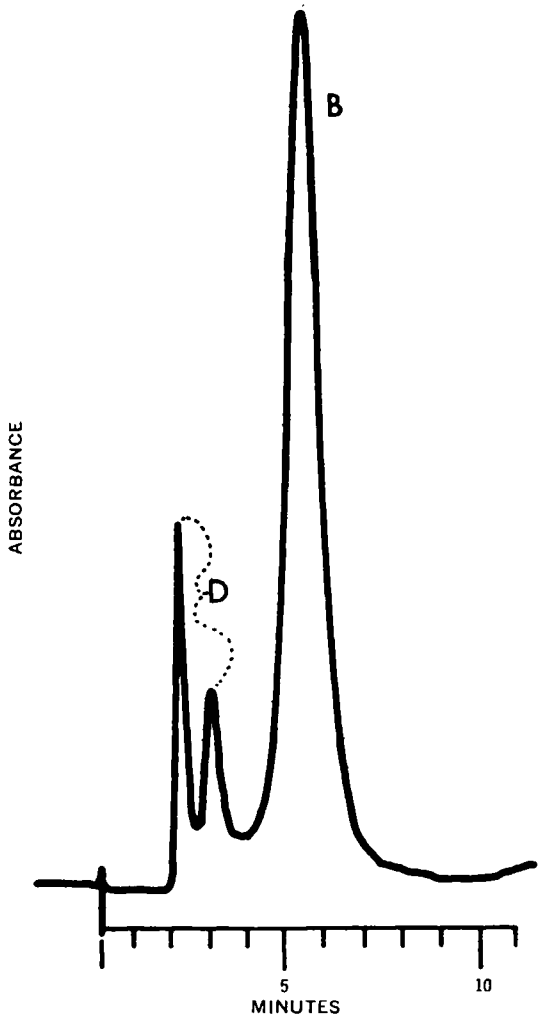

Figure 2—*Chromatogram of a contaminated bulk sample of ampicillin trihydrate. Key: B, ampicillin; and D, unidentified impurities.*

EXPERIMENTAL

Materials—A liquid chromatograph[1] was used with a UV detector; the flow rate was approximately 1.0 ml./min. A strong anion-exchange column[2], 1.0 m. by 2.1 mm. i.d., was obtained already prepared. Reagents were 0.01 *M* KH_2PO_4 buffer, pH 6.5; chloroform, reagent grade; and ampicillin trihydrate, FDA working standard.

Assay Procedure—Place the contents of 10 nitrofurantoin (50–100 mg.) capsules, or the powder from 10 ground tablets, into a 15-ml. centrifuge tube. Add 5.0 ml. of water and shake. Centrifuge the suspension, and decant the supernatant layer through a funnel containing a wad of glass wool into a second 15-ml. centrifuge tube. Add 10.0 ml. of chloroform to the second tube and shake vigorously. Allow the aqueous and chloroform layers to separate; then inject 5.0 μl. of the aqueous layer into the chromatograph for the ampicillin analysis.

Using an ampicillin reference standard at a concentration of 2.0 mg./ml. in distilled water, prepare a standard curve over a 1.0–10.0-mcg. range by chromatographing aliquots ranging from 0.5 to 5.0 μl. Obtain the peak area of each chromatogram by the method of peak height times width at half-height, and calculate the results by the following formula: micrograms ampicillin per dose unit tested = [(micrograms ampicillin from standard curve) (microliters total volume of solution)]/[(number of dose units tested) (microliters sample solution injected)].

RESULTS AND DISCUSSION

This method is quantitative for gross contamination of ampicillin in nitrofurantoin over a range of 1.0–10.0 mcg. of ampicillin. The standard curve is linear over this range. The constant retention time for ampicillin is an index of its identity.

The aqueous ampicillin solution must be extracted with chloroform to remove undefined chromophoric substances which gave a retention time very close to that of ampicillin. Because ampicillin is very water soluble, recovery was satisfactory. As shown in Fig. 1 (I), the ampicillin peak is well resolved from that of nitrofurantoin.

The sensitivity of this procedure is limited by the fact that 1.0 mcg. is the smallest amount of ampicillin that can be detected and quantitated accurately in the instrument used. Control samples were spiked at this level with 5.0 ml. of an aqueous solution containing 0.2 mg./ml. of ampicillin. A contamination of 0.1 mg./nitrofurantoin dose was assumed, so it was necessary to use 10 doses/5.0 ml. of water. The chromatogram of a sample of nitrofurantoin spiked at 0.1 mg. of ampicillin/dose is shown in Fig. 1 (I). Recovery of ampicillin from the spiked control sample was 94.0%.

Figure 1 (II) shows a chromatogram of nitrofurantoin capsules in which no ampicillin was detected. Figure 1 (III) shows a chromatogram of a sample of a nitrofurantoin capsule that was found to be contaminated with 158 mcg. of ampicillin/capsule dose.

Despite the limited sensitivity of this procedure, it provides useful data that cannot be obtained by other known methods. This procedure also makes it possible to perform identity studies by collecting fractions corresponding to the respective peaks in the chromatogram. The peaks preceding that of ampicillin could be collected separately or together and subjected to further analysis. The procedure may also be used to determine ampicillin in other drug formulations if excipients are removed in the preparative phase of the method to avoid exceeding the load capacity of the strong anion-exchange column as stated by the manufacturer.

This method has been used to examine ampicillin samples for purity. The chromatogram for the ampicillin FDA working standard and some commercial bulk samples showed a single, symmetrical peak, whereas other commercial ampicillin bulk samples yielded multiple-peaked chromatograms (*e.g.*, Fig. 2), indicative of the presence of impurities. These findings will be further investigated.

Estimation of Diiodohydroxyquin in Nonaqueous Media

K. L. K. PARANJOTHY* and S. K. BANERJEE▲

Abstract □ A method for estimating diiodohydroxyquin in dosage forms by nonaqueous titration was developed. Acetic anhydride was the most suitable solvent for titration.

Keyphrases □ Diiodohydroxyquin formulations—nonaqueous titrimetric analysis □ Titrimetry, nonaqueous—analysis, diiodohydroxyquin

The development of new drugs has encouraged the introduction of new methods of analysis and control. The importance of assay methods involving nonaqueous titration cannot be overemphasized. Since the estimation of active ingredients in medicinal dosage forms may not be carried out as smoothly as with active ingredients in the absence of excipients and other inactive additives, some modifications in the method of estimation may be necessary.

Diiodohydroxyquin (I) is a well-known amebicide. It has been recommended in the treatment of lambliasis, balantidal dysentery, and trichomonas vaginitis. Reports have appeared on the estimation of diiodohydroxyquin by colorimetry (1), polarography (2), the oxygen flask method (3), and iodometry (4). Feltkamp (5) determined iodochlorhydroxyquin (5-chloro-7-iodo-8-hydroxyquinoline) by nonaqueous titration. Some of the mentioned methods have been made official, but no work seems to have been reported for the estimation of I by nonaqueous titration.

Table I—Analysis of I in Dosage Forms (Synthetic Mixture)

Synthetic Tablet Mixture	Mixture Constituents	Amount[a], mg.	Recovery[b], %
1	I	300	100.4 ± 0.3
	Starch	30	
	Talc	2	
	Lactose	60	
2	I	300	101.1 ± 0.32
	Sugar	20	
	Sodium alginate	10	
	Starch	10	
	Stearic acid	2	
	Lactose	50	

[a] About 300 mg. accurately weighed I was taken each time. [b] Each figure represents the mean of five readings.

Table II—Analysis of I in Tablets (Manufactured Preparations)

Manufacturer	Drug	Labeled Amount	Recovery[a], %
—	I	—	100.1 ± 0.6
A	I	300 mg./tablet	100.15 ± 0.32
B	I	300 mg./tablet	100.32 ± 0.18

[a] Each figure represents the mean and standard deviation of at least five readings.

In the present study, an attempt was made to find a suitable method of estimation of I as such and in dosage forms in nonaqueous media.

EXPERIMENTAL

A pH meter[1] using a glass electrode[2] and a saturated calomel electrode was used. The aqueous potassium chloride solution in the saturated calomel electrode was replaced by a saturated solution of lithium chloride in acetic acid. The electrode pair was dipped in acetic anhydride for at least 24 hr. before use. The solvents and reagents used were of analytical reagent grade. Malachite green (0.3%) solution in acetic acid was used as the indicator.

Estimation of I in Dosage Forms—About 300 mg. of accurately weighed I was placed in a conical flask and dissolved in 30 ml. of acetic anhydride by heating. The solution was cooled to room temperature, 3–5 drops of Malachite green indicator was added, and the mixture was titrated by 0.1 *N* perchloric acid in acetic acid to a yellow end-point. A blank was performed, and an appropriate correction was made. Each milliliter of 0.1 *N* perchloric acid is equivalent to 0.039698 g. of diiodohydroxyquin. (The end-point was checked potentiometrically using glass and modified calomel electrode pairs.)

Synthetic Mixture—About 300 mg. of accurately weighed I was placed in a conical flask. The various excipients were added in the amounts occurring generally in tablet formulations. Acetic anhydride (30 ml.) was added, and the solution was heated to dissolve the drug (excipients settled). The titration was performed as described for the estimation of I in pure form, commencing with the words: "3–5 drops of Malachite green . . . ."

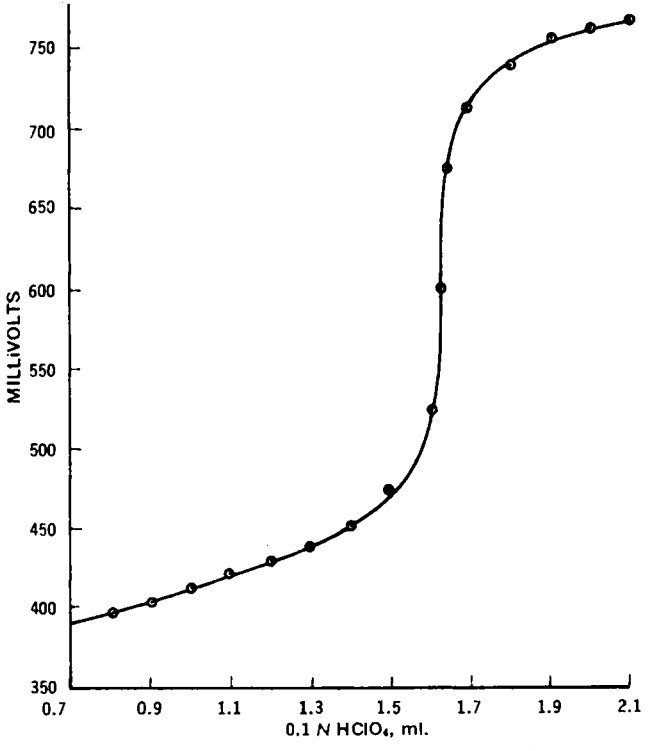

Figure 1—*Titration curve of diiodohydroxyquin (67.5 mg.).*

[1] Systronics Type 322.
[2] Toshniwal.

Table III—Analysis of I in Dosage Forms (Manufactured Preparations)

Drug	Labeled Amount	Recovery[a], % Proposed Method, Non-aqueous Titration	Official Method	Colorimetry
I	—	100.1	97.3	99.1
I	300 mg./tablet	100.3	98.2	99.3

[a] Each figure represents the mean of at least five readings.

Manufactured Preparations—Twenty tablets were weighed and reduced to a fine powder. An accurately weighed quantity of powder, equivalent to 300 mg. of I was added to 30 ml. of acetic anhydride. The mixture was then gently heated (excipients settled). After cooling to room temperature, the titration was performed as described for the estimation of I in pure form, commencing with the words: "3–5 drops of Malachite green. . . ."

RESULTS AND DISCUSSION

The nature of the titration curve of I is shown in Fig. 1. In the preliminary trials, the estimation of this drug in acetic acid resulted in overestimation, probably due to the consumption of perchloric acid by certain excipients. However, on using acetic anhydride as the solvent with Malachite green as the indicator, the end-point was sharp and the recoveries were better than with acetic acid. The color change of the indicator was checked potentiometrically. Tables I and II show the recovery.

Table III shows the results obtained by the proposed method, by the official method (4), and by colorimetry (1). It is apparent from these data that good recoveries were achieved by nonaqueous titration. The official method is a time-consuming and cumbersome procedure with lower recoveries. In the colorimetric method, Beer's law is obeyed in a very narrow range (0.05–0.3 mg.) and the recovery of the drug is not satisfactory. The proposed nonaqueous method of titration is a rapid and simple technique, giving accurate results.

Assay of Thiotepa by PMR Spectrometry

LINDLEY A. CATES

Abstract □ A rapid (10 min.), accurate, and precise (SD = 0.6%) analytical method for thiotepa and thiotepa for injection involving PMR is described. The procedure, which was tested on two spectrometer models, employs an inexpensive solvent and internal standard and does not require preparative treatment.

Keyphrases □ Thiotepa—PMR analysis, aziridinyl protons □ Aziridinyl derivatives—PMR analysis of thiotepa □ PMR spectroscopy—analysis, thiotepa

During the characterization of potential oncolytics, the methylene protons of aziridinyl moieties present in some of these agents were readily detected by proton magnetic resonance (PMR) spectrometry. This observation led to an interest in the quantitative analysis of an official drug by this instrumental method. Thiotepa [*N,N',N''*-triethylenethiophosphoramide, tris(1-aziridinyl)phosphine sulfide] meets the criteria of a good candidate for assay by PMR spectrometry because it is soluble in an inexpensive, nondeuterated solvent and gives a simple spectrum. In addition, the assay procedure presented here, in contrast to other PMR drug analysis (1, 2), does not require processing of the sample prior to instrumental examination; in view of this drug's chemical lability, this is especially advantageous. Only additions of an internal standard and solvent to the sample are required. Although thiotepa is a low dosage pharmaceutical, giving solutions of about 1.9% concentration in this assay, the integral values for the peak areas can be measured with sufficient accuracy and precision.

All of these factors provide for a simple, accurate, and rapid analytical method for thiotepa and this pharmaceutical's parenteral formulation. The USP XVIII procedures for these items involve lengthy and laborious titrimetric and IR spectrophotometric methods, respectively. To determine the capabilities of different

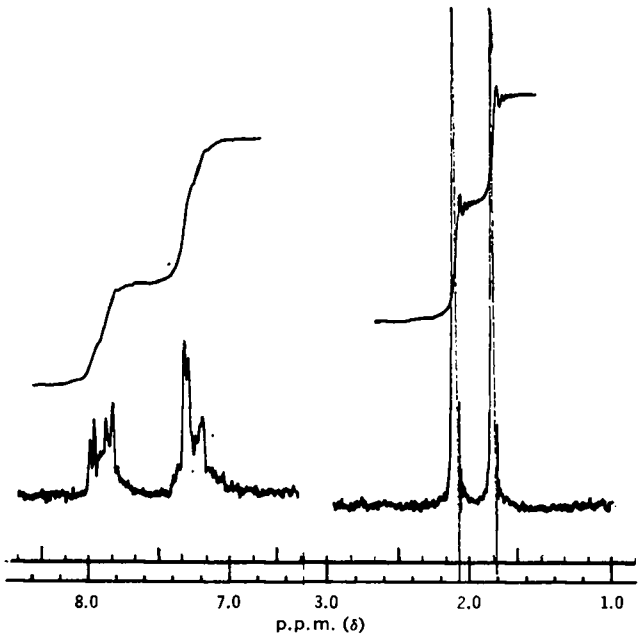

Figure 1—*PMR spectrum of benzoic acid (left) and thiotepa (right) in carbon tetrachloride.*

types of PMR spectrometers in this quantitative evaluation, two models (I[1] and II[2]) were employed in most assays.

EXPERIMENTAL

The following were used: standard, thiotepa[3]; internal standard, benzoic acid USP[4]; samples, thiotepa for injection USP[5]; and solvent, carbon tetrachloride[6].

To the standard or sample[7], add about 24.00 mg.[8] of internal standard, accurately weighed, and 0.8 ml. of solvent. Stopper and shake for 2 min. and then filter, *via* a cotton pledget, at least 0.4 ml. into a PMR tube. After placing the tube in the spectrometer, adjust the spin rate to eliminate spinning side bands and the power level and amplitude to obtain integral values corresponding to 20–30 mm. Integrate the peak areas occurring between δ 1.83–2.15 and δ 7.10–8.09 at least five times.

The percent of drug may be calculated using the following equation:

$$\text{percent thiotepa} = \frac{A_t}{A_b} \times \frac{EW_t}{EW_b} \times \frac{W_b}{W_t} \times 100 \quad \text{(Eq. 1)}$$

where:

A_t = average integral value for thiotepa
A_b = average integral value for benzoic acid
EW_t = molecular weight of thiotepa/12 = 15.77
EW_b = molecular weight of benzoic acid/5 = 24.42
W_b = weight in milligrams of benzoic acid
W_t = weight in milligrams of thiotepa added or declared

RESULTS AND DISCUSSION

The PMR spectrum of pure thiotepa shows only a doublet (δ 2.00, J = 16 Hz. using trimethylsilane as reference. Fig. 1). Benzoic acid was chosen as the internal standard since it is a pure, stable, inexpensive, readily obtainable material whose aromatic protons absorb at a point (complex of peaks at δ 7.10–8.09) where there is no interference with the absorption peaks caused by the drug (Fig. 1). The peak areas produced by 24 mg. of the internal standard are approximately the same as those resulting from 15 mg. of thiotepa.

The results of the quantitative determination of a series of thiotepa standards are shown in Table I. Considering the small sample weight, the procedure is unexpectedly accurate with a good precision of ±0.6%. In addition, it provides a means of identification and detection of impurities. Table II summarizes the analysis of commercial preparations. There is good agreement with declared values using both instruments, with Model II uniformly giving slightly higher values. Measurements shown in both tables are within the USP monograph's limits of 97.0–102.0 and 95.0–110.0% for thiotepa and thiotepa for injection, respectively.

Another comparison of measurements taken with Models I and II is indicated in Table III. The samples did not decompose at the same rate, but both instruments gave similar results.

Sample 9 was examined (II) after 2 weeks at room temperature to indicate the presence of 54.4% thiotepa. Neither the spectrum nor the integral peak area value of the internal standard in this sample showed change, but two broad areas of absorption resulting from materials of undetermined nature appeared at about δ 3.9–4.6 and δ 2.5–3.9, the latter interfering slightly with the baseline of thiotepa's integral values.

Spectrophotometric Analysis of Primary Aliphatic Amines with Dichlone

A. A. ABOU-OUF, ALY M. TAHA▲, and M. B. SAIDHOM

Abstract □ A spectrophotometric method is described for the determination of some primary aliphatic amines of pharmaceutical interest *via* reaction with dichlone (2,3-dichloro-1,4-naphthoquinone). A mixture of an ethanolic solution of the amine, or amine salt and sodium bicarbonate, with the chromogenic reagent was heated at 65° for 25 min. After acidification to pH 4, the majority of amines yielded an orange-colored product, λ_{max} 475 nm. Some compounds reacted without heat, yielding other colors such as rose (500 nm. with piperazine), yellow (420 nm. with cysteine), and blue (630 nm. with isoniazid) suggesting different products. Molar absorptivities ranged from 900 to 5000. Under the described assay conditions, only primary aliphatic and cyclic secondary amines reacted. Primary aromatic (except some readily oxidizable ones), secondary or tertiary aliphatic, and/or aromatic amines were found not to interfere. The pharmaceutical compounds assayed included histamine, norepinephrine, serotonin, neomycin, leucine, cysteine, aminocaproic acid, ethanolamine, aminophylline, piperazine, and isoniazid. The amines are assayed in the 0.005–0.15-mg./ml. range with a relative standard deviation of 0.02–0.03. The possible composition of the colored products is discussed.

Keyphrases □ Amines, primary aliphatic—colorimetric analysis with dichlone □ Dichlone—used in colorimetric analysis of primary aliphatic amines □ Colorimetry—analysis, primary aliphatic amines using dichlone

The reaction of dichlone (2,3-dichloro-1,4-naphthoquinone) with a number of aliphatic and aromatic amines to yield colored products was reported (1–4) in the course of synthesis of new compounds and the chromatographic separation of amines. Dichlone, a potent fungicide (5), is also a minor dye intermediate (6). There are, however, no reported examples of the quantitative determination of amines using dichlone.

In this work, a spectrophotometric procedure is proposed to assay primary aliphatic amines *via* reaction with dichlone in ethanolic solution. The selectivity, sensitivity, and precision of the proposed method were determined. The scope and limitations relative to pharmaceutical preparations were explored.

EXPERIMENTAL

Equipment—Spectra and absorbance measurements were made using two spectrophotometers[1]. A constant-temperature bath maintained at 65 ± 2° was utilized for accelerating color development.

Reagents and Chemicals—Dichlone was obtained commercially[2]. All other chemicals used were analytical reagent or pharmaceutical grade obtained from various manufacturers and were purified, when necessary, by redistillation, recrystallization, or chromatography before use.

Dichlone Reagent—The desired concentration was 1×10^{-6} mole/ml. (0.227 mg./ml.). The reagent (22.7 mg.) was dissolved in warm ethanol, cooled, and diluted to 100 ml. with ethanol. This solution was stable for 4 weeks.

Amines—Fresh solutions of the amines or amine salts (0.025 mg./ml.) were prepared daily in ethanol and kept at 4°.

[a] Using 1 mg./ml. in ethanol. [b] Reacted in the cold. [c] Purified by chromatography.

Bicarbonate Solution—Sodium bicarbonate (840 mg.) was dissolved in glass-distilled water and diluted to 100 ml. with the same water; the final concentration was 8.4 mg./ml.

Procedure—One milliliter of the amine solution was mixed with 1.0 ml. of the reagent solution. With amine salts, 1.0 ml. of the solution of the amine hydrochloride or sulfate was mixed with 1.0 ml. of sodium bicarbonate solution and 1.0 ml. of the reagent solution. In either case, the mixture was maintained at 65 ± 2° for 25 min. Then the solution was cooled to room temperature, the pH was adjusted to 3–4 with 10% hydrochloric acid, and the solution was diluted to 10 ml. with ethanol in a volumetric flask. The absorbance of this solution was measured at 475 nm., or at the λ_{max} if different, against a reagent blank similarly treated.

RESULTS

Influence of Chemical Structure—The colors produced on reacting dichlone with various amines are indicated in Table I. The colors obtained when extending the reaction to selected pharmaceutical amines are given in Table II.

Quantitative Determination of Amines—Table III summarizes the data of the quantitative analysis of selected amines of biological and pharmaceutical interest by the proposed spectrophotometric method. These amines assayed at least 100% by established and

Chloroquin phosphate	No color	—	—
Benzocaine	No color	—	—
Sulfanilamide	No color	—	—

[a] Using 1 mg./ml. solution. [b] Reacted without heat.

compendial methods of analysis as follows: histamine, reaction with 2,4-dinitrofluorobenzene (7); serotonin, colorimetric analysis with 1-nitroso-2-naphthol (8); neomycin, the BP microbiological method using *Bacillus pumilus* (9); piperazine citrate and leucine, nonaqueous titrimetry (USP procedure) (10); aminophylline (for ethylenediamine content), titration with 0.1 *N* sulfuric acid using bromcresol green as indicator (11); and isoniazid, iodometric analysis (12).

Standard Curves—Standard curves can be constructed by plotting observed absorbance readings *versus* the volume taken of equimolar concentrations of various amines in the range 0.005–0.150 mg./ml. (1×10^{-5}–1×10^{-7} mole/ml.). In all cases, Beer's law held for the system.

Analysis of Mixtures—Table IV illustrates the analytical data obtained for various mixtures of amines of biological and pharmaceutical interest analyzed for the primary aliphatic amine component.

DISCUSSION

Reaction Involved and Influence of Chemical Structure—In the analytical procedure presented, dichlone (I) reacts with a primary aliphatic amine to yield an orange color. Chemically, the colored product is most likely a 2-amino-3-chloro-1,4-naphthoquinone derivative (II), formed by 1,4-addition to the quinone followed by reoxidation with excess reagent (13). This is in agreement with published data (14) concerning the reaction of dichlone with some aliphatic amines. Further verification of this assumption was obtained by comparing the spectrum of a typical orange product (dichlone with *n*-butylamine) with that of 2-amino-1,4-naphthoquinone (III) (Fig. 1). The aminonaphthoquinone was synthesized by an independent route (15) from 1,4-naphthoquinone and sodium azide in acetic acid. The two spectra are practically superimposable, suggesting the same basic chromophore.

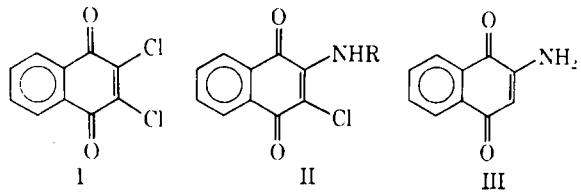
[a] Mean value of three determinations. [b] Mixture of commercial neomycins (A, B, and C).

Dichlone was reported to react with primary aromatic amines under certain conditions of synthesis (1, 16, 17). Under the analytical conditions described, however, only primary aliphatic amines reacted to a measurable extent. Some primary aromatic amines with sensitive nuclei (*e.g.*, *p*-aminophenol, *p*-phenylenediamine, and *p*-dimethylaminoaniline) gave red colors (Table I). This was probably due to oxidation by the quinone reagent rather than reaction by 1,4-addition, since identical colors were obtained when these compounds were treated with inorganic oxidizers such as potassium persulfate. Failure of sulfanilamide, 1-naphthylamine, *o*-toluidine, and benzocaine to yield colors (Tables I and II) supports the view that, under the mild conditions of the procedure, primary aromatic amines do not interfere. Similarly, secondary and tertiary aliphatic or aromatic amines failed to yield measurable colors (Tables I and II).

Some compounds (*e.g.*, cyclic secondary aliphatic amines, ethylenediamine, cysteine, and isoniazid) reacted rapidly without heat to yield colors different from the orange color obtained with the majority of amines (Fig. 2). This finding strongly suggests different types of products. In the case of cysteine, the product is probably a thioether at the 3-position of the quinone, in line with the analogous reaction of 2-methyl-1,4-naphthoquinone (K_3) with sulfhydryl compounds (thioglycollic acid and cysteine) to form a thioether linkage with a characteristic absorption at 420–430 nm. (18, 19). With the present data alone, however, it is difficult to reach a conclusion concerning the true nature of these colored products. After heating at 65° for 20–30 min., these different colors changed to orange, λ_{max} 475 nm.



I II III

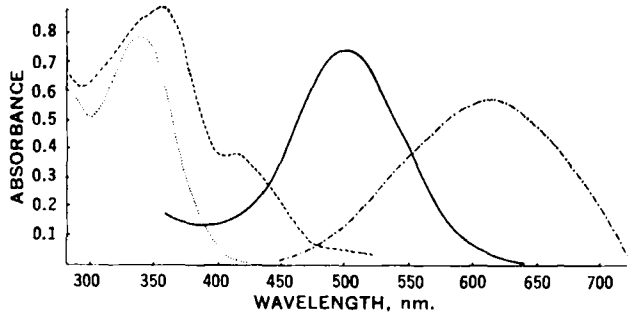


Figure 2—*Spectra of dichlone and its reaction products. Key: · · ·, dichlone (1 × 10⁻⁶ mole/ml.); - - -, with cysteine (3 × 10⁻⁶ mole/ml.); – – –, with piperazine (5 × 10⁻⁶ mole/ml.); and –·–, with isoniazid (4 × 10⁻⁷ mole/ml.).*

Quantitative Applications—Data in Tables III and IV reveal the suitability of the proposed method for the determination of pharmaceutical primary amines in the presence of primary aromatic and/or secondary and tertiary aliphatic amines in amounts of 0.005–0.150 mg./ml. with a standard deviation of ±2–3%.

Reagent blank readings at wavelengths of maximum absorbance are very low (Fig. 2). The main absorbance of the reagent is at 345 nm. No interference by excess unreacted reagent was noticed. This was further verified by the complete extraction of unreacted dichlone with ethylene chloride from the acidified (pH 3–4) aqueous colored solution. The color remained in the acidified aqueous layer because of protonation of the amino group (Structure II). No difference in absorbance readings between extracted and unextracted samples was observed.

Color Development and Stability—Color development at room temperature was too slow, but formation of the color was greatly accelerated at 60–70°. Maximum color intensity was obtained after 25 min. (Fig. 3) and was unchanged after 24 hr. at room temperature.

Limitations—The proposed method is fairly sensitive and selective for primary aliphatic amines. The procedure, however, must be considered nonspecific with regard to degradation products (unless degradation involves loss of the primary amine function) as well as other potential interfering substances.

Although cyclic secondary amines reacted, the probability of their presence with primary aliphatic amines in the same biomedia or dosage form is slim. Furthermore, these cyclic amines exhibited an absorbance maximum different from 475 nm. (at 500 nm.), so any problems arising from overlap of the spectra for the two species may be overcome by the use of differential analysis.

CONCLUSION

The analytical method presented is essentially a microprocedure with fair sensitivity (0.005–0.150 mg./ml.), good accuracy (from −0.9 to +1.3% error), and precision (0.02–0.03 *RSD*). The method offers a relatively simple and rapid means of analysis of some pharmaceutical primary aliphatic amines in admixture with secondary or tertiary aliphatic or primary aromatic amines.

The reagent is available commercially or easily synthesized (20), and its solutions are stable at room temperature for convenient periods. The colors formed are also stable.

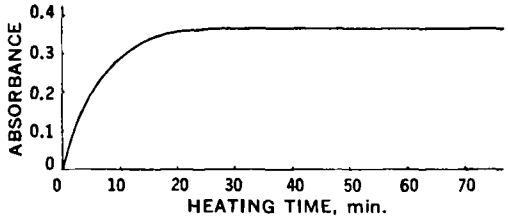

Figure 3—*Rate of color development. Histamine (5 × 10⁻⁶ mole/ml.) with dichlone (1 × 10⁻⁶ mole/ml.).*

Rapid Quantitative GLC Analysis of Digoxin

ARTHUR H. KIBBE and OSCAR E. ARAUJO▲

Abstract □ A quantitative method of assaying digoxin by GLC was developed. The pure drug in both tablet and powder form can be assayed rapidly and accurately by this procedure.

Keyphrases □ Digoxin tablets and powder—GLC analysis □ GLC—analysis, digoxin tablets and powder

The advantages of GLC involve its speed of operation, its high degree of resolution, and its potential to yield quantitative results.

Jelliffe and Blankenborn (1) were the first to use GLC to separate cardiac glycosides. Several investigators have since used GLC qualitatively as a means of identifying these glycosides (2–4).

Various quantitative colorimetric assays for digoxin have been reported, and subsequent attempts at automating these methods have been undertaken (5–9). The GLC analysis of digoxin on nonselective phases has been studied with various degrees of success.

Watson and Kalman (10) assayed plasma levels of digoxin by GLC. Their procedure took 5 hr./assay and involved both TLC and GLC steps. Watson and Kalman (10) used electron-capture detection, while Wilson *et al.* (2) used the trimethylsilyl ethers of cardenolides which required high temperature and high flow rates of the carrier gas. Tan (3) questioned the formation of the silyl ethers reported by Wilson *et al.* and others.

It is apparent that the quantitative GLC methods of analysis reported rely on the production of derivatives and require much time as well as laborious manipulative steps. The method proposed in this investigation eliminates all of these drawbacks.

EXPERIMENTAL

Equipment—A chromatographic system[1] with a flame-ionization detector was used. The gas flow rates were: hydrogen, 35 ml./min.; air, 300 ml./min.; and carrier gas (nitrogen), 50–100 ml./min. Operating conditions were: oven temperature, 285°; and injection port and detector temperature, 330°. All injections were made with a 5-μl. syringe[2].

Columns—Three types of columns were used. Column A was a 2-m. glass U-tube (2 mm. i.d.) packed with 2.5% OV-1 on 80–100-mesh Chromosorb A[3]. Columns B and C were 0.5-m. copper U-tubes (4 mm. i.d.) packed with 2.5% OV-1 on 80–100-mesh Chromosorb A and 3% OV-17 on 80–100-mesh Chromosorb A, respectively.

Reagents—The silylating reagent was prepared just prior to use by mixing 1 ml. of trimethylchlorosilane[4] and 10 ml. of hexamethyldisilazane[4] with 10 ml. of dry pyridine as a solvent. The pyridine was stored over potassium hydroxide to ensure dryness. The hexamethyldisilazane and trimethylchlorosilane were stored under nitrogen and extracted from sealed vials with a syringe. The volume was then replaced with dry nitrogen gas. The sample to be silylated

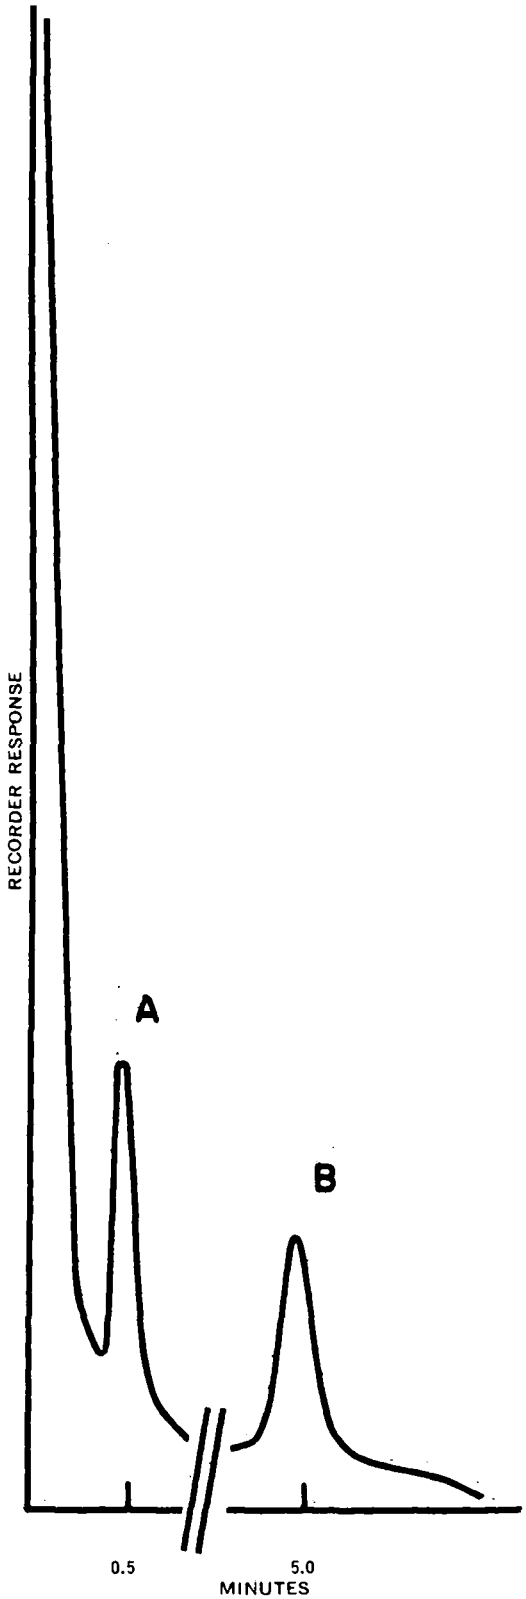

Figure 1—*Representative chromatogram of a mixture of: (A) cholesterol and (B) digoxigenin.*

Table I—Retention Time (Minutes)

	Column A	Column B	Column C
Cholesterol (unsilylated)	2.0	0.67	0.5
Cholesterol (silylated)	2.0	0.67	0.5
Digoxigenin (unsilylated)	15.0	5.33	3.67
Digoxigenin (silylated)	15.0	5.0	3.67

was made to react with 1 ml. of the reagent at room temperature before being injected into the gas chromatograph.

TLC—The purity of the digoxin[5] and digoxigenin[6] used was verified by TLC using two solvent systems: cyclohexane–acetone–acetic acid (49:49:2) and ethyl acetate–water–methanol (80:5:5). All solvents were analytical grade.

Glass plates precoated with 0.2 mm. of silica gel G[3] were used. The spots were visualized by spraying with 50% aqueous sulfuric acid and heating at 110° for 2–3 min. A second more reliable visualization method was also employed by preparing a spray consisting of a mixture of a 3% aqueous solution of chloramine-T and a 25% alcoholic solution of trichloroacetic acid. The two solutions, in a ratio of 1:4, were mixed just prior to use. After spraying, the plate was heated in an oven at 110° for 7 min. The blue spot then became visible under UV light at a wavelength of 385 nm.

Internal Standard—Cholesterol was used as an internal standard in the amount of 0.02 mg.

Reference Standard—Digoxin and digoxigenin were both employed in amounts varying from 0.05 to 0.2 mg.

Sample Preparation—A sample of either 0.1 mg. of powdered digoxin or the equivalent amount in tablet form was dissolved in 2 ml. of a pyridine–water (50%, v/v) solution. A volume of 0.1 ml. of 0.1 *N* sodium hydroxide was added, and the mixture was heated on a steam bath for 30 min. to convert completely the digoxin to digoxigenin. The solution was then evaporated to drynesss and redissolved in 100 μl. of dry pyridine. An aliquot of 10 μl. of a stock solution containing 2 mcg./μl. of cholesterol in pyridine was added. From this solution, a 1-μl. sample was injected into the gas chromatograph and the areas under the curves were calculated by means of a disk integrator.

RESULTS AND DISCUSSION

A typical chromatogram for the unsilylated compounds is shown in Fig. 1. The results indicated that both silylated and nonsilylated compounds exhibit similar retention times using all three columns (Table I). From this standpoint, there appeared to be no advantage in silylating the compound. Due to the high temperature of operation, difficulty was experienced in maintaining a firm seal between Column A and the metal connections. The Teflon ferrel, which normally would be used for this purpose, began to melt at the temperatures at which the injector and detector were operated. In addition, the retention times were much longer for Column A than for Columns B and C.

The standard curve was generated by plotting A_D/A_C against W_D/W_C, where A_D and A_C are the areas under the curve for digoxigenin and cholesterol, respectively, and W_D and W_C are the respective weights for digoxigenin and cholesterol. The results along with the analysis of variance are shown in Table II.

Table II—Standard Curve Data For Digoxigenin–Cholesterol

$\frac{A_D}{A_C}$[a]	$\frac{W_D}{W_C}$[b]
3.48	16.47
2.08	10.83
2.50	8.95
1.51	7.58
0.89	6.55

Analysis of Variance

Source	*df*	Sum of Squares	Mean Square	*F* Ratio
Regression	1	22.68	22.67	29.66
Residual	4	3.06	0.76	
Total	5	25.72		

Variables in Equation

Coefficient	0.20
Standard error	0.0013
Intercept	0.057

[a] Area ratio (digoxin–cholesterol). [b] Weight ratio (digoxin–cholesterol).

As indicated under sample preparation, all the digoxin was hydrolyzed to digoxigenin. The latter can then be used indirectly to calculate the amount of digoxin in the sample by using a ratio of molecular weights. From the data in Table II, an unknown quantity of digoxigenin can be obtained by calculating W_D from Eq. 1:

$$\frac{A_D}{A_C} = 0.20\frac{W_D}{W_C} + 0.057 \qquad \text{(Eq. 1)}$$

NMR Analysis of Pharmaceuticals X: Determination of Methsuximide and Phensuximide in Capsules

JOHN W. TURCZAN▲ and BRUCE A. GOLDWITZ

Abstract □ A method for the quantitative analysis of methsuximide and phensuximide using NMR is reported. For samples of the pure drugs, results were accurate to 0.3% or less with standard deviations of 0.6% or less. Analysis of capsules of each drug by NMR and NF XIII procedures indicated a maximum difference of 1.5%, but generally the difference was less than 1.0%. This procedure is recommended for the analysis of these drugs since it provides good quantitative results together with a unique spectrum as confirmatory identification.

Keyphrases □ Methsuximide and phensuximide capsules—NMR analysis □ Phensuximide and methsuximide capsules—NMR analysis □ NMR spectroscopy—analysis, methsuximide and phensuximide capsules

Methsuximide (*N*,2-dimethyl-2-phenylsuccinimide, I) and phensuximide (*N*-methyl-2-phenylsuccinimide, II) are two succinimide derivatives which are pharmacologically active anticonvulsants. Their use is primarily in the control of petit mal epilepsy.

Several analytical approaches have been successfully applied to the isolation and determination of I and II in biological media. A quantitative procedure for the determination of both I and II in serum was developed by Huisman (1). The method involves nitration of the phenyl rings and separation of the products by TLC, followed by subsequent diazotization and coupling to produce a color measured at 550 nm. Gardner-Thorpe *et al.* (2) used TLC and examination under UV light to estimate the presence of some anticonvulsant succinimides in blood.

Other properties have been exploited to analyze for both I and II in pharmaceutical systems and as pure chemical entities. The assay procedures for II studied by Mativa (3) include titration, reaction in buffered medium to obtain a fluorescent product, and reaction with fuming nitric acid to form a colored product whose color intensity is read in an alkaline acetone solution. The extension of Mativa's technique to I was investigated (4) with satisfactory results.

The methods adopted by NF XIII (5) for the determination of both I and II in capsule dosage forms involve a chloroform extraction and subsequent UV light absorption measurement.

This paper describes a method involving NMR spectrometry[1] to determine I and II in capsule dosage forms. The method utilizes carbon tetrachloride[2] as the solvent for I and 10% methylene chloride[2] in carbon tetrachloride as the solvent for II, and hexamethylcyclotrisiloxane[3] (III) is employed as the internal standard for both drugs. Known mixtures and commercial capsules were analyzed by this technique. Quantitative analysis using NMR offers the advantages of speed, simplicity, and specificity for the active ingredients.

[a] Hexamethylcyclotrisiloxane.

EXPERIMENTAL

Standards and Samples—Methsuximide and phensuximide reference standards[4] and commercial methsuximide and phensuximide capsule preparations were used.

Procedure—Place a counted number of capsules into a 125-ml. glass-stoppered conical flask. Carefully crack the outer shell of each capsule with the end of a glass rod. Using a calculated amount of carbon tetrachloride for I or 10% methylene chloride in carbon tetrachloride for II, so that the final volume will contain the solute to be measured in a concentration of about 80 mg./ml., first wash down the end of the stirring rod to ensure quantitative retention of the sample powder and then add the remainder of the solvent to the flask. Add an accurately weighed amount of III, the internal standard, to the sample solution so that its final concentration is about 25 mg./ml. Stopper the flask and swirl, gently at first, to effect solution. Allow the outer shells and insoluble excipients to rise to the top and then transfer about 0.4 ml. of the bottom solution to an analytical NMR tube. Place this tube in an NMR spectrometer and obtain the spectrum, adjusting the spin rate so that no spinning side bands occur between 0.4 and 0.6 p.p.m. and between 6.8 and 7.7 p.p.m. using the δ-scale to express magnetic field strength. All peak field positions are referenced to tetramethylsilane (IV) at 0 p.p.m. Integrate the peaks of interest at least five times.

The amount of I or II may then be calculated as follows:

$$\frac{\text{mg. I or II}}{\text{capsule}} = \frac{A_s}{A_h} \times \frac{EW_s}{EW_h} \times \frac{\text{mg. III}}{\text{number of capsules}} \quad \text{(Eq. 1)}$$

[1] A Varian A-60 NMR spectrometer, equipped with a V-6031 variable-temperature probe having a six-turn insert, was used.
[2] Fisher Scientific Co., Fair Lawn, N. J.

[4] Parke, Davis & Co., Detroit, Mich.

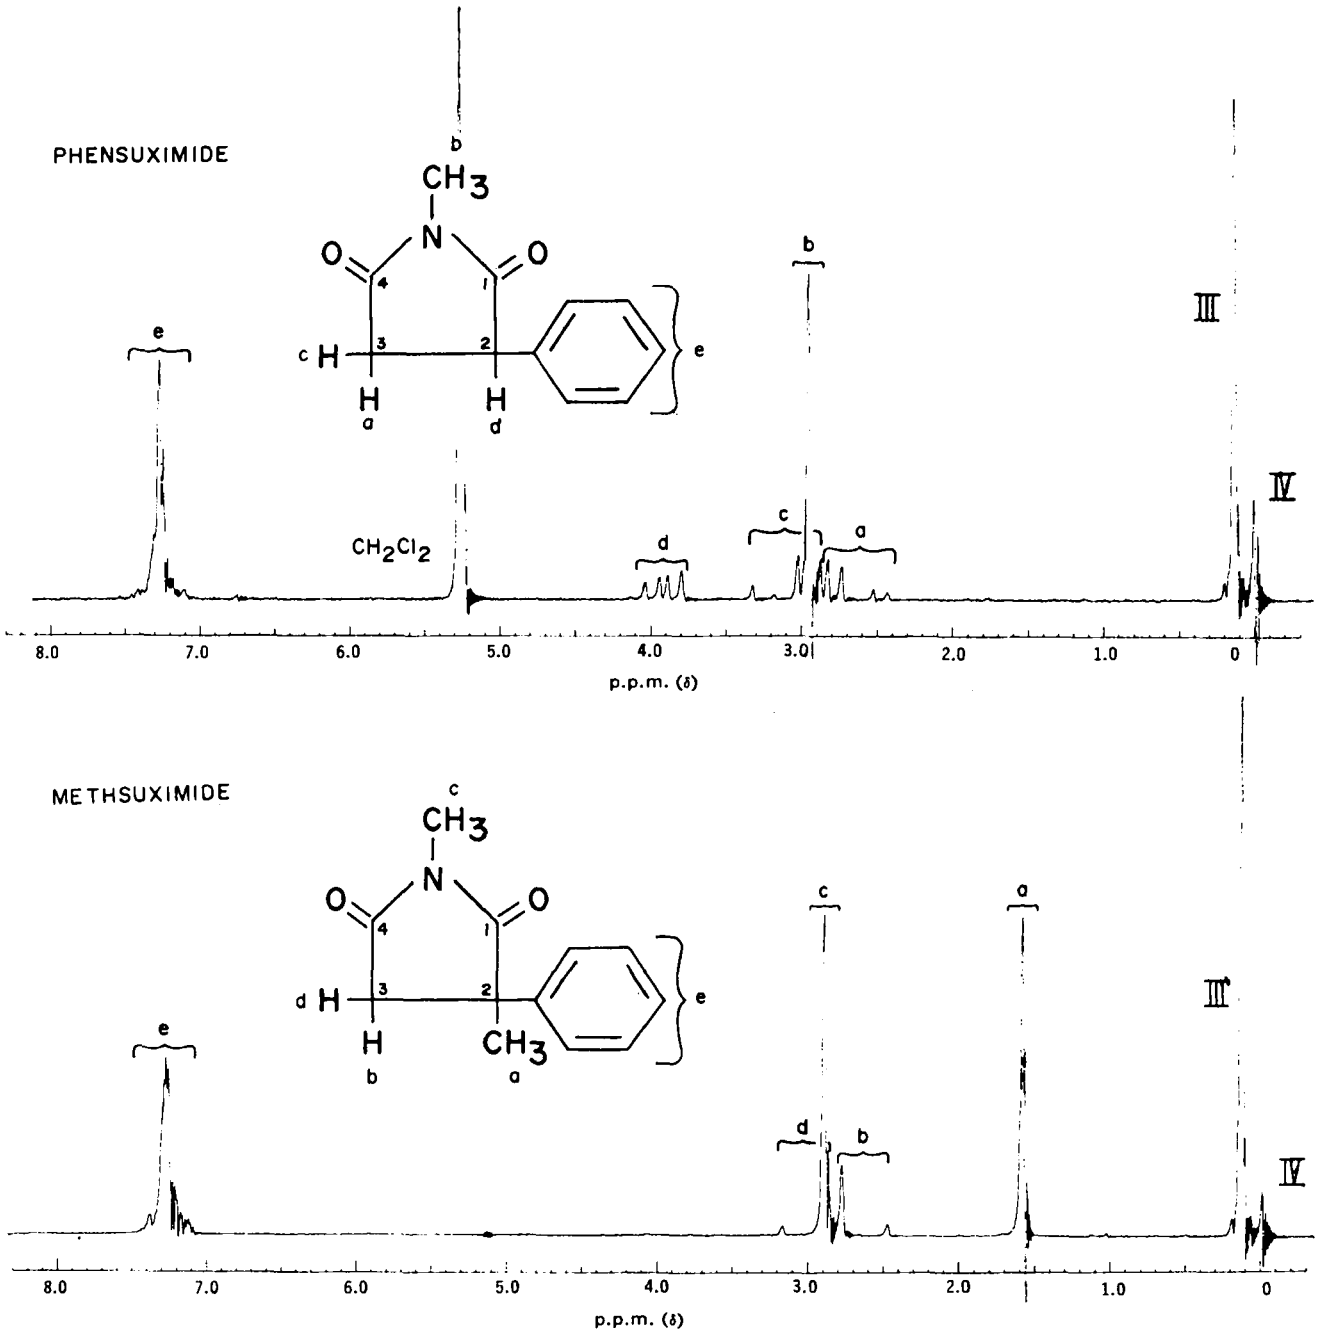

Figure 1—*NMR spectra of phensuximide in 10% methylene chloride in carbon tetrachloride and of methsuximide in carbon tetrachloride (III, hexamethylcyclotrisiloxane; and IV, tetramethylsilane).*

where:

A_s = integral value of the signal representing I or II
A_h = integral value of the signal representing III
EW_s = formula weight of I/5 = 40.65 or formula weight of II/5 = 37.84
EW_h = formula weight of III/18 = 12.35

RESULTS AND DISCUSSION

Although the two succinimide compounds, I and II, are very similar structurally, different solvents were required. The extreme solubility of both I and III in carbon tetrachloride plus the lack of resonance signals makes carbon tetrachloride the obvious choice of solvent for these solutes in this procedure. However, II does not exhibit the same solubility in pure carbon tetrachloride, but a 10% methylene chloride in carbon tetrachloride solvent system was satisfactory. The methylene chloride solvent component introduces no interference since its protons absorb at 5.25 p.p.m., a region not occupied by any other peaks.

The applicability of III as an internal standard has been demonstrated previously (6–8). It appears as a single spectral signal at an extreme upfield position. This combination of solvent system and internal standard provides the opportunity for a clear, interference-free identification of the active ingredient in addition to quantitative results.

The NMR spectra of I and II under the described analytical conditions are depicted in Fig. 1. The amounts of both succinimide derivatives are determined from the integration of the broad resonance pattern at about 7.25 p.p.m. due to the five phenyl protons at position 2 on the succinimide ring and the integration of the singlet at about 0.14 p.p.m. resulting from the 18 methyl protons of the internal standard III.

In addition to quantitative analysis, the hydrogen resonance characteristics are useful for qualitative purposes and are interpretable. In I, the two singlets at about 1.59 and 2.90 p.p.m. are due to

5	500	496.0	99.2	497.5	99.5

the methyl protons at position 2 and on the nitrogen, respectively, of the succinimide ring. The two methylene protons at position 3 are nonequivalent and exhibit a characteristic *AB* pattern between 2.4 and 3.2 p.p.m. For Compound II, the three protons on the methyl group bonded to the nitrogen appear as a singlet at about 2.95 p.p.m. The methylene protons at position 3 couple with the methine proton at position 2 to form an intricate *ABX* pattern between 2.4 and 4.1 p.p.m.

The analysis of a group of standard I and II mixtures by NMR is summarized in Table I. As noted, the method is accurate and precise for I and II, with a standard deviation of 0.6 and 0.4%, respectively. The relative proportions of III to either I or II show no significant bearing on the accuracy of the determination for the range of proportions shown in Table I.

The potential value of the proposed NMR analysis to dosage forms was established by the measurement of the content of I and II in capsules. Table II summarizes the results of the analysis of six lots of I capsules and five lots of II capsules. For comparative purposes, the same capsules were analyzed by the NF XIII method, a UV spectrophotometric determination using the phenyl group absorption characteristics that occur in a spectral region not unaccustomed to harboring UV-absorbing interferences. The two procedures generally agreed to within 1%. No interference from any capsule excipients was observed.

As demonstrated previously, the use of NMR for quantitative analysis offers a number of advantages, which were experienced in this case as well. The procedure is simple and rapid, an advantage shared by other spectroscopic analyses. However, in the matter of specificity, NMR does stand alone, since the recorded spectrum provides unique field positions of the various protons for unambiguous identification (less complex than IR) and offers specific peaks for integration and subsequent quantitative interpretation. It is to be hoped that the advantages of NMR coupled with the welcome availability of less expensive, reliable instruments will encourage the use of this technique in quantitative analysis.

A System for Automated Polarographic Analysis

L. F. CULLEN, M. P. BRINDLE, and G. J. PAPARIELLO▲

Abstract □ A sensitive and potentially highly versatile automated polarographic procedure was developed. A polarographic analyzer is interfaced with a continuous-flow system which completely removes interfering dissolved oxygen. Inclusion of a peristaltic valve in the manifold design allows an extended sampling period at steady-state conditions, at the same time increasing the productive rate of the system by a factor of two. High-resolution scans of the sample stream with a multifunctional polarographic analyzer set to monitor diffusion current while the applied potential is varied have the capability of quantitating electroactive compounds in the presence of decomposition products or formulation components. The capabilities of the method were demonstrated by collecting data on tablet and capsule formulations of lorazepam, a 1,4-benzodiazepine. Fifteen samples per hour can be assayed with a relative standard deviation of ±1.4% at the 0.5-mg. lorazepam level. The method is applicable to unit-dose analysis of lorazepam in the 0.5–6-mg./dose range.

Keyphrases □ Polarography—automated system and procedure, analysis of lorazepam tablets and capsules □ Lorazepam tablets and capsules—analysis, automated polarographic procedure

In recent years, polarographic techniques have been finding wide application in pharmaceutical analysis. Requests for a large number of assays to assist in evaluating the pharmaceutical acceptability and chemical stability of various dosage forms for new investigational drugs prompted the development of an automated polarographic method of analysis for tablet and capsule formulations.

Previously reported automated techniques employing polarized electrodes in continuous-flow systems (1–3) have been restricted to the measurement of diffusion current at a constant potential due to limitations imposed by the use of conventional continuous-flow dynamics. However, it is necessary to monitor diffusion current as a function of varying applied potential when quantitating electroactive compounds in the presence of decomposition products or formulation components that interfere in the fixed potential technique. In designing a completely automated analytical system capable of producing authentic polarograms, several unique problems in continuous-flow analysis were encountered.

The automatic analyzer system[1] described was developed following a systematic consideration of the capabilities and limitations of standard automated modules. The technique interfaces a multifunctional polarographic analyzer with a continuous-flow system employing sophisticated design features. The capabilities of the method were demonstrated by collecting data on tablet and capsule formulations of lorazepam [7-chloro-5-(*o*-chlorophenyl)-1,3-dihydro-3-hydroxy-2*H*-1,4-benzodiazepin-2-one]. This potentially versatile analytical system expands the capabilities of automated analysis to include polarography, a well-established electrochemical technique.

EXPERIMENTAL

Apparatus—A standard automatic analyzer[1] system was employed consisting of the following modules: (*a*) a SOLIDprep sampler, programmed at 15 samples/hr. with a sample aspiration stage set at 40–90 units; (*b*) proportioning pumps[2] (three required); (*c*) a continuous filter, speed 2; (*d*) a peristaltic valve[3]; (*e*) a polarographic analyzer equipped with a mechanical drop timer[4]; (*f*) a circulating constant-temperature unit[5]; (*g*) a 25.4-cm. (10-in.) linear potentiometric strip-chart recorder[6]; and (*h*) transmission lines (Solvaflex) and proportioning tubes.

The dimensional details of the polarographic flow cell used in this investigation were presented by Lento (1). To prevent deterioration from the predominantly nonaqueous supporting electrolyte considered, the cell was machined from a transparent 4.44-cm. (1.75-in.) rod[7].

Supporting Electrolyte—The supporting electrolyte consisted of 0.1 *M* sodium acetate and 0.1 *M* acetic acid in methanol–water (8:2, v/v). In the preparation of the supporting electrolyte, reagent grade materials were used without further purification.

Nitrogen—Prepurified grade nitrogen[8] was used in the deaeration unit.

Automated Methodology—A flow diagram indicating the arrangement of the apparatus employed in this system is presented in Fig. 1. Figure 2 is a schematic wiring diagram of the necessary synchronization control circuits.

In performing the analyses, standards are placed on the sample plate followed by samples of intact or powdered tablets or capsules. At the end of a series of 20 samples, additional standards are placed on the sample plate. Samples are introduced into the SOLIDprep unit and dispersed in the methanolic sodium acetate–acetic acid supporting electrolyte. Following dissolution of the drug, the sample is aspirated into the flow system and automatically filtered to remove insolubles. To prevent mechanical obstruction at the tubing connections from insoluble excipient materials, a decantation trap is placed between the SOLIDprep unit and the proportioning pump.

After passage through the continuous filter module, the filtrate is segmented with nitrogen and pumped to the inlet manifold of the "steady-state extension unit." The extension unit employs a differential flow rate principle and synchronized valve control to prolong the duration of the sample's steady state. From the outlet manifold of the steady-state extension unit, the expanded sample stream is directed to the inlet of the continuous deaerator. Within this unit, a high velocity stream of methanol-saturated nitrogen is employed to transform the sample into a thin, turbulent liquid film. Entrained by the gas stream, the film is transported rapidly through the deaeration coil, which provides the surface area necessary for efficient oxygen removal. Thermostatic control of the purging gas is provided

to protect the electrolyte system from evaporational losses. The sample is withdrawn from the outlet connection of the deaerator and transported to the polarographic flow cell. Segmenting nitrogen is also drawn from the purging unit into the sample effluent for the purpose of providing a secondary deaeration stage in which residual dissolved oxygen is removed from the sample stream.

The polarographic analyzer and recorder are synchronized to initiate a scan at the moment the sample attains steady state at the flow cell. The instrument is used in the current-sampled d.c. polarographic mode (4) with the mechanical drop timer operating at 1 drop/sec. For lorazepam, the polarographic scan is conducted at a rate of 5 mv./sec., starting at an initial potential of −0.86 v. and continuing to −1.76 v. Calculations are made through comparison of the diffusion currents observed with standards and solid dosage formulation samples.

RESULTS AND DISCUSSION

Manifold Design Considerations—In the development of an automated continuous-flow system that employs a scanning analytical technique, such as polarography, it is necessary to meet design criteria not ordinarily encountered in conventional automated methodologies. Since a scan may be conducted only while the sample concentration at the detector is held constant, it is necessary to achieve steady states of appreciable duration within the flow system. This requirement presents a considerable design problem in automated manifolds operating at rapid assay rates.

The elapsed time required for a single polarographic determination is expressed by the equation:

$$t_p = \frac{\Delta E}{R} \qquad \text{(Eq. 1)}$$

where t_p is the scan duration in seconds, ΔE is the width of the voltage range to be studied in millivolts, and R is the voltage scan rate expressed in millivolts per second.

The extent of the potential region that must be scanned is determined by the positions of the polarographic waves characteristic of the compounds under investigation and the electrolyte system employed. Both the rate at which the scan is conducted and the polarographic mode utilized affect the definition of the recorded polarogram (5). With a given polarographic mode, the maximum permis-

sible scan rate depends on the precision and resolution required for the specific determination of interest. Through the conditions imposed on the values of ΔE and R (Eq. 1), the minimum acceptable steady-state duration is controlled by the requirements of the particular assay.

In the quantitation of lorazepam, for example, it was found necessary to scan a voltage region of 900 mv., *i.e.*, from −0.86 to −1.76 v. *versus* mercury pool electrode. For the desired level of resolution, the maximum scan rate was determined experimentally to be 5 mv./sec. By using Eq. 1, the minimum permissible steady-state period, *i.e.*, the scan duration, was calculated to be approximately 3 min. However, because of normal diffusion in the flow system, the sample aspiration stage must be somewhat longer than the required steady-state period.

A study of the diffusional characteristics of the automated polarographic system revealed that 1 min. is required for the transition between successive steady states within the flow cell. This study was conducted by monitoring diffusion current *versus* time at an applied potential of −1.5 v. and observing the transients that resulted when an alternating series of lorazepam standards and empty sample cups were placed in the SOLIDprep sample tray. Thus, to supply the required 3 min. of steady state, a sample aspiration period of at least 4 min. is necessary.

The requirement for protracted aspiration imposes a severe limitation on the available assay rate of a conventional automatic analyzer system employing the SOLIDprep unit for sample dissolution. The required sample homogenation time and instrument design limitations restrict the sample aspiration stage of the SOLIDprep operating cycle to a maximum of 50% of the programmed cycle period. Therefore, with a 4-min. aspiration period, the minimum cycle duration is 8 min. This assay rate, *i.e.*, 7.5 samples/hr., would not have offered a significant advantage over manual polarographic procedures.

Steady-State Extension—The steady-state extension unit (Fig. 1) was developed to overcome the assay rate limitations encountered with conventional automated systems. This unit provides a twofold increase in assay rate with no loss of sensitivity or resolution.

Operationally, a peristaltic valve module is employed to permit selective collection and release of steady-state material. The valve is programmed to route the inlet sample stream to one of the storage coils, while the other coil provides sample to the outlet manifold. With each successive valve cycle, the inlet and outlet channels alternate and the flow directions in the storage coils reverse. The valve cycle is synchronized to coincide with the termination of a sample steady state at the extension unit inlet. The closing of an inlet channel causes the steady-state portion of the sample stream to be selectively retained at the upper end of the associated storage coil. The simultaneous opening of the coil's outlet channel releases this ma-

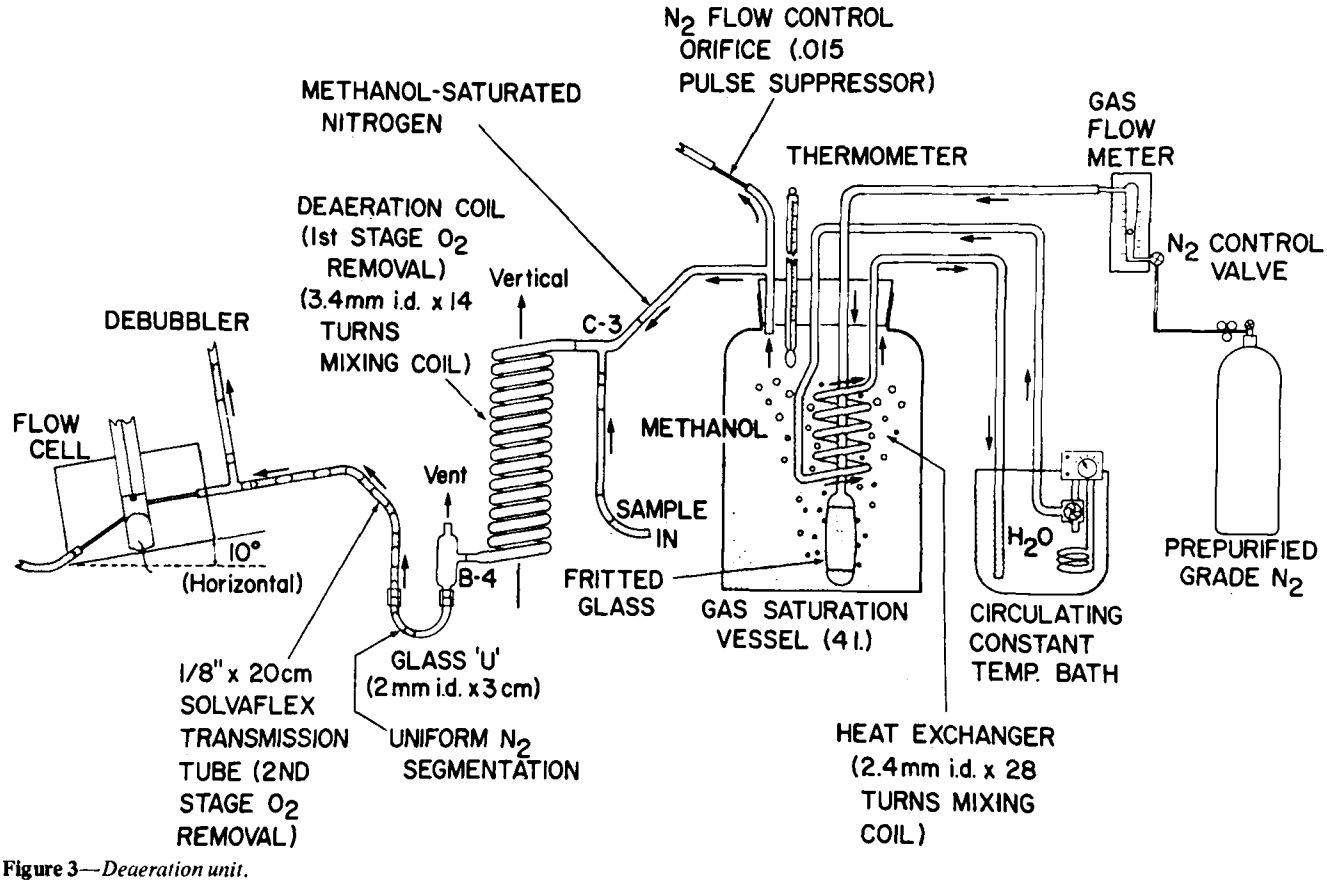

Figure 3—*Deaeration unit.*

terial to the extension unit's outlet manifold. The alternating collection and release of sample in conjunction with the inlet-outlet flow rate differential provide the desired steady-state extension. The required synchronization is accomplished through electrical interconnection of the valve's indexing switch with the programming mechanism of the SOLIDprep unit (Fig. 2).

A detailed description of the extension unit's operational principles, capabilities, and various applications will be published in the near future.

Deaeration Unit—For polarographic applications demanding high sensitivity and precision, it is essential to exclude dissolved oxygen from the electrode environment. This requirement is not easily satisfied in continuous-flow systems. Additionally, the low solubility of the model compound, lorazepam, in aqueous media complicated the deaeration problem by necessitating the use of a predominantly methanolic supporting electrolyte. Existing techniques for the continuous removal of oxygen from automatic analyzer streams (1, 3) and chromatographic column effluents (6–8) would not fulfill the requirements of the automated polarographic system. Generally, these methods are intended for use in aqueous solvent streams and are not designed to handle the exceptionally high oxygen solubility encountered in the supporting electrolyte of interest. Furthermore, the reported deaeration methods make no provisions to protect volatile solvents from excessive evaporation. Those techniques intended specifically for chromatopolarographic applications are not designed for use in segmented automatic analyzer streams and usually require the fabrication of sophisticated apparatus.

The continuous-flow deaerator (Fig. 3) was developed to meet the stringent performance criteria of this automated polarographic procedure. The apparatus consists entirely of standard automatic analyzer fittings and readily available laboratory equipment. The unit's effectiveness was evaluated at sample flow rates of 1–5 ml./min. for both air-segmented and nitrogen-segmented streams of supporting electrolyte. Within this range, oxygen removal was found to be essentially quantitative; *i.e.*, no detectable contribution from oxygen was observed in the residual current at a full-scale current sensitivity of 0.5 μamp. The nitrogen flow rate in each case was adjusted to yield uniform segmentation of the sample stream at the outlet of the deaerator, corresponding to nitrogen flow rates of 1–2 l./min. This high level of performance suggests that the deaerator will effectively remove oxygen from any common polarographic electrolyte. The unit's small hold-up volume, about 0.5 ml., and rapid sample transit, about 20 sec., minimize diffusional mixing in the flowing stream.

The volatile nature of the supporting electrolyte and the rapid nitrogen flow rates within the deaerator necessitated thermostatically controlled presaturation of the purging gas. The circulating constant-temperature bath is adjusted to maintain nitrogen temperatures at the saturation vessel outlet of 2 ± 1° above the ambient temperature of the laboratory.

Instrument Synchronization—The operation of the automated system depends upon precise synchronization of the steady-state extension unit and the polarographic analyzer with the flowing sample stream. To eliminate the possibility of synchronization-drift problems, which could result from the use of separate timing mechanisms, both the peristaltic valve module and the polarographic analyzer were interfaced with the programming mechanism of the SOLIDprep unit. The two cam-operated microswitches (Fig. 2) are accessory switches within the SOLIDprep programmer and were employed to provide common time-base control of all necessary synchronization signals.

The external circuit between terminals 5 and 12 on the accessory connector of the polarographic analyzer controls the scanning functions of the instrument. When this circuit is closed, the applied cell potential reverts to the selected initial value and the instrument is placed in a standby mode. Opening of the circuit initiates the voltage scan. The constant −15-v. signal available at terminal 12 is also employed to activate the relay connected to the remote control terminals, 13 and 14, of the recorder. Cam 10 is adjusted to initiate the voltage scan at the beginning of sample steady state within the polarographic cell. Cam 8 is adjusted to provide a momentary closure in the peristaltic valve's control circuit as the terminal portion of a sample steady state enters the extension unit's inlet manifold.

Current-Sampled d.c. Polarography—High polarographic resolution requires the use of an electrode drop rate that is rapid in comparison to the scan rate, *i.e.*, the individual drops are closely spaced along the polarogram's potential axis. Consequently, it is desirable to utilize a drop rate that is also more rapid than is commonly

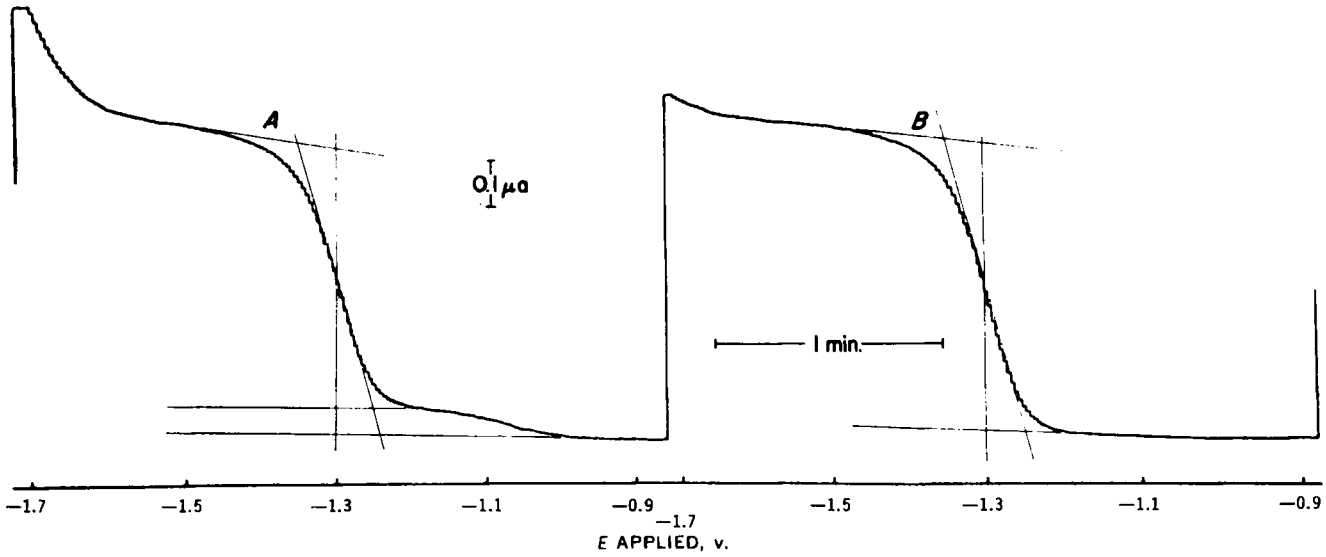

Figure 4—*Reproduction of lorazepam polarograms at the 2-mg. level and 15-sample/hr. assay rate. Key: A, intentionally degraded sample; and B, lorazepam reference standard.*

employed in manual procedures. However, dropping mercury electrodes that display suitably short natural drop periods at the electrocapillary maximum tend to become unstable at moderately negative applied potentials. For this reason, it is not practical to depend on natural drop-fall when operating at high drop rates (9).

To provide the required drop rate, this system employs an electrode with a long natural drop period (2.5 sec.) in conjunction with a mechanical drop timer which induces drop separation at precisely timed, selected intervals of 1 sec. Just prior to the mechanical removal of the drop, the current flowing in the cell is sampled electronically. An output proportional to this current is stored and presented to the recorder until the cell is again sampled electronically 1 sec. later, just prior to removal of the next mercury drop. When using this current-sampled d.c. mode, a peak-current polarogram is obtained in which all drop-induced fluctuations are removed electronically without introducing the waveform distortions characteristic of damping circuits. This polarographic mode is particularly well suited to automated applications since the smooth, well-defined waveforms may be rapidly and easily interpreted.

Typical polarograms of intact and intentionally degraded lorazepam, generated by the automated system at an assay rate of 15 samples/hr., are reproduced in Fig. 4. The fine definition obtained with the current-sampled d.c. presentation is apparent. The quiet residual current baseline is indicative of the low noise level achieved in the system. In the polarogram of the thermally degraded sample of lorazepam, the wave associated with the decomposition product appears at an $E_{1/2}$ of −1.1 v. and the wave at $E_{1/2}$ of −1.3 v. corresponds to the intact material. The excellent separation between these waves permits precise quantitation, by the established extrapolation technique described by Meites (9), of intact lorazepam.

Suitability as Analytical Method—Specificity of the method for analysis of the model compound, lorazepam, in the presence of its thermal degradation products was demonstrated by comparing analytical values of intentionally degraded samples to those obtained by quantitative TLC. In the TLC procedure, the lorazepam was separated from its degradation products on a silica gel chromatographic plate using a development solvent system of benzene–dioxane–ethanol (5:4.4:0.6). A zone of the silica gel encompassing the intact lorazepam spot was scraped from the plate. The lorazepam was eluted from the adsorbent with 95% ethanol and subsequently assayed by a UV spectrophotometric procedure to obtain a quantitative value. Since there is good agreement between the values by the two techniques (Table I), it is concluded that the automated polarographic procedure is stability indicating.

The linearity of the diffusion current–concentration relationship

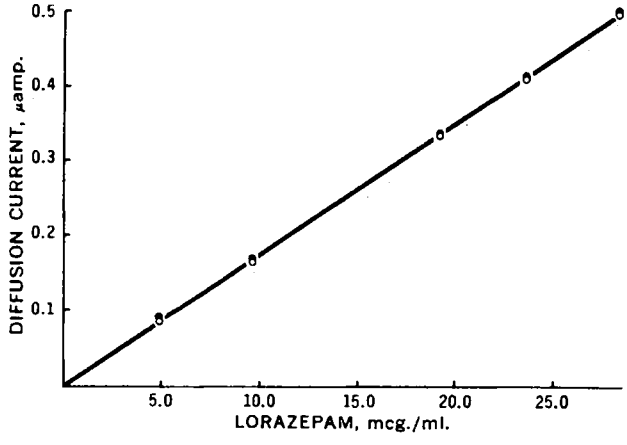

Figure 5—*Relationship of diffusion current to lorazepam concentration.*

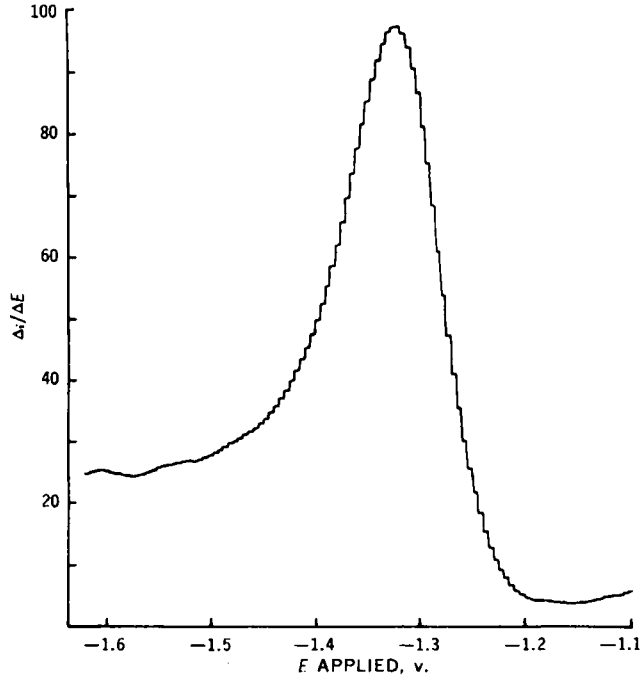

Figure 6—*Reproduction of a constant-amplitude differential pulse polarogram of lorazepam at the 2-mg. level and 15-sample/hr. assay rate.*

was shown by analyzing standards of lorazepam, yielding concentrations in the homogenization vessel in the range of 5–30 mcg./ml. ($1.5–9.5 \times 10^{-5}$ *M*) (Fig. 5). This concentration range corresponds to lorazepam levels of 0.25–6.0 mg. in the finished product, with the SOLIDprep unit delivering a fixed volume between 50 and 200 ml. of diluent. The actual measured lower limit of sensitivity is 0.05 mg./sample, corresponding to 3×10^{-6} *M* in the flow cell.

Both the precision and accuracy of this technique were determined by adding known quantities of lorazepam in the 0.5–2.0-mg. range to tablet excipient mixtures and measuring the percentages recovered. Twelve replicate assays at the 0.5-, 1.0-, and 2.0-mg. lorazepam/tablet levels produced relative standard deviations of ±1.4, ±1.4, and ±1.2%, respectively, with recoveries of 99% of the theoretical amount present in all three cases.

The effect of common inert tablet components on this automated polarographic procedure when applied to lorazepam was investigated to uncover any possible interfering material. In this study, inactive component–lorazepam ratios of 200:1 for lactose, 100:1 for talc and microcrystalline cellulose[9], and 50:1 for calcium sulfate, magnesium stearate, stearic acid, potassium polacrilin[10], methylcellulose[11], and starch were evaluated. No interference was experienced from these materials at these levels.

Further Applications—Preliminary investigations indicate that the automated method is readily adaptable to a wide variety of polarographic assay procedures. The use of a multifunctional polarographic analyzer permits the system to be operated in other polarographic modes. A constant-amplitude differential pulse polarogram of lorazepam obtained by the automated technique is presented in Fig. 6. This polarographic mode of operation offers increased sensitivity and expands method capabilities by permitting the resolution of closely spaced polarographic waves.

Simultaneous Semiautomated Determination of Pentaerythritol Tetranitrate or Mannitol Hexanitrate and Phenobarbital in Tablets

D. J. BROWN▲ and D. G. COOK*

Abstract □ A semiautomated spectrophotometric method for the simultaneous determination of pentaerythritol tetranitrate or mannitol hexanitrate and phenobarbital in single tablets is described. The organic nitrate ester component is assayed by a colorimetric procedure involving the diazotization of *p*-chloroaniline with nitrite formed by alkaline hydrolysis with tetramethylammonium hydroxide and coupling of the resultant compound with *N*-1-naphthylethylenediamine. The intensity of the color is measured at 570 nm. for pentaerythritol tetranitrate and at 613 nm. for mannitol hexanitrate. Phenobarbital is determined by UV absorption at 241 nm. after extraction into chloroform followed by extraction into aqueous base. The effect of one component on the assay results of the other is reported. Results from the semiautomated method are in agreement within ±3% with those from USP and NF methods. The coefficients of variation for the semiautomated procedure are 1.60, 0.68, and 1.24% for pentaerythritol tetranitrate, mannitol hexanitrate, and phenobarbital, respectively.

Keyphrases □ Pentaerythritol tetranitrate or mannitol hexanitrate and phenobarbital tablets—simultaneous spectrophotometric analysis □ Mannitol hexanitrate or pentaerythritol tetranitrate and phenobarbital tablets—simultaneous spectrophotometric analysis □ Phenobarbital and pentaerythritol tetranitrate or mannitol hexanitrate tablets—simultaneous spectrophotometric analysis □ Colorimetry—analysis, pentaerythritol tetranitrate or mannitol hexanitrate in tablets with phenobarbital □ UV spectrophotometry—analysis, phenobarbital in tablets with pentaerythritol tetranitrate or mannitol hexanitrate

Pentaerythritol tetranitrate and mannitol hexanitrate are both organic nitrate esters believed capable of coronary dilation. Their onset of action is slower and their duration much longer than nitroglycerin. They are used therapeutically in the prophylaxis of attacks of angina pectoris.

Phenobarbital, due to its sedative effect, has also been shown to have value in the prevention of angina pectoris attacks. It is not uncommon, therefore, to find pharmaceutical preparations containing both phenobarbital and one of the organic nitrate drugs as active ingredients. The purpose of this study was to find a suitable

was shown by analyzing standards of lorazepam, yielding concentrations in the homogenization vessel in the range of 5–30 mcg./ml. ($1.5–9.5 \times 10^{-5}$ *M*) (Fig. 5). This concentration range corresponds to lorazepam levels of 0.25–6.0 mg. in the finished product, with the SOLIDprep unit delivering a fixed volume between 50 and 200 ml. of diluent. The actual measured lower limit of sensitivity is 0.05 mg./sample, corresponding to 3×10^{-6} *M* in the flow cell.

Both the precision and accuracy of this technique were determined by adding known quantities of lorazepam in the 0.5–2.0-mg. range to tablet excipient mixtures and measuring the percentages recovered. Twelve replicate assays at the 0.5-, 1.0-, and 2.0-mg. lorazepam/tablet levels produced relative standard deviations of ±1.4, ±1.4, and ±1.2%, respectively, with recoveries of 99% of the theoretical amount present in all three cases.

The effect of common inert tablet components on this automated polarographic procedure when applied to lorazepam was investigated to uncover any possible interfering material. In this study, inactive component–lorazepam ratios of 200:1 for lactose, 100:1 for talc and microcrystalline cellulose[9], and 50:1 for calcium sulfate, magnesium stearate, stearic acid, potassium polacrilin[10], methylcellulose[11], and starch were evaluated. No interference was experienced from these materials at these levels.

Further Applications—Preliminary investigations indicate that the automated method is readily adaptable to a wide variety of polarographic assay procedures. The use of a multifunctional polarographic analyzer permits the system to be operated in other polarographic modes. A constant-amplitude differential pulse polarogram of lorazepam obtained by the automated technique is presented in Fig. 6. This polarographic mode of operation offers increased sensitivity and expands method capabilities by permitting the resolution of closely spaced polarographic waves.

Simultaneous Semiautomated Determination of Pentaerythritol Tetranitrate or Mannitol Hexanitrate and Phenobarbital in Tablets

D. J. BROWN▲ and D. G. COOK*

Abstract □ A semiautomated spectrophotometric method for the simultaneous determination of pentaerythritol tetranitrate or mannitol hexanitrate and phenobarbital in single tablets is described. The organic nitrate ester component is assayed by a colorimetric procedure involving the diazotization of *p*-chloroaniline with nitrite formed by alkaline hydrolysis with tetramethylammonium hydroxide and coupling of the resultant compound with *N*-1-naphthylethylenediamine. The intensity of the color is measured at 570 nm. for pentaerythritol tetranitrate and at 613 nm. for mannitol hexanitrate. Phenobarbital is determined by UV absorption at 241 nm. after extraction into chloroform followed by extraction into aqueous base. The effect of one component on the assay results of the other is reported. Results from the semiautomated method are in agreement within ±3% with those from USP and NF methods. The coefficients of variation for the semiautomated procedure are 1.60, 0.68, and 1.24% for pentaerythritol tetranitrate, mannitol hexanitrate, and phenobarbital, respectively.

Keyphrases □ Pentaerythritol tetranitrate or mannitol hexanitrate and phenobarbital tablets—simultaneous spectrophotometric analysis □ Mannitol hexanitrate or pentaerythritol tetranitrate and phenobarbital tablets—simultaneous spectrophotometric analysis □ Phenobarbital and pentaerythritol tetranitrate or mannitol hexanitrate tablets—simultaneous spectrophotometric analysis □ Colorimetry—analysis, pentaerythritol tetranitrate or mannitol hexanitrate in tablets with phenobarbital □ UV spectrophotometry—analysis, phenobarbital in tablets with pentaerythritol tetranitrate or mannitol hexanitrate

Pentaerythritol tetranitrate and mannitol hexanitrate are both organic nitrate esters believed capable of coronary dilation. Their onset of action is slower and their duration much longer than nitroglycerin. They are used therapeutically in the prophylaxis of attacks of angina pectoris.

Phenobarbital, due to its sedative effect, has also been shown to have value in the prevention of angina pectoris attacks. It is not uncommon, therefore, to find pharmaceutical preparations containing both phenobarbital and one of the organic nitrate drugs as active ingredients. The purpose of this study was to find a suitable

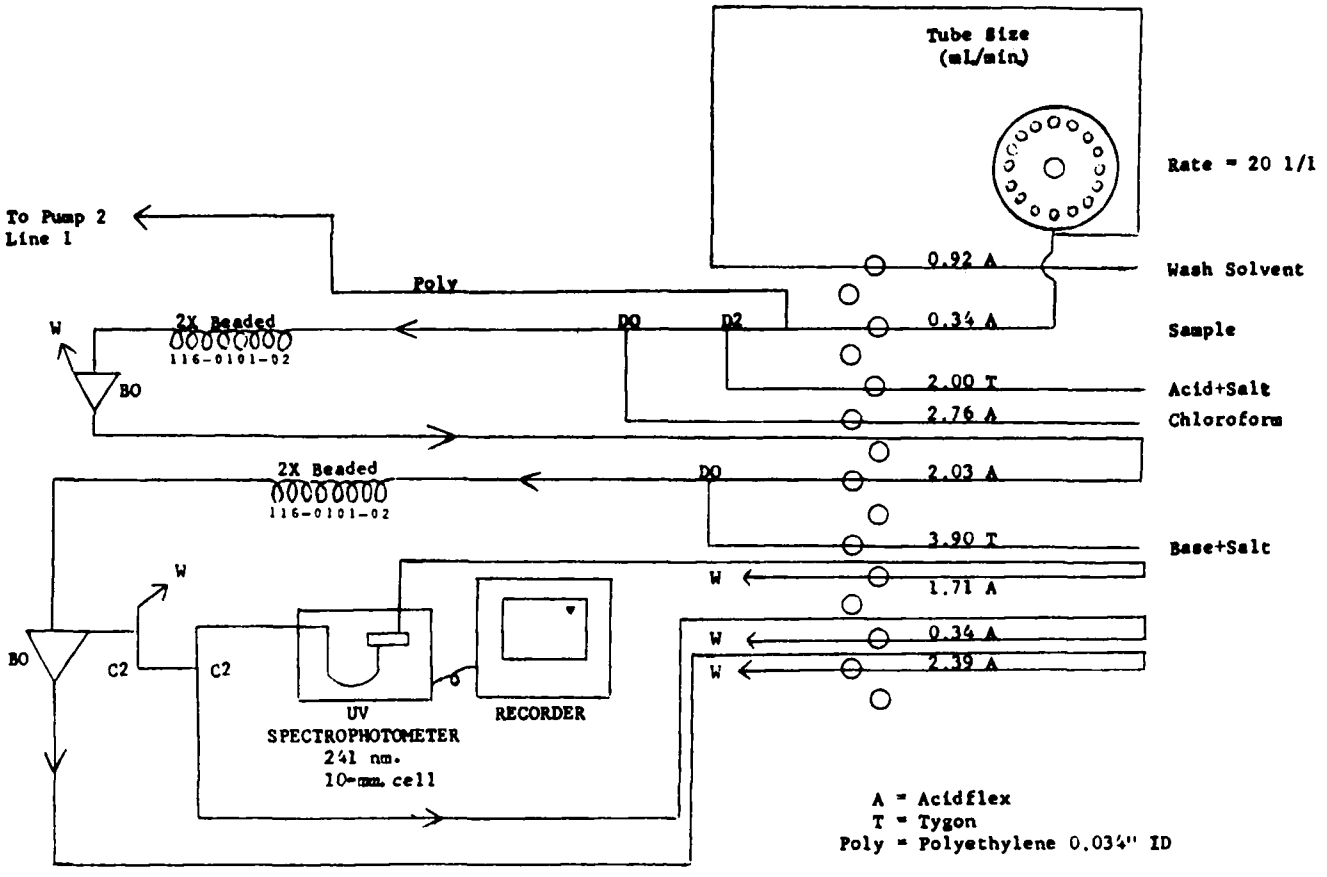

Figure 1—*Flow diagram for UV determination of phenobarbital.*

method for the simultaneous semiautomated determination of this type of pharmaceutical formulation.

Various chromatographic techniques for the detection and estimation of organic nitrate esters have been reported. A column chromatographic scheme to separate many organic nitrate esters, followed by a set of color tests for qualitative analysis was described (1). Paper chromatography followed by reaction with diphenylamine under the influence of UV radiation was used (2) for quantitative estimation. GC (3) and TLC (4) techniques have also been reported. In general, however, chromatographic procedures are not well suited for automation.

Polarographic (5) and titrimetric (6) procedures have also been described. However, most analytical methods for organic nitrate esters are spectrophotometric. Although IR methods are known (7, 8), colorimetric procedures are by far the most common. Nitration of phenoldisulfonic acid with the nitrate moiety of the ester to yield a colored ion in basic solution is the basis of several procedures (9–12).

Various methods have been developed in which nitroglycerin is subjected to alkaline hydrolysis with the formation of nitrite, which is then determined colorimetrically (13–17). Pentaerythritol tetranitrate and other related compounds have been determined similarly (18). Several organic nitrate esters including pentaerythritol tetranitrate and mannitol hexanitrate were estimated (4) after extraction from TLC plates using alkaline hydrolysis followed by diazotization of sulfanilic acid and coupling with α-naphthylamine. One approach (17), using *p*-chloroaniline and *N*-1-naphthylethylenediamine to form a color, was found to be satisfactory in the semiautomated determination of pentaerythritol tetranitrate or mannitol hexanitrate.

A comprehensive review of methods available for barbiturates was given recently (19). A double-extraction UV spectrophotometric procedure (20) was chosen, with some modifications, as a basis for the determination of phenobarbital.

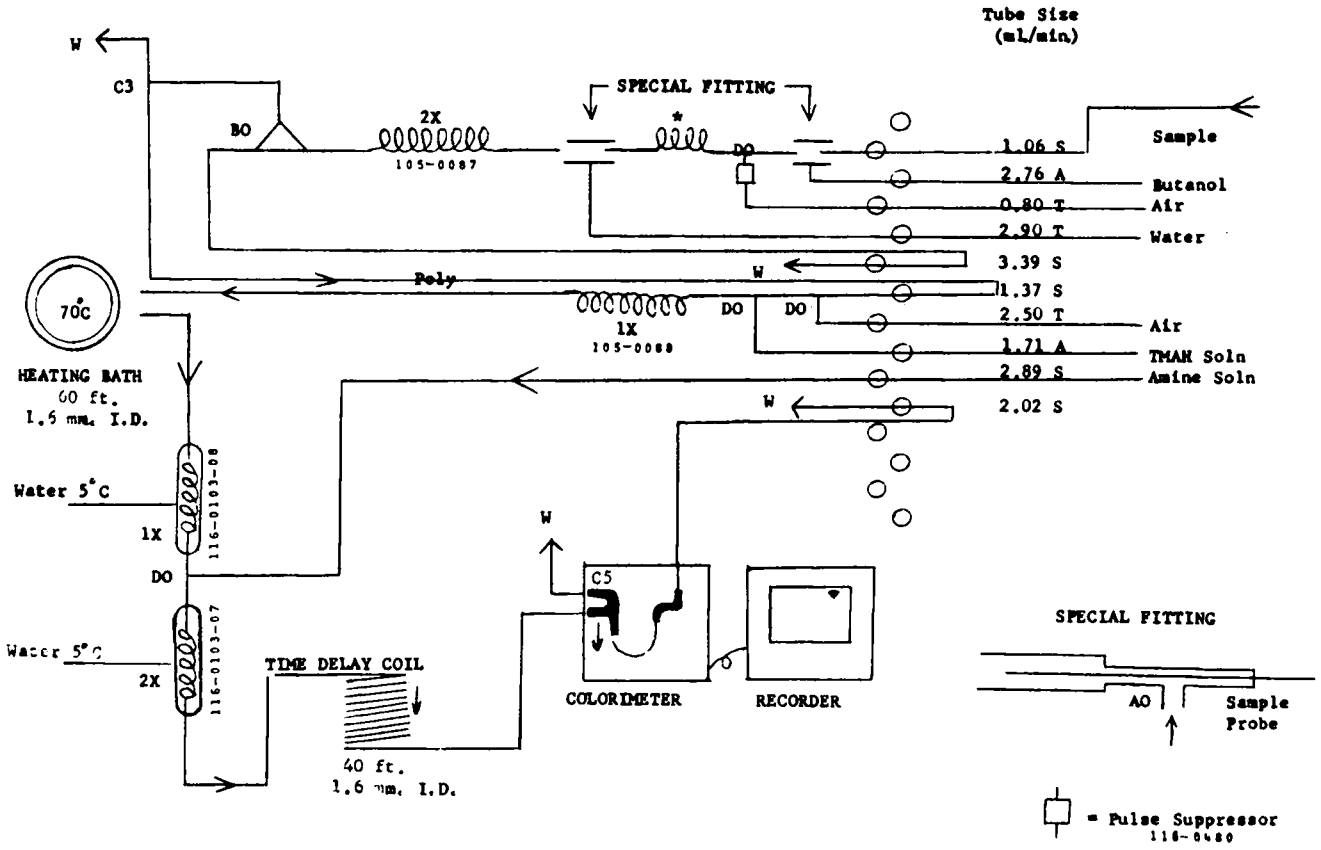

Figure 2—*Flow diagram for the determination of pentaerythritol tetranitrate or mannitol hexanitrate. *Twelve 2.54-cm. (1-in.) diameter turns of 0.086-cm. (0.034-in.) polyethylene tubing. Colorimeter: pentaerythritol tetranitrate, 570 nm.; mannitol hexanitrate, 613 nm.; 10-mm. cell.*

reagent grade except *n*-propanol, which was of highest purity available.

Tetramethylammonium Hydroxide, 1.5%—Dilute 150 ml. of 10% aqueous tetramethylammonium hydroxide to 1.0 l. with alcohol USP. Prepare fresh daily.

Amine Solution—Dissolve 0.5 g. of *N*-1-naphthylethylenediamine dihydrochloride in 100 ml. of concentrated hydrochloric acid. Dissolve 0.5 g. *p*-chloroaniline in 500 ml. of *n*-propanol. Then mix both solutions together, cool, and dilute to 1.0 l. with *n*-propanol. Prepare fresh daily.

Sulfuric Acid (1 N) Saturated with Sodium Chloride—Dilute 27.8 ml. of concentrated sulfuric acid to 1.0 l. with water. Add sodium chloride until saturated.

Sodium Hydroxide (0.01 N) in 1% Aqueous Sodium Chloride—Dissolve 10.0 g. of sodium chloride in 500 ml. of water. Add 10.0 ml. of a 1 *N* aqueous sodium hydroxide solution and dilute to 1.0 l. with water.

Wash Solvent—Prepare by mixing water, methyl isobutyl ketone, and alcohol USP (1:1:2).

Standard Solution—Add appropriate amounts of pentaerythritol tetranitrate or mannitol hexanitrate and phenobarbital corresponding to the amounts found in the sample (usually 10–20 mg. of pentaerythritol tetranitrate or 15–32 mg. of mannitol hexanitrate and 15–32 mg. of phenobarbital) to 25.0 ml. of water. Add 25.0 ml. of methyl isobutyl ketone and shake the mixture vigorously on a wrist-action shaker for 15 min. Dilute to 100.0 ml. with alcohol USP.

Apparatus—The automated analysis system[1] consisted of the following components: a sampler II; three proportioning pumps I; two spectrophotometers[2,3] modified by disengaging the wavelength scan drive, each equipped with a 10-mm. flow cell[4]; a heating bath constructed from a heating coil, temperature control box[5], and a cone drive stirrer[6]; and a water bath[7] set at 5°. A piece of glassine weighing paper was placed over the entrance to the photocell compartments in the visible spectrophotometer.

Procedure—The automated system is assembled according to the flow diagram shown in Figs. 1 and 2. Two proportioning pumps are used for the organic nitrate section of the system, and one proportioning pump is for the phenobarbital section. In performing the analysis, individual tablets are prepared according to the procedure given for the standard solution with the exception that an ultrasonic bath can be used to disintegrate the tablets in the water before the addition of methyl isobutyl ketone. The sample and standard solutions are sampled from 4.0-ml. polystyrene cups by the sampler, with a sampling rate of 20 cups/hr. and a sample-to-wash ratio of 1:1. A sampling pattern of two standards, five samples, one standard . . . five samples, one standard is used. The first standard peak is ignored in the calculations.

After sampling, the flow is split into two streams. The stream for the phenobarbital determination is acidified with 1 *N* sulfuric acid and extracted with chloroform. The acid is saturated with sodium chloride to eliminate emulsion formation. The chloroform layer is then extracted with 0.1 *N* sodium hydroxide in 1% sodium chloride; sodium chloride is used to reduce the organic solvent solubility in the aqueous phase. A combination of two debubblers is used before the aqueous stream enters the flow cell to eliminate any air bubbles or chloroform drops. The spectral measurement is made against air as reference at 241 nm.

The stream for the organic nitrate determination is diluted with butanol and extracted with water. The butanol layer (upper layer) is resampled, mixed with tetramethylammonium hydroxide solution, and delayed approximately 5 min. in a 70° heating bath to hydrolyze the organic nitrate ester and form nitrite. The solution is cooled to 5°, mixed with amine solution, and delayed approximately 5 min. at room temperature. The intensity of the resulting color is deter-

mined at 570 nm. for pentaerythritol tetranitrate. Mannitol hexanitrate is determined off the maximum at 613 nm. to reduce sensitivity in order to accommodate normal dosage levels. From the absorbance values the content per tablet is calculated.

RESULTS AND DISCUSSION

When the organic nitrate ester portion of the procedure was being developed, Schlieren effects were encountered in the 10-mm. flow cell used in the spectrophotometer. These effects, which manifest themselves by producing a jagged broad baseline, were eliminated by using a suggested[5] procedure similar to a reported technique (21, 22). A piece of glassine weighing paper was placed over the entrance to the photocell compartments for both the sample and reference cells. The paper has a diffusing effect on the light striking it and produces a steady baseline. Schlieren effects were not a problem in the phenobarbital assay, since an aqueous rather than an organic solvent passes through the flow cell.

To obtain reproducible results for pentaerythritol tetranitrate and mannitol hexanitrate, the cooling bath temperature must remain constant. Apparently, the diazotization coupling reaction is extremely temperature dependent.

Conformity to Beer's law was observed for pentaerythritol tetranitrate, mannitol hexanitrate, and phenobarbital over a range of concentrations exceeding those obtained from common dosage levels.

The number of moles of nitrate ion released from 1 mole of ester upon alkaline hydrolysis was previously investigated. A lack of stoichiometry for nitroglycerin was reported (15), probably because of complex competitive reactions involved in the decomposition of

[a] Standard = 15.1 mg./100 ml. [b] Average of three readings.

nitrate esters. Others, however, reported (17) that nearly 2 moles of nitrate ion is released per mole of nitroglycerin. In addition, nonstoichiometric results for pentaerythritol tetranitrate were reported (18).

The alkaline hydrolysis of pentaerythritol tetranitrate and mannitol hexanitrate through the present semiautomated system was investigated by comparing the absorbance obtained from the ester solutions to that obtained from a definite concentration of nitrite solution. Since the partitioning of nitrite ions between butanol and water is considerably different from that for organic nitrate esters, the semiautomated system was modified to bypass the partitioning step for this experiment. The modification consisted of attaching the exit end of the polyethylene tubing coil directly to the C-3 fitting (Fig. 2). Standard solutions of the esters were prepared using mixtures of pentaerythritol tetranitrate and lactose and of mannitol hexanitrate and lactose, which were previously standardized according to the NF procedure (12). Potassium nitrite (0.1 *M*) was standardized against sulfanilamide and diluted to obtain a suitable concentration in a final solvent of water–methyl isobutyl ketone–alcohol USP (1:1:2). For every mole of ester, 3.48 moles of nitrite ion is released from mannitol hexanitrate and 1.45 moles from pentaerythritol tetranitrate under the given conditions of hydrolysis.

Phenobarbital Interference in Nitrate Assay—The effect of a variation of phenobarbital concentration on the pentaerythritol tetranitrate and mannitol hexanitrate assays can be seen in Tables I and II. The average error in the nitrate results was less than ±2%. The nature of this slight interference is unclear. Under actual sample assay conditions, phenobarbital is added to the nitrate standard and this small error is essentially eliminated.

Nitrate Interference in Phenobarbital Assay—Tables III and IV show the effect of pentaerythritol tetranitrate and mannitol hexanitrate on the phenobarbital assay. In general, the interference is small and, as in the case of the phenobarbital interference in the nitrate assay, is eliminated by using a mixture of nitrate ester and phenobarbital for the phenobarbital standard.

Table V—Recoveries from Mixtures Based on Various Manufacturers' Formulations

Manufacturer	Composition	Dosage, mg./Tablet	Recovery[a], %

	Phenobarbital	16	--	98.2	98.8

[a] Average of two determinations. [b] Average of five readings.

Accuracy—Recovery studies were made on mixtures containing excipients and active ingredients corresponding to several manufacturers' formulations (Table V).

Several composites of 20 tablets each from various commercial samples were analyzed by the automated procedure and appropriate manual procedures. The NF procedure for pentaerythritol tetranitrate tablets (12) was used for pentaerythritol tetranitrate and mannitol hexanitrate. A factor of 0.7456 was used to calculate the mannitol hexanitrate levels (10). Phenobarbital was assayed by the USP procedure for phenobarbital tablets (23). The results (Table VI) are in agreement within ±3%.

Precision—The system coefficients of variation for pentaerythritol tetranitrate, mannitol hexanitrate, and phenobarbital were determined by measuring the absorbances obtained from a series of 25 cups of the appropriate standard solution. The following results were obtained: pentaerythritol tetranitrate, 1.60%; mannitol hexanitrate, 0.68%; and phenobarbital, 1.24%.

Interferences—Low results for phenobarbital were obtained by the automated method for the analysis of tablets containing methylcellulose or carboxymethylcellulose, since these agents inhibit the extraction of the barbiturate into chloroform.

SUMMARY

A semiautomated spectrophotometric procedure has been described for the simultaneous determination of pentaerythritol tetranitrate or mannitol hexanitrate and phenobarbital present in a single tablet.

Conformity to Beer's law was observed for the three drugs over a range of concentrations exceeding those obtained from common dosage levels.

The effect of one component on the assay results of the other is minimal at common dosage levels and can be essentially eliminated by using a mixture of nitrate ester and phenobarbital for the standard.

Assay results by the semiautomated procedure are in agreement with those obtained by manual procedures within ±3%.

Methylcellulose and carboxymethylcellulose interfered with the phenobarbital determination.

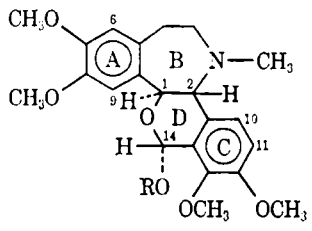
Isolation of Alpinigenine from *Papaver bracteatum*

I. LALEZARI▲, A. SHAFIEE, and P. NASSERI-NOURI*

Abstract □ Dried latex of *Papaver bracteatum* was shown to contain 2.3% of alpinigenine. The structure was assigned on the basis of physical properties and spectroscopic analysis.

Keyphrases □ Alpinigenine—isolation from *Papaver bracteatum*, structure determination □ *Papaver bracteatum*—isolation of alpinigenine and its structure determination

In a continuing research program with chemotaxonomic studies of the papaver genus in Iran (1), the latex of *Papaver bracteatum*[1] was subjected to chromatographic analysis. In addition to the major alkaloid thebaine (1), another fraction was eluted, which, upon purification, was found to be alpinigenine as reported by Maturova *et al.* (2). NMR data ($J_{1,2}$ = 9 Hz.) were consistent with a *trans*-configuration of the B–D ring junction. For the elucidation of the stereochemistry at C_{14}, the alkaloid was treated with a methanolic solution of hydrochloric acid and two fractions were isolated by TLC. The slow moving fraction (R_f 0.68) was unchanged alpinigenine. The fast moving fraction (R_f 0.81) was shown to be epialpinine, previously reported by Maturova *et al.* (3) and Shamma *et al.* (4). These data prove that the alpinigenine separated in this work was not changed at C_{14} under equilibrating conditions and had the most stable configuration at C_{14} (Structure I). Similar results were indicated by Mann *et al.* (5).



I

alpinigenine: R = H
epialpinine: R = CH_3

EXPERIMENTAL[2]

Isolation of Alpinigenine—Dried latex (10 g.), obtained by incision of immature capsules of the plant, was treated with dilute ammonia to obtain a soft paste and extracted by trituration with chloroform (150 ml.). The extract was filtered and evaporated under reduced pressure, and the residue was treated with oxalic acid solution (4%, 50 ml.), filtered, and washed with water (20 ml.). The combined aqueous solutions were made alkaline with ammonia and extracted with chloroform (4 × 25 ml.). The organic layer was dried (sodium sulfate), filtered, and evaporated. The residue was subjected to TLC (silica gel), using acetone–chloroform–triethylamine–methanol (4:3:2:1) as eluting solvent. The fast moving fraction (R_f 0.9), after crystallization from methanol, gave 0.23 g. of alpinigenine, m.p. 185–186° [lit. (3) m.p. 193–195°]; UV_{max} 230 (log ε 4.2) and 284 (log ε 3.8) nm.; NMR: δ 7.35 (q, 2H, H_{10} and H_{11}), 6.95 and 6.67 (2s, 2H, H_6 and H_9), 6.4 (s, 1H, H_{14}), 5.8 (d, 1H, H_1, $J_{1,2}$ = 9 Hz.), 4.08 (d, 1H, H_2, $J_{1,2}$ = 9 Hz.), 3.95 and 3.86 (2s, 12H, OCH_3), 3.7–3 (m, 4H, aliphatic), and 2.34 (s, 3H, NCH_3) p.p.m.; mass spectrum: *m/e* 401 (M^+), 222 (base peak), 208, and 179 (large abundance of ions). The slow moving fraction (R_f 0.83) gave, on crystallization from aqueous ethanol, thebaine (2.8 g.), m.p. 198° [lit. (1) m.p. 198°].

Stereochemistry of Alpinigenine at C_{14}—The isolated alpinigenine (100 mg.) was dissolved in methanol (20 ml.), and a saturated methanolic solution of hydrochloric acid (2 ml.) was added. After standing for 2 hr. at room temperature, the solvent was evaporated and the residue was made alkaline with ammonia and extracted with chloroform. The organic layer was evaporated and the residue was subjected to TLC (silica gel), using ether (saturated with water)–acetone–diethylamine (85:8:7). The fast moving fraction (R_f 0.81, m.p. 56–58°) could not be crystallized. Its IR spectrum in chloroform solution, as well as other spectral data, was identical with those reported for epialpinine. The slow moving fraction (R_f 0.68) was unchanged alpinigenine.

[1] The plant was identified by A. Zargari, Professor of Botany, Tehran University. A herbarium sample of the plant material has been deposited in the Missouri Botanical Garden, St. Louis, Mo.

[2] Melting points were taken on a Kofler hot-stage microscope and are uncorrected. UV spectra were recorded on a Unicam SP 800 instrument. IR spectra were obtained with a Leitz model III spectrograph. NMR spectra were determined in deuteriochloroform with a Varian A60A instrument. Mass spectra were determined with a Varian Mat 111 instrument.

Phosphorus–Nitrogen Compounds XV: *N*-1-Adamantylphosphoramidic Dichloride and Dimethyl and Diphenyl *N*-1-Adamantylphosphoramidate

L. A. CATES[A], R. L. GALLIO, and M. B. CRAMER

Abstract □ *N*-1-Adamantylphosphoramidic dichloride and the dimethyl and diphenyl esters of the corresponding acid were synthesized and evaluated for biological activity. The dimethyl ester delayed the onset of tremorine-induced tremors and reduced locomotor activity, while the diphenyl derivative slightly antagonized perphenazine-induced catatonic reactions. None of the agents displayed activity against lymphoid leukemia.

Keyphrases □ *N*-1-Adamantylphosphoramidic dichloride—synthesis, pharmacological screening as antiparkinsonism and anticancer agents □ *N*-1-Adamantylphosphoramidate, dimethyl and diphenyl—synthesis, pharmacological screening as antiparkinsonism and anticancer agents □ Amantadine derivatives—synthesis of *N*-1-adamantylphosphoramidic dichloride and dimethyl and diphenyl *N*-1-adamantylphosphoramidate as potential antiparkinsonism and anticancer agents □ Antiparkinsonism agents, potential—synthesis of amantadine derivatives, screening □ Anticancer agents, potential—synthesis of amantadine derivatives, screening

Among the many derivatives containing the adamantyl moiety, the most extensively studied is amantadine (1-adamantanamine, I). Early investigations of this agent mainly involved its antiviral properties, whereas several recent studies were concerned with antiparkinsonism activity. The beneficial effects in Parkinson's disease have been related to release of dopamine from neuronal storage sites (1, 2) rather than through anticholinergic mechanisms (1, 3), which is the basis for the action of agents commonly employed in treating this disease state.

Since good cholinolytic activity in three phosphoramidates, especially in those containing the diphenylphosphate grouping, was found previously (4), the two esters reported here were considered as potential antiparkinsonism agents. Amantadine, in addition to having therapeutic action *per se*, contributes the highly lipophilic adamantyl moiety to ensure ready distribution of the compounds to the CNS. A recent study (5) employed this grouping in the design of an analog of procyclidine hydrochloride. The effect of introducing an adamantyl fragment in prospective therapeutic agents has been the subject of many other inquiries (6); no investigation, however, has been reported on the consequence of phosphorylation of the 1-amino derivative of adamantane[1].

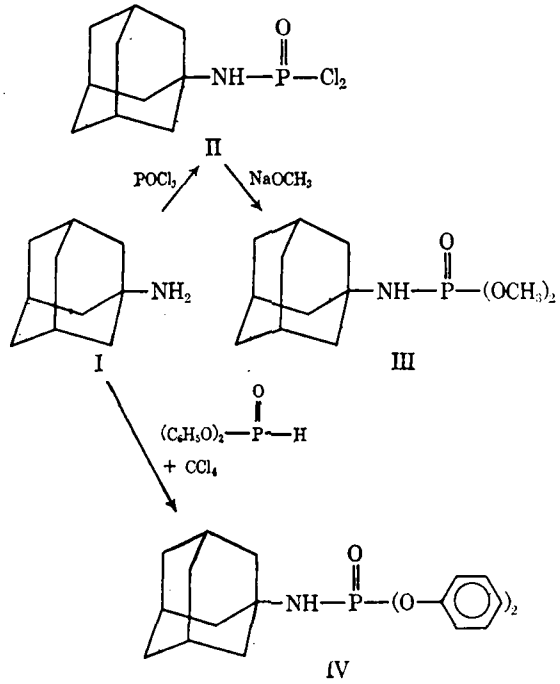
DISCUSSION

The desired adamantylphosphoramides (III and IV) were prepared by reacting sodium methoxide with *N*-1-adamantylphosphoramidic dichloride (II) and diphenylphosphonate with I and carbon tetrachloride (Scheme I). Compound II was synthesized using the phosphorus oxychloride–amine method (7). Information pertinent to these compounds, including spectral data, is presented in Table I.

Compounds III and IV were screened for antiparkinsonism activity by two methods. The onset of tremorine-induced tremors in mice, occurring within 10 min., was prolonged to 25 min. in the case of III at a dose of 250 mg./kg. No prolongation was noted with III at 125 mg./kg. or with IV at 250 mg./kg. Derivative III (250 mg./kg.) also doubled the period required for tremor induction produced by oxotremorine. Perphenazine-induced catatonic reactions were antagonized to the extent of 8% (III) and 25% (IV). These tests, summarized in Table II, indicate a potential activity of a weak nature for the esters in Parkinson's disease. Locomotor activity in mice was also shown to be reduced 25% by III. During gross observation studies, III caused ataxia and hindlimb paralysis and IV produced sedation and hypnosis in mice (250 mg./kg.). None of three new adamantylphosphoramides gave a beneficial response when tested against L-1210 lymphoid leukemia[2].

EXPERIMENTAL

***N*-1-Adamantylphosphoramidic Dichloride (II)**—This compound was prepared using the method of Michaelis (7) whereby a solution of freshly distilled phosphorus oxychloride (20.0 g., 0.13 mole) in anhydrous ether (20 ml.) was placed in a flask fitted with a thermometer, drying tube, and dropping funnel. Amantadine (20.0 g., 0.13 mole) and triethylamine (14.6 g., 0.14 mole) in anhydrous ether (150 ml.) were added dropwise with magnetic stirring



Scheme I

[1] During the time of this writing, the diphenyl ester was reported in Abstract 49, Division of Medicinal Chemistry, 165th ACS National Meeting, Dallas, Tex., Apr. 1973, by Warner, Mirth, Day, Turesky, and Soloway.

[2] The rationale for anticancer properties in these compounds and a description of active related agent(s) will be presented in a future paper.

[a] Perphenazine (5 mg./kg.) 15 min. pretreatment. [b] Performed by the screening contractors of the National Cancer Institute. Only highest, nontoxic dose is indicated. [c] No survivors out of six. [d] Compound followed with tremorine (0.6 mg./kg.) in 30 min. [e] Compounds followed with oxotremorine (0.5 mg./kg.) in 15 min. [f] Sodium carboxymethylcellulose, 1%.

over 1 hr. at 5–10°, during which time a white precipitate formed. After remaining overnight at room temperature, the reaction mixture was filtered and the filtrate was spin-evaporated to yield 25.0 g. of crystalline material. Recrystallization from ether gave the pure product.

Dimethyl *N*-1-Adamantylphosphoramidate (III)—To a stirred solution of II in 25 ml. of methanol was added a sodium methoxide solution prepared by reacting 1.15 g. of sodium metal with 30 ml. of absolute methanol. The temperature of the reaction mixture rose 30° and a white precipitate formed. After cooling and filtering, water was added to the filtrate and, when kept overnight, yielded 3.3 g. of III.

Diphenyl *N*-1-Adamantylphosphoramidate (IV)—According to the procedure of Atherton *et al.* (8), I (9.0 g., 0.06 mole) and triethylamine (6.0 g., 0.06 mole) in 80 ml. of carbon tetrachloride were placed in a flask fitted in the same manner as described for II. Diphenylphosphonate (11.7 g., 0.5 mole) in 15 ml. of carbon tetrachloride was added dropwise to this solution over 30 min. with a temperature rise of 35° and formation of a dense, white precipitate. After remaining overnight, the reaction mixture was filtered and the filtrate was spin-evaporated to yield a granular substance which gave 13.2 g. of pure IV when recrystallized from dilute ethanol.

Male Swiss albino mice (18–25 g.) in groups of four were used in the pharmacological screening. Compounds III and IV were suspended in 1% sodium carboxymethylcellulose and tested for antagonism of tremorine- (9) and oxotremorine- (10) induced tremors and perphenazine-produced catatonia (11). Atropine (2 mg./kg.) prevented tremorine-caused tremors for over 1 hr., except in the case of one animal which had tremor induction in 25 min. In addition, III reduced locomotor activity[3] by 25% at a dose of 250 mg./kg.

Stability of Aspirin in Liquid and Semisolid Bases III: Effect of Citric and Tartaric Acids on Decomposition in a Polyethylene Glycol Base

C. W. WHITWORTH▲, H. W. JUN, and L. A. LUZZI

Abstract □ The decomposition of aspirin in a polyethylene glycol base was inhibited by citric and tartaric acids at 45, 26, and 4°. Even in the presence of added water, citric acid tended to slow the decomposition process while several other additives failed to influence it.

Keyphrases □ Aspirin, stability in liquid and semisolid bases—effect of citric and tartaric acids on decomposition in polyethylene glycol base □ Suppositories—inhibition of aspirin decomposition by citric and tartaric acids, polyethylene glycol base □ Polyethylene glycol—aspirin stability, inhibition of decomposition by citric and tartaric acids □ Degradation, aspirin—inhibition by citric and tartaric acids in polyethylene glycol-type suppository

Aspirin decomposes rapidly when incorporated into a polyethylene glycol suppository base. The process was found to be partly due to transesterification (1) and is greatly temperature dependent.

Mixtures of polyethylene glycols have been used extensively as suppository bases for several years (2). These mixtures have desirable characteristics as bases since they do not require refrigeration, provided the incorporated drugs are stable at room temperature. Aspirin is less stable in these polyethylene glycol bases than in cocoa butter, which has to be refrigerated to prevent melting. The purpose of this study was to stablize aspirin in a polyethylene glycol suppository base using additives while retaining the essential characteristics of the base. Of the several additives tested, citric and tartaric acids proved promising. Less effective substances included calcium gluconate, colloidal silica, and acetic acid.

EXPERIMENTAL

Reagents—The basic polyethylene glycol formula into which aspirin and additives were incorporated was as follows: polyethylene glycol 400[1], 24.8%; polyethylene glycol 1540[1], 30.4%; polyethylene glycol 6000[1], 40.0%; and polysorbate 60[2], 4.8%.

The different concentrations of citric acid[3] and tartaric acid[3] were based on the weight of the suppository vehicle. The ingredients were melted at 55° with stirring, and aspirin[4] equal to 12% of the base-additive mixture was stirred into the melted mixture. The mixture was poured with stirring into suppository molds and permitted to congeal. Each batch was divided into three portions for storage at 45, 26, and 4°.

Analytical Method—Assays were performed at short intervals at the beginning of the study and at greater intervals as the rate of degradation slowed.

Each suppository was dissolved in 100 ml. of chloroform containing 1% acetic acid. A 1:50 dilution was made, and the absorbance was read at 278 nm. for aspirin and at 308 nm. for salicylic acid on a spectrophotometer[5]. The moles of each were determined from a standard curve, and the mole percent (percent decomposition) of salicylic acid was calculated.

RESULTS AND DISCUSSION

The results with all concentrations of citric and tartaric acids were somewhat similar. Figure 1 shows the decomposition of aspirin at 45, 26, and 4° in the polyethylene glycol suppository base when no additive was used. As in numerous other studies (3), the decomposition of aspirin was highly temperature dependent. The decomposition was approximately 26% in 28 days at 45°, about 18% in 80 days at 26°, and approximately 3% in 100 days at 4°. Refrigeration of aspirin suppositories utilizing a polyethylene glycol base is a necessity.

Figure 2 shows the decomposition of aspirin in the polyethylene glycol base in the presence of 1% citric acid. The decomposition was inhibited particularly at 26 and 4°. At 45°, the decomposition reached about 23% at 28 days; at 26°, it was around 11% after 102 days; and at 4°, it reached just over 2% in 110 days.

An increase in citric acid concentration to 5% resulted in a further decrease in the decomposition rate at 26 and 4°, but no change was noted at 45°. The decomposition at 26° reached about 8% in 100 days, while at 4° it was only about 1%.

There was little or no improvement in the stability of aspirin with 10% citric acid compared to the 5% concentration. Citric acid at the 10% level inhibited the decomposition of aspirin even in the presence of 5% added water. The rate of decomposition was greater than that shown without water but less than that of the control.

[2] Atlas Chemicals.
[3] J. T. Baker Chemical Co.
[4] Merck and Co.
[5] Beckman DU.

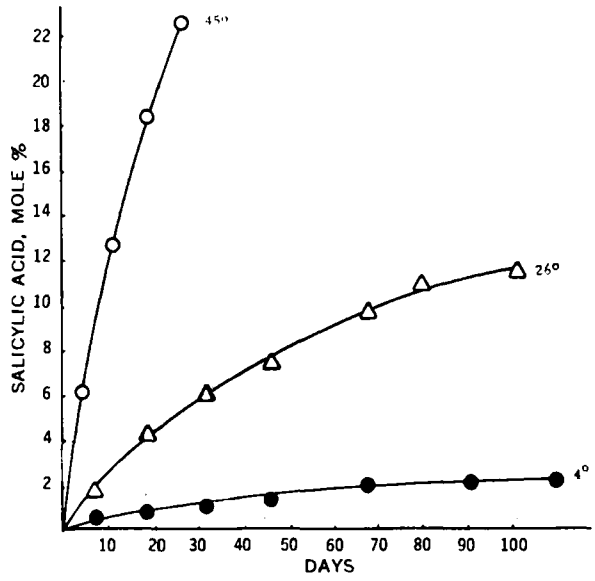

Figure 2—*Mole percent decomposition of aspirin with time in a polyethylene glycol base containing 1% citric acid.*

The effect of 10% tartaric acid on aspirin decomposition in this base was studied for a limited period, and the results were similar to those obtained with 5 and 10% citric acid for a comparable time. The percent decomposition at 26° was slightly lower with tartaric acid, but little difference was noted between these similar acids at 45 and 4°.

CONCLUSIONS

Certain substances can be added to a polyethylene glycol-type aspirin suppository mixture without appreciably changing its properties. Of the several additives studied, citric and tartaric acids inhibited decomposition. A 5% concentration of citric acid appeared to be the optimum concentration necessary to hinder decomposition. The importance of refrigeration at 4° on decomposition of aspirin in polyethylene glycol was evident.

Biological Activity of Pentobarbital Metabolites

H. D. CHRISTENSEN▲, L. BARNETT, and F. I. CARROLL

Abstract □ The (1′*S*,3′*R*)-, (1′*S*,3′*S*)-, (1′*R*,3′*R*)-, and (1′*R*,3′*S*)-5-ethyl-5-(3′-hydroxy-1′-methylbutyl)barbituric acid metabolites of pentobarbital are relatively inactive and, therefore, cannot account for the differences in potency found between *R*(+)- and *S*(−)-pentobarbital. The (1′*S*,3′*R*)- and (1′*S*,3′*S*)-hydroxypentobarbital metabolites have very weak sedative activity when administered to CF-1 mice intravenously at an AD_{90} anesthetic dose of *RS*-pentobarbital.

Keyphrases □ Pentobarbital metabolites—anesthetic and behavioral activity in mice □ Barbituric acid metabolites, pentobarbital—anesthetic and behavioral activity in mice □ Anesthetic activity—pentobarbital metabolites, mice

The diastereoisomeric pairs of 5-ethyl-5-(3′-hydroxy-1′-methylbutyl)barbituric acid were first shown by Maynert and Dawson (1) to be biotransformation products of pentobarbital. More recently, the four optical isomers of 3′-hydroxypentobarbital were isolated in this laboratory from metabolism studies of optically pure *R*(+)- and *S*(−)-pentobarbital (2, 3). *R*(+)-Pentobarbital is metabolized to approximately equal amounts of the two hydroxylated metabolites in contrast to (*S*)-pentobarbital in which the ratio is 9:1. The *S*(−)-isomer is more toxic and potent as an anesthetic agent in mice than is the *R*(+)-isomer or the racemate (4). Maynert and Dawson (1) reported that the diastereoisomeric metabolites were inactive. Dickert *et al.* (5) found that (1′*RS*,3′*SR*)-3′-hydroxypentobarbital, prepared by synthetic methods, had very weak anticonvulsant activity and no anesthetic properties. Pharmacological differences in the enantiomers of pentobarbital and the respective ratios of their 3′-hydroxy enantiomers indicated the desirability of determining if some 3′-hydroxypentobarbital isomers were active and contributing to the differences in the activity of the pentobarbital stereoisomers.

EXPERIMENTAL

The structure and absolute stereochemical assignment of *R*- and *S*-pentobarbital as well as the four optically active 3′-hydroxypentobarbital metabolites were reported previously (6–9). The optical rotations and melting-point values for pentobarbital stereoisomers are: (*RS*), m.p. 129–130°; (*R*), $[\alpha]_D$ +13.1°, m.p. 121–122°; and (*S*), $[\alpha]_D$ −13.2°, m.p. 121–122°. For 3′-hydroxypentobarbital the values are: (1′*RS*,3′*RS*), m.p. 145–147°; (1′*RS*,3′*SR*), m.p. 191–192°; (1′*R*,3′*R*), $[\alpha]_D$ +12.8°, m.p. 170–176°; (1′*R*,3′*S*), $[\alpha]_D$ +30.5°, m.p. 202–205°; (1′*S*,3′*S*), $[\alpha]_D$ −15.3°, m.p. 181–183°; and (1′*S*,3′*R*), $[\alpha]_D$ −31.5°, m.p. 208–210°.

Biological activity was assessed by administering each epimer at the AD_{90} anesthetic dose of *RS*-pentobarbital to 10 CF-1 male mice.

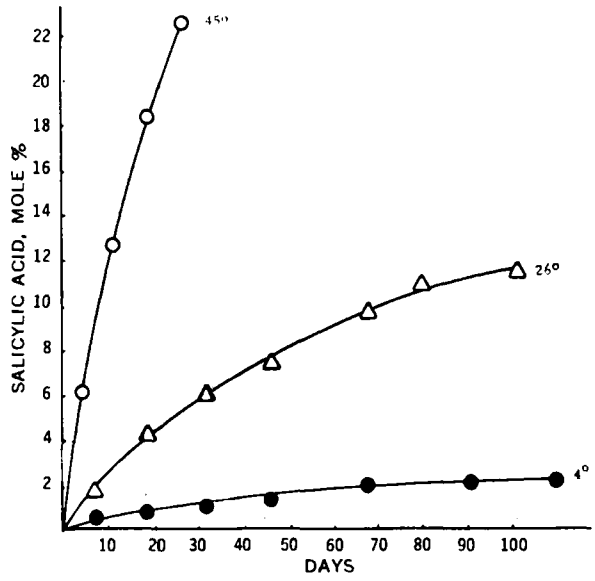

Figure 2—*Mole percent decomposition of aspirin with time in a polyethylene glycol base containing 1% citric acid.*

The effect of 10% tartaric acid on aspirin decomposition in this base was studied for a limited period, and the results were similar to those obtained with 5 and 10% citric acid for a comparable time. The structure and absolute stereochemical assignment of *R*- and *S*-pentobarbital as well as the four optically active 3′-hydroxypentobarbital metabolites were reported previously (6–9). The optical rotations and melting-point values for pentobarbital stereoisomers are: (*RS*), m.p. 129–130°; (*R*), $[\alpha]_D$ +13.1°, m.p. 121–122°; and (*S*), $[\alpha]_D$ −13.2°, m.p. 121–122°. For 3′-hydroxypentobarbital the values are: (1′*RS*,3′*RS*), m.p. 145–147°; (1′*RS*,3′*SR*), m.p. 191–192°; (1′*R*,3′*R*), $[\alpha]_D$ +12.8°, m.p. 170–176°; (1′*R*,3′*S*), $[\alpha]_D$ +30.5°, m.p. 202–205°; (1′*S*,3′*S*), $[\alpha]_D$ −15.3°, m.p. 181–183°; and (1′*S*,3′*R*), $[\alpha]_D$ −31.5°, m.p. 208–210°.

Biological activity was assessed by administering each epimer at the AD_{90} anesthetic dose of *RS*-pentobarbital to 10 CF-1 male mice.

Table I—Comparison of Activities of 3′-Hydroxy Metabolites to Pentobarbital

Compound	Number of Animals	Number Anesthesized	Average Duration of Anesthesia, min. ± *SD*	Time to Onset of Anesthesia, min.	Behavioral Alterations[a]
Pentobarbital					
RS	20	19	110 ± 24	3.1	+++
R(+)	10	1	35 ± —	10.0	+++
S(−)	10	10	114 ± 32	2.0	+++
3′-Hydroxypentobarbital					
1′*RS*,3′*RS*	10	0	— —	—	+
1′*RS*,3′*SR*	10	0	— —	—	+
1′*R*,3′*R*	10	0	— —	—	−
1′*R*,3′*S*	10	0	— —	—	−
1′*S*,3′*S*	10	0	— —	—	+
1′*S*,3′*R*	7	0	— —	—	+

[a] Indicates the magnitude: + = positive and − = none.

The behavior and time of onset and duration of anesthesia, measured as sleeping time, were observed. Each 3′-hydroxypentobarbital metabolite was further evaluated in five mice with a behavioral examination (10). This consisted of a systematic observation method for assessing the behavioral and physiological state of the mouse and its response to drugs. The pattern profile of various classes of pharmacological agents can be identified and differentiated, and the relative potency of members of the same class of drugs can be established. The dose volume used, 10 ml./kg. i.v., was administered *via* the tail vein.

The free acid was dissolved in 0.1 *M* aqueous sodium hydroxide to give the monosodium salt and diluted to appropriate volume with physiological saline.

RESULTS

The comparison of activity for *R*(+)- and *S*(−)-pentobarbital and the six 3′-hydroxypentobarbital derivatives of *RS*-pentobarbital is shown in Table I. Each compound was administered at 40 mg./kg. i.v.

The potency difference between the *R*(+)- and *S*(−)-pentobarbital is shown by the relative number of mice exhibiting sleeping by loss of the righting reflex. There is a slightly faster onset of action with the *S*(−)-form than with racemic pentobarbital. All *R*(+)-treated mice were very sedated; two of these mice just failed to meet the sleeping criterion of complete loss of the righting reflex for at least 1 min. None of the mice administered a 3′-hydroxypentobarbital metabolite was close to the sleeping criterion. However, the animals treated with the two racemic isomers as well as the two optically active metabolites having the 1′*S* configuration were sedated for approximately 1 hr. By using the screening test of the mouse's behavioral and physiological state, mice treated with 1′*RS*, 3′*RS*, 3′*SR*; and 1′*S*,3′*S* exhibited behavioral alterations of decreased awareness, increased positional passivity, and sedation. The onset of action is between 15 20 min. and lasts for approximately 1 hr. This screen is subjective, but the slight difference observed between the 3′-hydroxy metabolites indicates some variation in potency. The order of potency is: (1′*S*,3′*R*) > (1′*RS*,3′*SR*) > (1′*S*,3′*S*) > (1′*RS*,3′*RS*). The (1′*R*,3′*R*)- and (1′*R*,3′*S*)-isomers produced no behavioral or physiological alteration at 40 mg./kg.

DISCUSSION

The 3′-hydroxy metabolites are not pharmacologically inert as reported (11), but their activity is much less than that of the parent compound. When they are administered intravenously, some sedation occurs. Dickert *et al.* (5) reported that the (1′*RS*,3′*SR*)-isomer, given orally to mice at 1 g./kg., did not produce anesthesia or ataxia. They did, however, observe weak anticonvulsant activity. The ED_{50} in the maximal electroshock test was observed at 310 mg./kg. Their results (5) and the data reported here indicate that the activity profile of the 3′-hydroxybarbiturates is not identical to that of their parent compound. The difference found in the potency of *R*(+)- and *S*(−)-pentobarbital cannot be ascribed to differences in accumulations of these metabolites. Their potency difference could be due to differences in the rate of metabolism, binding properties, or relative penetration capacity to the receptor sites as well as other factors.

Effect of Addition of Sodium Salts to Salicylic Acid–Cetrimide System

LUCY S. C. WAN

Abstract □ The viscosity of salicylic acid–cetrimide systems was altered in the presence of sodium salts. The viscosity variation was associated with the degree of salicylic acid saturation of the surfactant solution and apparently not with the pH of the system. The increase in viscosity was probably due to formation of sodium salicylate by a reaction of the sodium additive with the acid and the interaction of this salicylate with the free cetrimide molecules in the system. The decrease in viscosity was attributed to the nonavailability of these surfactant molecules.

Keyphrases □ Salicylic acid–cetrimide systems—effect of sodium salts on viscosity □ Cetrimide–salicylic acid systems—effect of sodium salts on viscosity □ Sodium salts—effect on viscosity of salicylic acid–cetrimide systems □ Viscosity, salicylic acid–cetrimide systems—effect of sodium salts

In past studies, additives of various types such as polar and nonpolar solvents (1) and surfactants that are anionic (2), cationic, and nonionic (3) were added to salicylic acid–cetrimide systems similar to those in the present investigation and the resulting change in viscosity was measured. This change was found to differ with the type of additive. As a continuation of these studies of viscosity response to additives, the effect of aqueous solutions of electrolytes that are mainly alkaline in reaction on the macromolecules formed by the interaction of salicylic acid with cetrimide (4) was investigated. Sodium salts of carboxylic and phosphoric acids as well as sodium carbonate were used.

EXPERIMENTAL

Materials—Cetrimide BP[1] and recrystallized salicylic acid, m.p. 158–159°, were the same as those described previously (1). The following were used: sodium citrate[2]; sodium tartrate[3]; sodium acetate[3]; sodium pyrophosphate[4]; sodium phosphate, dibasic[4]; sodium phosphate, tribasic[4]; sodium phosphate, monobasic[4]; and sodium carbonate[4].

Measurement of Viscosity at 25°—The method described earlier (1) was adopted[5].

Measurement of pH—This was determined using a pH meter[6].

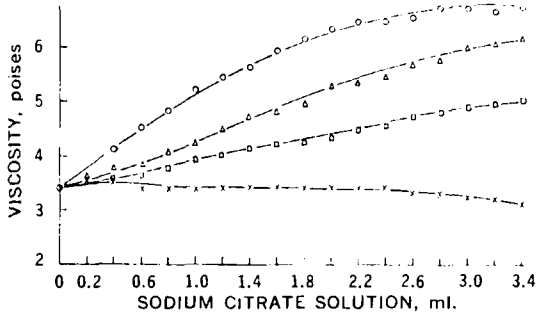

Figure 1—*Effect of sodium citrate solutions of varying concentration on the viscosity of systems containing 1.4% salicylic acid and 5% cetrimide (50 g.) at 25°. Key (sodium citrate, % w/v): ○, 10; △, 6; □, 4; and ×, 1. Shear rate = 78.56 sec.*$^{-1}$.

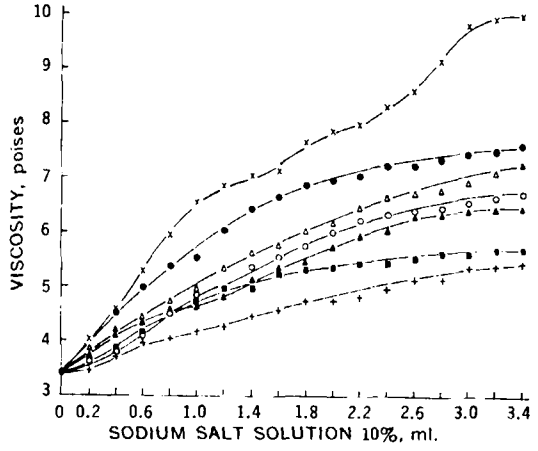

Figure 2 *Viscosity increase due to addition of sodium salt solutions (10% w/v) to systems containing 1.4% salicylic acid and 5% cetrimide (50 g.) at 25°. Shear rate = 78.56 sec.*$^{-1}$.

RESULTS AND DISCUSSION

Figure 1 shows the change in viscosity of salicylic acid–cetrimide systems with the addition of sodium citrate solutions of different concentrations. The viscosity increased in the presence of the sodium additive, the increase being higher with a greater volume of the salt solution. However, with a low concentration, a slight decrease in viscosity was noted. A similar rise in viscosity was found with

sodium acetate, sodium tartrate, sodium carbonate, and various sodium phosphates (Fig. 2). Increasing the total volume of sodium tartrate solution incorporated beyond the amount shown in Fig. 2 did not result in any further change, and the viscosity remained constant (Fig. 3). This situation also applied to the other sodium salts mentioned previously.

Sodium carbonate demonstrated the most marked viscosity effect (Fig. 2). This effect was found to be dependent on the amounts of salicylic acid and cetrimide present in the system, *i.e.*, the degree of saturation of the system. In related dispersions without additives, it was shown that, on the whole, maximum viscosity was attained at or near saturation (4). The viscosity behavior of systems consisting of the surfactant and such quantities of salicylic acid so as to produce undersaturated and oversaturated dispersions, when sodium carbonate solutions were added, was different in each type of system (Fig. 4). Where the salicylic acid concentration was less than that required for saturation, the viscosity alteration resembled that described previously. However, when the acid content exceeded what was necessary for saturation, there was a decrease or a small increase initially; subsequently, a reduction occurred, followed by a marked increase in viscosity. With sodium phosphate, dibasic, and sodium citrate solutions (Fig. 5), there was only a viscosity decrease in such systems and a rise in viscosity in those that were not saturated. The other sodium salts used also exhibited the same effect. The difference in behavior could be attributed to the fact that sodium carbonate is a strong alkali. This was supported by a similar viscosity variation observed when the sodium hydroxide solution was incorporated into identical systems.

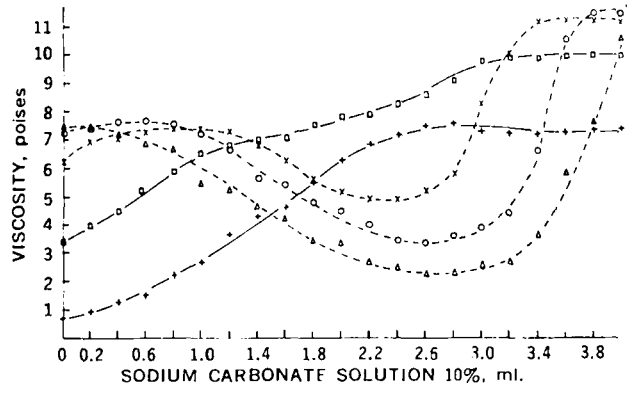

Figure 4—*Relationship between viscosity change and saturation of salicylic acid–cetrimide system (50 g.) in the presence of sodium carbonate solution (10% w/v) at 25°. Key (salicylic acid, % w/v): +, 1.2; □, 1.4; ×, 1.6; ○, 1.7; △, 1.8; ——, undersaturated; and - - -, oversaturated. Cetrimide = 5% w/v. Shear rate = 78.56 sec.$^{-1}$.*

In the presence of sodium salts, the pH values obtained differed from one additive to another and with varying volumes of the same salt solution (Table I). Compared to the effect of sodium carbonate in the corresponding system (Table II), the pH variation (2.45 to 6.95) of the latter was very marked. The pH of the systems in Table I is strongly acidic, although the additive solutions are alkaline in reaction (Table III), with the exception of sodium phosphate, monobasic. In those systems containing different amounts of salicylic acid, the increase was greater with undersaturated than with oversaturated systems (Table II). This is due to the lower concentration of salicylic acid in the former case. A comparison of the change in viscosity (Fig. 4) with those of pH (Table II) showed that pH increased with the sodium carbonate solution added, irrespective of whether there was an increase or a decrease in viscosity. This suggested that the alteration in viscosity was not associated directly with the pH of the system concerned.

A previous report (4) showed that salicylic acid interacts with cetrimide, resulting in the formation of a viscous product. In the current study, unsaturated systems contained insufficient salicylic acid to interact with all of the surfactant molecules, leaving free

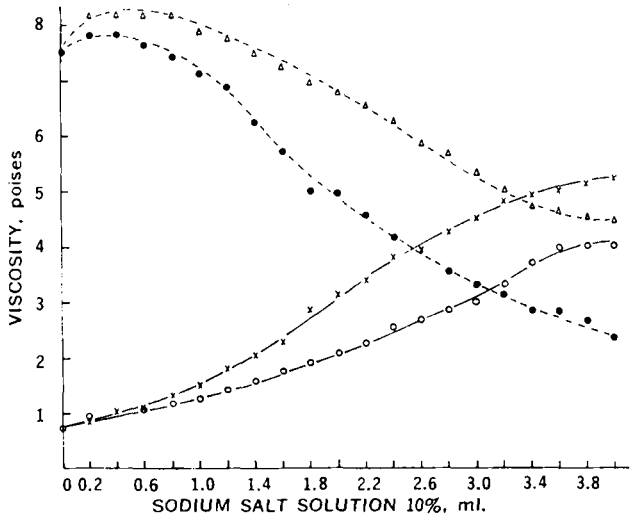

Figure 5—*Change in viscosity of salicylic acid–cetrimide systems (50 g.) that are oversaturated (salicylic acid 1.8% and cetrimide 5%) and undersaturated (salicylic acid 1.2% and cetrimide 5%) on addition of sodium citrate and sodium phosphate, dibasic, solutions (10% w/v) at 25°. Key: - - -, oversaturated; ●, sodium citrate; △, sodium phosphate, dibasic; ——, undersaturated; ×, sodium citrate; and ○, sodium phosphate, dibasic. Shear rate = 78.56 sec.$^{-1}$.*

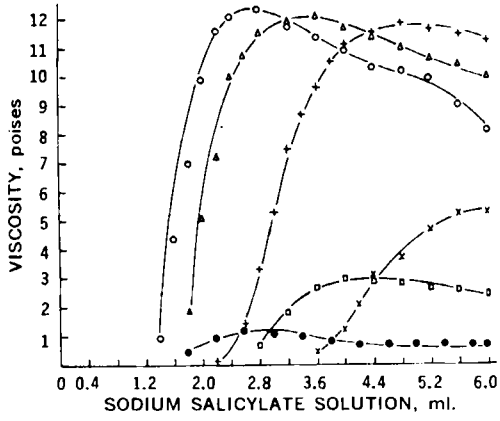

Figure 6—*Viscosity variation of a fixed concentration of cetrimide (5% w/v) with varying sodium salicylate solutions and a fixed concentration of sodium salicylate solution (10% w/v) with varying amounts of cetrimide at 25°. Key (sodium salicylate, % w/v): ○, 40; △, 30; and +, 20. Key (cetrimide, % w/v): ●, 1.0; □, 2.0; and ×, 3.0. Shear rate = 78.56 sec.$^{-1}$.*

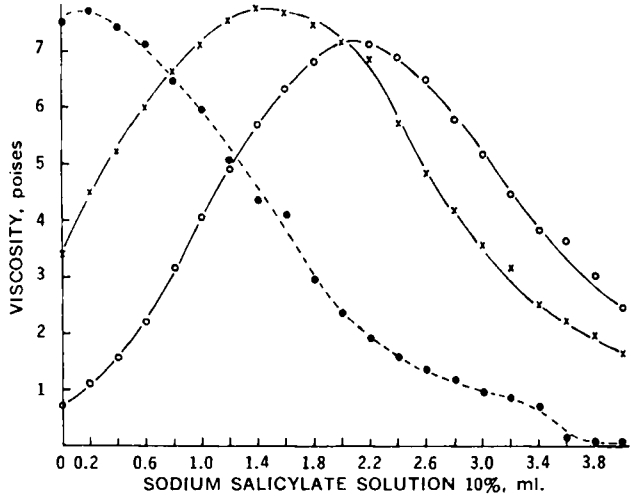

Figure 7—*Viscosity behavior of systems (50 g.) containing 5% cetrimide and different quantities of salicylic acid in the presence of sodium salicylate at 25°. Key (salicylic acid, % w/v): ●, 1.8; ×, 1.4; ○, 1.2; ——, undersaturated; and - - -, oversaturated. Shear rate = 78.56 sec.$^{-1}$.*

cetrimide molecules for possible reaction with the added sodium salt. However, it was found that the addition of sodium salts to cetrimide in the absence of salicylic acid produced no effect on the viscosity of the solution. Therefore, it is not likely that the observed increase in viscosity is brought about by a simple reaction involving only surfactant molecules and the sodium salt.

The increase in viscosity may be due to a reaction between the sodium additive and the salicylic acid, with the tendency to form sodium salicylate. This sodium salicylate will interact with the free cetrimide molecules in unsaturated systems to give rise to the high viscosity values determined, in the same manner as was found when sodium salicylate solutions were allowed to interact with the surfactant solution without the acid (Fig. 6). Variation of the sodium salicylate or cetrimide concentration in the interaction between these two compounds resulted in a viscosity increase followed by a decrease as the volume of sodium salicylate solution became larger. When the cetrimide concentration was increased to 5% to correspond with that used in the systems studied so far, no increase in viscosity was recorded even after 4 ml. of sodium salicylate solution was incorporated. This is because, with a greater amount of surfactant, more sodium salicylate is required to effect a change in viscosity, as can be seen in the viscosity behavior of the 5% cetrimide solution when different quantities of sodium salicylate were added (Fig. 6).

The viscosity reduction occurring in oversaturated dispersions could be caused by a change in the salicylic acid concentration due to a removal of the excess acid brought about by a reaction of the latter with the sodium additive. But since most surfactant in the system would have interacted with the acid, no increase in viscosity resulted. Further evidence in support of these suggestions can be obtained from the results shown in Fig. 7. In undersaturated systems, the viscosity increased in a similar manner to that due to the addition of sodium salts (Figs. 1 and 2). However, after reaching a maximum, the viscosity decreased. This reduction could be attributed to a loss of free cetrimide molecules from the system because of the interaction with sodium salicylate. In oversaturated dispersions, only a lowering in viscosity was produced, as was stated earlier in relation to sodium citrate and sodium phosphate, dibasic (Fig. 5), since surfactant molecules were not available for the interaction with sodium salicylate.

In the case where the sodium additive is a strong alkali, such as sodium carbonate, the pattern of viscosity response varied with the volume of sodium carbonate solution added (Fig. 4). When adequate solution of the alkali was included, the amount of salicylic acid remaining would no longer be in excess of that essential for saturating the cetrimide solution and hence the system was not likely to be oversaturated anymore. Subsequent additions of sodium carbonate solution, therefore, increased the viscosity in accordance with that which occurred in the undersaturated systems. With the other sodium salts used, even when the total volume of the additive solution was increased to 8 ml., no subsequent increase in viscosity was produced after a prior decrease in viscosity.

The findings of this study suggest that viscosity variation of salicylic acid–cetrimide systems in the presence of some sodium salts depends on the availability of free cetrimide molecules and the interaction of the resultant sodium salicylate with these surfactant molecules. It did not seem to be governed by pH.

Table III—pH of Solutions of Sodium Salts

Salt Solution	pH
Sodium citrate 1%	8.55
Sodium citrate 4%	8.6
Sodium citrate 6%	8.65
Sodium citrate 10%	8.75
Sodium tartrate 10%	8.0
Sodium acetate 10%	8.6
Sodium pyrophosphate 10%	10.5
Sodium phosphate, tribasic, 10%	11.95
Sodium phosphate, dibasic, 10%	9.45
Sodium phosphate, monobasic, 10%	4.9
Sodium carbonate 10%	10.75

Sodium Cyanate: Chemical Properties Relevant to Sickle Cell Disease Therapy

ROBERT F. LABBE

Abstract □ A purification procedure for sodium cyanate and some of its chemical properties relevant to clinical studies on sickle cell disease are described. In aqueous solution, sodium cyanate decomposes to ammonia and sodium bicarbonate, the latter being the only contaminant detected after purification. The rate of cyanate reaction with water increases with temperature, concentration, and decreasing pH. The most convenient method of sterilization is dry heat. Under the conditions of time, temperature, and concentration to which erythrocytes are most likely to be exposed in clinical application, sodium cyanate can be considered stable to aqueous solution, except for its reaction with proteins and other biological materials.

Keyphrases □ Sodium cyanate—purification, analysis, sterilization, stability □ Sickle cell disease—therapy, relevant chemical properties of sodium cyanate

In 1971, Nalbandian (1) proposed the use of urea in treating sickle cell disease. Since urea equilibrates with cyanate and cyanate carbamylates proteins, reactions that have been the bases of numerous chemical investigations, Cerami and Manning (2) hypothesized that cyanate was an active agent in the desickling of cells by urea. It has now been established that the two compounds act by different mechanisms. Urea disrupts hydrophobic bonds to cause a reversible desickling of erythrocytes. By contrast, cyanate carbamylates the four terminal valine residues of hemoglobin and possibly other sites to cause an irreversible desickling effect. Since the biological effects of sodium cyanate received little mention in the early literature (3), biochemical and pharmacological studies (4–8) are being conducted as a prelude to more extensive clinical testing of the compound as a possible therapeutic agent for sickle cell disease.

Clinical and toxicological investigations of cyanate have generally used the sodium salt, which is not commercially available in purified form. Recrystallization of sodium cyanate from alcohol is about the extent of information available on the subject of purification. Reactions of cyanate with water in alkaline and acidic conditions have been studied from kinetic and thermodynamic points of view (9, 10), but the chemistry of the compound relative to its handling and use as a drug has not been previously discussed. This report describes the purification of sodium cyanate and some chemical properties that pertain to its clinical application.

EXPERIMENTAL

Purification—Sodium cyanate of a technical grade was purchased[1] and had a supplier-indicated purity of 98% and water content of 0.5%. The compound was stated to have been prepared from urea and sodium carbonate. As obtained, the sodium cyanate was a slightly gray powder having some odor. The scale of the purification procedure developed can be adjusted to meet individual needs, but the amounts used here can be processed in common laboratory ware. Sodium cyanate is added with rapid stirring to water preheated to 60° (180 g./l.). Stirring is continued until the salt is completely dissolved but not for more than 5 min. The hot turbid solution is filtered as rapidly as possible through a preheated medium-porosity sintered-glass filter overlaid with a pad of cellulose[2]. The residue is washed with a small amount of 60° water. The filtrate is reheated to 60° and, while maintaining this temperature, 1.5 volumes of reagent grade methanol is added with rapid stirring; some sodium cyanate is salted out during the addition of the methanol. The solution is cooled and kept at 4° overnight. The sodium cyanate is removed in a precooled coarse sintered-glass filter. It is washed on the filter twice with cold methanol–water (3:2) and once with cold methanol; a volume equivalent to about one-tenth that of the original solution is used for each wash. The pure white sodium cyanate crystals are spread to facilitate rapid air drying at room temperature in a dust-free environment.

Cyanate Assay—The cyanate assay was based upon a method described by Werner (11) in which a blue copper–pyridine–cyanate complex is extracted into chloroform for colorimetric measurement. The original method, as improved by Marier and Rose (12) to gain sensitivity, was modified slightly for simplicity. To carry out the assay, up to 4.0 ml. of solution containing 5–50 μmoles of cyanate is placed in a glass-stoppered tube. Pyridine (0.1 ml.) and 0.1 *M* cupric sulfate (0.2 ml.) are added, and the volume is brought to 5.0 ml. with water. Chloroform (3.0 ml.) is added and the tube is shaken vigorously. After the phases separate, the chloroform layer is removed and its absorbance is read at 700 nm. The blank contains no cyanate. A calibration curve prepared using reagent grade potassium cyanate is shown in Fig. 1. From these data, it was determined that A_{700}/μmole cyanate = 0.0118. This assay is not suitable for use with biological fluids, a problem to be discussed more fully.

Bicarbonate and Cyanide Assays—The bicarbonate assay is a simple gravimetric procedure in which the sample is placed in a closed, evacuated system; then carbon dioxide is released with 1 *N* sulfuric acid and trapped in barium hydroxide. The formed barium carbonate is removed, washed with water and ethanol, dried, and weighed as a measure of the bicarbonate present in the original sample. The releasing and trapping of carbon dioxide are carried out quickly, and no error due to the acid-catalyzed conversion of cyanate was detectable. Cyanide was assayed by the method of Aldridge (13). Interference was encountered when large amounts of cyanate were used to assay for cyanide in the purified material. To a limited extent, this problem could be solved by increasing the amount of bromine, the excess of which was readily removed with arsenious acid as described by Aldridge.

RESULTS

The yield from the purification procedure was about 70% (126 g./l.). The product of the essentially one-step process has proven suitable for clinical use[3].

Despite the fact that the Aldridge cyanide assay is not entirely specific (14) and that cyanate prepared from urea probably should not contain cyanide (12), testing for the presence of this highly toxic substance seemed justified. Assay of the commercial sodium cyanate showed a cyanide content of 1030 p.p.m. The purified material had less than 2 p.p.m., the lowest level that was detectable by the assay used.

[1] K & K Laboratories, Plainview, NY 11803

[2] The commercial sodium cyanate contained sufficient insoluble material that an unprotected sintered-glass filter became clogged quickly. To alleviate the problem, a cellulose slurry was prepared by blenderizing some soft filter paper in water and using this to form a protective covering on the filter.

[3] Personal communication, E. E. Langer.

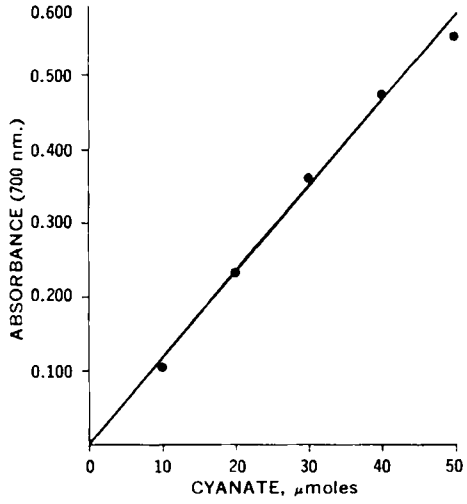

Figure 1—*Cyanate standard curve.*

A 3 *M* solution of the commercial sodium cyanate showed a slight broad absorbance at 266 and 285 nm. Contaminants responsible for this absorbance were undetectable after purification.

Occasionally, purified preparations had a distinct odor of ammonia due to the reaction (Scheme I) of cyanate with residual moisture:

$$NCO^- + 2H_2O \rightarrow NH_3 + HCO_3^-$$

Scheme I

In a series of purified preparations, the sodium cyanate assayed 93–100%, with a mean of 97%. Several preparations falling throughout this range of cyanate values were assayed for sodium bicarbonate. In every case, the remaining percentage could be fully accounted for as sodium bicarbonate.

The thermal stability of a purified and thoroughly dried sodium cyanate sample was demonstrated by heating at 200° for 2 hr. with no detectable loss. However, in aqueous solution, cyanate is quite unstable to heat. Autoclaving at 250° for 20 min. resulted in a 30% loss from a 0.01 *M* solution and a 65% loss from a 0.1 *M* solution. By contrast, a 0.1 *M* solution at 38° was far more stable (Fig. 2).

Cyanate stability was also very dependent upon concentration, as shown by the time course of decomposition at 38° in an aqueous solution (Fig. 2). A 0.1 *M* solution decomposed only 4% while a 1.0 *M* solution decomposed 79% in 29 hr. A 2.0 *M* solution lost cyanate at about twice the rate of the 1.0 *M* solution. Saturated sodium cyanate held at 60° as in the purification process decomposed to the extent of 90% in 3 hr. The rates of decomposition always began slowly, increased during the early phase of the reaction, and then remained linear until the reaction was nearly completed.

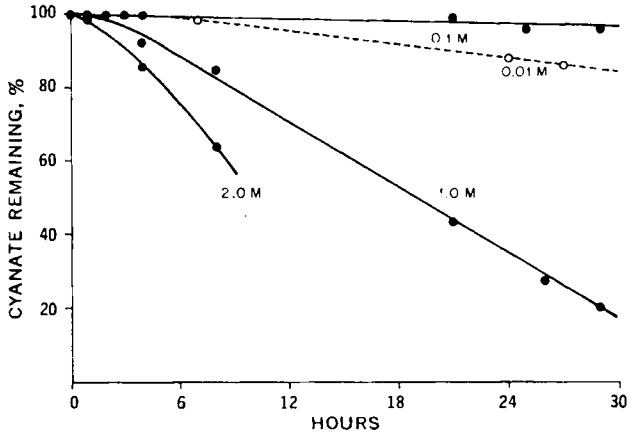

Figure 2—*Cyanate stability. The curves represent the rates of decomposition of sodium cyanate at 38° in aqueous solution. Key: ——, rates at pH 9.8; and ---, rates at pH 7.0.*

Most stability studies were with unbuffered solutions in the range of pH 9.2–9.8. At low pH, cyanate reacted with water more rapidly. This effect was observed in 0.1 *M* *N*-ethylmorpholine buffer at pH 7.0 where 0.01 *M* sodium cyanate at 38° decomposed to the extent of 12% in 29 hr. and 45% in 120 hr. At 4°, no detectable loss occurred in 120 hr.

DISCUSSION

Although the purification of sodium cyanate gave only a 70% yield, it is a simple and rapid procedure. Of the incurred loss, about one-third was due to retention in the methanol-water solvent (19 g./l.). The only by-product identified was sodium bicarbonate. The essentially total removal of cyanide indicated the effectiveness of the purification.

The cyanate assay, as modified from the Werner method (11), was moderately sensitive and very satisfactory for aqueous solutions. The reaction was unaffected by cyanide or thiocyanate. The major limitation of the assay was due to interference from many components found in biological materials. Cupric ions reacted with some common buffers such as phosphate and tromethamine to interfere with the formation of the colored complex. Protein not only interfered with complex formation but also removed cyanate during the deproteinization process. For these reasons, the assay cannot be performed in the presence of biological materials, in which case the use of isotopically labeled cyanate appears to be the best available method.

For clinical application, sodium cyanate often must be sterilized. One of two possibilities appears useful. An appropriate solution can be freshly prepared and filter sterilized. Alternatively, purified and thoroughly dried sodium cyanate is extremely stable to heat, withstanding temperatures to 700° (15). Therefore, the compound can be heat sterilized in vials for the preparation of solutions at the time and in the concentration needed. The latter method has the advantage that sterile sodium cyanate can be stored indefinitely and be available at all times.

The reaction of free cyanate with water to produce ammonia and bicarbonate probably occurs *in vivo*, as evidenced by Cerami's (7) findings in a mouse experiment. The animal was injected with $NaO^{14}CN$; during the following 24 hr., 72% of the radioactivity was recovered as $^{14}CO_2$. In the concentrations that might be anticipated clinically, neither of the breakdown products would likely be of serious consequence.

The accumulation of bicarbonate as cyanate reacts with water may be responsible for the increasing decomposition rate seen during the initial phase of the reaction. Lister (16) noted that carbonate ions can catalyze the decomposition of cyanate in alkaline solution. The effects of concentration, temperature, and pH on cyanate stability qualitatively parallel the reaction rate constants reported by Hagel *et al.* (9) for similar experimental conditions. Thus, in the concentrations, at the temperatures, and for the times to which erythrocytes would likely be exposed in clinical use, cyanate can be considered stable toward reaction with water and should remain available for carbamylation of hemoglobin.

Distribution of Aspirin in Rumen and Corpus Tissues of Rat Stomach during First Four Minutes after Administration

CLARENCE H. MORRIS[A], JOHN E. CHRISTIAN, ROBERT R. LANDOLT, and WARREN G. HANSEN

Abstract □ Autoradiography was used to determine the distribution of aspirin and/or its metabolites in the mucosa, submucosa, and muscularis of the rumen (nonglandular portion) and corpus (glandular portion) tissues of the rat stomach 4 min. after administration. A significant localization of aspirin and/or its metabolites was observed in the submucosa regions of both the rumen and corpus. In addition, the innermost portion of the rumen mucosa acted as a barrier toward absorption when compared to the corpus mucosa. This factor may be important in the mechanism of lesion production in the corpus tissue and the lack of lesion production in the rumen.

Keyphrases □ Aspirin (and metabolites), distribution—rumen and corpus tissues, rat stomach, 4 min. after administration □ Gastric lesions—aspirin (and metabolites) distribution 4 min. after administration, rumen and corpus tissues, rat stomach, histoautoradiography □ Autoradiography—aspirin (and metabolites) distribution 4 min. after administration, rumen and corpus tissues, rat stomach

Several mechanisms have been proposed to explain the production of gastric lesions by salicylates (1, 2). Davenport (3) and Martin (4) developed chemical models based on interaction of the compound with cellular constituents following absorption of the compound into the cell.

Previous studies (5) showed that some rats develop gastric lesions in the corpus portion of the stomach within 5 min. following oral administration of aspirin. Lesions have not been produced in the rumen under the same experimental conditions. Therefore, it was of interest to compare the relative quantities and distribution of aspirin and/or its metabolites in the mucosa, submucosa, and muscularis of the rumen and corpus tissues of the rat stomach shortly after oral administration of aspirin-7-^{14}C.

MATERIALS AND METHODS

Aspirin was administered to rats as previously described (6), with the exception that each animal received 0.01 mc. (0.93 mg.) of aspirin-7-^{14}C.

Preparation of Emulsion Slides—Standard size microscope slides were cleaned by soaking for 24 hr. in a 10% solution of dichromic acid. Following the acid bath, the slides were washed in flowing tap water for 1 hr. followed by two consecutive 30-min. rinses in distilled water. The slides were then dipped in a subbing solution (5 g. gelatin and 0.5 g. of chrom alum in enough water to make 1000 ml.) and dried vertically. Next, the slides were dipped into a liquid emulsion[1], previously warmed to 43°. This work was performed under a safelight[2]. The slides were withdrawn from the emulsion at a uniform rate and checked under the safelight to ensure that the emulsion was uniformly distributed and free from bubbles, and the moist emulsion was wiped from one side. Then the slides were placed in a test tube rack in a vertical position and allowed to dry. After drying, the slides were placed in light-tight boxes and stored at −20° until used.

Tissue Cutting and Mounting—The entire stomach was removed from the animal 2 min. after oral administration. Four minutes after oral administration, the entire stomach was frozen in liquid nitrogen. From this point until development of the autoradiograms, the tissues remained frozen to prevent relocation of the aspirin and/or its metabolites. Cross-sectional segments of rumen and corpus were cut from the stomach, with a cold scalpel, and mounted on a previously cooled brass block using a drop of mounting medium[3]. After equilibration at −15°, 10-μ sections of rumen and corpus were cut with a microtome mounted in a cryostat[4]. The sections were transferred under the safelight from the microtome blade to the emulsion slides (also maintained at −15°). The mounted tissue sections were stored in light-tight boxes at −20° for 9–18 days to allow exposure of the photographic emulsion.

Photographic Processing of Liquid Emulsion Slides—All solutions were maintained at 4° throughout the photographic processing to reduce the possibility of detachment of the tissue from the emulsion. The most satisfactory staining was obtained if the tissue was fixed in methanol. The slides were then developed[5] for 10 min., rinsed in distilled water for 1 min., fixed[6] for 15 min., and rinsed in distilled water for 30 sec.

Staining Techniques—The tissue sections were stained with lithium carmine followed by picric acid, as described by Witten and Holstrom (7). All solutions were maintained between 10 and 15°. After the slides were removed from the final xylene bath, coverslips were mounted with Canada balsam.

RUMEN

CORPUS

Figure 1—*Photomicrogram of cross section of rumen and corpus tissues, showing the (1) serosa, (2) muscularis, (3) submucosa, (4) mucosa, and (5) lumen.*

Grain Counting—The distribution of ^{14}C-compounds in the lumen, mucosa, submucosa, and muscularis regions of the rumen and corpus tissues (Fig. 1) was measured by counting grains of silver in the emulsion. A grid of 25 fields of 100 μ^2 each was optically superimposed over each region (Fig. 2) and the net number of grains per unit area was determined from each field in the emulsion below the following regions: (*a*) lumen, (*b*) mucosa along the mucosa–lumen interface, (*c*) mucosa along the mucosa–submucosa interface, (*d*) submucosa, and (*e*) muscularis. Grains were counted in two rumen and two corpus sections from each of two animals. In addition, the percentage of the net number of grains per unit area in each region relative to the net number of grains per unit area in the lumen was determined. Student's *t* test was used to determine the significance of the difference between the means of the net grains per unit area between the mucosa along the mucosa–submucosa interface and the submucosa. The *F* test was made prior to the *t* tests to test for homogenicity of variance. When the variances were not homogeneous, an adjusted *t* value was calculated from the formula developed by Cochran and Cox (8).

RESULTS

The distribution of aspirin and/or its metabolites in the mucosa, submucosa, and muscularis regions of the rumen and corpus tissues is presented in Table I. An increase in net grains per unit area is shown in the submucosa of each section from both rumen and corpus when compared to the mucosa. This increase is significant at the 99.9% confidence level as determined by the Student *t* test. In addition, by comparing rumen and corpus values of the average percent in each region relative to the lumen, it is evident that the rumen mucosa along the mucosa–lumen interface acts as a barrier against the absorption of aspirin and its metabolites. The quantities of labeled compounds found in the mucosal and submucosal regions of the corpus are significantly higher (at the 95% confidence level) than the quantities found in the corresponding regions of the rumen; however, quantities found in the muscularis regions of the rumen and corpus are not significantly different from each other.

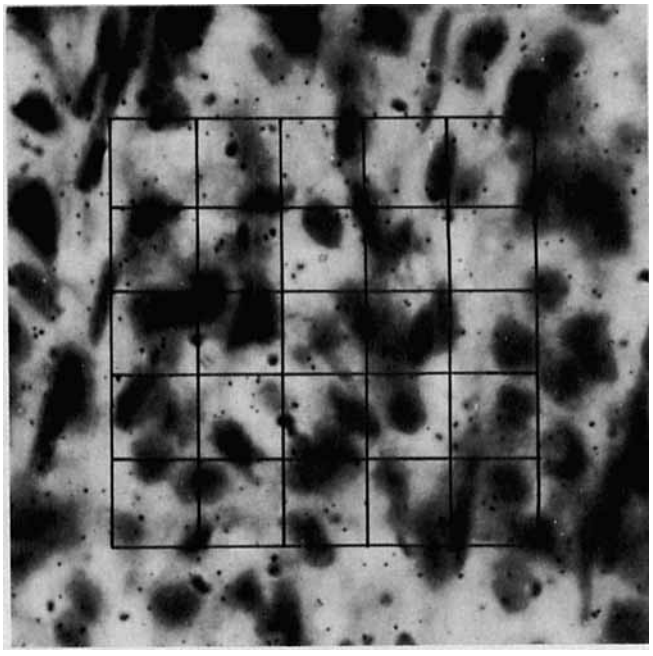

Figure 2—*Photomicrogram of a typical histoautoradiogram, showing silver grains in the emulsion below the corpus mucosa. Each small square of the grid has an area of 500 μ^2. Since the microscope was focused on the silver grains, the tissue appears to be slightly out of focus.*

DISCUSSION

Histoautoradiography showed that the rumen mucosa acted as a barrier toward absorption of aspirin and/or its metabolites, whereas the corpus tissue permitted much higher levels of penetration. In addition, there was a significant increase in aspirin (and/or metabolite) levels in the submucosa of the rumen and corpus tissue than in the other regions. In another study (6), significantly higher levels of salicylic acid were found in the corpus tissue than in the rumen tissue. Finally, it has been shown (5, 9) that lesions appear in the corpus portion but not in the rumen portion of the stomach following oral administration of aspirin. Taking these observations into consideration, one might speculate that the mechanism of lesion production is a function of absorption of aspirin and the subsequent

Table I—Average Net Grains per Field in Rumen and Corpus Tissue

Region	Corpus		Rumen	
	Mean Grains per Unit Area	Percent Relative to Lumen[a]	Mean Grains per Unit Area	Percent Relative to Lumen
Lumen	85.3	100	110.8	100
Mucosa at mucosa–lumen interface	22.0	25.7	2.5	2.2
Mucosa at mucosa–submucosa interface	6.8	7.9	2.0	1.8
Submucosa	23.3	27.3	11.2	10.1
Muscularis	3.7	4.3	2.5	2.2

[a] Average percent of the net number of grains in each region of the tissue as compared to the average net number present in the lumen.

hydrolysis of aspirin to salicylic acid within the corpus tissue. One might also speculate that the submucosa may be the site of the initial injury due to the apparent buildup of aspirin and metabolites at that level.

Effect of Adsorbed Surfactant on Particle–Particle Interactions in Hydrophobic Suspensions

J. V. BONDI*, R. L. SCHNAARE▲, P. J. NIEBERGALL, and E. T. SUGITA

Abstract □ The degree of flocculation of sulfamerazine suspensions as represented by relative sedimentation volume was determined as a function of both surfactant and electrolyte concentration. The results emphasize the importance of knowing the location as well as the concentration of the surfactant and are consistent with the Derjaguin, Landau, Verwey, and Overbeek theory.

Keyphrases □ Suspensions, hydrophobic (sulfamerazine)—degree of flocculation, relative sedimentation volume, effects of surfactant (sodium dodecyl polyoxyethylene sulfate) and electrolyte concentration □ Surfactants (sodium dodecyl polyoxyethylene sulfate)—effect on particle–particle interactions in hydrophobic (sulfamerazine) suspensions □ Sodium dodecyl polyoxyethylene sulfate—effect on flocculation of sulfamerazine suspensions □ Sulfamerazine suspensions—effect of adsorbed surfactant on particle–particle interactions □ Flocculation, sulfamerazine suspensions—effects of surfactant and electrolyte concentration

Controlled flocculation has been the subject of many papers over the past 15 years (1–5). Haines and Martin (1, 2) suggested that suspension flocculation can be controlled by modifying the charge surrounding suspended hydrophobic particles by the addition of electrolyte. For example, the addition of aluminum chloride to 2% sulfamerazine suspensions containing dioctyl sodium sulfosuccinate reduced the ζ-potential essentially to zero, producing pharmaceutically stable suspensions characterized by high final sedimentation volumes.

Wilson and Ecanow (3) took issue with the work of Haines and Martin for several reasons: (*a*) since flocculation was reported to have occurred spontaneously, the true ζ-potential could not have been measured; (*b*) it was unlikely that van der Waals' forces would be operative with particles greater than 2–5 μm.; and (*c*) the effect of electrolyte on the surfactant was not taken into account. During a subsequent investigation, they observed the formation of a precipitate when dioctyl sodium sulfosuccinate at concentrations used by Haines and Martin was mixed with aluminum chloride. Flocculation was interpreted as being due to a chemical reaction between the surfactant and the electrolyte instead of a reduction of the ζ-potential.

Matthews and Rhodes (4–6) studied suspensions of sulfamerazine and griseofulvin prepared with sodium lauryl sulfate, which is precipitated by aluminum chloride, and sodium dodecyl dioxylated sulfate, which apparently is not precipitated by aluminum chloride. The addition of aluminum chloride to both suspensions resulted in aggregation. Different sedimentation rates were observed; however, final sediment heights were identical. They interpreted the aggregation mechanism as "flocculation" for the suspension containing sodium lauryl sulfate and as "coagulation" for the suspension containing sodium dodecyl dioxylated sulfate. Ecanow *et al.* (7) claimed that both suspensions were "flocculated" on the basis of equal final sediment volumes and sediment compressibility. The difference in sedimentation rate was considered to be a function of aggregate structure, number, and geometry.

Two possible mechanisms have been proposed to explain flocculation (8–10): absorption bridging by the surfactant between suspension particles and cross-linking of suspension particles produced by metal-ion interactions with the adsorbed surfactant. Coagulation is an aggregation process resulting from a reduction in the ζ-potential to a point where attractive forces predominate. The aggregate is dense and nonporous and forms a caked sediment.

hydrolysis of aspirin to salicylic acid within the corpus tissue. One might also speculate that the submucosa may be the site of the initial injury due to the apparent buildup of aspirin and metabolites at that level.

[a] Sodium dodecyl polyoxyethylene sulfate. [b] Initial concentration equal to the CMC in pure water.

Another possible mechanism for flocculation is aggregation at relatively large interparticle distances as predicted by the Derjaguin, Landau, Verwey, and Overbeek (DLVO) theory (6, 11–13). Coagulation is interpreted as aggregation in the primary minimum, resulting in a closely packed, tightly bound aggregate; flocculation is interpreted as aggregation in the secondary minimum, resulting in a loose, weakly bound network. An attractive feature of such an explanation is an allowance for electrolyte effects other than chemical interactions.

This article reports investigations on suspension aggregation and offers the following observations on sulfamerazine suspensions.

EXPERIMENTAL

The surfactant, sodium dodecyl polyoxyethylene sulfate, supplied as a 50% hydroalcoholic solution[1], was purified by diluting with acetone to precipitate the inorganic salts present, filtering, and removing the solvents by vacuum distillation. The purified surfactant as an oil was diluted to a known volume with water and standardized with benzethonium chloride according to the method described by Epton (14) and modified by Weatherburn (15). All concentrations of the surfactant are expressed as equivalents of benzethonium chloride per liter, since the exact molecular weight is not known.

Sulfamerazine[2] powder was used as received. The mean volume surface diameter and specific surface area were determined[3] to be 2.48 μm. and 1.77 m.²/g., respectively. Adsorption isotherms of the surfactant on sulfamerazine were determined at three concentrations of sodium chloride and in pure water. Thus, it was possible to prepare suspensions in which the relative concentrations of the surfactant adsorbed and free in solution were known.

Suspensions were prepared by adding a known volume of the surfactant solution to a weighed quantity of sulfamerazine powder. The mixture was stirred continuously for 16 hr., at which time it was transferred to a glass sedimentation tube having an inside diameter of 1.9 cm. The suspensions fell into one of three categories: Series A, prepared at various electrolyte concentrations and an initial concentration of surfactant equal to the critical micelle concentration (CMC) of the surfactant in water; Series B, prepared at various electrolyte concentrations and at surfactant concentrations such that the particle surface was saturated with surfactant; and Series C, prepared at constant electrolyte concentration and various surfactant concentrations.

RESULTS AND DISCUSSION

The Series A suspensions in Table I were prepared with an initial concentration of surfactant equal to the CMC in water. Consequently, the surface of the particles was only partially covered with surfactant. A very high relative sediment volume, H_u/H_0, was observed, indicating a large degree of aggregation. The sediment was very loosely packed, and the supernate was clear, indicating flocculation.

Cross-linking of surfactant by metal ions, shown to occur with aluminum ion and sodium dodecyl sulfosuccinate and sodium lauryl sulfate (3, 4), seems an improbable explanation for the flocculation of Series A suspensions considering the high degree of flocculation at zero sodium chloride concentration. Such a mechanism would also demand a dependence of H_u/H_0 on electrolyte concentration, which is obviously absent. Adsorption bridging would allow for the lack of dependence on electrolyte concentration but seems an unlikely mechanism for a charged surfactant.

There remains the flocculation mechanism as described by the DLVO theory. The high degree of flocculation at zero electrolyte concentration indicates very little, if any, charge repulsion between particles, *i.e.*, a very small or zero ζ-potential. Such a condition would result only from a very low charge density on the particles which follows from the low initial concentration of surfactant. The DLVO theory predicts that at low ζ-potential and/or relatively large distances, particle particle interactions would be insensitive to electrolyte concentration (16, 17).

The Series B suspensions, by contrast, were prepared at surfactant concentrations such that the particle surface was completely saturated. It follows that the surface charge or ζ-potential at zero electrolyte concentration would be considerably higher than that of the corresponding Series A suspension. This was evidenced by the reduced degree of flocculation, as indicated by the lower relative sedimentation volume.

The addition of 0.24 *M* sodium chloride resulted in a dramatic decrease in the relative sedimentation volume. The sediment was dense (centrifugation reduced H_u/H_0 to 0.14) and the supernate was cloudy, indicative of either a monodispersed or a coagulated system. The sedimentation rate was the slowest of the series, again indicating either a monodispersed (11) or a coagulated suspension, depending on whether flow is laminar or turbulent (9).

Considering that the particles have a negative charge at zero electrolyte concentration:

1. The addition of sodium chloride could increase the adsorption of the surfactant such that at 0.24 *M* electrolyte the ζ-potential is sufficient for a monodispersed state. That adsorption is increased is evident from the data in Table I. Also, the neutralization of charge by counterions would have to be negligible. Electrolyte addition beyond 0.24 *M* would progressively increase adsorption and cause neutralization of the negative charge, with the net effect being a degree of flocculation.

2. The addition of sodium chloride could neutralize the charge on the particles essentially to zero, resulting in a coagulated system. Further addition of electrolyte would charge the particles by adsorption of counterions, reestablishing a degree of flocculation.

It would be impossible to distinguish between these two explanations without further experimental observations. The ζ-potential would go through a maximum in the first and a minimum in the second. The DLVO theory does, however, offer a possible explanation for the behavior of the Series B suspensions, whereas cross-linking does not seem to be applicable.

A similar comparison is found for the Series C suspensions. Cross-linking would predict a direct relationship between the surfactant concentration and H_u/H_0. The inverse relationship found experimentally is explainable within the framework of the DLVO theory. An increase in surfactant concentrations would increase the surface charge and decrease the degree of flocculation.

It is obvious from these observations that the effect of electrolytes

on flocculation behavior depends not only on the surfactant concentration but also on the location of the surfactant and the degree of surface coverage by the surfactant. Electrolyte effects at one surfactant level can be eliminated or even reversed by changing the surfactant concentration.

It is also suggested that aggregation in a secondary potential energy minimum as described by the DLVO theory is a valid mechanism for interpreting flocculation. Flocculation mechanisms would then be classified as: (*a*) adsorption bridging, (*b*) cross-linking or chemical bridging, and (*c*) DLVO aggregation (secondary minimum). And coagulation would be defined by: (*a*) film–film bonding, and (*b*) DLVO aggregation (primary minimum).

Synthesis and Antifungal Activity of Polyhalophenyl Esters of Nitrocarbanilic Acids VI

I. LALEZARI▲, G. MOHTAT, F. AFGHAHI, and M. ALILOU

Abstract □ Twenty-two polyhalophenyl esters of *meta*- and *para*-nitrocarbanilic acids were synthesized and tested for antifungal activity against *Candida albicans*, *Penicillium notatum*, and *Aspergillus fumigatus*. The 2,4,6-trichlorophenyl ester of *m*-nitrocarbanilic acid was found to be the most active compound.

Keyphrases □ Nitrocarbanilic acids, polyhalophenyl esters—synthesis, antifungal activity □ Polyhalophenyl esters, nitrocarbanilic acids—synthesis, antifungal activity □ Antifungal agents, potential—synthesis and testing of 22 polyhalophenyl esters of nitrocarbanilic acids

In continuing research with the syntheses of new carbamic acid derivatives (1–5) with antifungal activity, a series of polyhalophenyl esters of *meta*- and *para*-nitrocarbanilic acids was prepared by interaction (Scheme I) of the corresponding nitrobenzoyl azide

$$NO_2C_6H_4CON_3 + ArOH \xrightarrow{\text{refluxing toluene}} NO_2C_6H_4NHCO_2Ar + N_2$$

Scheme I

with polyhalophenols in refluxing toluene, and physical data were compiled (Table I).

All prepared compounds were tested against *Candida albicans* 28012, *Penicillium notatum* S-13, and *Aspergillus fumigatus* CDC 24[1] *in vitro* using BBL Sabouraud dextrose agar medium.

Each compound was tested at 5, 10, and 25 mcg./ml. All compounds were dissolved in acetone at a concentration of 5 mg./ml. These solutions were diluted with hot culture medium to the desired concentrations and autoclaved at 120° for 2 hr. Five replicates of each concentration were prepared.

The antifungal activity of all compounds tested except XIX and XX was insignificant at a concentration of 5 mcg./ml. Compounds XII and XV showed only slight growth inhibition at concentrations of 25 mcg./ml. (Table II).

EXPERIMENTAL[2]

m-Nitrocarbanilic acid *p*-tolyl ester was prepared as follows. *m*-Nitrobenzoyl azide (1.92 g., 0.01 mole) in 20 ml. of dry toluene was refluxed for 2 hr. To the boiling mixture, *p*-cresol (1.08 g., 0.01

[1] Microorganisms were obtained from the Department of Parasitology, Public Health Institute, Tehran, Iran.

[2] Melting points were taken on a Kofler hot stage microscope and are uncorrected. The IR spectra were determined with a Leitz spectrograph model III. NMR spectra were obtained on a Varian A 60A instrument. Mass spectra were recorded on a Varian Mat 111 instrument. *m*- and *p*-Nitrobenzoyl azides were prepared according to Curtius *et al.* (6).

on flocculation behavior depends not only on the surfactant concentration but also on the location of the surfactant and the degree of surface coverage by the surfactant. Electrolyte effects at one surfactant level can be eliminated or even reversed by changing the surfactant concentration.

It is also suggested that aggregation in a secondary potential energy minimum as described by the DLVO theory is a valid mechanism for interpreting flocculation. Rapid, Simultaneous GLC Determination of Phenobarbital, Primidone, and Diphenylhydantoin

ROBERT J. PERCHALSKI*, K. N. SCOTT*†, B. J. WILDER*†▲, and R. H. HAMMER‡

Abstract □ A rapid method is described for the simultaneous determination of phenobarbital, primidone, and diphenylhydantoin. The method gives greater sensitivity and reproducibility for phenobarbital and primidone than the short methods now in use, maintains the efficiency of much longer techniques, and takes only 45 min. from the time the sample is received until the results are reported.

Keyphrases □ Phenobarbital—rapid, simultaneous GLC determination with primidone and diphenylhydantoin □ Primidone—rapid, simultaneous GLC determination with phenobarbital and diphenylhydantoin □ Diphenylhydantoin—rapid, simultaneous GLC determination with phenobarbital and primidone □ GLC—rapid, simultaneous determination of phenobarbital, primidone, and diphenylhydantoin

Since the introduction of the on-column methylating reagents, tetramethylammonium hydroxide (1, 2) and trimethylphenylammonium hydroxide (3), the extraction and GLC analysis of anticonvulsant drugs have been greatly simplified. These reagents are normally used as either a dilute (0.1–0.2 *M*) solution (4, 5) or a concentrated (24%) solution (6, 7) in methanol. The methods published to date concerning two of the three primary anticonvulsants, phenobarbital and primidone, are lacking in sensitivity or reproducibility or the extraction time required is unnecessarily long.

This paper describes a combination of two methods (5, 6) which increases the sensitivity and reproducibility of the analysis of phenobarbital and primidone and also decreases the time necessary to give a clean, efficient extraction.

EXPERIMENTAL

Apparatus—A gas chromatograph[1] with four flame-ionization detectors was used for the determinations. The column was a 1.82-m. (6-ft.) by 2-mm. i.d. glass U-tube packed with 3% OV-17 (phenyl methyl silicone oil) on 80–100-mesh Chromosorb W-HP. The injection port was heated to 360° and the detector to 260°. The column temperature was programmed from 140 to 220° at 8°/min. The carrier gas flow rate was adjusted to around 60 ml./min. to give a retention time of 5.0 ± 0.2 min. for methylated diphenylhydantoin at 220°.

Reagents—Trimethylphenylammonium hydroxide[2] was available as a 0.1 *M* solution in methanol; it was concentrated to 1.5 *M* under dry nitrogen over low heat. 5-(*p*-Methylphenyl)-5-phenylhydantoin[3] (I) and phenylethylmalonamide[4] were also used.

Procedure—One milliliter of plasma, 0.50 ml. of the internal standard (20 mg. I diluted to 500 ml. with 0.1 *N* NaOH), 0.5 ml. 0.1 *N* NaOH, 0.5 ml. of a 1.0 *M* H_3PO_4 buffer, pH 2.7, and 13 ml. of ether were combined in a 50-ml. centrifuge tube. The tube was sealed by wetting the ground-glass portion of the stopper with distilled water before insertion, shaken mechanically for 10 min., and centrifuged at 2000 r.p.m. for 1 min. The ether was transferred to a 15-ml. conical centrifuge tube and evaporated under nitrogen at 50°. The residue was taken up in 5 ml. of toluene, and 50 μl. of 1.5 *M* trimethylphenylammonium hydroxide was added. The tube was shaken for 1 min. and then centrifuged for 2 min.; 1 μl. of the lower phase was injected into the chromatograph.

Drug levels were determined from a standard curve of the peak height ratio of the drug to the internal standard *versus* concentration. Phenobarbital levels were determined by summing the heights of the three peaks shown in Fig. 1 after adjusting to constant peak width. The total phenobarbital (Pb) peak height is given by Eq. 1:

$$h_{Pb} = \frac{w_1}{w_3}h_1 + \frac{w_2}{w_3}h_2 + h_3 \qquad \text{(Eq. 1)}$$

where h is the height and w is the width at half height of the peaks shown by the subscripts. The peak width ratios are constant for any given set of chromatographic conditions.

RESULTS AND DISCUSSION

The chromatogram of an extracted sample containing therapeutic levels of phenobarbital, primidone, and diphenylhydantoin, along with an extraction of standard plasma, is shown in Fig. 1. The first two phenobarbital peaks shown in this figure are produced in the chromatograph during on-column methylation with 1.5 *M* trimethylphenylammonium hydroxide. They are also the only peaks produced by methylation of the total product of the aqueous alkaline hydrolysis of phenobarbital. GLC and NMR studies of these two products indicate that they are methylated derivatives of phenyl-

Rapid, Simultaneous GLC Determination of Phenobarbital, Primidone, and Diphenylhydantoin

ROBERT J. PERCHALSKI*, K. N. SCOTT*†, B. J. WILDER*†▲, and R. H. HAMMER‡

Abstract □ A rapid method is described for the simultaneous determination of phenobarbital, primidone, and diphenylhydantoin. The method gives greater sensitivity and reproducibility for phenobarbital and primidone than the short methods now in use, maintains the efficiency of much longer techniques, and takes only 45 min. from the time the sample is received until the results are reported.

Keyphrases □ Phenobarbital—rapid, simultaneous GLC determination with primidone and diphenylhydantoin □ Primidone—rapid, simultaneous GLC determination with phenobarbital and diphenylhydantoin □ Diphenylhydantoin—rapid, simultaneous GLC determination with phenobarbital and primidone □ GLC—rapid, simultaneous determination of phenobarbital, primidone, and diphenylhydantoin

Since the introduction of the on-column methylating reagents, tetramethylammonium hydroxide (1, 2) and trimethylphenylammonium hydroxide (3), the extraction and GLC analysis of anticonvulsant drugs have been greatly simplified. These reagents are normally used as either a dilute (0.1–0.2 *M*) solution (4, 5) or a concentrated (24%) solution (6, 7) in methanol. The methods published to date concerning two of the three primary anticonvulsants, phenobarbital and primidone, are lacking in sensitivity or reproducibility or the extraction time required is unnecessarily long.

This paper describes a combination of two methods (5, 6) which increases the sensitivity and reproducibility of the analysis of phenobarbital and primidone and also decreases the time necessary to give a clean, efficient extraction.

EXPERIMENTAL

Apparatus—A gas chromatograph[1] with four flame-ionization detectors was used for the determinations. The column was a 1.82-m. (6-ft.) by 2-mm. i.d. glass U-tube packed with 3% OV-17 (phenyl methyl silicone oil) on 80–100-mesh Chromosorb W-HP. The injection port was heated to 360° and the detector to 260°. The column temperature was programmed from 140 to 220° at 8°/min. The carrier gas flow rate was adjusted to around 60 ml./min. to give a retention time of 5.0 ± 0.2 min. for methylated diphenylhydantoin at 220°.

Reagents—Trimethylphenylammonium hydroxide[2] was available as a 0.1 *M* solution in methanol; it was concentrated to 1.5 *M* under dry nitrogen over low heat. 5-(*p*-Methylphenyl)-5-phenylhydantoin[3] (I) and phenylethylmalonamide[4] were also used.

Procedure—One milliliter of plasma, 0.50 ml. of the internal standard (20 mg. I diluted to 500 ml. with 0.1 *N* NaOH), 0.5 ml. 0.1 *N* NaOH, 0.5 ml. of a 1.0 *M* H_3PO_4 buffer, pH 2.7, and 13 ml. of ether were combined in a 50-ml. centrifuge tube. The tube was sealed by wetting the ground-glass portion of the stopper with distilled water before insertion, shaken mechanically for 10 min., and centrifuged at 2000 r.p.m. for 1 min. The ether was transferred to a 15-ml. conical centrifuge tube and evaporated under nitrogen at 50°. The residue was taken up in 5 ml. of toluene, and 50 μl. of 1.5 *M* trimethylphenylammonium hydroxide was added. The tube was shaken for 1 min. and then centrifuged for 2 min.; 1 μl. of the lower phase was injected into the chromatograph.

Drug levels were determined from a standard curve of the peak height ratio of the drug to the internal standard *versus* concentration. Phenobarbital levels were determined by summing the heights of the three peaks shown in Fig. 1 after adjusting to constant peak width. The total phenobarbital (Pb) peak height is given by Eq. 1:

$$h_{Pb} = \frac{w_1}{w_3}h_1 + \frac{w_2}{w_3}h_2 + h_3 \qquad \text{(Eq. 1)}$$

where h is the height and w is the width at half height of the peaks shown by the subscripts. The peak width ratios are constant for any given set of chromatographic conditions.

RESULTS AND DISCUSSION

The chromatogram of an extracted sample containing therapeutic levels of phenobarbital, primidone, and diphenylhydantoin, along with an extraction of standard plasma, is shown in Fig. 1. The first two phenobarbital peaks shown in this figure are produced in the chromatograph during on-column methylation with 1.5 *M* trimethylphenylammonium hydroxide. They are also the only peaks produced by methylation of the total product of the aqueous alkaline hydrolysis of phenobarbital. GLC and NMR studies of these two products indicate that they are methylated derivatives of phenyl-

ethylmalonamide, a metabolite of primidone. However, the recovery of phenylethylmalonamide from plasma using this extraction technique is 9.9% at a concentration of 20 mcg./ml. of plasma and 8.5% at a concentration of 5 mcg./ml. of plasma. Gallagher and Baumel (8) reported levels of phenylethylmalonamide in serum of 10 and 12 mcg./ml. in two patients who had been taking primidone (750 mg./day) for more than 2 years. Therefore, for practical drug level determinations, it is safe to assume that these peaks are produced on the column by phenobarbital and are not the result of the metabolism of primidone. The third peak has been shown by NMR to be 1,3-dimethylphenobarbital. A study is underway to determine the structures of the two methylated derivatives of phenylethylmalonamide.

Table I shows the variation of the peak height ratios of the three phenobarbital peaks over 2 hr. for one sample. Each peak has been found to vary continuously with time in an unpredictable manner, supporting the necessity of using all three peaks for quantitation. Data are shown for the three separate peaks and their combined total using two identically prepared columns. The range of variation of the ratios for each peak as a percentage of the total ratio is also shown. The same values were calculated for seven replicate samples analyzed on one column, and these showed relative standard deviations of 28, 12, 18, and 5% for peaks one, two, three, and the total, respectively.

To show that the response-mole ratios of phenobarbital peaks one and two are equivalent to peak three after correction, standard samples containing phenobarbital, primidone, diphenylhydantoin, and the internal standard were extracted and chromatographed. The samples were four each of six levels containing from 100.4 to 4.02 mcg. of phenobarbital/ml. of plasma. Each sample was run on two columns simultaneously and averages of the measured values were used. The ratio of the concentration of phenobarbital to that of diphenylhydantoin was constant for all samples. Peak height ratios were calculated for phenobarbital, using the total height from Eq. 1, and for diphenylhydantoin. The ratio for phenobarbital was divided by that for diphenylhydantoin for each sample, giving a mean of 2.04 with a relative standard deviation of 8%.

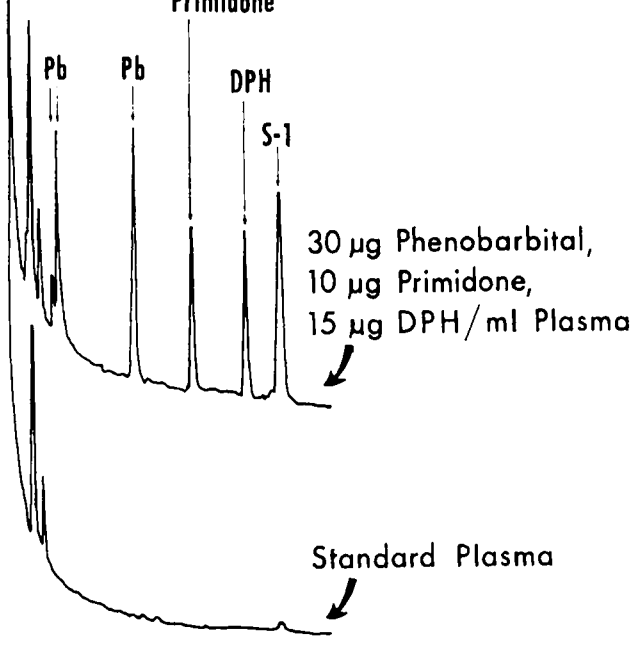

Figure 1—*Typical chromatogram. Upper trace shows extraction of plasma containing therapeutic levels of phenobarbital (Pb), primidone, and diphenylhydantoin (DPH); lower trace shows extraction of standard plasma. S-1 is the internal standard.*

The recoveries of phenobarbital, primidone, and diphenylhydantoin were 100, 72, and 100%, respectively, and the calibration curve for each drug was linear over the concentration range normally found in plasma. The relative standard deviations of six replicate extractions of a patient sample containing all three drugs were 3.2% for 32.7 mcg. of phenobarbital, 3.3% for 7.66 mcg. of primidone, and 5% for 12.2 mcg. of diphenylhydantoin/ml. of plasma. The limit of detection for each drug is 0.5 mcg./ml. of plasma.

The extraction procedure described is as clean and efficient as longer extractions now in use, yet it takes only 25 min. The method is applicable to the other hydantoin and succinimide anticonvulsants, except methsuximide and mephenytoin, in which case the derivatizing reagent is added directly to the ether residue. We are presently adapting the method to analyze small volumes of plasma and whole blood so that accurate multiple-drug determinations can be made from finger-stick samples.

Interfacial Concentration Observed during Dissolution

Keyphrases ☐ Dissolution of solids, descending column model – relationship to interfacial concentration ☐ Interfacial concentration – relationship to descending column dissolution ☐ Descending column dissolution – relationship to interfacial concentration

Sir:

In a recent series of papers, Kildsig and coworkers (1–4) investigated dissolution from compressed pellets in a static column of solvent, under conditions where the flat surface of the solid was either the lower or the upper boundary of the column (ascending and descending models, respectively). It was concluded that in the descending case an interfacial concentration, c_i, significantly lower than the saturation concentration, c_s, is operative and that c_i is related to energy parameters of the solid–liquid interface. The argument of the authors is not conclusive, however, and their experimental data can be interpreted in a more simple and convenient way which does not require the assumption of $c_i < c_s$.

When compared with the diffusion-controlled ascending case, the descending model represents a completely different hydrodynamic system which is usually described in terms of free convection; that is, whenever the dissolving surface is not at the bottom of the liquid, then inverse density gradients are generated within the liquid and these, in turn, induce macroscopic convectional flow accompanied by a drastic increase of the rate of mass transfer. Systems similar to the descending column have been investigated with respect to flow pattern and mass transfer, *e.g.*, laminar flow along a vertical flat surface (hanging pellet) (5, 6), laminar or turbulent flow around a single dissolving sphere (7), and convectional flow along a horizontal circular surface (static disk) (8, 9). In the last case, the flow pattern may be visualized from the analogous process of heat-induced convection (10, 11).

The descending model of Kildsig and coworkers fits into this series of free convectional dissolution systems, with one peculiarity; the solid surface extends over the entire cross section of the column. This complicates establishment of a typical, convectional flow pattern. One might speculate that in the absence of any disturbances the system starts from a convection-free metastable state, which is identical with the ascending case where mass transfer is restricted to molecular diffusion. However, from Fig. 5 of *Reference 1*, it is evident that the system actually was in a convectional state right from the beginning of the experiment. It must be left open what kind of flow pattern prevailed under the experimental conditions; some possibilities are gross laminar flow of the entire liquid column, a bundle of laminar flow cells distributed over the cross section, and a random flow of liquid packets similar to those proposed by Danckwerts (12) for his surface renewal concept.

No attempt will be made to develop a complete mechanistic model which accounts for all of the experimental data reported by the authors. However, it is demonstrated with two examples that the concept of free convection is capable of treating the observations without any need for an abnormal interfacial concentration. Three additional points are made which show that the cited arguments are based on rather insecure premises.

For any free convectional system, a distinct solute front is typical and represents the portion of the liquid that had first been in contact with the dissolving solid. The velocity of this front is governed by hydrodynamics (solubility, viscosity, and density as a function of concentration), and a constant velocity is not unexpected. Also, a correlation between front velocity and solubility, as shown in Tables III and IV of *Reference 4*, is consistent with such a concept and does not require explanation in terms of interfacial energy parameters.

When comparing dissolution rates of one solute in different solvents, an inverse correlation with solubility, such as the one shown in Fig. 2 of *Reference 3*, is not unusual and gives no verification that the descending dissolution is interfacially controlled. In the particular case, nearly a 10-fold increase in viscosity is found for the solvents (30°, viscosities in centipoises) (13): *n*-hexane, 0.29; *n*-heptane, 0.37; cyclohexane, 0.82; *trans*-decalin, 1.8; and *cis*-decalin, 2.7[1]. Since the viscosity is known to have a retarding effect on diffusion and, particularly, convection, and since the viscosity increase more than compensates for the increase in solubility, it is not surprising that the rate of dissolution decreases from hexane to decalin. Again, there is no need to rely on interface phenomena.

In *Reference 1* (p. 216), the authors restrict diffusion to the upward direction in the gravitational field. This is not true since molecular diffusion by definition is independent of any external forces. In addition, all of the solutes are of low molecular weight, <200. Even in an associated or highly solvated state, these particles are far below the limit where directional flow under the influence of gravity (*i.e.*, sedimentation) is likely to be observable. Hence, it is hard to see how "solvated solute molecules flow through the stationary liquid solvent, the fluid elements or holes comprising the liquid solvent acting as a channeling or dispersion medium" (4, p. 1592). The only acceptable concept is that of macroscopic flow, *i.e.*, convection.

For all four examples shown in Figs. 8–11 of *Reference 4*, the agreement between experimental data points and the fitted telegraph equation is by no means perfect; rather, the examples disprove the applicability of this

[1] It is not clear from the Krause and Kildsig paper (3) whether the *cis*- or *trans*-isomer was used.

equation. Under these circumstances, any extrapolation to zero distance is arbitrary. The concentration profiles shown in Fig. 7 of *Reference 1* are speculative since the actual interfacial concentration and the initial concentration gradient cannot be assessed from the experimental data with sufficient accuracy. In addition, the assumption of a constant nonsaturated interfacial concentration independent of the initial concentration gradient (as shown in Fig. 7) is not consistent with a transport model involving two consecutive rate processes.

Since the telegraph equation is not applicable, it is meaningless to ask whether the random-walk model with autocorrelation is appropriate to the descending column. However, even if perfect agreement had been obtained with the equation, this would not be more than a formal quantitative description. The authors' attempt to establish a mechanistic analogy between their descending dissolution and the mutual displacement of two miscible phases in a porous medium would still be questionable.

Total Rate Equation for Decomposition of Prostaglandin E_2

Keyphrases ☐ Prostaglandin E_2 decomposition log rate–pH profile, rate equation ☐ Dehydration, prostaglandin E_2—log rate–pH profile, rate equation

Sir:

Monkhouse *et al.* (1) recently presented the 60° log rate–pH profile for the dehydration of prostaglandin E_2 (PGE_2)[1] from pH 1 to 10. Between pH 4 and 10, the log of the rate data was correlated by a straight line with a slope of about 0.3. Our 60° rate data substantially agree with the reported (1) 60° profile. However, we recently completed a 25° log rate–pH profile from pH 1 to 12 which appears to shed more light on the nature of the decomposition reaction between pH 4 and 10.

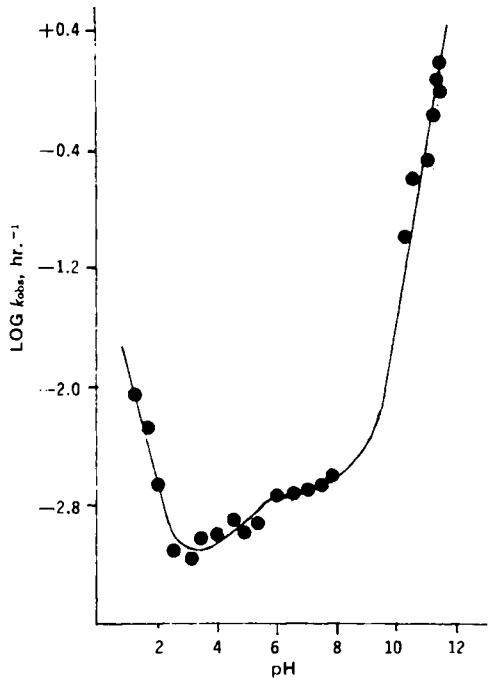

Figure 1—*Log rate–pH profile for decomposition of PGE_2 at 25.0°.*

Figure 1 shows the log rate–pH profile for the decomposition of PGE_2 in water–methanol (95:5 v/v) at 25.00 ± 0.05°. The apparent first-order rates were determined in hydrochloric acid and formate, acetate, phosphate, carbonate, and sodium hydroxide buffers at a constant ionic strength of 0.10. The apparent first-order rate constants were determined by following the disappearance of the substrate by a TLC procedure specific for PGE_2.

Although it may initially appear that the region between pH 4 and 9 is linear, the observed 25° rate constants (k_{obs} values) were best correlated by a rate equation depending upon the pKa of the prostaglandin[2]:

$$k_{obs} = k_H \cdot a_H \cdot (1 - \alpha) + k_{H_2O}(1 - \alpha) + k_{OH} \cdot a_{OH} \cdot (\alpha) + k^1_{H_2O}(\alpha) + k^{11}(\alpha) \quad \text{(Eq. 1)}$$

where k_H is the specific hydrogen-ion catalytic constant, k_{H_2O} is the catalytic constant for the water reaction of PGE_2, k_{OH} is the specific hydroxide-ion catalytic constant, $k^1_{H_2O}$ is the catalytic constant for the water reaction of ionized PGE_2, and k^{11} represents a catalytic constant for a reaction of PGE_2 in the ionized form. The hydrogen- and hydroxide-ion activities are represented by a_H and a_{OH}, respectively, and $(1 - \alpha)$ and (α) represent the fractions of PGE_2 in the unionized and ionized form, respectively.

The line in Fig. 1 was calculated from Eq. 1, and the points correspond to the experimentally observed apparent first-order rate constants. Buffer catalysis and isomerization at C_8 and C_{15} (2) did not appear to contribute significantly to the overall rate expression.

[1] PGE_2 is 11α,15(*S*)-dihydroxy-9-oxo-5-*cis*,13-*trans*-prostadienoic acid.

[2] The pKa of PGE_2 under the conditions of the kinetic experiments was determined to be 5.00.

equation. Under these circumstances, any extrapolation to zero distance is arbitrary. The concentration profiles shown in Fig. 7 of *Reference 1* are speculative since the actual interfacial concentration and the initial concentration gradient cannot be assessed from the experimental data with sufficient accuracy. In addition, the assumption of a constant nonsaturated interfacial concentration independent of the initial concentration gradient (as shown in Fig. 7) is not consistent with a transport model involving two consecutive rate processes.

Since the telegraph equation is not applicable, it is meaningless to ask whether the random-walk model with autocorrelation is appropriate to the descending column. However, even if perfect agreement had been obtained with the equation, this would not be more than a formal quantitative description. The authors' attempt to establish a mechanistic analogy between their descending dissolution and the mutual displacement of two miscible phases in a porous medium would still be questionable.

Total Rate Equation for Decomposition of Prostaglandin E_2

Keyphrases ☐ Prostaglandin E_2 decomposition log rate–pH profile, rate equation ☐ Dehydration, prostaglandin E_2—log rate–pH profile, rate equation

Sir:

Monkhouse *et al.* (1) recently presented the 60° log rate–pH profile for the dehydration of prostaglandin E_2 (PGE_2)[1] from pH 1 to 10. Between pH 4 and 10, the log of the rate data was correlated by a straight line with a slope of about 0.3. Our 60° rate data substantially agree with the reported (1) 60° profile. However, we recently completed a 25° log rate–pH profile from pH 1 to 12 which appears to shed more light on the nature of the decomposition reaction between pH 4 and 10.

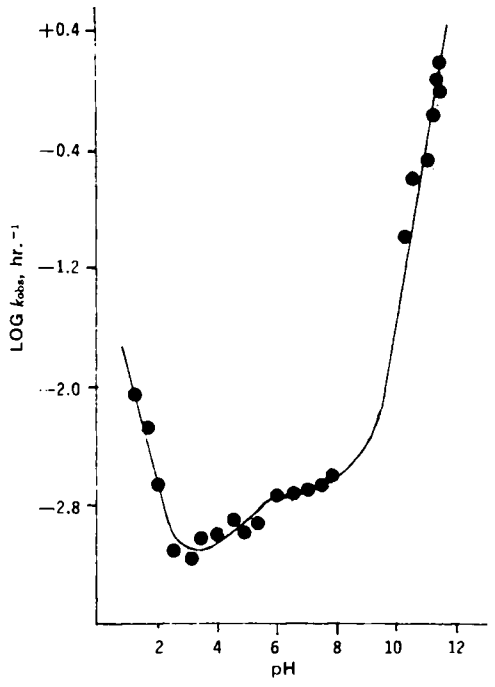

Figure 1—*Log rate–pH profile for decomposition of PGE_2 at 25.0°.*

Figure 1 shows the log rate–pH profile for the decomposition of PGE_2 in water–methanol (95:5 v/v) at 25.00 ± 0.05°. The apparent first-order rates were determined in hydrochloric acid and formate, acetate, phosphate, carbonate, and sodium hydroxide buffers at a constant ionic strength of 0.10. The apparent first-order rate constants were determined by following the disappearance of the substrate by a TLC procedure specific for PGE_2.

Although it may initially appear that the region between pH 4 and 9 is linear, the observed 25° rate constants (k_{obs} values) were best correlated by a rate equation depending upon the pKa of the prostaglandin[2]:

$$k_{obs} = k_H \cdot a_H \cdot (1 - \alpha) + k_{H_2O}(1 - \alpha) + k_{OH} \cdot a_{OH} \cdot (\alpha) + k^1_{H_2O}(\alpha) + k^{11}(\alpha) \quad \text{(Eq. 1)}$$

where k_H is the specific hydrogen-ion catalytic constant, k_{H_2O} is the catalytic constant for the water reaction of PGE_2, k_{OH} is the specific hydroxide-ion catalytic constant, $k^1_{H_2O}$ is the catalytic constant for the water reaction of ionized PGE_2, and k^{11} represents a catalytic constant for a reaction of PGE_2 in the ionized form. The hydrogen- and hydroxide-ion activities are represented by a_H and a_{OH}, respectively, and $(1 - \alpha)$ and (α) represent the fractions of PGE_2 in the unionized and ionized form, respectively.

The line in Fig. 1 was calculated from Eq. 1, and the points correspond to the experimentally observed apparent first-order rate constants. Buffer catalysis and isomerization at C_8 and C_{15} (2) did not appear to contribute significantly to the overall rate expression.

[1] PGE_2 is 11α,15(*S*)-dihydroxy-9-oxo-5-*cis*,13-*trans*-prostadienoic acid.

[2] The pKa of PGE_2 under the conditions of the kinetic experiments was determined to be 5.00.

A more detailed account of this work will be published.

Constituents of *Cannabis sativa* L. VI: Propyl Homologs in Samples of Known Geographical Origin

Keyphrases □ *Cannabis sativa* L.—propyl homologs in samples of known geographic origin □ Cannabidivarin and (−)-Δ⁹-*trans*-tetrahydrocannabivarin—identified in cannabis samples of known geographical origin

Sir:

Recent developments in identifying propyl homologs of cannabinoids prompted this communication. We wish to report the presence of cannabidivarin[1] and (−)-Δ⁹-*trans*-tetrahydrocannabivarin in freshly grown cannabis from known geographical locations. We routinely employed GLC and TLC[2] to identify the C_3-homologs. Some samples were identified by combined GLC–mass spectrometry[3].

Vollner *et al.* (1) identified cannabidivarin (I) from a sample of hashish in 1969. Gill *et al.* (2) later identified (−)-Δ⁹-*trans*-tetrahydrocannabivarin (II) from a sample of tincture of cannabis. Merkus (3) reported the presence of cannabivarin (III) in samples of Nepal hashish. This research group reported the presence of I and II in a sample of freshly grown *Cannabis sativa* L. from Indian seed stock (IN-B) grown in Mississippi (4).

De Zeeuw *et al.* (5) reported that propyl cannabinoids seem to depend on sample origin: samples from countries like India, Nepal, and Pakistan contained significant amounts of propyl cannabinoids, whereas samples from Middle Eastern and Mediterranean countries contained much lower amounts. Our own findings using only those variants from exact geographical locations confirm and extend the previously thought abundance of propyl cannabinoids in freshly grown *C. sativa* L. (Table I).

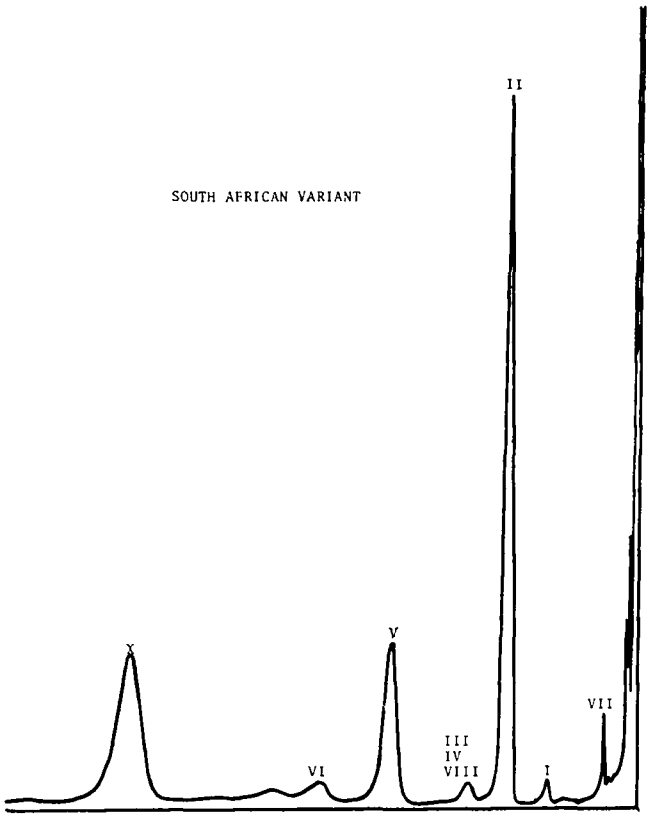

Figure 1—*Chromatogram of South African* C. sativa *L. (coded SA-E). Key: I, cannabidivarin; II, (−)-Δ⁹-trans-tetrahydrocannabivarin; III, cannabivarin; IV, cannabichromene; V, (−)-Δ⁹-trans-tetrahydrocannabinol; VI, cannabinol; VII, (−)-Δ⁹-trans-tetrahydrocannabiorcol; VIII, cannabidiol; and X, 4-androstene-3,17-dione (internal standard).*

The percentages of I and II given in Table I are normalized reports. Each cannabinoid is reported as its percentage in regard to total cannabinoid content. These data were obtained by a GLC–computer[4] analysis based on relative retention times of routine cannabis analysis[5].

Figure 1 of an African variant (seed code SA-E) contained 1.70% of I; 53.69% of II; 2.75% of III, cannabichromene (IV), and cannabidiol (VIII); 23.41% of (−)-Δ⁹-*trans*-tetrahydrocannabinol (V); and 4.38% of cannabinol (VI). Peak number VII was tentatively identified as (−)-Δ⁹-*trans*-tetrahydrocannabiorcol[6], first reported by Vree *et al.* (6).

Figure 2 of an Afghanistan variant (seed code AF-A) contained 8.35% of I; 5.34% of II; 12.48% of III, IV, and VIII; 1.94% of cannabigerol monomethyl ether (IX); 58.93% of V; and 2.03% of VI. The age of the material analyzed in Figs. 1 and 2 was 20 weeks. A previous literature report (7) showed that cannabinoid contents vary within each variant according to age.

[1] Since Vollner *et al.* (1) used cannabidivarin (divarinyl group) for the C_3H_7 side chain of cannabidiol (olivetyl group C_5H_{11}), and Merkus (3) used cannabivarin for the C_3H_7 side chain of cannabinol, we shall use the following trivial names: cannabidivarin, (−)-Δ⁹-*trans*-tetrahydrocannabivarin, and cannabivarin. Gill *et al.* (2) used "divarol" for the C_3H_7 side chain: (−)-Δ⁹-*trans*-tetrahydrocannabidivarol.

[2] Beckman GC-45, GC-72-5, and GC-5. Procedures described by Turner and Hadley (7) were used. Silica gel G precoated plates from Brinkmann were used for TLC analysis; petroleum ether–ether (4:1) was the solvent.

[3] Varian Series 1400 gas chromatograph interfaced with Dupont 21-492.

[4] Digital PDP-8 computer.

[5] A comprehensive listing of the relative retention times can be found in *Reference 7*.

[a] Y = young plants prior to sexual differentiation, F = female, M = male, and X = mixture of male and female. [b] – = possible (very small peaks), t = trace amounts (approximately 1%), and + = 1–5%.

Therefore, the data in Table I showing variation of I and II in regard to geographical location are not unusual and would be anticipated.

Just as the C_5H_{11} (olivetyl group) side-chain neutral cannabinoids exist predominately as their carboxylic

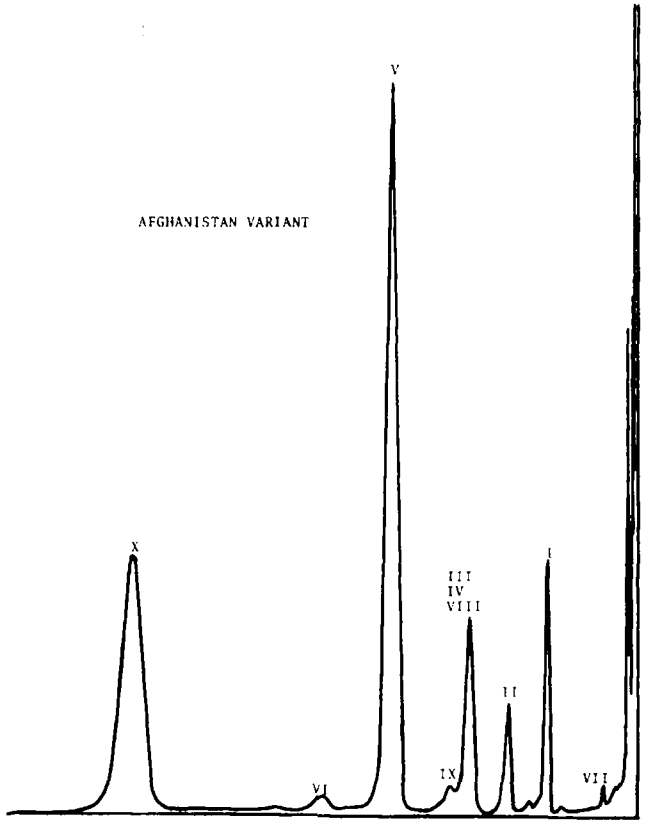

Figure 2—*Chromatogram of Afghanistan* C. sativa *L. (coded AF-A). Key: I, cannabidivarin; II, (−)-Δ⁹-trans-tetrahydrocannabivarin; III, cannabivarin; IV, cannabichromene; V, (−)-Δ⁹-trans-tetrahydrocannabinol; VI, cannabinol; VII, (−)-Δ⁹-trans-tetrahydrocannabiorcol; VIII, cannabidiol; IX, cannabigerol monomethyl ether; and X, 4-androstene-3,17-dione (internal standard).*

Table II—Mass Spectral Data

Trimethylsilyl Derivatives of Cannabinoids	*m/e*
(−)-Δ^9-*trans*-Tetrahydrocannabinolic acid	502
(−)-Δ^9-*trans*-Tetrahydrocannabivarinic acid	474
Cannabidiolic acid	574
Cannabidivarinic acid	546

acid derivatives in fresh *C. sativa* L. (8), so do the C_3H_7 (divarinyl group) side chains. GLC–mass spectrometry analysis of an Indian (IN-B) variant, silylated according to a reported procedure (9), contained a significant *m/e* at 546, corresponding to the trisilylated (trimethylsilyl ester bisether) derivative of I. Additionally, a significant *m/e* at 474 is indicative of disilylated (trimethylsilyl ester–ether) II. These data agree with the mass spectral data obtained for silylated acid derivatives of VIII and V, having *m/e*'s of 574 and 502, respectively (Table II). TLC was employed for identification of III, which has a relative retention time corresponding to IV and VIII. Compound III was not clearly observed in fresh samples of cannabis but was observed when samples containing II were heated. Thus, no data are presently available on the acid derivative of III.

Propyl homologs are, indeed, found in aerial parts of *C. sativa* L. plant material from many geographical locations. The abundances of propyl homologs vary, as do the pentyl homologs, in regard to geographical origin. However, we do not believe it feasible to determine exact geographic origin using the propyl homologs as "locators." Moreover, the propyl homologs exist predominately as their carboxylic acid derivatives as do the pentyl homologs.

Coacervate Formation by Inorganic Salts with Benzalkonium Chloride

Keyphrases ☐ Coacervate formation—sodium chloride and sodium carbonate with benzalkonium chloride ☐ Sodium chloride—coacervate formation with benzalkonium chloride ☐ Sodium carbonate—coacervate formation with benzalkonium chloride, effect of concentration on coacervate volume and refractive index ☐ Inorganic salts, sodium chloride and sodium carbonate—coacervate formation with benzalkonium chloride ☐ Benzalkonium chloride—coacervate formation with sodium chloride and sodium carbonate

Sir:

A number of dilute aqueous solutions of proteins (1), polyelectrolytes (2), association colloids (3–5), carbonates (6), and lipids (6) have been investigated and found capable of forming coacervates under proper conditions. The essential feature of the coacervation phenomenon is the spontaneous separation of a homogeneous macromolecular or microionic aqueous solution into two immiscible aqueous solution phases. One aqueous layer contains most of the colloid and is termed the coacervate, while the second aqueous layer is colloid poor and is termed the equilibrium liquid. These coacervate systems are of growing general scientific (7, 8) and biological (9) interest.

The term biphasic coacervate system refers to the coacervate phase in contact with its equilibrium liquid phase. The term monophasic solution refers to the one-phase micellar solution.

Coacervation has been observed in some dilute soap solutions, and it has been reported (5) that coacervation in cationic detergent systems shows pronounced specificity to the anion and lesser sensitivity to the cation of the added electrolyte. Shah *et al.* (3) reported coacervate formation between the cationic surfactant, benzalkonium chloride, and the organic aromatic compound, sodium salicylate.

This communication reports on coacervate formation by sodium salts of inorganic monovalent and

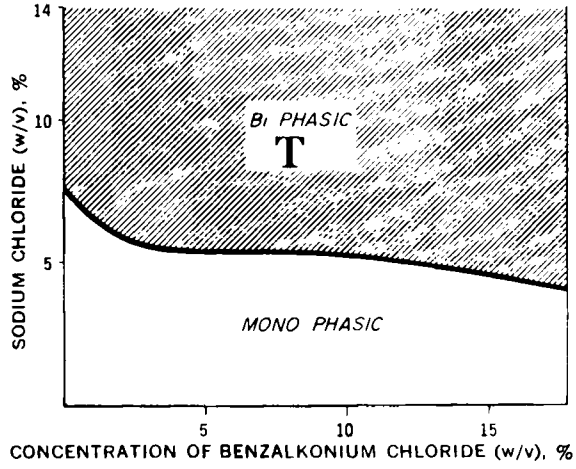

Figure 1—*Phase transition diagram of sodium chloride-benzalkonium chloride coacervate system at 25°. Shaded area [T] represents the region in which biphasic coacervate system can be formed with lighter coacervate phase.*

Coacervate Formation by Inorganic Salts with Benzalkonium Chloride

Keyphrases ☐ Coacervate formation—sodium chloride and sodium carbonate with benzalkonium chloride ☐ Sodium chloride—coacervate formation with benzalkonium chloride ☐ Sodium carbonate—coacervate formation with benzalkonium chloride, effect of concentration on coacervate volume and refractive index ☐ Inorganic salts, sodium chloride and sodium carbonate—coacervate formation with benzalkonium chloride ☐ Benzalkonium chloride—coacervate formation with sodium chloride and sodium carbonate

Sir:

A number of dilute aqueous solutions of proteins (1), polyelectrolytes (2), association colloids (3–5), carbonates (6), and lipids (6) have been investigated and found capable of forming coacervates under proper conditions. The essential feature of the coacervation phenomenon is the spontaneous separation of a homogeneous macromolecular or microionic aqueous solution into two immiscible aqueous solution phases. One aqueous layer contains most of the colloid and is termed the coacervate, while the second aqueous layer is colloid poor and is termed the equilibrium liquid. These coacervate systems are of growing general scientific (7, 8) and biological (9) interest.

The term biphasic coacervate system refers to the coacervate phase in contact with its equilibrium liquid phase. The term monophasic solution refers to the one-phase micellar solution.

Coacervation has been observed in some dilute soap solutions, and it has been reported (5) that coacervation in cationic detergent systems shows pronounced specificity to the anion and lesser sensitivity to the cation of the added electrolyte. Shah *et al.* (3) reported coacervate formation between the cationic surfactant, benzalkonium chloride, and the organic aromatic compound, sodium salicylate.

This communication reports on coacervate formation by sodium salts of inorganic monovalent and

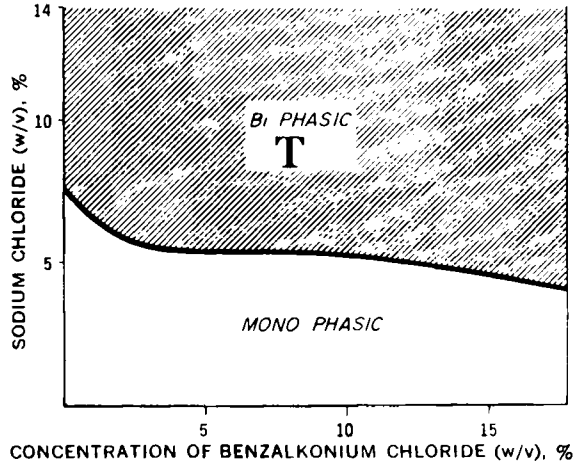

Figure 1—*Phase transition diagram of sodium chloride-benzalkonium chloride coacervate system at 25°. Shaded area [T] represents the region in which biphasic coacervate system can be formed with lighter coacervate phase.*

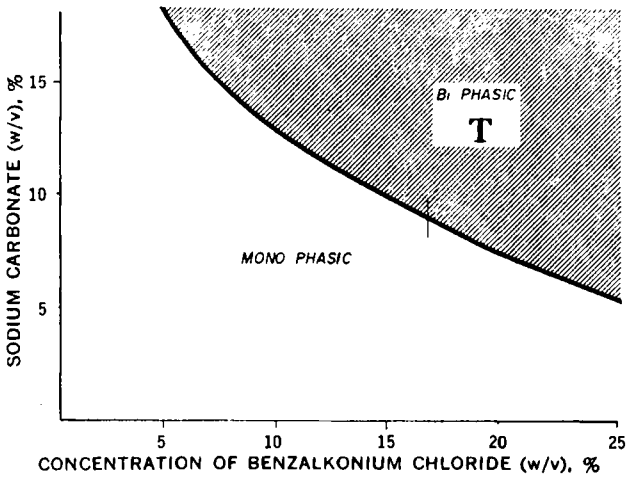

Figure 2—*Phase transition diagram of sodium carbonate–benzalkonium chloride coacervate system at 25°. Shaded area [T] represents the region in which biphasic coacervate system can be formed with lighter coacervate phase.*

bivalent anions, *i.e.*, sodium chloride and sodium carbonate, with benzalkonium chloride. Also reported is the effect of sodium carbonate concentration on the coacervate volume and refractive index of the coacervate phase.

The coacervate systems were obtained by mixing the indicated concentrations (Fig. 1) of salt and benzalkonium chloride in water. Figure 1 shows the phase transition diagram of the sodium chloride and benzalkonium chloride coacervate system at the points of coacervate formation. Figure 2 shows the phase transition diagram of the sodium carbonate and benzalkonium chloride coacervate system. These diagrams illustrate two main regions: (*a*) biphasic coacervate system, represented by the shaded area; and (*b*) monophasic solution, represented by nonshaded area. In both coacervate systems, the formed coacervate phase was lighter than the equilibrium liquid phase.

Figure 3 represents the effect of the sodium carbonate concentration on the refractive index and coacervate volume. For this study, 100 ml. of coacervate systems, containing 25% (w/v) benzalkonium chloride with 5.6, 6.0, 7.0, 8.0, and 10.0% sodium carbonate, was prepared. The systems were allowed to equilibrate for 24 hr. at room temperature (25°). The volume of coacervate was noted as the percent of the whole system. The refractive index of the coacervate phase was measured at 25° using a refractometer[1].

Possible Errors and Role of Mercuric Chloride in Using Trinder's Reagent for Assay of Salicylates in Urine Specimens

Keyphrases ☐ Salicylates in urine—analysis, Trinder's reagent with and without mercuric chloride ☐ Mercuric chloride in Trinder's reagent—effect on salicylate analysis in urine ☐ Trinder's reagent, with and without mercuric chloride—effect on salicylate analysis in urine ☐ Colorimetry—analysis, salicylates in urine, Trinder's reagent with and without mercuric chloride

Sir:

Trinder's reagent has been used in many colleges of pharmacy as a colorimetric agent to assay urinary salicylate and thereby to estimate the bioavailability of compounds such as aspirin, sodium salicylate, and *p*-aminosalicylic acid (1–4). The assay procedure is simple. One milliliter of the urine sample is usually diluted with 5 ml. of the reagent, and the absorbance of the resultant solution at 540 nm. is measured using the properly diluted (with water or urine blank) reagent as a reference solution. The absorbances of the urine samples

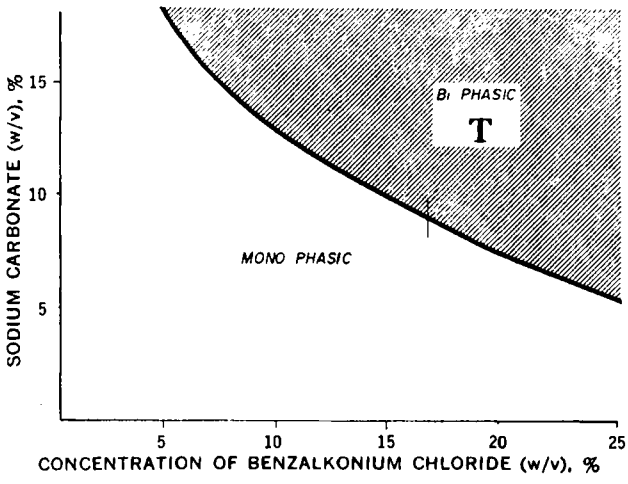

Figure 2—*Phase transition diagram of sodium carbonate–benzalkonium chloride coacervate system at 25°. Shaded area [T] represents the region in which biphasic coacervate system can be formed with lighter coacervate phase.*

bivalent anions, *i.e.*, sodium chloride and sodium carbonate, with benzalkonium chloride. Also reported is the effect of sodium carbonate concentration on the coacervate volume and refractive index of the coacervate phase.

The coacervate systems were obtained by mixing the indicated concentrations (Fig. 1) of salt and benzalkonium chloride in water. Figure 1 shows the phase transition diagram of the sodium chloride and benzalkonium chloride coacervate system at the points of coacervate formation. Figure 2 shows the phase transition diagram of the sodium carbonate and benzalkonium chloride coacervate system. These diagrams illustrate two main regions: (*a*) biphasic coacervate system, represented by the shaded area; and (*b*) monophasic solution, represented by nonshaded area. In both coacervate systems, the formed coacervate phase was lighter than the equilibrium liquid phase.

Figure 3 represents the effect of the sodium carbonate concentration on the refractive index and coacervate volume. For this study, 100 ml. of coacervate systems, containing 25% (w/v) benzalkonium chloride with 5.6, 6.0, 7.0, 8.0, and 10.0% sodium carbonate, was prepared. The systems were allowed to equilibrate for 24 hr. at room temperature (25°). The volume of coacervate was noted as the percent of the whole system. The refractive index of the coacervate phase was measured at 25° using a refractometer[1].

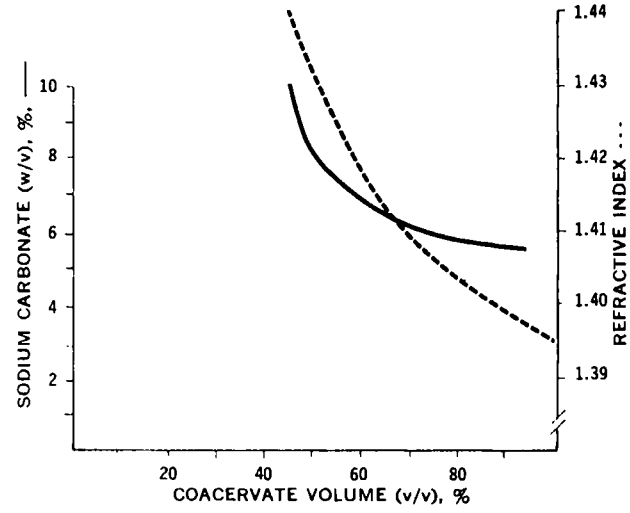

Figure 3—*Volume and refractive index of coacervate phase of sodium carbonate–25% benzalkonium chloride coacervate system at 25°.*

Sir:

Trinder's reagent has been used in many colleges of pharmacy as a colorimetric agent to assay urinary salicylate and thereby to estimate the bioavailability of compounds such as aspirin, sodium salicylate, and *p*-aminosalicylic acid (1–4). The assay procedure is simple. One milliliter of the urine sample is usually diluted with 5 ml. of the reagent, and the absorbance of the resultant solution at 540 nm. is measured using the properly diluted (with water or urine blank) reagent as a reference solution. The absorbances of the urine samples

Table I—Absorbances at 540 nm. of Various Urine Blank Samples

Urine Samples	Subjects 1	2	3	4	5	6
Before breakfast	0.05	0.10	0.23	0.05	0.17	0.06
Breakfast–lunch	0.22	0.08	0.20	0.13	0.14	0.05
Lunch–supper	0.22	0.09	0.19	0.17	0.12	0.06
Supper–bedtime	0.39	0.12	0.21	0.22	0.15	0.06

Table II—Absorbances of Sodium Salicylate in Urine after Adding Trinder's Reagent Prepared with or without Mercuric Chloride (an Average of Two Studies)

Concentrations of Sodium Salicylate, mg./ml.	With Mercuric Chloride	Without Mercuric Chloride
0.125	0.180	0.179
0.500	0.728	0.723
1.000	1.439	1.424

collected after dosing are corrected for the absorbance of the blank urine sample usually taken before dosing in the calculation of the salicylate concentrations in the urine. In doing so, it is assumed that the basic blank absorbances of the urine samples not due to ingested salicylates remain essentially unchanged during the period of study. To our knowledge, no data have been published to support this assumption.

In the bioavailability study of aspirin dosage forms using Trinder's reagent, we have occasionally found that the subjects excreted much more salicylate than ingested. We were also often puzzled by the fact that the absorbances of the urine samples after dosing were much lower than the absorbance of the blank sample. We thought that these observations might result from the intrasubject variation of the urinary blank contribution, and the present study was undertaken to explore this possibility. Urine specimens of six normal adult subjects who had not taken salicylates or other drugs during the previous week and the day of study were collected at various times during the day: before breakfast, between breakfast and lunch, between lunch and supper, and between supper and bedtime. Normal food and fluid uptake were allowed. Specimen absorbances at 540 nm., measured with a spectrophotometer[1] after adding the colorimetric agent, are shown in Table I. An absorbance of 0.1 corresponds to a urinary concentration of 0.07 mg./ml. of sodium salicylate. The possibility of marked intersubject and intrasubject blank variations is clearly demonstrated from these data. The highest blank reading found in the supper-to-bedtime urine of the Subject 1 corresponded to 0.273 mg./ml. of sodium salicylate. If one uses the urine of Subject 1 collected before breakfast as a blank sample, this subject can be calculated to excrete 159 mg. of sodium salicylate during the day even when he ingested no salicylate. This calculation was based on the average absorbance of three samples and a urine output of 1 l. An error of this magnitude is obviously unacceptable when one is evaluating the bioavailability of 324–648 mg. (5–10 grains) of an aspirin preparation administered as a single dose. In Subjects 2, 3, and 5, the excretion of salicylates can sometimes be underestimated if one also uses the urine sample collected before breakfast as a blank. For Subject 6, all blank readings were quite low and consistent.

The inclusion of mercuric chloride (4% w/v) in Trinder's reagent was used primarily to precipitate protein during salicylate analysis of serum or plasma samples (1). Since urine samples normally contain only a negligible amount of protein, it was interesting to determine whether its inclusion is necessary. Such a study seemed especially significant in light of the pollution problem of the mercury compound and its relatively high cost. One milliliter of various standard solutions of sodium salicylate in urine was diluted with 5 ml. of the Trinder reagent prepared with or without mercuric chloride. Their absorbances at 540 nm. were measured using suitable blanks as references. As shown in Table II, absorbances of solutions were essentially not affected by the absence of mercuric chloride and all followed Beer's law in the range studied. A similar phenomenon was also observed for salicylate dissolved in distilled water. Therefore, it is concluded that the mercuric chloride included can be deleted from Trinder's reagent for the assay of salicylates in urine or other aqueous media not containing proteins.

REVIEWS

The Bimolecular Lipid Membrane: A System. By MAHENDRA K. JAIN. Van Nostrand Reinhold, 450 W. 33rd St., New York, NY 10001, 1972. 464 pp. 14 × 23 cm. Price $22.50.

This well-written and extensively referenced (more than 1300 references) book is highly recommended for all those interested in the molecular structure of biological membranes. Whereas biomembranes are characterized by a multiplicity of phenomena which have been described at the macroscopic as well as the microscopic level, there is in this multiplicity of phenomena an underlying set of physical and chemical principles. Jain has attempted (and succeeded admirably in this attempt) to present an exposition of these principles sufficient to provide a basis for understanding the specialized literature and complex phenomena associated with biomembranes.

Chapters 1–2 are introductory. Chapter 1 provides an excellent historical view of biomembranes and sets the framework for *in vitro* modeling. Chapter 2 reviews the surface chemistry of lipids. It is the only weak chapter in the book. Chapters 3–9 deal with the formation and stability of black lipid membranes (BLM), intrinsic properties of BLM, permeability characteristics and extrinsic properties of BLM, energy transduction in biological systems, excitability, and membrane hyperstructure and organization. Each of these chapters is well organized, sufficiently detailed, and extremely well referenced. The many tables (including summary tables) and illustrations aid the reader greatly.

One minor criticism of this reviewer is that not enough attention has been paid to comparing the BLM model system to other models such as monolayers and spherules.

In summary, the book is highly recommended to all investigators interested in the molecular structure of biomembranes and who are ready to accept the fact that even complex biological phenomena are based on physical and chemical principles.

Evaluations of Drug Interactions—1973 (First Edition). Prepared by the Drug Interactions Project of the American Pharmaceutical Association with the assistance of the American Dental Association, the American Medical Association, the American Society of Hospital Pharmacists, the Food and Drug Administration, and the National Library of Medicine. Published by the American Pharmaceutical Association, 1973. xxxii + 358 pp. 15.5 × 23 cm. Price $10.00.

This reference source utilizes a new approach for generating information on drug interactions. Previous publications in this field have relied heavily on personal assessments and/or gleaning the literature for reports and listing those found. In "Evaluations of Drug Interactions—1973," as the title suggests, assessments of drug interaction reports have been prepared, utilizing subpanels composed of individuals knowledgeable in a specific area of drug interactions. In addition to subpanels that reviewed the material for scientific content, subpanels composed of pharmacy and medical practitioners were also established to review the generated information from the standpoint of applicability to use by the practitioner in practice. About 200 persons contributed to the preparation of the first edition, with approximately 100 persons serving on scientific review subpanels, 25 on the practitioner review panel, and a number of special reviewers from cooperating agencies and pharmaceutical manufacturers' representatives.

The first edition includes 104 drug drug interaction monographs, 25 chapters of background information on drug interactions by pharmacological classes, a general chapter on the mechanisms and clinical implications of drug interactions, and Tables of Normal Values. The index identifies, by nonproprietary name, drugs to which a specific monograph is devoted and drugs which are discussed in monographs. Major trade names are included in the index, referenced to their appropriate nonproprietary name.

Monographs are divided into seven easily identifiable sections: Summary, Related Drugs, Pharmacological Effect and Mechanism, Evaluation of Clinical Data, Clinical Significance, Recommendations, and References. A listing of nonproprietary and major trade names of drugs mentioned in the monograph follows the references.

The four-colored sections (front matter is green; monographs, white; chapters, blue; and index, pink), the Table of Contents which has all monograph titles listed alphabetically by both the first drug name in the title and the second, and the extensive index promote ease of use. An additional feature is a reprint of the monograph section of the Table of Contents which is suitable for posting by the practitioner.

The acquisition of this new reference source on drug interactions should be considered by all health-care practitioners striving toward the goal of rational drug therapy.

REVIEW ARTICLE

Fundamentals of Interaction of Ionizing Radiations with Chemical, Biochemical, and Pharmaceutical Systems

STEPHEN G. SCHULMAN

Keyphrases ☐ Radiation chemistry—review of interactions with chemical, biological, and pharmaceutical systems ☐ Ionizing radiation—effect on solids, liquids, and gases, interactions with biological systems, review ☐ Biological considerations—effect of ionizing radiation on carbohydrates, amino acids, peptides, proteins, enzymes, vitamins, and nucleic acids, review ☐ Radioprotection—chemical and pharmaceutical considerations, review

The effects of ionizing radiations produced by radioactive isotopes, particle accelerators, nuclear reactions, and X-ray generating devices upon matter have been of interest in chemistry and biology for several decades. Ionizing radiations are known to produce highly reactive ionic and free radical species in chemical substances, which lead to stable chemical products, usually very different from those obtained from the normal chemical reactions of these substances. In biological systems, the reactions caused by ionizing radiations are usually detrimental to the organism, resulting in mutagenesis, incapability to reproduce, organic damage, and even death. However, some aspects of radiation effects are beneficial. Studies of the effects of ionizing radiations upon solids elucidated the nature of the defect solid state and assisted advances in solid-state electronic components. The modification of polymeric materials by treatment with ionizing radiations often enhances the mechanical and thermal stabilities of these materials and has already been exploited commercially.

Interest in the chemical and biological effects of ionizing radiations in the pharmaceutical sciences has never been great, probably as a result of the lack of application of radiation science to pharmaceutical science. However, in recent years there has been a surge of interest in toxicology, drug interactions, and clinical pharmacy in general. A significant fraction of the population is exposed to substantial levels of ionizing radiations in the form of X-rays, γ-rays (cancer patients), or a variety of high-energy nuclear radiations (workers in nuclear research and in fields utilizing radioisotopes). The author believes that the effects of ionizing radiations on the biochemical systems in living organisms, particularly man, constitute a branch of toxicology. Moreover, in cancer patients who are subjected to unusually high dosages of ionizing radiations while they may be taking substantial dosages of a variety of drugs regularly, the direct or indirect effects of ionizing radiations upon the drug (*in vivo*) and ultimately upon the patients themselves constitute a special area of drug interactions. Virtually no definitive research has been undertaken in these areas, and very little has even been accomplished with regard to the effects of ionizing radiations upon pure drugs. This review was written to introduce the pharmaceutical community to the fundamental principles underlying the interactions of ionizing radiations with matter in the hope that interest will be stimulated in this area.

The intent of this work is not all inclusiveness; rather, it is a concise exposition of the fundamental principles underlying radiation chemistry and contains a representative selection of references to works of major interest throughout the history of the subject. Several excellent review articles already in the literature were freely drawn upon in preparing this review.

THEORETICAL CONSIDERATIONS

This section deals with the fundamental nature of the interactions of high energy radiations with matter, from the absorption of the radiation to the eventual establishment of chemical equilibrium in the system. The overall process may be divided into three stages (1):

1. The physical stage, entailing the dissipation of the radiant energy in the system. Its duration is of the order of 10^{-15} sec., the time scale representative of electronic absorption in molecules.

2. The physicochemical stage, consisting of processes that lead to the establishment of thermal equilibrium in the system. Its duration is of the order of 10^{-14}–10^{-12} sec., the time scale of vibrational and other thermal relaxation phenomena in molecules.

3. The chemical stage, consisting of diffusion and chemical reaction of the reactive species leading to chemical equilibrium. It lasts upward of 10^{-8} sec., depending on the rate constants and diffusion coefficients of the reactive species and the lifetimes of the reactive species.

Physical Stage—The interaction of ionizing radiation with a medium results initially in ionization and electronic excitation. At very high energies or with very heavy ionizing particles, it is also possible to effect nuclear excitation and dislocation. These processes occur regardless of the nature of the radiation. The mechanism of excitation and ionization by charged particles is different, however, from that by high energy photons. These mechanisms are, therefore, discussed separately.

Charged Particles—The interaction of charged particulate radiations, such as protons, α-particles, and β-rays, with a medium consists predominately of electrostatic coulomb excitation and ionization of the atomic and molecular electrons in the medium. According to Bethe's (2) semiclassical treatment, the energy transferred per unit length of path to the medium by a heavy particle of charge Ze and velocity v is:

$$\frac{dE}{dx} = \frac{4\pi Z^2 e^4 n}{mv^2} \ln \frac{2mv^2}{I} \qquad \text{(Eq. 1)}$$

where n is the mean electron density (number of electrons per unit volume) of the medium, m is the electronic mass, I is a mean excitation potential for the medium ($I = 11.5Z$ ev. for $Z \leq 30$, $I = 8.8Z$ ev. for $Z \geq 30$ where Z is the mean atomic number of the medium), and dE/dx is the energy gained by the medium per unit path length. The latter term is generally referred to as the linear energy transfer (LET) of the radiation. If electrons (β-rays) are the ionizing particles, the expression for LET is changed slightly to:

$$\frac{dE}{dx} = \frac{4\pi Z^2 e^4 n}{mv^2} \ln \left(\frac{mv^2}{2I} \sqrt{\frac{\epsilon}{2}} \right) \qquad \text{(Eq. 2)}$$

where ϵ is the basis of the natural logarithms.

Equations 1 and 2 yield some interesting conclusions about the transfer of energy by charged particles. First, the rate of energy loss of a charged particle in a given medium is proportional to the electron density in the medium. Second, because the factor v^2 outside the logarithmic term is more important than that inside, the rate of energy loss increases as the particle slows down. Third, if two particles of equal energy but different mass are compared, the heavier one will have a smaller velocity and hence a higher LET. As a consequence, an α-particle will produce many more excitations and ionizations per unit path length than a β-particle of the same energy. This is important in the interpretation of effects due to different types of radiation.

High Energy Electromagnetic Radiations—When high energy photons such as X-rays and γ-rays pass through matter, they lose energy by three mechanisms: (*a*) photoelectric absorption, in which the photon transfers its entire energy to an electron; (*b*) Compton scattering, in which the photon transfers part of its energy to an electron; and (*c*) pair production, in which the photon disappears and a high energy electron and positron are formed. The relative contribution of each mechanism to the total energy loss depends upon the energy of the photon. For photons in the 100-kev.–2-Mev. range, the principal mode of absorption by the medium is Compton scattering (3); much higher photon energies favor pair production (at least 1.02 Mev. is required to produce a pair) while lower energies favor photoelectric absorption. The principal effect of the absorption of high energy photons is the production of energetic electrons, which then dissipate their energies by the mechanism already discussed. In addition, ions are produced, the fate of which will be discussed.

In general, the effect of transfer of energy from an energetic particle to the medium is to produce along its path a variety of electronically excited molecules and ions as well as free electrons. Secondary electrons are also formed along with the ions. The electronic transitions resulting in the formation of these species occur in short times (10^{-15} sec.) compared to molecular vibration times (10^{-14} sec.). Little is known about the relative amounts of these species in the several electronic states, especially in the liquid and solid states.

Physicochemical Stage—This stage lasts about 10^{-14}–10^{-12} sec., which is of the order of magnitude of molecular vibration times, during which internal molecular rearrangements can take place.

During the physicochemical stage, the excited molecules and ions dissipate their excess energy by bond rupture, internal conversion, energy transfer to neighboring molecules, *etc.* Therefore, an understanding of these processes is fundamental to radiation chemistry (4). Also, during this stage the low energy secondary electrons produced during the physical stage interact with the environment. There are two divergent theoretical views on this phenomenon as it occurs in pure water. One theory (5, 6) assumes that secondary electrons lose kinetic energy due to attraction by the parent ion and by inelastic collisions with other molecules. After several collisions, these electrons, when they are sufficiently slowed, are recaptured by the parent ions. The recapture process transforms the parent ion into an excited neutral molecule which can then decompose into hydrogen ions and hydroxyl radicals produced close together.

According to the other view (6, 7), the electron loses

its kinetic energy through vibrational and rotational excitation of the medium. The dipole vibration loss lowers the energy of the electron to about 0.2 ev. in about 10^{-12} sec. at a distance larger than 50 Å from the parent ion. It is then surrounded by water molecules corresponding to the IR value of the dielectric constant of about 5 and, thereafter, it is thermalized by rotational excitation of water in about 10^{-11} sec. Since that is the relaxation time of the water dipole, the electron cannot be recaptured by the parent ion; it becomes solvated and produces a hydrogen atom according to: $e_{aq}^- + H_2O \rightarrow H\cdot + OH_{aq}^-$. The parent ion dissociates according to: $H_2O^+ \rightarrow H^+ + OH$.

Consequently, according to the latter model, the hydrogen ions and hydroxyl radicals that result from a given primary ionization are quite far apart; according to the former model, they are quite close. The difference between the initial distribution of these radicals is important for the chemical stage of radiolysis (6).

Chemical Stage—During this stage, the reactive intermediates (ions and radicals) produced in the previous stages diffuse away from their sites of production and undergo chemical reactions. Two subjects are of great importance in the chemical stage: (*a*) the relative importance of ionic *versus* free radical reactions, and (*b*) the rates of diffusion and reaction of the chemically reactive species.

Ionic versus *Free Radical Reactions*—Current theory and experiments indicate that ionic processes are most important in the radiation chemistry of gases (8–12). These processes consist mainly of ion-neutral molecule reactions in which collisions between these entities result in secondary ionization, neutralization, and cluster formation. In condensed systems, however, the main reactive species produced in the physicochemical stage, which react in the chemical stage, are believed to be free radicals. Their primary modes of reaction are atomic abstraction, radical recombination, and addition to π-bonds.

Diffusion Kinetics—The treatment of the rates of disappearance of reactive species has been effected, to a fair degree of accuracy, through the "radical diffusion model" (13). This model is based upon the assumption that the macroscopic laws of diffusion and reaction kinetics are applicable to the system in spite of the spatial inhomogeneity of the "spurs" (localized sites) in which the radicals are formed (3, 5). To compensate partially for the grossness of this assumption, the kinetic equations are expressed in terms of probability densities rather than concentrations of the various reactive species (13). The probability densities describe the average behavior of a statistical ensemble of radical spurs ($\geq 10^{14}$ spurs). The rate of disappearance of a reactive species (x_i) from the medium in which it is formed is given by:

$$\frac{\partial c_i(r,t)}{\partial t} = D_i\nabla^2 c_i - k_i c_i - \sum k_{ij} c_i c_j + \sum_1 \bar{k}_1 c_1 + \sum_{m,n} \bar{k}_{m,n} c_m c_n \quad \text{(Eq. 3)}$$

where $c_i(r,t)$ is the probability density of x_i at time t after the onset of the chemical stage and a distance r from the spur in which it is formed, D_i is the diffusion coefficient of x_i, ∇^2 is the three-dimensional Laplacian operator, k_i is the first-order rate constant for the disappearance of x_i, k_{ij} is the second-order rate constant for the reaction of x_i with x_j, $\bar{k}_1$ is the first-order rate constant for the appearance of x_i from the radiolysis of x_1, and $\bar{k}_{m,n}$ is the second-order rate constant for the appearance of x_i by reaction of x_m with x_n, whose probability densities are c_m and c_n, respectively. Given the initial distributions $c_i(r,0)$, it is possible in principle to integrate numerically the simultaneous, nonlinear, differential equations obtained for each species involved in the process. Once the functions $c_i(r,t)$ are known, one can calculate the amounts of chemically stable products formed.

The radical diffusion model has been criticized on the grounds that: (*a*) the use of probability densities instead of concentrations neglects interactions between nonreacting molecules (correlation) (14), (*b*) it is merely an assumption that the reactive species are in thermal equilibrium with the medium at the onset of the chemical stage (1), and (*c*) too many unknown parameters (rate constants) must be determined (13). Nevertheless, it does provide a reasonable working model of the chemical stage of radiolysis and will have to suffice until it is replaced with a better theoretical treatment.

GASES

The irradiation of gases results in the ionization of the gas molecules (8). Since the distances between molecules in a gas are great, there is a good chance that the ion may escape its counterelectron and engage in reactions of its own (6). This is not a likely process in a condensed medium, because the medium will exert a retarding effect upon ejected electrons and slow them enough to be recaptured rather quickly (6).

A free ion in a gas may be in a vibrationally excited state. The excited ion may possibly have sufficient excess vibrational energy to dissociate during the lifetime of a single vibration ($\sim 10^{-14}$ sec.). This has been observed occasionally in the case of small molecules but is a very rare process in molecules of molecular weight greater than 44 (15).

Free positive ions appear to react in gas media by three principal modes. First, a positive ion may attract other molecules to itself by dipole induction as the ion is thermalized (11). This has the effect of forming an ion cluster in which the charge and excess energy of the ion are delocalized over the entire cluster. This situation is similar to exciton formation in solids. The cluster then may be neutralized by absorbing an electron from the medium. Chemical reaction ensues, resulting in the formation of molecular products. An example of reaction *via* cluster formation is the formation of cuprene from the gas phase radiolysis of acetylene (16) according to the sequence:

$$C_2H_2 \xrightarrow{\alpha} C_2H_2^+ + e^-$$

$$C_2H_2^+ + 20C_2H_2 \rightarrow (C_{42}H_{42})^+ \xrightarrow{e^-} \underset{\text{cuprene}}{C_{42}H_{42}}$$

Second, the ion may capture a neutral molecule by constraining the molecule to move in an orbit around

it. Neutralization may occur, resulting in a complex molecule. For example, consider the interaction between methane and the methane ion to form ethane and hydrogen (17):

$$CH_4^+ + CH_4 \rightarrow (CH_4)_2^+$$

$$(CH_4)_2^+ + e^- \rightarrow H_2 + C_2H_6$$

Alternatively, ion molecule reactions may result in catastrophic processes as, for example (18):

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH\cdot$$

$$H_2^+ + H_2 \rightarrow H^+ + H + H_2$$

and:

$$CH_3^+ + CH_4 \rightarrow C_2H_5^+ + H_2$$

Third, an ion may become thermalized and recapture an electron, resulting in the formation of an excited neutral molecule which can then dissociate into free radicals by several different mechanisms (depending upon which excited states are involved). The free radicals then react with other molecules in the system to begin a chain of reactions leading to the final products. An example of this type of process is the formation of ozone by the radiolysis of oxygen (19):

$$O_2 \xrightarrow{\alpha} O_2^+ + e,\ O_2^+ + e^- \rightarrow (O_2^*) \rightarrow 2O\cdot$$

$$O\cdot + O_2 \rightarrow 2O_3$$

This is an example of a one-component gas reaction. In multicomponent reactions, common processes are oxidation, hydrogenation, polymerization, and reverse reactions.

The irradiation of a system containing oxygen can result in the formation of species such as O_2^+, formed by ionization, or O_2^-, formed by electron capture. These ions can dissociate according to the reactions (19):

$$O_2^+ \rightarrow O\cdot + O^+$$

$$O_2^- \rightarrow O\cdot + O^-$$

Species such as O^+ and $O\cdot$ are strongly oxidizing and react with hydrogen to form water and hydrogen peroxide. Carbon monoxide reacts with oxygen to form carbon dioxide; hydrocarbons react with oxygen to form carbon dioxide, water, and partial oxidation products; and ammonia reacts with oxygen to form water and oxides of nitrogen.

If oxygen is mixed with a gas that by itself undergoes some specific radiolytic reaction, the effect of the oxygen generally predominates over the usual path of radiolysis. This is known as "exclusivity of oxidation" (15).

The presence of hydrogen in a gas system that is being irradiated results in the formation of hydrogen ions which are not as reactive as oxygen positive ions. Hence, hydrogenation does not proceed with the exclusivity seen with oxidation. The irradiation of ethylene in the presence of hydrogen results in the formation of some ethane, but the principal product is still polyethylene (15).

Gas phase polymerization of unsaturated hydrocarbons proceeds by the formation of ions which then attack π-bonds in a chain reaction. Small polymers (3–20 monomer units) are formed independent of temperature and pressure conditions, while the formation of long-chain polymers is dependent upon temperature and pressure as well as the presence of foreign "initiator" species (15). Polymerization of saturated molecules can also occur with elimination of hydrogen; *e.g.*:

$$2CH_4 \rightarrow H_2 + C_2H_6$$

and:

$$2C_2H_6 \rightarrow CH_4 + C_3H_8$$

In some radiolyses of unicomponent or multicomponent gases, the product yields are considerably lower than would be expected from the ion yields measured by dosimetry. The low yields may often be accounted for by the occurrence of reverse reactions. The products formed by radiolysis can react with each other to give the starting material back (15).

In addition to ionization, two other processes may occur in gas phase radiolysis. One, electron capture, has already been mentioned in connection with oxidation. The other is the splitting of a neutral molecule into positive and negative ions; *e.g.*:

$$CHCl_3 \rightarrow CHCl_2^+ + Cl$$

Both of these processes have a reasonable chance of occurring only if the molecules being irradiated contain electronegative atoms (20).

LIQUIDS

The irradiation of liquids results in the formation of ions in the same way as it does in gases. The ejected electrons are usually thermalized within the electric field of the parent ion. Most of these ion-pairs culminate in recapture of the ejected electrons leaving the molecules in a highly excited state, which may return to the ground state or the lowest allowed excited state by internal conversion, luminescence, or energy transfer (21–23). Alternatively, the highly excited neutral molecules may split into free radicals (24). In addition to these processes, some ion-pairs may be sufficiently longlived to diffuse away from the site of production and react ionically with the surrounding medium (6). However, the free radicals are currently believed to be the most important reactive species formed. Once free radicals are formed along the track of an ionizing particle, they may combine with each other while they are in close proximity, or they may diffuse away from the spur and react with molecules in the bulk of the liquid medium. Those that recombine within the spur react so rapidly that they cannot be detected by physical or chemical methods. They form stable molecular products, which are known as the molecular yield. Those radicals that diffuse away from the spur and react with medium can be detected by physical methods, such as electron spin resonance spectroscopy (25), and chemical methods, such as compound formation with radical scavengers (*e.g.*, iodine and diphenylpicrylhydrazine), and are called the radical yield. The mechanisms of chemical radiation effects are frequently

determined by comparison of relative molecular and radical yields. The radiation chemistry of liquids has developed along two distinct paths—that of water and aqueous solutions (26–28) and that of organic liquids (29, 30). Each area has enough distinction to warrant separate discussion.

Water and Aqueous Solutions—The irradiation of pure water is believed to result in two dissociative processes. The first is the direct dissociation of water into hydrogen atoms and hydroxyl radicals:

$$H_2O \rightarrow H\cdot + OH\cdot$$

The second reaction is the ionization of water to yield a hydrogen ion, a hydroxyl radical, and a hydrated electron:

$$H_2O \rightarrow H^+ + OH\cdot + e_{aq}^-$$

The second mechanism was identified through the detection of the absorption spectrum of the hydrated electron. The hydrated electron is an extremely powerful reducing agent and reduces water according to:

$$e_{aq}^- + H_2O \rightarrow H\cdot + OH^-$$

It reduces the hydrogen ion according to:

$$e_{aq}^- + H^+ \rightarrow H\cdot$$

Since the latter two reactions result in the same products as direct radiolysis, and since the products of reduction by the hydrogen atom and the hydrated electron are identical, it is frequently impossible to determine whether the hydrated electron or the hydrogen atom is the principal reducing species in aqueous solutions. In acid solutions, it is reasonable to assume that the hydrated electron will reduce hydrogen ions (H^+) almost exclusively and that hydrogen atoms ($H\cdot$) will therefore be the predominant reducing species; but, in neutral and basic solutions, the hydrated electron may be assumed to predominate. The ultimate molecular products of the radiolysis of pure water are hydrogen gas and hydrogen peroxide, formed by the reactions:

$$H\cdot + H\cdot \rightarrow H_2$$

$$OH\cdot + OH\cdot \rightarrow H_2O_2$$

Of course, hydrogen atoms can react with hydroxyl radicals ($OH\cdot$) to form water, but this process is impossible to detect experimentally.

The radiation chemistry of aqueous solutions may be considered from two points of view. The first, called "target theory," considers the direct effect of ionizing radiations upon the solute molecules. The second approach regards transformations in the solute molecules to be due to interactions with the reactive intermediates formed by the radiolysis of water. Since most aqueous systems are relatively dilute, the latter approach seems to be more reasonable on a purely statistical basis. Kinetic studies of dilute aqueous systems have indeed borne out this supposition. The radiation chemistry of aqueous solutions then becomes the free radical and redox chemistry of $H\cdot$, $OH\cdot$, and e_{aq}^-.

The effectiveness of radicals in producing chemical changes, other than formation of molecular hydrogen and hydrogen peroxide, in aqueous systems depends upon the LET of the ionizing radiation which produces these radicals. A high LET particle, such as an α-particle or a proton, produces a large concentration of radicals along its short track. These radicals are likely to recombine, forming molecular products, before they can diffuse away from the spurs in which they are formed. Low LET particles produce low radical concentrations along their tracks, minimizing the probability of recombination so that the radicals can diffuse away from the spurs and initiate chemical reactions. Protons and α-particles, therefore, result in high molecular yields while β- and γ-rays result in high radical yields.

One popular device for measuring radiation dosage, the Fricke dosimeter, is based upon the oxidation of the ferrous ion by hydroxyl radicals produced in the radiolysis of a dilute aqueous solution of ferrous sulfate:

$$Fe^{+2} + OH\cdot \rightarrow Fe^{+3} + OH^-$$

The presence of dissolved oxygen alters the nature of the redox properties of irradiated water as a consequence of the "radical scavenging" property of oxygen. Molecular oxygen has two unpaired electrons. One of these can form a covalent bond with a hydrogen atom, forming the hydroperoxy radical ($HO_2\cdot$). This species can act either as an oxidizing or as a weak reducing agent:

$$HO_2\cdot + Fe^{+2} \rightarrow Fe^{+3} + HO_2^-$$
(oxidizing)

and:

$$HO_2\cdot + Cu^{+2} \rightarrow Cu^+ + H^+ + O_2$$
(reducing)

The main consequence is that while solutions in pure irradiated water have about equal oxidizing and reducing capabilities, the presence of oxygen in these solutions can result, in some cases, in very strong oxidizing properties due to the conversion of the reducing hydrogen atom to the predominately oxidizing hydroperoxy radical. In general, the presence of oxygen in aqueous solutions leads to alterations of the mechanisms of radiolyses due to the "exclusivity of oxidation." A brief summary of some representative free radical reactions in aqueous solution follows.

Hydrogen Atom—

$$H\cdot + D_2 \rightarrow HD + D\cdot$$

$$H\cdot + H_2O_2 \rightarrow OH\cdot$$

$$H\cdot + O_2 \rightarrow HO_2\cdot$$

$$H\cdot + Fe(H_2O)_n^{+2} \rightarrow Fe^{+3}(H_2O)_{n-1} + OH^- + H_2$$

$$H\cdot + Ce^{+4} \rightarrow Ce^{+3} + H^+$$

$$H\cdot + Fe^{+3} \rightarrow Fe^{+2} + H^+$$

$$H\cdot + Cu^{+2} \rightarrow Cu^+ + H^+$$

$$H\cdot + I_2 \rightarrow H^+ + I^- + I\cdot$$

$$H\cdot + NO_2^- \rightarrow NO\cdot + OH^-$$

$$H\cdot + CH_4 \rightarrow CH_3\cdot + H_2$$

$$H\cdot + HCOOH \rightarrow H_2 + \cdot COOH$$

$$H\cdot + CH_3COOH \rightarrow H_2 + \cdot CH_2COOH$$

Hydroxyl Radical—

$$OH\cdot + H_2 \rightarrow H_2O + H\cdot$$

$$OH\cdot + D_2 \rightarrow HOD + D\cdot$$

$$OH\cdot + H_2O_2 \rightarrow H_2O + HO_2\cdot$$

$$OH\cdot + Fe^{+2} \rightarrow Fe^{+3} + OH^-$$

$$OH\cdot + HSO_4^- \rightarrow OH^- + HSO_4\cdot$$

$$OH\cdot + Ce^{+3} \rightarrow Ce^{+4} + OH^-$$

$$OH\cdot + Tl^+ \rightarrow Tl^{+2} + OH^-$$

$$OH\cdot + I^- \rightarrow OH^- + I\cdot$$

$$OH\cdot + NO_2^- \rightarrow OH^- + \cdot NO_2$$

$$OH\cdot + CH_4 \rightarrow H_2O + CH_3\cdot$$

$$OH\cdot + HCOOH \rightarrow H_2O + \cdot COOH$$

$$OH\cdot + CH_3COOH \rightarrow H_2O + \cdot CH_2COOH$$

Hydroperoxy Radical—

$$HO_2\cdot + HO_2 \rightarrow H_2O_2 + O_2$$

$$HO_2\cdot + OH \rightarrow H_2O + O_2$$

$$HO_2\cdot + H_2O_2 \rightarrow H_2O + O_2 + OH\cdot$$

$$HO_2\cdot + Fe^{+2} \rightarrow Fe^{+3} + HO_2^-$$

$$HO_2\cdot + Fe^{+3} \rightarrow Fe^{+2} + H^- + O_2$$

$$HO_2\cdot + Ce^{+4} \rightarrow Ce^{+3} + H^+ + O_2$$

$$HO_2\cdot + Cu^{+2} \rightarrow Cu^+ + H^+ + O_2$$

Organics—An important difference between the radiation chemistry of water and of organic liquids is that the concept of the spur, a reasonably well-defined volume in which the formation of the reactive species occurs along the track of the ionizing particle, becomes somewhat hazy (31). The reason for this is that the radicals formed in water show a preference for recombination rather than reaction with the environment immediately after formation. The volume in which recombination is likely defines the spur. The radical products of irradiated organic liquids, however, are more likely to interact with their immediate environment than to undergo recombination. This is evidenced by the low molecular yields of hydrogen from irradiated organic systems.

The radiation chemistry of hydrocarbons and their derivatives has been extensively investigated (32). An important difference between gas phase and liquid phase radiolysis of hydrocarbons exists in that the breaking of carbon–carbon bonds is an important primary process in the gas phase, while the rupture of carbon–hydrogen bonds is almost exclusive in the liquid phase. Another important difference between analogous reactions in gas and liquid phases occurs in the polymerization process. In gas phase polymerizations, the presence of radical scavengers, such as iodine and benzoquinone, does not appreciably alter the yields of polymeric products. In the liquid phase, however, the yields of the polymers obtained from the irradiation of materials like vinyl chloride are seriously curtailed by the addition of radical scavengers. This indicates that polymerization in the liquid state occurs primarily by a free radical mechanism, whereas in the gaseous state it occurs by an ionic mechanism. The irradiation of polymeric materials results in cross-linking of polymer chains and grafting of dissimilar polymeric materials. This treatment of polymers contributes considerable tensile strength and heat resistance to the irradiated polymers and is already being exploited commercially.

Irradiation of saturated aliphatic compounds typically results in unsaturation, polymerization, and isomerization. The radiolysis of cyclohexane illustrates all three processes. The initial step in the radiolysis of cyclohexane results in the formation of energetic cyclohexyl radicals and hydrogen atoms. If the radicals produced are very energetic, cyclohexane can be formed by the abstraction of hydrogen from a cyclohexyl radical either by a hydrogen atom or by another cyclohexyl radical. If the radicals become thermalized, recombination of radicals can occur to give bicyclohexyl. A less frequent process occurring in the thermalized cyclohexyl radical is rearrangement followed by hydrogen atom capture to yield methylcyclopentane.

The irradiation of alkyl halides results in cleavage of the carbon halogen bond. The radiolysis of methyl iodide, for example, yields ethane and molecular iodine.

Alcohols, upon radiolysis in the liquid state, yield aldehydes and vicinal glycols (33–35). For example, consider the radiolysis of methanol:

$$CH_3OH \rightarrow \cdot CH_2OH + H\cdot$$

$$\cdot CH_2OH \rightarrow H_2C{=}O + H\cdot$$

and:

$$2\cdot CH_2OH \rightarrow CH_2OHCH_2OH$$

Although it would be expected that high LET radiations would favor glycol formation and low LET radiations would favor aldehyde formation, the opposite is true. This indicates that the mechanisms involved are not as simple as the schemes would lead one to believe.

The irradiation of alcohols frozen to glasses at liquid nitrogen temperature results in deep coloration of the glasses (36). Methanol turns a brilliant purple while ethanol turns blue. These colored glasses are stable if kept in the dark at low temperatures. Exposure to visible or UV light results in bleaching of the alcoholic glasses as well as elimination of the electron spin resonance signal observed in the colored glasses. The nature of the colored glasses is not well understood, but the colors are believed to be due to the absorption spectra of trapped free radicals in the glasses. The product yields from the bleached glasses are different from those of irradiated glasses that have not been exposed to light. This indicates that the trapped radicals might be photolyzed by visible and UV light.

The irradiation of aromatic compounds generally results in considerably lower yields of radiolysis products than does irradiation of aliphatic compounds of similar molecular weight and functional group composition (37–39). This has been attributed to the effectiveness of the delocalized π-orbitals in these compounds in accommodating excitation energy without permitting the molecule to dissociate. Nevertheless,

some radiolysis does occur. Benzene is known to yield biphenyl, phenylcyclohexadiene, and a polymeric material of average composition $(C_6H_7)_x$, which behaves like an unsaturated hydrocarbon. The low yields of hydrogen molecules (H_2) observed in benzene radiolysis are due to attack of hydrogen atoms upon the benzene ring to form phenylcyclohexadiene and the polymer. Dimerization and polymer formation are also characteristic of the radiation chemistry of other aromatic hydrocarbons. The resistance of polystyrene $(-C_6H_5CHCH_2-)_n$ to cross-linking, compared with polyethylene, is further evidence of the stability of aromatics to radiation effects. Nitrobenzene is also very stable to radiation damage.

In addition to being stable to radiation, aromatic compounds frequently protect other, more radiosensitive compounds from radiolysis (40). An example of this is the protection of liquid cyclohexane from extensive radiolysis by the addition of a small amount of benzene. This protective effect of benzene is probably due to energy transfer from cyclohexane to benzene, followed by dissipation of the excitation energy by the aromatic π-system.

Finally, one important general feature of the radiation chemistry of liquids is that excited or reactive molecules are formed in close proximity and are quite likely to react with one another. This situation is not encountered in photochemistry, and it is this phenomenon that makes liquid phase radiation chemistry so interesting.

SOLIDS

Because of the "fixed" positions of atoms in crystalline lattices, the effect of irradiation of solids (41, 42) includes atomic displacements as well as electronic excitation and ionization. While electronic alterations of materials affect their chemical behavior, atomic displacements in solids have a much more pronounced effect upon the physical properties of crystals. To dislodge an atom from its normal lattice position, a certain amount of energy must be transferred to the atom by an irradiating particle. Because of the large mass of the atoms, electrons and photons are relatively ineffective in producing substantial numbers of atomic dislocations. The heavier particles—α-particles, protons, deuterons, and neutrons—are much more effective in this process. Furthermore, unlike the primary effect of ionizing radiations in producing electronic disturbances through electrostatic effects, the predominant effect that is required to produce atomic dislocations is the direct knock-on process.

Two basic types of lattice defects, point defects and line defects, occur in all real crystals and at very high concentrations in irradiated crystals. Point defects result from the displacements of atoms from their normal lattice sites. These displaced atoms usually occupy a site not in the lattice framework and are then known as "interstitials." The empty lattice site left behind by the interstitial is called a "vacancy." A vacancy produced by displacement of an anion or cation, along with its interstitial ion, is called a Frenkel pair or simply a Frenkel defect. In some cases, the displaced ions are removed so far from their vacancies that they form a new layer at the crystal surface. The vacancies left behind are called Schottky defects. Frenkel and Schottky defects play very important roles in the properties of solids altered by radiation damage.

Line defects (dislocations) are produced by slippage or shear of the crystal lattice. If the slippage is perpendicular to a face of the crystal so that the lattice planes on either side of the dislocation are parallel but displaced with respect to one another, the defect is called an edge dislocation. If the slippage is angular, as if produced by rotation about the shear axis, so that lattice planes on either side of the defect are not perpendicular, the defect is called a screw dislocation.

A consideration of the effects of irradiation of crystalline materials requires that the nature of the crystal be understood. There are four broad classifications of crystal types, according to the nature of the interatomic forces holding the crystal together. In metallic crystals the atoms are thought to form a quasi-ionic lattice arrangement with the valence electrons, which bind the lattice delocalized throughout the crystal so that they cannot be identified with any one atom. Valence crystals, such as diamonds, consist of a lattice in which the atoms are bonded by conventional covalent interaction throughout the lattice. This implies that a valence crystal could be considered a giant molecule. Molecular crystals (*e.g.*, naphthalene and water) are regular arrangements of well-defined molecules which are bound together in the lattice by van der Waals' and hydrogen bonding forces. Finally, the ultimate in electronic localization occurs in ionic crystals, in which the lattice is composed of alternating positive and negative ions held together by strong electrostatic attractions. Sodium chloride is a typical example of an ionic crystal. The predominant effects of ionizing radiations on these crystal types will be considered separately, because these effects are manifested as characteristics of the crystal type.

Metallic Crystals—The effects of ionizing radiations upon metals are entirely due to atomic displacement. Because of the delocalization of electrons throughout the crystal, no persistence of ionization can occur; a positive hole formed by an electron ejection is always refilled by an electron from the conduction band. As a result, no chemical decomposition can occur because of ionization. On the other hand, sufficiently energetic radiations can cause atomic displacements. The production of interstitial atoms in the lattice has the effect of "swelling" the crystal. This results in a lowering of the density of the crystal. The irradiation of a crystal of copper increases the critical shear stress considerably (43). This is believed to be due to the migration of thermalized interstitials and vacancies to the sites of naturally occurring dislocations in the copper crystal. These interstitials impede the vibration and slippage of the dislocations, resulting in greater resistance to shear. This "pinning of dislocations" is also used to explain why copper behaves like a tuning fork when struck with a hammer after irradiation while it gives a dull "thud" when struck prior to irradiation.

Perhaps the most obvious evidences of radiation damage in metallic crystals are the increase of electrical

resistivity and the decrease of thermal conductivity in irradiated crystals. This is believed to be due to scattering of electrons and photons by vacancies and interstitials which behave like impurities and destroy the order of the lattice necessary for high conductivity.

The obvious effects of radiation damage in metallic crystals can be reversed by "annealing." This process consists of heating the irradiated materials so that the "energy of activation" required to push an interstitial back into a vacancy is supplied (44).

Valence Crystals—The stable, symmetrical bonding occurring in valence crystals results in the failure of these crystals to demonstrate quasichemical changes such as depolymerization or reaction of the matrix with displaced entities. Unlike metals, however, valence crystals have no conduction electrons and can therefore retain electronic dislocations as well as atomic displacements. The trapping of dislocated electrons in the crystal by potential wells, such as those created by atomic vacancies, results in coloration of the normally transparent valence crystals. This is due to the low excitation energies of trapped electrons as opposed to σ-bonded electrons.

The irradiation of semiconducting valence crystals like silicon and germanium usually drastically decreases the conducting properties of these crystals (45). Large numbers of Frenkel defects are produced and act as traps for conducting electrons and holes, thereby altering the concentrations of conducting species. Bombardment of n-type germanium with deuterons converts the germanium to a p-type semiconductor.

Ionic Crystals—Irradiation of ionic crystals results in atomic and electronic dislocations. The trapping of displaced electrons by anion vacancies results in a pseudoatomic system which usually has a manifold of closely spaced, electronic energy levels. This results in the absorption of visible and near UV light which gives these crystals their characteristic colors. These pseudoatomic electrons and their vacancies are called color centers (46). The polarizations of the spectra of these color centers depend upon the symmetry of the electric field produced by atoms surrounding the trapped electron. Some of the color centers commonly produced by irradiation of ionic crystals are: F-centers (octahedral symmetry), consisting of an electron trapped by a simple halide-ion vacancy; M-centers (isoceles, triangular symmetry), consisting of the delocalized coupling of an F-center with an adjacent anion-cation vacancy pair (Seitz defect); and V-centers, consisting of a singly charged halogen molecule anion in a normal lattice site, behaving as a trapped hole by virtue of its molecular bond. The exposure of colored ionic crystals to visible or UV light results in bleaching of the colorations induced by irradiation. While this bleaching is being carried out, the crystals become photoconductive when a potential difference is imposed across them. This implies that the bleaching process is due to annealing of trapped electrons. If a sufficient potential difference is placed across the crystal, the color centers will migrate through it. In some cases where the crystal remains uncolored upon irradiation, thermoluminescence is observed in the annealing process.

The dissolution of a heavily irradiated crystal of sodium chloride in water will result in the evolution of hydrogen and chlorine from the solution. The solution also turns alkaline, presumably due to the reactions of trapped holes and electrons with water (47):

$$e^- + H_2O \rightarrow {}^1/_2\, H_2 + OH^-$$

$$\text{hole}^+ + Cl^- \rightarrow {}^1/_2\, Cl_2$$

Trapped electrons also account for the ability of irradiated sodium chloride to initiate polymerization in acrylonitrile.

Irradiation of nitrates, chlorates, perchlorates, and bromates results in the liberation of oxygen (48, 49). In potassium perchlorate, irradiation results in explosion of the crystal due to internal buildup of oxygen.

Molecular Crystals—The irradiation of substances that form crystals containing discrete molecules, held together by dispersion forces, results in radiolysis in the conventional sense. For example, the radiolysis of aliphatic carboxylic acids in the solid state yields hydrogen, carbon monoxide, and carbon dioxide (50). The relative yields of these gases depend upon the strength of the bonds involved in radiolysis and their frequency of occurrence. These considerations apply as well to liquids and gases and suggest no special solid-state effects. This is the case for the γ-radiolysis of bromotrichloromethane (51), where no difference in the yield of bromine is observed for irradiation of solid or liquid bromotrichloromethane. Differences are observed between the radiolysis patterns of liquids and molecular crystals of the same materials, but these seem to be more the exception than the rule and may generally be attributed to stronger caging effects in the solid than in the liquid (52).

Energy transfer in molecular crystals seems to be a well-established phenomenon. Irradiated crystals of anthracene containing only a trace of naphthacene show the characteristic green fluorescence of naphthacene rather than the violet of the main constituent (53). If the material is dissolved in benzene, the anthracene fluorescence predominates. This phenomenon is often seen in mixed, scintillating crystals (54).

The irradiation of ice results in formation of trapped hydrogen and hydroxyl radicals as well as the hydrated electron (55). Dilute solutions of Cd^{+2}, Zn^{+2}, and Mg^{+2} in ice have been reduced to the unstable Cd^+, Zn^+, and Mg^+, respectively, upon irradiation (56). Apparently, some mobility is enjoyed by some radical species in the ice lattice.

The irradiation of surface catalysts alters the properties of these catalysts through defect production on the surfaces (57). These defects have been observed to enhance and inhibit catalytic activity in specific cases. For example, irradiation of silica gel enhances the rate of hydrogen–deuterium exchange on it (58). On the other hand, irradiation of zinc oxide decreases the rate of hydrogenation of ethylene on it (59).

CHEMICAL PROTECTION FROM IONIZING RADIATIONS

The effects of ionizing radiations upon chemical and biological systems may be minimized or even eliminated by the addition of certain chemical compounds to the system to be irradiated. These compounds react

either directly with the radiation or, more often, with the reactive species produced by the radiations. In so doing, they are themselves transformed into other substances, but their transformation results in the preservation of the integrity of the original chemical or biological system.

At the molecular level, several mechanisms account for the protection of irradiated systems by chemical agents. These are: (*a*) energy transfer and charge transfer, in which an ionized or excited molecule transfers its charge or excess energy to a protecting molecule either by collision or by resonance transfer at a distance; (*b*) scavenging, in which a protecting radical scavenger reacts with radicals from the initial actions of the radiation before they can attack other molecules in the system; and (*c*) complex formation, in which a protective molecule can form complexes that are either more or less susceptible to radiation than the original substance.

Energy and Charge Transfer—The transfer of charge or excitation energy (60) must be fast enough to compete with dissociation processes if protection is to occur. In some cases, an activated molecule can dissociate within 10^{-14} sec., the time for one molecular vibration. However, localization of energy in a particular bond usually requires 10^{-13}–10^{-9} sec. To remove energy or charge from an activated molecule effectively, the protector should have a slightly lower ionization or excitation potential. In fluid systems the rate of charge transfer is limited by diffusion; the donor and acceptor must be in contact. Excitation energy, however, can be exchanged by molecules as much as 70 Å apart by "Förster energy transfer," a dipole–dipole interaction. One requirement of this process is partial overlap of the absorption spectrum of the energy acceptor and the emission spectrum of the energy donor. Energy transfer is radiationless, comparable in rate to molecular vibration and thus more efficient than luminescence in deactivating highly excited molecules. Transfer processes of this type are extremely efficient in crystalline materials where the high degree of order permits excitation energy to travel in excitons which traverse the crystal faster than its vibrational relaxation time. Crystalline structure also facilitates charge transfer by providing conduction bands in which electrons can freely move about.

Energy conversions within a molecule can decrease the probability of decomposition. Energy can be dissipated so rapidly by internal conversion that its localization in any one bond is improbable. Paramagnetic additives such as transition metal ions are useful in this context as strong spin-orbit coupling increases the number of energy states available to the original molecules. Aromatic compounds are protective because they can probably dissipate acquired excitation energy throughout their extensively delocalized π-systems (61–63).

Scavenging Intermediates—The addition of certain compounds that readily react with free radicals can effectively prevent these radicals, which are primary products of ionizing radiations, from causing secondary damage in the system. Molecular iodine is a very effective radical scavenger, forming iodo compounds (64, 65) with radicals and leaving behind iodine atoms to do further scavenging, *e.g.*:

$$CH_3\cdot + I_2 \rightarrow CH_3I + I\cdot$$

$$CH_3\cdot + I\cdot \rightarrow CH_3I$$

Oxygen is a diradical which enhances radiation damage by forming radicals with other radicals. An example of the latter process is the scavenging of hydrogen atoms by molecular oxygen to form the hydroperoxy radical (65):

$$H\cdot + O_2 \rightarrow HO_2\cdot$$

Complexes—Certain compounds may exert protective action by forming molecular complexes with the original molecules of the system. These complexes might be less sensitive to radiolysis or attack by radicals or they may be better able to transfer charge and excitation energy than the original compound. Protection can also result from the formation of complexes across particularly sensitive bonds in the original compound. For example, the degradation of polyisobutylene is reduced about 50% by copolymerization with 20% styrene (66). The radiation resistance of the porphyrin ring is enhanced by complexing it with vanadium and other metals.

The most obvious application of chemical protection from ionizing radiations is to biological systems. For a protective agent to be biologically practical, it must be nontoxic at protective concentrations, easily introduced to the organism, widely distributed, and remain intact for long periods of time before irradiation. Many substances of all kinds have been applied to this problem. The most effective to date have been compounds like cysteine, because of the scavenging property of the mercapto (—SH) group and the ease of oxidation of the amino ($-NH_2$) group, and cystamine (67), because of complex formation with, and ease of oxidation of, the disulfide linkage. None of the compounds studied to date has been effective enough for use in man, predominately because of their high toxicities.

MOLECULES OF BIOLOGICAL SIGNIFICANCE

The effects of ionizing radiations on living organisms are frequently observed but not completely understood. There are two distinct theories of the actions of ionizing radiations on the components of living cells that result in chemical transformations leading to mutation or cell death. The first of these is the "target theory" (3, 68). This approach regards only those events that produce ionizations in biologically significant molecules as being important. The main evidence for this simple idea is that, in many cases, the amount of damage to a given organism varies logarithmically with the dose of radiation, implying that the amount of damage possible in a cell is proportional to the number of radiosensitive species remaining undamaged and therefore capable of reacting. A less direct mechanism would not require the proportionality of dose and unaffected material because some of the total dose would be channeled out to processes other than the biologically significant ones.

The other theory is based upon such an indirect relationship between the incident radiation and the af-

fected, biologically significant molecules (69). In this approach, the solvent, water, interacts with the radiation, forming ions and radicals. These reactive species in turn react with the biologically significant molecules, causing radiation damage. Radiation biology, under this approach, is simply a branch of the radiation chemistry of aqueous solutions. As such, the recombination of hydrogen atoms and hydroxyl radicals to form hydrogen and hydrogen peroxide (the molecular yield) effectively competes with the biological molecules for the effects of the radiation. There is evidence that both the target and indirect processes occur and that no one theory accounts for all of the observed biological effects of radiation at the molecular level (4).

This section considers the effects of ionizing radiations on molecules known to have biological significance and the relationship of the radiation chemistry of these molecules to radiation effects observed in living organisms.

Carbohydrates—The irradiation of aqueous solutions of carbohydrates (70–74) has the same effect as it does upon alcohols. The hydroxyl groups are attacked to yield carbonyl compounds. Under anoxic conditions, dimeric products and ultimately polymers are also formed. The primary alcohol groups of carbohydrates are especially radiosensitive. Mannitol is readily oxidized to mannose and sorbitol is oxidized to glucose. While oxidation of primary alcohol groups is favored by aerobic conditions, high yields from the oxidation of secondary alcohol groups are favored by anoxic conditions.

The irradiation of polysaccharides results predominately in their degradation. This explains why fruits and vegetables become soft on irradiation. This degradation occurs both in solution and in the dry state.

Amino Acids and Peptides—The irradiation of amino acids (75) results in transformation of both the amino and the carboxylic functions (76). In the dry state, glycine is decarboxylated to methylamine upon irradiation; in dilute aqueous solution, however, the amino group is hydrolyzed to give glyoxalic acid, acetic acid, and formaldehyde. In solutions of concentrations greater than 2%, methylamine again becomes an important product. The other amino acids are similar to glycine in their radiolytic behavior. Alanine, for example, gives ethylamine and carbon dioxide in the dry state and pyruvic acid and ammonia in aqueous solution (77, 78).

The aromatic amino acids, when irradiated in aqueous solution, show effects that are typical of aromatic compounds and amino acids (79, 80). Phenylalanine is deaminated in aerated solutions with the formation of a ketone. The aromatic ring remains relatively stable to radiolytic decomposition.

The irradiation of peptides results in a chemistry similar to that of the amino acids but also in the breakage of the peptide bond (81). In aqueous solution, all irradiated peptides give ammonia whether or not free amino groups are present.

When irradiated in the dry state, the thiol- and disulfide-containing amino acids degrade to keto acids with the evolution of carbon dioxide and hydrogen sulfide. In solution, however, the thiol and disulfide groups are excellent radical scavengers and free radical attack on these groups precludes deamination. The ultimate result of irradiation of thiol-containing amino acids is their oxidation to disulfides. Thus, irradiation of an aqueous solution of cysteine results in the formation of cystine (82–84). The irradiation of the disulfides results in higher oxidation products. For example, cystine gives cystine disulfoxide in aqueous solution. Reduction of disulfides to thiols is not generally observed.

Proteins and Enzymes—The irradiation of proteins (85) results in the formation of free radicals in the sites of disulfide bonds (86). Aromatic amino acids in the proteins are also particularly susceptible to attack, decarboxylation and deamination being common results of irradiation (87, 88). Rupture of the peptide linkage is characteristic of the radiolysis of proteins (87, 89). In the case of enzymes, the destruction of peptide linkages is accompanied by a decrease in biological activity (90). This decrease continues after irradiation is stopped (91). The mechanisms of radiolysis in the dry state and in solution are different, but the results are usually similar. One important difference between these results is the degradation of proteins by dry state irradiation compared with the increase of molecular weight through cross-linking in solution (92). In general, the radiation chemistry of proteins and enzymes may be considered a special case of the radiation chemistry of peptides and amino acids.

Respiratory Proteins, Vitamins, and Coenzymes—*Respiratory Proteins*—These substances are iron-porphyrin-protein complexes. Irradiation of these substances may produce effects in the porphyrin ring or in the protein, but oxidation or reduction of the iron almost always is involved. The iron in cytochrome c (ferricytochrome c) is reduced to the ferrous state in the presence of benzoate ion (93). Under alcoholic conditions, the ferric form is favored. Hemoglobin and oxyhemoglobin are both oxidized from the ferrous to the ferric state, destroying the property of oxygen transport (94–97). Large radiation doses result in attack on the porphyrin ring and denaturation of the protein. When irradiated in the dry state in the absence of oxygen, hemoglobin becomes insoluble due to protein denaturation. Myoglobin behaves in a similar manner to hemoglobin but is considerably more radiosensitive (94). Hemocyanin is a copper-containing respiratory protein of molecular weight more than 10 times that of hemoglobin. In this case, attack at the protein part of the molecule predominates (98).

Vitamins and Coenzymes—The irradiation of coenzyme I (diphosphopyridine nucleotide) results in reduction of the pyridine carboxamido ring. The product of this reduction is probably a dimer, which is itself radiosensitive (99).

The B-group vitamins, thiamine and riboflavin, are destroyed upon irradiation in dilute aqueous solutions. Riboflavin is reduced in air-free solutions to a semiquinone form (100). Niacin is decarboxylated on irradiation in air-saturated aqueous solutions (101).

Upon irradiation in aqueous solution, aminobenzoic acid is destroyed by deamination and decarboxylation (102–104). Sulfanilamide and sulfathiazole are inacti-

vated, presumably due to deamination (105). Upon irradiation, the cobalt in vitamin B_{12} is reduced from the cobaltic to the cobaltous state.

The plant hormone auxin has been shown to be radiosensitive. The product of the irradiation of auxin (β-indoleacetic acid) is a polymer similar to that obtained in the radiolysis of indole (106).

Nucleic Acids—The nucleic acids DNA and RNA are responsible for the transmission of genetic information and protein synthesis. Both processes are dependent upon the ordering of purine and pyrimidine bases, which are bound to the main body of the molecule by riboside linkages. The main body of these molecules consists of ribose (5-carbon sugar) molecules linked together by phosphoric acid units to form a long strand. The purine and pyrimidine bases branch off from the chain at the ribose sites. It is believed that the DNA molecule consists of two helically intertwined strands of nucleic acid held together by hydrogen bonding between purine and pyrimidine pairs on opposite strands.

The irradiation of nucleic acids ruptures hydrogen bonds which hold DNA strands together, resulting in polymerization, deamination, and dehydroxylation of purine and pyrimidine bases, fission of sugar base linkage, liberation of the purine bases, destruction of the pyrimidine bases, oxidation of the sugar moiety, and breakage of the nucleotide chain with liberation of inorganic phosphates. In the presence of oxygen, irradiation leads to the formation of hydroperoxides of the pyrimidine bases but not of the purine bases (107–114).

In general, the purine bases appear to be much more stable to radiolysis than the pyrimidine bases (113, 114), probably due to the greater π-delocalization energy of the purines which provides a pathway for nondestructive energy dissipation. Furthermore, the pyrimidine bases are known to undergo free radical reactions more readily than the purine bases. The order adenine > guanine $\gg$ cytosine > uracil > thymine has been established for the relative resistances of the bases to radiolysis. In the presence of oxygen, in aqueous solutions, uracil and thymine form stable hydroperoxides while cytosine forms an unstable hydroperoxide which decomposes to a variety of products (113–116).

Irradiation of DNA in the solid state, at liquid nitrogen temperature, yields radicals in which, as indicated by electron spin resonance measurements, the unpaired spin is delocalized over the entire chain and does not belong to any one unit of the giant molecule (117). Addition of small amounts of water to this system does not alter the nature of the DNA radicals produced, but a two-to-one excess of water results in the annihilation of the electron spin resonance signal for DNA with the appearance of a strong signal due to water radicals. It has been postulated that this protective effect is due to energy transfer which is made possible in an excess of water by structuring of the water, thus providing a pathway for the formation of a delocalized water radical or exciton. Electron spin resonance studies of irradiated nucleoprotein solutions indicate that the protein takes most of the radiation damage, protecting the nucleic acid moiety.

The damages caused by ionizing radiations in nucleic acids and their components are obviously detrimental to the passage of genetic information, which requires specific orders of intact purine and pyrimidine bases in the DNA strands. Alterations in these bases and the DNA molecules in general can lead to mutations and lethal genes. The disruption of RNA molecules interferes with protein synthesis and can result in eventual cell death.

PHARMACEUTICAL SYSTEMS

Most pharmaceutical studies related to the effects of ionizing radiation have been confined to the study of radioprotective drugs. A few studies of the effects of drugs on irradiated organisms and of irradiation on drug-dosed organisms have also been carried out. As mentioned earlier, the effects of ionizing radiation can be minimized by certain chemical compounds. Among the agents employed as radioprotective drugs are the sulfhydryl compounds, notably cysteine, estrogens, and bacterial lipopolysaccharides.

One way in which these protective agents exert their effect is by scavenging free radicals resulting from biological radiation damage. In this instance, the radioprotective agent reacts with a free radical to form a less reactive free radical or a molecule that is insufficiently reactive to interact with cellular components. Aminothiols work well in this context. Grenan and Copeland (118) studied the structure-radioprotective activity relationship of the aminothiols (β-mercaptoethylamine homologs) and found all derivatives to exhibit some radioprotective effect. Vasin (119) found that increasing the length of the alkyl side chains resulted in loss of antiradiation properties. He also found indole analogs of esadrine and ephedrine and the indolylalkylamino alcohols possessing a third amino group to be quite effective in suppressing radiation damage. Recently, Langendorff (120) found that a significant relationship exists between cyclic adenosine monophosphate and radioprotection and hypothesized that cyclic adenosine monophosphate plays a major role in radioresistance.

Organoselenium compounds such as selenocystine, selenomethionine, colloidal selenium, selenoxanthene, selenoxanthone, and selenochromone were found to be similar to, and in some cases superior to, cysteine in radiation protection (121). Dimethyl sulfoxide has also demonstrated radioprotective properties, as has phenylhydrazine (122, 123). Imidazole and erythropoietin were found to increase the survival of irradiated mice, with the highest survival rate being after administering the drug 5 min. prior to irradiation (124). A bile acid sequestrant was also found to be effective in preventing GI effects of whole body irradiation. Parkinson (125) found this to be an effective means of reducing the severity of effects and the morbidity associated with irradiation of the GI tract. To reduce the toxicity seen with the administration of these agents, Vlastislav (126) suggested a causal relationship between radioprotection and immunization by protein antigen interactions with such agents as β-lactin, casein, and human serum albumin.

The interpretations of these phenomena are obviously largely speculative. In this regard, the study of com-

bined influences of drugs and ionizing radiation at the molecular level should prove a most fertile area for future investigation.

Chemical Modification of Lincomycin: Synthesis and Bioactivity of Selected 2,7-Dialkylcarbonate Esters

A. A. SINKULA▲ and C. LEWIS

Abstract □ A series of lincomycin 2,7-dialkylcarbonate esters was synthesized to enhance the pediatric acceptability of lincomycin. Several diester derivatives are sufficiently tasteless to warrant consideration as candidates for pediatric formulations. Preliminary bioactivities [mouse median protective dose (CD_{50}) bioassay] indicated several derivatives to be equivalent in subcutaneous activity to lincomycin hydrochloride. Four diester derivatives exhibited oral bioactivity comparable to that of lincomycin. Serum hydrolysis studies on certain 2,7-diesters of lincomycin established that a high degree of esterase activity is present in the serum of several different rodent species. This phenomenon appeared to be limited to these species.

Keyphrases □ Lincomycin 2,7-dialkylcarbonate esters—synthesis as tasteless derivatives, bioactivity compared to lincomycin hydrochloride □ Carbonate esters of lincomycin—synthesis as tasteless derivatives, bioactivity compared to lincomycin hydrochloride □ Pediatric formulations, potential—synthesis, activity of lincomycin 2,7-dialkylcarbonate esters □ Tasteless lincomycin derivatives—synthesis, activity of 2,7-dialkylcarbonate esters □ Antibacterial agents, potential—synthesis of lincomycin 2,7-dialkylcarbonate esters

The use of bioreversible derivatives for the modification of certain pharmaceutical properties of lincomycin (I) was reported previously (1, 2). This paper represents a continuation of that systematic effort and is concerned with lincomycin 2,7-dialkylcarbonate ester derivatives. The goal of this work was the synthesis of several

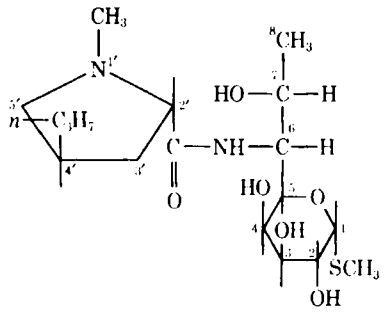
Chemical Modification of Lincomycin: Synthesis and Bioactivity of Selected 2,7-Dialkylcarbonate Esters

A. A. SINKULA▲ and C. LEWIS

Abstract □ A series of lincomycin 2,7-dialkylcarbonate esters was synthesized to enhance the pediatric acceptability of lincomycin. Several diester derivatives are sufficiently tasteless to warrant consideration as candidates for pediatric formulations. Preliminary bioactivities [mouse median protective dose (CD_{50}) bioassay] indicated several derivatives to be equivalent in subcutaneous activity to lincomycin hydrochloride. Four diester derivatives exhibited oral bioactivity comparable to that of lincomycin. Serum hydrolysis studies on certain 2,7-diesters of lincomycin established that a high degree of esterase activity is present in the serum of several different rodent species. This phenomenon appeared to be limited to these species.

Keyphrases □ Lincomycin 2,7-dialkylcarbonate esters—synthesis as tasteless derivatives, bioactivity compared to lincomycin hydrochloride □ Carbonate esters of lincomycin—synthesis as tasteless derivatives, bioactivity compared to lincomycin hydrochloride □ Pediatric formulations, potential—synthesis, activity of lincomycin 2,7-dialkylcarbonate esters □ Tasteless lincomycin derivatives—synthesis, activity of 2,7-dialkylcarbonate esters □ Antibacterial agents, potential—synthesis of lincomycin 2,7-dialkylcarbonate esters

The use of bioreversible derivatives for the modification of certain pharmaceutical properties of lincomycin (I) was reported previously (1, 2). This paper represents a continuation of that systematic effort and is concerned with lincomycin 2,7-dialkylcarbonate ester derivatives. The goal of this work was the synthesis of several

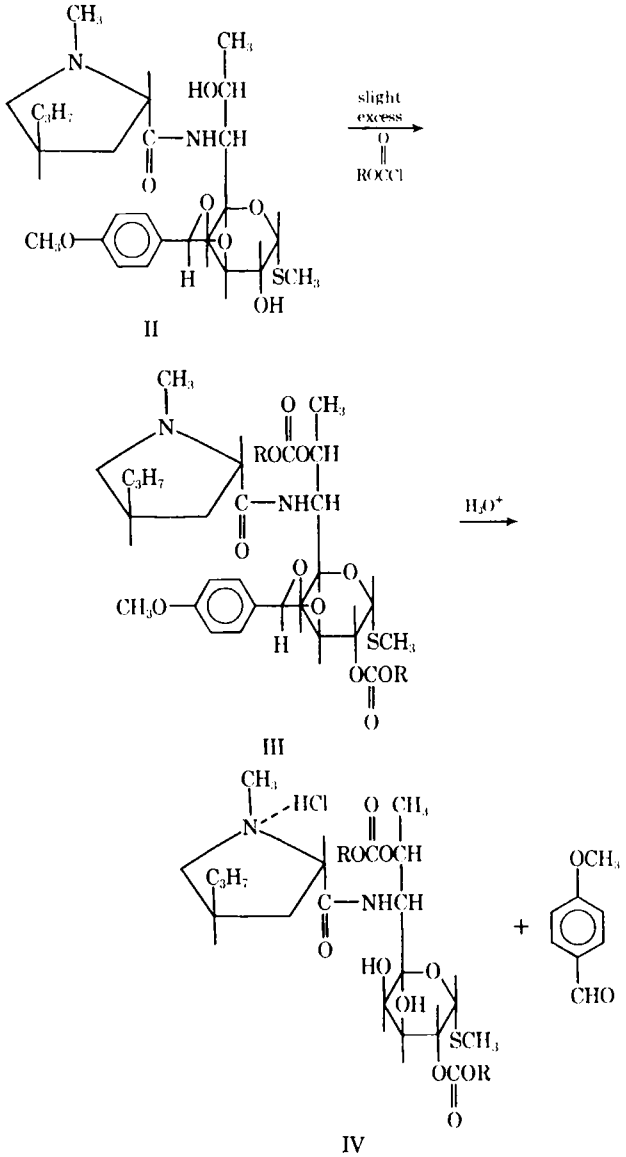


I

lincomycin 2,7-dialkylcarbonate esters sufficiently insoluble in aqueous media to warrant acceptability as candidates for a pleasant-tasting suspension of lincomycin for pediatric use.

RESULTS AND DISCUSSION

Chemistry—Lincomycin 2,7-dialkylcarbonate esters were synthesized according to Scheme I. The reaction of 3,4-*O*-(*p*-methoxybenzylidene)lincomycin (II) (3) with a slight excess (0.005–0.06 mole) of alkyl chloroformate afforded the desired 3,4-*O*-(*p*-methoxybenzylidene)lincomycin 2,7-dialkylcarbonate ester (III). Acidic hydrolysis of III produced lincomycin 2,7-dialkylcarbonate hydrochloride (IV) and anisaldehyde.



II

III

IV

Scheme I

Reaction temperature played an important role in the synthesis of III and IV. When the reaction mixture was cooled to 0° prior to addition of alkyl chloroformate, a pyridine–alkyl chloroformate complex precipitated which effectively prevented the formation of III. This situation prevailed even when the reaction mixture was recooled and more alkyl chloroformate was added. The problem was circumvented by cooling the reaction medium to −35° prior to addition of alkyl chloroformate. Subsequent slow warming of the reaction mixture to room temperature allowed formation of III exclusively.

When the formation of III was complete, the reaction mixture was poured into ice water and the pH was adjusted to 2–3 with concentrated hydrochloric acid. The resulting suspension was extracted with ether. Removal of the ether produced a yellow gum, which was dissolved in aqueous methanol acidified to pH 1–2. Hydrolysis of the *p*-methoxybenzylidene moiety proceeded smoothly. After hydrolysis was completed, the pH of the solution was adjusted to 4 with sodium bicarbonate. The solvent was removed *in vacuo* and the residue was extracted with ether. All derivatives were purified by recrystallization. Synthetic details are outlined in the *Experimental* section.

Bioactivity—*In Vitro*—The derivatives were all intrinsically inactive *in vitro* when tested by both the broth dilution and standard curve assay techniques (Table I). The methodology for determining *in vitro* bioactivity was described previously (3). In these assays, pure lincomycin base was assigned a potency of 1000 mcg./mg.

In Vivo—The antibacterial activities of the derivatives, as established in mice experimentally infected with *Staphylococcus aureus* (UC 76), are listed in Table II. All results were calculated as lincomycin base activity and are reported as the median protective dose

Table I—*In Vitro* Antibacterial Activity of Lincomycin 2,7-Dialkylcarbonate Derivatives by Broth Dilution and Standard Curve Assays[a]

Lincomycin Ester Hydrochloride	Activity Compared to Lincomycin Hydrochloride, MIC, mcg./mg.[b] Broth Dilution	Standard Curve
2,7-Dimethyl	<10 (<1)	1 (0.1)
2,7-Diethyl	<10 (<1)	1 (0.1)
2,7-Di-*n*-propyl	<10 (<1)	4 (0.4)
2,7-Di-*n*-butyl	<10 (<1)	5 (0.5)
2,7-Diisobutyl	<10 (<1)	1 (0.1)
2,7-Di-*n*-pentyl	<10 (<1)	5 (0.5)
2,7-Di-*n*-hexyl	<10 (<1)	6 (0.6)
2,7-Dicyclohexyl	~10 (1)	1 (0.1)
2,7-Dicyclohexylmethyl	~10 (1)	1 (0.1)

[a] Results expressed as micrograms of lincomycin base activity per milligram of ester and as percent of lincomycin base activity (in parentheses). [b] Pure lincomycin base = 1000 mcg./mg. MIC = minimal inhibitory concentration.

Table II—*In Vivo* Bioactivity of Lincomycin 2,7-Dialkylcarbonates[a] in Mice Experimentally Infected with *Staphylococcus aureus*

Lincomycin Ester Hydrochloride	Relative Median Protective Dose (CD_{50})[b] Subcutaneous	Oral
2,7-Dimethyl	0.53	0.59
2,7-Diethyl	0.96	0.86
2,7-Di-*n*-propyl	0.80	0.50
2,7-Di-*n*-butyl	1.04	0.65
2,7-Diisobutyl	0.75	0.40
2,7-Di-*n*-pentyl	1.66	0.51
2,7-Di-*n*-hexyl	2.35	0.83
2,7-Dicyclohexyl	0.68	0.04
2,7-Dicyclohexylmethyl	0.40	0.04

[a] Activities calculated as lincomycin base equivalents. [b] Median protective dose relative to that of lincomycin (lincomycin = 1.0). Mice challenged with approximately 100 lethal doses of *S. aureus*.

Table III—Hydrolysis of Lincomycin 2,7-Dialkylcarbonates in Serum from Various Animal Species

Serum Source	Di-carbonate Derivative	Lincomycin Activity[a], mcg./ml. 0 hr.	3 hr.	6 hr.	24 hr.
Mouse	Dipentyl	6.0	7.0	6.5	5.9
	Dihexyl	5.2	5.6	7.0	5.9
Rat	Dipentyl	3.3	5.1	5.5	6.0
	Dihexyl	3.8	5.1	5.5	6.0
Gerbil	Dipentyl	4.0	3.1	4.7	5.2
	Dihexyl	3.1	5.2	4.0	5.2
Rabbit	Dipentyl	0	6.5	5.8	6.4
	Dihexyl	0	3.0	4.5	4.8
Dog	Dipentyl	0	0	0	0
	Dihexyl	0	0	0	0
Monkey	Dipentyl	0	0	~0.32	1.8
	Dihexyl	0	0	0	1.0
Human	Dipentyl	0	0	0	~0.32
	Dihexyl	0	0	0	0
pH 7.0 buffer, no serum	Dipentyl	0	0	0	0
	Dihexyl	0	0	0	0

[a] Expressed as the MIC at the time of sampling. Limit of assay = 0.32 mcg./ml.; *i.e.*, 0 value = <0.32 mcg./ml. Original sample contained a theoretical 7-mcg./ml. (base equivalent) aliquot before hydrolysis.

(CD_{50}) in milligrams per kilogram per day. Also, a comparison to lincomycin was made with each determination, and the activity of the ester was expressed as the ratio between the bioactivity of lincomycin (considered as 1) and that of the derivative. Median protective doses (CD_{50}'s) observed with the subcutaneous route of administration demonstrated that the derivatives were absorbed and hydrolyzed readily by the mouse. Orally, good CD_{50} bioactivities were shown with the dimethyl, diethyl, di-*n*-butyl, and dihexyl esters. The di-*n*-propyl, diisobutyl, and dipentyl esters did not protect the infected animals as well as did lincomycin. The dicyclohexyl and dicyclohexylmethyl esters afforded virtually no protection to the infected animals.

Several diester derivatives were subjected to *in vitro* hydrolysis using serum from various animal species. They were tested at 10 mcg./ml. (about 7 mcg./ml. lincomycin base equivalent, depending on the derivative) at 37° in 50% fresh serum diluted in pH 7.0, 0.05 *M* tromethamine buffer. Samples were taken for testing at various times over 24 hr. At the end of each sampling time, the enzymes present in the serum were inactivated by immersing the sample in boiling water for 10 min. All derivatives were stable to boiling at pH 7.0 for greater than 20 min., and no derivative was hydrolyzed at 37° in pH 7 tromethamine buffer in 24 hr. In those instances where serum hydrolyzed the derivative, boiled serum was inactive. Samples were assayed for lincomycin bioactivity with the *Sarcina lutea*-sensitive assay (4).

Table III lists results with the dipentyl and dihexyl derivatives of lincomycin in mouse, rat, gerbil, monkey, dog, rabbit, and human serum. The striking activity of rodent serum is obvious. In these tests, the zero-time sample approximated a 5-min. sample, and all rodent serum exhibited hydrolytic activity in this short time.

Table IV summarizes the results from experiments in which the diethyl, dipropyl, di-*n*-butyl, dicyclohexyl, and dicyclohexylmethyl derivatives were exposed to the hydrolytic action of rat and human serum. Again, the high esterase activity for these derivatives was apparent in rat serum. Very little, if any, activity was exhibited by human serum.

EXPERIMENTAL

Typical reaction conditions are illustrated for the synthesis of lincomycin 2,7-dialkylcarbonate esters. Analytical data are listed in Table V.

Lincomycin 2,7-Dimethylcarbonate Hydrochloride—Anisylidene lincomycin base (II) (21 g., 0.04 mole) was dissolved in 200 ml. of pyridine and placed in a 500-ml. round-bottom flask fitted with an overhead paddle stirrer, a calcium chloride drying tube, and a dropping funnel. The solution was cooled to −35° using a dry ice–acetone bath. Methyl chloroformate (8 g., 0.08 mole) was added dropwise with stirring. Upon completion of addition, the reaction flask was slowly warmed to room temperature. TLC [silica gel[1] and a solvent system of hexane–ether–pentan-2-one–methanol–concentrated ammonium hydroxide (60:20:20:9:1)] indicated formation of predominately a lincomycin monomethylcarbonate along with some lincomycin dimethylcarbonate. The reaction mixture was again cooled to −35° and an additional 10 g. of methyl chloroformate was added dropwise. A second thin-layer chromatogram indicated that the reaction was not complete. The cooling procedure was again repeated and 15 g. more of methyl chloroformate was added. The reaction was again slowly warmed to room temperature. TLC showed that reaction was essentially complete.

Table IV—Hydrolysis of Lincomycin 2,7-Dialkylcarbonates by Human and Rat Serum

Serum Source	Dicarbonate Derivative	Lincomycin Activity, mcg./ml.[a] 0 hr.	3 hr.	24 hr.
Rat	Diethyl	6.4	7.0	8.4
	Dipropyl	6.0	7.5	7.0
	Di-*n*-butyl	7.5	8.2	7.5
	Dicyclohexal	1.1	4.5	4.6
	Dicyclohexylmethyl	5.4	8.2	7.5
Human	Diethyl	0	0	1.1
	Dipropyl	0	0	1.2
	Di-*n*-butyl	0	0	0.8
	Dicyclohexyl	0	0	0
	Dicyclohexylmethyl	0	0	0

[a] Activity expressed as the MIC in micrograms per milliliter. Limit of assay = 0.32 mcg./ml.; *i.e.*, 0 value = <0.32 mcg./ml. Original sample contained a theoretical ~7-mcg./ml. (base equivalent) aliquot before hydrolysis.

The mixture was poured into 1500 ml. of ice water which had been acidified to pH 2 with hydrochloric acid. About 1500 ml. of ether was used to extract the reaction product from water. Two hundred milliliters of ethanol was also added to ensure complete solubility of the precipitate in ether. The organic layer was evaporated on a steam bath. The resulting residue was dissolved in 100 ml. of acetone, and ether was added to the cloud point. The anisaldehyde which separated was decanted, and the ether–acetone solution was allowed to stand at room temperature for 2 days. The crystals that formed were collected and washed with acetone and then ether and air dried.

Lincomycin 2,7-Di-*n*-propylcarbonate Hydrochloride—Anisylidene lincomycin base (II) (31.5 g., 0.06 mole) was dissolved in 350 ml. of analytical reagent grade pyridine. The solution was cooled, with stirring, to −35° in a dry ice–acetone bath. *n*-Propyl chloroformate (22.06 g., 0.18 mole) was added dropwise from a dropping funnel to the cooled pyridine solution. The temperature of the reaction mixture was kept at −30 to −35° until all of the chloroformate had been added.

The resulting clear solution was stirred for 2 hr. at room temperature. TLC showed that reaction was complete. The reaction mixture was then poured into 2 l. of ice water, and the pH was adjusted to 3 with concentrated hydrochloric acid. The resulting aqueous suspension was extracted with two 500-ml. portions of ether, the ether layer was washed with 300 ml. of water and dried with anhydrous magnesium sulfate, and the ether was removed on a steam bath. A light-yellow syrup (47 g.) was obtained.

The syrup was dissolved in a mixture of 300 ml. of absolute methanol and 100 ml. of water and the pH of the solution was adjusted to 0.9 with concentrated hydrochloric acid. After 2 hr., sodium bicarbonate solution was added to raise the pH of the solution to 3.2. The methanol was removed under vacuum, and the resulting aqueous syrup was extracted with 100 ml. of ether–chloroform (1:1). The ether–chloroform layer was dried with magnesium sulfate, and the solvent was removed by warming on a steam bath. The resulting syrup was dissolved in 200 ml. of chloroform, and anhydrous acetone was added to the cloud point; this mixture was allowed to stand overnight in a refrigerator, resulting in crystallization of the product.

[a] Melting points are of hydrated samples and were determined on a Thomas-Hoover melting-point apparatus and are uncorrected.

acetone bath was added, dropwise with stirring, 100 g. (1 mole) of cyclohexanol. The temperature of the reaction was maintained at about −20°. Upon completion of the cyclohexanol addition, the reaction was slowly warmed to room temperature. During warming, the mixture was stirred well to remove excess phosgene. After bubbling ceased, the reaction was connected to a water aspirator and the last traces of phosgene and hydrogen chloride were removed. The mixture was then aerated for 20 min. with nitrogen. The chloroformate was distilled at 27–31°/100 μ [lit. (6) 46–47°/2–3 mm.].

Anisylidene lincomycin base (II) (31.5 g., 0.06 mole) was dissolved in 350 ml. of analytical reagent grade pyridine and cooled to −35°. Cyclohexyl chloroformate (29.3 g., 0.18 mole) was added dropwise to this cooled solution. As the solution was slowly warmed, a precipitate formed. This precipitate was filtered, and 15 g. of cyclohexyl chloroformate was added to the recooled reaction mixture. The solution turned deep red as it warmed to room temperature. The mixture was stirred for 12 hr., after which time ice water was added and the mixture was acidified to pH 3 with concentrated hydrochloric acid. The resulting gum was dissolved in 1000 ml. of ether and dried with anhydrous magnesium sulfate. Removal of the solvent resulted in a reddish-brown gum, which was dissolved in 300 ml. of absolute methanol. Then 100 ml. of water was added to this solution, and the pH was adjusted to 0.8 with concentrated hydrochloric acid. The solution was stirred for 2 hr. Removal of methanol under reduced pressure afforded an aqueous suspension, which was extracted with 150 ml. of chloroform. The chloroform layer was dried with anhydrous magnesium sulfate and the solvent was removed. The resulting syrup was allowed to stand in a refrigerator overnight, and the crystals were collected on a filter and washed with ether. The crystals were finely powdered, suspended in 250 ml. of acetone ether (1:4), filtered, and dried.

GLC Determination of Phenylephrine Hydrochloride in Human Plasma

LAWRENCE J. DOMBROWSKI▲, PATRICK M. COMI, and EDWARD L. PRATT

Abstract □ A sensitive GLC method for the determination of phenylephrine in human plasma is described. Its application to *in vivo* phenylephrine levels in humans is currently being investigated. In the procedure, plasma components that interfere with the assay were removed using ion-exchange chromatography. Derivatization of the isolated phenylephrine hydrochloride with trifluoroacetic anhydride produced a sharp symmetrical peak when chromatography was carried out using a QF-1 column and monitored with an electron-capture detector. The method, when applied to plasma containing known amounts of added phenylephrine hydrochloride (12.5–50.0 ng./ml.) gave an average recovery of 80%. The standard deviation based on 15 determinations was 10%.

Keyphrases □ Phenylephrine hydrochloride—GLC using electron-capture detection, human plasma □ GLC, electron-capture detection—analysis, phenylephrine hydrochloride in human plasma

Phenylephrine hydrochloride {(−)-*m*-hydroxy-α-[(methylamino)methyl]benzyl alcohol hydrochloride}, a well-recognized sympathomimetic amine, has been in commercial use for many years. It is a vasoconstrictor and pressor drug chemically related to epinephrine and ephedrine. It is used in surgery, ophthalmoscopic examination, and diagnostic procedures and also has been employed as a nasal decongestant. However, a sufficiently sensitive chemical method has been unavailable for measuring this drug in man.

Various assay methods involving spectrophotofluorometry, UV spectroscopy, and colorimetry have been used to measure phenylephrine in its many available pharmaceutical preparations (1–10). These procedures permit measurement of milligram or microgram quantities of phenylephrine. They do not respond with the sensitivity required to measure phenylephrine in biological systems that may contain <1 p.p.m. of drug.

Two *in vivo* studies in humans were reported using tritium-labeled phenylephrine (11, 12). The tagged drug was administered orally in a normal dosage form as the hydrochloride salt and in a timed-release preparation as a protocolloid tannate complex. These studies provided valuable tritium blood concentration–time profiles using a liquid scintillation counting technique. However, the nonspecificity of the measuring system did not permit any evaluation of the intact phenylephrine concentration. The primary purpose of this work was to develop a sensitive and specific assay procedure for measuring unchanged phenylephrine in human plasma.

GLC previously was used for the determination of other sympathomimetic amines. After derivatization, the amines were chromatographed to produce narrow and symmetrical peaks (13). Acylated halogenated derivatives, particularly the fully trifluoroacylated phenolic amines, were readily measured at the nanogram level with an electron-capture detector. The high detection sensitivity of the trifluoroacetate derivatives formed in the analysis of dopamine (14) and 3-methoxy-4-hydroxyphenylethylene glycol (15) suggested a similar approach for the determination of phenylephrine. In this laboratory the treatment of phenylephrine hydrochloride with an excess of trifluoroacetic anhydride produced a single characteristic peak when chromatographed on a 1.82-m. (6-ft.) column of 3% QF-1. This process served as a basis for developing a sensitive assay procedure. The developed method permitted determination of 25 ng. phenylephrine hydrochloride/2 ml. plasma. Prior to derivative preparation, it was necessary to use a cation-exchange column for removal of plasma components that interfered with the GLC measurement. Details of the method are presented here along with results of a phenylephrine recovery study.

EXPERIMENTAL

Instrumentation—Final measurements were made with a gas chromatograph[1] equipped with an electron-capture detector. Adequate separations were realized on a 1.82-m. (6-ft.) × 2-mm. i.d. glass column packed with 3% QF-1 coated on Gas Chrom Q, 100–120 mesh. The column temperature was maintained at 150°, and the helium flow rate was adjusted to 50 ml./min. The detector and inlet temperatures were kept 40° higher than the column temperature. The meter range of the instrument was set at 1×10^{-9} amp., and the high voltage was adjusted to 50 v. All derivatized samples were diluted with redistilled ethyl acetate, and a 5-μl. aliquot was applied to the column.

Reagents—Cation-exchange resin[2], 50–100 mesh, was purified and conditioned as follows. Mix 30 g. resin with 100 ml. 6 *M* hydrochloric acid in a 250-ml. beaker. Repeat washes six times, discarding each acid wash. Wash the resin free of acid, using distilled water, and store the resin in distilled water until needed. The glass column containing the resin was described previously (16). The height of the resin in the column was between 4 and 5 cm.

Diatomaceous earth[3] was purified by a standard procedure (17).

Trifluoroacetic anhydride[4] was redistilled. The middle third fraction was collected in a suitable vessel, placed in a desiccator, and refrigerated at 5° until ready for use. Under these pretreatment and storage conditions, the reagent was stable for several weeks.

Ethyl acetate (reagent grade) was redistilled and the middle third fraction was collected.

Standard chromatographic tubes (25 × 200 mm.) were used.

Assay for Plasma—Transfer 1–2 ml. of plasma to a 50-ml. beaker. Adjust the volume to 4 ml. with distilled water and add, with thorough mixing, 1 g. each of sodium carbonate and sodium chloride. Blend the solution with 4 g. diatomaceous earth and transfer the homogeneous mixture to a standard chromatographic tube containing a glass wool plug in its outlet stem. Pack firmly by tapping with a glass rod and then place a glass wool plug on top of the packed column. Position the chromatographic tube directly above a 50-ml. glass-stoppered centrifuge tube containing 4 ml. of 0.1 *M* hydrochloric acid.

Pass 44 ml. of water-washed ethyl acetate through the column and collect the effluent in the centrifuge tube. Shake the stoppered tube for 3 min., centrifuge, and then withdraw and reserve the aqueous acid phase. Reextract the ethyl acetate with 4 ml. of 0.1 *M* hydro-

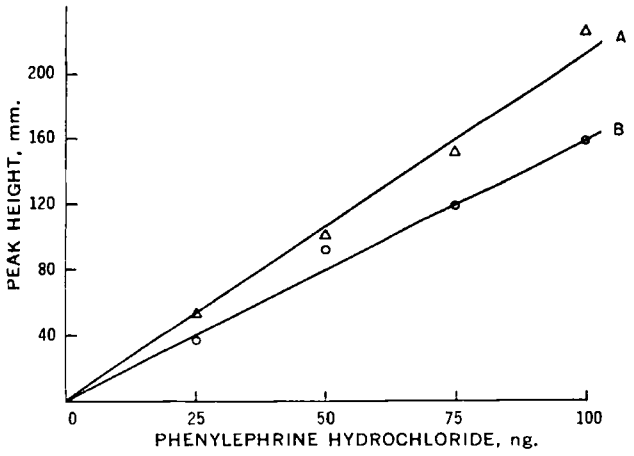

Figure 1—*Response curves for standard phenylephrine hydrochloride (curve A) and for plasma samples containing added amounts of phenylephrine hydrochloride (curve B).*

chloric acid and pool the acid extracts. Transfer the acid pool to a column containing a prepared cation-exchange resin and adjust the flow rate to 1–2 ml./min. Wash the column with three 3-ml. volumes of 0.1 *M* hydrochloric acid after the sample extracts completely pass into the column. Terminate flow from the column after the last wash just passes into the resin. Discard the effluent volume.

Position the column above a 10-ml. graduated cylinder and then elute phenylephrine with two 3-ml. volumes of 1 *M* hydrochloric acid. Measure the volume in the cylinder (about 6.3 ml.) and then transfer 2.0 ml. to a 5-ml. beaker. With a slight displacing current of nitrogen and a steam bath, evaporate the contents of the beaker to dryness. Cool the beaker to room temperature and then add 0.2 ml. trifluoroacetic anhydride. Seal the beaker with aluminum foil and place in an oven at 34 ± 1° for exactly 10 min. Remove the beaker to a well-ventilated hood at room temperature. Remove foil, permitting excess trifluoroacetic anhydride to evaporate spontaneously and completely. Dissolve the remaining residue in exactly 0.4 ml. (dry) ethyl acetate. Inject 5 μl. into the gas chromatograph readied for use as described in the *Instrumentation* section. Calculate the peak height measured at the retention time previously established for the acylated phenylephrine derivative.

Assay precision was considerably improved when two 2-ml. aliquots of the 1 *M* hydrochloric acid effluent were evaporated to dryness, the residues were derivatized, and the measured peak heights were averaged.

Preparation of Standard Calibration Curve—Dissolve phenylephrine hydrochloride reference standard in 0.1 *M* hydrochloric acid and dilute with 0.1 *M* hydrochloric acid to provide a solution containing 20 ng./ml. In duplicate, transfer 1.0, 2.0, 2.5, and 3.5 ml. of the standard solution to respective 5-ml. beakers corresponding to 20, 40, 50, and 70 ng. phenylephrine hydrochloride, respectively. Evaporate to dryness the contents of all eight beakers. Add 0.2 ml. trifluoroacetic anhydride to each standard and then continue with the derivatization procedure as directed previously. After removing excess reagent, dissolve the residue with 1.3 ml. (dry) ethyl acetate and introduce a 5-μl. volume into the gas chromatograph. Construct a calibration curve from averaged measured peak height for each standard concentration.

RESULTS AND DISCUSSION

The reaction of trifluoroacetic anhydride with phenylephrine hydrochloride led to the formation of a single derivative, having a retention time of approximately 3.6 min. The derivative is presumed to be that of the fully trifluoroacetylated molecule.

When aliquots of plasma containing increasing amounts of added phenylephrine hydrochloride were carried through the entire assay procedure, the phenylephrine derivative peak height increased in proportion to the amount of drug added (Fig. 1). Processing 2 ml. plasma (blank) through the entire procedure did not give any peaks that interfered with the assay. Figure 2 shows chromatograms resulting from processing 2 ml. plasma and 2 ml. plasma spiked with 25 ng. phenylephrine hydrochloride. The spiked sample peak at this

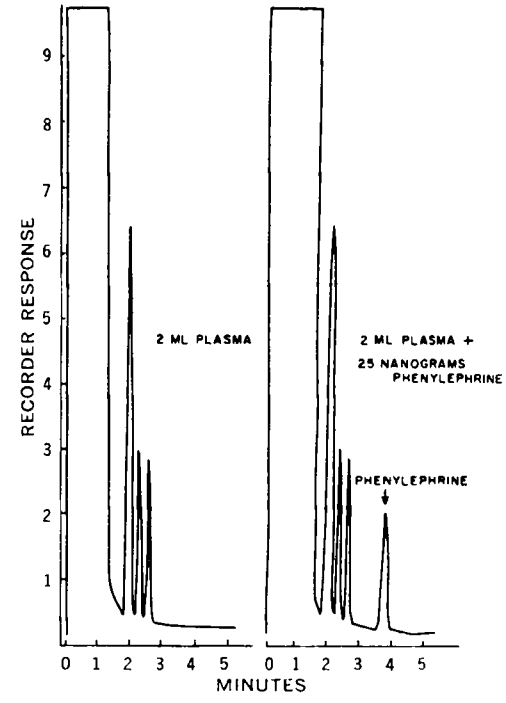

Figure 2—*Chromatogram of 2-ml. plasma sample compared to a parallel sample containing 25 ng. of phenylephrine hydrochloride.*

concentration is readily evident when compared to the blank. When the instrument was set at maximum sensitivity, the phenylephrine peak was always measured on either a positive or a negative sloping baseline. Standards were not carried through the complete assay procedure as described for the plasma samples. Nanogram quantities of standard phenylephrine hydrochloride were subjected only to reaction with trifluoroacetic anhydride and then chromatographed. A standard curve constructed in this manner (Fig. 1) was used to compute the phenylephrine recoveries from plasma spikes. Results conducted on 15 plasma samples containing known amounts of added phenylephrine are shown in Table I. Overall reproducibility was ±10% and the average recovery was 80%. Repeated injections of 5 μl. of a standard yielded no variable greater than 1.5% and demonstrated that the column did not require priming.

An internal standard, although not employed in this study, may result in improved assay precision for measuring phenylephrine in plasma. A suitable choice might be metanephrine. This particular compound is structurally similar to phenylephrine and produced a similar detector response when derivatized with trifluoroacetic anhydride and chromatographed as directed for phenylephrine. The retention time for the metanephrine derivative was about 7.5 min.

Diatomaceous earth column chromatography, providing 80% recovery, was the most efficient process of those considered for the initial separation of phenylephrine base from the basified plasma solution. For example, two 20-ml. ethyl acetate extractions of the basified plasma solution yielded only a 50–55% recovery of added phenylephrine.

The phenylephrine base contained in the ethyl acetate effluent was extracted quantitatively with two 4-ml. volumes of 0.1 *M* hydrochloric acid. The complete retention of phenylephrine from these acid extracts on the cation-exchange resin was readily attained. Interfering plasma components were removed by washing the resin column with 0.1 *M* hydrochloric acid. Phenylephrine then was quantitatively eluted from the resin column using stronger acid. This was readily accomplished using 6 ml. of 1 *M* hydrochloric acid.

Previous studies involving acylation of primary and secondary amines generally were conducted using the amine in the form of its free base (18–20). In this laboratory, an occasional difficulty was encountered when isolating nanogram quantities of some amine bases, particularly when extracting them from biological systems. Studies indicated that the amines were extracted readily with an organic solvent, but some losses occurred in attempting to concentrate them by solvent evaporation. The problem was thought to be caused by both amine volatility and air oxidation of the base. To

[a] Mean.

avoid any phenylephrine losses in this study, it was decided to concentrate the drug from plasma and acylate it as its hydrochloride salt. This was readily accomplished after eluting phenylephrine off the resin and evaporating to dryness the 1 *M* hydrochloric acid effluent. Measurable losses of nanogram quantities of phenylephrine were not realized when the salt residue was subjected to excess heating at 60°. In fact, excess heating is recommended in the procedure to ensure complete removal of any residual amounts of the 1 *M* hydrochloric acid which, if present, seriously interfere with the subsequent derivatization reaction.

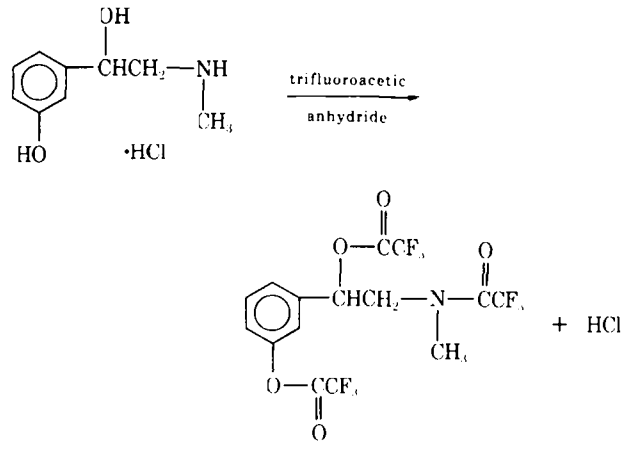
The best conditions found for acylating phenylephrine hydrochloride were 10 min. and 34°. This treatment permitted phenylephrine measurement at maximum sensitivity and reproducibility. Slight changes in the acylating conditions adversely affect the phenylephrine derivatization process and, hence, the reproducibility of the method. For instance, reaction times beyond 10 min. produced erratic results and shorter times yielded responses indicative of incomplete acylation. Furthermore, sensitivity was reduced if the reaction temperature was lowered to 25°. Because of the sensitive nature of the reaction, all samples and standards involved in a single run were derivatized simultaneously and subjected to identical conditions with respect to time and temperature. A fresh set of standards was prepared for each new series of plasma samples assayed.

A problem associated with the acylation of amine salts is the liberation of an equivalent amount of acid. With phenylephrine hydrochloride, this can be represented as shown in Scheme I. The released hydrochloric acid, if not removed, can hydrolyze the ester or amide group of the fully acylated molecule, thereby resulting in a loss of phenylephrine detection sensitivity. If a large excess of trifluoroacetic anhydride were employed, the acylation of phenylephrine was more complete and interferences from the liberated hydrochloric acid were negligible. Both the excess reagent and the liberated hydrochloric acid were effectively removed by spontaneously evaporating the solutions to dryness, preferably in a low humidity environment. The reagent is volatile (b.p. 39°) and the evaporation was complete within a few minutes at ambient temperature. The use of heat or a stream of forced nitrogen to aid the evaporation process should be avoided since both of these procedures result in a loss of the acylated derivative. Nanogram quantities of the derivative in dry ethyl acetate were stable for at least 24 hr.

CONCLUSION

A method was presented for measuring intact phenylephrine in plasma. The lowest amount of the drug measured in this study was 25 ng./2 ml. body fluid (Fig. 2). If desired, this sensitivity can be improved. For example, instead of employing a 2-ml. aliquot resulting from the 6.3 ml. of 1 *M* hydrochloric acid effluent, the entire 6.3-ml. volume could be used for the assay, producing a threefold increase in sensitivity.

This assay method has not been applied to an actual *in vivo* study of phenylephrine in humans. It is our contention, however, that the proposed analytical procedure, because of its sensitivity, provides



Scheme I

the best approach of those methods currently available for investigating phenylephrine blood levels in man following medication.

Alkylation Reactions of Hydantoins and Succinimides

D. K. YUNG*▲, T. P. FORREST†, M. L. GILROY*, and M. M. VOHRA‡

Abstract □ Five anticonvulsant agents, namely, diphenylhydantoin, mephenytoin, ethotoin, ethosuximide, and phensuximide, and a number of other hydantoins were investigated in their reactions with *p*- and *m*-nitrobenzyl bromides in the presence of sodium carbonate. The structures of the alkylation derivatives and other products formed in the reactions were studied. On the basis of the melting points of the alkylation derivatives, it was possible to identify and differentiate the five anticonvulsants. 3-*p*-Nitrobenzyl-5,5-diphenylhydantoin, *N*-*p*-nitrobenzyl-2-ethyl-2-methylsuccinimide, and 3,3′-diethyl-5,5′-diphenylhydantil, at a dose of 1 g./kg. given orally, provided no protection against pentylenetetrazol-induced seizures in mice.

Keyphrases □ Hydantoins and succinimides—alkylation with nitrobenzyl bromides, anticonvulsant properties of products □ Succinimides and hydantoins—alkylation with nitrobenzyl bromides, anticonvulsant properties of products □ Anticonvulsants - alkylation reactions of hydantoins and succinimides □ Alkylation reactions—hydantoins and succinimides

Many substituted hydantoins and succinimides are anticonvulsants. For identification purposes, some of these chemical compounds, namely, diphenylhydantoin (I), mephenytoin (II), ethotoin (III), ethosuximide (IV), and phensuximide (V), were treated with nitrobenzyl bromides in the presence of a weak base to form crystalline alkyl derivatives. There are several possible structures available for these alkyl derivatives, because alkylation could occur at more than one site in the hydantoin and succinimide molecules. This study reports on the structures of the alkylation derivatives and other products formed in the reactions.

EXPERIMENTAL[1]

5-Phenylhydantoin—This compound was obtained from benzaldehyde, ammonium carbonate, and potassium cyanide *via* the Bucherer–Berg reaction. The yield was 86%, m.p. 180.5–182° [lit. (1) m.p. 179°].

5-Ethyl-5-phenylhydantoin—This compound was obtained from propiophenone, ammonium carbonate, and potassium cyanide *via* the Bucherer–Berg reaction. The yield was 69%, m.p. 199° [lit. (2) m.p. 199°].

3-Methyl-5,5-diphenylhydantoin—The procedure reported by Dudley and Bius (3) was followed. The yield was almost quantitative, m.p. 214–215.5° [lit. (4) m.p. 213–214°].

General Procedure for Alkylation Reactions—A solution of the alkylating agent (0.01 mole) in 60 ml. of ethanol was added to a mixture of a hydantoin or succinimide (0.01 mole), sodium carbonate (0.02 mole), and 30 ml. of water. The reaction mixture was stirred under reflux for 1.5 hr. and cooled. The alkylated products were then isolated by one of the following three methods. The physical constants for the alkylated products prepared together with the recrystallization solvent are summarized in Tables I and II.

Method A—The material that separated from the reaction mixture after cooling was collected by filtration and washed thoroughly with water to yield the crude product. Alkyl derivatives isolated by this method were 3-*p*-nitrobenzyl-5,5-diphenylhydantoin (VI), 3-*m*-nitrobenzyl-5,5-diphenylhydantoin (VII), 3-*p*-nitrobenzyl-5-ethyl-5-phenylhydantoin (VIII), and 3,3′-bis(*p*-nitrobenzyl)-5,5′-diphenylhydantil (IX).

Method B—After the cooled reaction mixture was filtered, water was added to the filtrate until cloudiness occurred. On cooling, a solid precipitated which was collected by filtration to give the crude product. Alkyl derivatives obtained by this method were 1-*p*-nitrobenzyl-3-methyl-5-ethyl-5-phenylhydantoin (X), 1-*p*-nitrobenzyl-3-methyl-5,5-diphenylhydantoin (XI), *N*-*p*-nitrobenzyl-2-ethyl-2-methylsuccinimide (XIV), *N*-*m*-nitrobenzyl-2-ethyl-2-methylsuccinimide (XV), and *N*-methyl-2-phenyl-2-*p*-nitrobenzylsuccinimide (XVI).

Method C—After the reaction mixture was filtered, the ethanol in the filtrate was distilled off to leave behind a brownish oily residue in the aqueous solution. The residue was separated and triturated with a small amount of methanol to yield the crude product. Alkyl derivatives obtained by this method were 3-ethyl-5-*p*-nitrobenzyl-5-phenylhydantoin (XII) and 3-ethyl-5-*m*-nitrobenzyl-5-phenylhydantoin (XIII).

The precipitate that separated from the reaction mixture when III was used yielded 2.2 g. (54%) of 3,3′-diethyl-5,5′-diphenylhydantil (XVII), m.p. 328–330° [lit. (3) m.p. 326–328°].

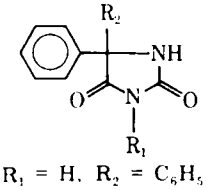
4,4′-Dinitrobibenzyl (XVIII)—This compound was obtained by reacting *p*-nitrobenzyl bromide (0.02 mole) with III (0.01 mole) in the presence of sodium carbonate under the conditions described for alkylation reactions. The crude product was collected from the cooled reaction mixture and washed with water. One recrystallization from ethanol and acetone gave 1 g. (35%) of pure 4,4′-dinitrobibenzyl (XVIII), m.p. 179.5–181° [lit. (5) m.p. 179–180°].

Acute Toxicity—The compound was suspended in 10% aqueous acacia and administered orally to male albino mice (20–30 g.) at a dosage of 2 g./kg. The mice were observed over 3 days.

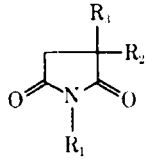
Antipentylenetetrazol Activity—The procedure of Swinyard *et al.* (6) was followed. The amount of pentylenetetrazol used for challenge was 85 mg./kg. and was given subcutaneously 2 hr. prior to the oral administration of the test compound.

RESULTS AND DISCUSSION

Reaction of diphenylhydantoin (I), obtained commercially, with *p*-nitrobenzyl bromide in the presence of sodium carbonate gave a crystalline alkyl derivative in 82% yield. Theoretically, alkylation could occur on the nitrogen atoms of the 1- and 3-positions and on the oxygen atoms of the 2- and 4-positions. Thus, the alkyl derivative of I could be VI, 1-*p*-nitrobenzyl-5,5-diphenylhydantoin (XIX), 2-*p*-nitrobenzoxy-4,4′-diphenyl-2-imidazolin-5-one (XX), 2-*p*-ni-



I: $R_1 = H$, $R_2 = C_6H_5$
II: $R_1 = CH_3$, $R_2 = CH_2CH_3$
III: $R_1 = CH_2CH_3$, $R_2 = H$



IV: $R_1 = H$, $R_2 = CH_3$, $R_3 = CH_2CH_3$
V: $R_1 = CH_3$, $R_2 = H$, $R_3 = C_6H_5$

[1] Melting points were determined on a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Elemental analyses were performed by Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England. The IR spectra were recorded on a Perkin-Elmer model 237B spectrophotometer in potassium bromide. A Varian model T-60 spectrometer was used to record the NMR spectra, with deuterated chloroform as solvent and tetramethylsilane as the internal reference.

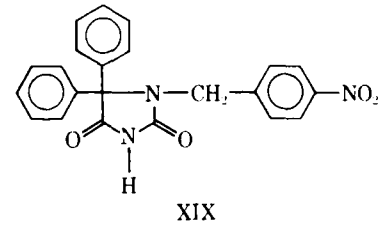
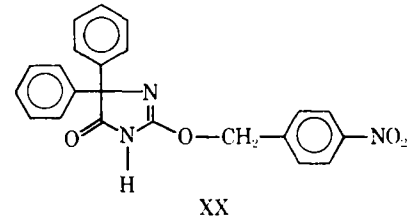
[a] Compound IX is 3,3′-bis(p-nitrobenzyl)-5,5′-diphenylhydantil. See text for structure.

trobenzoxy-5,5-diphenyl-2-imidazolin-4-one (XXI), or 4-p-nitrobenzoxy-5,5-diphenyl-3-imidazolin-2-one (XXII). Chatten and Levi (7), in their study of the reaction of barbiturates with the same alkylating agent and under the same conditions, postulated that alkylation took place on the C-4 and C-6 oxygen atoms of the barbiturate molecule.

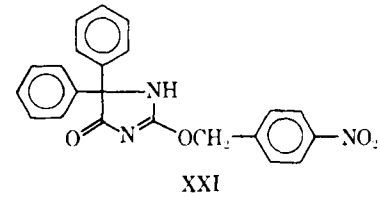
Results of IR studies on I and the reaction product showed that



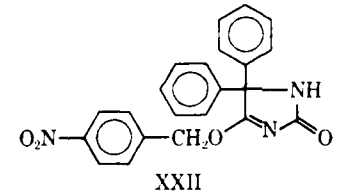
XIX



XX



XXI



XXII

the oxygen atoms of the 2- and 4-positions were not involved in the alkylation of I. In both IR spectra, two carbonyl peaks were observed at 1770 and 1718 cm.$^{-1}$, indicating that alkylation could not have occurred on the oxygen of the 2- or 4-position (8). Consequently, the alkyl derivative of I could only be VI or XIX.

The NH absorption bands of I and its alkylation product were not well resolved enough in the 3315–3220-cm.$^{-1}$ region to permit a reliable structural assignment to the alkylation product. However, since the UV absorption maximum of the alkyl derivative was not shifted in alkaline solution, and in view of the report by Stuckey (9) that only hydantoins having a hydrogen atom at the 3-position showed a shift in the absorption maximum, it would appear that the alkyl derivative of I was VI and not XIX.

To demonstrate that the nitrogen atom of N-3 in I was indeed the more reactive site for alkylation, 3-methyl-5,5-diphenylhydantoin was treated with p-nitrobenzyl bromide using the same conditions as with I. As expected, the reaction proceeded much more slowly. About 81% of the starting hydantoin was recovered. Only a 20% yield of a crystalline product was isolated, and this product was identified as 1-p-nitrobenzyl-3-methyl-5,5-diphenylhydantoin (XI) by IR and NMR data (Table III). The reaction of I with the same bromide gave no corresponding N-1 alkyl derivative. Examination of the IR spectrum of the parent hydantoin showed that there were one sharp and intense NH band at 3315 cm.$^{-1}$ and two prominent carbonyl bands in the 1775–1690-cm.$^{-1}$ region. The spectrum of XI contained two carbonyl bands and two aromatic nitro bands but no NH band at 3315 cm.$^{-1}$. The disappearance of the NH absorption band indicated that the crystalline reaction product was indeed XI.

Similar results were observed in the reaction of II. There was a 34% yield of the alkylation product 1-p-nitrobenzyl-3-methyl-5-ethyl-5-phenylhydantoin (X), whose IR spectrum contained no NH-

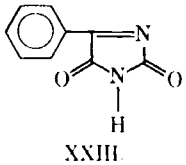
stretching absorption. About half of II was recovered unreacted. When 5-ethyl-5-phenylhydantoin was used, the expected N-3 alkylation product, 3-p-nitrobenzyl-5-ethyl-5-phenylhydantoin (VIII), was isolated in 76% yield.

The reaction of III with p-nitrobenzyl bromide in equimolar concentration was complicated by the fact that III dimerized in alkaline solution to form 3,3′-diethyl-5,5′-diphenylhydantil (XVII) in 54% yield. In addition to this dimer, about a 9% yield of the alkylation product 3-ethyl-5-p-nitrobenzyl-5-phenylhydantoin (XII) was also isolated. The IR spectrum of XII showing strong NH, carbonyl, and aromatic nitro absorption bands was in agreement with the assigned structure. The chemical shift of the benzylic methylene group is consistent with its attachment at a carbon rather than a nitrogen atom. Therefore, it seems reasonable that alkylation has occurred at the 5-position and not at the 1-position of III.

Dimerization of similar hydantoin molecules has been reported in the literature. Edward and Nielsen (10) reported that, in aqueous alkali at room temperature, 5-phenylhydantoin absorbed molecular oxygen to give 5,5′-diphenylhydantil. These workers speculated that the reaction probably involved the oxidation of the carbanion of 5-phenylhydantoin to 5-hydroxy-5-phenylhydantoin which, in the form of the pseudobase (XXIII), condensed with a second molecule of 5-phenylhydantoin to yield the product. For this reason, in two separate experiments the reaction of III with the nitrobenzyl bromide was carried out under nitrogen to determine if the formation of XVII could be prevented. However, in both cases the dimer



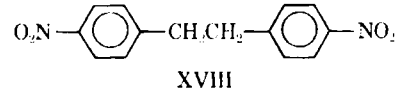
XXIII

was still the major product and the yield of XII was in no way increased.

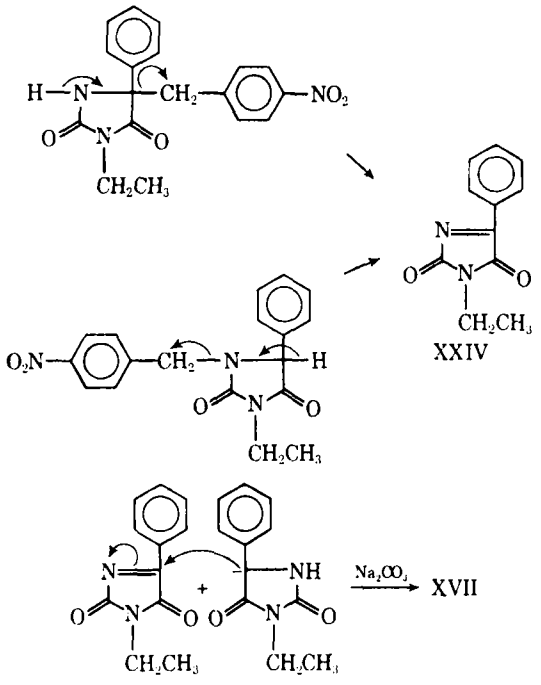
In another attempt to increase the yield of XII, III was treated with two equivalents of p-nitrobenzyl bromide. The reaction under these conditions gave the similar percent yield of XII, but there was no formation of XVII. Instead, the major product, in 35% yield, was 4,4′-dinitrobibenzyl (XVIII). The identity of XVIII was confirmed by comparison of its melting point, mixed melting point, and IR spectrum with an authentic sample. The formation of XVIII was totally unexpected. Reaction of sodium carbonate and p-nitrobenzyl bromide without III did not give any XVIII. It appears that the hydantoin molecule has an important role to play in the production of XVIII.

The formation of the hydantoin dimer XVII as the major product when p-nitrobenzyl bromide was used in equimolar quantity and the formation of the reagent dimer XVIII when the alkylating agent was in excess raised interesting questions. Since carrying out the alkylation reaction in a nitrogen atmosphere did not stop the production of XVII, it seems that air oxidation is not the mechanism of formation in the presence of p-nitrobenzyl bromide. A plausible mechanism could involve the elimination of the stabilized benzylic carbanion from the 1- or 5-alkylated derivative to form the pseudobase XXIV. The dimer could then be formed by reaction of the carbanion and XXIV (Scheme I).

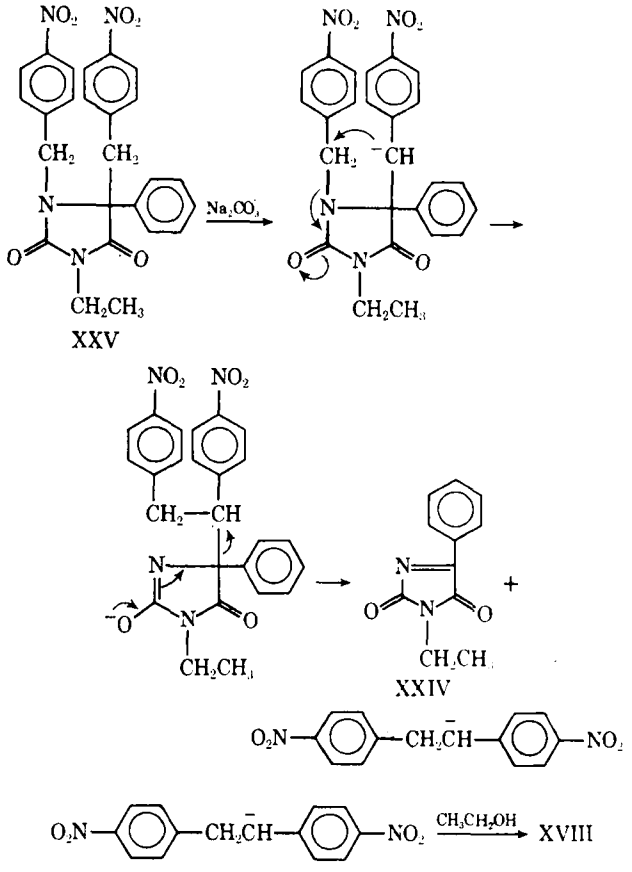
The formation of the reagent dimer XVIII when there was an excess of p-nitrobenzyl bromide could have been caused by the rearrangement of the dialkyl derivative 1,5-bis(p-nitrobenzyl)-3-ethyl-5-phenylhydantoin (XXV) (Scheme II). Such a rearrangement



XVIII



Scheme I—Proposed mechanism for the formation of 3,3'-diethyl-5,5'-diphenylhydantil (XVII)

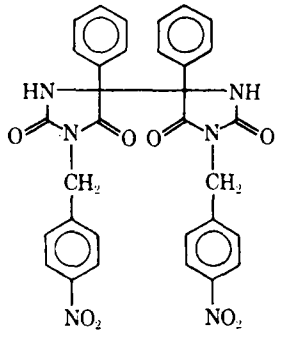


Scheme II—Proposed mechanism for the formation of 4,4'-dinitrobibenzyl (XVIII)

requires that the benzylic protons be acidic, as would be the case in the *p*-nitro derivative but not the *meta*-isomer. Such a mechanism is supported by the fact that alkylation of III with *m*-nitrobenzyl bromide under similar conditions did not produce the analogous 3,3'-dinitrobibenzyl. The hydantoin dimer XVII and the alkyl derivative 3-ethyl-5-*m*-nitrobenzyl-5-phenylhydantoin (XIII) were the two products isolated.

The interesting formation of XVII and XVIII prompted the study of 5-phenylhydantoin in the same manner as III. When 5-phenylhydantoin was allowed to react with *p*-nitrobenzyl bromide in a 1:1 ratio, only the dimer of the N-3 alkylated derivative 3,3'-bis-(*p*-nitrobenzyl)-5,5'-diphenylhydantil (IX) was isolated in 32% yield. However, when 5-phenylhydantoin was treated with the nitrobenzyl bromide in a 1:2 ratio, IX and XVIII were obtained in 20 and 45% yields, respectively.

On the basis of the results obtained, a general statement can be made on the alkylation pattern of the hydantoin molecule in a weak base medium. Alkylation occurs at the 1-, 3-, and 5-positions but not at the 2- and 4-positions of the molecule. The 3-position is most reactive and is always the major site for alkylation. Alkylation at the 1-position occurs less readily than alkylation at the 5-position when there is a phenyl substituent on the 5-position. When both the 3- and 5-positions are blocked, N-1 alkylation can take place. If the 3-position is substituted and the 1- and 5-positions are both available, the formation of a hydantoin dimer is highly possible in the presence of air or when *p*-nitrobenzyl bromide is used as the alkylating agent. If the 3-position is also available, then an N-3 alkylated hydantoin dimer is obtained.



IX

The reactions of the succinimides IV and V with *p*-nitrobenzyl bromide were straightforward. *N*-*p*-Nitrobenzyl-2-ethyl-2-methylsuccinimide (XIV) was obtained in 40% yield, and its identity was confirmed by IR and NMR spectra.

When V was treated with *p*-nitrobenzyl bromide, a 31% yield of a bright-orange reaction product was isolated. The IR spectrum showed the presence of two carbonyl groups and an aromatic nitro grouping. The chemical shift of the protons in the NMR spectrum indicated that the *p*-nitrobenzyl substituent was attached at the 2-position. Thus, the colored reaction product was identified as *N*-methyl-2-phenyl-2-*p*-nitrobenzylsuccinimide (XVI). Like II, there was no reaction between V and *m*-nitrobenzyl bromide.

The alkylation products of I–V with *p*- and *m*-nitrobenzyl bromides are crystalline compounds with sharp and reproducible melting points. Therefore, these products can be used as derivatives for identification and differentiation. As indicated in Tables I and II, the five anticonvulsant drugs studied can be identified and differentiated on the basis of the melting points of these derivatives. Unfortunately, the usefulness of the *p*- and *m*-nitrobenzyl derivatives in identifying or differentiating III from the other four hydantoins appears to be limited because the derivatives could only be obtained in low yields.

The reaction procedures developed for the pure drugs were successfully applied to the various dosage forms of I, II, IV, and V. To have a workable quantity of products, at least 250 mg. of drug in the sample was required. It was also observed that if a sodium salt was used in the formulation, the salt had to be first neutralized with dilute hydrochloric acid to yield the free acid; the free acid was then redissolved in sodium carbonate solution for the alkylation reaction. The aqueous solution of sodium diphenylhydantoin, when allowed to react directly with *p*-nitrobenzyl bromide, produced an almost quantitative yield of *trans*-4,4'-dinitrostilbene, m.p. 290–292° [lit. (11) m.p. 289.5–291°]. In a solution of this basicity, *p*-nitrobenzyl bromide can be ionized to form the carbanion, which displaces the bromide from another molecule of the alkylating agent. The stilbene

was believed to have been formed after elimination of hydrobromide from this displacement intermediate.

Samour *et al.* (12) reported that some alkoxymethyl derivatives of I were effective anticonvulsants. Therefore, it was of interest to test some alkyl derivatives for anticonvulsant activity. Three compounds representing three different chemical structures were studied. Results of the biological testings showed that VI, XIV, and XVII, when suspended in 10% acacia and given orally, exhibited no activity against pentylenetetrazol-induced seizures in mice at a dose of 1 g./kg. According to the acute toxicity studies, these compounds appeared to be relatively nontoxic. None of the animals died as a result of oral administration at a 2-g./kg. dose level, which was the maximum amount of the compound that could be suspended in an appropriate volume of 10% acacia.

Kinetics and Factors Affecting Stability of Methylprednisolone in Aqueous Formulation

M. I. AMIN▲ and J. T. BRYAN

Abstract □ An investigation was made of the factors affecting the rate of degradation of methylprednisolone solubilized by polysorbate 80 in an aqueous formulation containing polar additives and a sequestering agent as a function of temperature at pH 4.6 and 5.1. The presence of polar additives decreased the apparent solubility of methylprednisolone in one formulation at pH 4.6 and 25°. However, since methylprednisolone was in solution, but not within the polyoxyethylene exterior of the polysorbate 80 micelles, it degraded at a faster rate. By selecting the proper concentration of polysorbate 80 and adjusting to the same pH of 4.6 in another formulation, the autoxidative degradation rate of the primary alcoholic group at C-21 was reduced to approximately half even in the presence of oxygen. The increase in stability was also evident from the increase of the apparent activation energy from 18.2 to 23.1 kcal./mole. The mechanism of solubilization and stabilization based on hydrogen bonding and inclusion into the polyoxyethylene exterior of the polysorbate 80 micelles is proposed.

Keyphrases □ Methylprednisolone aqueous formulations—effect of polysorbate 80 solubilization on stability, mechanism, kinetics □ Polysorbate 80—effect on methylprednisolone stability in aqueous formulations, mechanism of solubilization □ Solubilization, methylprednisolone—effect of polysorbate 80 on stability in aqueous formulations, mechanism, kinetics □ Stabilization of methylprednisolone in aqueous formulations—polysorbate 80 solubilization

In the pharmaceutical field, the phenomenon of micellar solubilization of drugs in aqueous solutions of surfactants is used not only for solubilizing the drug but also for protecting against degradative processes such as hydrolysis and autoxidation. The stabilization of esters against alkaline hydrolysis in aqueous solutions containing nonionic, cationic, and anionic surfactants has been reported (1–3). Vitamin A alcohol solubilized in an aqueous nonionic surfactant solution was reported (4) to be more stable to autoxidation than vitamin A solubilized in cottonseed oil. Similarly, vitamin A alcohol solubilized in aqueous nonionic surfactant solution containing 30% (w/v) glycerin was more stable to autoxidation than vitamin A solubilized in arachis oil (5).

Nonionic surfactant polysorbate 80 (polyoxyethylene 20 sorbitan monooleate) increased the solubility and the stability of methylprednisolone in aqueous solutions prepared by heating between 40° and the decomposition point (6). However, the quantitative data regarding the extent of stabilization of methylprednisolone were not presented (6).

This article deals with the factors affecting the chemical stability of methylprednisolone solubilized by

was believed to have been formed after elimination of hydrobromide from this displacement intermediate.

Kinetics and Factors Affecting Stability of Methylprednisolone in Aqueous Formulation

M. I. AMIN▲ and J. T. BRYAN

Abstract □ An investigation was made of the factors affecting the rate of degradation of methylprednisolone solubilized by polysorbate 80 in an aqueous formulation containing polar additives and a sequestering agent as a function of temperature at pH 4.6 and 5.1. The presence of polar additives decreased the apparent solubility of methylprednisolone in one formulation at pH 4.6 and 25°. However, since methylprednisolone was in solution, but not within the polyoxyethylene exterior of the polysorbate 80 micelles, it degraded at a faster rate. By selecting the proper concentration of polysorbate 80 and adjusting to the same pH of 4.6 in another formulation, the autoxidative degradation rate of the primary alcoholic group at C-21 was reduced to approximately half even in the presence of oxygen. The increase in stability was also evident from the increase of the apparent activation energy from 18.2 to 23.1 kcal./mole. The mechanism of solubilization and stabilization based on hydrogen bonding and inclusion into the polyoxyethylene exterior of the polysorbate 80 micelles is proposed.

Keyphrases □ Methylprednisolone aqueous formulations—effect of polysorbate 80 solubilization on stability, mechanism, kinetics □ Polysorbate 80—effect on methylprednisolone stability in aqueous formulations, mechanism of solubilization □ Solubilization, methylprednisolone—effect of polysorbate 80 on stability in aqueous formulations, mechanism, kinetics □ Stabilization of methylprednisolone in aqueous formulations—polysorbate 80 solubilization

In the pharmaceutical field, the phenomenon of micellar solubilization of drugs in aqueous solutions of surfactants is used not only for solubilizing the drug but also for protecting against degradative processes such as hydrolysis and autoxidation. The stabilization of esters against alkaline hydrolysis in aqueous solutions containing nonionic, cationic, and anionic surfactants has been reported (1–3). Vitamin A alcohol solubilized in an aqueous nonionic surfactant solution was reported (4) to be more stable to autoxidation than vitamin A solubilized in cottonseed oil. Similarly, vitamin A alcohol solubilized in aqueous nonionic surfactant solution containing 30% (w/v) glycerin was more stable to autoxidation than vitamin A solubilized in arachis oil (5).

Nonionic surfactant polysorbate 80 (polyoxyethylene 20 sorbitan monooleate) increased the solubility and the stability of methylprednisolone in aqueous solutions prepared by heating between 40° and the decomposition point (6). However, the quantitative data regarding the extent of stabilization of methylprednisolone were not presented (6).

This article deals with the factors affecting the chemical stability of methylprednisolone solubilized by

polysorbate 80 in aqueous formulations and also the mechanism of solubilization and stabilization. Since the other drug components present were extremely stable, their stability data are not reported.

EXPERIMENTAL

Materials—The following were used: polysorbate 80 USP, purified[1]; disodium edetate USP[2]; methylprednisolone NF, sterile micronized; neomycin sulfate powder USP; lincomycin hydrochloride monohydrate[3]; hydrochloric acid, analytical reagent grade; 30% sodium hydroxide solution; and purified water USP. Since polysorbate 80 USP contained 7.2–14.8% of polyoxyethylene glycol, it was purified by the procedure of Malkemus and Swan (7). The presence or absence of polyoxyethylene glycol in the surfactant was determined by the method of Ginn *et al.* (8). Other ingredients were used as received.

Preparation of Formulations—The formulations shown in Table I were prepared using Procedure B of Johnson (6). Polysorbate 80 and disodium edetate were dissolved in 90% of the purified water. The solutions were then heated to 58–63°, and methylprednisolone was added and dissolved by stirring for 90 min, or until dissolved. Solutions were allowed to cool to 30° or below, and neomycin sulfate and lincomycin hydrochloride monohydrate were added and dissolved by continuous stirring. The solutions were allowed to stand for at least 2 hr., the pH was adjusted (initial pH approximately 6.9), and purified water was added to adjust the final volume. The solutions were then filtered through a 0.45-μ cellulose filter[4] and packaged. These packaged samples were stored in a constant-temperature oil bath, dry heat oven, or metal cabinets in a room equilibrated at 25°. Samples were removed periodically and assayed according to the general procedure for methylprednisolone by blue tetrazolium using a semiautomated analyzer. Methylprednisolone, having a primary α-keto group adjacent to a primary hydroxyl group, reacts with blue tetrazolium in the presence of tetramethylammonium hydroxide to form a colored solution. The blue tetrazolium is reduced and the absorbance of the color complex is measured spectrophotometrically in comparison with a standard solution. A decrease in potency, as determined by this method, indicates the degradation of the side chain at the C-17 position.

Solubility Profile: Polysorbate 80–Water Solutions—*Equilibration*—Polysorbate 80–water solutions containing excess methylprednisolone were equilibrated at 25° for 5 days in 100-ml. vials in a constant-temperature water bath, equipped with an oscillating-type shaker[5]. The vials were then allowed to stand for 2 days at 4°, and the contents were filtered through a 0.45-μ cellulose filter[4] and assayed.

Assay Procedure—The aqueous polysorbate 80–methylprednisolone solutions were diluted 1:25 with 95% 3A alcohol. Polysorbate 80 solution diluted in the same manner as the sample was used as a blank in the assay to eliminate error due to the absorbance of the surfactant. The absorption maximum at 243 nm. was used to calculate the steroid concentration. An absorptivity (1%, 1 cm.) of 398.11 was used. The presence of polysorbate 80 at the dilutions used did not significantly change the absorptivity value from that obtained with solution in 95% alcohol. Since the samples were analyzed immediately after dilution, the degradation of the side chain at the C-17 position was considered to be insignificant.

Solubility Profile: Polysorbate 80–Water Formulations—*Preparation of Formulations*—Polysorbate 80–water formulations containing various amounts of polysorbate 80 were prepared following Procedure B of Johnson (6) and adjusted to pH 4.5 and 5.0. These formulations were similar to Lot A of Table I, except that they did not contain methylprednisolone and the amounts of polysorbate 80 were the same as in the polysorbate 80–water solutions.

Equilibration—The same method of equilibration followed for polysorbate 80–water solutions was used.

Assay Procedure—Methylprednisolone was determined according to the general procedure for steroids by blue tetrazolium.

RESULTS AND DISCUSSION

The rate of autoxidation reactions in solution depends upon the pH, thermal energy of UV light, oxygen concentration, and concentration of heavy metal ions. Since the degradation of prednisolone (9) in aqueous buffer solutions containing disodium edetate was less at pH 4 than at pH 5.0, these formulations (Table I) were made to contain disodium edetate and the pH was adjusted between 4.5 and 5.0. A pH of 4.5 was selected as the lower limit because polysorbate 80 hydrolyzed at pH values lower than 4.0 and at high temperatures, producing an irreversible colloidal milky precipitate.

The primary degradation pathway for methylprednisolone in these formulations appears to be autoxidation of the primary alcoholic grouping at C-21. This is consistent with the observation that, in alkaline aqueous solutions and in the presence of air, prednisolone degraded to a steroidal acid as a major component (10). Thus, the pH of the formulations decreased. The photolytic degradation of methylprednisolone observed (11) in aqueous solutions of tyloxapol (oxyethylated tertiary octylphenol formaldehyde polymer)[6] was absent. This was confirmed using TLC and assaying the methanol eluate spectrophotometrically at 242 nm. for the 22-month old samples of Lots A and B stored at room temperature. The concentration of methylprednisolone in both lots was unchanged from the initial value. Also, the photolytic degradation of the formulations packaged in ampuls and stored in an oil bath would be at a minimum, since the oil baths were located in a room where the UV light exposure was negligible.

The autoxidation of methylprednisolone followed an apparent first-order process under all experimental conditions. Typical first-order plots of the thermal degradation of methylprednisolone are shown in Figs. 1 and 2.

The effects of various factors on the apparent first-order thermal degradation of methylprednisolone in aqueous formulations are shown in Table II. The apparent first-order rate constants were calculated from the slopes of log percent residual concentration–time data by means of a least-squares regression analysis.

Effect of Oxygen Concentration—The concentration of oxygen present does affect the rate of degradation of methylprednisolone. The magnitude of the apparent first-order rate constant at room temperature for Lot B, packaged in syringes (Roehr) sealed in aluminum foil with no head space, was 1.5 times smaller than that

of Lot A, packaged in 30-ml. vials and having a head space (Table II). The amount of polysorbate 80 and the pH were the same in these lots.

Effect of Purified Polysorbate 80 Concentration—The amount of polysorbate 80 used in these formulations plays a vital role in stabilizing methylprednisolone, as can be seen from the higher value of the apparent first-order rate constant at room temperature for Lot C than Lot D-1 (Table II). Lot C was prepared using 3.58% (w/v) polysorbate 80 to dissolve 0.575 mg./ml. of methylprednisolone. This amount of polysorbate 80 was higher than the actual value of 3.35% (w/v) obtained from the solubility profile for methylprednisolone in polysorbate 80–water solutions (Fig. 3). Surprisingly, the solubility of methylprednisolone decreased in the presence of soluble polar additives, as seen in the solubility profile for methylprednisolone in polysorbate 80–water formulations adjusted to pH 5 (Fig. 3). Thus, Lot D-1 was made with 4.1% (w/v) polysorbate 80 to dissolve 0.575 mg./ml. methylprednisolone. The solubility profile at pH 4.5 in polysorbate 80–water formulations (not shown) had exactly the same slope as the solubility profile at pH 5.

An increase in pH decreases the micellar molecular weight and the hydration per unit mass of surfactant (12). This would be expected to reduce the solubility at pH 5. However, this was not observed since the pH range of formulations studied was very narrow.

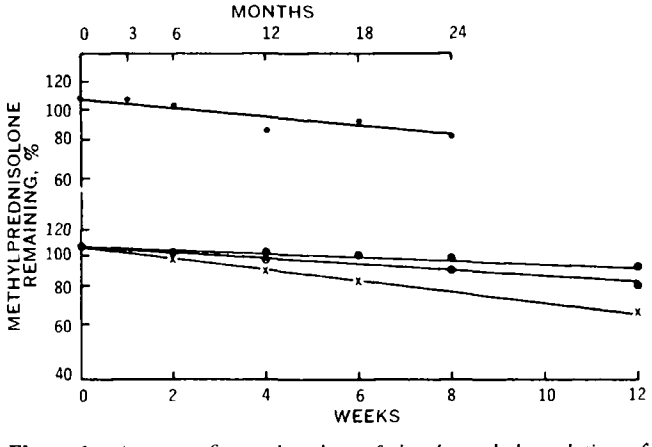

Figure 1—*Apparent first-order plots of the thermal degradation of methylprednisolone in Lot A, containing 3.58% (w/v) purified polysorbate 80, at pH 5.1. Key: (top) •, 25°; (bottom) ●, 40°; ◓, 47°; and ×, 54°.*

Effect of Temperature on Solubilization of Methylprednisolone—An increase in temperature increased the solubility of methylprednisolone. Furthermore, the methylprednisolone stayed in solution even after Lot D-1 was frozen, allowed to come to room temperature, filtered, and assayed. The assay results were exactly the same when compared with those for Lot D-1 stored at 4°. These results show that methylprednisolone will be in solution regardless of the temperature used during the manufacture of the formulation.

Effect of pH and Temperature—As stated previously, the pH of the formulations decreased, possibly due to the steroidal acids produced by the autoxidation of methylprednisolone. However, the extent of pH decrease in Lots A and D was the same; namely, 0.15 pH unit after 24 months at 25°. Likewise, the extent of pH decrease in Lots A and D was also the same; namely, 0.25 pH unit after 6 months at 40°.

Arrhenius plots for the degradation of methylprednisolone in Lots A and D are shown in Fig. 4. The apparent activation energies calculated from the least-squares slopes of the apparent first-order rate constants *versus* the reciprocal of absolute temperatures for Lots A and D are shown in Table III. Also shown are the values of $t_{90\%}$, the time in months required to reach 90% of methylprednisolone concentration in Lots A, C, D, and E, which were stored at room temperature. From the data in Table III, it is apparent that the shelflife of methylprednisolone in these aqueous formu-

lations is increased by adjusting to a proper pH and selecting the proper concentration of the nonionic surfactant.

Mechanism of Solubilization and Stabilization—Several articles described the mechanism of solubilization of drugs in the presence of surfactants (3, 13, 14). In these formulations, no attempts were made to determine the exact mechanism of micellar solubilization of methylprednisolone. However, the probable mechanism seems to be hydrogen bonding of the polar groups of the steroid with the hydrated polyoxyethylene portion on the surface, as well as incorporation into the polyoxyethylene groups of the polysorbate 80 micelles. The mechanism of hydrogen bonding appears to be adsorption of water-soluble polar additives (15) in competition with methylprednisolone adsorption on the exterior surface of the nonionic micelle. The data from the solubility profile (Fig. 3) indicate that a possible mechanism may also be incorporation of methylprednisolone into the polyoxyethylene group of the polysorbate 80 micelle. Since a large excess of polar additives (neomycin

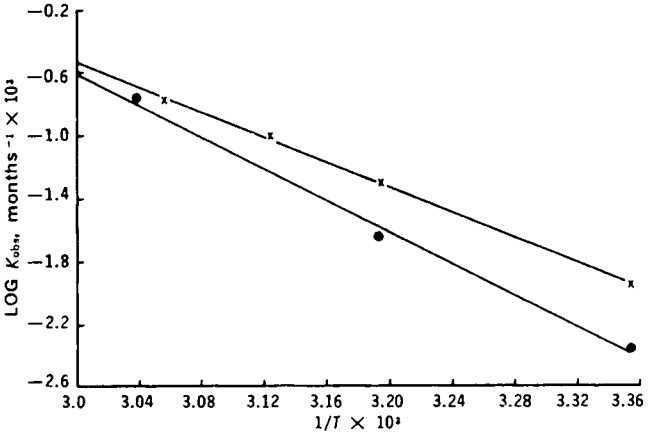

Figure 4—*Arrhenius plots for the degradation of methylprednisolone. Key:* ×, *Lot A, 3.58% (w/v) purified polysorbate 80 and initial pH of 5.1; and* ●, *Lot B, 4.1% (w/v) purified polysorbate 80 and initial pH of 4.6.*

Table III—Apparent Activation Energies

Lot Number	E_a, kcal./mole	$t_{90\%}$[a], Months at Room Temperature
A	18.22	17.85
C	—	25.08
D[b]	23.09	56.38
E	—	30.98

[a] See Table I for initial concentration of methylprednisolone; 0.5 mg./ml. is considered as 100%. [b] See Table II.

sulfate and lincomycin hydrochloride) is present and adsorbs on the exterior surface of the polysorbate 80 micelle, there is more likelihood that methylprednisolone is solubilized into the exterior of the polysorbate 80 micelle. Thus, since a certain amount of methylprednisolone was free in the aqueous phase of Lot C, pH 4.6, it degraded approximately twice as fast as Lot D-2, pH 4.6, where, methylprednisolone was associated on the surface and into the polyoxyethylene exterior of the polysorbate 80 micelle. Because the aggregation number and the amount of water bound per unit mass of nonionic surfactant are greater at low pH values (12), oxygen attack was slower in Lot C, pH 4.6, than in Lot A, pH 5.1.

At 54–56°, the ratio of rate constants $k_{app(Lot\ A)}/k_{app(Lot\ D)}$ is closer to 1, which increases approximately to 2.6 at 25°. This can be interpreted as follows. At 54–56°, the micellar structure is disrupted in Lot D, thus preventing inclusion of the methylprednisolone into the exterior of the polysorbate 80 micelles. Consequently, the rate of degradation in Lot D is approximately the same as in Lot A. At 25°, there is negligible disruption of the micellar structure in Lot D, resulting in a lower k_{app} and thus a higher ratio of rates of degradation.

Reaction of Cyclic Acid Anhydrides with Ethyl Cyanoacetate

EDWARD E. SMISSMAN▲, MICHAEL WACHTER, CHARLES BARFKNECHT, and R. BRUCE GABBARD

Abstract □ The reactions of cyclic carboxyanhydrides and substituted cyclic carboxyanhydrides with ethyl sodiocyanoacetic ester were studied. The resulting dicarboxylic acid esters failed to undergo Dieckmann cyclization.

Keyphrases □ Cyclic acid anhydrides—reaction with ethyl sodiocyanoacetate, absence of Dieckmann cyclization □ Sodiocyanoacetic acid ethyl ester—reaction with cyclic acid anhydrides, absence of Dieckmann cyclization □ Ring formation reactions, potential cyclic acid anhydrides and ethyl sodiocyanoacetate, absence of Dieckmann cyclization

In a previous paper, the preparation of an A-D ring analog of the tetracycline molecule, I, was discussed (1). A review of the chemistry of the tetracyclines (2) and of the substituents necessary for the desired biological activity based on numerous structure–activity relationship studies (3) was published.

With this general information in view, the possibility of cyclizing a properly constituted alicyclic molecule, II, to obtain the polysubstituted ring A, III, of tetracycline as an intermediate in the A-D ring synthesis (1) (Scheme I) and for biological testing was investigated.

DISCUSSION

The acylation of ethyl sodiocyanoacetate with cyclic carboxyanhydrides to give half-esters of α-cyano-β-ketodicarboxylic acids was reported (4). This procedure was modified to give the diester rather than the half-ester in the acylation of ethyl sodiocyanoacetate with glutaric or succinic anhydrides.

To utilize this method to prepare diethyl 2-cyano-3-hydroxy-4-*N*,*N*-dimethylamino-2-heptenedioate, II*a*, the previously unreported *N*,*N*-dimethylglutamic anhydride was required. *N*,*N*-Dimethylglutamic acid, IV*a*, was prepared by a modification of the method of Bowman and Stroud (5), which involved the reductive condensation of glutamic acid with formaldehyde under hydrogen. All attempts to convert IV*a* to the anhydride, V*a*, by known procedures failed.

N-Carbethoxyglutamic acid, IV*b*, was prepared by the method of Aberhalden and Kautzsch (6) and was cyclized by refluxing in acetic anhydride to give the corresponding anhydride, V*b*. On treatment of V*b* with ethyl sodiocyanoacetate, diethyl 2-cyano-3-hydroxy-4-*N*-carbethoxyamino-2-heptenedioate, II*b*, was produced. The assignment of the *N*-carbethoxyamino group to the 4-position was based on an analogous reaction by Bergman and Zervas (7). They reported the treatment of *N*-carbobenzoxyglutamic anhydride, V*c*, with ammonia to give *N*-carbobenzoxyisoglutamine, VI, which was then decarbobenzoxylated to isoglutamine. By analogy, the product of V*b* with sodiocyanoacetate would be expected to yield II*b* rather than the isomeric diethyl 2-cyano-3-hydroxy-6-*N*-carbethoxyamino-2-heptenedioate, VII*a*.

Attempts to cyclize II*b* utilizing sodium ethoxide and potassium *tert*-butoxide to produce the desired cyclohexanedione failed.

It was assumed that the preparation of III failed where R′ = H because the molecule II forms the anion VIII*a* or IX in preference to VIII. Formation of the desired cyclic compound is not possible when the enolic oxygen bears the negative charge as in IX (Scheme II). To circumvent this possibility, the enolic hydroxyl was protected as the enol methyl ether, II*c*, by treatment with diazomethane. It was assumed that VIII and VIII*a* would be in facile equilibrium. The assignment of the location of the ethyl and methyl ester groups in II*c* was undertaken by NMR studies. Ethyl acetate shows a triplet centered at δ1.25 and a quartet at δ4.12 for the ethyl function, while ethyl cyanoacetate shows peaks at δ1.32 and 4.27. The ethyl group in the latter is being deshielded by the electronegative groups in the acid portion of the molecule. The ethyl absorption in II*c* is at δ1.42 and 4.47. Since the ethyl group is deshielded, it is assigned to the 1-carboxyl function.

N-Phthalylglutamic anhydride, V*d*, proved to be a more convenient intermediate for the preparation of an amino-substituted pimelate. The reaction of V*d* with ethyl sodiocyanoacetate in xylene, followed by esterification of the resulting acids with diazomethane, gave two crystalline compounds. These compounds were shown to be the *cis*- and *trans*-isomers of VII*b* by the spectral data. Mass

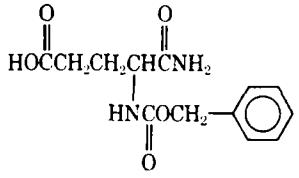
f: X = $(C_6H_5CH_2)_2N$



VI

spectroscopy was conclusive in establishing that they were the 6-*N*-phthalyl geometric isomers. Both *cis*- and *trans*-VII*b* gave identical fragmentation patterns, with a base peak of *m/e* 219. This peak arises from a McLafferty-type rearrangement (Scheme III) The 4-*N*-phthalyl isomer, II*e*, cannot give rise to a peak of *m/e* 219 by a similar rearrangement or fragmentation.

Attempts at the Dieckmann condensation of VII*b* failed.

Since the 4-phthalimido compound, II*e*, could not be obtained, other systems were explored to secure an open-chain precursor of the tetracycline A ring with a nitrogen function at C-4. *N*-Trifluoroacetylglutamic anhydride, V*e*, was viewed as a potential precursor with a labile *N*-protecting group. The reaction of V*e* with ethyl sodiocyanoacetate, followed by esterification with diazomethane, yielded 2-trifluoroacetamidopentanedioate, IV*e*, as the only isolable product.

Despite previous failures in attempts to prepare *N,N*-dimethylglutamic anhydride, V*a*, it was thought that increasing the basicity of the nitrogen in such a system would lead to the desired 4-*N*-substituted heptenedioate. *N,N*-Dibenzylglutamic acid, IV*f*, contains a more basic nitrogen than the phthalyl or trifluoroacetyl

derivatives and was prepared by a modification of a reported procedure (8). Compound IV*f* was converted to the corresponding anhydride, V*f*, by heating with acetic anhydride.

Anhydrous potassium carbonate has been found effective as a reagent in the acylation of cyanoacetic esters with simple anhydrides (9). Use of these conditions for the reaction with V*f* and esterification of the products with diazomethane produced a mixture of heptenedioate esters. Column chromatography of this mixture gave an oil, which was identified as ethyl methyl 2-cyano-3-methoxy-4-*N,N*-dibenzylamino-2-heptenedioate, II*f*. The structure was assigned primarily from the mass spectrum along with the NMR and IR spectra. The mass spectrum of II*f* showed a base peak of *m/e* 296 below 100°. This represents a simple fragmentation of the C—C bond adjacent to the nitrogen typical of tertiary amines. The 4-*N,N*-dibenzyl isomer, II*f*, can give rise to this fragmentation, whereas the 6-*N,N*-dibenzyl isomer, VII*c*, cannot (Scheme IV).

The use of sodium hydride gave superior yields of II*f* as compared to the method utilizing potassium carbonate. This procedure gave adequate quantities of II*f* to allow numerous attempts at the Dieckmann cyclization under various conditions. Potassium *tert*-butoxide in benzene, triethylamine in benzene, sodium hydride in benzene, and sodium hydride in dimethylformamide all proved to be unsuccessful in the cyclization.

Since the cyclization failed, it was decided to attempt an isomerization of the substituted enol lactone, X. The half-ester ethyl hydrogen 2-cyano-3-hydroxy-2-hepteneoate, II*d*, was treated with acetic anhydride to give a neutral compound in quantitative yield.

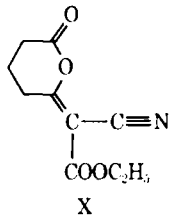
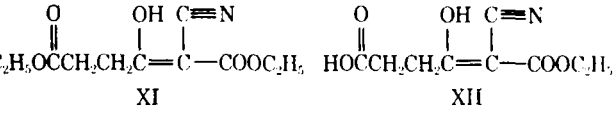
Scheme IV



X



XI XII

The enol lactones of the α-cyano-β-keto acids have not been reported previously. The compound was slowly soluble in sodium bicarbonate with effervescence; it gave a gradually deepening red color on reaction with ferric chloride solution within 20 min.; a strong band at 5.60 μ was present in the IR, indicating a vinyl ester structure. Thus, Compound X was established as the enol lactone rather than a cyclohexanedione. Compound X could not be isomerized to a 2,6-cyclohexanedione with sodium ethoxide (10) or boron trifluoride (11) or by thermal rearrangement.

Succinic anhydride was allowed to react with an equivalent amount of ethyl sodiocyanoacetate in the presence of ethanol to produce diethyl 2-cyano-3-hydroxy-2-hexenedioate, XI. This compound was partially hydrolyzed with hydrochloric acid to yield ethyl hydrogen 2-cyano-3-hydroxy-2-hexenedioate, XII, which was identical to the compound previously reported (4, 12).

EXPERIMENTAL[1]

Diethyl 2-Cyano-3-hydroxy-2-hexenedioate, XI A sodium dispersion was added under nitrogen to dry xylene (250 ml.) and absolute ethanol (12 ml.) until the stirred suspension was gray. The color was discharged by the addition of 1–2 ml. of ethanol. Ethyl cyanoacetate (22.5 g., 0.20 mole) was added all at once, resulting in a thick milky suspension. Succinic anhydride (20.0 g., 0.20 mole) was added immediately, and the thick emulsion became a yellowish turbid suspension. The mixture was stirred for 4 hr., after which it was shaken with 100 ml. water. The xylene layer was separated and the aqueous layer was extracted with ether (2 × 100 ml.). The xylene and ether extracts were combined and the solvent was removed to give an oily residue. The residue was distilled under reduced pressure. A fraction, b.p. 150–156°/0.1 mm., solidified on standing and was recrystallized (petroleum ether, b.p. 60–68°) to give 10 g. (21%) of a colorless crystalline material, m.p. 52.5–53.0° [lit. (4) m.p. 51°].

Ethyl Hydrogen 2-Cyano-3-hydroxy-2-heptenedioate, IId—The previous procedure was modified by heating the reaction vessel to 100° after 20 g. (0.20 mole) of ethyl cyanoacetate had been added to the sodium dispersion. A forceful current of nitrogen was introduced to entrain the ethanol vapors; when the ethanol had been removed, the heating was discontinued and 21 g. (0.10 mole) of glutaric anhydride was added. The procedure following the addition of glutaric anhydride was the same as previously described. Twenty-four grams (57%) of ethyl hydrogen 2-cyano-3-hydroxy-2-hepteneoate, IId, was obtained [lit. (4) m.p. 136°].

Anal.—Calc. for $C_{10}H_{13}NO_5$: C, 52.86; H, 5.77; N, 6.17. Found: C, 52.91, 52.95; H, 5.85, 5.95; N, 5.98.

If this modification was not followed, 20% of the half-ester and 14% of a colorless oil, diethyl 2-cyano-3-hydroxy-2-heptenedioate, IIh, were obtained. The latter formed a green crystalline chelate with cupric acetate, m.p. 120–121°.

Anal.—Calc. for $C_{21}H_{32}CuN_2O_{10}$: C, 50.20; H, 5.30; N, 4.95. Found: C, 50.49; H, 5.48; N, 4.75.

Ethyl 2-Pentanolidenecyanoacetate, X—Ethyl hydrogen 2-cyano-3-hydroxy-2-hepteneoate, IId (10 g., 0.05 mole), was refluxed in acetic anhydride (25 ml., 0.25 mole) until solution was effected. The excess acetic anhydride and the acetic acid were distilled *in vacuo*. The solid residue was crystallized from benzene–petroleum ether (b.p. 60–68°). Ethyl 2-pentanolidenecyanoacetate, X (10 g., 100%) was obtained as colorless plates, m.p. 104–106°.

Anal.—Calc. for $C_{10}H_{11}NO_4$: C, 57.41; H, 5.30; N, 6.70. Found: C, 56.98; H, 4.97; N, 6.54.

***N*-Carbethoxyglutamic Acid, IVb** The method of Aberhalden and Kautzsch (6) was followed. A colorless oil (22 g., 50%), soluble in water, was obtained from 29.4 g. (0.20 mole) glutamic acid and 21.7 g. (0.20 mole) ethyl chloroformate.

***N*-Carbethoxyglutamic Anhydride, Vb**—*N*-Carbethoxyglutamic acid (22.0 g., 0.10 mole) was refluxed with 50 ml. (0.50 mole) acetic anhydride for 1 hr. The excess acetic anhydride and acetic acid were removed *in vacuo*. *N*-Carbethoxyglutamic anhydride (20 g., 100%) was obtained as a pale-yellow oil.

Diethyl 2-Cyano-3-hydroxy-4-*N*-carbethoxyamino-2-heptenedioate, IIb—The procedure for the preparation of diethyl 2-cyano-3-hydroxy-2-heptenedioate, IIh, was followed. *N*-Carbethoxyglutamic anhydride (20 g., 0.10 mole) and 11.3 g. (0.10 mole) ethyl cyanoacetate were used and yielded 14 g. of a liquid acidic toward sodium bicarbonate. This material was distilled *in vacuo*. Diethyl 2-cyano-3-hydroxy-4-*N*-carbethoxyamino-2-heptenedioate, IIb (2.5 g., 7%), was obtained as a colorless liquid, b.p. 98°/6 mm.; n_D^{25} 1.454. The distillation flask contained a considerable amount of carbonaceous material.

Anal.—Calc. for $C_{15}H_{22}N_2O_7$: C, 52.62; H, 6.47; N, 8.18. Found: C, 52.96; H, 6.28, 6.24; N, 8.10, 8.15.

***N*-Phthalylglutamic Anhydride, Vd** The procedure was essentially that of King and Kidd (13). A suspension of L-glutamic acid (16.8 g., 0.113 mole) and phthalic anhydride (16.8 g., 0.113 mole) in 60 ml. of dry pyridine was refluxed for 2 hr. The solution was cooled, filtered, and evaporated under reduced pressure. Acetic anhydride (45 ml.) was added, the solution was heated at reflux for 3 min. and then cooled, and the solvent was partially removed. Crystallization began upon evaporation of the acetic anhydride and was completed upon the addition of 300 ml. of ether. After filtering and washing with ether, 21.5 g. of a white solid, m.p. 194–199°, 70% yield, was obtained. Two recrystallizations from ethyl acetate afford Vd, m.p. 200–204° [lit. (13) m.p. 195–200°].

Ethyl Hydrogen 2-Cyano-3-hydroxy-6-*N*-phthalimido-2-heptenedioate—A suspension of sodium hydride (0.632 g. of 57% NaH, 0.015 mole) was washed three times with dry dioxane, and then 125 ml. of dioxane was added to the reaction vessel. The vessel was equipped with a nitrogen inlet, and ethyl cyanoacetate (1.7 g., 0.015 mole) in 25 ml. of dioxane was added dropwise with stirring over 10 min. The mixture was heated at reflux for 2 hr. and a milky suspension formed. *N*-Phthalylglutamic anhydride, Vd (3.89 g., 0.015 mole), was added as a solid and the mixture was heated at reflux for 18 hr. After cooling, the dioxane was removed under reduced pressure and equal volumes of water and ether were added. A solid (0.4 g.), insoluble in either layer, was filtered. The aqueous layer was acidified with dilute hydrochloric acid and extracted three times with ether. The ethereal layer was dried (magnesium sulfate) and gave 3.8 g. of a viscous, nondistillable, yellow-orange oil. The NMR spectrum of this crude material indicated a mixture of heptenoic acids.

The insoluble material (0.4 g.) was dissolved in 25 ml. of ether–methanol (9:1) and esterified with diazomethane to give 411 mg. of a yellow oil, which was shown to be dimethyl 2-*N*-phthalimidopentanedioate: IR (chloroform): 1780–1720 cm.$^{-1}$, no C≡N stretch; NMR ($CDCl_3$): δ 2.3–2.7 (m, 4, CH_2CH_2), 3.63 (s, 3, OCH_3), 3.75 (s, 3, OCH_3), 4.93 (broad t, 1, methine H), and 7.84 (broad s, 4, aromatic H); mass spectroscopy: *m/e* 305 (parent peak) and 186 (base peak).

Ethyl Methyl 2-Cyano-3-methoxy-6-phthalimido-2-heptenedioate, VIIb The crude heptenoic acids (3.6 g.) were dissolved in 75 ml. of ether–methanol (9:1). An ethereal solution of diazomethane, generated from *N*-nitrosomethylurea, was added to this solution at 0°. Addition was continued until the effervescence ceased. The solvent was removed under reduced pressure to yield 3.7 g. of a yellow-orange nondistillable oil. TLC and NMR showed the oil to be a mixture of at least three compounds. The crude heptenedioate esters (3.0 g.) were chromatographed on 100 g. of silica gel, using chloroform as the eluting solvent. The first fraction eluted (550 mg.) was a colorless oil. Recrystallization from chloroform–hexane (1:1) gave 507 mg. of a white solid, m.p. 150–151°; IR (chloroform): 2960, 2220, 1780, 1720, 1580, 1380, 1125, and 1060 cm.$^{-1}$; NMR ($CDCl_3$): δ 1.24 (t, 3, CH_3), 2.85–3.25 (m, 2, CH_2), 3.0–

[1] Melting points were obtained on a calibrated Thomas-Hoover Unimelt and are corrected. IR data were recorded on a Beckman IR-10 spectrophotometer. NMR data were recorded on Varian Associates A-60, A-60A, and HA 100 spectrometers using tetramethylsilane as an internal standard. Microanalyses were performed by Midwest Microlab, Inc., Indianapolis, Ind., and on an F & M 185 C, H, N analyzer.

3.3 (m, 2, CH_2), 3.75 (s, 3, OCH_3), 4.08 (s, 3, OCH_3), 4.1 (q, 2, CH_2CH_3), 4.98 (t, 1, methine H), and 7.86 (d, 4, aromatic H); UV (ethanol) λ_{max}: 261, 241, and 231 nm.; mass spectroscopy: *m/e* 399 (parent peak), 219 (base peak), 187 (90%), 132 (20%), and 104 (20%).

Anal.—Calc. for $C_{20}H_{20}N_2O_7$: C, 60.00; H, 5.03; N, 7.00. Found: C, 59.71; H, 4.91; N, 6.80.

A second fraction was collected which contained 750 mg. of a pale-yellow oil. Trituration of this oil with ether gave 532 mg. of a white solid, m.p. 90–91°; IR (chloroform): 2960, 2215, 1780–1720, 1575, 1380, 1210, and 1040 cm.$^{-1}$; NMR ($CDCl_3$): δ 1.27 (t, 3, CH_3), 2.4 2.95 (m, 4, CH_2CH_2), 3.76 (s, 3, OCH_3), 4.08 (s, 3, OCH_3). 4.2 (q, 2, CH_2CH_3), 4.95 (t, 1, methine H), and 7.85 (d, 4, aromatic H); UV (ethanol) λ_{max}: 261, 241, and 231 nm.; mass spectroscopy: *m/e* 399 (parent peak), 219 (base peak), 187 (90%), 132 (20%), and 104 (20%).

Anal.—Calc. for $C_{20}H_{20}N_2O_7$: C, 60.00; H, 5.03; N, 7.00. Found: C, 60.13; H, 5.17; N, 6.91.

The two isomers were obtained in the same overall yield using potassium carbonate as the base. The reaction was performed in dioxane using the same molar quantities reported in the synthesis of ethyl methyl 2-cyano-3-methoxy-4-*N,N*-dibenzyl-2-heptenedioate.

cis- and *trans*-VII*b* were also obtained using xylene as the reaction solvent. However, the yields were lower and the product composition was nearly identical by NMR.

Reaction of Ethyl Methyl 2-Cyano-3-methoxy-6-phthalimido-2-heptenedioate, VII*b*, with Sodium Hydride—Sodium hydride (25 mg. of 57% in mineral oil, 5.8×10^{-4} mole) was suspended in 10 ml. of dry benzene. Compound VII*b* (231 mg., 6.0×10^{-4} mole, m.p. 150–151°), in 10 ml. of dry *N,N*-dimethylformamide, was added dropwise to the suspension. A red-orange color, indicative of anion formation, developed within 30 min. The reaction was stirred at 25° for 22 hr. and, on workup, 210 mg. of starting material was recovered unchanged.

N*-Trifluoroacetylglutamic Anhydride, V*e—Compound V*e* was prepared by a modification of the method of Weygand and Leising (14). Trifluoroacetic anhydride (30 ml.) was added slowly to 10 g. of glutamic acid. After the resulting solution was cooled, 250 ml. of dry ether was added and a slightly exothermic reaction occurred. The solution was immediately decanted and diluted with 600 ml. of dry hexane. The mixture was cooled to 0° for 2 hr., and the crystals were filtered and washed sparingly with hexane. The resulting white needles were dried over calcium hydroxide in a vacuum desiccator. Recrystallization from chloroform gave 11.0 g. (72%) of white needles, m.p. 61–64°. Further recrystallization gave 9.1 g., m.p. 68–71° [lit. (14) m.p. 70°]; NMR ($CDCl_3$–CD_3COCD_3): δ 2.2–2.6 (m, 2, CH_2), 3.05–3.3 (m, 2, CH_2), and 5.1 (t, 1, methine H).

Attempted Synthesis of Ethyl Methyl 2-Cyano-3-methoxy-4-trifluoroacetamido-2-heptenedioate—A suspension of sodium hydride (300 mg. of 57% NaH, 0.007 mole) in 50 ml. of dioxane and 750 mg. (0.0067 mole) of ethyl cyanoacetate were allowed to react as before to form the sodio salt. After the milky suspension was cooled, 1.5 g. (0.0067 mole) of *N*-trifluoroacetylglutamic anhydride, V*e*, in 20 ml. dioxane was added slowly. The suspension was stirred at 25° for 16 hr. and treated as previously described for the *N*-phthalyl derivative.

The resulting oil was methylated with diazomethane to give 1.1 g. of a yellow oil. Chromatography on silica gel, using chloroform as the eluting solvent, gave only one isolable compound. It was shown to be dimethyl 2-*N*-trifluoroacetylpentanedioate by comparison of its IR and NMR spectra with that of the corresponding phthalimido derivative; IR (chloroform): 1725 cm.$^{-1}$, no C≡N stretch; NMR ($CDCl_3$): δ 2.2–2.6 (m, 4, CH_2CH_2), 3.7 (s, 3, OCH_3), 3.8 (s, 3, OCH_3), and 4.7 (broad t, 1, methine H).

N,N*-Dibenzylglutamic Acid, V*f—The procedure of Kanao and Sakayari (8) to prepare 1-benzyl-5-oxo-pyrrolidinecarboxylic acid was modified to obtain *N,N*-dibenzylglutamic acid. Glutamic acid (22.05 g., 0.15 mole), 16 g. sodium hydroxide in 256 ml. of 60% ethanol, and benzyl chloride (40.64 g., 0.32 mole) were stirred for 48 hr. at 25° (heating the reaction leads to decreased yields). The solution was neutralized to approximately pH 7 with cold, dilute hydrochloric acid and the ethanol was removed. The solution was extracted with ether, and an insoluble material was filtered (5.4 g.). The aqueous solution was made acid to congo red paper with hydrochloric acid and allowed to stand for 4 hr. A white solid (11.6 g.) precipitated and was filtered. The two solids were combined, stirred with hot water (85°), and filtered. The remaining solid was recrystallized from ethanol to give 6.7 g. of *N,N*-dibenzylglutamic acid, m.p. 214–217° [lit. (8) m.p. 215°].

The aqueous filtrate was cooled and 5.1 g. of 1-benzyl-5-oxo-pyrrolidinecarboxylic acid was obtained, m.p. 157–159° [lit. (8) m.p. 160°].

N,N*-Dibenzylglutamic Anhydride, V*f—Acetic anhydride (35 ml.) was added to *N,N*-dibenzylglutamic acid (6.0 g., 0.018 mole). The resulting suspension was heated to 80°, whereupon a deep-blue solution was formed. The heating was discontinued and the solution was immediately cooled. The acetic anhydride was removed under reduced pressure. Trituration of the resulting blue solid with ether gave 4.9 g. of a white solid. Recrystallization from chloroform–ether gave 4.1 g. (74%) *N,N*-dibenzylglutamic anhydride, V*f*, m.p. 110–112°; IR (KBr): 1810, 1780, 1760, 1060, 1020, 740, and 700 cm.$^{-1}$; NMR ($CDCl_3$): δ 1.9–2.3 (m, 2, CH_2), 2.5–2.9 (m, 2, CH_2), 3.7 (t, 1, methine H), 3.85 (s, 2, benzyl CH_2), 3.95 (s, 2, benzyl CH_2), and 7.4 (m, 10, aromatic H).

Ethyl Methyl 2-Cyano-3-methoxy-4-*N,N*-dibenzylamino-2-heptenedioate, II*f*—To a suspension of sodium hydride (1.75 g. of 57%, 0.04 mole) in 250 ml. of anhydrous benzene was added 4.5 g. (0.04 mole) of ethyl cyanoacetate. The suspension was cooled, 12.4 g. (0.04 mole) of *N,N*-dibenzylglutamic anhydride, V*f*, was added, and the mixture was refluxed for 16 hr. After cooling, the benzene was removed and equal volumes (250 ml.) of water and ether were added to the reaction mixture. The ether layer was separated and concentrated to give 11.3 g. of a mixture of acids. The mixture of acids was dissolved in anhydrous ether and esterified with diazomethane to give 11.4 g. of material.

Column chromatography on silica (300 g.) of 8.7 g. of the material and elution with chloroform afforded 1.1 g. of dimethyl 2-*N,N*-dibenzylaminopentanedioate; IR (chloroform): 1725 cm.$^{-1}$; NMR ($CDCl_3$): δ 1.8–2.7 (m, 5, aliphatic CH), 3.3 4.2 (2s–m, 10, OCH_3–benzylic CH_2), and 7.35 (s, 10, aromatic H); mass spectroscopy: *m/e* 355 (parent peak) and 296 (base peak).

A second material (1.7 g.) was obtained as a pale-yellow oil and proved to be the desired compound, II*f*; IR (chloroform): 2225, 1720, 1575, 1440, 1130, and 700 cm.$^{-1}$; NMR ($CDCl_3$): δ 1.27 (t, 3, CH_3), 1.65–3.2 (m, 4, CH_2CH_2), 3.35–4.4 (overlapping peaks, 13, 2-OCH_3, 2-benzyl CH_2, CH_2CH_3, methine H), and 7.33 (m, 10, aromatic H); mass spectroscopy: *m/e* 450 (parent peak), 296 (base peak at 19–88°), and 392 (base peak at 129°).

Anal.—Calc. for $C_{26}H_{30}N_2O_5$: C, 69.33; H, 6.66; N, 6.22. Found: C, 69.03; H, 6.68; N, 6.36.

Metabolites of Bromazepam, a Benzodiazepine, in the Human, Dog, Rat, and Mouse

MORTON A. SCHWARTZ*▲, EDWARD POSTMA*, STANLEY J. KOLIS*, and ARTHUR S. LEON†

Abstract □ The biotransformation of bromazepam, 7-bromo-1,3-dihydro-5-(2-pyridyl)-2*H*-1,4-benzodiazepin-2-one, was studied in four species. Four metabolites were identified and their excretion was quantitatively determined. The major urinary metabolites excreted by three women given single 12-mg. oral doses of bromazepam-5-^{14}C were the conjugated forms of 3-hydroxybromazepam (I), accounting for 13–30% of the dose, and 2-(2-amino-5-bromo-3-hydroxybenzoyl)pyridine (IV), accounting for 4–25% of the dose. Conjugated I was also the major metabolite in three dogs and four groups of mice administered ^{14}C-bromazepam, but its excretion by four rats was very limited. Together with I, Metabolite IV and 2-(2-amino-5-bromobenzoyl)pyridine were detected in the excreta of the human, dog, rat, and mouse. Although the pyridyl *N*-oxide derivative of bromazepam was not detected as a metabolite in any species, the N_4-oxide was a minor metabolite in dog urine. This is the first reported instance of metabolic N_4-oxidation of a 1,4-benzodiazepin-2-one.

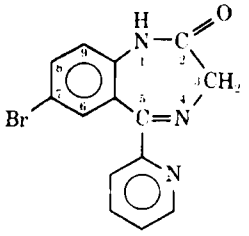
Keyphrases □ Bromazepam (a benzodiazepine) metabolism in human, dog, rat, and mouse, identification of metabolites, mechanisms discussed □ Benzodiazepine derivatives—metabolism of bromazepam in human, dog, rat, and mouse, identification of metabolites, mechanisms discussed □ Biotransformation—identification of bromazepam metabolites in human, dog, rat, and mouse □ Metabolites, bromazepam—identified in urine and feces of humans, rats, dogs, and mice

Bromazepam [7-bromo-1,3-dihydro-5-(2-pyridyl)-2*H*-1,4-benzodiazepin-2-one and formerly designated Ro 5-3350] was reported (1) to possess central nervous system activity in animals and antianxiety activity in humans. This drug is a member of the benzodiazepine class of compounds whose metabolism was recently reviewed (2).

In this study, the metabolites of bromazepam were identified and quantitated in various species to: (*a*) detect species differences in metabolic pathways, and (*b*) compare the biotransformation of bromazepam with that of other benzodiazepines. Bromazepam labeled with ^{14}C in either the C_2- or C_5-position was used. Bromazepam-5-^{14}C was preferred (but was not available for the initial studies in dog and mouse) because if metabolic cleavage of the diazepine ring occurred, resulting in the loss of atoms 2, 3, and 4, the label would remain with the benzoylpyridine moiety. A chemical cleavage of this ring by acid hydrolysis was used in the development of a GLC assay of bromazepam (3).

EXPERIMENTAL

Labeled Drug and Determination of ^{14}C—Prior to preparing each drug formulation, TLC with System 1 (described below) and the determination of the ^{14}C migrating with authentic bromazepam confirmed that the radiochemical purity of both C_5- and C_2-labeled bromazepam remained at 97 and 98%, respectively, throughout the study. Furthermore, at the end of the study, the compounds identified as metabolites were cochromatographed with each labeled bromazepam. Only one compound, 3-hydroxybromazepam (I), was found to be a possible contaminant of the labeled drugs,



bromazepam

but only to the extent of <0.7% of the ^{14}C of bromazepam-5-^{14}C and <0.3% of the ^{14}C of bromazepam-2-^{14}C.

The determination of radioactivity in urine, in homogenates of feces in 50% ethanol, in ethyl acetate extracts of both, and on particles of silica gel was accomplished by liquid scintillation spectrometry as previously described (4).

Design of Human and Animal Studies—Three Negro females[1] (Subjects 1, 2, and 3) were not given any medication chronically for at least 3 weeks prior to labeled bromazepam administration. After obtaining informed consent, each subject received two tablets, each containing 6 mg. of bromazepam-5-^{14}C with a specific activity of 4.3 μc./mg. The excipients (starch, lactose, microcrystalline cellulose[2], magnesium stearate, and FD&C certified dyes) and the type of tablet compression [single compression using a 0.86-cm. (0.34-in.) flat-faced punch] were chosen to duplicate the formulation and size of the tablets currently used in the clinical trials. Subject 1, 51 years of age and weighing 88 kg., developed influenza 4 days after the labeled drug was given and recovered without treatment with drugs. Subject 2, 36 years of age and weighing 57 kg., also developed influenza after a week on this study and was treated with phenazopyridine hydrochloride. Subject 3, 48 years of age and weighing 85 kg., received aspirin and hydrochlorothiazide (50 mg.) on several occasions but no chronic drug treatment during the study. Daily collections of urine and feces were made until the excretion of ^{14}C decreased to barely measurable levels.

Four nonfasted 11–12-kg. male dogs (beagles) were given single oral doses of ^{14}C-bromazepam in gelatin capsules. Dog 1 was given 5 mg./kg. of bromazepam-2-^{14}C (specific activity 2.3 μc./mg.), whereas the remaining dogs received the same dose of bromazepam-5-^{14}C (specific activity 1.0 μc./mg.). Urine and feces were collected daily for as long as readily measurable amounts of ^{14}C were excreted.

Bromazepam-5-^{14}C (1.0 μc./mg.) was dissolved in a vehicle consisting mainly of 50% propylene glycol, 10% ethanol, 1.5% benzyl alcohol, and an aqueous acetate buffer[3] and was administered to four nonfasted male Charles River rats at a dose of 2 mg./kg. Two 230-g. rats received an intravenous dose and two 285-g. rats were given the drug orally by intubation. Solutions of bromazepam-2-^{14}C (27 μc./mg.) and bromazepam-5-^{14}C (35 μc./mg.) in the same parenteral vehicle, after dilution with water to avoid toxicity due to the ingredients of the vehicle, were injected intravenously into nonfasted Carworth Farms 1S 20-g. male mice at a dose of 1.0 and 0.3 mg./kg., respectively. Two groups of three mice each (Groups I and II) received the C_2-labeled drug, and two groups (Groups III and IV) were given bromazepam-5-^{14}C. Each group was placed in a separate cage. Urine and feces were collected from the four rats and four groups of mice until excretion of ^{14}C was barely measurable.

Table I—Excretion of Radioactivity Derived from ^{14}C-Bromazepam by Human, Dog, Rat, and Mouse

Subject or Animal	Dose Administered and Route	Duration, Days	Excretion of ^{14}C in Percent of Dose Administered Urinary	Fecal	Total
Human					
1	12 mg. bromazepam-5-^{14}C p.o.	14	59.1	2.1	61.2
2	12 mg. bromazepam-5-^{14}C p.o.	11	74.0	2.0	76.0
3	12 mg. bromazepam-5-^{14}C p.o.	17	78.6	5.9	84.5
Dog					
1	5 mg./kg. bromazepam-2-^{14}C p.o.	24	46.7	18.5	65.2
2	5 mg./kg. bromazepam-5-^{14}C p.o.	10	52.0	25.8	77.8
3	5 mg./kg. bromazepam-5-^{14}C p.o.	4	15.5	58.7	74.2
4	5 mg./kg. bromazepam-5-^{14}C p.o.	10	37.0	27.0	64.0
Rat					
1	2 mg./kg. bromazepam-5-^{14}C i.v.	4	28.0	59.1	87.1
2	2 mg./kg. bromazepam-5-^{14}C i.v.	4	32.0	58.2	90.2
3	2 mg./kg. bromazepam-5-^{14}C p.o.	6	17.1	58.3	75.4
4	2 mg./kg. bromazepam-5-^{14}C p.o.	6	19.9	65.0	84.9
Mouse					
Group I	1 mg./kg. bromazepam-2-^{14}C i.v.	4	49.9	24.2	74.1
Group II	1 mg./kg. bromazepam-2-^{14}C i.v.	4	62.3	17.3	79.6
Group III	0.3 mg./kg. bromazepam-5-^{14}C i.v.	6	58.3	20.5	78.8
Group IV	0.3 mg./kg. bromazepam-5-^{14}C i.v.	6	60.9	19.7	80.6

Extraction of Labeled Metabolites—Aliquots of urine from each species and of fecal homogenates (further diluted 1:5 with water) from the dog, rat, and mouse, each containing at least 10^5 d.p.m. of ^{14}C, were extracted with ethyl acetate. Following the initial extraction at pH 9.0, the aqueous phase was incubated with a commercial preparation of β-glucuronidase and arylsulfatase[4], which was added to a final concentration of 1% (v/v). This incubation at pH 5.5 and 37° for 2–3 hr., which previously yielded maximum hydrolysis of conjugated benzodiazepine metabolites (5), was followed by serial extraction at pH 9.0, 7.0, and 2.0. All pH adjustments were made by the addition of dilute acid or alkali; at each designated pH, two consecutive volumes of ethyl acetate, each equaling the aqueous volume, were shaken with the aqueous phases for approximately 10 min. each. The combined extract at each pH was analyzed for ^{14}C and the extracts obtained at pH 9.0 were concentrated and examined by TLC.

TLC for Metabolite Separation, Identification, and Quantitation—Silica gel containing a fluorescent indicator[5] was used for TLC with the following solvent systems: 1, heptane–ethyl acetate–ethanol–concentrated ammonia (50:50:10:3); 2, heptane–chloroform–ethanol–concentrated ammonia (50:50:20:1); 2*a* and 2*b*, same solvents in the proportions of 25:75:10:0.5 and 50:50:50:1, respectively; 3, isopropanol–concentrated ammonia (100:1); 4, heptane–chloroform–ethanol (5:5:1); 5, ethyl acetate–methyl ethyl ketone–ethanol–concentrated ammonia (90:10:10:0.5); 6, benzene–ethyl acetate–ethanol–concentrated ammonia (80:20:20:1); 7, heptane–methylene chloride–ethanol–concentrated ammonia (50:50:25:1); 7*a*, same solvents in proportions of 50:50:50:1; 8, ethyl acetate–ethanol–concentrated ammonia (95:5:1); 9, chloroform–ethyl acetate–ethanol–concentrated ammonia (50:50:12:3); 10, heptane–benzene–ethanol–concentrated ammonia (50:50:20:0.5); 11, heptane–chloroform–ethanol–acetic acid (10:10:1:2); and 12, chloroform–ethanol–concentrated ammonia (95:5:0.5).

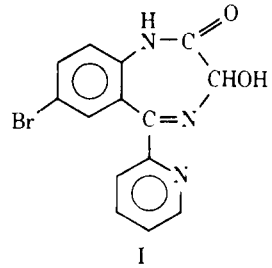
The use of one-dimensional TLC for metabolite separation followed by identification of the isolated metabolites by cochromatography with reference compounds or by spectroscopic techniques has been described (2). Individual urinary and fecal metabolites were determined by comparative two-dimensional TLC. In this analysis, both identification and quantitation result from the demonstration that, on two-dimensional TLC with at least two different solvent system pairs, a consistent amount of ^{14}C extracted from urine or feces migrates as a reference compound added as an internal standard. The solvent system pairs were designated by the number of each system in the order used, and the reference compounds were located by viewing the developed chromatoplate under shortwave UV light. Silica gel containing each reference compound was suspended in the fluor for the determination of ^{14}C.

In additional experiments, each identified metabolite added to water was shown by spectrophotometric assay to be quantitatively extracted at the pH used in its extraction from the biological sample. This demonstrated that no correction factor for incomplete extraction was required in calculating the excretion of each metabolite.

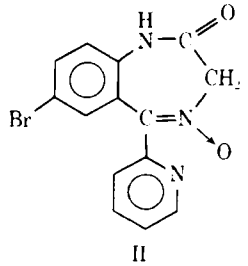
RESULTS

Excretion of Radioactivity by Each Species—The excretion of ^{14}C is summarized in Table I. The total excretion of ^{14}C by the human subjects ranged from 61 to 85% of the dose, with almost all of this radioactivity excreted in the urine. While the total excretion of ^{14}C by dogs was in this same range, a greater amount of the dose was excreted in the feces. The markedly high fecal excretion of orally administered ^{14}C by Dog 3 (59% of the dose) suggested that absorption of labeled bromazepam was impaired in this animal. In rats, the high fecal excretion of radioactivity was seen after both oral and intravenous administration of C_5-labeled drug, suggesting that biliary excretion was important in this species. In mice given either bromazepam-2-^{14}C or bromazepam-5-^{14}C intravenously, the excretion of radioactivity was similar to that obtained with man and dog; urinary excretion of ^{14}C predominated and the recovery of the dose was not complete.

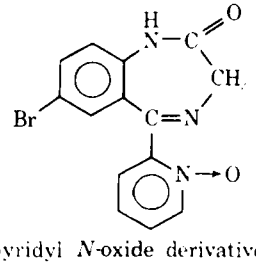
The reason for the incomplete excretion of all of the administered radioactivity, most evident in the human and dog, is not clear at this time. Since this loss is not limited to the administration of the C_2-labeled drug, it is not due to extensive metabolic cleavage of the diazepine ring and elimination of the C_2-carbon as carbon dioxide.



I



II



pyridyl *N*-oxide derivative

[4] Glusulase, Endo Labs., Garden City, N. Y.

[5] Precoated chromatoplates, Camag DF-B (Camag Inc., New Berlin, Wis.) and Q4F (Quantum Industries, Fairfield, N. J.), were used for two-dimensional TLC with Solvent Systems 5–6 and 10–6, respectively; chromatoplates prepared with SilicAR 7-GF-5 (Mallinckrodt Chemical Works, St. Louis, Mo.) were used with all other systems.

Table II—Metabolite Identification by Comparative Two-Dimensional TLC

Reference Compound	Labeled Metabolite Source[a]	TLC Systems	Percent of ^{14}C Migrating as Reference Compound
I	Dog 1 urine	1–2	95
		3–1	90
	Dog 2 urine	5–6	73
		8–9	80
		2*b*–7*a*	74
IV	Subject 3 urine	10–6	44
		2*a*–3	45
		2–11	45
III	Dog 2 feces	5–6	12
		2–7	14
		8–9	12

[a] Ethyl acetate extracts obtained by extraction at pH 9.0 of the glusulase-treated urine or feces were cochromatographed with reference compounds.

Apparently, a portion of the drug-derived ^{14}C is excreted very slowly.

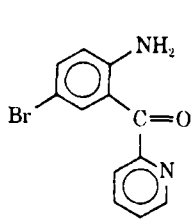
Identification of Urinary Metabolites—Reference compounds of interest were 3-hydroxybromazepam [I, 7-bromo-1,3-dihydro-3-hydroxy-5-(2-pyridyl)-2*H*-1,4-benzodiazepin-2-one], 4-oxide derivative [II, 7-bromo-1,3-dihydro-5-(2-pyridyl)-2*H*-1,4-benzodiazepin-2-one 4-oxide], pyridyl *N*-oxide derivative [7-bromo-1,3-dihydro-5-(2-pyridyl-2-oxide)-2*H*-1,4-benzodiazepin-2-one], 2-(2-amino-5-bromobenzoyl)pyridine (III), and 2-(2-amino-5-bromo-3-hydroxybenzoyl)-pyridine (IV). Evidence for I being a metabolite had been obtained in an earlier investigation (unpublished) of bromazepam metabolism in the dog. Evidence that IV is a urinary metabolite in the dog and rabbit was reported (6) during the present studies. Compound II and the pyridyl *N*-oxide derivative allowed differentiation between metabolic oxidation at the 4-nitrogen and pyridyl nitrogen, respectively.

Preliminary one-dimensional TLC of extracts of dog urine suggested that I, III, and IV were metabolites. Representative results from two-dimensional TLC, which confirmed their status as metabolites and allowed for their quantitation, are shown in Table II. The consistent migration of ^{14}C with the designated reference compound in extracts chosen because of their relatively high content of the metabolite in question is evident.

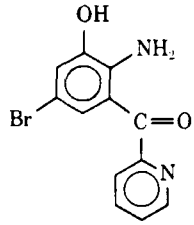
Also detected in the initial examination of dog urine by one-dimensional TLC was a directly extractable metabolite, which was purified first by TLC with System 1 and then by TLC of the eluted metabolite with System 2. The spectra resulting from low-resolution mass spectrometry[6] of a 4-mcg. sample of this metabolite showed that oxygen had been added to the bromazepam molecule and indicated, from the strong loss of *m/e* 16, that this metabolite was either the 4-oxide (II) or a pyridyl *N*-oxide derivative of bromazepam. Two-dimensional TLC, in which the isolated metabolite was cochromatographed with each isomer, clearly supported the identification of this metabolite as II.

This result was unexpected because metabolic *N*-oxidation of a benzodiazepine at the 4-position had not previously been reported. Further evidence for this structure was obtained by characterizing the benzoylpyridine formed on acid hydrolysis of the metabolite. A 50-mcg. sample of isolated metabolite was hydrolyzed in 6 *N* sulfuric acid, and the benzoylpyridine was extracted as previously described (3). When tested by TLC (System 4) and GLC[7] [using a 1.82-m. (6 ft.) 3% OV-17 column with inlet, column, and flame-ionization detector temperatures of 275, 240, and 290°, respectively], the metabolite hydrolysis product chromatographed as authentic III, supporting the identification of the intact metabolite as II.

The pyridyl *N*-oxide derivative was sought as a urinary or fecal metabolite in all four species investigated. However, no measurable or consistent amount of the ^{14}C of any extract examined migrated with this reference compound, thus indicating that it was not a metabolite of bromazepam.



III



IV

Quantitative Profile of Bromazepam and Metabolite Excretion—The extractability of the urinary metabolites of each species is presented in Table III. The urinary metabolites of man and dog are excreted mainly as conjugates hydrolizable by glusulase to labeled compounds extractable at pH 9.0. This is not true for the rat and mouse. In the rat, roughly one-quarter of the urinary ^{14}C is extractable at pH 9.0, both before and after glusulase treatment; in the mouse, the directly extractable ^{14}C represents the major metabolite fraction. An appreciable amount of urinary ^{14}C is extracted at pH 2.0 in both the rat and mouse. Fecal samples from dogs, rats, and mice were also extracted and, in general, less ^{14}C was extractable at each pH than was found for the respective urine samples.

The metabolites were quantitated in the pH 9.0 extracts obtained before and after glusulase treatment. As seen in Table IV, the excretion of unchanged bromazepam by each species accounted for only 1–2% of the dose. The major urinary metabolites excreted by the human subjects were the conjugated forms of I and IV. Subject 2 differed from the other two in excreting a larger amount of I (31% of the dose) and a smaller amount of IV (only 4% of the dose).

In Dog 3, in which most of the ^{14}C was excreted in the feces, 73% of the fecal ^{14}C was found to be unchanged bromazepam. Since the absorption of bromazepam in this animal was severely limited, only data from the other three dogs were used to compile the average excretion values shown in Table IV. The major urinary metabolite was conjugated I (20% of the dose). A small amount of urinary II was also excreted by dogs, and the dog was the only species in which measurable amounts of II were found in the urine.

Compound I was not excreted as a major metabolite by the rat, in contrast to the human and dog. Since only small amounts of III and IV were also found in the urine, most of the ^{14}C excreted by rats remained unidentified. The dominant metabolite excreted by mice was I, accounting for 36% of the dose. However, in contrast to its excretion mainly as a urinary conjugate by the human and dog, urinary I was excreted by the mouse primarily unconjugated. Very little III and IV and no detectable amounts of II were excreted by the mice; almost all radioactivity not excreted as I remained unidentified.

DISCUSSION

The excretion of conjugated 3-hydroxylated derivatives is prominent in humans and dogs, but not in rats, administered various 1,4-benzodiazepin-2-ones (2). The present results show that bromazepam also fits this pattern. In addition, the finding that Metabolite I, although mostly unconjugated, is a major urinary metabolite of bromazepam in the mouse suggests that this species metabolizes bromazepam as do the human and dog. The difference in the pattern of metabolites excreted by the mouse and rat may hold true for benzodiazepin-2-ones in general. Recently, a considerable fraction of an intravenous dose of either diazepam[8] or desmethyldiazepam was found (7) to be secreted in the bile of the mouse, but not in the bile of the rat, as the conjugated 3-hydroxy metabolite, oxazepam[9].

In the rat the preferred metabolic reaction apparently is hydroxylation of benzodiazepines at the *para*-position of the 5-phenyl ring (2). This is also true for oxazepam metabolism in the rat (8). However, since the major metabolites of bromazepam in the rat were not

[6] A Consolidated Electronics Corp. 21-110 mass spectrometer produced the spectra, which were interpreted by Ms. J. Pao and Dr. W. Benz.

Table III—Extractability of the Urinary Radioactivity Excreted by Human, Dog, Rat, and Mouse[a]

Serial Extraction with Ethyl Acetate	Percent of Urinary Radioactivity in Each Extract[b]			
	Human (3)[c]	Dog (4)[c]	Rat (4)[c]	Mouse (4)[c]
Preglusulase at pH 9.0	6.4 ± 0.75	10 ± 1.9	24 ± 2.8	48 ± 1.9
Postglusulase at pH 9.0	63 ± 7.4	63 ± 9.7	21 ± 6.2	22 ± 2.4
at pH 7.0	6.5 ± 2.0	5.6 ± 1.0	8.0 ± 3.6	3.1 ± 0.2
at pH 2.0	9.2 ± 1.8	4.0 ± 1.1	18 ± 2.5	17 ± 2.2
Total	85	83	71	90

[a] In each instance, the sample extracted was pooled urine representing over 90% of the final amount of ^{14}C eliminated in the urine. [b] Since the extractability within each species appeared to be unaffected by the position of ^{14}C labeling or the route of ^{14}C-bromazepam administration, the mean ± standard deviation is presented. [c] Number of individual subjects or animals whose urine was extracted.

Table IV—Excretion of Bromazepam and Metabolites by Human, Dog, Rat, and Mouse

Excreted Component	Percent of Dose Excreted[a]								
	Human Urine			Dog (3)		Rat (4)		Mouse (4)	
	Subject 1	Subject 2	Subject 3	Urine	Feces	Urine	Feces	Urine	Feces
Bromazepam	1.1	1.2	1.8	Negl.[b]	1.6 ± 0.2	0.7 ± 0.4	1.0 ± 0.3	0.6 ± 0.1	0.5 ± 0.1
I (Nonconjugated)	0.5	1.6	0.7	Negl.	1.7 ± 0.7	1.6 ± 0.3	Negl.	22.7 ± 2.6	4.1 ± 0.9
I (Conjugated)	12.8	29.8	12.5	19.9 ± 8.9	1.3 ± 0.5	Negl.	Negl.	8.2 ± 1.3	1.1 ± 0.4
II (Nonconjugated)	Negl.	Negl.	Negl.	2.5 ± 1.4	Negl.[c]	Negl.	Negl.	Negl.	Negl.
III[d]	1.7	Negl.	3.5	Negl.[c]	0.9 ± 0.4[c]	0.6 ± 0.1	Negl.	1.6 ± 0.3[c]	Negl.
IV[e]	10.2	3.9	24.6	2.5 ± 1.8[c]	1.7 ± 1.6[c]	1.4 ± 0.6	Negl.	0.9 ± 0.1[c]	Negl.
Unidentified ^{14}C	31.4	36.8	33.4	19.6 ± 1.8	16.7 ± 3.0	18.2 ± 5.6	55.8 ± 5.7	22.0 ± 2.0	13.2 + 1.9
Total ^{14}C	57.7	73.3	76.5	44.5 ± 7.7	23.9 ± 4.6	22.5 ± 6.6	56.8 ± 5.6	56.0 ± 5.1	18.9 ± 2.9

[a] The values presented, individual values for the three subjects and mean ± standard deviation for the number of animals shown in parentheses for each species, were obtained from the analysis of pools of urine or feces which accounted for at least 90% of the ^{14}C excreted by each route. In addition to the solvent systems shown in Table II, System 11–12 was used (particularly in the quantitation of Metabolite IV). [b] Negl. indicates that less than 0.5% of the dose was excreted. [c] Average of results from two animals. [d] Compound III was found mainly in the postglusulase extract, indicating its apparent excretion as a conjugate. [e] Compound IV was found mainly in the postglusulase extract of urine and in the preglusulase extract of feces.

identified, there is no evidence for hydroxylation of the 5-pyridyl ring in this species.

Metabolic cleavage of the diazepine ring of medazepam[10] (9) and nitrazepam[11] (10) to form both a benzophenone and a phenolic benzophenone hydroxylated *ortho* to the amino function has been found in the human. Therefore, the excretion of III and IV as metabolites of bromazepam in the human is not surprising. From the magnitude of conjugated IV excretion by the three women (4, 10, and 25% of the dose), it is evident that both 3-hydroxylation and benzoylpyridine formation must be considered important pathways in the human.

One novel pathway, the formation and urinary excretion of bromazepam N_4-oxide (II), occurred in the dog but not in the human, rat, or mouse. Although the reduction of the N_4-oxide function of a benzodiazepin-2-one 4-oxide (demoxepam) was shown to occur in the dog (11), oxidation of this diazepine ring nitrogen has not been reported until now. Interestingly, the pyridyl nitrogen of bromazepam was apparently not oxidized since the pyridyl *N*-oxide derivative was not detected as a metabolite in any of the four species. Whether or not N_4 oxidation is a metabolic reaction unique to bromazepam cannot be known until a thorough search for the corresponding N_4-oxide metabolites of other benzodiazepines is made.

The present quantitative findings are similar to recent data[12] obtained from two human subjects given 6 mg. of bromazepam-5-^{14}C intravenously; the subjects excreted 10 and 15% of the dose in the urine as I (mostly conjugated) and 16% as IV (again mostly conjugated) in 24 hr. In addition, the rat excreted I, III, and IV as urinary metabolites, with IV, at 4–5% of the dose, being excreted to a greater extent than the other two.

On the basis of the results obtained to date, it is apparent that the metabolites excreted by humans were also excreted to some extent by the dog, rat, and mouse, whereas only the dog excreted II.

Identification of Urinary Metabolites of *p*-Phenoxyphenol Methanesulfonate in Rat and Man

F. F. SUN

Abstract □ The urinary metabolites of *p*-phenoxyphenol methanesulfonate (I) in rat and man were characterized. The drug was extensively metabolized in both species and excreted mainly in the form of conjugated phenolic compounds. The major metabolite of I in both species was identified as the conjugated monohydroxylated compound, *p*-(4-hydroxyphenoxy)phenol methanesulfonate (II). Three minor metabolites were also characterized and tentatively identified as: (*a*) a dihydroxylated derivative, probably *p*-(3,4-dihydroxyphenoxy)phenol methanesulfonate (III); (*b*) a hydroxy and methoxy derivative, probably *p*-(4-hydroxy-3-methoxyphenoxy)phenol methanesulfonate (IV); and (*c*) a dihydroxy and methoxy derivative (V). The exact positions of the aromatic substituents in these three compounds were not rigorously established. Compounds II and IV were found in both free and conjugated forms, but Compounds III and V were found in the conjugated form only. Qualitatively, the metabolites of I found in rat and human urine were similar. The hypolipidemic activity of II was equivalent to that of the parent compound.

Keyphrases □ *p*-Phenoxyphenol methanesulfonate—identification of urinary metabolites, rat, man □ Urinary metabolites—*p*-phenoxyphenol methanesulfonate, rat, man

p-Phenoxyphenol methanesulfonate[1] (I, $C_{13}H_{12}O_4S$, mol. wt. 264) has been shown to be an active hypocholesterolemic agent in both surfactant[2]-treated and dietary cholesterol and cholic acid-fed rats. Its pharmacological properties were reported previously (1). To study the absorption, metabolism, and excretion of this compound in animals and man, a GLC method for measuring the intact drug was developed. Little, if any, unchanged drug was found in the urine of I-treated rats. Analysis of the urine specimens, using TLC techniques, indicated that the compound was metabolized to several products. Therefore, studies were initiated to: (*a*) identify the major urinary metabolites of this compound in rats and man, and (*b*) determine the biological activities of the major metabolites in rat and man.

EXPERIMENTAL

Dosage and Collection of Samples *Rat*—Micronized I was suspended in 0.25% methylcellulose in sterile water with a glass Teflon homogenizer. The suspension was administered orally to five Sprague–Dawley rats at a dose of 100 mg./kg. Urine samples were collected quantitatively for 24 hr. postadministration. A second group of five rats, dosed with the vehicle only, served as controls.

Man—Five subjects each received orally a single 1-g. dose of I in hard filled capsules. Urine specimens were collected quantitatively 24 hr. postadministration. Urine specimens collected prior to drug administration were used as controls.

Method—All urine specimens were extracted and analyzed with a previously described GLC–mass spectrometric procedure (2). The pooled urine samples were acidified to pH 3.5 with acetic acid and extracted six times with chloroform. The chloroform layers were separated and concentrated under reduced pressure. The extracted urine was heated at 45° for 1 hr. under reduced pressure to remove the dissolved chloroform and then hydrolyzed with a mixture of β-glucuronidase and aryl sulfatase[3] in 0.1 *M* sodium acetate buffer at pH 5.0 for 16 hr. at 37°. The hydrolyzed urine samples were then extracted five times with chloroform. The chloroform layers were separated, combined, and evaporated to dryness. Control urine was processed in the same manner.

The extracted residues from the unhydrolyzed and hydrolyzed urine specimens were chromatographed on silica gel G-254 thin-layer plates, using chloroform–methanol (95:5) as the developing solvent. The chromatograms were examined under UV light, and zones that appeared on the plates with the drug-treated urine extract but not on the plates of the control were scraped and eluted with chloroform–methanol (4:1). The purified metabolite was evaporated to dryness and silylated with bis(trimethylsilyl)acetamide before injection into a gas chromatograph–mass spectrometer[4], equipped with a 1.21-m. (4-ft.) column of 1% SE-30 on 80–100-mesh Gas Chrom Q. The oven was operated isothermally at 200° and the ionization potential was set at 70 ev. Carrier gas (helium) flow was kept at 60 ml./min.

RESULTS

A gas chromatogram of the crude extract from β-glucuronidase–aryl sulfatase-hydrolyzed human urine is shown in Fig. 1. Three peaks, with retention times of 1.55, 2.4, and 2.85 min., were found in the drug-treated urine extract but were absent in the control. The small peak found at the retention time of 3.9 min. was not related to the drug. Unchanged I, which should have a retention time of 0.66 min., was not detectable in this analysis.

Figure 2 shows a thin-layer chromatogram of the same extract. Again three components are present in the urine extract from drug-treated human subjects but not in the control. Each zone was scraped off the plate, eluted with solvent, derivatized with bis(trimethylsilyl)-acetamide, and injected into the gas chromatograph–mass spectrometer. Four drug-related compounds were identified. Two metabolites were found in the more polar zone (R_f 0.49). The identification of these compounds is described in the following sections.

***p*-(4-Hydroxyphenoxy)phenol Methanesulfonate**—The *p*-hydroxylated metabolite of I (Compound II) separated readily from partially purified urine extracts as white flaky crystals. The isolated material, m.p. 128–129°, appeared 99% pure as judged by GLC. Elemental analysis indicated that the compound had an empirical formula of $C_{13}H_{12}O_5S$.

Anal.—Calc. for $C_{13}H_{12}O_5S$: C, 55.71; H, 4.29; S, 11.43. Found: C, 55.82; H, 4.58; S, 11.35.

The UV spectrum was similar to the parent drug except the weaker bands (271 and 277 nm. in the unchanged drug) were shifted 5 nm. to the longer wavelengths. Addition of base (0.1 *N* NaOH) to the ethanolic solution shifted the strong absorption band (230 nm. in the unchanged drug) 12 nm. to the long wavelength side (242 nm. in the metabolite), indicating the presence of a monohydric phenol (3). In the IR spectrum of the metabolite, the 695 cm.$^{-1}$ band of the unchanged drug (monosubstituted phenyl) was absent, and strong absorption bands were observed at 820 (*p*-substituted phenyl), 1195 (phenol C—O vibration), and 3460 (OH vibration) cm.$^{-1}$, indicating good agreement with the structural assignment. The NMR spectrum

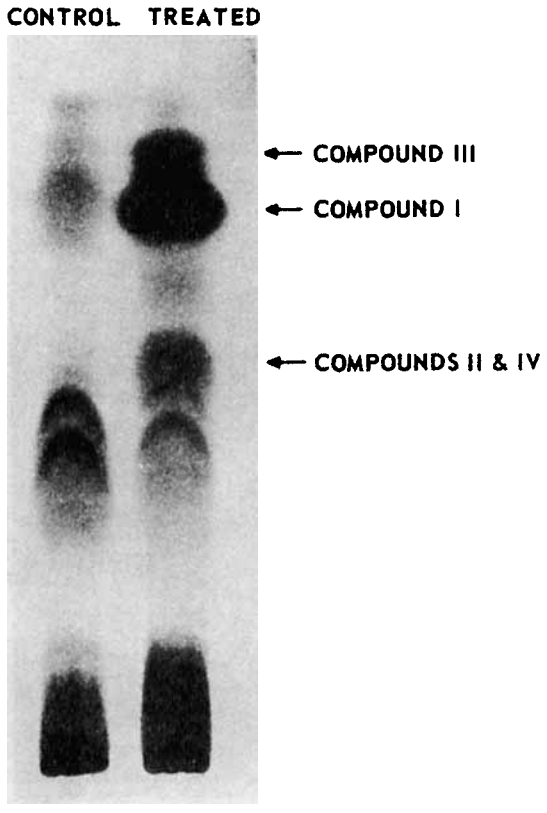

Figure 2—*Thin-layer chromatograms of extracts from β-glucuronidase–aryl sulfatase-hydrolyzed human urine.*

showed two sets of *AA'BB'* multiplets, indicating that the hydroxyl substitution was *para*. Furthermore, the isolated material gave a strong positive response to bipyridyl ferric chloride reagent (4), which is characteristic of phenolic compounds. Conclusive identification of the isolated material was obtained from mass spectral analyses. The isolated Compound II, Fig. 3*a*, showed a strong mass ion at 280 (molecular ion) and fragmentation ions at 201, 173, 145, 117, 93, and 65. The loss of methanesulfonate (M − 79 = 201) was characteristic of all compounds related to I. Subsequent loss of mass 28 (CO) was characteristic of phenols. The assignment of major fragments is summarized in Table I. The trimethylsilylated derivative of I (Fig. 3*b*) showed a similar type spectrum, except all mass peaks were found 72 mass units higher. Therefore, it was concluded that this compound was the *p*-hydroxylated metabolite of I.

Table I—Common Mass Peaks Appearing in *p*-Phenoxyphenol Methanesulfonate-Related Compounds

m/e	Structure	Comments
M − 79	Loss of $-SO_2CH_3$	Appears in all spectra
M − 28	Loss of CO	Appears in all spectra
M − 15	Loss of CH_3	Appears in all trimethylsilyl ethers and all phenyl methyl ethers
M − 30	Loss of HCHO	Appears in all phenyl methyl ethers
M − 88	Loss of C_3H_8OSi	Appears in trimethylsilyl ethers of dihydric phenols
273		Appears in all trimethylsilyl ethers
93		Appears in all free phenolic compounds
77		Appears in all spectra
65		Appears in all spectra

Compound II was subsequently synthesized by reacting 4,4'-oxydiphenol with methanesulfonyl chloride in pyridine at 0°. The reaction mixture was poured into a mixture of ice water and extracted with chloroform. Compound II was isolated from the extract by silica gel column chromatography. The authentic material had identical chromatographic and spectroscopic (UV, IR, NMR, and mass) characteristics to the isolated material. The hypolipidemic activity of II was tested in the surfactant[2]-induced hypercholesterolemic rats and was found to be equivalent to that of the parent I.

In the urine of both species, the major portion of II existed as conjugates. A trace amount was also found in the free form.

Dihydroxy Metabolite—Compound III was a minor metabolite found only in conjugated form. The amount present in the urine was insufficient for isolation. This compound gave a brownish-red spot on the thin-layer plate when sprayed with bipyridyl ferric chloride reagent, indicating that it was a phenol. The mass spectrum of the bis(trimethylsilyl) derivative is shown in Fig. 4. The molecular ion was observed at *m/e* 440, and strong fragmentation ions were observed at 361 (M − 79) and 273 [M − 79 − $(CH_3)_3SiO$]. Subsequent loss of 28 mass units (CO) was not as prominent as in II. The positions of the two hydroxyl groups were difficult to assign. However, since the predominant product produced by the enzymatic hydroxylation of *p*-substituted phenol is catechol (6), the structure of III was probably *p*-(3,4-dihydroxyphenoxy)phenol methanesulfonate.

Hydroxy Methoxy Metabolite—Compound IV was found both free and conjugated in the urine of rat and man. It was isolated by preparative TLC from the mother liquor remaining after crystallization of I. Attempts to crystallize IV were unsuccessful. The mass spectrum of IV (Fig. 5*a*) showed a strong molecular ion at mass 310. Loss of methanesulfonate (M − 79) and subsequent loss of 28 mass units (CO) identified IV as a drug-related compound. In the mass spectrum of the trimethylsilyl derivative (Fig. 5*b*), prominent ions were observed at 382 (M^+) and 303 (M − 79). In both spectra, loss of 30 (CH_2O) or 31 (CH_3O) mass units from the molecular ion or the M − 79 ion indicated the presence of a phenyl methyl ether linkage (8). The IR spectrum of IV was quite similar to that of II. Strong bands, observed at 3460 $cm.^{-1}$, were assigned to the phenolic OH. The aromatic system and the methanesulfonate group of the parent

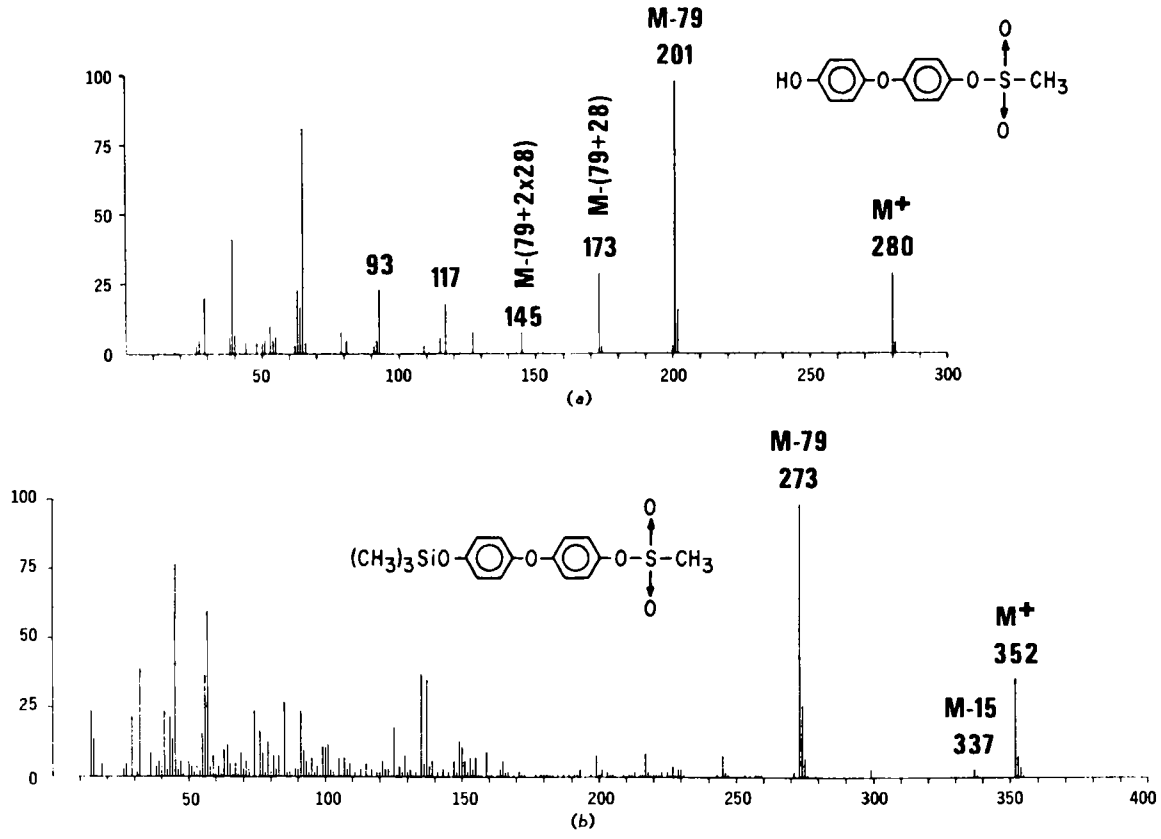

Figure 3—*Mass spectra of Compound II. Key:* (a), *free phenol; and* (b), *trimethylsilyl derivative.*

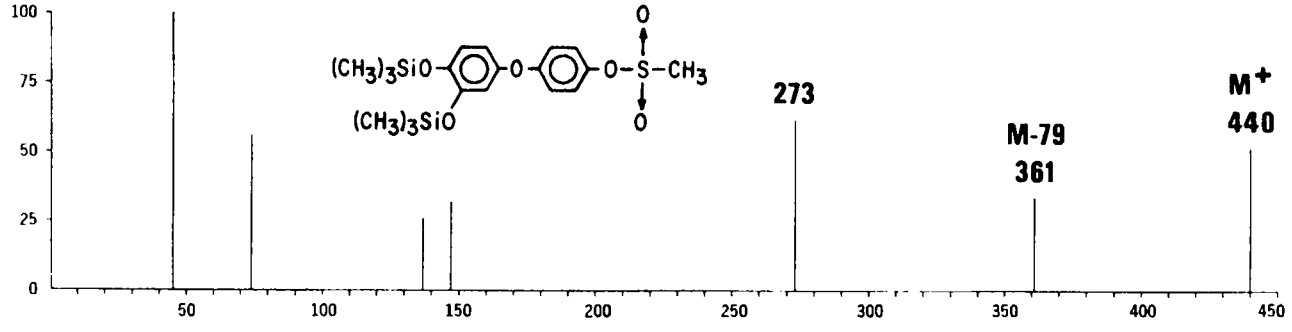

Figure 4—*Mass spectrum of bis(trimethylsilyl) derivative of Compound III.*

compound were still present. Neither the presence of methoxy nor the position of aromatic substitution could be conclusively established by IR spectroscopy.

NMR spectroscopy indicated the presence of a methoxy group *ortho* or *meta* to a *para*-substituted hydroxy group on the phenoxy ring. The methoxy group showed a singlet at δ 3.78 and shifted only one of the aromatic protons (*meta* to the methoxy) upfield to δ 6.9. An unperturbed *AA'BB'* multiplet centered at δ 7.21 indicated that the phenol ring was still intact. Since the predominant product from enzymatic hydroxylation of phenol is catechol (9) and since catechol-*O*-methyltransferase will not methylate resorcinol (8), it is unlikely that the methoxy group would substitute *meta* to the free *para*-substituted hydroxy group on the phenoxy ring. Therefore, IV is tentatively assigned a 4-hydroxy-3-methoxyphenoxyphenol molecular structure.

Dihydroxy Methoxy Metabolite—Compound V, a minor metabolite of I, could not be isolated in pure form. Evidence for its presence was obtained solely from GLC–mass spectrometric analysis of crude urine extracts. It was observed in the urine of both species only in conjugated form. After silylation with bis(trimethylsilyl)-acetamide, a strong mass ion at *m/e* 470 (Fig. 6) was observed corresponding to the disilylated derivative of Compound V. Loss of methanesulfonate (M − 79) and carbon monoxide (M − 28) indicated the presence of a drug-related compound. The presence of methoxy group was confirmed by the loss of 30 (CH_2O) mass units.

DISCUSSION

These results indicate that orally administered I followed typical metabolic pathways for aromatic compounds (9) and produced a group of phenolic compounds and their conjugates (Scheme I). The major routes of metabolism were: (*a*) hydroxylation of the phenoxy ring, and (*b*) conjugation of the resulting phenols with glucuronic acid or sulfate. A small portion of the hydroxylated I was further metabolized to yield the corresponding catechol, which underwent *O*-methylation to the methoxyphenol derivatives. Essentially all of the metabolites were excreted as either glucuronic acid or sulfate conjugates.

Since the NMR spectra of IV could not be factored with certainty because of the overlapping of the two highly coupled sets of aromatic hydrogens, plus the fact that not enough quantities of III and V were isolated for detailed NMR study, the exact positions of the aromatic substituents in III–V were not rigorously established. However, the limited information obtained from the NMR study of IV provided some clues for further speculation. As described

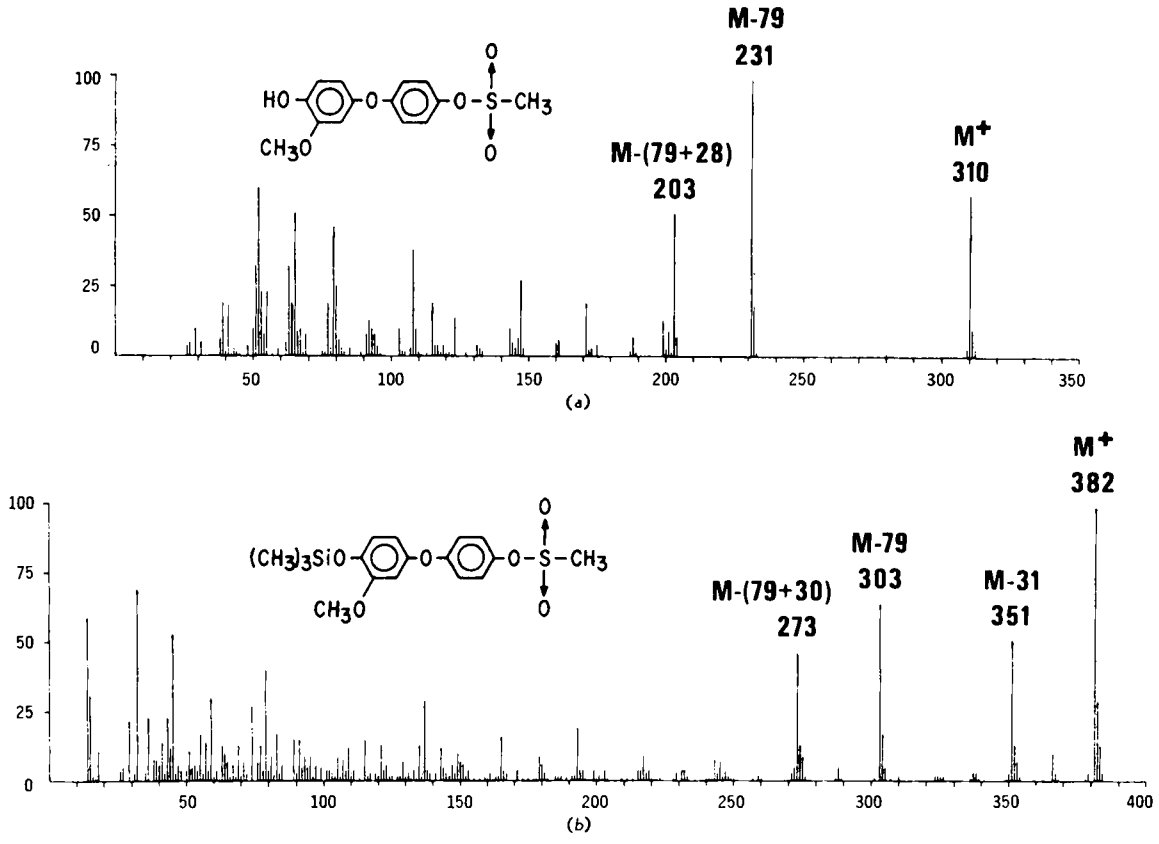

Figure 5—*Mass spectra of Compound IV. Key:* (a), *free phenol; and* (b), *trimethylsilyl derivative.*

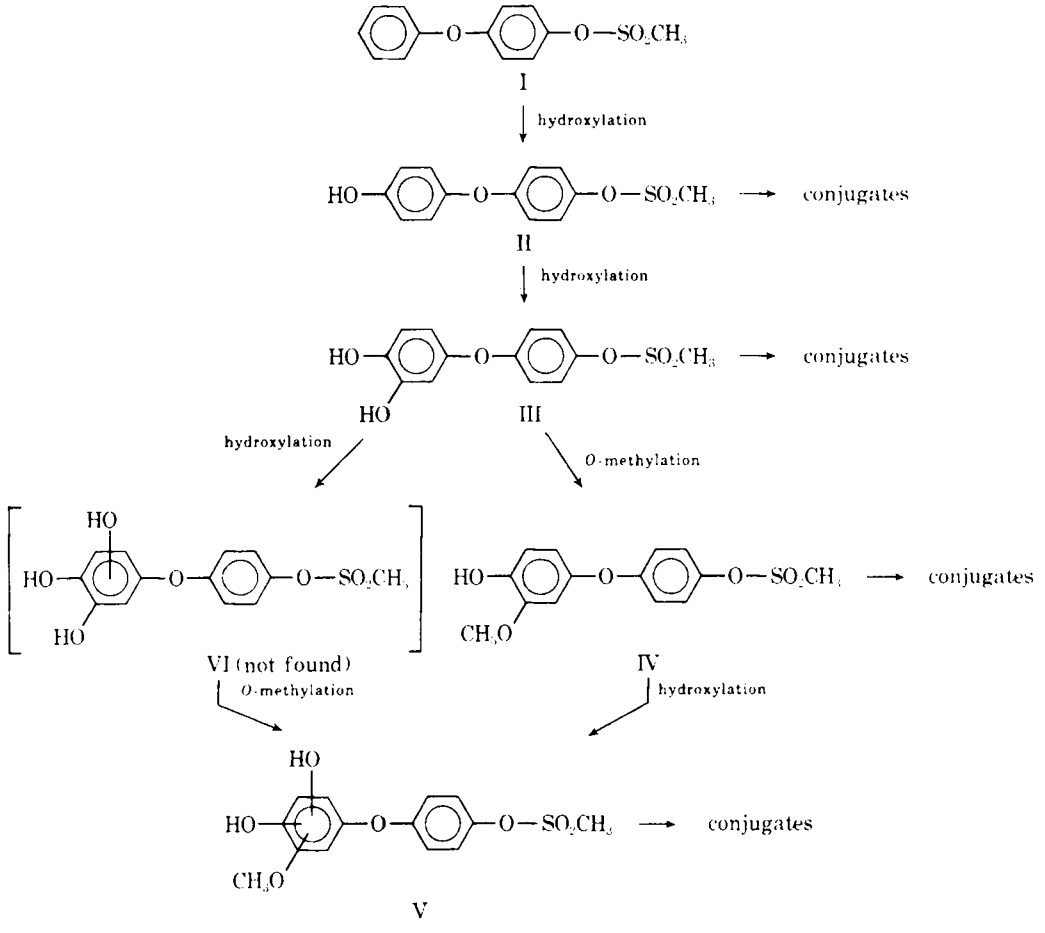

Scheme I—Proposed metabolic pathways of I in rat and human

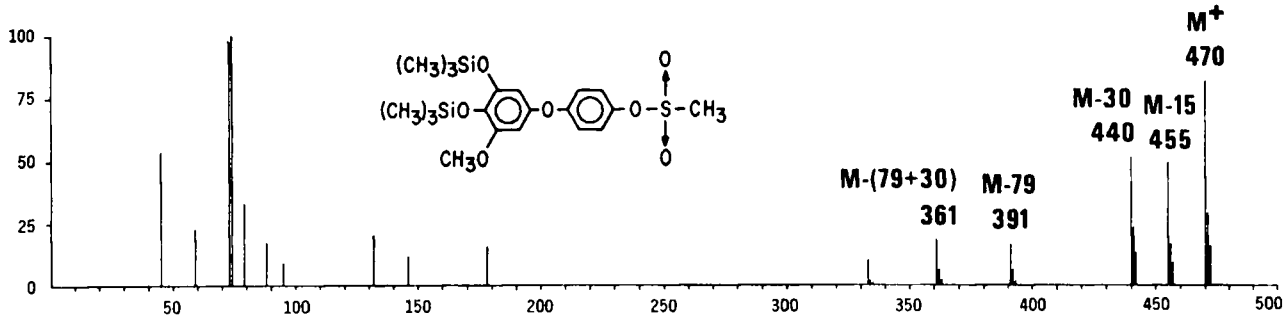

Figure 6—*Mass spectrum of bis(trimethylsilyl) derivative of Compound V.*

previously, the most probable structure for IV appeared to be 4-methoxy-3-hydroxyphenoxyphenol methanesulfonate. If this structure is correct, then III, presumably the precursor of IV, should have the structure of 3,4-dihydroxyphenoxyphenol methanesulfonate. The catechol structure would also be in line with the predicted hydroxylation product of II, since it was shown (6) that the principal hydroxylation product of *p*-substituted monophenol is the corresponding catechol. For example, *p*-cresol, *p*-nitrophenol, and *p*-chlorophenol are all hydroxylated to the corresponding catechol derivatives in rabbits (9). The structure of Compound V was even more obscure. It could be the hydroxylation product of IV or generated from III by hydroxylation followed by *O*-methylation. An unequivocal identification must await the synthesis of all possible isomers for comparison.

In view of the absence of unchanged drug in the urine, the rate of metabolism must be much faster than the rate of excretion. Quantitatively, the monohydroxylated compound (I) was the most abundant metabolite in the urine. In the human, the 24-hr. post-administration urinary excretion of I accounted for about 15–30% of the dose.

Since radioisotopically labeled I is not available, the extraction efficiency of drug-related materials from the urine is unknown. The possibility exists that some extremely water-soluble metabolite(s) of the parent drug was not found because of unfavorable partition coefficients between chloroform and water, for example, the trihydroxylated metabolite (VI), which would be the precursor of IV if it resulted from metabolized hydroxylation of III.

Mesoionic Purinone Analogs IV: Synthesis and *In Vitro* Antibacterial Properties of Mesoionic Thiazolo[3,2-*a*]pyrimidin-5,7-diones and Mesoionic 1,3,4-Thiadiazolo[3,2-*a*]pyrimidin-5,7-diones

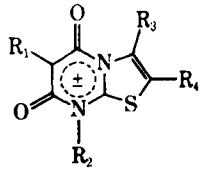
R. A. COBURN[▲] and R. A. GLENNON

Abstract □ Derivatives of two members of a new and unusual class of heterocycles, termed mesoionic purinone analogs, were synthesized and examined for *in vitro* antibacterial activity. Mesoionic thiazolo[3,2-*a*]pyrimidin-5,7-diones and mesoionic 1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5,7-diones, which are isoconjugate with xanthine, were found to exhibit antibacterial activity against both Gram-negative and Gram-positive organisms. Several mesoionic 1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5,7-diones possess significant levels of activity against *Proteus vulgaris* and *Staphylococcus aureus*.

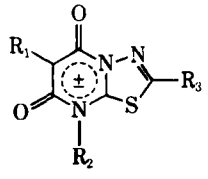
Keyphrases □ Mesoionic purinone analogs—synthesis and antibacterial properties of mesoionic thiazolo (or 1,3,4-thiadiazolo) [3,2-*a*]-pyrimidin-5,7-diones □ Mesoionic thiazolo (and 1,3,4-thiadiazolo) [3,2-*a*]pyrimidin-5,7-diones—synthesis and antibacterial screening □ Xanthine (mesoionic) analogs—synthesis and antibacterial properties of mesoionic thiazolo (and 1,3,4-thiadiazolo) [3,2-*a*]pyrimidin-5,7-diones □ Antibacterial activity—synthesis and screening of mesoionic thiazolo (or 1,3,4-thiadiazolo) [3,2-*a*]pyrimidin-5,7-diones

Formulation of a large, virtually unknown, class of mesoionic compounds, which are isoelectronic and isosteric to the purinones, was described previously (1, 2). They have been termed mesoionic purinone analogs because they cannot be satisfactorily represented by *any* covalent or single dipolar valence bond structure. Due to the large number of such analogs[1], they have been divided into two classes; Class I analogs are based upon known five-membered ring mesoionic systems (1, 3), and Class II analogs are based upon known six-membered ring mesoionic systems (2, 4). These two classes are further subdivided into xanthine, hypoxanthine, and purin-2-one analogs.

The compounds in this report, mesoionic thiazolo-[3,2-*a*]pyrimidin-5,7-diones[2] (I) and mesoionic 1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5,7-diones[3] (II), are Class II mesoionic xanthine analogs. Quantum chemical studies of this subclass were reported (2), and convenient synthetic routes for their preparation were described (5). Molecular orbital studies of these analogs, in comparison with their covalent isomers, indicated an enhanced degree of chemical reactivity, an increase in charge separation and dipole moment, and an increase in electron affinity, which suggests an enhanced ability to participate in charge-transfer interactions as electron acceptors. Chemical studies (5) of the reaction of these compounds with amines suggested their potential function as selective acylating agents.



I



II

The synthesis of a number of derivatives of mesoionic thiazolo[3,2-*a*]pyrimidin-5,7-diones and 1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5,7-diones is reported here, along with the results of *in vitro* antibacterial screening as a part of an initial pharmacological investigation of this new class of compounds.

SYNTHESIS

Compounds I*a*–I*h*, with the exception of I*e*, were prepared as outlined in Scheme I. 2-Aminothiazoles were acylated by the use of acyl chlorides or acid anhydrides to obtain the amides, IV (Table I), which were reduced *via* lithium aluminum hydride to the corresponding 2-alkylaminothiazoles, V (Table II). 2-Bromo-5-nitrothiazole was treated with 3,4-dichlorobenzylamine to obtain V*e*. Heating the 2-alkylaminothiazoles, V, with the malonate esters, VI (R_3 = H,CH_3), gave the mesoionic xanthine analogs, I, in good yield (Table III). The mesoionic thiadiazolopyrimidiones, II, were prepared by an analogous procedure.

tion was completed, stirring was continued at room temperature for 1 hr. Filtration and evaporation of the filtrate *in vacuo* gave the crude product. Recrystallization from isopropanol gave 5.2 g. (66.3%) of IV*d* as white crystals, m.p. 198–199°; IR (chloroform): 1675 (m) cm.$^{-1}$; NMR ($CDCl_3$): δ 1.9–2.2 (m, 15H, adamantyl protons), 7.2 (d, 1H, thiazole proton), and 7.7 (d, 1H, thiazole proton). Table I lists the analytical data.

The 2-acylaminothiazoles, IV*a*–IVc (Table I), were prepared in the same manner as IV*d*.

2-(1-Adamantylmethylamino)thiazole (V*e*) A solution of IV*d* (1.3 g., 5 mmoles) in 20 ml. of tetrahydrofuran was added dropwise with stirring to a suspension of lithium aluminum hydride (0.2 g., 5.2 mmoles) in 20 ml. of tetrahydrofuran at 0°. After refluxing for 3 hr., water was slowly added at 0° until the evolution of hydrogen ceased. Filtration and evaporation of the filtrate *in vacuo* gave a colorless oil which crystallized upon standing. Recrystallization from isopropanol gave 1.1 g. (88%) of V*d* as white flakes, m.p. 104–105°; IR (chloroform): 3450 (m) and 2900 (s) cm.$^{-1}$; NMR ($CDCl_3$): δ 2.0 (m, 15H, adamantyl protons), 3.3 (s, 2H, —CH_2—), 6.2 (broad signal, 1H, —NH—), 6.8 (d, 1H), and 7.4 (d, 1H, thiazole protons). Table II lists the analytical data.

The 2-alkylaminothiazoles, V*a*–V*c* (Table II), were prepared in the same manner as V*d*.

2-(3,4-Dichlorobenzylamino)-5-nitrothiazole (V*e*)—2-Bromo-5-nitrothiazole (2.1 g., 10 mmoles) in 20 ml. of tetrahydrofuran was added dropwise with stirring to 3,4-dichlorobenzylamine (3.5 g., 20 mmoles) at 0°. After stirring at room temperature for 2 hr., the reaction mixture was filtered and the filtrate was evaporated *in vacuo* to give a brown oil which crystallized upon standing overnight (16 hr.). Recrystallization from isopropanol gave 2.1 g. (68.9%) of V*e* as yellow crystals, m.p. 150°; IR (KBr): 1510 (s) and 1470 (s) cm.$^{-1}$; NMR (dimethyl sulfoxide-d_6): δ 4.6 (s, 2H, —CH_2—), 7.3–7.7 (m, 3H, phenyl protons), and 8.35 (s, 1H, thiazole proton). Table II lists the analytical data.

Table III—Properties of Mesoionic Thiazolo[3,2-*a*]pyrimidin-5,7-diones (I) and Mesoionic 1,3,4-Thiadiazolo[3,2-*a*]pyrimidin-5,7-diones (II)

[a] I = isopropanol, M = methanol, A = acetonitrile, B = benzene, DA = dimethylformamide–acetonitrile, and D = dimethylformamide.

Anhydro(6-methyl-7-hydroxy-8-(1-adamantylmethyl)thiazolo[3,2-*a*]pyrimidinium-5-one) Hydroxide (I*d*)—Compounds V*d* (0.37 g., 1.5 mmoles) and VI*b* (0.74 g., 1.5 mmoles) were mixed and heated on an oil bath (160°) until a clear melt resulted (5 min.). A slow stream of nitrogen was passed through the flask during the heating period to remove 2,4,6-trichlorophenol. When cool, the resultant product was triturated with 30 ml. of anhydrous ether and collected. Recrystallization from benzene gave 0.31 g. (62.4%) of I*d* as white crystals, m.p. 210–211°; IR (chloroform): 1685 (s) and 1630 (s) cm.$^{-1}$; NMR ($CDCl_3$): δ 2.3 (m, 18H, $-CH_3$ and adamantyl protons), 4.2 (s, 2H, $-CH_2-$), 7.7 (d, 1H), and 8.5 (d, 1H, thiazole protons). Table III lists the analytical data.

Anhydro(2,6-dimethyl-7-hydroxy-8-benzyl-1,3,4-thiadiazolo-[3,2-*a*]pyrimidinium-5-one) Hydroxide (II*b*)—2-Benzylamino-5-methyl 1,3,4-thiadiazole (7) (1.0 g., 5 mmoles) and VI*b* (2.4 g., 5 mmoles) were combined and heated at 160°, under a slow stream of nitrogen, until a clear melt resulted (3 min.). The product was triturated with 30 ml. of anhydrous ether, collected, and recrystallized from isopropanol to give 0.45 g. (64.3%) of II*b* as white crystals, m.p. 227–228°; IR (chloroform): 1685 (sh) and 1635 (s) cm.$^{-1}$; NMR ($CDCl_3$): δ 2.1 (s, 3H, $-CH_3$), 2.7 (s, 3H, thiazole $-CH_3$), 5.3 (s, 2H, $-CH_2-$), and 7.4 (s, 5H, phenyl protons). Table III lists the analytical data.

Compounds I*a*–I*c*, I*e*, and II*a* (Table III) were prepared in the same manner as I*d*, by heating at 160° until a clear melt resulted (about 1–5 min.) and then triturating with anhydrous ether to remove any unreacted starting material.

Partition Coefficients—The partition coefficient (*P*) of I*i* (R_1 = R_3 = R_4 = H, R_2 = C_2H_5) was determined in an octanol–aqueous buffer system (8). A master solution was prepared by dissolving I*i* in a pH 7.4 aqueous phosphate buffer to achieve a concentration of 2.9 $\times$ 10^{-4} mole/l. Dilutions of this solution were shaken for 10 min. with 20 ml. of octanol in Run A and with 25 ml. of octanol in Run B. These mixtures were then centrifuged, and the aqueous phase was examined by UV spectroscopy (242 nm.) to determine the aqueous concentration of I*i*. A blank was run without octanol to obtain the extinction coefficient in the buffer solution. The value of *P* was determined by dividing the concentration of I*i* in octanol by the concentration of I*i* in the buffer solution. Thus, the log *P* determined for I*i* was −1.41 for Run A and −1.44 for Run B. The log *P* for I*i* was taken as the average of the two runs or −1.425. Due to the additive nature of substituent constants (8, 9), the partition coefficients (log *P* values) could thus be calculated employing the π-values of the various substituents. Table IV lists the partition coefficients calculated for the mesoionic compounds employed in this investigation.

Antibacterial Testing Procedure—The following organisms were employed in this study: *Escherichia coli* (ATCC 11775), *Proteus vulgaris* (ATCC 13315), *Pseudomonas fluorescens* (ATCC 13525), *Pseudomonas aeruginosa* (ATCC 15691), *Bacillus subtilis* (ATCC 6051), *Streptococcus faecalis* (ATCC 8043), and *Staphylococcus aureus* (ATCC 12600). A lawn was prepared on Meuller-Hinton blood (5%) agar plates, using 1 ml. of a 24-hr. growth of the test organism in brain-heart infusion broth. Paper disks (6 mm.), im-

pregnated with 2 mg. of the test compounds, were placed on the agar and incubated for 24 hr. at 37°. *Ps. fluorescens* was incubated for 48 hr. at 25°.

Included on each plate were one or more disks[5] impregnated with the following commercially available antibacterial agents: furazolidone[6], 100 mcg./disk; sulfadimethoxine[7], 250 mcg./disk; sulfamerazine, 250 mcg./disk; and sulfamethoxypyridazine, 250 mcg./disk.

The tube dilution method was carried out using brain–heart infusion broth (5 ml.) with 10-, 25-, 50-, 100-, 250-, and 500-mcg./ml. concentrations of test compound. The broth was inoculated with 0.05 ml. of a 24-hr. growth of the test organism adjusted to a constant value of turbidity near that observed for full growth. Turbidity was measured at 6-hr. intervals using a spectrophotometer[8] (650 nm.). Full growth was usually reached in 12–18 hr. in a control tube.

RESULTS AND DISCUSSION

The zones of inhibition observed for Compounds *Ia*–*Ih* and *IIa*–*IId* against the test bacteria are shown in Table V. All but three of these mesoionic compounds (*Ie*, *Id*, and *IId*) exhibited bacteriostatic activity against two or more of the test organisms. None of the mesoionic compounds displayed any activity against *E. coli*. Against the other Gram-negative bacteria, Compounds *Ib*, *If*, *Ig*, *IIa*, and *IIc* showed zones of inhibition comparable to or greater than those of the standards. Compounds *Ih*, *IIa*, and *IIc* displayed significant zones of inhibition against Gram-positive organisms. Thiadiazolopyrimidiones *IIa* and *IIc* are notable for their activity against all of the test organisms except *E. coli*.

The activity of these compounds suggested the inclusion of a number of the monocyclic thiazole and thiadiazole precursors in the disk screening procedure, but no significant activity was observed.

To assay the levels of activity of the more active compounds, *If*, *IIa*, and *IIc* were tested by the broth tube dilution method, using nitrofurantoin[9] as a standard for comparison. The minimum inhibitory concentration (MIC) and the concentration inhibiting 50% of full growth (ID_{50}) for these compounds against *P. vulgaris* and *Staph. aureus* are shown in Table VI.

Compound *If* exhibited only a low level of activity against both organisms in this test. Compound *IIc* displayed greater activity than *If* in both cases, while *IIa* exhibited activity against *Staph. aureus* comparable to that of nitrofurantoin. Against *P. vulgaris*, *IIa* was about half as active as the standard. At a concentration of 250 mcg./ml., *IIa* was bactericidal against *P. vulgaris* but not against *Staph. aureus*. All three tested compounds showed some inhibition of growth at the 10-mcg./ml. level.

The range of lipophilicity represented by the derivatives *Ia*–*Ih* is quite large ($\Delta \log P = 4.85$). The most lipophilic mesoionic thiazolopyrimidiones, *Ic*, *Id*, and *Ie*, exhibited the lowest spectrum of activity. With the exception of *Ih*, the more active derivatives in this series have log *P* values between 0 and 1 (*If*, 0.5; *Ig*, 1.3; and *Ib*, 1.0). The thiadiazolopyrimidines *IIa*–*IId* are more hydrophilic and cover a more restricted range of lipophilicity (*IIb*, −0.2, to *IIc*, −2.8). Of more importance in this series is the apparent requirement for an unsubstituted 2-position (R_3 = H). Much more quantitative data concerning the activity of many more derivatives will be required before meaningful structure–activity relationships will be revealed.

The mesoionic thiazolopyrimidiones are nonbasic while the mesoionic thiadiazolopyrimidiones are very weakly basic. Both are stable to hydrolytic ring opening. Mesoionic thiazolopyrimidiones have been recrystallized from 5% aqueous hydrochloric acid (5). Refluxing either in aqueous solutions of strong mineral acids or alkali does produce ring-opened products (5). All reported derivatives have been found to be stable to heat and light in air.

CONCLUSION

The spectrum of *in vitro* activity exhibited by a significant number of the mesoionic thiazolo[3,2-*a*]pyrimidiones, I, and mesoionic thiadiazolo[3,2-*a*]pyrimidiones, II, suggests that these compounds should be considered a new and novel class of antibacterial agents. Several features of these compounds are significant. While they inhibited the growth of both Gram-negative and Gram-positive bacteria *in vitro*, no activity was displayed against *E. coli*. Furthermore, a number of the mesoionic compounds exhibited comparable or greater activities, as evidenced by their zones of inhibition, than several of the sulfa drugs or nitrofurans employed as standards.

Pharmacokinetic Profile of Diazepam in Man following Single Intravenous and Oral and Chronic Oral Administrations

S. A. KAPLAN▲, M. L. JACK, K. ALEXANDER, and R. E. WEINFELD

Abstract □ Four subjects each received single intravenous and oral 10-mg. doses of diazepam and 10 mg. orally every 24 hr. for 15 days. The intravenous blood level data were fitted with a three-compartment open-model system containing both a "shallow" and a "deep" peripheral compartment. The "apparent" half-life of elimination of diazepam following intravenous administration ranged from 21 to 37 hr., and the calculated volume of distribution ranged from 160 to 205% of body weight. The rate at which diazepam returns to the central compartment from the deep peripheral compartment, k_{31}, was shown to be the rate-controlling factor in the elimination of diazepam and in the formation of desmethyldiazepam. Orally administered diazepam was rapidly and completely absorbed. Following chronic administration of 10 mg. diazepam every 24 hr., the minimum and maximum steady-state (plateau) levels of diazepam can be successfully predicted or calculated utilizing the pharmacokinetic parameters obtained following intravenous administration. Diazepam blood levels plateau at approximately Day 7 of treatment at twice the blood levels observed on Day 1. Desmethyldiazepam blood levels are within the range of the diazepam blood levels and exhibit an apparent half-life range from 50 to 99 hr. after the last dose of diazepam on Day 15.

Keyphrases □ Diazepam—pharmacokinetic profiles after single intravenous and oral and chronic oral administrations, man □ Pharmacokinetic profiles—diazepam after single intravenous and oral and chronic oral administrations, man □ Absorption kinetics—diazepam after single intravenous and oral and chronic oral administrations, man

Diazepam[1], 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one, is effective in the symptomatic relief of tension and anxiety states as well as for the relief of skeletal muscle spasms (1–8).

The drug exhibits a low aqueous solubility of 50 mcg./ml. and a pKa of 3.4 (9). The transfer characteristics of diazepam across the everted rat intestinal sac are consistent with good absorbability (10). This suggests that, once in solution, the permeability (absorbability) of diazepam across the GI mucosa will not be a rate-limiting factor following oral administration of the drug.

The major metabolic pathways of diazepam (Scheme I) have been described in various animal species and in man (11–17). In man, the major metabolite measurable in the bloodstream is desmethyldiazepam. In the urine, the glucuronide conjugate of oxazepam is the major detectable metabolite (11).

The present study was designed to elucidate the

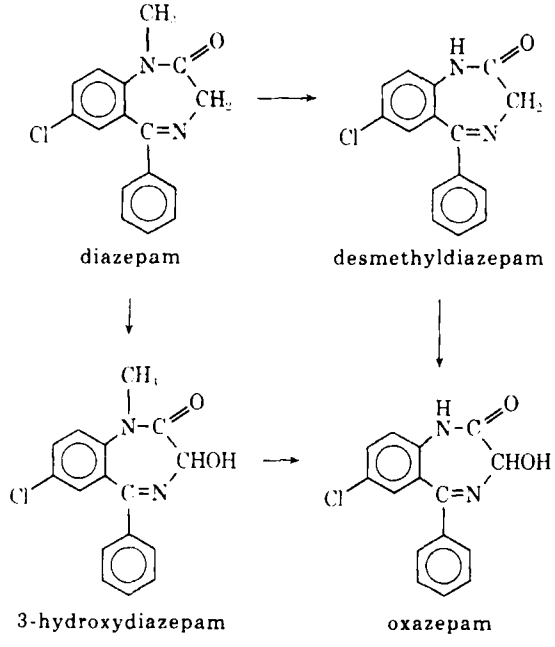
pharmacokinetic profile of diazepam in man following intravenous administration and to evaluate the physiological availability and disposition following single oral and chronic oral administrations of the drug.

EXPERIMENTAL

Clinical Protocol—Four healthy male volunteers, ages 25–43, each received a single 10-mg. dose of diazepam administered intravenously and orally 1 week apart[2]. Commencing 1 week thereafter, each subject received a 10-mg. oral dose of diazepam every 24 hr. for 15 days. The subjects were fasted for 7 hr. prior to receiving the single-dose administrations, and food was withheld for the 1st hr. postadministration.



Scheme I—Major metabolic pathways of diazepam

[2] The clinical aspects of the study were conducted at the Deer Lodge Research Unit, Deer Lodge, Mont., under the direction of Dr. James D. Moore.

Blood specimens were obtained at the time intervals indicated in Tables I and II for each treatment. The total volumes of urine voided were collected at 24-hr. intervals from −24 to 0, 0 to 24, and 24 to 48 hr. postadministration following the single intravenous and oral administrations. All specimens were frozen for subsequent analysis.

Analytical Method—Blood and urine specimens were analyzed for diazepam and desmethyldiazepam by the electron-capture GLC procedure of de Silva and Puglisi (18), with a sensitivity of 0.001 mcg./ml. for each component using a 1-ml. specimen.

RESULTS AND DISCUSSION

The diazepam and desmethyldiazepam blood level data following the single-administration studies are presented in Table I for all four subjects and plotted for one subject in Fig. 1. The blood level data following the chronic administration studies are presented in Figs. 2–5. The pharmacokinetic profile following the single intra-

venous and oral administrations of diazepam are summarized in Tables II and III, respectively.

Following the intravenous administration of diazepam, a triexponential blood level curve was observed in all four subjects as exemplified for Subject 3 in Fig. 1. The pharmacokinetic profile of diazepam was determined utilizing the data obtained following the intravenous administration of the drug. The data suggested that the pharmacokinetic evaluation would require minimally a three-compartment open-model system (19). The first two exponential phases with rate constants π and α reflect two different types of distribution phenomena, *i.e.*, distribution from the central compartment into a rapidly equilibrating or "shallow" peripheral compartment and a slowly equilibrating "deep" peripheral compartment. The third exponential phase, with a rate constant β, is referred to as the "apparent" elimination rate of the drug from the body. All three rate constants, π, α, and β, are hybrid first-order rate constants, each influenced by all of the individual processes involved in the disposition of the drug.

Solution of the differential equations of the three-compartment open model (Scheme II) yields the following integrated equation describing the blood level–time curve after intravenous administration:

$$(C_p)_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where $(C_p)_t$ is the concentration of drug in the blood at time t, and P, A, and B are the ordinate axis intercepts. The individual rate constants of the model, k_{12}, k_{21}, k_{13}, k_{31}, and k_{el}, are calculable from P, A, B, π, α, and β (20). These rate constants do not necessarily apply to any anatomically defined tissue compartments but are meaningful in defining the disposition of drug from the central compartment.

The total volume of distribution of diazepam (21), V_d, was found to be 196, 183, 161, and 205% of body weight for Subjects 1 through 4, respectively, following a 10-mg. intravenous administration of diazepam. The volume of the central compartment, V_p, was calculated to be 33.7, 20.5, 49.8, and 31.4% of body weight for Subjects 1 through 4, respectively. The size of the central compartment is consistent with the utilization of a three-compartment open pharmacokinetic model system in which elimination is occurring from the central compartment (22).

The intravenous blood level data were fitted to the triexponential equation by means of a "nonlinear" regression analysis computer program (23). The pharmacokinetic parameters of diazepam obtained for each subject following intravenous administration are summarized in Table II. The rate constants associated with the rapidly and slowly equilibrating sites in the peripheral compartments ranged from 3.1 to 22.4 hr.$^{-1}$ for π and from 0.21 to 0.73 hr.$^{-1}$ for α, respectively. These values correspond to apparent half-life ranges of 2–13 min. and 0.95–3.1 hr., respectively. The overall elimination rate constant, β, ranged from 0.019 to 0.026 hr.$^{-1}$, corresponding to an apparent half-life range of 26.7–36.5 hr. The magnitude of the three hybrid rate constants, π, α, and β, reflect an extremely rapid initial distribution of diazepam and a slow apparent elimination rate of drug from the body.

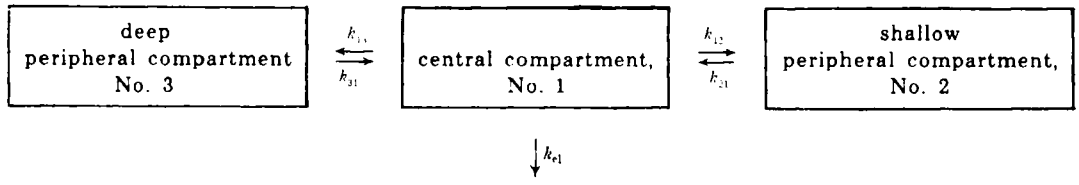

Scheme II—Three-compartment open-model pharmacokinetic system for diazepam

The individual rate constants, k_{12}, k_{21} and k_{13}, k_{31}, reflect the rate of distribution into and out of the shallow and deep peripheral compartments, respectively. The mean ratio of k_{21}/k_{12} of 1.4, reflecting return and entry of drug within the shallow peripheral compartment, suggests rapid equilibration and relatively free transfer of drug between the central and shallow compartments. The mean ratio of k_{31}/k_{13} of 0.3, reflecting return and entry of drug within the deep peripheral compartment, suggests slow equilibration plus drug binding to tissue or protein sites in this compartment, with a corresponding slow return of drug to the central compartment.

The magnitude of k_{31} was small within each subject. This rate constant represents the rate of return of drug from the deep peripheral compartment to the central compartment. This finding suggests that the rate-controlling step in the elimination of diazepam from the body is the rate at which the drug is released from the deep peripheral compartment. The mean ratio of β/k_{el} of 0.18 indicates that only 18% of the diazepam in the body is in the central compartment, available for elimination at any time (24).

By using the rate constants obtained following intravenous administration (Table II), the drug levels in the central and the two peripheral compartments were simulated for each subject (Fig. 6). These simulations clearly show that the deep peripheral compartment contains more diazepam than either the central or shallow peripheral compartment. This finding emphasizes the importance of the return of drug to the central compartment from the deep peripheral compartment as the rate-controlling step in the overal elimination profile of diazepam.

Following the intravenous administration of diazepam, desmethyldiazepam was detected in the blood. Initially, desmethyldiazepam is formed rapidly but then, at approximately 12 hr. postadministration, there is an apparent change in the formation rate constant; the blood levels of desmethyldiazepam continue to rise but very slowly. This slower apparent formation rate constant of desmethyldiazepam was calculated directly from the desmethyldiazepam blood level data after the 12-hr. data point by the method of least squares and found to be essentially equal to the overall elimination rate constant, β, of diazepam in each subject. The initial apparent formation rate constant of desmethyldiazepam was determined by "feathering" (24) the initial portion of the desmethyldiazepam blood level curve. The rate constants are reported in Table IV. Such findings indicate that the overall elimination of diazepam occurs almost exclusively *via* the desmethyldiazepam pathway and that the formation of desmethyldiazepam is, in turn, rate dependent upon the return of diazepam from the deep peripheral compartment.

Overall, the pharmacokinetic profile indicates that k_{31}, the rate of return of drug from the deep peripheral compartment, and not k_{el}, the true elimination rate constant, is the rate-controlling factor in the elimination of diazepam from the body. Therefore, the characteristics of the deep peripheral compartment would be of importance relative to understanding the physiological disposition character-

istics of diazepam in man. Alterations in the binding characteristics of drug to tissues or proteins associated with this compartment may yield marked alterations in the pharmacokinetic profile of the drug, whereas factors that affect the metabolism *per se* (*e.g.*, in the liver) may only minimally affect this pharmacokinetic profile.

Van der Kleijn (26) reported that diazepam is extensively protein bound in the dog. By using whole body autoradiography, he also showed that certain tissues, *i.e.*, brain, kidney, liver, myocardium, and digestive system, show large and rapid uptake of radioactive diazepam following the intravenous administration of diazepam to mice (27). These same tissues, in turn, show a very slow decline of diazepam levels. Although there was a rapid uptake of drug by the adipose tissues, there was a corresponding rapid decline of drug in these tissues, suggesting that drug is not strongly bound to adipose tissue. The observed extensive protein binding and the slow release of diazepam from tissues such as the brain, heart, and digestive system are consistent with the deep compartment of the proposed pharmacokinetic model. The slow release of diazepam from such protein and tissue binding sites probably determines the rate of metabolism and, therefore, elimination of diazepam from the body.

Single Oral Administration—Each subject received a single 10-mg. oral dose of diazepam. The blood levels and urinary excretion data are presented in Tables I and III, respectively, for all four subjects, and the blood level data are plotted in Fig. 1 for Subject 3.

Table IV—Formation Rate Constants for Desmethyldiazepam

	Subject			
	1	2	3	4
Overall elimination rate constant of diazepam, $hr.^{-1}$	0.019	0.026	0.024	0.021
Formation rate constant of desmethyldiazepam after 12 hr., $hr.^{-1}$	0.020	0.028	0.030	0.016
Initial formation rate constant of desmethyldiazepam, $hr.^{-1}$	0.546	0.427	0.329	0.351

Following the single oral administration of 10 mg. diazepam, the blood levels peaked at 1–1.5 hr. in all four subjects, indicating rapid absorption. When using the area under the blood level curve as an index of the extent of absorption, absorption appears to be essentially complete. The ratios of the areas under the oral blood level curves to that of the areas under the intravenous blood levels are 1.2, 0.90, 0.97, and 0.94 for Subjects 1 through 4, respectively.

The overall elimination rate constant, β, calculated following oral administration of diazepam (Table III) approximates the corresponding rate constant obtained following intravenous administration of the drug in each subject.

The evaluation of the oral diazepam blood level data relative to peak heights, peak times, areas under the blood level curves, and the first-order absorption rate constant (28) indicates that diazepam is rapidly and completely absorbed following oral administration in man. In addition, the physiological disposition characteristics do not appear to be dependent upon the route of administration. These characteristics are further confirmed by the similarity of the blood level curves of the metabolite desmethyldiazepam, determined following the intravenous and oral administration of diazepam.

The urinary excretion data following the single intravenous and oral administration of diazepam are presented in Tables II and III. Less than 0.05% of the administered dose was recovered in the urine as intact diazepam, indicating complete biotransformation of diazepam in man. The conjugated biotransformation product of desmethyldiazepam was identified in the urine, accounting for approximately 2.5–9% of the administered dose. The conjugates of oxazepam and 3-hydroxydiazepam were detected but not quantitated. Following the administration of radioactive diazepam, approximately 70% of the administered dose was reported (11, 16, 17) to be excreted in the urine and approximately 10% to be excreted in the feces.

Chronic Oral Administration—A 10-mg. dose of diazepam was administered every 24 hr. for 15 days to each of the four subjects. Blood specimens were obtained at 1, 2, and 24 hr. following each administration and analyzed for diazepam and desmethyldiazepam. The blood levels are presented in Figs. 2–5.

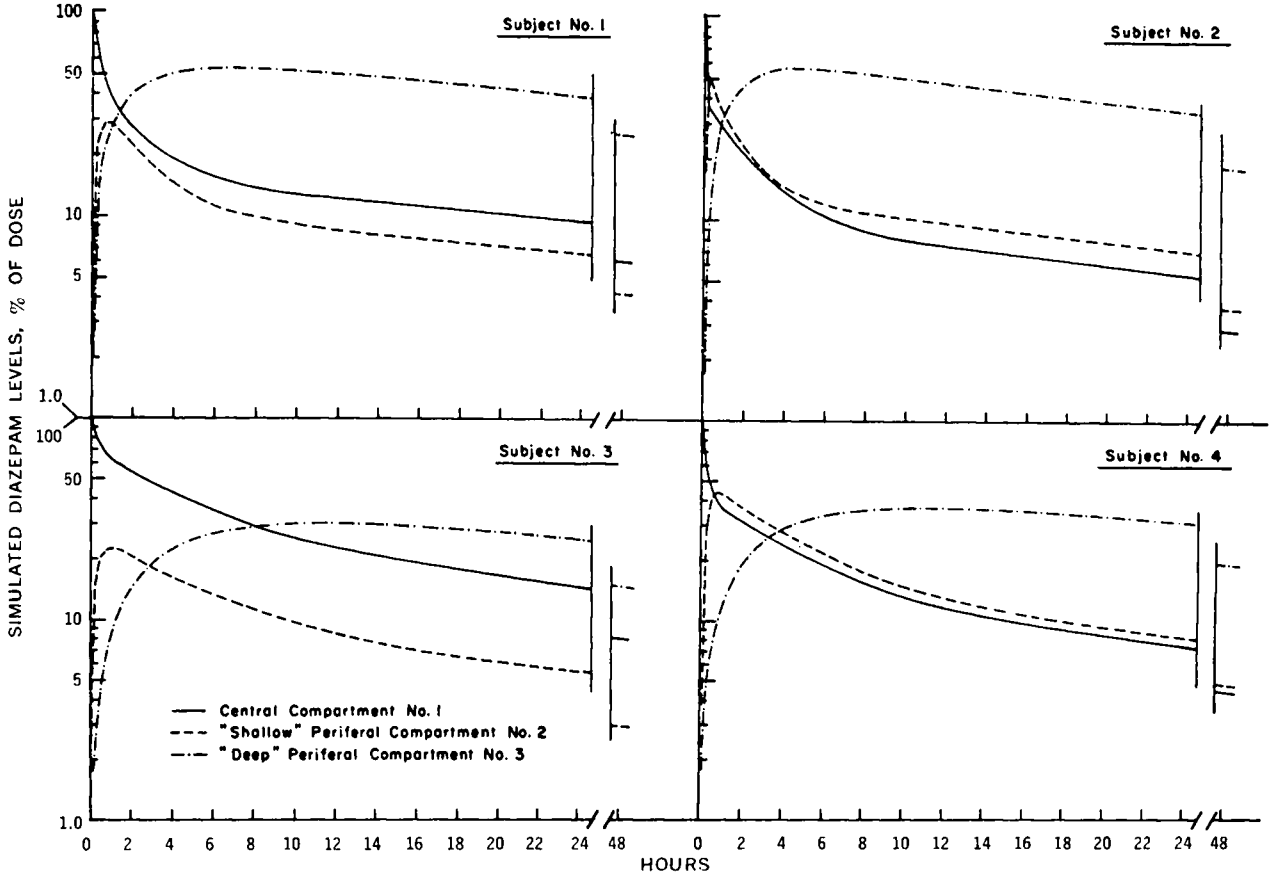

Figure 6—*Simulated compartmental drug level profile of diazepam in Subjects 1–4.*

The diazepam blood level curves following the 10-mg. oral chronic administration of diazepam to four subjects every 24 hr. were simulated by adapting the equations presented by Boxer *et al.* (29). Such an equation is applicable for diazepam because diazepam is both rapidly and completely absorbed. Since the intravenous blood level curve of diazepam is triexponential, the Boxer equation was modified to take into account the contributions of each exponential phase. Therefore, the simulated chronic oral dosing diazepam blood level curves were computed using the pharmacokinetic parameters obtained following the intravenous administration of diazepam to each subject, with the assumption that diazepam was rapidly and completely absorbed. Since the absorption rate constant is much larger than the disposition rate constants, the exponential associated with the absorption can be deleted from the blood level equation without affecting the predicted blood level profile.

Therefore, using Eq. 1 the blood level at any time, t, is the sum of the contributions of each exponential. By applying the Boxer equation for each exponential phase, the sum of the three exponentials will be the blood level at that time. The Boxer equation for a monoexponential is given by Eq. 2:

$$C_{p_n} = \frac{C_0 - C_0 r^n}{1 - r} \qquad \text{(Eq. 2)}$$

where C_{p_n} = blood level following the nth dose at time t, C_0 = initial blood level at time t, and $r = e^{-\beta\tau}$, where β is the slope of the exponential phase and τ is the dosing frequency.

For a triexponential, this equation becomes:

$$C_{p_n} = \frac{P_0 - P_0 r_1^n}{1 - r_1} + \frac{A_0 - A_0 r_2^n}{1 - r_2} + \frac{B_0 - B_0 r_3^n}{1 - r_3} \qquad \text{(Eq. 3)}$$

where P_0, A_0, and B_0 are the contributions of the respective exponentials at the initial time t, and $r_1 = e^{-\pi\tau}$, $r_2 = e^{-\alpha\tau}$, and $r_3 = e^{-\beta\tau}$.

Equation 3 was used to simulate the chronic blood level curves of diazepam for each subject. The simulated chronic diazepam blood level curves (Figs. 2–5) correspond well with the experimental blood level data points. Steady-state (plateau) diazepam blood levels were evident by the 7th day of the study. There was an approximate threefold difference between the mean maximum and minimum diazepam steady-state blood levels (Table V) observed at 1 and 24 hr. following administration, respectively.

The mean steady-state maximum and minimum blood levels were approximately twofold greater than the corresponding blood levels observed on Day 1. The calculated elimination rate constant, β, observed following the last dose on Day 15 approximated the corresponding rate constant observed following the single oral administration of the drug. This finding of relatively constant steady-state diazepam blood levels substantiates the constancy of the absorption, distribution, metabolism, and excretion with each administration of the drug, with all processes following apparent first-order kinetics. Such a steady-state profile for diazepam indicates that unpredicted drug accumulation will not occur and suggests no enzyme induction of diazepam metabolism. In their reported bioavailability data of diazepam, based on steady-state plasma levels, Berlin *et al.* (30) observed a small variation in steady-

Table V—Calculated and Experimental Diazepam Steady-State Blood Levels (Micrograms per Milliliter)

	Subject			
	1	2	3	4
Calculated minimum steady-state level	0.088	0.066	0.099	0.094
Experimental minimum steady-state level	0.104	0.068	0.085	0.078
Calculated maximum steady-state level	0.212	0.204	0.289	0.277
Experimental maximum steady-state level	0.235	0.210	0.224	0.238

state levels between subjects and half-lives of elimination consistent with the data presented herein.

The desmethyldiazepam blood level data obtained following the single intravenous and oral administrations of diazepam (Table I) do not lend themselves to pharmacokinetic evaluation. In all four subjects, the desmethyldiazepam blood levels continued to increase during the 48-hr. experimental period. In most instances, the increasing desmethyldiazepam levels were approximately equal to the declining diazepam blood levels during the 24–48-hr. interval following both intravenous and oral administrations of diazepam. As previously discussed, the formation rate of desmethyldiazepam is influenced by k_{31}, the rate at which diazepam is returning from the deep peripheral compartment to the central compartment.

Following the chronic dosing of 10 mg. diazepam every 24 hr. for 15 days, the desmethyldiazepam maximum–minimum blood level range of 0.16–0.09 mcg./ml. was within the range of the minimum steady-state diazepam blood levels (Figs. 2–5). The smaller range of maximum-to-minimum desmethyldiazepam blood levels is reflecting the slow formation and elimination rates of desmethyldiazepam. Following the last dose of diazepam on Day 15, the apparent half-life of elimination of desmethyldiazepam ranged from 50 to 99 hr. The observed slow decline in desmethyldiazepam levels after the administration of diazepam is slower than might be anticipated after desmethyldiazepam is administered due to the continued formation of the metabolites.

The overall elimination rate of diazepam, which is shown to relate directly to the formation rate of desmethyldiazepam, appears to be a major determining factor in the blood level profile of diazepam and its metabolites in various species. The more rapid the observed diazepam-to-desmethyldiazepam conversion rate, the more rapid is the onset of desmethyldiazepam blood levels. In contrast to man, the dog exhibits a conversion rate that is so rapid that diazepam is barely detected and desmethyldiazepam is essentially the exclusive blood component. In the rat, the conversion rate is negligible so the diazepam is the major blood component. The negligible desmethyldiazepam levels in the rat, however, may also be the result of the metabolic pathway to the 4-hydroxy derivatives (14, 15, 31).

SUMMARY

Four subjects each received a single intravenous and oral 10-mg. dose of diazepam and 10 mg. orally every 24 hr. for 15 days. The intravenous blood level data were fitted with a three-compartment open-model system containing both a shallow and a deep peripheral compartment. The half-lives corresponding to the third exponential are a measure of the overall elimination rate of the drug from the body and ranged from 21 to 37 hr. following intravenous administration. The volume of distribution ranged from 160 to 205% of body weight. The data suggest that the rate at which diazepam returns to the central compartment from the deep peripheral compartment, k_{31}, is the rate-controlling factor in the elimination of diazepam and in the formation rate of desmethyldiazepam.

Following oral administration, diazepam was absorbed rapidly and completely. The elimination rate observed following oral administration approximates that observed following intravenous administration.

Following the multiple oral dosing of 10 mg. diazepam every 24 hr. for 15 days, the diazepam blood levels plateau at approximately Day 7. The mean maximum–minimum diazepam plateau levels were 0.225–0.084 mcg./ml., and the half-life of elimination after the 15th dose was approximately the same as that seen following a single dose of diazepam. The corresponding desmethyldiazepam maximum–minimum levels of 0.16–0.09 mcg./ml. are within the lower range of the diazepam blood levels. The smaller range of maximum–minimum desmethyldiazepam levels results from its slow formation and elimination rate. Following the last dose of diazepam, the apparent half-life of elimination of desmethyldiazepam ranged from 50 to 99 hr.

The minimum and maximum steady-state (plateau) levels of diazepam can be successfully predicted (calculated) as a function of the pharmacokinetic parameters obtained following the intravenous administration of drug to each subject. This confirms the reproducibility of the apparent first-order absorption and physiological disposition characteristics of diazepam from administration to administration.

Electrokinetic Studies of Bacteria III: Effect of Polyvalent Metal Ions on Electrophoretic Mobility and Growth of *Streptococcus faecalis*

HANS SCHOTT▲ and C. Y. YOUNG

Abstract □ The effect of the polyvalent cations calcium, lead, copper, chromium, iron III, and thorium on *Streptococcus faecalis* was investigated by microelectrophoresis and by growth inhibition measurements. Thorium and the (hydrolyzed) ferric ion inverted the charge of the bacteria from negative to positive. The other cations merely reduced the absolute value of the negative ζ-potential at the concentrations investigated, which were limited because all measurements were performed at an ionic strength of 0.01 *M*. The order of effectiveness in changing the ζ-potential was thorium $\cong$ ferric $\gg$ chromium $\gg$ copper > lead > calcium, in accordance with the Schulze–Hardy rule. The effect of the salts on the growth of the bacteria was studied by the pour plate, growth curve, and turbidity methods. The order of effectiveness in inhibiting the bacterial growth was thorium > ferric > copper. The other cations produced no detectable growth inhibition at concentrations up to about 0.003 *M*. With the exception of chromium, there is a rank-order correlation between the ability of the polyvalent metal salts to reduce the ζ-potential of the bacteria and to inhibit their growth.

Keyphrases □ Electrokinetics—effect of polyvalent metal ions on electrophoretic mobility and growth of *Streptococcus faecalis* □ Electrophoretic mobility, *Streptococcus faecalis*—effect of calcium, lead, copper, chromium, ferric, and thorium ions, ζ-potential □ Bacterial growth, *Streptococcus faecalis*—effect of calcium, lead, copper, chromium, ferric, and thorium ions, pour plate, growth curve, and turbidity methods □ *Streptococcus faecalis*—effect of polyvalent metal ions on electrophoretic mobility and growth □ Metal ions, polyvalent—effect on electrophoretic mobility and growth of *Streptococcus faecalis* □ Zeta-potential—calculated for *Streptococcus faecalis*, effect of polyvalent metal ions.

The effect of salts of heavy metals on bacteria has been the subject of many studies. However, the mechanism of their antibacterial action, the "oligodynamic effect," is not understood (1). The effect of heavy metal cations on the charge of the cell wall of bacteria and spores has been assessed by electrophoresis (2–7). A possible correlation between antibacterial action and surface charge modification was never investigated; it is the topic of the present study.

EXPERIMENTAL

Electrophoresis Procedures—The methods were as described previously (8, 9), except as noted. The bacteria, *Streptococcus faecalis*, were incubated in the liquid growth medium at 37° for 18–24 hr., being in the stationary phase when harvested. Their suspensions were centrifuged for 10 min. at 9000 r.p.m. The bacteria were freed of adhering nutrients by resuspending the sediment three times in 0.010 *M* $NaNO_3$ or KCl and centrifuging for 10 min. at 9000 r.p.m. each time. When the polyvalent metals were in the form of nitrates, sodium nitrate was used for washing; it was also added to polyvalent metal salt solutions to adjust the ionic strength. When necessary, potassium chloride was used for the chlorides and sulfates. Electrophoretic measurements and viability assessments were made on bacterial suspensions of ionic strength equal to 0.010 *M*. It was shown (8) that the electrophoretic mobility of *S. faecalis* was not affected by changing buffers and other electrolytes from K^+ to Na^+ salts. Electrophoretic mobilities were measured after the bacteria had been in contact with the polyvalent cations for 30 min. at room temperature. Whenever tested, increases or decreases of 15 min. in the time of contact produced no significant change in mobility. The glass cell used had a cell constant of 62.4 $cm.^{-1}$, compared to 67.6 $cm.^{-1}$ for the plastic cell (8). The cell constants are used to calculate the specific conductance of the suspensions.

The solutions were not buffered in order to prevent precipitation or complexation of the polyvalent cations by the buffers used previously, namely, phosphate, acetate, or phthalate. Fortunately, the electrophoretic mobility of *S. faecalis* had been found (8) to be independent of pH between 4 and 7. Salts of polyvalent cations were freshly dissolved to avoid extensive hydrolysis.

Bacteriological Procedures—Three methods were used to assess the antibacterial activity of the heavy metal salts, designated as pour plate, growth curve, and turbidity methods. In the first two methods, the bacteria were treated in the same way as for the electrophoresis studies. After 18–24 hr. of incubation in the liquid growth medium, when the bacteria were in the stationary phase, the suspensions were centrifuged, washed by centrifugation three times with 0.010 *M* KCl or $NaNO_3$, and suspended for 30 min. at room temperature in solutions containing different concentrations of polyvalent metal salts. The ionic strength of these solutions was adjusted to 0.010 *M* with potassium chloride or sodium nitrate when necessary. In the blank experiments, the bacteria were given the identical treatment except that potassium chloride replaced the polyvalent metal chlorides and sulfates, and sodium nitrate replaced the polyvalent metal nitrates.

In the *pour plate method*, after the suspensions had been standing for 30 min., 1-ml. aliquots were diluted 10^4–10^6-fold with distilled water, and 0.1-ml. portions of the diluted suspension were mixed in petri dishes with 5% molten brain–heart infusion agar[1]. After 20 hr. of incubation at 37°, the number of colonies was counted. The difference between the plate counts of samples treated with potassium chloride or sodium nitrate and with polyvalent cation salts is due to the antibacterial action of the latter.

In the *growth curve method*, the suspensions already described, containing one of the heavy metal salts and/or potassium chloride or sodium nitrate, were left to stand for 30 min. At that time, 1-ml. aliquots were withdrawn and added to 100-ml. portions of a sterile liquid growth medium contained in 300-ml. culture flasks equipped with side arms. The growth medium contained 1% yeast extract[1], 1% bacto-tryptone[1], 0.1% dextrose, 0.050 *M* K_2HPO_4, and 0.050 *M* KH_2PO_4 and had a pH of 6.8. This medium was given a higher phosphate concentration than the 0.0023 *M* concentration of the medium previously used to increase the growth rate of the bacteria. The higher phosphate content reduced the lag time (defined below) from 3.5 to 2.6 hr. The culture flasks were shaken in a 37° bath. Absorbance measurements at 640 nm. were made at hourly intervals by inserting the side arm into a spectrophotometer[2]. During the logarithmic phase, absorbances were measured every 30 min.

The growth curves (plots of absorbance *versus* incubation time) are based on the "adjusted net absorbance" (*AA*), which is the "net absorbance" (*NA*) corrected for light scattering. Net absorbance is the difference between the absorbance after the specified incubation time and the absorbance immediately after inoculation. The relationship between *NA* and *AA* is given (10) by:

$$NA = AA - 0.1(AA)^2 - 0.002(10AA - 2)^2 \quad \text{(Eq. 1)}$$

This equation can be simplified, for *NA* values between 0.196 and

about 0.9 (10), to:

$$AA = 1.800 - 0.1\sqrt{321.3 - 330NA} \qquad \text{(Eq. 2)}$$

The adjusted net absorbance of the suspensions is directly proportional to the bacterial concentration, as demonstrated in Fig. 1. *S. faecalis* was grown in the medium described, the suspension was diluted with the growth medium in different proportions, and the absorbance was measured at 640 nm. for each dilution.

Any differences between the growth curves (plots of *AA versus* time) of bacteria treated with polyvalent metal salts and of bacteria treated with sodium nitrate or potassium chloride, such as extended lag phase, reduced growth rate in the exponential phase, or lower bacterial concentration in the stationary phase, are a measure of the antibacterial activity of the former.

The following parameters were investigated in the growth curve method: lag time, generation time, and absorbance in the stationary phase. Lag time and generation time were obtained from semilogarithmic plots of adjusted net absorbance *versus* time.

Lag time, *L*, in hours, is defined (11) by the equation:

$$\log\left(\frac{AA}{0.01}\right) = K(T - L) \qquad \text{(Eq. 3)}$$

where the lag *L* is the time, obtained by extrapolation of the linear portion of the plot corresponding to the exponential growth phase, at which $AA = 0.01$. For time $T = L$, $\log(AA/0.01) = 0$ and $(AA/0.01) = 1$. Instead of specifying the slope *K* of the semilogarithmic plot, the generation time (11) was determined, which is the time required to double the number of cells or the adjusted net absorbance during the logarithmic phase.

In the *turbidity method*, heavy metal salts and/or potassium chloride or sodium nitrate were incorporated into the original, low phosphate growth medium (8, 9) so that the ionic strength of the added electrolytes was 0.010 *M*. These media, contained in culture flasks with side arms, were inoculated with *S. faecalis*, and their absorbance at 640 nm. was measured before and after 24 hr. of incubation at 37° in a shaking bath. After the 24-hr. period, the bacteria were in the stationary phase. Any differences in turbidity increase between suspensions containing polyvalent cations and the blank suspensions containing Na^+ or K^+ are due to the antibacterial action of the polyvalent cations.

RESULTS AND DISCUSSION

Electrokinetic Measurements— The results of the electrophoresis studies are presented in Table I. The pH values were determined just before and just after the mobility measurements. If the difference between the two values was more than 0.5 unit, both values are listed. Single values represent the average pH when the determinations before and after the electrophoretic measurements agreed within 0.5 unit of pH. Negative values for the electrophoretic mobility indicate that the bacteria were negatively charged and migrated to the positive pole. Two samples of the same strain, ATCC 9790, supplied by the American Type Culture Collection about 10 months apart, gave identical mobility values within the precision of the measurements. The earlier measurements were made with the plastic cell (8), while the later measurements were made with a glass cell. The two sets of measurements are combined in Table I.

Polyvalent cations reduced the negative charge of the cell wall progressively as their concentration in the solution was increased while the ionic strength was maintained constant at 0.010 *M*. This change in ζ-potential is due to chemisorption of the cations as exemplified for a divalent cation Me^{+2} by Scheme I, in which W represents the cell wall. Whenever a monovalent Na^+ was replaced by a divalent cation, one fixed negative charge of the cell wall was replaced by one fixed positive charge because polyvalent cations are firmly attached to the carboxylate groups in the wall. Carboxylates of di- and trivalent cations undergo little or no dissociation because the bonds between the carboxylate groups and the cations are chiefly covalent and/or coordinate covalent. Their attachment to

$$W\text{—}COO^- Na^+ + Me^{+2}(NO_3)_2^{-2} \rightleftharpoons W\text{—}COO\cdots Me^+(NO_3)^- + Na^+ NO_3^-$$

Scheme I

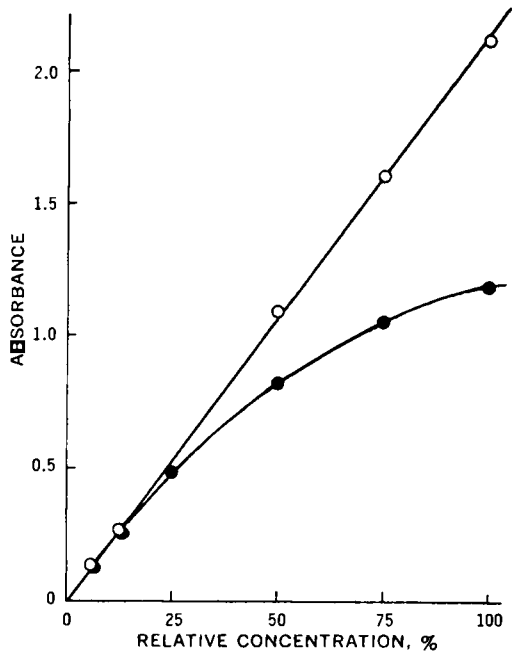

Figure 1—*Growth curve method: effect of dilution on net absorbance of suspensions of* S. faecalis *at 640 nm. Key:* ●, NA; *and* ○, AA.

the carboxylate groups in the cell wall made the di- and trivalent cations an integral part of the bacterium; they were chemisorbed in the Stern layer. Potassium and sodium ions originally bound to the carboxylate groups of the cell wall were extensively dissociated and hence constituted the counterions, being located in the Stern layer and in the diffuse or Gouy double layer (12) surrounding the bacterium. The di- and trivalent cations which replaced them are not dissociated from the carboxylate groups. Therefore, as the reaction (Scheme I) proceeds, the counterions at the cell wall are progressively changed from Na^+ or K^+ to NO_3^-, reducing the negative charge of the cell.

In this cation-exchange process, the tetravalent cation thorium actually inverted the sign of the charge of the bacteria from negative to positive. The di- and trivalent cations could not be used at high enough concentrations to cause charge reversal because of the upper concentration limit corresponding to the ionic strength of 0.010 *M* adopted in all electrophoresis measurements.

When combining the information from Fig. 2 with Table IV of *Reference 8*, it is seen that cation concentrations required to produce

[a] Constant ionic strength of 0.01 *M* achieved by addition of potassium chloride or sodium nitrate. [b] Determined at or prorated to a dilution of $1:10^7$. [c] Standard deviation of average count. [d] Number of plates counted.

comparable reductions in electrophoretic mobility and, hence, in ζ-potential are in the ratio of 1:100:900:8000 for Th^{+4}, Cr^{+3}, the average of the three divalent cations, and K^+. Qualitatively, this is in accordance with the Schulze–Hardy rule (12).

The ratio is higher by an order of magnitude than the ratio of the flocculation concentrations for tetra-, tri-, di-, and monovalent counterions predicted by the Derjaguin–Landau–Verwey–Overbeek theory, namely, $1/4^6:1/3^6:1/2^6:1/1^6 = 1:5.6:64:4100$ (12). The most likely explanation for this discrepancy is the occurrence of specific interactions between the polyvalent cations and the cell wall. The theoretical flocculation values are based on lack of specificity, the charge of the counterion being the only factor considered in the reduction of the ζ-potential by added electrolytes. In view of the affinity of the carboxylate group for heavy metal cations, specific interactions must have occurred and probably account for most, if not all, of the low concentrations or high concentration ratios at which the polyvalent cations caused the observed reductions in electrophoretic mobility.

Ferric nitrate produced charge reversal and nearly identical positive electrophoretic mobilities at all three concentrations tested, the lowest of which was 4.2×10^{-4} *M*. The tetravalent thorium nitrate produced comparable positive mobilities at a similar concentration, namely, 8×10^{-4} *M*, while the trivalent chromium cation did not reverse the negative charge of the bacteria at concentrations as high as 16.7×10^{-4} *M*. The exceptional behavior of ferric nitrate is ascribed to extensive hydrolysis, which produces a variety of polyvalent hydroxylated cations in solution such as $Fe_3(OH)_4^{+5}$. These are more effective charge-inverting species than Fe^{+3} (13). The occurrence of extensive hydrolysis of ferric nitrate in bacterial suspensions was shown by a deepening of their color to a reddish brown shortly after dissolving the nitrate in water.

Of the divalent cations, Cu^{+2} was the most effective in reducing the electrophoretic mobility and Ca^{+2} the least effective. As shown in Table I, Cu^{+2}, Pb^{+2}, and Ca^{+2} at a concentration of 0.0010 *M*

Average of two readings taken between 21 and 27 hr. of incubation time.

reduced the electrophoretic mobility by 0.41, 0.21, and 0.14 (microns/sec.)/(volts/cm.), respectively. These differences or specific effects are ascribed to increasingly stronger binding of the cations to the carboxylate groups in the cell wall when going from Ca^{+2} to Pb^{+2} to Cu^{+2}, in line with their increasing ability to form stable complexes with carboxylated polymers (14, 15).

Bacteriological Results—*Pour Plate Method*—Aqueous solutions of heavy metal salts are frequently acid. To determine how much of their antibacterial activity is due to the heavy metal ions and how much to acidity, it is necessary to determine the effect of acidity on bacterial inhibition in the absence of heavy metals. This was accomplished by exposing the bacteria for 30 min. to the following three buffer solutions of 0.010 *M* ionic strength: 0.010 *M* potassium acetate (pH 7.2), 0.010 *M* acetic acid + 0.0096 *M* KBr (pH 3.3), and 0.00667 *M* phosphoric acid + 0.00580 *M* KCl (pH 2.4). After the 30-min. exposure, aliquots of the suspensions were serially diluted with distilled water in a $1:10^7$ ratio, and the viability of the bacteria was determined by the pour plate method. The average colony counts ($\pm SD$ of the average count) of quadruplicate or quintuplicate experiments were 100 ± 18, 97 ± 6, and 53 ± 12 at the pH values of 7.2, 3.3, and 2.4, respectively. Only the most acid of the treating media produced a significant decrease in viability. None of the heavy metal solutions had pH values below 3.3. Therefore, all inhibitory effects are due to the cations.

Detailed studies with cupric sulfate indicated that the reproducibility of the pour plate method was not very good. Over a 4-week period, eight plates were inoculated with bacteria pretreated with 0.0025 *M* $CuSO_4$, using the same procedures including identical dilutions. The corresponding blanks were inoculated at the same times with bacteria pretreated with 0.010 *M* KCl.

Four of the plates inoculated with bacteria exposed to cupric sulfate had no growth; others had as many as 50 and 76 colonies. However, when the *F* test was applied to the plate counts made at the four levels of cupric sulfate employed (0, 0.0001, 0.0010, and 0.0025 *M*), the trend of increasing inhibition with increasing cupric sulfate concentration was statistically significant: the *F* value obtained exceeded the critical *F* value at the 5% level.

Eleven blank tests, in which the bacteria were pretreated with potassium chloride, were run for the three levels of cupric sulfate. The standard deviation of the average count of the 11 blanks was 28% of that average.

As can be seen from Table II, calcium nitrate, lead nitrate, and chromic nitrate produced no significant inhibition at the concentrations tested; thorium nitrate was the most effective antibacterial agent, followed by ferric nitrate.

Growth Curve Method—The effect of the acidity of the treating solution on the growth of the bacteria was determined by measuring growth curves in the following five buffer solutions: phosphate (pH 7.1), containing 0.00584 *M* KH_2PO_4 + 0.00082 *M* K_2HPO_4; acetate (pH 7.0), containing 0.010 *M* potassium acetate; acetic acid (pH 3.45), containing 0.010 *M* acetic acid + 0.0096 *M* potassium bromide; acetic acid (pH 3.5), containing 0.010 *M* acetic acid + 0.0096 *M* potassium chloride; and phosphoric acid (pH 2.35), containing 0.00667 *M* phosphoric acid + 0.0058 *M* potassium chloride. The ionic strength of the five solutions is approximately 0.01 *M*. After 30 min. contact time, aliquots were incubated and the growth curves determined.

The results (Table III) indicate that the acidity of the treating solution had only a small effect on the three growth curve parameters. The exception is the acetic acid solution containing potassium bromide which caused increases in lag and in generation time. Its pH was a full unit higher than that of the phosphoric acid solution which caused little or no inhibition, indicating that the potassium bromide rather than the pH was responsible for the inhibition caused by the acetic acid potassium bromide buffer. A comparable solution containing potassium chloride instead of bromide caused little inhibition.

Since the lowest pH in the heavy metal solutions was 3.6, any antibacterial activity caused by heavy metal salts is, therefore, due to the cations rather than to a reduction in pH.

Of the results listed in Table IV, the most pronounced inhibition is the increase in lag caused by two thorium nitrate solutions. Lesser inhibitions are the decreased growth in the stationary phase caused by the most concentrated thorium nitrate solution and the increased lag caused by the two copper sulfate solutions.

Turbidity Method—The only cation that showed any inhibition on the growth of *S. faecalis* according to the turbidity method was copper (Table V). Thorium and ferric ions caused no significant inhibition at concentrations at which they completely inhibited the growth of bacteria in the pour plate method. This is evidently due to lowering of the concentration or even disappearance of the free cations due to one of the following three reactions: hydrolysis of the heavy metal salts in the relatively alkaline nutrient broth (initial pH 6.5) causing precipitation of basic salts or hydroxides, particularly of the trivalent and tetravalent cations; precipitation of the phosphates (initial phosphate concentration 0.0023 *M*); and complexation by polypeptides and other organic compounds present in the liquid growth medium. Increased turbidity on addition of salts to the growth medium was noticed for thorium and especially for lead. The marked turbidity that developed when lead nitrate was added to the growth medium was cleared by the addition of nitric acid. It renders the apparent inhibition of bacterial growth by lead nitrate suspect.

Calcium chloride apparently stimulated the growth of the bacteria somewhat. Growth stimulation is well known for salts of magnesium, another alkaline earth metal (16).

The pour plate and the growth curve methods differed from the turbidity method in that the bacteria were treated with unbuffered solutions of the heavy metal salts in the former two. The only possible additives were potassium chloride or sodium nitrate. This precluded the precipitation or complexation of the polyvalent cations by ingredients of the growth medium prior to their coming into contact with the bacteria; the bacteria were treated with the cations at their full nominal concentrations.

Table V—Effect of Heavy Metal Salts Added to Low Phosphate Growth Medium on Growth of *S. faecalis*

0.010 *M* $NaNO_3$	0.85–0.03 = 0.82
0.00167 *M* $Fe(NO_3)_3$	0.85–0.10 = 0.75
None	0.75–0.04 = 0.71
0.010 *M* $NaNO_3$	0.75–0.03 = 0.72
0.00167 *M* $Cr(NO_3)_3$	0.80–0.08 = 0.72
None	0.75–0.04 = 0.71
0.010 *M* $NaNO_3$	0.75–0.03 = 0.72
0.0010 *M* $Th(NO_3)_4$	0.82–0.13 = 0.69

[a] Uncorrected absorbance at 640 nm. after 24 hr. of incubation at 37° minus initial absorbance.

Another shortcoming of the turbidity method is that it measured the effect of the heavy metal salts on the bacteria only in the stationary phase, whereas the growth curve method included the lag and exponential phases as well.

CONCLUSIONS

Combining the results of the methods for measuring growth inhibition gives the following order of decreasing antibacterial activity for the cations employed in this study: thorium > ferric > copper. The remaining cations were ineffective at the concentrations employed. Sprowls and Poe (17) likewise found the antibacterial activity of ferric and copper salts to be greater than that of salts of lead and of other transition metals.

The order of decreasing effectiveness in reducing the electrophoretic mobility was: thorium ≅ ferric ≫ chromium ≫ copper > lead > calcium. With the exception of the chromium ion, there is a correlation in the rank order of growth inhibition and of reduction in the absolute value of the ζ-potential. This indicates that the strength with which polyvalent cations are attached to the outer portion of the bacterial cell wall is similar to the strength with which they are attached to the site where they exert their strongest antibacterial action.

Peyote and Related Alkaloids XVI: Synthesis of 3,4,5-Trimethoxyphenylalanine, an Amino Acid Analog of Mescaline

MANOHAR L. SETHI, G. SUBBA RAO*, and GOVIND J. KAPADIA▲

Abstract □ Contrary to an earlier literature report, acid hydrolysis of diethyl α-acetamido-α-3,4,5-trimethoxybenzylmalonate during the synthesis of 3,4,5-trimethoxyphenylalanine has been shown to lead to a mixture of products. The major hydrolysis products were isolated and identified by NMR and mass spectrometry as 3,4,5-trimethoxyphenylalanine (34%), 4-hydroxy-3,5-dimethoxyphenylalanine (13%), 3-hydroxy-4,5-dimethoxyphenylalanine (8%), and 3,4-dihydroxy-5-methoxyphenylalanine (5%). Under basic conditions, the acetamidomalonate ester as well as its formamido analog, obtained by the condensation of trimethoxybenzyl chloride and diethyl formamidomalonate, gave low yields (5–7%) of the required trimethoxyphenylalanine. However, no phenolic side-products were formed under basic conditions. An efficient alternative synthesis of 3,4,5-trimethoxyphenylalanine has been accomplished; it involves the condensation of hydantoin with trimethoxybenzaldehyde followed by hydrogenation and basic hydrolysis of the resulting 5-(3,4,5-trimethoxybenzylidine)hydantoin. GC–mass spectrometric examination of the peyote amino acid fraction gave no evidence for the presence of trimethoxyphenylalanine and other trioxygenated phenylalanine analogs obtained during these synthetic studies.

Keyphrases □ 3,4,5-Trimethoxyphenylalanine (mescaline analog)—synthesis □ Peyote and related alkaloids—synthesis of 3,4,5-trimethoxyphenylalanine (amino acid analog of mescaline) □ Mescaline derivatives—synthesis of 3,4,5-trimethoxyphenylalanine

In recent studies on peyote [*Lophophora williamsii* (Lem.) Coult.] constituents, the authors examined the amino acid fraction of the cactus and reported the occurrence of several novel nonproteinic amino acids (1–5). These include four C_1-carboxytetrahydroisoquinolines (I–IV), two *N*-alkyl-α-amino acids (V and VI), and a pyrrole-2-carboxylic acid (VII).

To identify additional unknown constituents present in the peyote amino acid fraction (3), the possible occurrence of trioxygenated analogs of phenylalanine was considered. Since mescaline (3,4,5-trimethoxyphenethylamine) is the major alkaloid present in the peyote cactus, synthesis of its amino acid analog, 3,4,5-trimethoxyphenylalanine (VIII), was undertaken to check for its natural occurrence. This amino acid analog of mescaline was also needed to evaluate its hallucinogenic and other biological activities.

RESULTS AND DISCUSSION

Synthesis by Literature Method—Synthesis of 3,4,5-trimethoxyphenylalanine (VIII) was reported previously by Acheson *et al.* (6). The procedure consists of preparation of the key intermediate, diethyl α-acetamido-α-3,4,5-trimethoxybenzylmalonate (IX), from 3,4,5-trimethoxybenzaldehyde (X) by successive reactions with sodium borohydride, thionyl chloride, and diethyl acetamidomalonate and its hydrolysis by 5 *N* HCl. The hydrolysis of the acetamidomalonate ester IX was reported to give the required amino acid VIII as its hydrochloride in 68% yield.

This procedure was repeated, and it was found that the acid hydrolysis of IX under identical conditions leads to a mixture of products. The hydrochloride, which separated on cooling the reaction mixture, was recrystallized from 5 *N* HCl (as reported in the previous procedure) to give needles, m.p. 241–242° dec. [lit. (6) m.p. about 242° dec.]. This crystalline product was found to be a mixture of four ninhydrin-positive compounds, designated A–D, by paper chromatography in Solvent System I, *n*-butanol–water–acetic acid (4:5:1). This finding is contrary to the report by Acheson *et al.* (6), who found their crystalline product to be a single-spot material by paper chromatography in Solvent Systems II, *n*-butanol–acetic acid–water (4:1:1), and III, isopropanol–ammonia–water (8:1:1). Four additional ninhydrin-positive components also were detected during paper chromatography of the mother liquor (the original reaction mixture after removal of the hydrochloride crystals) in Solvent System I. The chromatographic data on the eight products formed during the acid hydrolysis of IX are given in Table I.

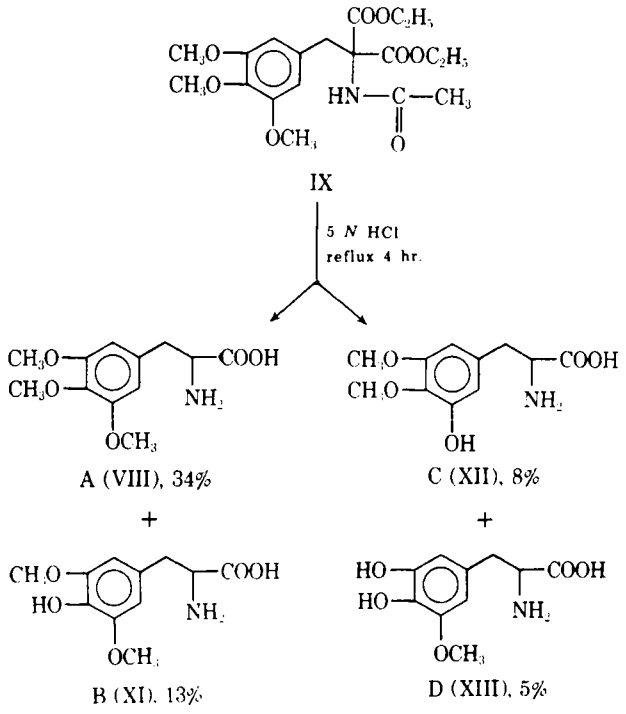
Isolation and Identification of Major Hydrolysis Products—Separation and isolation of the major hydrolysis products, A–D, were accomplished by preparative paper chromatography, and the following yields were obtained based on the isolated homogeneous products: A, 34%; B, 13%; C, 8%; and D, 5%. Identification of the isolated compounds (Scheme I) was carried out by NMR and mass spectral methods.

The major product, A, was obtained as fine needles, m.p. 243–244°, by recrystallization from aqueous hydrochloric acid. Based upon its NMR and mass spectra, Compound A was identified as the hydrochloride of the target amino acid, 3,4,5-trimethoxyphenylalanine (VIII). The mass spectrum of A showed the parent ion at *m/e* 255 and the base peak at *m/e* 181 corresponding to the trimethoxybenzyl ion (Scheme II).

The NMR spectrum (deuterium oxide solvent) of Compound A exhibited two singlets corresponding to the aromatic methoxyls at δ 3.87 (6H, methoxyls at C-3 and C-5) and 3.8 (3H, methoxyl at C-4), a singlet at δ 6.6 (2H) for the aromatic protons at C-2 and C-6, and multiplets at δ 3.2 (2H) and 3.7 (1H) p.p.m. assignable to the benzylic protons and the proton on the carbon bearing the carboxyl group, respectively.

The mass spectra of Compounds B and C indicated these two amino acids to be monodemethylated products of VIII. Both compounds showed parent ions at *m/e* 241 and the base peak at *m/e* 167 corresponding to the monohydroxydimethoxybenzyl ions (Scheme III).

Structural assignments to the monodemethylated amino acids, B (4-hydroxy-3,5-dimethoxyphenylalanine, XI) and C (3-hydroxy-4,5-dimethoxyphenylalanine, XII), were made on the basis of their NMR spectra in neutral and alkaline media. In deuterium oxide



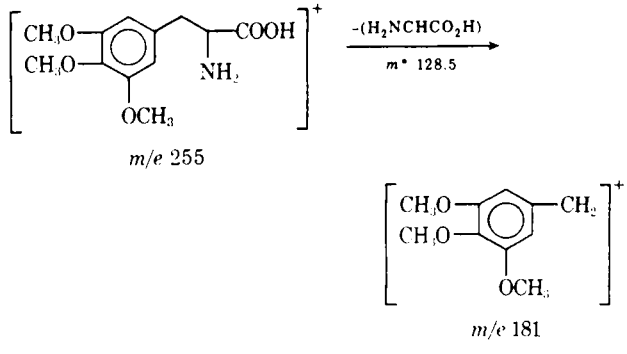
Scheme I

solvent, Compound B (XI) showed two singlets at δ 3.85 (6H, aromatic methoxyls at C-3 and C-5) and 6.65 (2H, aromatic protons at C-2 and C-6) p.p.m. Upon addition of sodium deuteroxide, the singlet corresponding to the aromatic protons at C-2 and C-6 in B (XI) shifted upfield by 0.11 Hz., which is consistent with their assignment to the *meta*-protons in relation to the phenolic hydroxyl at the C-4 position (7).

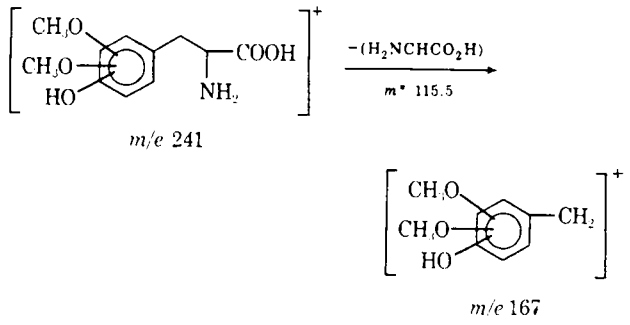
The NMR spectrum of C (XII) in deuterium oxide exhibited four singlets at δ 3.84 (3H, aromatic methoxyl at C-4), 3.86 (3H, aromatic methoxyl at C-3), 6.68 (1H, aromatic proton at C-2), and 6.71 (1H, aromatic proton at C-6) p.p.m. The two benzylic protons and the proton on the carbon bearing the carboxyl group in the spectra of acids B (XI) and C (XII) showed the expected multiplets, as in the case of trimethoxyphenylalanine (VIII).

Compound D was found to be a dihydroxymonomethoxy derivative of phenylalanine based on its mass spectrum, which showed the parent ion at *m/e* 227 and the base peak at *m/e* 153 arising from the loss of the fragment, H_2NCHCO_2H. Its NMR spectrum in deuterium oxide showed three singlets at δ 3.82 (3H, aromatic methoxyl at C-5), 6.69 (1H, aromatic proton at C-2), and 6.66 (1H, aromatic proton at C-6) p.p.m. and multiplets at δ 3.19 (2H, benzylic protons) and 3.71 (1H, proton on the carbon carrying carboxyl group) p.p.m. On the basis of these spectral characteristics, Compound D was identified as 3,4-dihydroxy-5-methoxyphenylalanine (XIII).

Chemical Method for Separation of VIII from Acid Hydrolysate—Since the separation of trimethoxyphenylalanine (VIII) from the phenolic amino acids, XI–XIII, formed during the acid hydrolysis



Scheme II



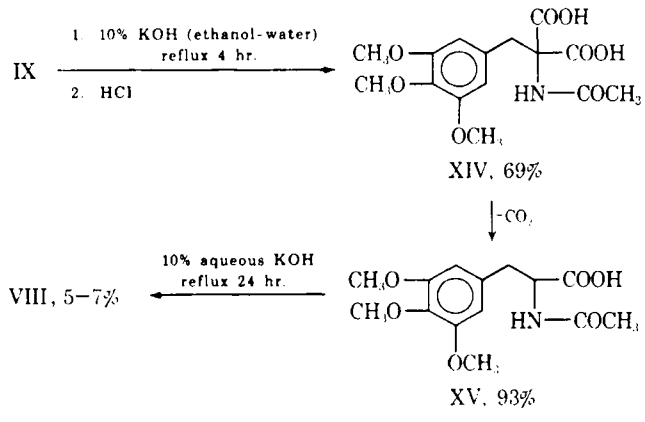
Scheme III

of the acetamidomalonate ester IX by the preparative paper chromatographic procedure was tedious, a chemical method for its isolation in larger quantities was developed.

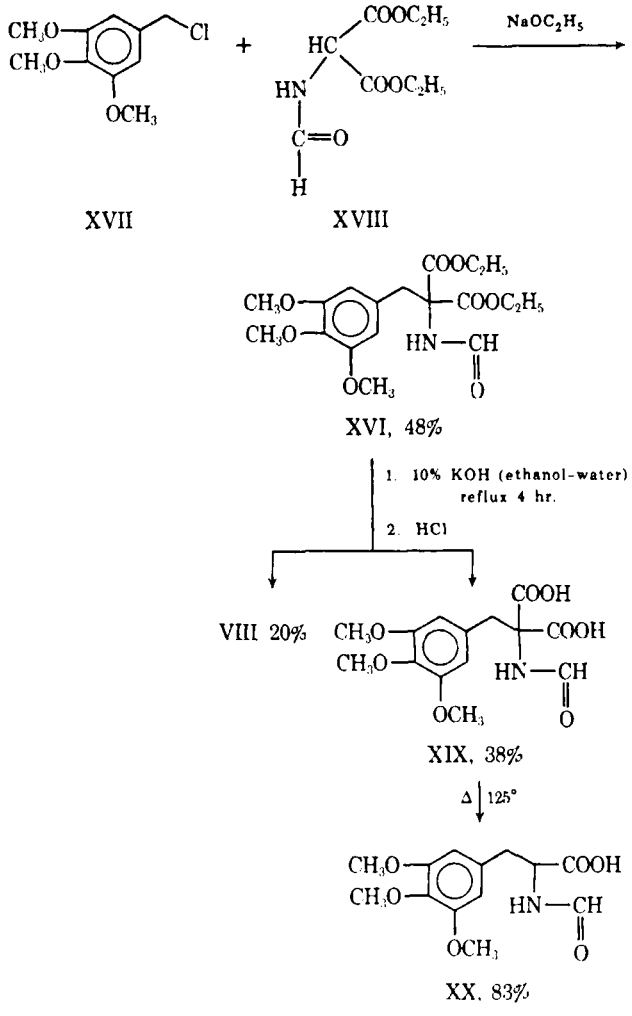
The hydrolysis mixture, consisting of VIII and accompanying phenolic amino acids, was refluxed with a methanol–sulfuric acid–ethylene dichloride mixture (4:0.4:6), and the resulting methyl esters were shaken with 10% NaOH and extracted with benzene. The benzene extract, upon removal of the solvent, gave exclusively the methyl ester of the nonphenolic amino acid, trimethoxyphenylalanine (30% yield), which was then hydrolyzed with 10% barium hydroxide to yield homogeneous trimethoxyphenylalanine (VIII) in 75% yield. The methyl esters of the phenolic amino acids, XI–XIII, were obtained from the aqueous sodium hydroxide layer by acidifying with carbon dioxide and extracting with chloroform.

Basic Hydrolysis of IX—To minimize the formation of phenolic amino acids during the hydrolysis of the acetamidomalonate ester (IX), the hydrolysis was carried out under basic conditions. Compound IX was refluxed for 4 hr. with 10% KOH in ethanol–water (1:1), which gave α-acetamido-α-3,4,5-trimethoxybenzylmalonic acid (XIV) in 69% yield. The dicarboxylic acid XIV readily decarboxylated when kept under vacuum, and the resulting *N*-acetyl-3,4,5-trimethoxyphenylalanine (XV, 93% yield) was again refluxed with 10% KOH. Hydrolysis of the *N*-acetyl derivative (XV) did not proceed smoothly, and only poor yields (5–7%) of trimethoxyphenylalanine (VIII) could be obtained. However, the hydrolysis product was found to consist solely of the required amino acid VIII and no phenolic amino acids were detected. Thus, hydrolysis of IX under basic conditions leads to a single product, VIII, but in low yields (Scheme IV).

Synthesis by Diethyl Formamidomalonate Method—Since hydrolysis of the acetamidomalonate ester IX under both acidic and basic conditions did not proceed satisfactorily, diethyl α-formamido-α-3,4,5-trimethoxybenzylmalonate (XVI) (Scheme V) was prepared and its hydrolysis was studied in an attempt to obtain better yields of the required trimethoxyphenylalanine (VIII). 3,4,5-Trimethoxybenzyl chloride (XVII) and diethyl formamidomalonate (XVIII) were condensed in the presence of sodium ethoxide to form the formamidomalonate ester, XVI (48% yield). Hydrolysis of the malonic ester XVI was carried out by refluxing for 4 hr. with 10% alcoholic KOH, which yielded the required VIII in 20% yield along with α-formamido-α-3,4,5-trimethoxybenzylmalonic acid (XIX, 38% yield). Compound VIII could be easily separated from



Scheme IV



Scheme V

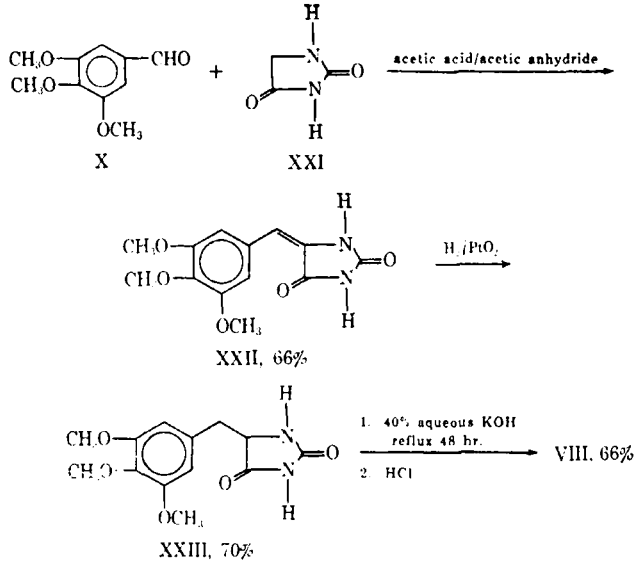
the reaction mixture by converting to its hydrochloride by acidification.

Decarboxylation of the malonic acid XIX by heating at 125° for 1 hr. gave *N*-formyltrimethoxyphenylalanine (XX) in 83% yield. However, as in the case of the *N*-acetyl derivative XV, basic hydrolysis of XX also gave low yields (5–7%) of 3,4,5-trimethoxyphenylalanine (VIII). During the basic hydrolysis of both acetyl and formyl derivatives, XV and XX, no phenolic products were encountered. This is in contrast to the hydrolysis under acidic conditions, which results in the formation of substantial quantities of phenolic amino acids.

Synthesis by Hydantoin Method—Although the condensation of 3,4,5-trimethoxybenzyl chloride (XVII) with both formamidomalonate and acetamidomalonate esters gave high yields of the corresponding acyl trimethoxybenzylmalonate esters, IX and XVI, their subsequent hydrolysis to the requisite 3,4,5-trimethoxyphenylalanine (VIII) proceeded in low yields. Both the formyl and acetyl derivatives of trimethoxyphenylalanine, XX and XV, formed during the synthetic procedures were quite resistant to hydrolytic cleavage.

To circumvent the formation of acyl derivatives of trimethoxyphenylalanine during the synthetic procedure, an alternative method involving a hydantoin derivative was tried (Scheme VI). 3,4,5-Trimethoxybenzaldehyde (X) was condensed with hydantoin (XXI) by refluxing for 24 hr. in glacial acetic acid–acetic anhydride, and the resulting 5-(3,4,5-trimethoxybenzylidine)hydantoin (XXII, 66% yield) was hydrogenated over platinum oxide to yield 5-(3,4,5-trimethoxybenzyl)hydantoin (XXIII, 70% yield). Basic hydrolysis of the hydantoin derivative XXIII gave high yields (66%) of the target amino acid, 3,4,5-trimethoxyphenylalanine (VIII).

GC–Mass Spectrometry of Peyote Amino Acid Fraction—During these synthetic studies, several trioxygenated phenylalanine derivatives (XI–XIII) were obtained in addition to 3,4,5-trimethoxyphen-



Scheme VI

ylalanine (VIII), the analog corresponding to mescaline. By using these as the reference compounds, the amino acid fraction of the peyote cactus was examined for their possible natural occurrence by the GC–mass spectrometric procedure described earlier (1–3). No evidence was obtained for the presence of trioxygenated analogs of phenylalanine in the peyote. This observation may be significant, since it may be taken as an indication that the carboxyl group does not survive beyond the stage of dihydroxyphenylalanine in the biosynthetic sequence leading to the trioxygenated alkaloids of peyote.

EXPERIMENTAL[1]

Compounds were visualized on paper chromatograms with the aid of ninhydrin and diazo spray reagents. The following compounds were purchased from a commercial source[2]: 3,4,5-trimethoxybenzaldehyde, diethyl formamidomalonate, diethyl acetamidomalonate, and hydantoin.

Diethyl α-Acetamido-α-3,4,5-trimethoxybenzylmalonate (IX)—Compound IX was synthesized according to the procedure of Acheson *et al.* (6). Diethyl acetamidomalonate (11 g.) was dissolved in a solution of sodium ethoxide (sodium, 1.18 g. in absolute alcohol, 75 ml.) by warming. To this stirred solution was added 3,4,5-trimethoxybenzyl chloride (10 g.) in five portions. The reaction mixture was refluxed for 6 hr., cooled, and filtered. The filtrate was concentrated to approximately half the volume, and water (50 ml.) was added. Extraction with ether (2 × 50 ml.) and evaporation of the dried (sodium sulfate) ether extract gave the ester IX (6.6 g.), which crystallized from benzene–petroleum ether as flakes, m.p. 116–117° [lit. (6) m.p. 116°].

Acid Hydrolysis of Acetamidomalonate Ester IX—The acetamidomalonate ester IX (907 mg.) was refluxed with 5 *N* HCl (30 ml.) for 4 hr. Upon cooling the reaction mixture, fine needles separated which were collected by filtration (392 mg.) and recrystallized from 5 *N* HCl to give needles, m.p. 241–242° dec. Acheson *et al.* (6) reported a melting point of about 242° dec. for their crystalline product, which they claimed to be 3,4,5-trimethoxyphenylalanine (VIII) hydrochloride.

Paper chromatographic data on this crystalline product and the mother liquor are given in Table I. The crystalline product consisted of four ninhydrin-positive components, A–D, while four additional compounds, E–H, were detected in the mother liquor.

[1] Melting points were taken on a Kofler micro-hot-stage and are corrected. NMR chemical shifts are given in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra were recorded at 70-ev, electron beam voltage. Spectra were recorded on Varian XL-100 NMR and LKB-9000 GC–mass spectrometers. Paper chromatography was performed on Whatman No. 1 paper.

	B	0.34	13
	C	0.43	8
	D	0.40	5
Mother liquor	E	0.81	Trace
	F	0.67	Trace
	G	0.22	Trace
	H	0.12	Trace

[a] See Scheme I for identification of Compounds A–D. [b] Yields reported are based on homogeneous products isolated by preparative paper chromatography (see *Experimental* for details).

A portion of this crystalline product (300 mg.) was subjected to preparative paper chromatography in Solvent System I and the following homogeneous products were isolated: A (110 mg.), B (42 mg.), C (26 mg.), and D (16 mg.). Identification of the isolated compounds, A–D, was carried out with the aid of their NMR and mass spectra (see *Results and Discussion* and Scheme I).

Chemical Method for Isolation of 3,4,5-Trimethoxyphenylalanine (VIII) from Acid Hydrolysate—The crystalline product (398 mg.) obtained during the acid hydrolysis of the acetamidomalonate ester IX was refluxed with ethylene dichloride (0.6 ml.) and concentrated sulfuric acid (75 mg.) in methanol (0.4 ml.) for 16 hr. The reaction mixture was cooled, the solvent was removed *in vacuo*, and water (2 ml.) was added. The aqueous solution was basified with 10% NaOH and extracted with benzene (3 × 5 ml.). Evaporation of the dried (sodium sulfate) benzene extract yielded the methyl ester of 3,4,5-trimethoxyphenylalanine (120 mg.). This methyl ester was hydrolyzed by refluxing with 10% $Ba(OH)_2$ for 24 hr., which yielded 3,4,5-trimethoxyphenylalanine (VIII) in 75% yield. From the aqueous sodium hydroxide solution, esters of the phenolic amino acids XI–XIII were obtained by acidification with carbon dioxide and extraction with chloroform.

Basic Hydrolysis of Acetamidomalonate Ester IX—Compound IX (1.02 g.) was dissolved in 10 ml. of ethanol–water (1:1) and refluxed with 10% KOH (20 ml.) for 4 hr. Ethanol was then removed *in vacuo* from the reaction mixture and acidified with concentrated hydrochloric acid. The crystalline precipitate formed was filtered, washed with cold water, and dried (0.69 g.) to give acetamido-3,4,5-trimethoxybenzylmalonic acid (XIV), m.p. 135–137°. Upon keeping the malonic acid XIV under vacuum for 2 days, decarboxylation occurred and gave 0.64 g. of *N*-acetyl-3,4,5-trimethoxyphenylalanine (XV), m.p. 190–191.5°.

Anal.—Calc. for $C_{14}H_{19}NO_6$: C, 56.56; H, 6.44; N, 4.71. Found: C, 56.38; H, 6.29; N, 4.67.

The *N*-acetyl derivative XV (0.102 g.) was refluxed with 10% KOH (25 ml.) for 20 hr. The reaction mixture was cooled and passed through a column of cation-exchange resin[3] (20 ml.). An additional 300 ml. of water was passed through the column, and the combined eluate was evaporated to dryness. The resulting residue was taken up in dilute hydrochloric acid (5 ml.) which, upon cooling, gave 7.3 mg. of 3,4,5-trimethoxyphenylalanine (VIII) as its hydrochloride, m.p. 243–244°.

Diethyl α-Formamido-α-3,4,5-trimethoxybenzylmalonate (XVI)—Diethyl formamidomalonate (XVIII) (2.02 g.) and 3,4,5-trimethoxybenzyl chloride (XVII) (2.15 g.) were added to a solution of sodium ethoxide (250 mg. of sodium dissolved in 12 ml. of absolute alcohol) and refluxed for 14 hr. The reaction mixture was filtered, and the filtrate was evaporated to dryness. The residue was suspended in water (50 ml.) and extracted with ether (3 × 50 ml.). Upon evaporation, the dried (sodium sulfate) ether extract gave 1.82 g. of crude product, m.p. 117–118°. Crystallization of this product from benzene–petroleum ether gave 1.68 g. of diethyl α-formamido-α-3,4,5-trimethoxybenzylmalonate (XVI), m.p. 120–121°.

[3] Amberlite, IRC 50 (H), Rohm & Haas Co.

Anal.—Calc. for $C_{18}H_{25}NO_8$: C, 56.39; H, 6.57; N, 3.65. Found: C, 56.45; H, 6.64; N, 3.55.

Basic Hydrolysis of Formamidomalonate Ester XVI—Compound XVI (0.6 g.) was refluxed with a mixture of 10% KOH (6 ml.) and ethanol–water (1:1, 14 ml.) for 4 hr. The reaction mixture was concentrated under argon atmosphere to 3 ml., cooled, and acidified with 18% HCl (4 ml.). Upon cooling the acidic solution, 192 mg. of formamido-3,4,5-trimethoxybenzylmalonic acid (XIX) separated out, m.p. 126–127°.

The mother liquor was freeze dried and the residue was shaken with hot methanol (3 × 15 ml.). The methanol extract was evaporated to dryness, and the residue was dissolved in water (5 ml.) and extracted with chloroform (5 × 10 ml.). Upon removal of the solvent, the chloroform extract gave 55 mg. of the malonic acid XIX. The aqueous layer was evaporated to dryness and the residue (350 mg.) was extracted with methanol (3 × 5 ml.). The methanol extract was left in the refrigerator overnight and deposited needles of 3,4,5-trimethoxyphenylalanine (VIII) as the hydrochloride (125 mg.), m.p. 243–244°.

Decarboxylation of the malonic acid XIX (55 mg.) was carried out by heating at 125° for 1 hr., which gave 40 mg. of *N*-formyl-3,4,5-trimethoxyphenylalanine (XX), m.p. 154–155°.

Anal.—Calc. for $C_{13}H_{17}NO_6$: C, 55.12; H, 6.05; N, 4.95. Found: C, 55.47; H, 6.22; N, 4.49.

Basic hydrolysis of the *N*-formyl derivative XX (30 mg.) was carried out as in the case of the *N*-acetyl derivative XV, which gave 2.2 mg. of 3,4,5-trimethoxyphenylalanine (VIII) as the hydrochloride, m.p. 243–244°.

5-(3,4,5-Trimethoxybenzylidine)hydantoin (XXII)—Hydantoin (5 g.) and 3,4,5-trimethoxybenzaldehyde (9.8 g.) were dissolved in a mixture of glacial acetic acid (15 ml.) and acetic anhydride (2 ml.) and refluxed for 24 hr. The reaction mixture was evaporated to dryness *in vacuo*, and the residue was taken up in cold water (500 ml.). Upon vigorous shaking, a yellow crystalline precipitate separated which was collected on a funnel by filtration and washed with cold water. The filtrate was extracted with chloroform (10 × 100 ml.) and the chloroform extract was evaporated to dryness, yielding additional quantities of the yellow crystalline product. The two yellow crystalline products were combined and recrystallized from ethanol–chloroform to yield 8.96 g. of 5-(3,4,5-trimethoxybenzylidine)hydantoin (XXII) as needles, m.p. 268–269°.

Anal.—Calc. for $C_{13}H_{14}N_2O_5$: C, 56.11; H, 5.07; N, 10.07. Found: C, 56.04; H, 5.06; N, 10.15.

5-(3,4,5-Trimethoxybenzyl)hydantoin (XXIII)—A suspension of XXII (2.61 g.) in methanol (40 ml.) was acidified with a few drops of dilute hydrochloric acid and hydrogenated in the presence of platinum oxide (200 mg.) at 30 p.s.i. pressure for 18 hr. The resulting colorless solution was filtered and evaporated to dryness. Crystallization of the resulting residue from methanol–benzene afforded 1.81 g. of white microcrystals of XXIII, m.p. 180–181°.

Anal.—Calc. for $C_{13}H_{16}N_2O_5$: C, 55.71; H, 5.75; N, 10.00. Found: C, 56.01; H, 5.87; N, 10.18.

3,4,5-Trimethoxyphenylalanine (VIII)—A solution of trimethoxybenzylhydantoin (XXIII, 280 mg.) in ethylene glycol monoethyl ether (5.5 ml.) was refluxed with potassium hydroxide (0.8 g. in 2 ml. of water) for 48 hr. The reaction mixture was evaporated to dryness, and the residue was suspended in water (5 ml.) and acidified with 10% HCl. The aqueous acidic solution was then evaporated to dryness, and the resulting residue was extracted with hot absolute alcohol (4 × 20 ml.). During the concentration of the alcohol extract, needle-shaped crystals appeared which were collected and recrystallized from absolute alcohol to give 193 mg. of 3,4,5-trimethoxyphenylalanine (VIII) as the hydrochloride as needles, m.p. 243–244°.

Anal.—Calc. for $C_{12}H_{17}NO_5 \cdot HCl$: C, 49.41; H, 6.17; N, 4.80. Found: C, 49.18; H, 6.33; N, 4.84.

SUMMARY AND CONCLUSIONS

1. Acid hydrolysis of the acetamidomalonate ester (IX) in the procedure of Acheson *et al.* (6) for the synthesis of 3,4,5-trimethoxyphenylalanine was shown to lead to a mixture of products. With the aid of preparative paper chromatography, the major hydrolysis products were isolated and identified by NMR and mass spectrometry as 3,4,5-trimethoxyphenylalanine (VIII, 34%), 4-hydroxy-3,5-dimethoxyphenylalanine (XI, 13%), 3-hydroxy-4,5-dimethoxyphenylalanine (XII, 8%), and 3,4-dihydroxy-5-methoxyphenyl-

alanine (XIII, 5%). A chemical method was developed for the separation of the amino acid VIII from the phenolic products present in the hydrolysis mixture.

2. Under basic conditions, hydrolysis of the acetamidomalonate ester IX gave low yields (5–7%) of the required amino acid VIII. However, no phenolic side-products were formed under this condition.

3. Synthesis of the formamidomalonate ester XVI and its hydrolysis under basic conditions were carried out in an effort to realize higher yields of trimethoxyphenylalanine (VIII). The hydrolysis of the ester XVI also gave unsatisfactory yields of the target amino acid VIII.

4. An efficient alternative synthesis of trimethoxyphenylalanine (VIII) was achieved which involves the formation of the hydantoin derivative XXIII and its hydrolysis under basic conditions (66% yield).

5. GC–mass spectrometric examination of the peyote amino acid fraction gave no evidence for the presence of trioxygenated phenylalanine analogs, VIII and XI–XIII. This observation suggests that the carboxyl group may not survive beyond the stage of dopa during the biosynthesis of the trioxygenated peyote alkaloids.

Enhanced Absorption of Digitoxin from Orally Administered Digitoxin–Polyvinylpyrrolidone Coprecipitates

ELLIOT I. STUPAK* and THEODORE R. BATES▲

Abstract □ The general applicability of the polyvinylpyrrolidone coprecipitation technique as a method for enhancing the GI absorption of orally administered hydrophobic drugs was explored with the cardiac glycoside digitoxin. The relative absorption characteristics of digitoxin alone and as a 1:9 (w/w) physical mixture and coprecipitate with polyvinylpyrrolidone were determined indirectly by measuring their oral LD_{50} values in rats. The *in vivo* data obtained provided evidence that digitoxin was absorbed from the coprecipitate at a significantly faster rate and was present in the body at a much higher level than when equivalent doses of either the drug alone or as a physical mixture with polyvinylpyrrolidone were orally administered. For example, one must orally administer approximately 11 times as much pure drug to reach the same amount of drug in the body as that attained following the administration of the drug as a coprecipitate. A correlation was found between the *in vitro* dissolution rates of these test systems at 37° and their *in vivo* toxicities.

Keyphrases □ Digitoxin absorption—enhanced using orally administered coprecipitate with polyvinylpyrrolidone, compared to separate drug and physical mixture □ Polyvinylpyrrolidone coprecipitate with digitoxin—enhanced *in vivo* absorption, compared to separate drug and physical mixture □ Coprecipitates, digitoxin–polyvinylpyrrolidone—enhanced *in vivo* drug absorption □ Drug absorption, digitoxin—enhanced using orally administered polyvinylpyrrolidone coprecipitate

Among the techniques that can potentially enhance the dissolution rate and, hence, the rate and/or extent of absorption of hydrophobic drugs is the formation of coprecipitates with pharmacologically inert, polymeric materials such as polyvinylpyrrolidone. This physicochemical drug modification offers the advantage of possibly enabling one to administer the drug orally in a form from which it is most available for GI absorption. Although several investigations (1–6) have demonstrated, *in vitro*, that the solubility and/or dissolution rates of drugs can be increased in this manner, little information is available in the literature related to the *in vivo* absorption pattern of drugs orally administered as polyvinylpyrrolidone coprecipitates. Recently, however, it was demonstrated (6) that both the rate and extent of absorption of the water-insoluble drug reserpine could be markedly enhanced when orally administered to rats in the form of a 1:5 (w/w) coprecipitate with polyvinylpyrrolidone.

The purpose of the present investigation was to ascertain, *in vivo*, the general applicability of the polyvinylpyrrolidone coprecipitation technique. To accomplish this aim, the absorption characteristics of digitoxin, a 1:9 (w/w) digitoxin–polyvinylpyrrolidone physical mix-

alanine (XIII, 5%). A chemical method was developed for the separation of the amino acid VIII from the phenolic products present in the hydrolysis mixture.

2. Under basic conditions, hydrolysis of the acetamidomalonate ester IX gave low yields (5–7%) of the required amino acid VIII. However, no phenolic side-products were formed under this condition.

ture, and a 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate were quantitatively studied by comparing their relative toxicities in the rat. The solubility and dissolution behavior of these systems were also examined.

EXPERIMENTAL

Materials—The digitoxin[1] and polyvinylpyrrolidone[2] employed in this study were pharmaceutical grade. The polyvinylpyrrolidone had an average molecular weight of 40,000. All other chemicals used were reagent grade and were used as received.

Preparation of Test Systems—The 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate and physical mixture were prepared in the manner previously described (6).

Unless otherwise specified, the gross particle size of the test systems was 297–420 μ for the 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate and 10–40 μ for the pure digitoxin and the drug contained in the 1:9 (w/w) physical mixture.

Protocol for *In Vivo* Absorption Studies—The GI absorption characteristics of digitoxin were assessed by comparing the relative oral toxicity of the drug from suspensions containing the pure drug and the 1:9 (w/w) drug–polyvinylpyrrolidone physical mixture and coprecipitate. Adult, male, Sprague–Dawley rats[3], weighing 150–250 g., were used as the test animals. The animals were fasted for 20–24 hr. prior to the oral administration of each test system as a suspension in a 0.50% (w/v) methylcellulose[4] aqueous vehicle. The dosing volume was held constant at 5.0 ml./kg. Fifteen rats were dosed with 60, 85, 110, or 185 mg./kg. of pure drug or an amount of the 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate containing 6, 7.5, 9, or 10 mg./kg. of digitoxin. The 1:9 drug–polyvinylpyrrolidone physical mixture was orally administered at drug dosage levels of 50 and 75 mg./kg.

The animals were housed in cages with wide, wire-mesh floors to prevent coprophagy and were observed for 72 hr. postdrug administration. At the end of this period, the total number of deaths was recorded. Throughout the entire experimental period, the animals were allowed free access to water; 8 hr. postdrug administration, the animals were placed back on food. The toxicity data were used to calculate the oral LD_{50} value for the test systems according to the method of Litchfield and Wilcoxon (7).

Protocol for *In Vitro* Dissolution Rate Studies—The stirrer-flask method (6) was used to assess the dissolution characteristics of the test preparations at 37°. The dissolution medium consisted of 350 ml. of a Clark–Lubs pH 7.4 phosphate buffer containing 0.005% (w/v) polysorbate 80 USP, and it was agitated at 150 r.p.m. At frequent intervals, subsequent to the introduction of a quantity of test preparation equivalent to 20 mg. of digitoxin, 3-ml. samples were removed from the flask with a filter pipet and immediately replaced with 3 ml. of fresh dissolution medium. The samples were assayed colorimetrically at 532 nm. for digitoxin content (8). The presence of polymer or polysorbate 80 in the samples did not interfere with the quantitative determination of digitoxin. All particulate dissolution rate experiments were performed in duplicate.

Table II—Relationship between the Oral Dose and Lethality of Digitoxin from a 1:9 (w/w) Coprecipitate with Polyvinylpyrrolidone

Dose of Drug[a], mg./kg.	Number of Animals Dosed	Number of Animals Dead[b]	Mortality, %
6.0	15	2	13.3
7.5	15	7	46.7
9.0	15	11	73.3
10.0	15	13	86.7

[a] Dose administered as a suspension in 0.50% (w/v) methylcellulose at a constant dosing volume of 5 ml./kg. [b] Animals observed for 72 hr. postadministration.

Equilibrium Solubility Determinations—The equilibrium solubility of digitoxin was determined at 37° in water, pH 7.4 phosphate buffer, and pH 7.4 phosphate buffer containing 1.0% (w/v) polyvinylpyrrolidone. Each system also contained 0.005% (w/v) polysorbate 80. Excess quantities of digitoxin were placed into 50-ml. glass-stoppered flasks together with 25.0-ml. portions of the solvent systems listed. All flasks were closed securely and mechanically shaken at 37° until equilibrium was attained. Equilibrium was established by repetitive sampling and was found to occur within 12–24 hr. The equilibrated samples were subjected to filtration[5] (0.45-μ pore size) at 37°, the filtrates were suitably diluted when necessary, and the concentration of drug in solution was determined colorimetrically by the procedure of Mesnard and Devaux (8).

RESULTS

Oral Toxicity Studies—The results of the oral toxicity experiments (Tables I and II) were used to construct the log–probability plots shown in Figs. 1 and 2. Based on these linear plots, the oral LD_{50} values for the drug alone and the 1:9 drug–polyvinylpyrrolidone coprecipitate and their corresponding 95% confidence intervals were calculated and found to be 88 (67.7–114) and 7.80 (7.03–8.66) mg./kg., respectively. An examination of these oral LD_{50} values indicates that one must orally administer approximately 11 times as much pure drug to reach the same amount of drug in the body as that attained following the administration of the drug as a coprecipitate. In addition, most of the rats given toxic doses of the digitoxin–polyvinylpyrrolidone coprecipitate usually developed characteristic neuromuscular signs and died at a much earlier time

[5] Millipore.

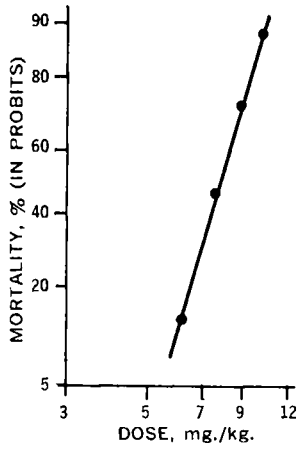

Figure 2—*Relationship between the oral dose and lethality of digitoxin from a 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate.*

than those animals dosed with the pure drug. For example, 75% of the deaths that resulted from the oral administration of a 10-mg./kg. dose of the drug as a polyvinylpyrrolidone coprecipitate occurred within 5–10 hr., with the remaining animals dying between 24 and 48 hr. On the other hand, 50% of the rats dosed with 185 mg./kg. of the pure drug died between 12 and 24 hr. and 50% between 24 and 48 hr.

Although visual inspection of the slopes of the linear plots shown in Figs. 1 and 2 suggests a lack of parallelism, the toxicity data, when statistically tested for parallelism according to the method of Litchfield and Wilcoxon (7), revealed that the two lines do not show any significant departure from parallelism ($p < 0.05$).

The 1:9 (w/w) digitoxin–polyvinylpyrrolidone physical mixture was orally administered at two drug dosage levels to two groups of rats to establish whether a simple, mechanical mixture of the two components would affect the oral toxicity of digitoxin. A comparison of the results of these toxicity tests with those obtained with the drug alone (Table I) reveals that the toxicity of digitoxin is essentially unaltered when administered as a suspension with polyvinylpyrrolidone.

Dissolution Rate and Equilibrium Solubility Studies—*In vitro* dissolution rate studies were conducted at 37° on particulate samples of the three digitoxin test preparations to establish whether this physicochemical parameter could be used to reflect the differences observed previously among their *in vivo* absorption characteristics. The rate of solution of a sample of pure *precipitated* digitoxin (particle-size range of 1–50 μ), prepared in the same manner as the coprecipitate system, was also evaluated. The results of these *in vitro* dissolution rate experiments, performed at pH 7.4 and under nonsink conditions, are shown in Figs. 3 and 4.

An examination of the dissolution rate profiles for the pure drug and the 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate

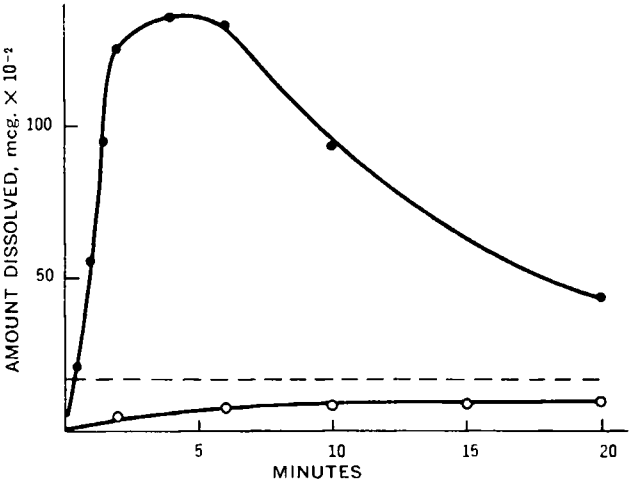

Figure 3—*Dissolution rates of digitoxin test preparation at 37°. Key: ○, pure digitoxin; ●, 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate; and - - -, equilibrium solubility of digitoxin in dissolution medium.*

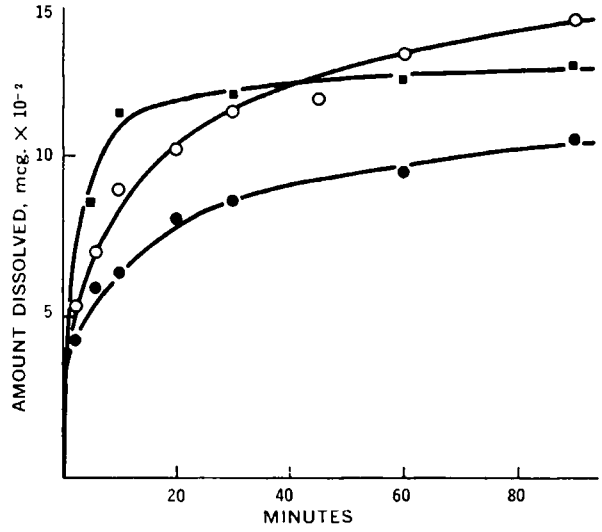

Figure 4—*Dissolution rates of digitoxin test preparations at 37°. Key: ○, Pure digitoxin; ●, digitoxin precipitated from chloroform; and ■, 1:9 (w/w) digitoxin polyvinylpyrrolidone physical mixture.*

(Fig. 3) reveals that the amount of drug in solution from the coprecipitate system rapidly and markedly exceeds the equilibrium solubility of the drug. After reaching a peak value in a relatively short period (*i.e.*, less than 5 min.), the amount of drug in solution slowly declines toward the equilibrium solubility value. However, even after 2 hr., the amount of digitoxin in solution from the coprecipitate system is nearly twice the equilibrium solubility value. On the other hand, the pure drug dissolves at a significantly slower rate and gradually approaches the equilibrium solubility value. The equilibrium solubility of digitoxin was unaffected by the amount of polyvinylpyrrolidone in solution from the coprecipitate system.

The peak, nonequilibrium (dynamic), solubility value for digitoxin from the 1:9 (w/w) coprecipitate, as determined from the dissolution rate experiments (Fig. 3), was 38.7 mcg./ml. or 13.5 mg./350 ml. of dissolution medium. This value exceeds the equilibrium solubility of the drug by a factor of 7–8 times. The magnitude of this factor compares favorably with the ratio of 11.3 obtained by comparing the oral LD_{50} value calculated from the pure drug to that for the 1:9 (w/w) digitoxin–polyvinylpyrrolidone coprecipitate.

The dissolution profiles for precipitated digitoxin (1–50 μ), pure digitoxin (10–40 μ), and the 1:9 (w/w) digitoxin–polyvinylpyrrolidone physical mixture are depicted in Fig. 4. The rates of solution of digitoxin from these three systems are quite similar in magnitude and markedly less than that previously noted for digitoxin from the 1:9 (w/w) coprecipitate (Fig. 3).

The equilibrium solubility of digitoxin at 37°, determined in various aqueous systems, was 4.8 mcg./ml. in water and pH 7.4 buffer and 4.9 mcg./ml. in pH 7.4 buffer containing 1% (w/v) polyvinylpyrrolidone. The concentration of polyvinylpyrrolidone used in this study was considerably higher than that which could be realized from the complete dissolution of the amount of polymer present in the samples of either the physical mixture or coprecipitate subjected to dissolution rate experimentation (1 *versus* 0.0514%).

DISCUSSION

Drug absorption may be assessed indirectly by quantitatively determining its oral toxicity (9, 10). This method is based on the fact that the toxicity of an orally administered drug is directly proportional to the logarithm of the amount of drug in the body or its blood level (11) which, in turn, is directly proportional to its rate of absorption from the GI tract. The two parameters most commonly employed to reflect the toxicity of a drug are its oral LD_{50} and LT_{50} (median lethal time of death) values.

In the present investigation, digitoxin alone or as a 1:9 (w/w) physical mixture or coprecipitate with polyvinylpyrrolidone was orally administered at various drug dosage levels to fasted rats and the percent mortality was determined as a means of comparing the absorption characteristics of the drug from the various test systems. The markedly lower oral LD_{50} value observed for the coprecipitated

drug as compared to the pure drug does not necessarily imply that digitoxin, when administered alone, is less available to the body than when administered in the form of polyvinylpyrrolidone coprecipitate. However, it strongly suggests that the peak level of digitoxin in the body after oral administration of the coprecipitate is far higher than that achieved following an equal dose of pure drug. This conclusion can be readily appreciated if one considers the case of a hydrophobic drug whose passive absorption is rate limited by the rate at which solution is effected within the GI fluids. In this type of absorption pattern, any change in the rate of solution of the drug in the GI fluids would produce a corresponding change in its absorption rate. Since dissolution must precede absorption, a faster dissolving form of the drug should be absorbed at a more rapid rate and possibly accumulate in the body to a greater extent than an *equal* dose of a slowly dissolving form of the same pharmacological agent (12).

The inherent toxicity of polyvinylpyrrolidone can be readily eliminated as a factor contributing to the marked decrease in the oral LD_{50} value for digitoxin from the coprecipitate. In this connection, it has been demonstrated that pure polyvinylpyrrolidone elicits no untoward effects when orally administered to rats in doses of up to 100 g./kg. The intravenous LD_{50} value for polyvinylpyrrolidone is also very high, being 12–15 g./kg. (13). This information, coupled with the results obtained following the oral administration of the physical mixture, indicates that the increased toxicity of digitoxin from the 1:9 (w/w) coprecipitate is not due to the presence of polyvinylpyrrolidone *per se* but to an increase in the amount of drug in the body produced by a marked enhancement in the rate at which drug absorption occurs from this test system.

Several *in vitro* dissolution rate and solubility experiments were performed to establish which physicochemical mechanism could best account for the marked enhancement observed in the dissolution rate of digitoxin from the 1:9 (w/w) drug–polyvinylpyrrolidone coprecipitate as compared to the pure drug. The mechanisms considered were: (*a*) the formation of a digitoxin–chloroform solvate during the preparation of the coprecipitate system, (*b*) an increase in the solubility of the drug due to the formation of a digitoxin–polyvinylpyrrolidone complex, and (*c*) the formation of a polymorphic or amorphous form of the drug as a result of coprecipitation with polyvinylpyrrolidone.

The formation of drug solvates has been shown to affect the dissolution rate of hydrophobic drugs significantly (14). In this connection, digitoxin has been shown to form solvates with ethanol and water, which are stable *in vacuo* at temperatures up to 118° (15). Since chloroform was used to prepare the digitoxin–polyvinylpyrrolidone coprecipitate system, the possibility existed that the enhanced absorption and dissolution characteristics of digitoxin from this system resulted from the formation of a 1:1 chloroform solvate. To explore this possibility, the dissolution rate of digitoxin precipitated from chloroform without polyvinylpyrrolidone was investigated.

The differences observed in the rates of solution of pure digitoxin and precipitated digitoxin are small (Fig. 4) and can most probably be attributed to differences in the particle-size distribution of the two test systems and/or some inhibition in the rate of solution brought about by the presence of a minute amount of chloroform in the precipitated drug crystals. The results of this experiment suggest that the increases noted in the dissolution of digitoxin from the 1:9 (w/w) polyvinylpyrrolidone coprecipitate cannot be due to the formation of a drug–chloroform solvate during the preparation of the coprecipitate system.

The dissolution characteristics of the 1:9 (w/w) digitoxin–polyvinylpyrrolidone physical mixture almost coincide with those obtained with the pure drug (Fig. 4). The slight increase noted in the initial rate of solution of digitoxin from the physical mixture, as compared to the pure drug, is most likely due to the ability of the hydrophilic polymer to enhance the wettability of the hydrophobic digitoxin particles. These results indicate that the mere presence of polyvinylpyrrolidone, at a concentration equal to that present in the 1:9 (w/w) coprecipitate, is not responsible for the enhanced dissolution rate of digitoxin from the coprecipitate. Also, the equilibrium solubility studies indicate that the increased solubility and dissolution rate of digitoxin from the 1:9 (w/w) drug–polyvinylpyrrolidone coprecipitate system are most probably not the result of the formation of a water-soluble complex between the drug and polyvinylpyrrolidone.

The similarity between the dissolution and solubility behavior of digitoxin from the 1:9 (w/w) drug polyvinylpyrrolidone coprecipitate and that previously observed with reserpine–polyvinylpyrrolidone coprecipitate systems (16), coupled with the fact that both drugs form *glass solutions* with the polymer, strongly suggests that a similar mechanism is operable. Accordingly, it may be proposed that a high energy form of digitoxin, most probably amorphous in nature, is formed as a result of coprecipitating the drug with polyvinylpyrrolidone and that its increased solubility characteristics are responsible for the marked enhancement in drug dissolution and absorption experienced with the coprecipitate system.

CONCLUSIONS

The data obtained in the present study demonstrate that coprecipitation with polyvinylpyrrolidone increases the solubility and dissolution rate of digitoxin and thereby significantly enhances the *in vivo* absorption of this hydrophobic drug. These observations, as well as those noted previously with reserpine (6, 16), indicate that it is quite possible that this technique might have general applicability to a wide variety of relatively water-insoluble drug entities whose absorption from the GI tract can be characterized as slow, erratic, and/or incomplete. The advantages of utilizing this technique in the pharmacological screening of new drugs for oral activity are numerous and self-evident. Its clinical applications are currently being explored in these laboratories.

High-Voltage Paper Electrophoresis for Characterization of Drug Metabolites

WALTER D. CONWAY▲, VIJAY K. BATRA, and ALAN ABRAMOWITZ

Abstract □ Methodology for obtaining reproducible measurements of the relative mobility of organic compounds over pH 2–12 using high-voltage paper electrophoresis is described. Use of the method for the elucidation of some structural features of simple molecules is illustrated by applying it to the characterization of metabolites of drugs excreted in the urine and bile of rats. The compounds studied included *p*-nitrophenol, 1-naphthol, salicylic acid, 4-nitrocatechol, probenecid, phenol red, and their metabolites.

Keyphrases □ Mobility–pH profiles, drug metabolites—determined using high-voltage paper electrophoresis □ Metabolites—characterized using high-voltage paper electrophoresis □ Structure characterization—mobility–pH profiles of drug metabolites determined using high-voltage paper electrophoresis □ Paper electrophoresis, high voltage—determination of mobility–pH profiles for drug metabolites

Paper electrophoresis has been widely used over the past 20 years for separating and characterizing molecules. An historical account and an extensive review of the work done prior to 1955 was presented by McDonald (1). The technique has been extensively applied in the fields of carbohydrate chemistry, amino acid and protein analysis, and inorganic chemistry.

Recent applications related to drugs include separation and identification of alkaloids (2); establishment of the radiopurity of ^{14}C-labeled methylglyoxal-bisguanylhydrazone; and separation of the metabolites of chlorpromazine (5, 6), carbiphene hydrochloride[1] (a basic amide analgesic) (7), catecholamines (8–10), isoproterenol (11), derivatives of fluorene and biphenyl (12), *p*-aminohippuric acid and its acetyl derivatives (13), cyclophosphamide (14), thalidomide (15), neostigmine (16, 17), and pronethalol (18).

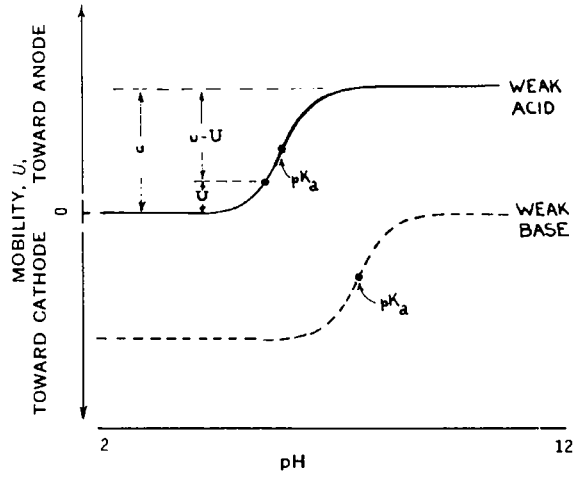

Figure 1—*Mobility–pH profiles of a weak acid and a weak base.*

[1] SQ 10,269.

Bond and Howe (18) classified the metabolites of pronethalol as acidic, basic, and amphoteric on the basis of electrophoretic mobility at a single pH; in the same way, Keberle *et al.* (15) classified thalidomide metabolites as monocarboxylic and dicarboxylic acids. Most investigators made separations in only one or two buffers and applied electrophoresis in much the same manner as other differential migration techniques such as TLC and paper chromatography. However, significant aspects of the structure of a substance can be ascertained simply from measurements of its electrophoretic mobility at several concentrations of hydrogen ion. This technique is particularly useful for determining structures of substances arising from drug metabolism.

THEORETICAL

The relationship of various factors affecting the mobility, U, of a spherical particle in an electrolyte under the influence of an electrical field was expressed (19) as Eq. 1:

$$U = \frac{Q}{6\pi\eta r}\left(\frac{1}{1+\kappa r}\right) \qquad \text{(Eq. 1)}$$

where Q is the electrical charge on the particle, r is its radius, η is the viscosity of the electrolyte, and κ is a parameter, the reciprocal of which is related to the thickness of the ionic double layer surrounding the particle. The equation implies that doubly charged ions migrate twice as fast as singly charged ions of equal size. Where $1/\kappa$ is small compared with r, a reasonable approximation in the case of organic drugs, there is an inverse dependence of mobility on the square of the radius of the particle.

The general shape of a plot of mobility *versus* pH for a weak monoprotic acid is characterized by a form of the Henderson–Hasselbalch equation:

$$\text{pH} = \text{pKa} + \log\left(\frac{U}{u-U}\right) \qquad \text{(Eq. 2)}$$

and can be advantageously illustrated as shown in Fig. 1. It is convenient to refer to this plot as the mobility–pH profile of a substance.

The shape of the mobility–pH profile is, in fact, identical with that of a plot of the ionized fraction of a monoprotic acid as a function of pH since it can be shown that:

$$\frac{U}{u-U} = \frac{\alpha}{1-\alpha} \qquad \text{(Eq. 3)}$$

where U is the mobility of a zone at any particular pH, u is the maximum mobility of the zone or the mobility of the anion in the case of a monoprotic acid, and α is the degree of dissociation of the weak acid (20). The term α may be obtained from the graph at any particular pH as the ratio of the distances U and u since:

$$\alpha = \frac{U}{u} \qquad \text{(Eq. 4)}$$

The degree of dissociation, α, may also be interpreted as that fraction of time spent in the ionized state by any individual molecule of a weak acid. The fraction varies from 0 at low pH to 1 at higher pH, where the region of constant mobility is reached. This interpretation of α is advantageous in rationalizing the shape of the mobility–pH profile.

As indicated by Eqs. 2 and 3, the profile of a weak monobasic

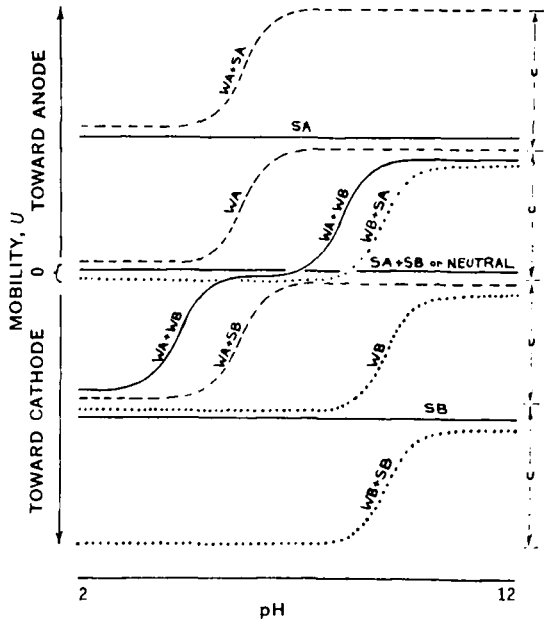

Figure 2—*Mobility-pH profiles of weak acids (WA), weak bases (WB), strong acids (SA), strong bases (SB), and amphoteric molecules containing combinations of these functional groups.*

acid will have: (*a*) zero mobility at low pH, where the acid is not ionized and is, therefore, electrically neutral; (*b*) a point of inflection where the pH of the electrolyte equals the pKa of the weak acid; and (*c*) a constant mobility toward the anode at high pH, characteristic of the anion resulting from ionization of the acid. The distance u will be related to the effective radius or volume of the ion. Under conditions of zero ionic strength, and assuming hydrodynamic behavior of ions equivalent to that of spheres, the distance u would be expected to be inversely related to the two-thirds power of the molecular weight.

The profile of a weak base can be described in completely analogous fashion, using Eq. 2, by considering the protonated form of the base to behave as a weak monoprotic acid, albeit bearing a unit positive charge at low pH. The weak base will, therefore, exhibit a constant maximum mobility toward the cathode in the region of low pH and zero mobility at high pH (Fig. 1).

The *shape* of the mobility-pH profile of either a weak acid or a weak base is thus defined by Eq. 2. The mobility increment, u, will depend upon the molecular weight of the substance, and the *position* of the sigmoid portion of the profile will be determined by the pKa of the substance.

Strong acids, such as sulfonic acids and sulfuric acid monoesters, will migrate toward the anode, and completely dissociated cations, such as quaternary ammonium compounds, will migrate toward the cathode at constant velocity independent of pH. The profile of an amphoteric substance should reflect the combined behavior of the acid and base functions.

The general features of the mobility-pH profiles predicted by Eq. 2 for molecules containing various combinations of strong and weak acid and base functional groups are illustrated in Fig. 2. The profiles are drawn for compounds of equal molecular weights and arbitrary pKa values. For clarity, the curves are shifted slightly on the vertical axis from their normal positions, which would overlap in the regions of constant mobility.

A measure of the pH interval over which ionization of a substance occurs may be obtained by drawing a line through the relatively linear portion of the mobility-pH profile and extrapolating it to its intersections with those portions of the profile that define regions of constant minimum and maximum mobility. It is useful to refer to this pH increment as the ionization interval. The relationship of this ionization interval to the shape of the mobility-pH profile may be seen by differentiating Eq. 2 with respect to pH and evaluating the resulting equation in terms of u at the point of inflection or pKa, where $U = u - U = u/2$, which gives:

$$\left[\frac{dU}{d(\mathrm{pH})}\right]_{\mathrm{pKa}} = \frac{U(u-U)}{U\log_{10} e} = \frac{u}{1.74} = \text{slope at pKa} \quad \text{(Eq. 5)}$$

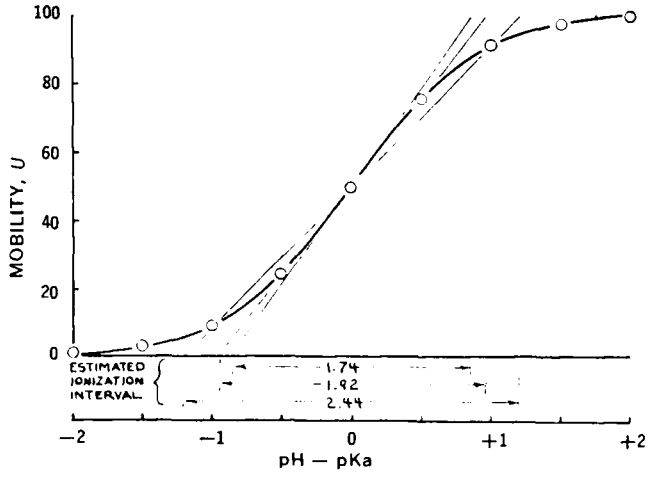

Figure 3—*Estimates of the ionization interval obtained from lines drawn tangent to the inflection point and through points on the mobility-pH profile at pH − pKa = ±0.5 and ±1.0.*

This implies that, irrespective of molecular weight, a line drawn tangent to a continuous plot of the mobility-pH profile at the pKa will intercept the values of minimum and maximum mobility with an intervening distance of 1.74 pH units for a monoprotic acid or base (Fig. 3). However, a line drawn through discontinuous experimental data points obtained at increments of 0.5–1.0 pH unit will have a slightly lower slope. For instance, the line drawn through points spaced 0.5 pH unit above and below the pKa will form intercepts with the minimum and maximum mobilities with an intervening distance of 1.92 pH units, and the intercepts derived from a line through points spaced 1.0 pH unit above and below the pKa will be 2.44 units apart (Fig. 3).

A diprotic acid will possess two electrical charges when fully ionized. The acid will be 50% ionized at a hydronium-ion concentration, $[H^+]$, given by Eq. 6:

$$[H^+] = \sqrt{K_1 K_2} \quad \text{(Eq. 6)}$$

where K_1 and K_2 are the apparent dissociation constants of the two ionizable groups. In logarithmic form, Eq. 6 becomes:

$$\mathrm{pH} = \frac{\mathrm{pK_1} + \mathrm{pK_2}}{2} \quad \text{(Eq. 7)}$$

The ionization and, consequently, the electrophoretic mobility of a diprotic acid may be conveniently expressed as:

$$\text{percent ionized} = 100\left(\frac{U}{u}\right) = 50\left(\frac{\Delta\sqrt{X}+2}{\Delta^2+\Delta\sqrt{X}+1}\right) \quad \text{(Eq. 8)}$$

where:

$$\Delta = \frac{[H^+]}{\sqrt{K_1 K_2}} \quad \text{(Eq. 9)}$$

$$X = \frac{K_1}{K_2} \quad \text{(Eq. 10)}$$

The mobility of a zone of a diprotic acid at a particular pH will be proportional to the charge on the acid at that pH. As described by Eq. 8, the profile will be symmetrical about the point where the acid is 50% ionized. At this point, $\Delta = 1$ or $\mathrm{pH} = \frac{1}{2}(\mathrm{pK_1} + \mathrm{pK_2})$. The *shape* of the profile will depend upon X, the ratio of the ionization constants (Eq. 10). The expected profiles for acids with $X = 4$, 10, 10^2, 10^3, and 10^4 are illustrated in Fig. 4.

The profile for a diprotic acid with $X = 4$ is identical with that of a monoprotic acid, and it is doubtful whether the profile for $X = 10$ could be experimentally distinguished from that of a monoprotic acid.

As X increases, the slope decreases; when X equals 100, the experimentally measured ionization interval would be expected to lie in the range of 4.1–4.7 pH units. When X is 10^3 or greater, the pro-

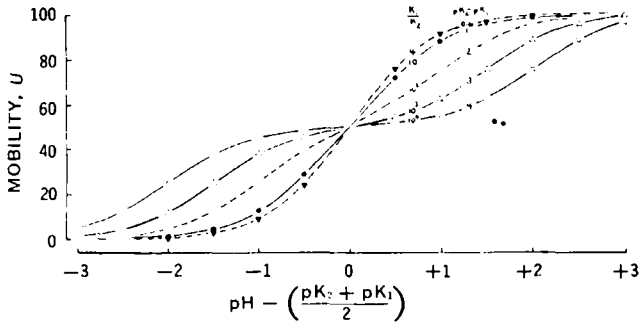

Figure 4—*Mobility-pH profiles of dicarboxylic acids.*

file would be expected to exhibit two sigmoid portions and the ionization interval for each of these portions would be expected to lie in the range of 1.9–2.4 pH units, identical to the value expected for a monoprotic acid. The ionization intervals for the profiles with X of 10^3 or more are measured with respect to the intercepts with the regions of 0 and 50 or 50 and 100 mobility units, since ionization of the individual functional groups is discernible. Thus, the mobility pH profile should serve to distinguish diprotic substances, when the pKa values of the ionizable groups differ by more than 1.5 or 2.0 units, from monoprotic substances.

Similar reasoning may be applied to determine the expected profiles for substances with three or more ionizable groups.

This theoretical description of electrophoresis strictly applies only to the migration of ions in free solution. Because of the tortuous path the migrating ions must follow around fibers and through constricted pores of the paper matrix, the rates of migration measured in paper electrophoresis are less than the mobilities measured in free solution. In addition, the phenomenon of electroosmotic flow and the variability of numerous parameters, including temperature, electrolyte viscosity and ionic strength, paper wetness, voltage gradient, and duration of a run, lead to considerable variability in measurements of migration rates.

However, if one prepares buffers of identical ionic strength and uses an electrically neutral substance to correct for electroosmotic flow and a completely ionized substance as a mobility standard, the effects of these variables cancel out in relation to the standard and reproducible values of relative mobility are obtained.

EXPERIMENTAL

Apparatus—A double-platen high-voltage paper electrophoresis apparatus[2] was used in conjunction with a power supply[3] (5000 v., 300 ma.) and a constant-temperature circulator[4]. The electrophoresis apparatus, which contains an upper and lower cooling platen, was modified (Fig. 5) by drilling and tapping the ends of the platens to permit attachment of aluminum angles [1.9 × 1.9 cm. (0.75 × 0.75 in.)] faced with a 0.63-cm. (0.25-in.) thickness of foam rubber.

Procedure—A sheet of Whatman 3MM filter paper [13.9 × 42.58 cm. (5.5 × 20.25 in.)] was marked at its midpoint with a light pencil line, and a series of light pencil lines were spaced at 5-cm. (2-in.) intervals on either side of the midpoint (Fig. 6).

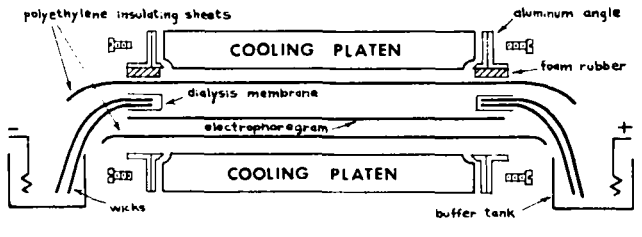

Figure 5—*Schematic diagram of electrophoresis apparatus.*

[4] Neslab model HX-75.

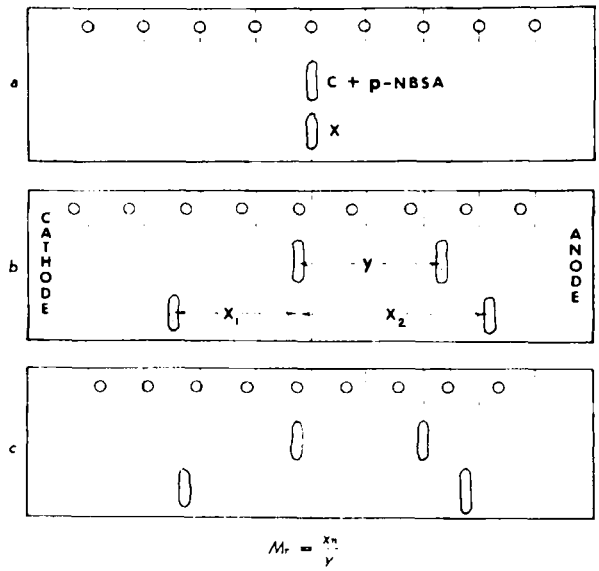

Figure 6—*Application of sample* (x) *and caffeine* (c) *and* p-*nitrobenzenesulfonic acid* (p-*NBSA*) *standards, evaluation of electrophoregram, and calculation of relative mobility* (M_r). *Key:* a, *before run;* b, *after normal run; and* c, *pattern distorted by electrolyte uptake via wicks.*

The paper was soaked in buffer for about 1 min., and some surplus buffer was removed by stroking each side of the paper with a glass rod. The wet sheet was centered on an 8-mil polyethylene [17.78 × 58.42 cm. (7 × 23 in.)] insulating sheet in the electrophoresis apparatus in which the circulating coolant had been adjusted to the desired temperature. A piece of "PE" polyester monofilament screen cloth[5] was placed on top of the paper, followed by three thicknesses of Whatman No. 1 filter paper and a second polyethylene insulating sheet. The apparatus was closed and a pressure of 5 psig. was applied to the lower platen for 2 min. When treated in this way at 20°, the Whatman 3MM paper reaches an equilibrium water content of approximately 71% in 1 min. and no additional water is lost for as long as 5 min.

The apparatus was then depressurized and opened. Except for the midpoint, the exposed upper portion of the paper strip was covered with a polyethylene sheet to prevent evaporation. Approximately 10-μl. aliquots of samples were applied to the midline as streaks approximately 2 cm. long. A 10-μl. aliquot of an aqueous solution containing 0.2% caffeine and 0.2% *p*-nitrobenzenesulfonic acid was applied as one sample. The protective polyethylene was removed, and samples of a few microliters of a 0.2% caffeine solution were applied to each pencil line approximately 2.54 cm. (1 in.) from the upper edge of the paper (Fig. 6*a*).

Wicks were prepared from two thicknesses of 10.89 × 13.97-cm. (4.25 × 5.5-in.) Whatman 3MM paper soaked in buffer, and one narrow end was covered to a distance of 4.44 cm. (1.75 in.) from the end with a single thickness of dialysis membrane, obtained by slitting a piece of dialysis tubing, 4.44-cm. (1.75-in.) flat width[6]. The wicks were placed with the dialysis membranes in contact with either end of the electrophoregram and not extending onto the platen beyond the foam rubber pads. The upper polyethylene insulating sheet was placed in position, and the apparatus was closed and pressurized to 5 psig.

Two pieces of polyethylene tubing [1.27-cm. (0.5-in.) o.d. × 0.16-cm. (0.069-in.) wall × 5.08-cm. (2-in.) length], slit lengthwise, were placed as clamps over the sides of the polyethylene insulating sheets and extended slightly beyond the aluminum angles (Fig. 7) on the high tension end of the apparatus. The high tension is the anode with the power supply used[3]. Previous work showed that almost all electrical shorts occur at this end of the apparatus and that most of them result from the deposition of moisture between the insulating sheets; when the moisture reaches the edge of the sheet, a spark jumps to

Ethylenediamine	Hydrochloric acid	0.100	0.050	10.0
Piperidine	Hydrochloric acid	0.100	0.050	11.2
Piperidine	Hydrochloric acid	0.550	0.050	12.2
Potassium hydroxide	Potassium chloride	0.010	0.040	12.0

the grounded platen. Placement of the polyethylene clamps as indicated prevents the moisture from reaching the edge of the strip and virtually eliminates shorting.

The voltage was typically adjusted to 5 kv. and allowed to remain for 15 min. The apparatus was then opened, and the electrophoregram was kept in a horizontal position and examined while wet with a short wavelength (254 nm.) UV lamp[7]. Positions of the standards and any samples which were visible were outlined with pencil. The strip was then suspended vertically, with one longer side at the top, and dried for 10 min. at 90° in a chromatogram drying oven[8] with the draft control half open. The dry electrophoregram was again examined under UV light to check the uniformity of drying. Uneven evaporation of the water will be indicated by a shift of the standard spots, particularly caffeine, from the positions marked before drying.

The pattern after a normal run is indicated in Fig. 6*b*, where all caffeine spots moved a uniform distance of several millimeters toward the cathode. The pattern shown in Fig. 6*c* is distorted as a result of buffer uptake through the wicks and is typically observed when a dialysis membrane is not used.

Distances (X) to the centers of the various sample spots are measured from the center of the caffeine spot and divided by the distance (Y) from the center of the caffeine spot to the center of the *p*-nitrobenzenesulfonic acid spot, and this fraction is multiplied by 100 to give the relative mobility.

Radioactive Substances—The locations of radioactive spots were determined by cutting the dry electrophoregram into strips and scanning these in a radiochromatogram scanner[9]. This presented no problem when scanning for ^{14}C-labeled compounds with a polyethylene terephthalate[10] window covering the counter tube. However, scanning ^{3}H-labeled compounds with the counter in the windowless mode caused very erratic counter behavior, characterized by spurious peaks and excessive count rates which drove the pen off-scale for prolonged periods. This behavior was traced to the attachment of conductive fibers of buffer-impregnated paper to the counter anode. This was overcome by modifying the counter to permit its operation with the strip feed and takeup reels rotating in a horizontal plane and the counter anode wires oriented vertically. Such operation required a counter gas flow rate of 400 ml./min. Careful attention must also be paid to the anode voltage, which should be no higher than the midpoint of the plateau region. These modifications totally eliminated the erratic counting with all buffers used except one composed of phosphoric acid and monobasic potassium phosphate at pH 2. Fibers from paper containing this buffer were readily attracted to the anode by electrostatic force, thereby preventing its use when scanning in the windowless mode.

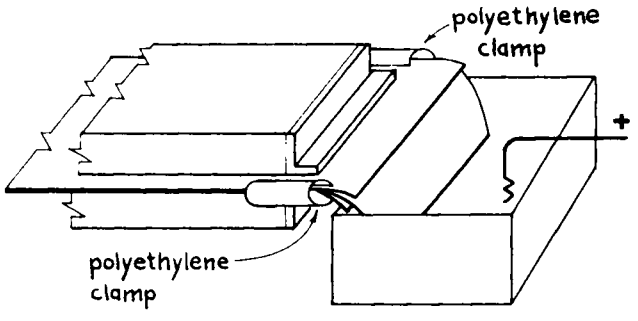

Figure 7—*Placement of polyethylene clamps to eliminate shorting.*

Buffers—Buffers were prepared with an ionic strength of 0.05, using the components indicated in Table I. The pH was measured prior to each run using a pH meter[11] on the standard scale. After a run, the buffer in the anode and cathode tanks was remixed and saved for reuse.

RESULTS AND DISCUSSION

The contribution of this technique to the elucidation of the structures of certain drug metabolites will be illustrated by the following presentation of the mobility–pH profiles of several samples obtained synthetically or from the urine or bile of animals dosed with the parent drug. The profiles were obtained from measurements in buffers about 1–2 pH units apart over approximately the 2.5–11.5 pH range. The profiles are not intended to define the characteristics such as pKa or molecular weight of the substance

with high precision, but they are sufficiently accurate to reveal characteristic structural features.

Salicylic Acid and Its Metabolites—The mobility-pH profiles (Fig. 8) of these substances are typical of those observed for weak acids, phenols, and glucuronide conjugates of acidic substances. They were obtained using synthetic samples of salicylic acid phenolic glucuronide, salicylic acid, gentisic acid, and salicyluric acid. The general shapes of the profiles are consistent with the properties discussed for Fig. 1. All of the substances show a pKa in the region of 3–3.5, characteristic of a carboxylic acid. Salicyluric acid shows a second pKa in the region of pH 9, consistent with ionization of a phenolic group. The mobility, 141, of salicyluric acid at pH 11.5 is approximately double that, 72, at pH 6, indicating the presence of two electrical charges and a single charge, respectively. Gentisic acid exhibits incomplete ionization of even one phenolic group at pH 11.5. Salicylic acid shows no ionization of the phenolic group at pH 11.5, as would be expected since the reported pKa for this group is 13.8 (23).

Closer scrutiny of the profiles reveals some deviations from the simple theory presented earlier. All of the substances migrate with relative mobilities less than those calculated, assuming mobility to be inversely related to the two-thirds power of the molecular weight. Predicted mobilities in the region of pH 6, relative to that of *p*-nitrobenzenesulfonic acid as 100, are: salicylic acid phenolic glucuronide, 150; salicylic acid, 130; gentisic acid, 120; and salicyluric acid, 106; the observed mobilities are 118, 96, 78, and 71, respectively. Thus, the predicted rank order of migration rates is observed, but the actual mobilities are considerably less relative to *p*-nitrobenzenesulfonic acid than predicted.

An ionization interval of 2.1 pH units was observed for salicylic and gentisic acids and 2.0 units for salicyluric acid. These are within the expected range of 1.9–2.4 pH units for monoprotic acids. The ionization interval of 3.0 units observed for the phenolic glucuronide of salicylic acid is within the range expected for dicarboxylic acids, with ionization constants differing by 1–2 pH units.

Conjugates of *p*-Nitrophenol—These profiles (Fig. 9) illustrate the application of the technique to glucuronic, sulfuric, and phosphoric acid conjugates, for which electrophoresis is particularly appropriate. These highly polar, water-soluble compounds are not readily extracted with organic solvents and are, therefore, not easily studied by conventional TLC or paper chromatography.

The mobility-pH profiles of commercially available samples of the glucuronide, sulfuric acid ester, and mono- and dihydrogen phosphate esters of *p*-nitrophenol are shown in Fig. 9. Although the phosphate esters are not ordinarily found as drug metabolites in mammals, they are found in insects; it is, therefore, interesting to determine whether the mobility-pH profile will distinguish these conjugates.

The profile for the glucuronide shows virtually no mobility at pH 2, an ionization interval of 2.3 units with a pKa slightly over 3, and a region of constant mobility above pH 5. The sulfuric acid ester is fully ionized over the entire pH range and shows the expected constant mobility. A similar constant mobility is seen for the monohydrogen phosphate, but its mobility is much less than that of the sulfate, reflecting its higher molecular weight. The dihydrogen phosphate ester exhibits mobility at low pH, reflecting the low pKa of one of its protons, an ionization interval of 2.2 units with a pKa in the vicinity of 5, and constant mobility above pH 7 where the molecule bears two negative charges.

The mobilities are in the expected order based on molecular weights, except that one would not expect the considerable separation seen for the sulfate and dihydrogen phosphate at low pH since these two compounds are actually identical in molecular weight. In experiments using paper chromatography with the various buffers as the developing solvents, the sulfuric acid ester was retarded to a greater extent than the phosphate, suggesting that electro-

II

phoretic separation of the two compounds is not a result of differential adsorption on the paper.

The mobility of the dihydrogen phosphate at high pH is not quite double that observed at low pH, as would be predicted by the presence of two electrical charges on the ion at high pH. A ratio of 1.7 was actually observed. Part of this discrepancy can be attributed to the fact that the runs were made in electrolytes of ionic strength 0.05. The theoretical ratio of 2.0 would be expected only at infinite dilution.

Conjugates of 2-Naphthol—The mobility–pH profiles of conjugates of 2-naphthol with glucuronic, sulfuric, and phosphoric acids are presented in Fig. 10. The profiles are analogous to the corresponding conjugates of *p*-nitrophenol and the same comments apply.

The applicability of this approach to the characterization of drug metabolites in a biological fluid was demonstrated after administration to a male rat by intraperitoneal injection of a 30-mg./kg. dose of 1-naphthol-^{14}C containing 10 μc. of ^{14}C. The mobility–pH profiles obtained using 10-μl. samples of the 24-hr. postmedication urine are shown by the data points in Fig. 11. The urine contained three substances. One moved with constant mobility over the entire pH range and accounted for 38% of the radioactivity. A second substance, accounting for 59% of the radioactivity, showed a pKa of about 3 and constant mobility above pH 4.5. The third material, which accounted for 3% of the radioactivity, remained at the origin.

This information alone suggests that the two major metabolites are conjugates with sulfuric and glucuronic acids. They are the metabolites of 1-naphthol in the rat. The lines in the figure were drawn independently from authentic samples of the indicated compounds and confirm the identity of the radioactive metabolites. The absence of either phosphate is apparent.

Metabolite of Probenecid—The mobility pH profile (Fig. 12) of a major metabolite excreted in rat bile after intravenous administration of probenecid-^{14}C was determined in conjunction with studies on the structure of the metabolite. It illustrates the value of the technique for detecting a metabolite of unexpected structure. Comparison of the metabolite profile with that of probenecid strongly suggested that the metabolite was not the expected acyl glucuronide of probenecid (I).

The molecular weight of I is 461, and this structure still contains only one ionizable group. Assuming the mobilities to be inversely related to the two-thirds power of the molecular weight, I would be expected to migrate about 60% as fast as probenecid, which has a molecular weight of 285. However, hydroxylation of probenecid followed by conjugation to an ether glucuronide would produce a species with a molecular weight of 477 and two carboxyl groups. The fully ionized molecule would then be expected to migrate about 27% faster than probenecid. The measurements in Fig. 12 indicate a 21% faster mobility for the metabolite. While it was not possible solely on the basis of this evidence to characterize fully the metabolite, it did guide further studies leading to the synthesis of *p*-(*N*-propyl,*N*-2-hydroxypropylsulfamoyl)benzoic acid, the aglycone of Metabolite II (21, 22).

Nitro- and Aminocatechols and Guaiacols—These profiles illustrate the application of the technique to compounds of similar

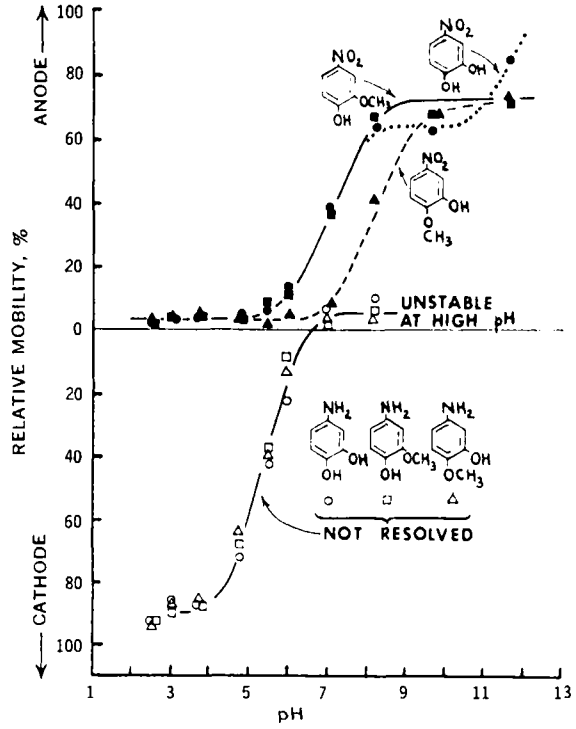

Figure 13—*Mobility–pH profiles for 4-nitrocatechol* (●), *4-nitroguaiacol* (■), *5-nitroguaiacol* (▲), *4-aminocatechol* (○), *4-aminoguaiacol* (□), *and 5-aminoguaiacol* (△).

molecular weight that differ only slightly in pKa and to basic compounds. The five compounds which might result from *O*-methylation and reduction of the nitro group of 4-nitrocatechol were prepared by standard synthetic procedures in conjunction with a study of the metabolic fate of 4-nitrocatechol. The mobility–pH profiles of these substances and 4-nitrocatechol itself are shown in Fig. 13. The amino compounds were not resolved and, unfortunately, were chemically unstable in solutions above pH 8. However, their profiles in the acidic range were of the expected shape and exhibited pKa values in the range of 5.5. The phenolic compounds show no mobility below pH 5 where they are not ionized. Both 4-nitrocatechol and 4-nitroguaiacol are unresolved below pH 7.5 and exhibit pKa values of about 7. The two compounds are resolved above pH 8, where the mobility of nitrocatechol is somewhat less than would be predicted by its smaller molecular weight. Partial ionization of the second phenolic group in 4-nitrocatechol is seen at pH 11. The 5-nitroguaiacol, by virtue of the lesser acidity of the *meta*-nitrophenolic group, is separated from the other phenols in the range of pH 6–9. The observed pKa values for 4-nitroguaiacol and 5-nitroguaiacol are in the range of those reported for *p*-nitrophenol, pKa 7.15, and *m*-nitrophenol, 8.40 (23).

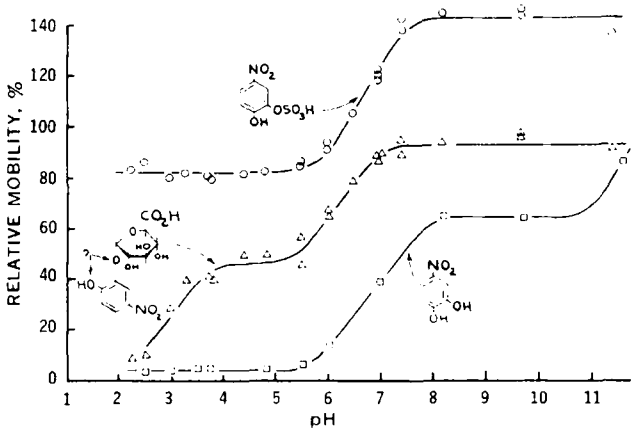

Figure 14—*Mobility–pH profiles of metabolites excreted in the urine of rats given 30 mg./kg. of 4-nitrocatechol intraperitoneally.*

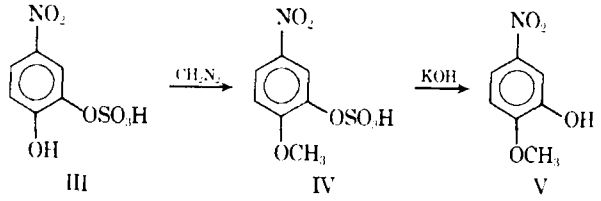

Scheme I

Metabolites of 4-Nitrocatechol This study illustrates the use of electrophoresis to establish the formation of both sulfuric acid and glucuronic acid conjugates and then to establish further the position of sulfuric acid conjugation by chemical conversion of the conjugate to a derivative of known structure which could be unequivocally identified by its mobility–pH profile.

Two yellow spots could be detected in the 0–24-hr. urine of rats given 4-nitrocatechol (30 mg./kg. i.p.). Only traces of the parent compound were detected. The mobility–pH profiles of the metabolites and 4-nitrocatechol are shown in Fig. 14. The profile of the metabolite with highest mobility is characteristic of a sulfuric acid ester, and it is identical with the profile of an authentic sample of 2-hydroxy-5-nitrophenyl sodium sulfate (III, Scheme I). The observed pKa in the neighborhood of 7 is also characteristic of a *p*-nitrophenolic group. Unfortunately, the isomeric 2-hydroxy-4-nitrophenol is unknown, so that it was impossible to determine whether the isomeric sulfuric acid esters could be separated. To confirm further the structure of the metabolite, the residue from evaporation of a small aliquot of urine was extracted with methanol, the extract was treated with diazomethane, and the product was hydrolyzed with dilute potassium hydroxide. Only 5-nitroguaiacol (V) could be found when the hydrolysate was examined by electrophoresis. This establishes the metabolite as III since it has been shown (Fig. 13) that the isomers 4-nitroguaiacol and 5-nitroguaiacol (V) are separable by electrophoresis.

The other metabolite exhibits a profile characteristic of a conjugate with glucuronic acid and has pKa values in the ranges of 3 and 6.5. The pKa in the range of 6.5 appears characteristic of a *p*-nitrophenolic group and suggests that conjugation here also occurs *meta* to the nitro group.

The ratio of the mobility of the doubly charged glucuronic acid conjugate (92 units) to that of the singly charged species (46 units in the 4–5 pH range) is 2.0, in contrast to the ratio of 1.7 observed for the sulfuric acid ester, III, and for the dihydrogen phosphates presented earlier (Figs. 9 and 10). The deviation may result partly because of the proximity of the two charges in the dihydrogen phosphates and III.

Visual examination of the electrophoregrams suggest that about equal amounts of the glucuronide and sulfuric acid ester are formed.

Metabolites of Phenol Red—In this study a completely unexpected metabolite was detected, which was then shown to be derived from an impurity in the sample of dye. Phenol red itself and three metabolites were detected by their color and fluorescence on electrophoregrams of the urine and bile obtained from rats after intravenous administration of phenol red (15 mg./kg.). The mobility–pH profiles are presented in Fig. 15. The metabolite with the highest mobility (△) was excreted only in urine and exhibited a mobility–pH

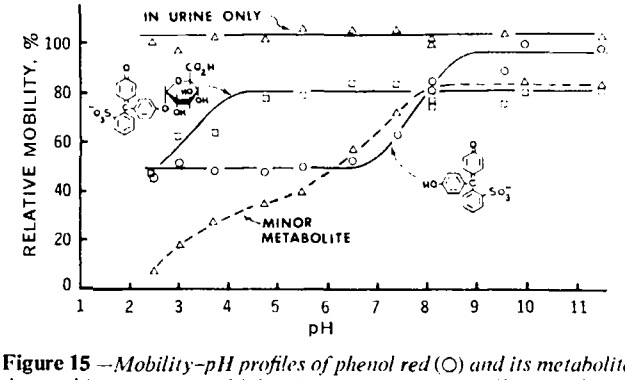

Figure 15 —*Mobility–pH profiles of phenol red* (○) *and its metabolites detected in the urine and bile of a rat given a 15-mg./kg. i.v. dose.*

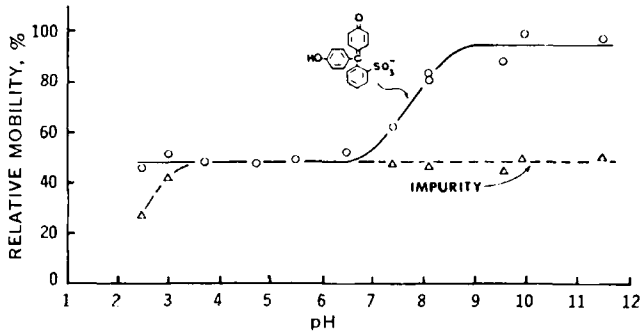

Figure 16 —*Mobility–pH profile of phenol red* (○) *and an impurity* (△) *which lacks the sulfonic acid group.*

profile characteristic of a conjugate with sulfuric acid. A second metabolite (□), with a profile characteristic of a conjugate with glucuronic acid, was excreted in both urine and bile. The biliary excretion of the glucuronide of phenol red was reported previously (24). These two metabolites, as well as phenol red, exhibit significant mobility at low pH due to the ionized sulfonic acid group. However, a minor metabolite (△) was also detected; it lacked the sulfonic acid group, as indicated by its lack of mobility at pH 2.5.

It was supposed that this third metabolite might have arisen from a nonsulfonic acid impurity in the sample of phenol red. Careful examination of electrophoregrams of the particular sample of phenol red did, in fact, reveal the presence of an impurity (Fig. 16) that lacked the sulfonic acid function. When a pure sample of phenol red, in which this substance was undetectable, was administered to rats, the third metabolite was not excreted, confirming the supposition that it arose from the impurity.

SUMMARY

Characterization of ionizable substances by means of their mobility–pH profile was applied to organic substances by Franc and Kovar (25), who calculated mobilities in various buffers relative to the mobility in a standard buffer and plotted what they called an electrophoretic spectrum. Others (27–32) have also referred mobilities to standard substances including *p*-nitrobenzenesulfonic acid and have corrected for electroosmotic flow using neutral substances including caffeine. However, previous workers have not prepared buffers to constant ionic strength.

Control of ionic strength, combined with the use of *p*-nitrobenzenesulfonic acid as a reference substance and caffeine to correct for electroosmotic flow, forms the basis for obtaining reproducible relative mobilities over a wide pH range. The agreement of the mobility–pH profile thus measured with that predicted from elementary theoretical considerations is adequate to permit practical use of the technique for elucidating some structural features of simple organic molecules. Use of the method has been illustrated by applying it to the characterization of the metabolites of several compounds.

Radioimmunoassay for Lysergide (LSD) in Illicit Drugs and Biological Fluids

LARRY J. LOEFFLER*▲ and JACK V. PIERCE†

Abstract □ A simple and convenient radioimmunoassay system was developed for the qualitative detection and quantitative determination of lysergide (LSD) in illicit drugs, human plasma, serum, or urine. The method utilizes a commercially available tritiated lysergide and specific antiserum, which can be obtained in large quantities from sheep after immunization with a lysergic acid–human serum albumin conjugate. Quantities of lysergide as low as 1 ng./ml. can be determined in plasma, serum, or urine, and lower levels can be detected qualitatively. The sensitivity of the assay is limited by the specific activity of the commercially available tritiated compound. Antibody cross-reactivity and, thus, interference in the assay were observed with other highly similar ergot alkaloids, such as ergonovine, methylergonovine, and ergotamine, but not with simpler indole structures.

Keyphrases □ Lysergide—radioimmunoassay of illicit drugs and biological fluids □ LSD—radioimmunoassay of illicit drugs and biological fluids □ Radioimmunoassay—lysergide (LSD) in illicit drugs and biological fluids □ Hallucinogens—radioimmunoassay of lysergide (LSD) in illicit drugs and biological fluids

The qualitative detection and quantitative determination of lysergide (LSD) in illicit drugs and in biological fluids have been a major interest in recent years because of the medical and social implications attendant its use. Chemical, spectral, and chromatographic methods for the determination of lysergide (IV*b*, Scheme I) were reviewed previously (1, 2), and it has been generally agreed that certain fundamental advances in microanalysis are required to detect and determine with confidence the nanogram or picogram levels, for example, of IV*b* or metabolites fleetingly present in urine or plasma after ingestion of the drug (1). A radioimmunoassay system (3) for IV*b* appears promising in this regard and was reported by one research group (4). This method (4) utilized rabbit antiserum to a lysergic acid–polylysine–hemocyanin conjugate, along with a specially synthesized lysergic acid–amino acid copolymer containing ^{125}I, and a double-antibody technique for the separation of free and bound IV*b* in the assay. Although details have not yet been reported, a commercial kit appears to be based upon similar methodology[1].

This paper reports the development and evaluation of a workable radioimmunoassay system for IV*b*. The system promises to be useful in the assay of illicit drug products or samples of biological fluids. The assay utilizes a commercially available tritiated IV*b* and specific antiserum which was obtained in large amounts from sheep after immunization with a direct covalent conjugate of lysergic acid (I) and human serum albumin (II). Separation of free and bound forms of IV*b* is achieved by the adsorption of unbound drug on dex-

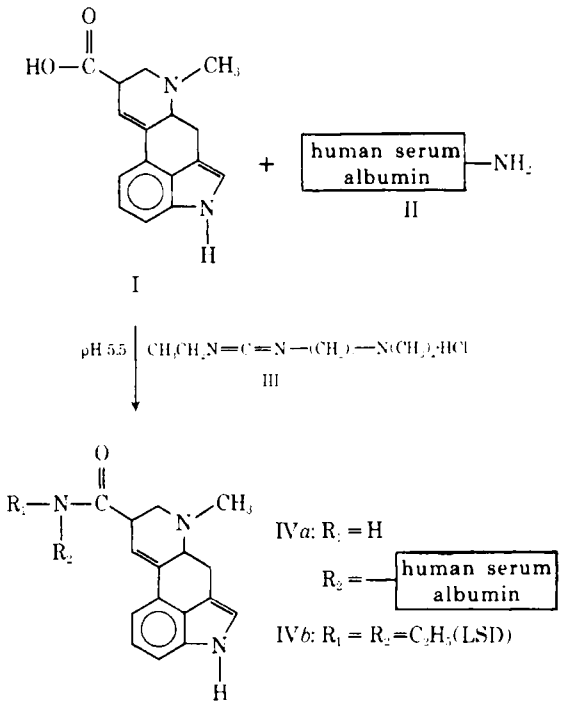

Scheme I—Covalent coupling of lysergic acid (I) to human serum albumin (II) by a water-soluble carbodiimide reagent (III), producing antigen (IVa)

tran-coated charcoal. To date, a sensitivity in the quantitative sense of about 1 ng. has been achieved using the commercially available tritiated IV*b*. Qualitatively, picogram levels may be readily detected.

EXPERIMENTAL

Materials—The following were used: human serum albumin[2] (crystalline, B grade), a coupling reagent *N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide hydrochloride[3], Freund's complete adjuvant[4], lysergide[5] (0.1 mg./ml. in ethanol), dextran[6] (radioimmunoassay grade), charcoal[6] (radioimmunoassay grade), 5-hydroxytryptamine (serotonin) creatinine sulfate complex[7], 5-hydroxy-L-tryptophan[7], tryptamine hydrochloride[7], *N*-methyltryptamine[7], 5-methoxy-*N*,*N*-dimethyltryptamine[7], octoxynol[8], 2,5-diphenyloxazole[9], and 2,2-phenylenebis(5-phenyloxazole)[9].

The D-lysergic acid[7] (I) employed in the conjugation to albumin was found to be homogeneous by TLC [silica gel, R_f 0.5, butanol–acetic acid–water (3:1:1)]. The radiolabeled lysergide[10] was generally labeled with tritium and had a specific activity of 1.9 c./mmole. General labeling refers to a random, *i.e.*, nonuniform and undetermined, distribution of tritium at various nonexchangeable positions.

Coupling of Lysergic Acid to Human Serum Albumin—To a solution of 24 mg. of lysergic acid (I) in 20.0 ml. of water containing 10% by volume ethanol was added 3.0 ml. of water containing 30 mg. human serum albumin (II) (Scheme I). To this was added in one portion a solution of 34 mg. *N*-ethyl-*N'*-(3-dimethylaminopropyl)-carbodiimide hydrochloride (III) in 2.0 ml. water. The pH of the solution was adjusted from 6.01 to 5.50 with 1 *N* HCl, and the mixture was stirred magnetically in a dark, stoppered vial at 25° for 42 hr. The reaction mixture was then placed in a dialysis bag and exhaustively dialyzed at about 5° for 1 week against distilled water, 4 *M* KCl, a buffer of pH 7.4 (0.15 *M* NaCl and 0.01 *M* phosphate), and finally water. All dialysates were measured in volume and absorbances were measured at 308 nm. (pH 7.4 buffer), the λ_{max} for lysergic acid. From absorbance measurements, it was calculated that about 5–6 mg. of lysergic acid was coupled to 30 mg. of human serum albumin. This corresponds to a content of about 40–50 moles of lysergic acid/mole of albumin in the conjugate. This value may be subject to a rather large error due to the rather low solubility of lysergic acid in the dialysate mixtures, with the possibility of precipitation, although this could not be visually observed. After dialysis, the contents of the bag were lyophilized to a fluffy off-white powder (IV*a*).

Preparation of Lysergic Acid–Human Serum Albumin Conjugate for Injection into Sheep—A solution of 4.0 mg. conjugate in 0.5 ml. pH 7.4 buffer (0.15 *M* NaCl and 0.01 *M* phosphate) was absorbed slowly into 0.8 g. partially dehydrated 7% polyacrylamide gel, which had been shredded by passing through a No. 25-gauge hypodermic needle from a syringe. The final product was desiccated to approximately 0.8 g. and placed in a 5-ml. disposable plastic syringe. Then Freund's complete adjuvant was drawn in through the needle to a volume of 4.0 ml. Immediately after vigorous shaking to resuspend the shredded gel, the mixture was injected into a sheep, using approximately 1 ml. at each of four intramuscular injection sites in both shoulders and flanks. A second sheep was injected similarly with a thoroughly emulsified mixture of 4.0 mg. of the conjugate in 1.8 ml. buffer and 2.2 ml. Freund's complete adjuvant.

Bleeding and Booster Immunization Schedule—Blood samples were collected from each animal initially, immediately prior to each booster immunization, and approximately 7–10 days after the booster. Boosters were composed of 1.0 mg. of conjugate in 4.0 ml. adjuvant–gel or emulsified adjuvant buffer and were given at 4, 6, 10, and 36 weeks after the initial injection of conjugate. Clotted blood was centrifuged after clot retraction, and the serum was decanted and kept frozen (−10°) after the addition of 0.05% sodium azide.

Radioimmunoassay Procedure: Determination of Standard Radioimmunoassay Curve for IV*b*—All samples each day were run in duplicate to obtain two consistent figures. In a typical experiment, 0.8 ml. pH 7.4 buffer (0.15 *M* NaCl and 0.01 *M* sodium phosphate) was added to each of 22 5-ml. polystyrene test tubes (12 × 75 mm.): that is, 11 sets of duplicates were run. Then 0.2 ml. buffer (or buffer containing test compound) or plasma, serum, or urine was added to make a final volume of 1.0 ml. To tubes containing plasma, 50 μl. of 0.2 *N* sodium citrate solution was also added. Next was added 10 μl. of 95% ethanol containing 1.0 ng. of randomly (nonuniformly) labeled ^{3}H-IV*b* (specific activity 1.9 c./mmole). This corresponds to about 13,000 d.p.m./tube or about 3000–4000 c.p.m. at the normal observed counting efficiency of 25–30%.

To obtain a standard calibration curve, 0–25-ng. quantities of cold IV*b* in a maximum of 100 μl. of 95% ethanol were added to selected tubes. Again to desired tubes was added 10 μl. of diluted or undiluted antiserum. After vigorous stirring for 5 sec. on a mixer (Vortex), the tubes were allowed to stand at room temperature for exactly 2 hr. After chilling to 0° for 15 min. in ice, 0.5 ml. of cold and well-mixed dextran-coated charcoal suspension[11] was added to each tube and the tube contents were mixed thoroughly once again. The tubes were then incubated for 15 min. at 0° and centrifuged in the cold (4°) for exactly 5 min. (5000 r.p.m.). Then the supernate was decanted carefully into 10 ml. of scintillation counting solution containing toluene (2 l.), octoxynol[8] (1 l.), 2,5-diphenyloxazole (12 g.), and 2,2-phenylenebis(5-phenyloxazole) (300 mg.). The samples were then counted[12].

Typical data on the composition of incubation mixtures, observed counts for a 10-min. period, and percent bound IV*b* are summarized in Table I. The channels ratio method was employed to determine counting efficiency, disintegrations per minute, and final percent binding figures. Figure 2 shows typical standard immunoassay curves obtained by plotting data of Table I or similar data. Aside from counting time, the entire procedure can be completed in about 4 hr. and involves only about 2 hr. of actual working time.

[a] The data are for samples containing pooled normal human serum (see text). Samples designated 1 contained no antiserum. All samples contained 0.8 ml. buffer, 0.2 ml. serum, and 10 μl. ethanol containing 1.0 ng. ^{3}H-IV*b*. Duplicate samples were assayed as indicated by the two figures for counts of radioactivity. The counting channel data only are shown. No dextran-coated charcoal was added to Tube 11; this, therefore, represents a standard of total counts added.

RESULTS AND DISCUSSION

As shown in Scheme I and as outlined in detail in the *Experimental* section, lysergic acid (I) was covalently coupled directly to human serum albumin (II) by the water-soluble carbodiimide derivative *N*-ethyl-*N'*-(3-dimethylaminopropyl)carbodiimide hydrochloride (III). The conjugate (IV*a*), which presumably contains lysergic acid residues coupled primarily to side-chain amino groups of lysine, thus contains all of the structural elements of IV*b* except for the two amide ethyl groupings. Calculations based upon the UV absorption maximum at 308 nm. for lysergic acid indicated binding of 40–50 moles of lysergic acid/mole of human serum albumin. Since the lysine content of this protein is about 58 residues/mole, this figure seems rather high. An abnormally high value may result from the rather low solubility of lysergic acid in aqueous buffers (filtrates from the coupling reaction), since the quantity coupled was calculated by difference.

Injection of the purified conjugate (4 mg.) in polyacrylamide gel and adjuvant at each of four injection sites in one sheep, followed by a booster injection with 1 mg. of conjugate after 4 weeks, resulted in an antiserum even after only 6 weeks which was capable of binding 35–45% of 1 ng. of radioactive IV*b* in 1 ml. of incubation mixture at a final dilution of 1:1000 and 75–85% at dilutions of 1:100. Figures 1 and 2 show percentage binding figures at various dilutions for serum obtained after the first booster immunization (6 weeks total). The binding capacity of antiserum taken from this sheep after the third and fourth boosters at 10 and 36 weeks appeared to be only slightly higher than that obtained at the 6-week period. The binding capacities of antiserum obtained from the second sheep (injected with antigen in adjuvant only, with no polyacrylamide gel) were slightly lower than those of the first sheep but were equally adequate for use in assays at the same dilutions (Figs. 1 and 2). The antiserums appear to have completely retained binding capacity after 18 months storage at −10°. Three typical standard calibration curves are reproduced in Fig. 2. Displacement of the labeled IV*b* (1.0 ng./ml.) by nonradioactive IV*b* from antiserum of final dilution 1:100 began at a concentration of about 1 ng./ml. and dropped off most dramatically between 2 and about 30 ng./ml. Final serum dilutions of 1:400 resulted in a reproducible standard

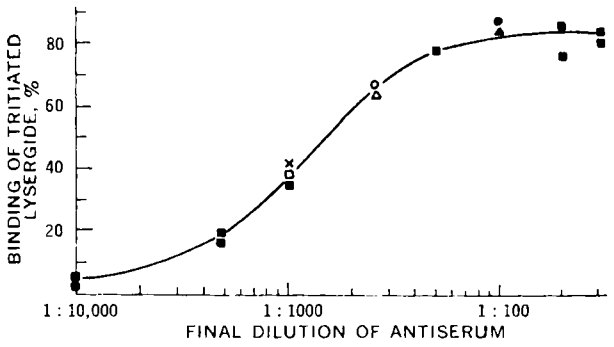

Figure 1—*Binding of tritiated lysergide (1.0 ng./ml.) by antiserum to a lysergic acid–human serum albumin conjugate. Key: ●▲○△□×, data as given in Table I and Fig. 2; and ■, additional experimental results.*

curve between 1 and 10 ng./ml. If conditions of the assay were adhered to rigidly, the standard curve varied only very slightly; however, a series of standards was always incorporated into each day's work.

The addition of up to 20% (0.2 ml./ml.) normal sheep serum, pooled normal human serum or normal human plasma, or human urine to the assay tubes did not appear to affect the shape or position of the immunoassay curves significantly. Blanks in the absence of antiserum amounted to 3–5% in all cases, and counts corresponding to this amount would have to be subtracted from unknowns. However, in all tubes containing human plasma, 50 μl. of 0.2 *N* sodium citrate was added to prevent clotting, which appeared to be triggered by the addition of the sheep antiserum. Observed binding appeared to be independent of time between 0.5 and 3 hr.; however, 2.0 hr. was employed routinely. Temperature and incubation time proved to be quite critical during adsorption of the free IV*b* to dextran-coated charcoal, and a 15-min. incubation time at 0° followed by 5 min. of centrifugation at 4° was optimum.

When using the assay procedure as described, the practical lower limit for quantitative determination of IV*b* appears to be about 1 ng. This limit is determined by the relatively low specific activity (1.9 c./mmole) of the labeled IV*b* available commercially; material of higher specific activity is too unstable for storage[13]. The use of smaller amounts of labeled IV*b* enabled detection and rough estimation of much smaller quantities of IV*b*, but the uncertainty arising from the decreased count measured increased dramatically.

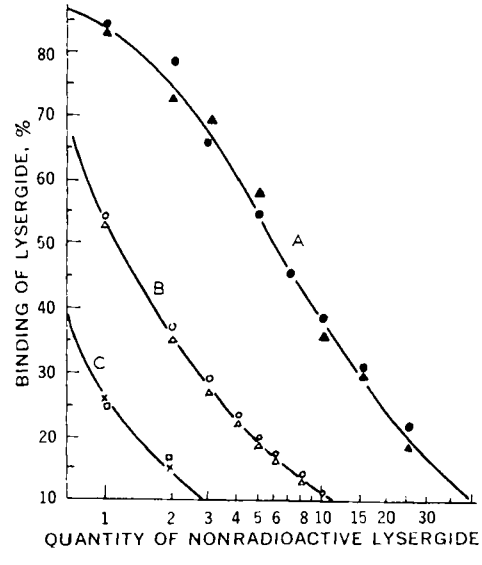

Figure 2—*Typical standard radioimmunoassay curves for the determination of lysergide at three antiserum dilutions (A, 1:100; B, 1:400; and C, 1:1000). Key: ●▲, ○△, and ×□ indicate duplicate assay results. The curves shown have not been mathematically fit.*

[13] A. Petty, New England Nuclear Corp., personal communication.

Several compounds structurally related to IV*b* were examined for their ability to cross-react with the antiserum obtained, *i.e.*, their ability to displace radiolabeled IV*b* from antibody binding sites. Antibodies were unable to distinguish among IV*b*, I, and the structurally similar ergot alkaloids ergonovine and methylergonovine. Ergotamine also exhibited cross-reactivity, but at approximately 10-fold higher concentrations. The following indoles did not exhibit any ability to displace radiolabeled IV*b* from antibody binding sites at concentrations of at least 10 mcg./ml. of incubation mixture: tryptamine, *N*-methyltryptamine, 5-methoxydimethyltryptamine, 5-hydroxytryptophan, and 5-hydroxytryptamine (serotonin). No exhaustive study of cross-reactivity was completed; however, these results compare in general with those reported by Vunakis *et al.* (4). Judging from information supplied in a commercial kit[14], antiserum produced by other methods may exhibit somewhat greater specificity. One outstanding example appears to be that these authors report little cross-reactivity with I at concentration levels similar to IV*b*, while these two compounds appear essentially indistinguishable using our antiserum.

SUMMARY

A quick and convenient radioimmunoassay system was developed for the quantitative determination of lysergide (IV*b*) in drug products, human plasma, serum, or urine at levels as low as 1 ng. or for its qualitative detection at picogram levels. Liter quantities of antiserum were obtained since sheep were employed for the production of antibodies. An advantage of the method is in its utilization of commercially available tritiated IV*b*; however, the low specific activity of this material also places a limit upon the sensitivity. The method also has the advantage of not requiring a second antibody technique for the separation of free and bound IV*b* but is based upon adsorption of free IV*b* to dextran-coated charcoal. Current efforts are directed toward the acquisition of IV*b* of higher specific activity and the development of methods utilizing immobilized antibodies for efficiently concentrating IV*b* in biological samples so that the quantitative assay may be extended to the picogram levels required in the study of the absorption, distribution, metabolism, and excretion of IV*b*. However, even in its current state the method promises to be of considerable utility in the assay of illicit drug samples and in animal investigations where larger quantities of lysergide IV*b* are employed.

Identification of a Blood Metabolite of Methsuximide by GLC–Mass Spectrometry

I. A. MUNI▲, C. H. ALTSHULER, and J. C. NEICHERIL

Abstract □ The chemical structure of a prominent methsuximide metabolite was determined by combined GLC mass spectrometry. The experimental data indicate that the metabolite is an *N*-demethylated methsuximide. A simple GLC method is described for simultaneous estimation of methsuximide and its metabolite in blood samples.

Keyphrases □ Methsuximide—identification of *N*-demethylated metabolite in blood, man and rabbits, GLC–mass spectroscopy □ GLC–mass spectroscopy—identification, methsuximide *N*-demethylated metabolite in blood □ GLC—analysis, methsuximide and *N*-demethylated metabolite in blood

An important aspect in the treatment of patients with epilepsy is the determination of an effective and safe dosage schedule of anticonvulsant drugs. The estimation of these drugs in physiological fluids, particularly in blood, provides useful metabolic information for practitioners. Many drugs used are actively metabolized *in vivo* (1–3), and the identification and quantitation of these metabolites are of considerable clinical importance.

A general procedure for the determination of anticonvulsants in blood was recently described (4). When the method was applied to patients who had been receiving methsuximide (*N*,2-dimethyl-2-phenylsuccinimide), it became apparent that the drug had been rapidly metabolized both in humans and in rabbits and that the major metabolite had GLC characteristics different than the parent drug.

The purpose of this investigation was to determine the chemical structure of the methsuximide metabolite. The GLC properties of both the human and animal

An important aspect in the treatment of patients with epilepsy is the determination of an effective and safe dosage schedule of anticonvulsant drugs. The estimation of these drugs in physiological fluids, particularly in blood, provides useful metabolic information for practitioners. Many drugs used are actively metabolized *in vivo* (1–3), and the identification and quantitation of these metabolites are of considerable clinical importance.

A general procedure for the determination of anticonvulsants in blood was recently described (4). When the method was applied to patients who had been receiving methsuximide (*N*,2-dimethyl-2-phenylsuccinimide), it became apparent that the drug had been rapidly metabolized both in humans and in rabbits and that the major metabolite had GLC characteristics different than the parent drug.

The purpose of this investigation was to determine the chemical structure of the methsuximide metabolite. The GLC properties of both the human and animal

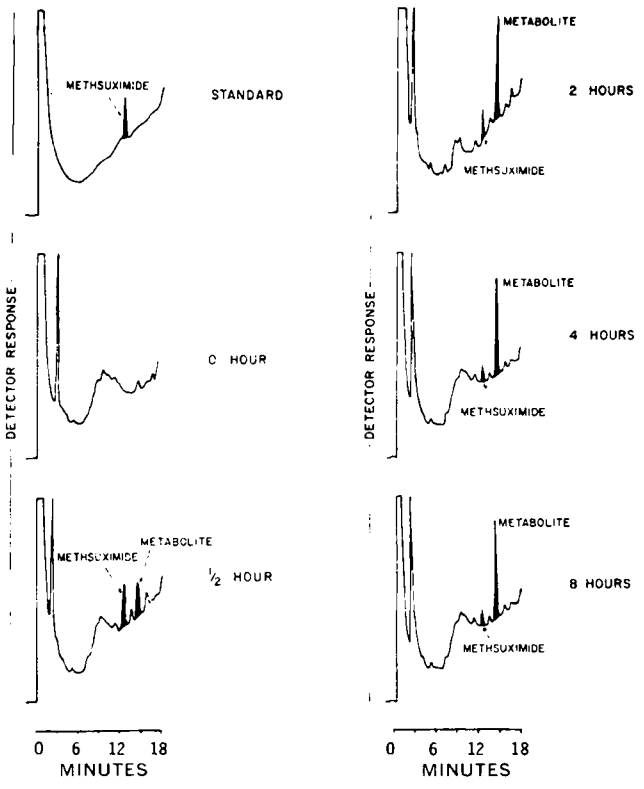

Figure 1—*Schematic diagram of methsuximide metabolism in rabbits (flame-ionization detection, 10% OV-17, 165–280°, 7.5°/min.).*

metabolite of methsuximide are similar. The present report describes its chemical characterization when separated from rabbit blood by GLC–mass spectrometry. A simple and rapid GLC method to determine the blood levels of methsuximide is also presented.

EXPERIMENTAL

Chemicals—Methsuximide[1], m.p. 50°, and methsuximide capsules[2] (300 mg.) were used. The solvents used were of analytical grade. *N,O*-Bis(trimethylsilyl)acetamide[3] was used for on-column trimethylsilylation.

Apparatus—An analytical gas chromatograph[4], equipped with a dual flame-ionization detector system, was used to monitor drug levels in blood samples. The separation was carried out on a 1.82-m. (6-ft.) long, U-shaped glass column packed with 10% OV-17 on Gas Chrom Q[5], 80–100 mesh.

The GLC–mass spectrometry[6] system interfaced to a data system[7] was used in the characterization of the methsuximide metabolite. A 0.61-m. (2-ft.) long, U-shaped glass column packed with 2% SE-30 on Gas Chrom Q[5], 80–100 mesh, was used for the separation of the metabolite. Monolinear temperature programming was used in both systems. The electron ionization energy was 70 ev. The ionization source temperature was maintained at 250°.

Procedure—*Drug Administration*—Several male rabbits, weighing 3.4–4.5 kg., were used. One methsuximide capsule (300 mg.) was administered orally to each animal, and the blood samples (about 4 ml.) were collected at intervals of 0.0, 0.5, 2.0, 4.0, and 8.0 hr.

Plasma Extraction—Two milliliters of plasma sample was acidified with 6 *N* HCl (50 μl.), and the drug as well as the metabolite was extracted with a mixture of 8 ml. of chloroform–isopropanol (9:1 v/v). The organic phase was filtered through phase-separating paper[8], and a 6-ml. sample of filtrate was concentrated to dryness at 35° under a gentle stream of nitrogen.

GLC Analysis—The dried samples were resuspended in 50 μl. of chloroform–isopropanol (1:1 v/v), and 2–5 μl. was injected into a gas chromatograph. Working standard curves of methsuximide were routinely established for drug quantitations.

GLC–Mass Spectrometry Studies—A chloroform–isopropanol extract (2 μl.) of the 4-hr. plasma sample was injected into a gas

Table I—Typical Recoveries of Methsuximide

chromatograph, and the underivatized compounds were subjected to GLC–mass spectrometry. On-column trimethylsilylation was achieved by injecting a mixture of 2 μl. of *N,O*-bis(trimethylsilyl)-acetamide and 2 μl. of concentrated blood extract. A chloroform–isopropanol solution containing standard methsuximide was also subjected to GLC–mass spectrometry analysis.

RESULTS AND DISCUSSION

The relative blood levels of methsuximide and its metabolite at 0.5, 2.0, 4.0, and 8.0 hr. after oral administration of 300 mg. of methsuximide are illustrated in Fig. 1. Methsuximide metabolizes rapidly *in vivo* to a major metabolite, and after 0.5 hr. the concentration of this metabolite in blood is relatively much higher than that of unchanged methsuximide.

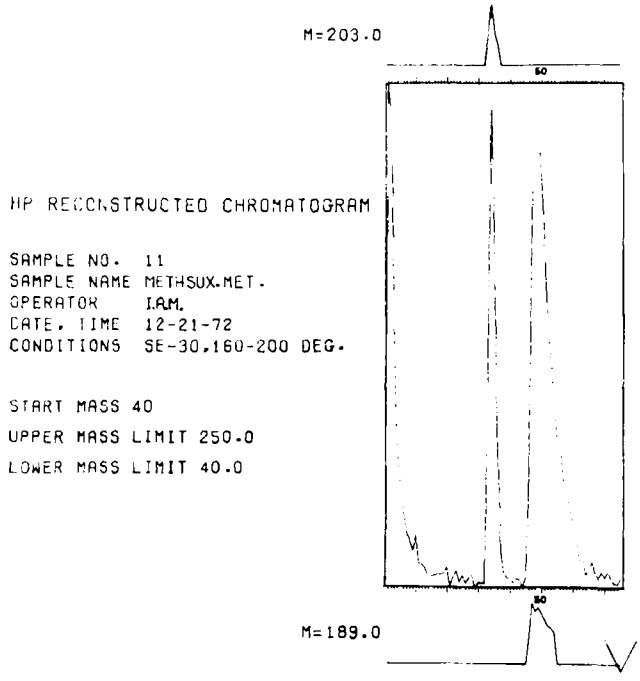

Figure 3—*Reconstructed chromatogram of plasma extract. M = 203 is a chromatographic peak for methsuximide, and M = 189 is a chromatographic peak for* N*-demethylated methsuximide.*

Table II—Relative Abundance of Several Fragment Ions of Methsuximide and Its Metabolite

Fragment Ion (*m/e*)	Relative Abundance, % Methsuximide	Relative Abundance, % Metabolite
203	10.22	– [a]
189	–	14.56
119	10.88	13.88
118	100.00	100.00
117	42.56	52.75
115	12.37	12.99
103	23.40	29.52
91	14.55	20.08
78	21.98	33.46
77	25.83	40.98
63	–	17.32
58	16.29	38.97
57	–	27.56
51	18.61	50.00
50	—	25.59
43	–	18.11
41	—	16.53

[a] Either no fragment ion was observed or the relative abundance (%) was less than 10%.

As shown in Fig. 1, methsuximide and its metabolite were successfully resolved on the OV-17 column; each compound produced a single GLC peak. Similar resolution was obtained using the SE-30 liquid phase. The flame-ionization detector gave a linear response for methsuximide, as well as its metabolite, under the experimental conditions used.

When added to plasma samples, the recoveries of methsuximide for both human and rabbit plasma were usually in the 96–103% range (Table I). Recoveries were comparable whether extractions were made immediately after adding methsuximide or after storing the plasma samples for 24–40 hr. at 5°.

As shown in Fig. 2, the mass spectra of methsuximide and its metabolite are simple, characteristic, and easy to interpret. The spectra were recorded from 0 to 650 a.m.u. In both spectra, the base peak (B) was observed at *m/e* 118 (Table II). Methsuximide and its metabolite were characterized by prominent clusters of fragment ions in the *m/e* 115–119, 73–78, and 50–58 regions. Methsuximide also showed significant peaks at *m/e* 203 (molecular ion, M), 103, and 91. The mass spectra of standard methsuximide and methsuximide extracted from blood samples were identical.

On-column trimethylsilylation resulted in a GLC peak shift for the methsuximide metabolite. The trimethylsilylated metabolite of methsuximide eluted earlier than the underivatized metabolite. On-column trimethylsilylation did not change the GLC retention time or the mass spectral characteristics of methsuximide. The mass spectrum of trimethylsilyl methsuximide metabolite showed fragment ions at *m/e* 261 (M), 246 (M − 15). 147 $[(CH_3)_2Si{=}O\ Si(CH_3)_3]$, 118, and 73 $[(CH_3)_3Si]$.

The GLC–mass spectrometry data indicate that the predominant blood metabolite of methsuximide is an *N*-demethylated methsuximide (Schemes I and II). *N*-Demethylation is the usual route of metabolism for several *N*-methylated anticonvulsant drugs (5, 6). Although demethylation ordinarily requires many hours for completion (5), metabolism of methsuximide seems to be relatively rapid in humans and animals.

Figure 3 is an illustration of the *XY* plot from the data system. The central portion of the figure is the total ion monitor output for all products with fragment ions between 40 and 250. The upper figure indicates that the first peak (scan numbers 30–40) had a fragment ion of 203, and the lower figure indicates that the second peak (scan numbers 48–58) had a fragment ion of 189.

SUMMARY

A relatively simple, rapid, and accurate GLC system is described. It was found to be useful in the monitoring of the physiological levels of methsuximide and its metabolite in one operation. The GLC–mass spectrometry data indicate that methsuximide is extensively metabolized *via N*-demethylation.

Electronic Spectra and Electronic Structures of Aminoanthracenes

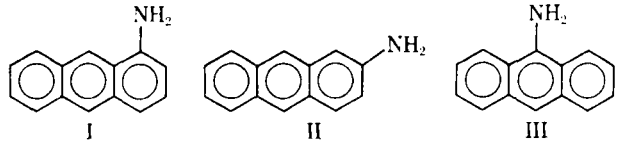
STEPHEN G. SCHULMAN▲, PETER J. KOVI, GEORGE TOROSIAN, HOWARD McVEIGH, and DORIS CARTER

Abstract □ The electronic absorption and fluorescence spectra of the cation derived from 9-aminoanthracene (9-anthrylamine), in water, are anomalous by comparison with those of the 1- and 2-anthrylammonium ions. The similarities of the spectra of the cation of 9-anthrylamine with those of anthrone and its cation lead to the conclusion that the former cation is not the 9-anthrylammonium ion but rather its tautomer, the protonated imine analogous to anthrone. In ethanol and in the solid state, measurable quantities of both the protonated imine and 9-anthrylammonium ions exist.

Keyphrases □ Aminoanthracenes—electronic spectra and electronic structures □ Absorption spectra, electronic, aminoanthracenes—determination □ Fluorescence spectra, electronic aminoanthracenes—determination □ Electronic spectra and electronic structures—determination, aminoanthracenes □ Anthrylamines—electronic spectra and electronic structures

The carcinogenicity of many polycyclic aromatic amines has been recognized since 2-naphthylamine was found to cause bladder cancers in workers in the dye industry (1, 2). Of the arylamines known to have carcinogenic properties, 1-aminoanthracene (I) and, especially, 2-aminoanthracene (2-anthrylamine) (II) are among the most virulent. However, to our knowledge, no carcinogenic properties have been reported for 9-aminoanthracene (III).

Of the functionally substituted aromatic molecules, the derivatives of anthracene have not been particularly well characterized, although many of them have been employed in the dye industry for many years. Recent studies have shown that, in particular, substitution in the 9-position of the anthracene ring often results in molecular species that are quite different in their chemical properties from other aromatic molecules (*e.g.*, benzene and naphthalene) substituted with the same functional groups. On the other hand, substitution in the 1- and 2-positions of the anthracene ring yields derivatives that are similar to the corresponding benzene and naphthalene derivatives. For example, in hydrocarbon solvents, the carboxyl groups of benzoic acid, 1- and 2-naphthoic acids, and 1- and 2-anthroic acids are coplanar and conjugated with the respective aromatic rings, while the carboxyl group of 9-anthroic acid (3) is perpendicular and unconjugated with the anthracene ring as a result of steric interference of the 9-carboxyl group with the peri hydrogen atoms in the 1- and 8-positions of the anthracene ring. Moreover, of the hydroxyanthracenes, 1- and 2-anthrols appear to be well-behaved phenolic molecules (4) while 9-anthrol exists predominately as its keto tautomer, anthrone, and only to a very slight extent as the phenolic 9-anthrol (5, 6).



I II III

Because of interests in the relationships between molecular electronic structure and biological (in this case carcinogenic) activity, the present investigation of the electronic structures of the isomeric aminoanthracenes by electronic absorption and fluorescence spectroscopy was undertaken.

EXPERIMENTAL

Reagents—The 1- and 2-aminoanthracenes[1], anthracene, and 9-aminoanthracene hydrochloride[2] were each recrystallized several times from absolute ethanol.

Analytical reagent grade sulfuric acid[3] was diluted with distilled, deionized water to prepare the solutions used to study the Hammett acidity region. Solutions in the pH range were citrate and phosphate buffers and sodium hydroxide solutions in distilled, deionized water.

Each sulfuric acid or buffer solution in a 10-ml. volumetric flask was injected with 100 μl. of a 1×10^{-2} *M* stock solution of the appropriate aminoacridine in absolute ethanol immediately prior to

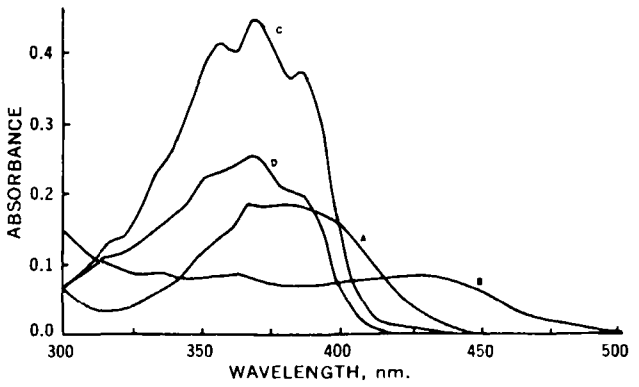

Figure 1—*Electronic absorption spectra of about 1 × 10⁻⁴ M 1-aminoanthracene (A) and 2-aminoanthracene (B) at pH 10.0 and of the respective anthrylammonium ions (C and D) at pH 1.0.*

the taking of spectra to minimize decomposition errors. The spectra of 1×10^{-5} *M* aqueous anthracene were taken in only one solution, pH 10.0.

Apparatus—Absorption spectra were taken on a spectrophotometer[4]. Fluorescence spectra were taken on a fluorescence spectrophotometer[5] whose monochromators were calibrated against the xenon line emission spectrum and whose output was corrected for instrumental response by means of a rhodamine-B quantum counter. The pH measurements were made on a pH meter[6] employing a silver-silver chloride-glass combination electrode[7]. IR spectra[8] were taken in silicone fluid.

RESULTS AND DISCUSSION

1- and 2-Aminoanthracenes—The electronic absorption spectra of 1- and 2-aminoanthracenes and their conjugate cations are shown in Fig. 1. The maxima of these and the corresponding fluorescence spectra, along with those of 9-aminoanthracene, its conjugate cation, and anthracene, for comparison, are presented in Table I.

The absorption and fluorescence spectra of the cations of the 1- and 2-isomers are highly structured and similar to those of anthracene itself. The absorption spectra of the neutral 1- and 2-aminoanthracenes, however, each show a diffuse band at ~400 nm. and a partially overlapping vibrational structured band at shorter wavelengths. The fluorescence spectra of the neutral amines are unstructured and lie at wavelengths (~500 nm.) much longer than those of the fluorescence of anthracene (~400 nm.). These spectra are typical of anthracene derivatives and of amino- and ammonium-substituted aromatics and may be explained as follows.

The absorption spectrum of anthracene in the 300–500-nm. region is comprised of two electronic transitions, designated $^1L_a \leftarrow {}^1A$ and $^1L_b \leftarrow {}^1A$ in Platt's system of classification of electronic transitions (7). ^1A designates the ground singlet state, and ^1L_a and ^1L_b are the two lowest electronically excited singlet states. The ^1L_a and ^1L_b

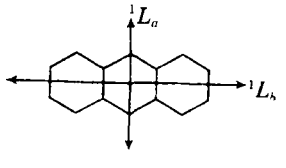
[a] The corresponding spectral features of anthracene in water (pH 10.0) are given for comparison. Spectral maxima are reported in nanometers.

states are derived from the promotion of an electron from the highest occupied π-orbital in the ground state to either of the two lowest unoccupied orbitals (π*) of the anthracene molecule (Scheme I).

In anthracene, the molecular skeleton is fairly rigid, restricting the vibrational freedom of the molecule. The vibrational subtransitions accompanying the electronic transitions occur with essentially no readjustment of the nuclear positions (vibrational motion) during electronic transition. This is a result of the greater rate of the average electronic transition (~10^{15} sec.$^{-1}$) compared with that of the average vibrational transition (~10^{14} sec.$^{-1}$) and represents a statement of the Franck–Condon principle (8, 9). As a result, the vibrational sublevels to which absorption takes place are well defined (quantized) and the vibrational-electronic (vibronic) fine structure of the absorption bands is thus distinct in anthracene. The $^1L_b \leftarrow {}^1A$ transition is polarized along the long axis and the $^1L_a \leftarrow {}^1A$ transition along the short axis of anthracene (Scheme II).

In smaller aromatic molecules (10) (*e.g.*, benzene and naphthalene), the $^1L_a \leftarrow {}^1A$ and $^1L_b \leftarrow {}^1A$ transitions are well resolved, with the $^1L_b \leftarrow {}^1A$ absorption lying at longer wavelengths. In higher aromatics (*e.g.*, tetracene and pentacene), the absorption bands representing the $^1L_a \leftarrow {}^1A$ transitions occur at longer wavelengths than $^1L_b \leftarrow {}^1A$ transitions (10). In anthracene, the absorption bands representing the two transitions overlap to such an extent that they are indistinguishable. However, it is generally believed that the long wavelength side of the $^1L_b \leftarrow {}^1A$ band lies at longer wavelengths than the $^1L_b \leftarrow {}^1A$ band in anthracene.

The introduction of an amino group into the anthracene ring affects the spectra in ways that depend upon the site of substitution in the ring. The amino group has a lone electron pair residing in an orbital on the nitrogen atom, with sp^3 hybrid characteristics. Although this orbital is not perpendicular to the anthracene ring, as are the carbon $2p_z$ orbitals comprising the π-system of the ring, it has a substantial component in that direction; therefore, some in-



Scheme II—Polarizations of the two lowest π → π transitions of anthracene*

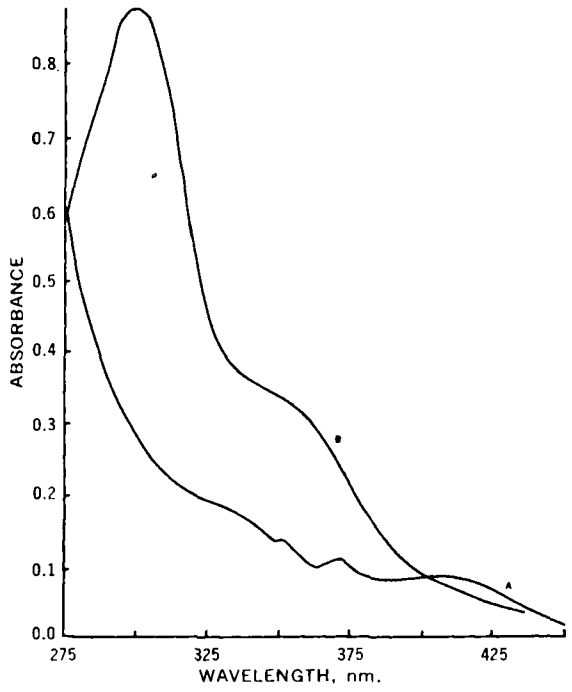


Figure 2—*Electronic absorption spectra of about 1 × 10⁻⁴ M 9-aminoanthracene (A) at pH 10.0 and of the protonated species derived from 9-aminoanthracene (B) at pH 1.0.*

teraction between the lone-pair and the π-system is to be expected even in the ground electronic state (conjugation or resonance interaction). Upon excitation, however, an electron may be transferred completely from the nitrogen lone-pair into a vacant π^*-orbital of the aromatic ring (intramolecular charge-transfer transition). This process results in greater conjugation of the amino group with the aromatic ring and produces rehybridization of the amino nitrogen atom to an sp^2-type configuration (coplanar with the ring) during the electronic transition [*i.e.*, the Franck-Condon principle is violated (11)].

In the perturbation model of aromatic substitution (12), the lone-pair orbital is at higher energy than the highest occupied π-orbital of the ring in the ground state. This occurs because the lone-pair electrons are not as stabilized as the π-electrons by the π-bonding interaction. Because the lone-pair orbital is higher in energy than the highest occupied π-orbital, the lowest energy transitions of the amino derivatives occur at lower energies (or longer wavelengths) than the lowest energy $\pi \rightarrow \pi^*$ transitions of anthracene itself. The promotion of an electron from the lone electron pair of the amino group is said to mix charge transfer into the $\pi \rightarrow \pi^*$ transitions of the parent hydrocarbon (in the terminology of the perturbation model). The rehybridization of the amino group during the absorption process results in the loss of vibrational structure in those transitions having a great deal of charge-transfer character. Because of the transition polarizations and orbital properties (charge densities) associated with the ^1L_a and ^1L_b excited states (the two lowest excited states), substitution in the 1- and 9-positions (α-positions) of the anthracene ring by an amino group introduces considerable charge-transfer character and vibrational blurring into the $^1L_a \leftarrow {}^1A$ transition of anthracene and practically none into the $^1L_b \leftarrow {}^1A$ transition. This is a result of the colinearity between the $^1L_a \leftarrow {}^1A$ transition, the direction of transfer of charge into the ring from an amino substituent in an α-position, and the perpendicularity between the $^1L_b \leftarrow {}^1A$ transition moment direction and that of charge transfer from an α-amino group. On the other hand, β-substitution (in the 2-position of anthracene) of an amino group results in a large angle between the $^1L_a \leftarrow {}^1A$ transition moment vector and the vector associated with the direction of charge transfer from a β-amino group to the anthracene ring but a much smaller angle between the latter and the $^1L_b \leftarrow {}^1A$ transition moment vector. Consequently, the $^1L_b \leftarrow {}^1A$ transition has the greatest degree of charge transfer, exhibits vibrational blurring, and lies at the longest wavelengths in 2-aminoanthracene while the $^1L_a \leftarrow {}^1A$ transition is only slightly affected.

Protonation of the nitrogen atoms of the anthrylamines removes the lone-pairs from conjugation with the aromatic system, so the spectra of all of the anthrylammonium ions are very close in appearance to that of anthracene, with slight displacements to longer wavelengths because the positive field effect of the ammonium substituent stabilizes the dipolar excited states slightly more than the nearly apolar ground states.

Fluorescence in 1-anthrylamine corresponds to the $^1L_a \rightarrow {}^1A$ transition; in 2-anthrylamine, it arises from the $^1L_b \rightarrow {}^1A$ transition because the ^1L_a and ^1L_b states are the lowest excited singlet states in the 1- and 2-isomers, respectively. During fluorescence, charge is transferred back from the anthracene ring to the amino group and is accompanied by rehybridization of the amino group from an sp^2 to an sp^3 situation. Consequently, the fluorescence bands of 1- and 2-aminoanthracenes are diffuse. That the fluorescence bands of the 1- and 2-aminoanthracenes appear at a much longer wavelength than the corresponding absorption bands is the result of a high energy of solvent cage reorientation, subsequent to excitation, which is reflected in the fluorescence but not in the absorption spectrum, and a small energy of solvent cage reorientation subsequent to emission, which is reflected in the absorption but not in the fluorescence spectrum (13). This is generally observed in intramolecular charge-transfer transitions of molecules which are more polar in the excited state than in the ground state.

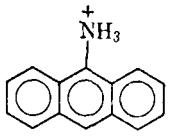
The fluorescences of the 1- and 2-anthrylammonium ions are similar to those of anthracene and, lacking intramolecular charge-transfer properties, are highly structured. On the basis of the present experiments, it cannot be stated with certainty whether the fluorescences of the anthrylammonium ions originate from the ^1L_a or ^1L_b states.

The similarities between the absorption and fluorescence spectra of anthracene and the anthrylammonium ions are typical of the spectroscopic behavior of arylammonium ions. For example, the spectra of the anilinium ion are similar to those of benzene, while the spectra of the 1- and 2-naphthylammonium ions are similar to those of naphthalene (14–16). Moreover, the differences between the absorption and fluorescence spectra of anthracene and the 1- and 2-anthrylamines are comparable to the differences between the absorption and fluorescence spectra of benzene and aniline and between those of naphthalene and the 1- and 2-naphthylamines. Thus, in the electronic structural sense, the 1- and 2-aminoanthracenes and their conjugate cations may be considered to be well-behaved aminoanthracenes and anthrylammonium ions, respectively.

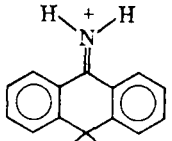
The pKa values for the prototropic equilibria at 25° between the 1- and 2-aminoanthracenes and their respective conjugate cations were determined by spectrophotometric pH titration and are: 1-aminoanthracene, 3.85 ± 0.00; and 2-aminoanthracene, 4.00 ± 0.04. These pKa values are representative of arylamines in general. Moreover, the slightly more acidic pKa of the 1-isomer is consistent with the weaker basicity of α-arylamines relative to β-arylamines. For example, the pKa of 1-naphthylamine is 3.92 and that of 2-naphthylamine is 4.11 (17). This difference is derived from the greater degree of conjugative interaction in α-positions than in β-positions of linearly annellated polyacene rings. The pKa values support the conclusion that the 1- and 2-aminoanthracenes and their conjugate cations are chemically well-behaved arylamines and arylammonium ions, respectively.

9-Aminoanthracene—The electronic absorption spectra of 9-aminoanthracene in alkaline and acidic aqueous solutions are shown in Fig. 2. The principal maxima of these spectra are listed in Table I. The absorption and fluorescence spectra of the neutral molecule (in alkaline solution) are similar to those of 1- and 2-aminoanthracenes. Because the 9-isomer is an α-substituted anthracene, the longest wavelength, diffuse absorption band must arise from the $^1L_a \leftarrow {}^1A$ transition while the shorter wavelength, structured band represents the $^1L_b \leftarrow {}^1A$ transition. The fluorescence of the neutral 9-isomer corresponds to the $^1L_a \rightarrow {}^1A$ emission. The spectra of 9-aminoanthracene indicate that it is a typical derivative of anthracene.

The spectra of 9-aminoanthracene in aqueous acidic media are quite different from those of the 1- and 2-anthrylammonium ions and of anthracene. The absorption spectrum of the cation derived from 9-aminoanthracene shows an intense structureless band at 301 nm. with a less intense structureless shoulder at 340 nm. This spectrum is similar in general appearance to the absorption spectrum of anthrone (6), whose intense band and shoulder lie at 275 and 305



IV



V

nm., respectively, and to that of the conjugate cation of anthrone (6), whose intense band and shoulder should occur at 351 and 375 nm., respectively (anthrone is the keto tautomer of 9-anthrol). The fluorescence of the cation derived from 9-aminoanthracene is structureless and has its maximum at 450 nm. Anthrone does not fluoresce, presumably because its lowest excited singlet state is of the n,π^*-type and favors radiationless deactivation of the lowest excited singlet state (18). However, the cation derived from anthrone demonstrates a structureless fluorescence band with a maximum at 475 nm.

That the absorption spectrum of the cation derived from 9-aminoanthracene, in water, lies at much shorter wavelengths than that of anthracene and lacks the characteristic vibrational structure of anthracene or the typical anthrylammonium ions indicates that the extended aromaticity of the anthracene ring in the cation has been disrupted. The similarity between the absorption spectra of the protonated amine and the neutral and protonated ketone, anthrone, strongly suggests that the cation of 9-aminoanthracene in water is not the 9-anthrylammonium ion (IV) but rather a tautomeric protonated imine (V). The similarities between the electronic structures of V and those of anthrone and its cation are obvious, thereby accounting for the similarities between their absorption spectra.

The absorption spectrum of V may be considered to be that of benzene substituted with an electron-withdrawing group. The intense band at 301 nm. corresponds to the $^1L_a \leftarrow {}^1A$ transition in benzene, and the shoulder at 340 nm. corresponds to the $^1L_b \leftarrow {}^1A$ transition in benzene. The ^1L_a and ^1L_b absorption bands of benzene, however, lie at 203 and 255 nm., respectively. The corresponding bands in anthrone, its cation, and V lie at much longer wavelengths because of the charge-transfer character mixed into the lowest excited singlet states of benzene by interaction with the vacant π-orbital of the keto, protonated keto, or protonated imino group. In anthrone, its cation, and V, the lower absorptive transitions entail transfer of an electron from the benzene ring to the electron-acceptor keto, protonated keto, or protonated imino functional group. The greater the electron-withdrawing strength of the electron-acceptor group, the lower are the energies of the long wavelength absorption bands. The order of the wavelengths of the absorption spectra, anthrone < protonated 9-aminoanthracene < protonated anthrone, follows from the greater electron-withdrawing capability of the protonated imine relative to anthrone by virtue of the formal positive charge on the nitrogen atom. The greater electron-withdrawing capability of protonated anthrone relative to the protonated imine is derived from oxygen's electronegativity being greater than that of nitrogen. The latter reasoning also accounts for the longer wavelength of fluorescence of protonated anthrone relative to that of the protonated imine.

The pKa 6.34 of the 9-isomer is anomalously high for an arylamine and supports the chemical distinction of at least one member of the 9-anthrylamine–protonated 9-anthrylamine conjugate pair from the corresponding species derived from 1- and 2-anthrylamines. Moreover, the pKa values of the anthrylamines are such that, except in the stomach, the 1- and 2-isomers are essentially entirely in the neutral form *in vivo*, while the 9-isomer is appreciably protonated at all biological pH's.

The keto–enol tautomerism of anthrone has been shown to favor quantitatively the keto form in water (6). In lower dielectric media, however, the enol form, although never predominant, exists in measurable amounts. Correspondingly, in acidic ethanol solutions a structured absorption band, with vibronic maxima at 386, 366, and 348 nm., appears in the spectrum of protonated 9-aminoanthracene in addition to the diffuse ^1L_a and ^1L_b bands of the protonated imine structure which lie at 294 and 325 nm. in ethanol, respectively. The structured absorption band in acidic ethanol has the appearance and position in the spectrum characteristic of an anthrylammonium ion and is thus assigned to the 9-anthrylammonium ion (IV). IR spectra of the commercial sample of 9-aminoanthracene hydrochloride showed carbon–nitrogen stretching frequencies at 1588 and 1400 cm.$^{-1}$. The latter is characteristic of arylammonium ions, and the former is characteristic of imino groups. In contrast, the IR spectra of the hydrochlorides of the 1- and 2-aminoanthracenes demonstrated only the ammonium-type C–N stretch at 1405 and 1400 cm.$^{-1}$, respectively. Hence, in the solid state, both the arylammonium and protonated imine tautomers of the cation from 9-aminoanthracene are stable. This serves to point out that IR spectra taken in nonaqueous media may be of only limited value in establishing the chemical natures of species present in biological systems. Electronic absorption and fluorescence spectroscopy, however, when applicable, are not subject to restriction to nonaqueous circumstances, often imposed upon IR measurements. Moreover, the electronic spectroscopic methods are more sensitive and less subject to interference by impurities.

Separation and Identification of Morphine and Its Metabolites and Congeners

S. Y. YEH

Abstract □ Morphine and its known and postulated metabolites and congeners, *i.e.*, morphine *N*-oxide, normorphine, pseudomorphine, morphine-*N*-methyl iodide, codeine, norcodeine, morphine-3-glucuronide, and morphine ethereal sulfate, were separated by TLC and GLC. The R_f values of nalorphine and nicotine and its metabolites and the retention times of nalorphine and seven other chemicals commonly used for GLC quantitative determination of morphine and codeine are also presented.

Keyphrases □ Morphine and metabolites—separation, identification, TLC and GLC □ TLC—separation, identification, morphine and metabolites □ GLC—separation, identification, morphine and metabolites

Studies in various animal species have shown that morphine is biotransformed to morphine-3- and 6-glucuronide (1–5), morphine-3-ethereal sulfate (6–8), morphine *N*-oxide (9, 10), normorphine (11–14), and codeine (15). Pseudomorphine (16), an oxidation product of morphine, and morphine glutathione (17) have also been postulated to be metabolites.

While investigating the pharmacokinetics and metabolism of morphine in man, need arose for the development of suitable methods for separation and identification of morphine and its metabolites. Although many procedures, including TLC and GLC, have been described for separation of morphine from its congeners, as mentioned in recent reviews (18, 19), none has been described for separation of morphine from its metabolites. This report describes the application of TLC and GLC for the separation and identification of these compounds.

EXPERIMENTAL

Morphine sulfate USP[1], codeine phosphate USP[1], and normorphine hydrochloride[2] were obtained. Pseudomorphine, morphine *N*-oxide, and morphine-*N*-methyl iodide were prepared by previously described methods (20–22). Morphine-3-glucuronide and morphine-3-ethereal sulfate were isolated from the urine of dog and cat, respectively (4, 8).

TLC[3]—The compounds were localized after development by spraying with potassium iodoplatinate reagent or ninhydrin reagent.

GLC—A chromatograph[4] equipped with dual-flame-ionization detectors and dual-pen recorders[5] was used for GLC. The columns (Table II) were conditioned at 275° under nitrogen, 30 ml./min., for 1 hr.; then at 340° without nitrogen for 4 hr.; and finally at 290° with nitrogen, 16 ml./min., for 72 hr. The temperatures of injector and detector were set at 255 and 295°, respectively; gas flow rates were 30 ml./min. for nitrogen and hydrogen and 300–400 ml./min. for compressed dried air.

Silylation of Morphine and Its Metabolites and Congeners—Methanol solutions of morphine, codeine, normorphine, norcodeine, morphine *N*-oxide, and morphine-*N*-methyl iodide were placed in acylation tubes[6] and evaporated to dryness under nitrogen in a water bath at 60–70°. To the residues were added 0.05 ml. acetonitrile and 0.05 ml. of bis(trimethylsilyl)trifluoroacetamide plus 10% trimethylchlorosilane[7]. The tubes were capped and shaken on a Vortex mixer for about 10 sec. After heating at 60–70° for 30 min., 1 μl. of the mixture was injected into the gas chromatograph.

Acetylation of Morphine and Its Metabolites and Congeners—Methanol solutions of morphine, codeine, normorphine, norcodeine, morphine *N*-oxide, and morphine-*N*-methyl iodide were placed in acylation tubes and evaporated to dryness under nitrogen in a water bath at 60–70°. The residues were either trifluoroacetylated with 0.2 ml. of trifluoroacetic anhydride or acetylated with 0.2 ml. of acetic anhydride and 0.1 ml. of pyridine. The tubes were sealed with screw caps, and the mixtures were warmed for 30 min. in an oil bath at 60–70°. Excess trifluoroacetic anhydride or acetic anhydride was removed under a stream of nitrogen in an oil bath. The residues were dissolved with 0.1 ml. of ethyl acetate by shaking on a Vortex mixer for 10 sec. One microliter of the solutions was injected into the gas chromatograph.

RESULTS AND DISCUSSION

TLC Separation of Morphine and Its Metabolites and Congeners—The R_f values of morphine and its metabolites, obtained with various thin-layer plates and developing solvent systems, are presented in Table I. A good separation of morphine from other free compounds, with the exception of norcodeine, was obtained with the silica gel precoated plates developed with a solvent mixture of ethyl acetate–methanol–ammonium hydroxide (17:2:1) or with the instant silica gel sheet developed with a mixture of *n*-butanol–*n*-

[a] Morphine-*N*-methyl iodide gave two peaks which may arise from thermal decomposition. [b] Trimethylsilyl-pseudomorphine did not emerge from the column at 290° after 1 hr. [c] The retention time for trifluoroacetyl-pseudomorphine was obtained at a column temperature of 290°.

butyl ether–ammonium hydroxide (25:70:2). Morphine and one spot of the resin[8] extract of a urine from a cigarette smoker had approximately the same R_f value on the silica gel plates. The two spots could be distinguished by their color after spraying with iodoplatinate reagent. Morphine had a blue-purplish color and the nicotine metabolite was gray. Also, the nicotine metabolite moved slightly ahead of the morphine.

Conjugated morphine metabolites, *i.e.*, morphine-3-glucuronide and morphine-3-ethereal sulfate, could be separated from the free drugs on the instant silica gel sheets developed either with ethyl acetate–methanol–ammonium hydroxide (28% ammonia) (17:2:1) or with *n*-butanol–acetic acid–water (35:3:10).

GLC Separation of Morphine and Its Metabolites and Congeners—The GLC data for morphine and its metabolites are presented in Table II. An earlier report (23) that silyl derivatives of norcodeine and normorphine were retained in the 3% SE-30 column (Column 1) even at 250° was in error. The error, which might be due to the incompleteness of the silylation of these compounds or to the low concentrations of these compounds applied, should be corrected with the present data. Since the trimethylsilyl derivatives of morphine and its metabolites could not be completely separated with the 0.91-m. (3-ft.) 3% OV-17 Column 2, the 1.82-m. (6-ft.) 3% OV-17 Column 3, or Column 1, acetyl derivatives of morphine and its free metabolites were prepared and examined with these columns. Good separations of these compounds, except morphine *N*-oxide and morphine, were obtained with Columns 1–3.

These data agree well with earlier data (25), except the retention times were longer in the present study. The difference in retention times was apparently due to the different size of supports used. The retention times of acetylnormorphine and acetylnorcodeine on Column 1 at 215° was too long for practical use, and the curves tailed. With temperature programming, the retention times of these compounds were considerably shortened and the peaks sharpened. The retention times of acetyl derivatives of codeine, morphine, norcodeine, and normorphine on Column 1, using temperature programming from 205 to 250° at 2°/min., were 7.3, 9.5, 16.4, and 18.2 min., respectively. Since the retention times of the acetyl derivatives of normorphine and norcodeine on Columns 1–3 were quite long and the curves tailed, trifluoroacetyl derivatives were prepared and examined on these columns.

The trifluoroacetyl derivatives of morphine and its free metabolites, except morphine *N*-oxide and normorphine, could be separated very well with Column 1 and gave sharp peaks (Fig. 1B).

Table III—Retention Time (Minutes) of Chemicals Used as Internal Standards for Quantitative Determination of Morphine and Its Metabolites

Compounds	Column 1, 100–120 Varaport			Column 2 (0.91-m.), 60–80 Gas Chrom Q			Column 3 (1.82-m.), 60–80 Gas Chrom Q		
	200°	205°	215°	200°	205°	215°	200°	230°	250°
Trifluoroacetyl-nalorphine	8.1	6.9	4.8	9.8	7.1	5.1	—	8.0	4.1
Tetraphenylethylene	10.6	8.5	6.1	19	15	10.2	>37	16.7	8.0
Cholestane	35	23.5	15.0	23.5	18.2	12	>30	22.0	10.5
Docosane	4.3	3.4	2.0	2.2	1.6	0.9	5.5	2.0	1.0
Tetracosane	8.2	6.6	4.5	3.6	3.0	2.2	11.8	4.2	1.8
Octradosane	33	25.5	17.4	16.0	12.8	8.0	>30	13.0	5.8
Methylarachidate	6.5	4.7	3.5	5.3	3.5	2.4	13.0	4.1	2.1
Methylbehanate	12.4	9.6	6.4	8.9	6.9	4.7	27.3	7.8	7.0

These compounds, except codeine and morphine *N*-oxide, could also be completely separated with Column 2 (Fig. 1A). The trifluoroacetyl-normorphine and trifluoroacetyl-norcodeine on Columns 2 and 3 showed some tailing. The retention time of trifluoroacetyl-pseudomorphine, prepared by heating pseudomorphine with trifluoroacetic anhydride for 2 hr., was 53 min. on Column 1 at 290°. Trifluoroacetyl-pseudomorphine did not emerge from Columns 2 and 3 at 290° for 2 hr. Trimethylsilyl-pseudomorphine, prepared by heating the compound with 0.1 ml. acetonitrile and 0.1 ml. bis(trimethylsilyl)trifluoroacetamide plus 10% trimethylchlorosilane at 60–70° for 2 hr., did not emerge from Columns 1–3 at 290° for 2 hr. Silylation or acetylation, either with trifluoroacetic anhydride or acetic anhydride, could be accelerated by heating the mixture in a screw-capped sealed tube at 60–70° for 0.5 hr. Acetylation with trifluoroacetic anhydride could not be completed without heating for at least 24 hr. During the preparation of this paper, a similar procedure for acetylation of codeine and its metabolites with trifluoroacetic anhydride appeared in the literature (24).

The trifluoroacetyl derivatives of morphine and its metabolites were quite unstable and lost their trifluoroacetyl moiety on standing in air or in ethyl acetate solution. Therefore, the mixture should be kept sealed in the trifluoroacetic anhydride medium until a few hours prior to injection. After removing the excess trifluoroacetic anhydride and dissolving the residue with ethyl acetate, the solution should be injected within a few hours. A low sensitivity was obtained when the solution was stored overnight. Trifluoroacetyl-morphine *N*-oxide was very unstable in ethyl acetate; the solution became yellow within 1 hr.

The retention times of seven other chemicals, which are commonly used as internal standards for quantitative determination of morphine and its metabolites and congeners by GLC, were determined on Columns 1–3 (Table III). The retention times varied with changes in temperature and type of column, but the basic pattern remained the same. Nalorphine has been suggested as an internal standard to be added to the urine for determination of morphine (25). The retention time of trifluoroacetyl-nalorphine on Column 1 interfered with the retention time of trifluoroacetyl-norcodeine; on Column 2, it interfered with that of trifluoroacetyl-codeine. Among the chemicals examined, tetraphenylethylene was the best internal standard for quantitative determination of trifluoroacetyl-morphine or trifluoroacetyl-codeine and their metabolites on Column 1.

Urinary disposition of narcotics is being currently investigated with the described TLC and GLC procedure. Quantitative determinations of urinary disposition of morphine in morphine-dependent subjects have been reported elsewhere (26).

Spectrophotometric Determination of Ampicillin in Presence of Hetacillin

PETER M. MONTELEONE▲, MICHAEL K. VASILJEV, and JOSEPH BOMSTEIN

Abstract □ A procedure was developed for measuring small amounts of ampicillin in hetacillin bulk powders and formulations. The method depends on forming a UV-absorbing compound with Ni (II) in dimethyl sulfoxide. The response is linear over a 15-fold range and accuracy is generally better than ±5–10% except near the minimum sensitivity level. Procedural details and data for the effects of operating parameters are presented.

Keyphrases □ Ampicillin—spectrophotometric determination in presence of hetacillin □ Hetacillin, bulk powders and formulations—spectrophotometric determination of small amounts of ampicillin □ Nickel (II)-dimethyl sulfoxide reagent—used in spectrophotometric determination of ampicillin in hetacillin powders and formulations □ UV spectrophotometry—determination of small amounts of ampicillin in hetacillin powders and formulations

Hetacillin is a recently introduced broad-spectrum antibiotic. Its preparation and physicochemical properties (1) and pharmacological studies (2, 3) were reported. Hetacillin, which possesses an imidazolidinyl moiety, equilibrates with ampicillin, and this equilibrium was studied *in vitro* (4, 5). The superior solution stability of hetacillin compared to ampicillin was pointed out (5).

To take full advantage of the stability of hetacillin, it is important to manufacture a product having, at most, a low level of ampicillin and to monitor the ampicillin content analytically in the presence of bulk hetacillin.

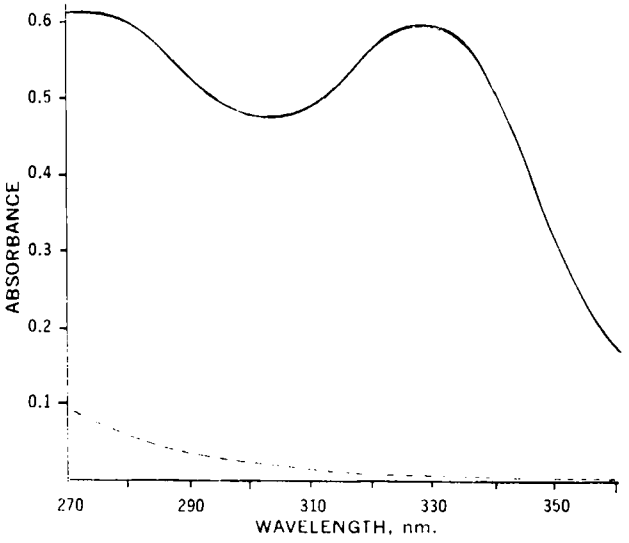

Figure 1—*Absorption spectra for ampicillin trihydrate with (——) and without (- - - -) Ni (II) in dimethyl sulfoxide. Ampicillin trihydrate concentration = 28 mcg./ml.*

Published methods for determining ampicillin depend on one of the following techniques: microbiological response (6), iodometry (6), hydroxamation (6), conversion to the penicillenic acid (7), or conversion to a fluorescing species (8). All of these approaches involve reaction and/or measurement in water. The rate of attainment of the hetacillin–ampicillin equilibrium in this medium, however, is too great to permit the selective determination of ampicillin. Both compounds are poorly soluble in nonpolar solvents, but they dissolve readily in the aprotic solvent dimethyl sulfoxide. The particular advantage of dimethyl sulfoxide, of course, is that the absence of water would be expected to inhibit the formation of ampicillin. By taking advantage of the presumed stability of hetacillin in dimethyl sulfoxide, the solubility of certain transition metal ions in the same solvent (9), and the tendency of amino compounds to form metal complexes, several organic compounds of interest were studied. This paper reports the use of Ni (II) in dimethyl sulfoxide to measure low levels of ampicillin in hetacillin and confirms the stability of the latter in this medium.

EXPERIMENTAL

Ni (II)–Dimethyl Sulfoxide Reagent—Stir 2.6 g. of finely powdered nickel sulfate ($NiSO_4 \cdot 6H_2O$) in 1 l. of dimethyl sulfoxide (ACS grade) for 5 hr. in a stoppered bottle. Filter through filter paper[1] to give a clear yellow solution containing about 0.5 mg. Ni (II)/ml., as determined by disodium edetate (EDTA) titration. The solution is stable indefinitely when protected from moisture.

Penicillins—Standard reference grade ampicillin trihydrate (99.2% purity) and hetacillin (97.0% purity) were used throughout.

Microbiological Analyses—The disk-plate method[2] (10), using a medium prepared by overlaying BBL Base Agar 10944 with BBL Seed Agar AA#1 and inoculated with *Sarcina lutea* (ATCC 9341), was used.

Spectrophotometry—Readings were taken on two spectrophotometers[3] in 1-cm. cells.

Analytical Procedure for Ampicillin in Hetacillin—*Standard Curve*—Dissolve 100 mg. ampicillin trihydrate in 100 ml. dimethyl sulfoxide. Dilute 5.00 ml. of this solution to 100 ml. with dimethyl sulfoxide. To five 25-ml. volumetric flasks, transfer respectively 0, 5.00, 10.00, 15.00, and 20.00 ml. of the previous solution, add 5.00 ml. of Ni (II)–dimethyl sulfoxide reagent to each, and dilute to volume with dimethyl sulfoxide. Stopper, heat exactly 10 min. at 50° in a

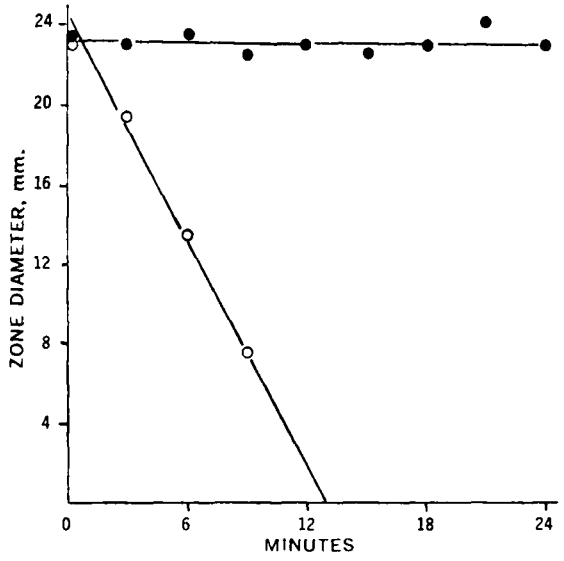

Figure 2—*Comparison of the reactivity of hetacillin (●) to ampicillin (○) when heated with Ni (II)-dimethyl sulfoxide at 50° for various times and assayed by the disk-plate microbiological method. Initial solutions had a potency of 20 mcg./ml.*

water bath, cool to room temperature, and measure the absorbance at 330 nm. against the standard containing no ampicillin as a blank. Plot absorbance *versus* concentration to obtain the standard curve.

Samples—Dissolve in dimethyl sulfoxide to contain 200 mcg. ampicillin/ml. Dilute a 10.00-ml. aliquot to 100 ml. with dimethyl sulfoxide. Pipet 20.00 ml. into a 25-ml. volumetric flask, add 5.00 ml. of Ni (II)-dimethyl sulfoxide reagent, and proceed in the same way as for standards.

EFFECTS OF ANALYTICAL VARIABLES

Figure 1 is the absorption spectrum for the product of the Ni (II)-dimethyl sulfoxide reaction with ampicillin trihydrate. Also shown is the absorption spectrum obtained when the same amount of ampicillin trihydrate is heated for 10 min. in dimethyl sulfoxide at 50° without the addition of Ni (II)-dimethyl sulfoxide reagent. Hetacillin, when treated with Ni (II)-dimethyl sulfoxide reagent under the same conditions as the ampicillin trihydrate, gave no significant absorbance at 330 nm.

The lack of reactivity of hetacillin to the Ni (II)-dimethyl sulfoxide reagent was also demonstrated by a microbiological method. In Fig. 2 the diameters of the zones of inhibition are plotted *versus*

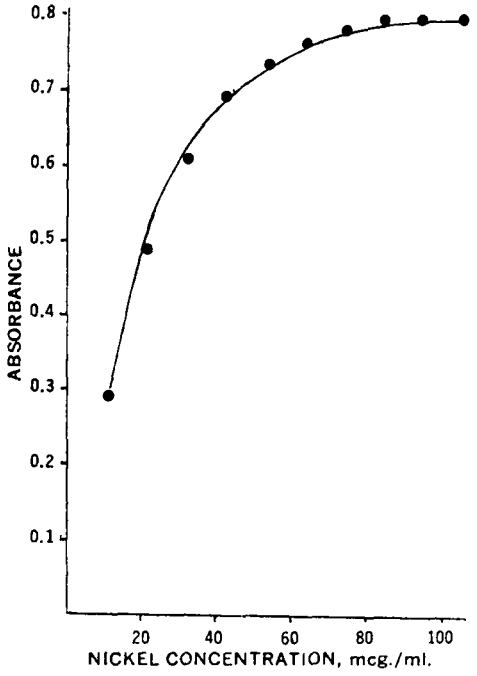

Figure 4—*Effect of Ni (II) concentration on the reaction of ampicillin with Ni (II) in dimethyl sulfoxide. Ampicillin trihydrate concentration = 38 mcg./ml.*

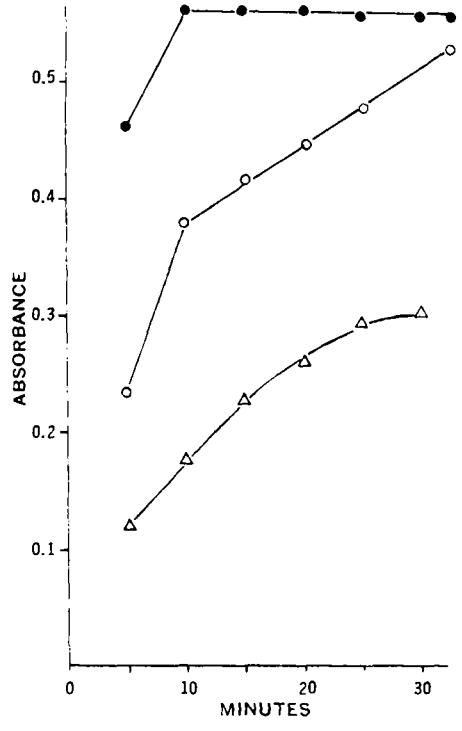

Figure 3—*Effect of temperature on the rate of reaction of ampicillin in Ni (II)-dimethyl sulfoxide reagent. Key: ●, 50°; ○, 40°; and △, 30°. Ampicillin trihydrate concentration = 28 mcg./ml.*

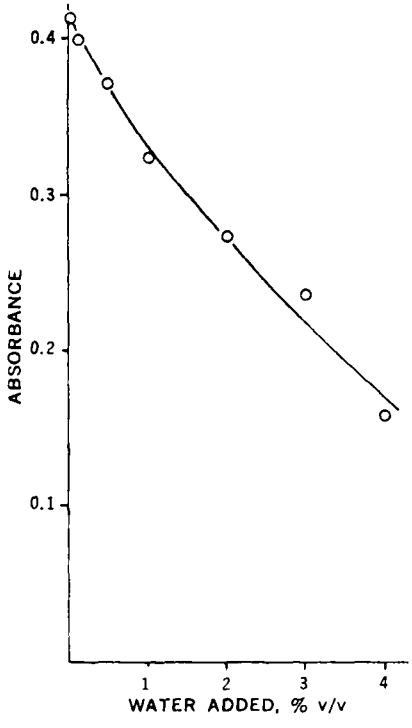

Figure 5—*Effect of added water on the reaction of ampicillin with Ni (II) in dimethyl sulfoxide. Ampicillin trihydrate concentration = 24 mcg./ml.*

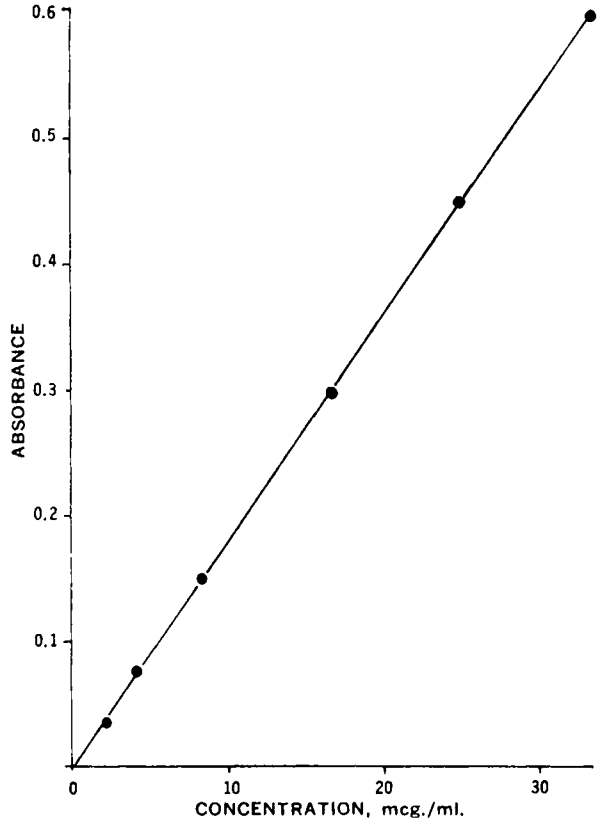

Figure 6—*Calibration curve for ampicillin trihydrate as determined by the Ni (II)–dimethyl sulfoxide reaction.*

reaction time at 50° for ampicillin and hetacillin. The size of the zone of inhibition produced by hetacillin is virtually unchanged over 24 min., whereas the last detectable bioactivity for ampicillin is obtained at 9 min. In addition to showing the lack of reactivity of hetacillin to Ni (II)–dimethyl sulfoxide, these data establish that ampicillin is converted to a nonantibiotic by reacting with Ni (II)–dimethyl sulfoxide reagent.

Table I—Recovery of Ampicillin Trihydrate Added to Potassium Hetacillin

The effects of temperature, time, and Ni (II) concentration on the rate of reaction of ampicillin are shown in Figs. 3 and 4. These data led to the adoption of the standard reaction conditions of 50° heating for 10 min. with a Ni (II) concentration of approximately 100 mcg./ml.

The effect of water on the sensitivity of the Ni (II)–dimethyl sulfoxide reaction for ampicillin is demonstrated in Fig. 5. The addition of 0.5% water to the reaction medium decreased the absorbance by approximately 10%. A very similar effect was obtained when methanol was added. The addition of acetonitrile or tetrahydrofuran, on the other hand, had no significant effect on absorbance. Consideration of these data led to the conclusion that alcohol and excessive water must be excluded from the reaction medium to obtain maximum sensitivity. Water is naturally allowed from three sources; it is calculated that the contribution of water from the ampicillin trihydrate will not be greater than 0.001%, the contribution from nickel sulfate will be less than 0.004%, and the contribution from dimethyl sulfoxide itself will be 0.02%. The water from the last two sources is maintained constant. The data shown in Fig. 5 are for water above that contributed by these three sources and show that water from sources such as wet glassware or aqueous samples may significantly affect sensitivity. The water naturally present in powdered samples should not be significant.

Figure 6 is a calibration curve for ampicillin trihydrate measured as the product of the Ni (II)–dimethyl sulfoxide reaction. A linear relationship exists between absorbance and concentration from at least 2 to 30 mcg./ml.

RESULTS

The described procedure was used to determine ampicillin in bulk hetacillin. Table I lists recovery data for bulk to which was added 0.75–41% ampicillin trihydrate. The original hetacillin was found to contain 1.65% ampicillin trihydrate. The same procedure appears to be satisfactory in the presence of compounds other than hetacillin (Table II). Except for the recovery at the lowest level, accuracy appears to be generally better than ±5–10% of the amount of ampicillin present.

DISCUSSION

Table III lists compounds tested for reaction with the nickel reagent and the results obtained. The nature of the response is consistent with the required presence of an α-aminoaryl acetyl group, although additional model compounds should be considered before the aryl group is determined as necessary.

The coincidence of the absorbance maximum with that shown by penicillenic acids suggests that the latter may be involved. This is almost certainly not the case, however, based on the following facts: (*a*) a number of the penicillins (Part A of Table III) have been shown to form penicillenic acids (11, 12), but only ampicillin produces the chromophore under these conditions; (*b*) at least one compound (Part C of Table III) is not capable of forming a penicillenic acid but gives a positive response to this procedure; and (*c*) the substitution of Ni (II) for the Cu (II) used in catalyzing the formation of penicillenic acids from intact penicillins leads to failure of that method.

The reactivity is assumed to be due to the ampicillin side chain alone, and Ni (II) presumably either complexes or catalyzes a reaction to form a chromophore in dimethyl sulfoxide. Since the application of Job's (13) method of continuous variation failed to support a simple molar relationship between ampicillin and nickel ion, there is no evidence that the chromophore is a complex. Complexation, of course, may be a step in the mechanism of reaction. Studies with additional model compounds are continuing.

Colorimetric Determination of Dipyrone

HASSAN ABDINE, SOBHI A. SOLIMAN[A], and MAGDI G. MORCOS*

Abstract □ The reaction product of dipyrone with nitrous acid was utilized for its colorimetric determination in the pure state and in tablets and injections. The derivative, so formed, obeys Beer's law in ammoniacal medium and had a maximum absorbance at 403 nm. The proposed method has the advantage over the iodometric USSR Pharmacopoeia IX method in that: (*a*) it can be applied to a much lower concentration of dipyrone, and (*b*) sodium sulfite, which is used as an antioxidant in dipyrone injections, does not interfere with the determination.

Keyphrases □ Dipyrone—colorimetric determination, bulk and formulations □ Colorimetry—analysis of dipyrone, bulk and formulations

Various methods have been described for the determination of dipyrone [sodium (antipyrinylmethylamino)methanesulfonate monohydrate]. It was determined gravimetrically as sodium sulfate after ashing with sulfuric acid (1). Several iodometric methods have been commonly used (2–4). Wirth (5) recommended that the sample be weighed instead of measured in the iodometric titration of dipyrone in parenteral preparations, and he proposed the determination of specific gravity as a method of assay. Iodometric methods have also been described for the determination of dipyrone in mixtures (6–8). One iodometric method (9) depends on the fact that dipyrone is split into sulfite by potassium cyanide in moderately alkaline solution and then the liberated sulfite is titrated with standard iodine solution in an acid medium. Trials were made (10) to explain the mechanism of the iodometric titration.

Dipyrone was also determined complexometrically after oxidation of the sulfite group to sulfate (11). Alternatively, the sulfate ion produced was titrated with barium chloride solution (12). Other methods include the titration of dipyrone with chloramine solution (13) and potentiometric titration with 0.1 *N* perchloric acid solution in nonaqueous solvents (14, 15).

The color produced when dipyrone reacted with sodium β-naphthoquinone-4-sulfonate was employed (16) for its identification and determination. This method was modified (17) to eliminate the interference by primary amines, and the reaction mechanism was explained (18). The color reactions of dipyrone with a Schiff reagent (19), 4-dimethylaminocinnamaldehyde (20, 21), quinone (22), and *p*-diazobenzenesulfonic acid (23) were used for its determination. Dipyrone was also determined colorimetrically by measuring the absorbance of its complex with copper chloride (24).

A spectrophotometric method was also described in which dipyrone was determined at 272 nm. (25). A rapid determination of dipyrone in solution by IR spectroscopy was also proposed (26). Furthermore, a polarographic method was suggested (27), in which a polarographically active derivative of this compound was determined.

In this report, a colorimetric method for determining dipyrone in the pure state and in tablets and injections is described.

EXPERIMENTAL

Apparatus and Reagents—The following were used: a spectrophotometer[1]; dipyrone, USSR Pharmacopoeia IX grade; sodium nitrite, chemical reagent; 2.0 *N* hydrochloric acid solution; and dilute ammonium hydroxide solution, prepared by diluting 33.3 ml. of concentrated ammonium hydroxide solution to 100.0 ml. with distilled water.

Construction of Standard Absorbance Graph—Prepare a series of solutions containing 40.0, 60.0, 80.0, 100.0, and 120.0 mg. dipyrone/5.0 ml. solution by dissolving 0.400, 0.600, 0.800, 1.000, and 1.200 g., respectively in distilled water in a series of five 50-ml. volumetric flasks and dilute to volume. Accurately measure 5.0 ml. of each solution and transfer into a series of five 50-ml. beakers. To each of the five beakers, add 0.5 g. of sodium nitrite followed by 20.0 ml. of 2.0 *N* hydrochloric acid solution. Heat gently with continuous stirring for 7 min. until the solutions begin to boil. Cool, transfer the contents of each beaker to a 100-ml. volumetric flask, and dilute to volume with 2.0 *N* hydrochloric acid solution. Accurately measure 2.0 ml. of each solution, transfer to a 25-ml. volumetric flask, and dilute to volume with dilute ammonium hydroxide solution. Shake well and measure the absorbance of each prepared solution at 403 nm. against a blank prepared by substituting 5.0 ml. of distilled water for 5.0 ml. of the dipyrone solution. Results are shown in Table I. The equation of the straight line was determined by the method of least squares, and the slope of the line was found to be 0.066.

Pure Compound—Weigh accurately about 0.750 g. of dipyrone, place in a 50-ml. volumetric flask, dissolve in distilled water, and dilute to volume. Measure accurately 5.0 ml. of the prepared solution, place in a 50-ml. beaker, and proceed as described previously. Measure the absorbance at 403 nm. against a blank prepared by substituting 5.0 ml. of distilled water for 5.0 ml. of the dipyrone solution. Determine the concentration from the straight-line equation using the measured absorbance. Results are shown in Table II.

Tablets—Weigh and powder 20 tablets. Transfer an accurately weighed quantity of the powder, equivalent to 0.750 g. of dipyrone, to a 50-ml. volumetric flask. Dissolve in distilled water, dilute to volume, and filter. Transfer 5.0 ml. of the filtrate, accurately measured, to a 50-ml. beaker and proceed as described previously. Measure the absorbance at 403 nm. against a blank prepared by substituting 5.0 ml. of distilled water for 5.0 ml. of the dipyrone solution. Determine the concentration from the straight-line equation using the measured absorbance. Results are shown in Table II.

Injections—Accurately measure 3.0 ml. of the mixed contents of injections, equivalent to 1.500 g. of dipyrone, and transfer to a 100-ml. volumetric flask. Dilute to volume with distilled water and shake well. Measure 5.0 ml. of this solution, place in a 50-ml. beaker, and proceed as usual. Measure the absorbance at 403 nm. against a blank prepared by substituting 5.0 ml. of distilled water for 5.0 ml. of the dipyrone solution. Determine the concentration from the straight-line equation using the measured absorbance. Results are shown in Table II.

RESULTS AND DISCUSSION

The nitrosation of dipyrone with sodium nitrite and 2.0 *N* hydrochloric acid solution produced a yellowish derivative, which was

[1] Unicam SP600.

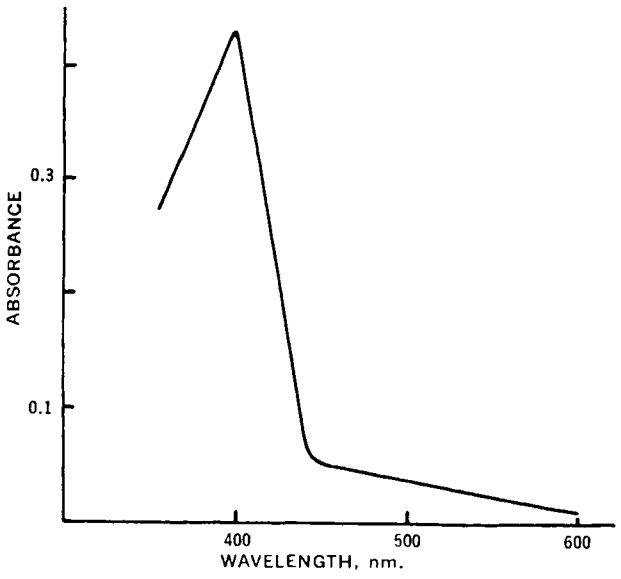

Figure 1—*Absorbance spectrum of dipyrone.*

intensified when the medium was made alkaline with ammonium hydroxide solution. This reaction was put on a quantitative basis to determine dipyrone in the pure state as well as in tablets and injections. The produced color had an absorbance peak at 403 nm. (Fig. 1) and obeyed Beer's law in a concentration range of 3.2–9.6 mg./100.0 ml. For a 72-hr. study period, the color was stable and gave no change in absorbance over a wide concentration range.

The scope of the method for control purposes was demonstrated by its application to a series of samples of dipyrone in the pure form and in different pharmaceutical forms such as tablets and injections (Table II). The presence of tablet excipients such as lactose, starch, and magnesium stearate did not interfere with the determination. The iodometric method adopted by USSR Pharmacopoeia IX also was used to determine dipyrone in the pure state and in tablets, and the results (Tables II and III) indicate that the proposed method is equivalent in accuracy and precision. However, the proposed method is more sensitive and selective.

The presence of reducing agents such as sodium sulfite, which are added to dipyrone injections as stabilizers, did not interfere with the proposed method. Such a reducing agent is expected to interfere with the iodometric method of USSR Pharmacopoeia IX because of the interaction of iodine and the reducing agent. Table IV shows the recovery data of dipyrone in prepared injections containing various amounts of sodium sulfite when the iodometric method was employed; dipyrone recoveries ranged from 100.81% in the absence of sodium sulfite to 125.79% when 48.0 mg. of this stabilizer was added.

The colored derivative formed when dipyrone is treated with sodium nitrite and hydrochloric acid solution is believed to be the

Optimum Conditions for GLC Analysis of Neomycin

MICHEL MARGOSIS*▲ and KIYOSHI TSUJI†

Abstract □ A previously described GLC method for the analysis of neomycin was critically examined to delineate the problems involved and to resolve the difficulties encountered in the procedure. The breakdown and/or adsorption of the silyl derivatives is minimized by modifying the injection port of one instrument so as to eliminate all metal and Teflon contact with the injected material.

Keyphrases □ Neomycin—GLC analysis, optimum conditions □ GLC—analysis, neomycin, optimum conditions

Neomycin is an antibiotic used extensively throughout the world. Many dermal, renal, and ototoxic reactions associated with its therapeutic use have been reported in the literature. These reports, however, do not indicate the chemical composition of the antibiotic bulk used in commercial formulations, although neomycin is known to be comprised of at least five different components in variable amounts (1). These neomycin fractions have different responses to various microorganisms and may also differ in therapeutic activity and potency as well as in pharmacological properties. Improved methods of analysis are necessary to elucidate and characterize the chemical nature of these substances.

A reported GLC method (2), which is regularly utilized at The Upjohn Company, appears to be the best, practical method available for the qualitative and quantitative analysis of neomycin fractions, particularly neomycin B and neomycin C isomers which normally predominate. The method had been under evaluation at the National Center for Antibiotic Analysis (NCAA) for some time. Test results by The Upjohn and NCAA laboratories were comparable for the potency values of commercial bulk samples containing a fairly low amount (less than about 5%) of neomycin C. However, there was poor interlaboratory correlation between results for the neomycin C content for most bulk samples. Be-

Optimum Conditions for GLC Analysis of Neomycin

MICHEL MARGOSIS*▲ and KIYOSHI TSUJI†

Abstract □ A previously described GLC method for the analysis of neomycin was critically examined to delineate the problems involved and to resolve the difficulties encountered in the procedure. The breakdown and/or adsorption of the silyl derivatives is minimized by modifying the injection port of one instrument so as to eliminate all metal and Teflon contact with the injected material.

Keyphrases □ Neomycin—GLC analysis, optimum conditions □ GLC—analysis, neomycin, optimum conditions

Neomycin is an antibiotic used extensively throughout the world. Many dermal, renal, and ototoxic reactions associated with its therapeutic use have been reported in the literature. These reports, however, do not indicate the chemical composition of the antibiotic bulk used in commercial formulations, although neomycin is known to be comprised of at least five different components in variable amounts (1). These neomycin fractions have different responses to various microorganisms and may also differ in therapeutic activity and potency as well as in pharmacological properties. Improved methods of analysis are necessary to elucidate and characterize the chemical nature of these substances.

A reported GLC method (2), which is regularly utilized at The Upjohn Company, appears to be the best, practical method available for the qualitative and quantitative analysis of neomycin fractions, particularly neomycin B and neomycin C isomers which normally predominate. The method had been under evaluation at the National Center for Antibiotic Analysis (NCAA) for some time. Test results by The Upjohn and NCAA laboratories were comparable for the potency values of commercial bulk samples containing a fairly low amount (less than about 5%) of neomycin C. However, there was poor interlaboratory correlation between results for the neomycin C content for most bulk samples. Be-

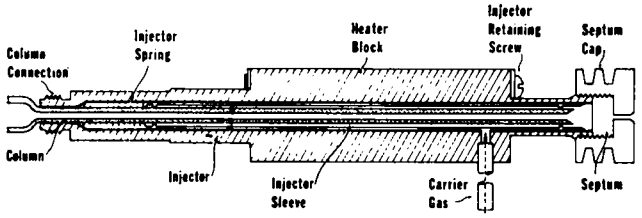

Figure 1—*Modification of injector block and column.*

cause of this discrepancy and other difficulties encountered in the performance of the analysis, a step-by-step critical examination of the procedure was undertaken by the two laboratories in close collaboration. This first resulted in two modifications of the procedure (3), namely: (*a*) use of a 0.61- or 0.91-m. (2- or 3-ft.) column packed with 3% OV-1 on Gas Chrom Q, 100–120 mesh, instead of a 1.83-m. (6-ft.) column with 0.75% OV-1 on Gas Chrom Q; and (*b*) combination of the trilaurin internal standard and the trimethylsilyldiethylamine reagent directly into Tri-Sil Z.

The objective of this article is to discuss the problems associated with this analysis.

EXPERIMENTAL

When the analyses were initially performed at NCAA[1], there were indications of serious sample degradation and solvent (pyridine) tailing. The direct on-column injections with a 15.24-cm. (6-in.) needle, as suggested by the manufacturer, did not alleviate the problem and proved too cumbersome for continuous repetitive application. To counteract these difficulties, the gas chromatograph was modified by drilling out the abutting metal separator ring in the injector block which connects the column to the injector system through a Teflon ferule and a Swagelok. A glass tube, about 14 cm. (5.5 in.) × 4 mm. o.d., was fused to one end of the column, extending it to the septum (Fig. 1)[2].

This column was packed within 1 cm. of the septum and plugged, if desired, with a minimum amount of silanized glass wool, thus minimizing any dead space. Glass wool is not really necessary in the inlet but is customarily used as a plug; it has at times been found to be deleterious to the analysis of silyl derivatives[3]. Caution is necessary when extending this column so that it fits easily into the metal sleeve of the injector block and that no undue strain, which could result in breakage, is applied when tightening the Swageloks.

This system provides a direct on-column injection, eliminates the glass insert, and obviates precolumn contact of sample to metal or glass at such elevated temperatures as 300°, as in this case. Another beneficial side effect is that solvent tailing is materially decreased.

RESULTS

Standard solution mixtures containing neomycin B (USP Reference Standard, Issue 1) and from 0 to 40% (w/w) of neomycin C [8246-DNR-58, 90.5% pure, with no neomycin B present as determined by GLC (4)] and several commercial samples were carefully prepared and analyzed. Since equal detector response was found for each neomycin isomer when used singly, the neomycin C content in all cases was calculated as the fraction of the sum of both peak areas.

Recovery of neomycin C was *not* linear at NCAA, even though the same packing material was used at both laboratories. However, results were reproducible and could be correlated with standard calibration mixtures for quantitative purposes. Further investigations revealed that the incomplete recovery of the neomycin C fractions was actually due to adsorption of the silylated derivatives onto the Teflon disk of the injector seal assembly in the gas chromatograph. Upon removal of this Teflon disk, linearity of recovery of the neomycin C fraction was achieved on an absolute scale, thus eliminating the need for calibrating standard mixtures which are not easily available. Concurrent analysis of several commercial lots in the laboratories of The Upjohn Co. and at NCAA have confirmed the usefulness of the method. The neomycin C values obtained by the triangulation method with the modified gas chromatograph at NCAA correlated well with those obtained with the electronic integrator attached to the other gas chromatograph at Upjohn. A paired *t*-test of the two sets of results listed in Table I showed no statistical difference at the 95% confidence level (calculated $t = 0.67$ for $n = 19$).

Table I—Determination of Neomycin C in Prepared Standard Mixtures and Commercial Bulk Neomycin Sulfate by GLC

Sample	Neomycin C, %: Lab 1[a]	Lab 2[b]
Standard 1	0.0	0.0
Standard 2	3.88	4.65
Standard 3	7.48	8.0
Standard 4	15.2	14.6
Standard 5	24.4	25.9
Standard 6	39.3	38.25
Lot 1	8.1	7.35
Lot 2	8.2	12.6
Lot 3	17.8	16.6
Lot 4	6.1	6.25
Lot 5	10.3	9.7
Lot 6	15.9	14.2
Lot 7	5.4	5.7
Lot 8	12.3	13.2
Lot 9	8.5	8.8
Lot 10	9.4	8.2
Lot 11	6.4	8.8
Lot 12	11.3	11.5
Lot 13	6.1	5.9
Lot 14	12.0	11.83

[a] Percent neomycin C for standards is actual percent weight in weight ratio. Commercial lots were analyzed with a Hewlett-Packard 402 with electronic integrator 3370A. [b] Results were calculated from a modified Perkin-Elmer 900 by triangulation.

Table II—Troubleshooting in GLC Analysis of Neomycin

Problem	Solution
Lot-to-lot variations in moisture content and solubility	Freeze dry and cap promptly
Indication of sample decomposition	Eliminate all metal contacts; ensure a complete glass system
Darkening of packing material in inlet	Use longer silylation time; use minimum amount of silanized glass wool and replace as needed
Asymmetrical neomycin peak	Readjust amount of trimethylsilyldiethylamine
Stability of trimethylsilyl derivative of neomycin	Use sealed reaction vials; store at refrigerated temperatures
Lack of quantitation	Use on-column injections; remove all metal and/or Teflon in inlet system; inject immediately after withdrawing sample from vial; maintain about same amount of sample injected to reproduce peak size and to improve statistics
On-column adsorption of trimethylsilyl derivative of neomycin	Remove Teflon from inlet; condition with trimethylsilyl derivative of neomycin
Short column life	Reduce column temperature (<300°); compensate with increased carrier flow rate

[1] On a Perkin-Elmer 900 gas chromatograph.

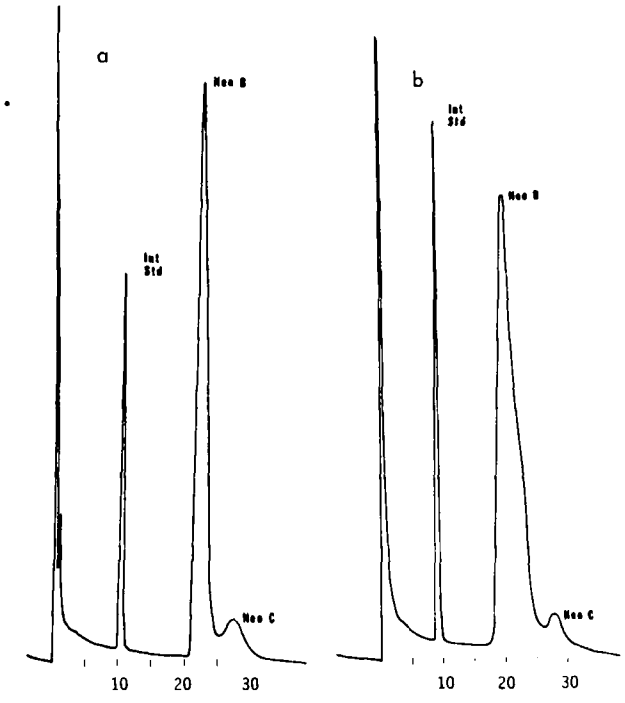

Figure 2—*Chromatogram of trimethylsilyl derivative of neomycin with: (a) proper amount of trimethylsilyldiethylamine, and (b) excess trimethylsilyldiethylamine.*

DISCUSSION

Because of the many potential sources of difficulties, strict adherence to the reported procedure (2, 3) is recommended to obtain reliable results. These problems are enumerated in Table II for convenience; and although each one is of material significance, the following are emphasized:

1. The column must be properly sample conditioned immediately before actual analysis.
2. The amount of trimethylsilyldiethylamine reagent added is critical in the formation of the derivative, as are the temperature and duration of the reaction (3). When the derivative is properly prepared, the neomycin B peak is symmetrical (Fig. 2).
3. Samples should be chromatographed as soon as possible after derivatization or kept refrigerated minimally until time of analysis so as to retain optimal stability. These neomycin derivatives degrade readily (3).

In summary, with proper techniques and caution, the GLC method for analysis of the neomycins can be successfully employed. This method has already been shown to be more specific and reliable than the microbiological method (4, 5). Even with GLC instruments offering poor linearity in recovery, satisfactory results can be obtained when they are correlated with authentic or reference standard calibration mixtures approximating the concentration level to be determined. This type of discussion might prove beneficial in similar analyses of high molecular weight oligosaccharides.

Determination of Copper and Manganese in Vitamin-Mineral Tablets by Atomic Absorption Spectrophotometry

YOUNG SOON CHAE, JAMES P. VACIK, and WILLIAM H. SHELVER▲

Abstract □ Atomic absorption spectrophotometry was utilized in the determination of copper and manganese in five different combination multiple-vitamin mineral tablets. The analysis of each tablet by direct determination was compared with analysis by the method of additions, and some small but statistically significant differences were noted. No molecular absorption was found in the analysis of manganese utilizing the nonresonance line of lead. The direct analysis of manganese and copper was simple and precise.

obtain meaningful results. Atomic absorption spectrophotometry promises to be a simple and an extremely specific analytical technique with sufficient precision for pharmaceutical analysis. Despite these desirable qualities, atomic absorption spectrophotometry has not been widely utilized in pharmaceutical analysis (1). Calcium (2), copper (3), iron (4), and cobalt (5) have been analyzed in pharmaceutical preparations by atomic absorption spectrophotometry, but none of these metals has been determined in multiple-vitamin–mineral tablets by this technique.

Copper has been analyzed (3) by atomic absorption spectrophotometry in ointments and in a tablet containing copper, cobalt, and iron with good precision and no indication of interferences. The effects of fuel mixtures and of mineral acids on the atomic absorption analysis of copper and manganese have been carefully studied (6). The extension of these studies to the analysis of copper and manganese in multiple-vitamin–mineral tablets seems feasible, although the analysis of manganese apparently has not been reported by atomic absorption spectrophotometry in any pharmaceutical products.

EXPERIMENTAL

Instrument—A double-beam spectrophotometer[1], equipped with a multielement (Mn–Cu–Co Cr–Ni) hollow cathode lamp and a single-slot burner head, was used for all atomic absorption measurements except for the two-line method where a single-element lead lamp was utilized. The instrument parameters are given in Table I.

Reagents—Standard stock solutions of manganese[2] and copper[2] contained 1000 and 10,000 p.p.m., respectively. All other reagents were ACS or USP grade. Distilled water was deionized by being passed through two mixed-bed resin columns, and it was used to make all solutions and to rinse all glassware.

Direct Method—Standard curves (Figs. 1 and 2) were obtained as follows. Manganese or copper solutions were prepared for calibration by diluting the standard stock solution to obtain concentrations of 0.5, 1.00, 2.00, 3.00, and 3.50 p.p.m. or 1.00, 2.00, 3.00, 4.00, and 5.00 p.p.m. respectively. Both standards were made up to contain 1% (w/v) hydrochloric acid. The instrument was optimized as to lamp position and the position of the burner head. The absorbances of the standard solutions of the element were determined in the 100 average mode with a minimum of three such readings. The regression line of the absorbance–concentration curves through zero was determined using a calculator[3], and the calibration curve was plotted. The calibration curves were determined each day that analytical runs were made by the direct method.

Twenty tablets of each preparation were accurately weighed to determine the average tablet weight. The tablets were crushed and ground to a fine powder with a mortar and pestle. A portion of each tablet powder equivalent to sufficient metal to give an absorbance between 0.100 and 0.300 was accurately weighed, transferred into a 100-ml. beaker, and dissolved in sufficient 10% (w/v) hydrochloric acid to yield a final concentration of 1% (w/v) when diluted. Each solution was filtered through filter paper[4] into a 100- or 200-ml. volumetric flask and diluted to the mark with deionized distilled water through the filter paper. Four separately weighed powdered samples were prepared from each different batch of tablets. The instrument was warmed for a minimum of 4 hr., and the blank solution [1% (w/v) hydrochloric acid solution] was aspirated for a minimum of 15 min. prior to any analytical procedure.

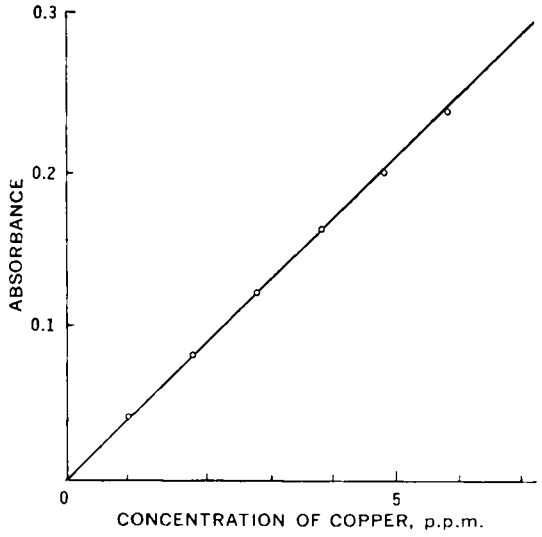

Figure 1—*Typical concentration–absorbance relationship for copper standard at 324.7 nm. Slope of the line = 0.0405 ± 0.0020. Sensitivity = 0.107 mcg./ml. The analysis was carried out on a spectrophotometer (see text) with a slit of 0.2 nm. and the readout in the 100 average mode.*

After aspirating the blank solution and setting the instrument to zero by means of the autozero function, the solution to be analyzed was aspirated and the absorbance was determined using the 100 average function. The first reading was discarded, and at least four successive readings were taken. The instrument was zeroed by aspirating blank solution prior to reading the next solution. The calibration curve and the analytical readings for all samples were taken for one element before changing the wavelength and carrying out similar analyses for the second element. Because of the different metal contents of the tablets and different instrument responses to manganese and copper, some samples required more dilute analytical solutions for manganese. The calculation of tablet content was carried out using the following equation:

$$\text{tablet content} = \frac{\text{absorbance} \times \text{volume analytical solution} \times \text{average tablet weight} \times \text{dilution factor}}{\text{slope of calibration line} \times 1000 \times \text{sample weight}} \quad \text{(Eq. 1)}$$

The mean and standard deviation (Tables II and III) for each tablet were calculated with a programmable calculator[5].

Method of Additions—The same analytical solutions and standard stock solutions used in the direct method were used in preparing solutions for analysis by the method of additions. Three solutions were used for each analysis, containing the same quantity (10 ml.) of tablet analytical solution and 0, 10, or 20 ml. of 10 p.p.m. copper standard solution or 0, 5, or 15 ml. of 10 p.p.m. manganese standard solution. The resulting solutions were diluted to 50.0 ml. with 1% (w/v) hydrochloric acid solution. The quantity of tablet analytical solution provided maximum absorbance for the solution containing the highest quantity of metal without exceeding the linear portion of the calibration curve (3.5 p.p.m. for manganese and 6 p.p.m.

5	1.25	1.456	116.5	0.7	1.400	112.0	1.6	18.759[d]

[a] The results represent an average of four determinations. [b] The results represent an average of four determinations, each one consisting of the extrapolation of the least-squares line to the *X*-intercept at zero absorbance. The least-squares line was derived from absorbance measurements at three different manganese concentrations. [c] Significant at the 0.05 level. [d] Significant at the 0.01 level.

for copper). The absorbance of each solution was read as described under the *Direct Method*. The content of the original solution was calculated by determining the regression line for the three solutions using the absorbance as the *Y*-value and the parts per million of the metal added for the *X*-coordinate. The negative of the *Y*-intercept divided by the slope gave the content in parts per million for the original solution. The tablet content can thus be calculated by Eq. 2:

$$\text{tablet content} = \frac{\text{p.p.m. metal} \times \text{volume analytical solution} \times \text{average tablet weight}}{1000 \times \text{sample weight}} \qquad \text{(Eq. 2)}$$

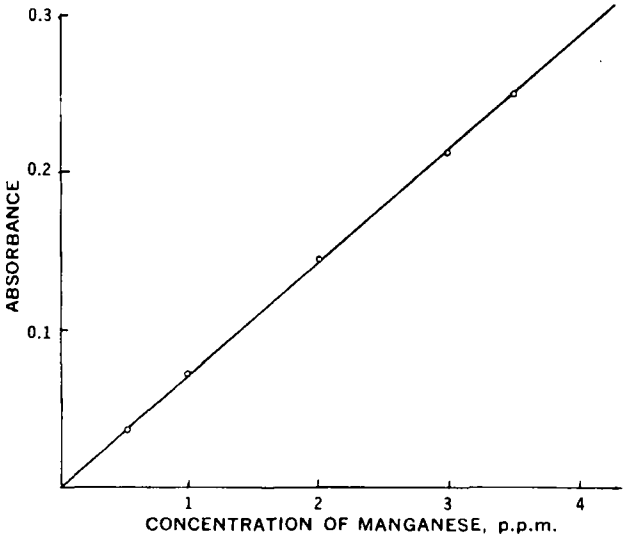

Figure 2—*Typical concentration–absorbance relationship for manganese standard at 279.5 nm. Slope of the line = 0.0713 ± 0.0012. Sensitivity = 0.061 mcg./ml. The analysis was carried out on a spectrophotometer (see text) with a slit of 0.2 nm. and the readout in the 100 average mode.*

The mean and the standard deviation for each tablet were determined as already described.

Two-Line Method—To examine the problem of possible molecular absorbance, a nonresonance line near the analytical wavelength was needed. Lead has a nonabsorbing line at 280.3 nm. near the analytical wavelength of manganese (279.5 nm.). Measurement of the absorbance of all standard solutions and of all analytical solutions using the lead line revealed no solutions with absorbances greater than 0.001 unit. Since absorbances this low would not have appreciable effects on the calculated results, the experiment was terminated.

Recovery Experiments—The recovery of copper and manganese was found by taking an aliquot of the tablet solution, diluting, and reading and then taking the same aliquot of the tablet solution, adding standard solutions of copper and manganese, diluting, and reading. The difference between the readings was divided by the slope of the calibration line for the respective element, and the resulting parts per million (measured) was divided by the amount added (theoretical) and multiplied by 100 to obtain the percent recovery (Table IV).

RESULTS AND DISCUSSION

Since there exists the possibility of matrix effects in the analysis of copper and manganese in the complex mixture produced by a multiple-vitamin tablet, three independent atomic absorbance techniques were selected to check the validity of the analysis: direct analysis, the method of additions, and the use of a nonresonance line adjacent to the manganese line.

The use of the nonresonance line of lead at 280.3 nm. near the analytical line for manganese at 279.5 nm. resulted in a maximum absorbance of 0.001 absorbance unit. The negligible absorbance in

Table IV—Recovery of Metals from Analysis of Multiple-Vitamin–Mineral Tablets

	Mean[a]	SD	Recovery, %
Copper	1.044	0.042	104.4
Manganese	1.018	0.006	101.8

[a] Each value represents the mean of 10 determinations.

all samples indicated that molecular absorbance was not interfering with the analysis of manganese in this procedure. The possibility of molecular absorption occurring at the analytical wavelength of copper seems small since the copper analytical wavelength is not far from the manganese line. No calculations are reported for the two-line method since the results would not differ from the results of the direct method.

A typical standard curve for copper (Fig. 1) reveals good linearity up to 6 p.p.m. The slope of the line gives a sensitivity of 0.107 mcg./ml., in agreement with reported (7) values, and the standard deviation of the slope indicated suitable accuracy. The results of the analysis of the tablets for copper are shown in Table II. Both the direct method (3% average *SD*) and the method of additions (5% average *SD*) show reasonable precision. Probably some error is produced by difficulties in obtaining homogeneous samples of the vitamin tablets, and this is supported by the differences in precision among the different tablets. The ability to obtain a homogeneous sample would depend upon the particular formulation of the tablet. Some tablets were extremely difficult to reduce to a fine powder while others were powdered with comparative ease. This method of sampling in the analysis of iron has been reported to give a higher variation than an ashing procedure (4). The increased error in the method of additions can be anticipated because of the larger number of pipetings and the extrapolation procedure required. Statistical comparisons of the two methods indicate that Tablet 5 showed a significant difference in the two analytical methods. Inspection of Table II shows that the significance was produced by the unusually small standard deviations associated with this tablet. Other workers (2) found a greater variance produced by the method of additions. The slightly higher results from the method of additions for the analysis of copper cannot be presently explained.

A typical standard curve for manganese (Fig. 2) was linear up to 3.5 p.p.m., and the sensitivity (0.061 mcg./ml.) agrees well with reported (7) values. The standard deviation of the slope is within acceptable limits. The results of the analysis of manganese in multiple-vitamin–mineral tablets (Table III) are more precise than the copper analysis. The average errors in the direct determination and in the method of additions (2 and 3% average *SD*, respectively), are extremely satisfactory. Unlike the copper analysis, there seems no direction in the differences in the two methods (Tablets 2 and 5 are lower by the method of additions and Tablets 1, 3, and 4 give higher results by the method of additions). The existence of the small, but significant, differences in the results of the two methods of determination might indicate a small matrix effect. Since the differences between the methods are small, the more convenient direct method can be used for all but the most crucial applications.

At the beginning of the project, the decision was made to produce the analytical solution by grinding the tablet and filtering the resulting suspension, thus avoiding ashing or digesting of the sample. This procedure obviously introduced some variation into the results; but from the results of Tables II and III, this effect cannot exceed 3% and is probably much less. By avoiding digestion or ashing, a solution is produced that can be utilized in the analysis of the vitamins soluble in 1% acid media, minimizing the number of solutions needed for the quality control of the multiple vitamins. The results (Table IV) indicate acceptable recovery for both manganese and copper and again demonstrate the smaller variability of the manganese analysis. The determination of manganese and, to a slightly lesser degree, copper by direct atomic absorption spectrophotometry is a simple and precise method of analyzing these metals in multiple-vitamin–mineral tablets.

Determination of Chloramphenicol Palmitate in Pharmaceutical Suspensions

SACHCHIDANANDA BANERJEE▲, KALYAN CHAKRABARTI, and ARUP KUMAR HALDAR

Abstract □ Three simple procedures for the quantitative determination of chloramphenicol palmitate in commercially available chloramphenicol palmitate oral suspensions are presented. One method is a modification of the USP method in which the suspension residue is washed with water prior to the USP specified steps of dissolving the residue in chloroform and determining the quantity spectrophotometrically. The second method takes advantage of the presence of two chlorine atoms in the side chain of chloramphenicol which can be converted into alkali chloride to be estimated potentiometrically with a standard silver nitrate solution. The third method is based on the liberation of chloramphenicol from chloramphenicol palmitate by treatment with dilute alkali at room temperature and microbiological assay of chloramphenicol using *Escherichia coli* (ATCC 10536). The potentiometric and microbiological assay methods were equally suitable for determination of chloramphenicol palmitate in all of the different suspensions tested. The microbiological assay method was more specific for the active antibiotic, was less cumbersome, and took less time.

Keyphrases □ Chloramphenicol palmitate—three methods of analysis in pharmaceutical suspensions □ Suspensions, chloramphenicol palmitate—three methods of analysis □ Antibiotics—analysis of chloramphenicol palmitate in pharmaceutical suspensions

In chloramphenicol palmitate oral suspensions containing 0.5% vanillin as the flavoring agent, the potency of chloramphenicol palmitate, as determined by the USP spectrophotometric method (1, 2), was always high. The results varied between 116 and 133% of the labeled content. However, the USP method was suitable

all samples indicated that molecular absorbance was not interfering with the analysis of manganese in this procedure. The possibility of molecular absorption occurring at the analytical wavelength of copper seems small since the copper analytical wavelength is not far from the manganese line. No calculations are reported for the two-line method since the results would not differ from the results of the direct method.

A typical standard curve for copper (Fig. 1) reveals good linearity up to 6 p.p.m. The slope of the line gives a sensitivity of 0.107 mcg./ml., in agreement with reported (7) values, and the standard deviation of the slope indicated suitable accuracy. The results of the analysis of the tablets for copper are shown in Table II. Both the direct method (3% average *SD*) and the method of additions (5% average *SD*) show reasonable precision. Probably some error is produced by difficulties in obtaining homogeneous samples of the vitamin tablets, and this is supported by the differences in precision among the different tablets. The ability to obtain a homogeneous sample would depend upon the particular formulation of the tablet. Some tablets were extremely difficult to reduce to a fine powder while others were powdered with comparative ease. This method of sampling in the analysis of iron has been reported to give a higher variation than an ashing procedure (4). The increased error in the method of additions can be anticipated because of the larger number of pipetings and the extrapolation procedure required. Statistical comparisons of the two methods indicate that Tablet 5 showed a significant difference in the two analytical methods. Inspection of Table II shows that the significance was produced by the unusually small standard deviations associated with this tablet. Other workers (2) found a greater variance produced by the method of additions. The slightly higher results from the method of additions for the analysis of copper cannot be presently explained.

A typical standard curve for manganese (Fig. 2) was linear up to 3.5 p.p.m., and the sensitivity (0.061 mcg./ml.) agrees well with reported (7) values. The standard deviation of the slope is within acceptable limits. The results of the analysis of manganese in multiple-vitamin–mineral tablets (Table III) are more precise than the copper analysis. The average errors in the direct determination and in the method of additions (2 and 3% average *SD*, respectively), are extremely satisfactory. Unlike the copper analysis, there seems no direction in the differences in the two methods (Tablets 2 and 5 are lower by the method of additions and Tablets 1, 3, and 4 give higher results by the method of additions). The existence of the small, but significant, differences in the results of the two methods of determination might indicate a small matrix effect. Since the differences between the methods are small, the more convenient direct method can be used for all but the most crucial applications.

At the beginning of the project, the decision was made to produce the analytical solution by grinding the tablet and filtering the resulting suspension, thus avoiding ashing or digesting of the sample. This procedure obviously introduced some variation into the results; but from the results of Tables II and III, this effect cannot exceed 3% and is probably much less. By avoiding digestion or ashing, a solution is produced that can be utilized in the analysis of the vitamins soluble in 1% acid media, minimizing the number of solutions needed for the quality control of the multiple vitamins. The results (Table IV) indicate acceptable recovery for both manganese and copper and again demonstrate the smaller variability of the manganese analysis. The determination of manganese and, to a slightly lesser degree, copper by direct atomic absorption spectrophotometry is a simple and precise method of analyzing these metals in multiple-vitamin–mineral tablets.

Determination of Chloramphenicol Palmitate in Pharmaceutical Suspensions

SACHCHIDANANDA BANERJEE▲, KALYAN CHAKRABARTI, and ARUP KUMAR HALDAR

Abstract □ Three simple procedures for the quantitative determination of chloramphenicol palmitate in commercially available chloramphenicol palmitate oral suspensions are presented. One method is a modification of the USP method in which the suspension residue is washed with water prior to the USP specified steps of dissolving the residue in chloroform and determining the quantity spectrophotometrically. The second method takes advantage of the presence of two chlorine atoms in the side chain of chloramphenicol which can be converted into alkali chloride to be estimated potentiometrically with a standard silver nitrate solution. The third method is based on the liberation of chloramphenicol from chloramphenicol palmitate by treatment with dilute alkali at room temperature and microbiological assay of chloramphenicol using *Escherichia coli* (ATCC 10536). The potentiometric and microbiological assay methods were equally suitable for determination of chloramphenicol palmitate in all of the different suspensions tested. The microbiological assay method was more specific for the active antibiotic, was less cumbersome, and took less time.

Keyphrases □ Chloramphenicol palmitate—three methods of analysis in pharmaceutical suspensions □ Suspensions, chloramphenicol palmitate—three methods of analysis □ Antibiotics—analysis of chloramphenicol palmitate in pharmaceutical suspensions

In chloramphenicol palmitate oral suspensions containing 0.5% vanillin as the flavoring agent, the potency of chloramphenicol palmitate, as determined by the USP spectrophotometric method (1, 2), was always high. The results varied between 116 and 133% of the labeled content. However, the USP method was suitable

for suspensions identical in other respects but containing flavoring agents such as soluble essence raspberry, essence apricot, or essence American ice cream. Vanillin is a commonly used and highly acceptable flavoring agent, and the use of a flavoring agent in the chloramphenicol palmitate oral suspension is permissible according to USP (3). It was, therefore, necessary to modify the USP method to make it useful for the assay of chloramphenicol palmitate suspensions containing vanillin.

Chloramphenicol palmitate cannot be estimated by the official method (1, 2) in combination with other drugs such as streptomycin, tetracycline, nitrofurantoin, sulfa drugs, or B vitamins. Several other methods have been suggested for the estimation of chloramphenicol palmitate in pharmaceutical formulations, including colorimetry (4, 5), reverse phase TLC (6), and column chromatography (7), but these methods are not always suitable for chloramphenicol palmitate in combination with other drugs. The polarographic method for chloramphenicol palmitate in commercial preparations cannot be used because of its solubility characteristics (8). A potentiometric method based on the chloride determination has been reported (9). Chloramphenicol contains two chlorine atoms in the side chain which can be converted into alkali chloride when refluxed with alkali and can be potentiometrically titrated with 0.1 *N* silver nitrate. This method can be extended to different suspensions of chloramphenicol palmitate in combination with the drugs mentioned previously.

Chloramphenicol palmitate has no antimicrobial activity and cannot be estimated by microbial assay. However, the drug can be hydrolyzed by alkaline hydrolysis and the liberated chloramphenicol can be determined microbiologically by measuring the zones of inhibition using *Bacillus subtilis* (10). Enzymatic hydrolysis of chloramphenicol palmitate by pancreatin (11–13) and the estimation of chloramphenicol by analyzing for total amyl nitro compounds by colorimetry has been reported (11). Although total hydrolysis by pancreatin (13) and by lipase (13, 14) has been described, the complete hydrolysis of chloramphenicol palmitate with pancreatin could not be obtained in the present experiments. Certain crystalline forms of chloramphenicol palmitate are not hydrolyzed or are only incompletely hydrolyzed (15, 16).

Amorphous chloramphenicol palmitate was used in these studies, and the purity of the substance was determined by IR spectrophotometry. Therefore, incomplete hydrolysis was not due to the nature of the chloramphenicol palmitate used. However, it might be due to the pancreatin used because enzyme activity is likely to vary from sample to sample. Because microbial methods are more sensitive than chemical assays and more specific for the active antibiotic, a microbiological method of assay of chloramphenicol palmitate in suspensions with or without other drugs or flavoring agents would be desirable. Therefore, a microbiological assay method of chloramphenicol palmitate in different formulations after alkaline hydrolysis was developed.

[a] Amount of chloramphenicol base contained in chloramphenicol palmitate, milligrams per milliliter. [b] One milliliter suspension contained chloramphenicol palmitate equivalent to 31.25 mg. chloramphenicol base.

EXPERIMENTAL

Determination of Chloramphenicol Palmitate by Modified USP Method—Four milliliters chloramphenicol palmitate oral suspension, equivalent to 125 mg. chloramphenicol, containing 20 mg. vanillin was quantitatively transferred to a sintered-glass crucible No. 4; 10 ml. water was added and the contents were quickly filtered by suction. The residue on the filter was washed twice with 10 ml. water by suction. The sintered crucible containing the residue was fitted into a dry 250-ml. filtering flask. The residue was dissolved in chloroform and the solution was collected in the filtering flask by suction, quantitatively transferred to a 250-ml. volumetric flask, and diluted to volume with chloroform. The remainder of the procedure was as described in the *Code of Federal Regulations* (2) commencing with: "Pipette 4 milliliters of the clear chloroform solution into a 100 milliliter volumetric flask . . ." The results of analysis of 10 samples by the USP method (1, 2) and the modified USP method are given in Table I.

Chloramphenicol palmitate oral suspensions identical in all respects to these samples but not containing vanillin were analyzed by both the USP method and the modified method (Table I). Recovery experiments were performed for the modified method to show that chloramphenicol palmitate was not dissolved by the additional washing procedure (Table II).

Determination of Chloramphenicol Palmitate in Suspensions Containing Chloramphenicol Palmitate in Combination with Other Drugs by Potentiometric Method—Ten to 20 ml. of the suspension, equivalent to about 300 mg. chloramphenicol, was quantitatively transferred to a 500-ml. round-bottom flask to which 20 g. sodium hydroxide and 80 ml. water were subsequently added. The mixture was refluxed on an open flame for 4 hr., cooled, acidified with nitric acid, quantitatively transferred to a 500-ml. volumetric flask, and diluted to volume with water. Two hundred milliliters of the solution was transferred to a 500-ml. beaker, and the alkali chloride solution was titrated with 0.1 *N* silver nitrate potentiometrically using silver–silver chloride and calomel electrodes. The total volume of 0.1 *N* silver nitrate required for 500 ml. was calculated. For a blank titration, the same volume of the sample as taken for alkaline hydrolysis was transferred to a 500-ml. beaker to which 5 ml. nitric acid and 80 ml. water were added. The mixture

Chloramphenicol palmitate (equivalent to 31.25 mg. chloramphenicol/ml.), thiamine hydrochloride (0.1 mg.), riboflavin (0.05 mg.), pyridoxine hydrochloride (0.05 mg.), niacinamide (1.5 mg.), cyanocobalamin (1.5 mcg.), and dexpanthenol (0.1 mg./ml.)	33.4 ± 0.659	32.2 ± 0.247	1.70

[a] Amount of chloramphenicol base contained in chloramphenicol palmitate, milligrams per milliliter. Values are mean of 10 observations ± standard error.

was titrated potentiometrically with 0.1 *N* silver nitrate. The difference between the two titrations represented the amount of chloride liberated from chloramphenicol. Each milliliter of 0.1 *N* silver nitrate is equivalent to 0.01616 g. of chloramphenicol. The results of analysis of different suspensions of chloramphenicol palmitate in combination with other drugs are given in Table III.

Determination of Chloramphenicol Palmitate in Suspensions by Microbiological Assay after Alkaline Hydrolysis—One milliliter of chloramphenicol palmitate oral suspension, equivalent to 31.25 mg. chloramphenicol, was transferred to a 25-ml. volumetric flask (the pipet was washed three times with water) and diluted to volume with ethanol. One milliliter of the ethanolic solution was transferred to a 200-ml. volumetric flask, treated with 10 ml. 0.01 *N* sodium hydroxide in ethanol, and kept at room temperature for 15 min. The solution was neutralized with 0.01 *N* hydrochloric acid and diluted to volume with 0.2 *M* phosphate buffer, pH 6.0. The liberated chloramphenicol was estimated microbiologically using *Escherichia coli* (ATCC 10536) as described in the *Code of Federal Regulations* (18) (Table IV), and recovery experiments were performed to determine the accuracy of the method (Table V).

Determination of Chloramphenicol Palmitate in Suspensions by Microbiological Assay after Enzymatic Hydrolysis—One milliliter chloramphenicol palmitate oral suspension, equivalent to 31.25 mg. chloramphenicol, was diluted to 100 ml. with water. One milliliter of the diluted suspension was transferred to a 100-ml. volumetric flask containing a suspension of 100 mg. pancreatin in 9 ml. of either tromethamine buffer, pH 9.0, or simulated intestinal fluid, pH 7.5. The mixture was incubated under toluene at 37° for 16 hr. and diluted to volume with 0.2 *M* phosphate buffer, pH 6.0; chloramphenicol was estimated microbiologically with *E. coli* (Table V).

Determination of Chloramphenicol Palmitate in Suspensions Containing Chloramphenicol Palmitate in Combination with Other Drugs by Microbiological Assay—The different dosage forms used are described in Table III. With the exception of the preparation containing tetracycline, all of the other preparations were hydrolyzed with 0.01 *N* sodium hydroxide in ethanol and chloramphenicol was estimated microbiologically as described earlier. For suspensions containing tetracycline, 2 ml. of the suspension, equivalent to 31.25 mg. chloramphenicol, was transferred to a 100-ml. centrifuge tube, mixed with 50 ml. of 0.1 *N* hydrochloric acid, and centrifuged at 10,000 r.p.m. for 15 min. The supernate was decanted and the residue was washed twice with 50 ml. 0.1 *N* hydrochloric acid by centrifugation. The residue contained chloramphenicol palmitate free from tetracycline as determined by microbiological assay. The residue was dissolved in ethanol and diluted to 25 ml. One milliliter of the ethanolic solution was hydrolyzed with 0.01 *N* sodium hydroxide in ethanol, and chloramphenicol was estimated microbiologically as described earlier (Table III).

sion contained 0.5% vanillin, a commonly used flavoring agent. If the method of extraction of the suspension is modified by washing the sample with water on a sintered crucible, dissolving the residue in chloroform, and determining the absorbance of the chloroform solution diluted with ethanol at 271 nm. according to the official method, the results obtained are very close to the labeled amount of chloramphenicol palmitate. According to the USP (3), chloramphenicol palmitate is insoluble in water, but Weiss *et al.* (17) reported that chloramphenicol palmitate is very slightly soluble in water, 1.05 mg./ml. water at 28°. According to them, to test the solubility of the drug, it must be shaken thoroughly for 2 min. The present authors observed that when the suspension was washed with three 10-ml. aliquots of water in quick succession in a sintered crucible No. 4 by suction, there was practically no loss of chloramphenicol palmitate (Table II). Washing on a sintered crucible is less cumbersome and more effective in removing substances likely to interfere with the spectrophotometric estimation of chloramphenicol palmitate than extracting with chloroform in a separator, which did not remove vanillin. When chloramphenicol palmitate suspension identical in all respects but without vanillin was estimated by both the USP method and the suggested modification, similar results were obtained (Table I). This further indicates that chloramphenicol palmitate is not eliminated by the water-washing procedure.

Suspensions of chloramphenicol palmitate were prepared with flavoring agents other than vanillin such as essence raspberry, essence American ice cream, or essence apricot. These essences did not interfere with the estimation of chloramphenicol palmitate by the USP method. Chloramphenicol palmitate oral suspension USP marketed in the United States may not contain vanillin. The preparation[1] marketed in India does not contain vanillin. Furthermore, the USP gives only a lower limit of the requirement of chloramphenicol palmitate in the suspension without specifying the higher limit. These reasons may explain the lack of this particular problem in the United States. In the light of these observations, the USP method of estimation of chloramphenicol palmitate may be suitably modified.

However, the modified USP method is not suitable for estimation of chloramphenicol palmitate in suspension when it is in combination with other drugs such as tetracycline, streptomycin, nitrofurantoin, sulfa drugs, and B vitamins. Drastic treatment of the suspension with sodium hydroxide to convert the chloride of chloramphenicol molecule to sodium chloride and determination of chloride with silver nitrate by potentiometric titration was found suitable for the estimation of chloramphenicol palmitate in the different dosage forms studied (Table III). The usefulness of this method, however, is severely limited because it is nonspecific for chloramphenicol and more complicated than other methods.

Chloramphenicol palmitate in suspensions, with or without other drugs, could be easily hydrolyzed with dilute alkali at room temperature to make chloramphenicol available for microbial assay. The presence of streptomycin, nitrofurantoin, sulfa drugs, or B vitamins in the concentrations present (Table III) had no effect on the test organism. In chloramphenicol palmitate suspension containing tetracycline, the latter must be removed because of its interference in the microbiological assay of chloramphenicol. The removal was carried out by washing with dilute hydrochloric acid, which did not remove chloramphenicol palmitate. The results of the microbiological assay with *E. coli* (Tables III and IV) and the recovery of added chloramphenicol palmitate (Table V) indicate the suitability of the method for the routine assay of chloramphenicol palmitate in the different forms of suspensions tested. The flavoring and coloring agents or the presence of streptomycin, nitrofurantoin, tetracyclines, sulfa drugs, or B vitamins did not interfere in the microbiological assay of chloramphenicol.

Since chloramphenicol palmitate is dissolved in ethanol prior to alkaline hydrolysis, polymorphism of the drug disappears. Therefore, the method of assay would not distinguish the different polymorphic forms, if present. This, however, is not a disadvantage as compared to the USP method which also does not take into consideration the polymorphic forms of chloramphenicol palmitate.

Enzymatic hydrolysis of chloramphenicol palmitate in suspension with pancreatin, either in simulated intestinal fluid (pH 7.5) or in tromethamine buffer (pH 9.0), released only about 80% of chloramphenicol from chloramphenicol palmitate in the present experiments (Table IV). Earlier reports, however, indicated complete enzymatic hydrolysis of chloramphenicol palmitate (13, 14). Our failure to obtain complete hydrolysis might be due to the pancreatin used whose enzyme activity is likely to vary from sample to sample. The data in Table IV show variations in hydrolysis, 21–28 mg./ml., indicating nonuniformity of enzyme action. Enzymatic hydrolysis followed by microbiological assay of chloramphenicol, therefore, may not always be suitable for the routine determination of chloramphenicol palmitate. In any case, hydrolysis of chloramphenicol palmitate with dilute alkali is much simpler than the enzymatic hydrolysis. Enzymatic hydrolysis, however, can indicate the presence of polymorph A crystals of chloramphenicol palmitate which is only hydrolyzed 0–5% (15, 16).

Acetonitrile–Diatomaceous Earth Column for Separation of Steroids and Other Compounds

ROBERT E. GRAHAM*▲ and CHARLES T. KENNER†

Abstract □ The retention characteristics of 53 compounds on an acetonitrile–diatomaceous earth column are given for elution with *n*-heptane followed by stripping with chloroform. Nineteen of the compounds were eluted completely, seven were eluted partially, and 27 (including the 12 corticosteroids tested) were not eluted at all by 150 ml. of *n*-heptane. Partially eluted compounds could be completely eluted by larger volumes of *n*-heptane. Elution characteristics in a group of similar compounds are affected greatly by relatively minor changes in structure. The recommended procedure furnishes a simple and rapid method for the separation of mixtures and for the detection of impurities or decomposition in standards. Several pharmaceutical preparations and known mixtures were analyzed as examples of the application of the column procedure to various products.

Keyphrases □ Steroids—separation using acetonitrile–diatomaceous earth column, retention characteristics of 53 compounds, detection of impurities □ Column chromatography—separation of steroids on acetonitrile–diatomaceous earth column, retention characteristics of 53 compounds, detection of impurities □ Acetonitrile–diatomaceous earth column—separation of steroids □ Diatomaceous earth–acetonitrile column—separation of steroids □ Chromatography, column—separation of steroids using acetonitrile–diatomaceous earth column, retention characteristics of 53 compounds, detection of impurities

The separation of mixtures of steroids and of steroids from other compounds in pharmaceuticals can be difficult if the preparation is other than the official one in USP XVIII (1) or NF XIII (2). Both aqueous and nonaqueous immobile phase systems are available for use with diatomaceous earth, but aqueous systems are the most popular for the separation of steroids (3). Examples of nonaqueous systems include the use of kieselguhr treated with dichlorodimethylsilane vapors to retain the less polar component of many solvent systems used in the separation of C_{12}–C_{18} fatty acids (4). This procedure is known as reverse phase chromatography and was used (5) for the analysis of progesterone in oil injectables. An acetonitrile immobile phase was suggested (6) for the separation of corticosteroids from decomposition products and interfering substances in the analysis of pharmaceuticals containing corticosteroids; this column was used also for the separation of estradiol valerate and estradiol isovalerate from estradiol[1].

This paper reports the elution characteristics of 53 compounds from the acetonitrile immobile phase column and the application of such a column to the separation of steroids of similar structure and to the analysis of pharmaceuticals containing either more than one steroid or interfering substances. The method is simple, flexible, and rapid; three determinations can be completed in approximately 3 hr., and the column can be modified for the removal of acidic, basic, and other water-soluble impurities by using trap layers (6).

EXPERIMENTAL

Equipment—The following were used: UV-visible recording spectrophotometer[2] with 1-cm. quartz cells, glass chromatographic columns for partition chromatography (2.2 × 25 cm., constricted at one end to 0.4 × 5 cm.) and an aluminum tamping rod to fit the column, gas–liquid chromatograph[3] with a flame-ionization detector and a 4-mm. × 0.91-m. (3-ft.) column of 3% SE-33 on 100–120-mesh Gas Chrom Q (column at 252°, detector at 280°, injector port at 258°, and nitrogen carrier gas flow rate at 40 ml./min.), IR spectrophotometer[4], electrobalance[5], and TLC plates coated with silica gel G with fluorescent indicator[6].

Reagents—*Solvents*—All solvents were spectro, certified, analytical reagent, USP, or distilled-in-glass grade. Acetonitrile, *n*-pentane, *n*-hexane, *n*-heptane, 2,2,4-trimethylpentane, cyclohexane, chloroform, methanol, alcohol USP, and absolute ethanol were used. Solvents used in the UV method should be checked photometrically to ensure the absence of aromatic hydrocarbons.

Acetonitrile–n-Heptane (Mutually Saturated)—Mix 25 ml. of acetonitrile and 300 ml. of *n*-heptane (sufficient for two determinations) in a separator, agitate vigorously for 2 min., and allow both layers to clarify. These mutually saturated solutions must be used whenever *n*-heptane or acetonitrile is called for in these directions. Mutually saturated acetonitrile and other hydrocarbons were prepared in the same way for studies without *n*-heptane.

Chloroform (Water Saturated)—Add 50 ml. of water to 250 ml. of chloroform in a separator, agitate for 2 min., and allow both layers to clarify. The water-saturated reagent is required when aqueous trap layers are inserted but should not be used otherwise.

Diatomaceous Earth[7]—Acid washed was used.

Standards—All standard solutions were prepared to contain 1.00, 0.040, or 0.0100 mg./ml. In some studies, individually weighed samples of the solid standards were used.

Alcohol Sulfuric Acid Reagent—Carefully and slowly add 80 ml. of cold, concentrated sulfuric acid (97% w/w) to 20 ml. of cold, absolute ethanol with constant agitation. Cool to room temperature before use. Prepare fresh monthly. Other reagents used in the determinative steps were prepared as directed in the method reference.

Proposed Procedure—*Sample Preparation*—

Tablets: Weigh 20 tablets, grind to pass a 60-mesh sieve, mix thoroughly, and accurately weigh a sample containing approximately 1 mg. of steroid into a beaker. Add 1.5 ml. of acetonitrile, cover the beaker, and swirl occasionally for 10 min. Add 1.5 ml. of *n*-heptane, and swirl until the sample is completely dissolved. As indicated in the tables, the same volumes of absolute methanol and water should be substituted for the acetonitrile and *n*-heptane for some compounds. Continue as directed under *Sample layer*.

Capsules: Weigh the contents of 20 capsules and mix thoroughly. Accurately weigh a sample containing approximately 1 mg. of the steroid into a beaker and proceed as directed under *Tablets* beginning with: "Add 1.5 ml. of acetonitrile, cover the beaker, ..."

Creams: Make a composite by mixing thoroughly the contents of several tubes or jars. Accurately weigh a sample containing approximately 1 mg. of the steroid into a beaker. Proceed as directed under *Tablets* beginning with: "Add 1.5 ml. of acetonitrile, cover the beaker, ..."

[2] Cary model 15.
[3] Barber Colman model 5000.
[4] Perkin-Elmer model 337.
[5] Cahn model G-2.
[6] Eastman No. 6060.
[7] Celite 545, Johns Manville Product Corp., New York, NY 10016

Standards: Accurately weigh approximately 2 mg. of the standard into a beaker. Proceed as directed under *Tablets* beginning with: "Add 1.5 ml. of acetonitrile, cover the beaker, ..."

Column Preparation—

Acetonitrile layer: Insert a glass wool plug in the bottom of the chromatographic column. Thoroughly mix 4.0 g. of diatomaceous earth with 4.0 ml. of acetonitrile, transfer to the column, and pack firmly.

Trap layers: Prepare and insert neutral, acidic, or basic aqueous trap layers as needed according to Graham *et al.* (6).

Sample layer: Thoroughly mix the dissolved sample, prepared as directed under *Sample Preparation*, with 3.0 g. of diatomaceous earth. Transfer to the column above the acetonitrile or trap layer and pack firmly. Dry wash the beaker consecutively with 1.0 g. of diatomaceous earth and glass wool and transfer to the top of the column. Retain the sample beaker for washing with the *n*-heptane and chloroform to be added to the column later.

Column Elution—Wash the sample beaker successively with from four to 12 (depending on the steroid being determined) 25-ml. portions of *n*-heptane and pour onto the column. Adjust the flow rate to 5–7 ml./min., and maintain the liquid head between 8 and 12 cm. above the column bed with a separator attached to the top of the column. Allow the last wash to drain completely. Wash the tip with alcohol USP and save the effluent for further treatment. Rinse the sample beaker with from five to seven (depending on the steroid being determined) 25-ml. portions of chloroform and pour each through the column, maintaining the liquid head as close to the top of the column as possible. Allow the last portion to drain completely from the column. Rinse the tip with alcohol USP and save the effluent for further treatment. Carefully evaporate either or both effluents to dryness on a steam bath under a hood with a current of air to ensure complete removal of the acetonitrile.

Determinative Procedures—*Sample Preparation*—Dissolve the residues from the *n*-heptane and/or chloroform effluents in alcohol USP or absolute methanol and dilute accurately to a volume containing approximately 10 mcg./ml. For GLC, dilute to a volume which contains approximately 1 mg./ml. Use a proper size aliquot of these solutions for quantitation by one of the following determinative methods.

Phenylhydrazine Method—Use the Silber–Porter (7) procedure without modification.

Isoniazid Method—Follow the Umberger (8) procedure using twice the recommended concentration of hydrochloric acid to increase the sensitivity.

UV Method—Scan the alcohol USP or the methanol solution of the sample residue in the region of absorbance using the same solvent as reference. Calculate by comparison with a standard of approximately the same concentration run concurrently.

Alcohol–Sulfuric Acid Method—Dissolve the sample residue in 0.50 ml. of absolute methanol and add 4.00 ml. of the alcohol–sulfuric acid reagent. Scan from 680 to 480 nm. and calculate by comparison with a standard of approximately the same concentration run concurrently.

GLC—Inject a proper size aliquot and calculate by comparison to a standard run concurrently using the area method.

Elution Studies—Each compound studied was put through the proposed procedure using 150 ml. of *n*-heptane and 125 ml. of chloroform. The amount of compound in each of the two eluates was determined by one determinative method to determine if the compound was retained or completely or partially eluted by the *n*-heptane.

Elution curves for those compounds partially or completely eluted by the 150 ml. of *n*-heptane were obtained using 300 ml. of *n*-heptane and collecting 15-ml. aliquots for analysis.

Separation Studies—Several mixtures prepared from standards were analyzed by the proposed method, using 300 ml. of *n*-heptane and 125 ml. of chloroform.

Decomposition Studies—During some elution studies using standards determined by the UV method, it was noted that shoulders appeared in the spectra in some aliquots and that two or more elution bands occurred in some cases. Further study to identify the products of suspected decomposition was performed for androst-4-ene-3,17-dione, dimethoxystilbestrol, norethandrolone, and testosterone enanthate, all of which had been purchased for use as standard substances.

Sample Studies—Several samples of steroid and other types of pharmaceutical preparations were run by the proposed method.

Table I—Effect of Various Hydrocarbons on Elution

Compound	Hydrocarbon	Recovery[a], %: Hydrocarbon Fraction	Recovery[a], %: Chloroform Fraction	Recovery[a], %: Total

[a] Based on the use of 150 ml. of hydrocarbon followed by 125 ml. of chloroform. [b] Aldrich Chemical Co., Milwaukee, Wis. [c] NF Reference Standard. [d] Nutritional Biochemical Corp., Cleveland, Ohio.

METHOD DEVELOPMENT

Length of Acetonitrile Trap Layer—Columns were prepared using methyltestosterone and diatomaceous earth–acetonitrile ratios of 2 g. plus 2 ml., 4 g. plus 4 ml., 6 g. plus 6 ml., and 8 g. plus 8 ml. Twenty 15-ml. aliquots of *n*-heptane were collected and analyzed by the UV method. The primary effect was the increase in the breakthrough volume of *n*-heptane required as the length of the acetonitrile layer increased. Since the breakthrough volume for the 2 g. plus 2 ml. column was less than desirable for many steroids, and the breakthrough volume for the 6 g. plus 6 ml. was larger than necessary, the 4 g. plus 4 ml. ratio was selected as the optimum.

Hydrocarbon Solvent—Various hydrocarbon solvents were studied using testosterone, methyltestosterone, and androst-4-ene-3,17-dione. In each case, the recommended procedure was followed using 150 ml. of the hydrocarbon and 125 ml. of chloroform and then analyzing the residues by the UV method. These three steroids were selected since they appear in both the hydrocarbon and chloroform effluents of the proposed method but in significantly different ratios. There are differences in the elution characteristics of the various solvents as shown in Table I. The hydrocarbon of choice for these three compounds is clearly cyclohexane, but elution data on other steroids prompted the selection of *n*-heptane.

Flow Rate of Hydrocarbon—Testosterone was run by the proposed method, except that the flow rate was adjusted to 1 ml./min. and the 300 ml. of *n*-heptane used was collected in 15-ml. aliquots for UV analysis. The experiment was repeated using a flow rate of 6 ml./min., and both rates were repeated using methandrostanolone. The main effects were a slight broadening of the peaks and the slightly larger volumes (less than 5%) required to attain the peak maxima at the more rapid flow rates. Therefore, the flow rate is not critical and the great saving in time offsets the slight broadening caused by the faster rate.

RESULTS AND DISCUSSION

Fifty-three different compounds were checked by the proposed method, using 150 ml. of *n*-heptane and 125 ml. of chloroform to determine if they were retained on the acetonitrile layer or were partially or completely eluted by the *n*-heptane (Table II). Since the chloroform completely strips the acetonitrile and dissolved substances from the column, any portion of the compound not eluted by the *n*-heptane appears in the chloroform effluent. All 12 corticosteroids listed in Table II [plus nine that were reported previously. (6)] were retained by acetonitrile and were not eluted by the hydrocarbon solvent, even though some were esterified in the C_{17} or C_{21} position. Of the remaining compounds, 19 were completely eluted by the *n*-heptane, seven were partially eluted by the

n-heptane, and 15 were retained by acetonitrile and determined in the chloroform effluent.

The elution curves for compounds that were partially or completely eluted by the *n*-heptane were determined using 15-ml. portions for a total of 300 ml. of the *n*-heptane (last column of Table II); typical elution curves are shown in Fig. 1. The elution curve for the removal of the acetonitrile has been reported (6).

Information concerning the effect of slight changes in structure upon the retention or elution of a compound is found in Table II. As an illustration, consider the first three compounds listed. Androstanolone is completely eluted by the 150 ml. of *n*-heptane, androst-4-ene-3,17-dione is partially eluted, and androst-4-ene-3,11,17-trione is retained completely by the acetonitrile layer. In the conversion of androstanolone to androst-4-ene-3,17-dione, the hydroxyl group at C_{17} is converted to a carbonyl and a single bond is converted to a double bond between C_4 and C_5. The further addition of a carbonyl at C_{11} to form androst-4-ene-3,11,17-trione completely reverses the elution characteristics of the androstanolone.

If the single bond between C_3 and C_5 in androstanolone is converted to a double bond, the resulting compound is testosterone (Table II), which differs from androst-4-ene-3,17-dione only by having a hydroxyl instead of a carbonyl at C_{17}. However, less than 10% of the testosterone but more than 50% of the androst-4-ene-3,17-dione is eluted by the 150 ml. of *n*-heptane. The addition

[a] Each mixture contained 2.00 mg. of each component. [b] Eluted in the *n*-heptane fraction. [c] Eluted in the chloroform fraction. [d] This mixture contained 26.0 mg. of progesterone. [e] *n*-Heptane added in two portions: 55 ml. plus 150 ml. The propionate was eluted completely in the first portion and the testosterone in the second.

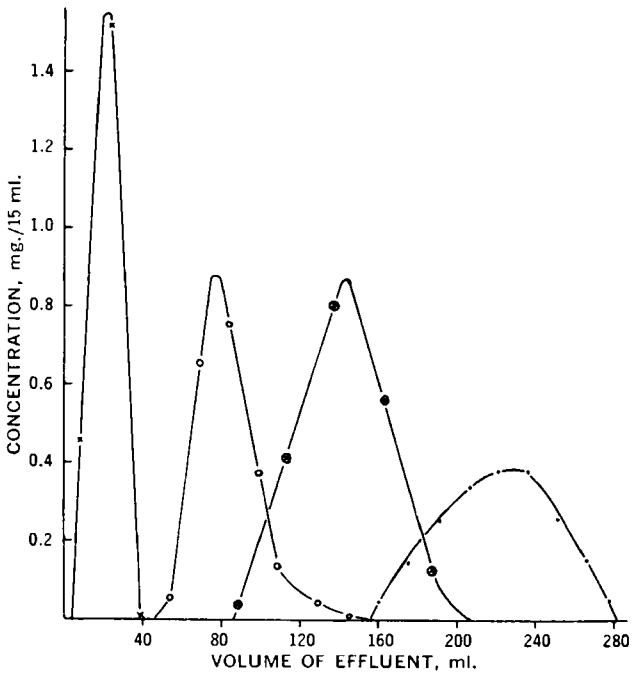

Figure 1—*Typical elution curves for steroids eluted in the* n-*heptane fraction. Key:* ×, *testosterone propionate;* ○, *methyltestosterone;* ⊗, *testosterone; and* ●, *medroxyprogesterone acetate.*

of a methyl group alpha to the C_{17} hydroxyl of testosterone produces methyltestosterone (Table II), which is essentially completely eluted by the *n*-heptane. While the addition of a double bond between C_4 and C_5 greatly decreases the amount of this type of steroid eluted by the *n*-heptane, the difference between a hydroxyl and a carbonyl at C_{17} increases the amount eluted by the *n*-heptane by approximately 50%. However, the effect of the addition of the double bond is offset by the steric hindrance caused by a methyl group alpha to C_{17} since methyltestosterone has essentially the same elution characteristics as androstanolone.

For steroids that are eluted by *n*-heptane, any change in structure that decreases the polarity of the molecule or increases steric hindrance decreases the volume of *n*-heptane necessary for complete elution. Conversely, any change that increases the polarity or decreases steric hindrance increases the volume necessary for complete elution.

Another example using estradiol, estradiol valerate, and estrone (Table II) shows the effect of changes in a single functional group. Estradiol is retained in the acetonitrile layer while estradiol valerate is eluted completely by the 150 ml. of *n*-heptane. Thus, esterification of the hydroxyl group at C_{17} completely reverses the elution characteristics. However, the compound estrone, which is formed by the conversion of the hydroxyl group at C_{17} to a carbonyl, has the same elution characteristics as estradiol. Any change that decreases the polarity of the estradiol molecule, such as esterification at either C_3 or C_{17} or formation of a methyl ether at C_3, apparently produces a molecule that can be eluted by *n*-heptane.

Similarly, diethylstilbestrol is retained by acetonitrile and appears in the chloroform effluent. Conversion to the dipropionate or dimethoxy derivative produces compounds that are eluted completely by *n*-heptane.

Results using the proposed method in the separation and determination of prepared mixtures are shown in Table III. The residues from the evaporation of the *n*-heptane and chloroform effluents were checked by TLC to ensure that separation was complete. For satisfactory separations, one compound should be eluted completely by the *n*-heptane while the other is retained by acetonitrile. The volume of *n*-heptane used depended upon the compounds being separated. The mixture of testosterone propionate, testosterone, and norethindrone is an example of the ability of the proposed method to separate two substances that are completely eluted by the *n*-heptane if there is a sufficient difference in the volumes necessary for complete elution. Information concerning the volumes necessary for complete elution is given in Table II.

The proposed method can also be used to detect decomposition in standard materials by running elution curves, using 15-ml. portions for determination by the UV method. As an example, the UV spectra for the last few portions in the elution of standard androst-4-ene-3,17-dione showed a shoulder at 280 nm. on the expected peak at 240 nm. The fact that the shoulder did not appear until the major portion of the standard had been eluted indicated that the impurity

Table IV—Determination of Pharmaceutical Samples

Type	Components and Declared Amounts	Trap Layer Used	*n*-Heptane Fraction, ml.	Chloroform Fraction, ml.	Found, Percent of Declared—Avg.	Found, Percent of Declared—Range	Number of Determinations

Tablet[a]	Methyltestosterone, 10 mg. Esterified estrogens, 1.25 mg.	Acidic	200	125	82 ND[b]	(81–82) ND	3 –
Cream[c]	Iodochlorhydroxyquin, 3% Hydrocortisone, 0.5%	Neutral Aqueous	150	125	99 103	(99) (103–104)	2 2
Tablet[d]	Sodium butabarbital	8% Sodium bicarbonate	150	125	88	(88)	2

[a] Recovery of added methyltestosterone standard was 101.0%. Sample contained stearic acid, which eluted with the *n*-heptane. [b] ND = not determined. [c] Cream also contained allantoin 1%, stearic acid, glycerol monostearate, petrolatum, squalene, propylene glycol, polyoxyethylene stearate, and methylparabens. [d] Tablet also contained stearic acid, which eluted in the *n*-heptane fraction.

was more polar than the standard, but the actual structure was not determined. The impurity in this case was estimated to be approximately 0.2%.

Similarly, the UV spectra for the volumes collected during the elution of standard dimethoxystilbestrol showed two separate components, one contained in the first 15-ml. fraction and the second contained in the fourth through seventh fractions. The first fraction contained 93.6% of the standard and was shown to be the dimethoxystilbestrol. The second compound was shown to be the monomethoxy by its IR spectrum and represented approximately 6.1% of the starting material. The norethandrolone standard was found to contain two impurities, one of which was less polar and the other more polar than norethandrolone, but the actual structures were not determined since they represented only about 0.6% of the original material.

A standard sample of testosterone enanthate, which previous work had indicated might be contaminated, was put through the elution procedure. The undecomposed standard was completely eluted in the first 75 ml. of *n*-heptane and was calculated to represent 64% of the original material. A second compound was eluted between 85 and 200 ml. of *n*-heptane and was shown to be testosterone by its IR spectrum. The complete elution volume of 200 ml. also agrees with the value listed in Table II for testosterone.

The results of several pharmaceutical samples determined by the proposed method are shown in Table IV. The replication and recovery of added standards are satisfactory for these types of materials. The sodium butabarbital tablet is included to illustrate the applicability of the method to samples other than steroids and steroid-like compounds. The butabarbital was present in the chloroform effluent.

The sample must be completely dissolved in the sample solvent before it is mixed with the diatomaceous earth to prepare the sample layer; otherwise, the elution peaks are not symmetrical. Most steroids and other compounds checked will dissolve satisfactorily in either the *n*-heptane–acetonitrile or methanol–water system, but the use of the *n*-heptane–acetonitrile usually produces more symmetrical elution peaks for compounds that are completely soluble in both systems. The volumes required for complete elution, however, are approximately the same for the individual compounds for either system. The *n*-heptane–acetonitrile should be used with all steroids containing an aromatic A ring, since these compounds tail badly when the methanol–water system is used.

In all cases, a white residue, which is insoluble in alcohol USP and methanol, is obtained upon evaporation of the chloroform fraction. The IR spectrum of the residue agrees with the IR spectrum of the diatomaceous earth, and the residue apparently is caused by the fact that some diatomaceous earth is either dissolved or rendered colloidal by the *n*-heptane–acetonitrile–chloroform mixture. The presence of the residue causes an increase in the baseline when the UV method is used for quantitation and must be removed before the measurement is made. The residue can be removed by filtration through a fine frit or can be allowed to settle for 30 or more min. before decantation of the solution. Alternatively, the beaker can be washed several times with small volumes of alcohol USP, methanol, or chloroform (be careful not to remove the residue) followed by evaporation before redissolving in the solvent of choice.

The proposed method can be used for the separation of steroids from steroid esters, for the detection of decomposition in steroid standards, and for the purification of steroid standards, as well as for the analysis of various pharmaceutical preparations. Work is continuing on the application of the method to the separation and determination of components other than steroids in pharmaceutical products.

Temperature Studies with Nonaqueous Emulsions

KEITH W. REICHMANN*▲ and ROBERT V. PETERSEN

Abstract □ Emulsions of glycerin and mineral oil were formed using anionic, cationic, and nonionic surfactants. Cetylpyridinium chloride and 2-amino-2-methyl-1,3-propanediol–linoleic acid combinations were employed to stabilize emulsions stored at four different temperatures for up to 120 days. Emulsions were prepared at three concentrations of each surfactant. The effects of temperature and aging on droplet size and viscosity were evaluated. The droplet size and viscosity checks were made at predetermined intervals throughout the study. The decrease in viscosity correlated well with droplet size growth. Only one cetylpyridinium chloride-stabilized emulsion showed positive signs of separation at the end of 120 days. All emulsions using 2-amino-2-methyl-1,3-propanediol separated at 45°, and the emulsion with the minimum 2-amino-2-methyl-1,3-propanediol concentration was also unstable at 35°.

Keyphrases □ Emulsions, nonaqueous—temperature dependency, glycerin–mineral oil emulsions with surfactants, droplet size and viscosity □ Surfactants, in glycerin–mineral oil emulsions—temperature dependency, viscosity and droplet size □ Stability, nonaqueous emulsions with surfactants effects of temperature, cetylpyridinium chloride and 2-amino-2-methyl-1,3-propanediol–linoleic acid as stabilizers □ Viscosity, glycerin–mineral oil emulsions with surfactants—effects of temperature

Previous publications from this laboratory (1–7) described the preparation and properties of some nonaqueous emulsions consisting of olive oil as the nonpolar phase and glycerin, propylene glycol, or polyethylene glycol 400 as the polar phase. The stability and viscosity changes of such nonaqueous emulsions over 120 days were reported (4); two anionic surfactants (condensation products of ammonia and of 2-amino-2-methyl-1,3-propanediol with the fatty acids available in olive oil) were used. Stable emulsions were obtained with concentrations of ammonia and 2-amino-2-methyl-1,3-propanediol as low as 0.0006 and 0.002%, respectively. The emulsifying effects of other anionic, cationic, and nonionic surfactants on the glycerin–olive oil system also were described (1, 2). In a study (5) on the effect of surfactant concentration on the interfacial viscosity of a glycerin–olive oil system, it was demonstrated that stability can be achieved in this type of emulsion with interfacial viscosities about 100 times lower than those considered necessary (8) in oil–water emulsions. When other glycols (polyols) were used in conjunction with olive oil, the emulsions with glycerin were found (6) to be more easily made and more stable than those from other polyols.

Although much work on emulsions is described in the literature, these cited studies constitute the majority of available references concerning nonaqueous emulsions. These publications made no reference to the effects of temperature on the nonaqueous emulsion system. The effects of temperature on emulsions with an aqueous phase have been reported (9–11), but information is needed regarding the effects of temperature on the stability of nonaqueous emulsions. For this reason, the present study was designed to explore the effects of temperature on selected nonaqueous emulsion systems. To broaden these studies, mineral oil was selected as the nonpolar phase instead of olive oil.

EXPERIMENTAL

The glycerin used had a purity of 99%[1], confirmed by its refractive index. The glycerin was heated to 180° and then sealed to ensure the absence of water. No further purification of any employed reagent was performed. When surfactant precursor amines were employed, 1% linoleic acid[2] was added to the mineral oil[3].

A phase volume of 0.5 was used in all experiments. The two methods employed for the mixing of reagents were described previously (1, 2). Briefly, Method I consisted of adding the surfactant or surfactant precursor (amine) to the glycerin. Then an equal volume of oil (with the linoleic acid, if needed) was added to the glycerin in a slow steady stream of about 1 ml./sec. while stirring in a blender[4]. The quantities of reagents and the procedure used in Method II were the same as in Method I, except the surfactant or surfactant precursor was added to the oil. Then the glycerin was added to the oil with stirring.

Emulsion stability was determined by close observation for 7 days. At the end of this period, the preparations were examined both macroscopically and microscopically for layer formation. If none was detected, the emulsion was termed "stable."

Two surfactants were selected to stabilize the emulsions for the extended time-temperature studies. The employed surfactant concentrations were determined as the lowest concentration producing stability for at least 30 days at room temperature, 10 times the lowest concentration, and a median concentration. Six solutions of the surfactants in glycerin were prepared. The surfactants used were 2-amino-2-methyl-1,3-propanediol (3, 20, and 30 mg./100 ml. emulsion) and cetylpyridinium chloride (40, 220, and 400 mg./100 ml.). Several sets of duplicate emulsions were prepared for data comparison. Extreme care had to be taken so emulsions would be as similar as possible.

The temperatures involved were 0, 25, 35, and 45°. Three sets of emulsions were prepared to represent each temperature and surfactant concentration used in the study.

Particle-size studies were conducted by the use of oil-immersion, phase-contrast photomicrography, with light at 475 nm. and 730 × magnification. Photomicrographs were prepared at predetermined time intervals (Days 1, 2, 4, 7, 14, 30, and 60 of the study) and were made for each surfactant concentration and temperature involved. Droplet size change was followed by dividing the photomicrographs into areas measuring 3.0 cm.^{2}, selecting the squares at random, and counting the droplets at different size intervals.

The total volume of the droplets for each size interval was determined by using the formula:

$$T_v = (n)(0.523d^3) \qquad \text{(Eq. 1)}$$

where T_v = total volume of droplets within interval, n = total

number of droplets within interval, d = mean droplet diameter of interval, and constant = $^1/_6\ \pi$.

The percent of the total volume within each interval for each day and temperature was determined by using the formula:

$$\%T_{va} = \frac{T_{va} \times 100}{(T_{va} + T_{vb} \cdots + T_{vn})} \qquad \text{(Eq. 2)}$$

where $\%T_{va}$ = percent of total volume of droplets represented for each size interval for a given day and temperature, and $T_{va,vb\cdots vn}$ = designation assigned to size intervals.

A Coulter counter[5] was also used to determine the droplet size. Droplet counts were made immediately after mixing the emulsion with saline electrolyte (0.9% aqueous solution of sodium chloride). The results of the experiments using the Coulter counter were then compared with the results of the visual counting of the photomicrographs. The Coulter counter was used to determine droplet size of all duplicate emulsions.

Viscosities[6] of the emulsions were measured on the same days that

the photomicrographs were prepared. Four speeds were used: 0.6, 1.5, 3.0, and 6.0 r.p.m. Viscosity measurements of the emulsions were made at the same temperature at which the samples had been stored. Temperature-controlled rooms provided the environment for 0 and 25°. The containers with the samples stored at 35 and 45° were placed in oil baths to maintain a constant temperature throughout the viscosity determination. The readings were first taken from the lowest revolutions per minute to the highest. Then a

revolutions per minute of 60 was applied for 10 min., and the viscosity was recorded as the revolutions per minute was decreased from 6.0 to 0.6. Thixotropy was demonstrated when the up (or increasing revolutions per minute) readings exceeded the down readings.

To check the validity of this work, duplicate emulsions of the same concentrations were prepared. The viscosities of these emulsions were recorded for 7 days and compared with those of the test emulsions.

Emulsion type was determined by both the phase dilution method and visual observation. The addition of methylene blue to the glycerin phase allowed sufficient observation with the use of an ordinary microscope to determine emulsion type.

RESULTS AND DISCUSSION

The effects of various anionic, cationic, and nonionic surfactants on glycerin-mineral oil systems are given in Table I. All emulsions were of the oil-in-glycerin type with four exceptions. These surfactants or surfactant precursors were all stearate esters or salts. Similar results were reported previously with glycerin olive oil systems (1, 2).

Although linoleic acid was added to the mineral oil when precursor amines were employed, stearic acid and palmitic acid also produced satisfactory results but required high concentrations. Further studies with stearic acid added to the mineral oil are presently being conducted in an effort to produce other glycerin-in-oil emulsions.

The photomicrographs produced a record of droplet size growth (Fig. 1). This was clearly seen when lower surfactant concentrations were employed. No droplet size change was apparent in emulsions prepared with high surfactant concentrations and stored at 0°, while other emulsions exhibited droplets of various sizes (Fig. 2).

Methods of particle-size analysis (12, 13) have been described, as have the problems of photomicrography (12). The use of oil-immersion, phase-contrast photomicrography eliminated many problems. The slides from which the photomicrographs were made were prepared several hours in advance to reduce particle movement. This procedure proved to be very satisfactory. Even at the high degree of magnification employed, droplets below 1 μ in diameter were difficult to resolve. Despite these limitations, the photomicrographs provided a reliable method from which droplet size data were obtained.

The Coulter counter instrument was used to confirm the data obtained from the photomicrographs. In almost every case, the data from the two methods were comparable and were in almost exact agreement in several instances.

One problem encountered with the Coulter counter was that of aggregation after the addition of the electrolyte solution. This became more marked with time, as reported previously (14, 15). It has been observed (16) that the Coulter counter is ideal for investigating aggregation phenomena. Count loss has also been reported (17).

Because of the occurrence of aggregation, the droplets of the emulsion samples were counted immediately after the introduction of the saline electrolyte. This sharply reduced aggregation and, as stated previously, gave results that were in agreement with those from the photomicrographs.

The droplets were counted from the photomicrograph in size intervals of 1 μ. The intervals used were: <0.05–1, 1–2, 2–3, 3–4, 4–5, and >5 μ. Very few droplets with a diameter >5 μ were present in the stable emulsions. However, some larger droplets were seen in some emulsions prior to demulsification. As close to 100% of the droplets as possible were represented in the calculations.

All diol–linoleic acid-stabilized emulsions stored at 45° were unstable. The preparations with a surfactant concentration (2-amino-2-methyl-1,3-propanediol) of 3 and 20 mg./100 ml. of emulsion were also unstable at 35°. Only one quaternary amine- (cetylpyridinium chloride) stabilized emulsion showed positive signs of separation. This emulsion, stored at 45°, had a quaternary amine concentration of 40 mg./100 ml. Although some inherent error was introduced, the droplets were assumed spherical and the mean diameter was determined by using the midpoints of the respective intervals. This procedure gave a parameter by which the change in droplet volume of the various emulsions could be compared (Table II). As the size of the droplet increases, a small number of droplets

can exert a great influence on the total combined volume of the droplets. The total volume of the internal phase generally increased throughout the test period.

Droplet size data obtained from duplicate emulsions were generally within 5% of the data of the test emulsions. Viscosity data correlation was more difficult, although results generally agreed within 10%. Exceptions were found in both cases, however. Care in emulsion preparation was extremely important in obtaining closely correlated data.

Representative examples of viscosity changes are found in Fig. 3. Viscosities of emulsions stored at high temperatures decreased more rapidly than those of emulsions of the same surfactant concentrations stored at a lower temperature. A decrease in viscosity generally corresponded with droplet size growth. This was very evident just prior to demulsification of the unstable emulsions. As expected, the viscosities of the emulsions stored at 0° were extremely high and appeared very stable. The emulsion viscosities increased with increasing surfactant concentration, a property described previously (18).

Thixotropy was exhibited after the 14th day of the study. The hysteresis loop can be drawn for a large number of the emulsions at all temperatures involved (Table III). Some emulsions of high surfactant concentration stored at the higher temperatures formed gels and exhibited erratic viscosity readings. Thixotropic properties have been shown to exist with other nonaqueous emulsion systems (4).

SUMMARY

Emulsions of glycerin and mineral oil were prepared using a number of different surfactants. Emulsions of the glycerin-in-oil type were produced only with the use of stearate salt or stearate ester surfactants.

Emulsions with 3, 20, and 30 mg./100 ml. of 2-amino-2-methyl-1,-3-propanediol and 40, 220, and 400 mg./100 ml. of cetylpyridinium chloride were prepared for temperature studies. The emulsions were stored at 0, 25, 35, and 45°. Emulsion stability, droplet size, and

[a] Measured with a Brookfield viscometer using spindle No. 4 for all 0° and 220-mg./100 ml. and 400-mg./100 ml. cetylpyridinium chloride readings. All other readings were with a No. 3 spindle. [b] Thixotropy demonstrated by two figures. The upper figure represents viscosities at the increasing spindle speed. The lower figure represents the viscosities at the decreasing spindle speed. [c] Erratic readings noted with many of the cetylpyridinium chloride emulsions since gels were formed with aging. [d] Demulsification had occurred.

viscosity were studied on Days 1, 2, 4, 7, 14, 30, and 60. Day 1 corresponded to the day the emulsions were prepared.

When stored at high comparable temperatures for the study period, emulsions stabilized by a quaternary amine (cetylpyridinium chloride) were more stable than those stabilized by a surfactant precursor amine (2-amino-2-methyl-1,3-propanediol) and linoleic acid. All emulsions stored at room temperature (25°) and at 0° were stable.

Photomicrographs were used to study droplet size change. High surfactant concentrations retarded droplet size growth. A sudden increase of droplet size preceded demulsification, as was very evident at high temperatures.

A rapid decrease in viscosity preceded demulsification. At high temperatures, the cetylpyridinium chloride-stabilized emulsions formed loose gels and exhibited erratic readings.

Thixotropy was demonstrated as the emulsions were allowed to age at least 2–4 weeks. It was manifested by the change in viscosity readings as the stress was increased from 0.6 to 6.0 r.p.m. and then reversed from 6.0 to 0.6 r.p.m.

Preformulation Studies II: Stability of Drug Substances in Solid Pharmaceutical Systems

J. TINGSTAD▲ and J. DUDZINSKI

Abstract □ The stability of drug substances in solid pharmaceutical systems is discussed. Theoretical models for various situations are proposed and their practical implications are considered.

Keyphrases □ Preformulation theory—stability of drug substances in solid pharmaceutical systems □ Drug stability in solid pharmaceutical systems—theory, preformulation □ Solid drug systems—stability of drug substance, theory

The stability of drug substances in solid pharmaceutical systems has been discussed in some detail previously (1–11 and the references cited therein). However, further treatment of the subject seems desirable for the following reasons.

1. In spite of the importance of solid dosage forms, there are relatively few quantitative reports on their chemical stability, primarily because of the complexities and difficulties involved.

2. This paper presents a somewhat different point of view than those of most references cited previously.

3. Some theoretical concepts need further clarification and application to practical stability studies.

DISCUSSION

Quantitative chemical stability studies on drug substances in solid dosage forms are difficult to perform for two primary reasons. First, analytical results tend to have more scatter because tablets and capsules are distinct dosage units rather than the true aliquots encountered with stability studies on drug substances in solution. Second, tablets and capsules are heterogeneous and discontinuous systems involving gas (air and water vapor), liquid (*e.g.*, adsorbed water), and solid phases, all of which can vary in concentration during an experiment.

Analytical error can be minimized by ensuring that content uniformity is satisfactory before initiating stability studies. The problems arising from the heterogeneity associated with these systems are more difficult to overcome, but the primary prerequisites for dealing with them are an awareness of their existence, an under-

viscosity were studied on Days 1, 2, 4, 7, 14, 30, and 60. Day 1 corresponded to the day the emulsions were prepared.

Preformulation Studies II: Stability of Drug Substances in Solid Pharmaceutical Systems

J. TINGSTAD▲ and J. DUDZINSKI

Abstract □ The stability of drug substances in solid pharmaceutical systems is discussed. Theoretical models for various situations are proposed and their practical implications are considered.

Keyphrases □ Preformulation theory—stability of drug substances in solid pharmaceutical systems □ Drug stability in solid pharmaceutical systems—theory, preformulation □ Solid drug systems—stability of drug substance, theory

The stability of drug substances in solid pharmaceutical systems has been discussed in some detail previously (1–11 and the references cited therein). However, further treatment of the subject seems desirable for the following reasons.

1. In spite of the importance of solid dosage forms, there are relatively few quantitative reports on their chemical stability, primarily because of the complexities and difficulties involved.

2. This paper presents a somewhat different point of view than those of most references cited previously.

3. Some theoretical concepts need further clarification and application to practical stability studies.

DISCUSSION

Quantitative chemical stability studies on drug substances in solid dosage forms are difficult to perform for two primary reasons. First, analytical results tend to have more scatter because tablets and capsules are distinct dosage units rather than the true aliquots encountered with stability studies on drug substances in solution. Second, tablets and capsules are heterogeneous and discontinuous systems involving gas (air and water vapor), liquid (*e.g.*, adsorbed water), and solid phases, all of which can vary in concentration during an experiment.

Analytical error can be minimized by ensuring that content uniformity is satisfactory before initiating stability studies. The problems arising from the heterogeneity associated with these systems are more difficult to overcome, but the primary prerequisites for dealing with them are an awareness of their existence, an under-

standing of their nature, and an appreciation of their practical significance. Some of these problems are as follows.

1. There can be a considerable time lag before physical pseudo-equilibrium is established. For example, appreciable time may elapse before the concentration of water (liquid and vapor phases) comes to equilibrium (1). This is especially true for gelatin capsules, because water present in the capsule shell must equilibrate with that in the formulation and in the surrounding air space.

2. This equilibrium can be upset by opening the container to remove samples for assay, since water vapor can then escape from containers stored at elevated temperatures.

3. If the container is pervious to gaseous diffusion, the stability picture may become confused. For example, Table I shows that at 60°, a water-labile component of a tablet formulation was considerably more stable in a water-permeable blister package than in a sealed glass bottle; at room temperature and 70% relative humidity, the situation was reversed. The tablets, manufactured and packaged at room temperature, probably lose considerable water through the film at 60°, thereby improving stability. At room temperature and 70% relative humidity, the diffusion of water vapor is in the opposite direction.

4. A number of phase changes could take place during the stability study. For example, salicylic acid from aspirin hydrolysis would be in solution until the saturation point is reached and then a solid phase would separate. In addition, sublimation and subsequent deposition of salicylic acid crystals on the dosage form and surface of the container often take place.

5. Solid-state reactions (*e.g.*, oxidation by atmospheric oxygen) may occur simultaneously with solution reactions, and the degradation rates may not be additive (5).

6. Because of the low water volumes involved, kinetic studies may be complicated by chemical equilibrium phenomena and other factors (7).

7. An increase in temperature increases reaction rates and (usually) solubility; this would have a double effect on the overall degradation rate (12). However, this may be partially offset by the lowered concentration of liquid water at higher temperatures.

These problems can be minimized by observing four fundamental rules when conducting quantitative kinetic studies on solid dosage forms. First, as mentioned earlier, content uniformity must be within satisfactory limits. Second, tightly sealed glass containers should be used unless an alternative package is involved. Third, the amount of water present in the dosage form should be determined, since the rate of degradation often depends on the amount of water present. Furthermore, the equilibrium between liquid and vapor phases varies with temperature; consequently, it would be more accurate to determine water concentration at each storage temperature. One approach is to add a measured amount of water to the formulation (5), but part of this water vaporizes into the air space in the container. Consequently, water determinations done on the stored samples have more meaning (10), especially when elevated temperatures are involved.

The fourth rule is that a separate, sealed sample should be taken for each assay point and water determination. If not, water equilibrium can be upset when the container is opened to remove samples. If these rules are observed, meaningful data can be gathered in many cases. The treatment of some of these data may involve relatively complex mathematics (1, 7, 10), but for many systems a few basic, relatively simple, theoretical concepts will suffice. These concepts are as follows.

1. The three most common reactions encountered in stability studies on solid systems are: (*a*) hydrolysis in solution (*e.g.*, aspirin); (*b*) oxidation, either in solution or in the solid state (*e.g.*, vitamin A); and (*c*) reactions between two ingredients.

2. When both Class (*a*) and Class (*b*) reactions are involved, the reaction rates can be additive or antagonistic. For example (assuming no oxidation in solution), adding water to a dry system would initiate hydrolysis but could decrease solid-state oxidation, probably by water adsorption on solid surfaces (5).

3. Class (*a*) reactions are usually zero order in solid dosage forms unless all of the reactant is in solution; then first-order kinetics usually prevail. However, in some situations (*e.g.*, if an acidic or basic degradation product catalyzes the reaction), the kinetics are more complicated. Class (*b*) reactions can be of various orders, although they are often first order if sufficient oxygen is present. Class (*c*) reactions can be of various orders, depending on the concentrations and solubilities of the reactants.

Table I—Degradation of Water-Labile Component of a Tablet Formulation in Two Different Packages under Different Storage Conditions

Package	—Amount Lost (%) in 8 Weeks at— 60°	Room Temperature (70% Relative Humidity)
Blister	11.6	7.0
Glass	84.4	0

4. A particular model or system should be carefully defined. For example, the Class (*a*) reactions described here assume that the reactant dissolves in an adsorbed film of water and that the concentration of adsorbed water is directly proportional to the total amount of water present. The discussion here of Class (*b*) reactions is limited to oxidation in the solid state. Finally, the mathematics describing a Class (*c*) reaction would be different, depending on whether one assumed solid state or solution reactions.

5. Although the models described here are consistent with many reported data, this consistency does not prove that degradations are occurring *via* mechanisms proposed in the model. The mechanisms of degradation for each individual situation would have to be proven by the usual rigorous procedures.

Because of the relatively small amounts of water present in these systems, concentrations (in solution) of degradation products may become significant as the reaction proceeds; then chemical equilibrium phenomena may complicate the kinetics (7). Furthermore, in some cases the drug substance may be less stable in a solid system with a small amount of water present than when the same ingredients are dissolved or suspended in a relatively large quantity of water (10). Nevertheless, many solid systems behave predictably according to the first three concepts above, especially during the first 10–40% of the reaction. Therefore, it would be useful to take a more detailed look at those predictable situations. Only Class (*a*) and Class (*b*) reactions will be considered here.

Figure 1 illustrates the effect of adding water to a solid system involving a relatively insoluble drug substance that degrades only in aqueous solution [Class (*a*), with assumptions mentioned in the fourth concept above]. With no water present, no degradation occurs. As successive amounts of water are added (assuming all of it is available as solvent), the amount of drug substance degrading per unit time increases proportionally:

$$d = k_0 \times v \qquad \text{(Eq. 1)}$$

where, for example, d is the amount degraded in 1 day, k_0 is the apparent zero-order rate constant[1] (in milligrams per milliliter per day), and v is the volume of water (in milliliters) present in the solid system. For example, if k_0 = 1 mg./ml./day and v = 0.1 ml., then d = 0.1 mg.; then if the water content is doubled to 0.2 ml., d would also double. Since the point is never reached where all of the drug substance is in solution, the plot consists of a single straight line with a slope of k_0.

In Fig. 2, the same assumptions are made except that the drug is relatively soluble. Up to point A, the amount of water present is not enough to dissolve all of the drug substance and the situation is identical to that in Fig. 1. After point A, all of the drug substance is in solution and first-order kinetics prevail:

$$d = (1 - e^{-k_1}) \times c \times v \qquad \text{(Eq. 2)}$$

where d and v have the same meaning as in Eq. 1, c is the initial concentration of drug substance (in milligrams per milliliter), and k_1 is the first-order rate constant in reciprocal days. Here, adding more water does not change the value of d (ignoring other dilution effects) because, for example, doubling v automatically decreases c by one-half. Thus, the slope is (ideally) zero when first-order kinetics pre-

[1] As pointed out previously (12), the apparent zero-order rate constant k_0 is equal to the first-order rate constant k_1 times the solubility of the drug substance in the solvent at the experimental temperature. Consequently, when the temperature is raised in accelerated studies, k_0 is increased by two factors: the temperature effect on k_1 and the temperature effect on the solubility of the drug substance.

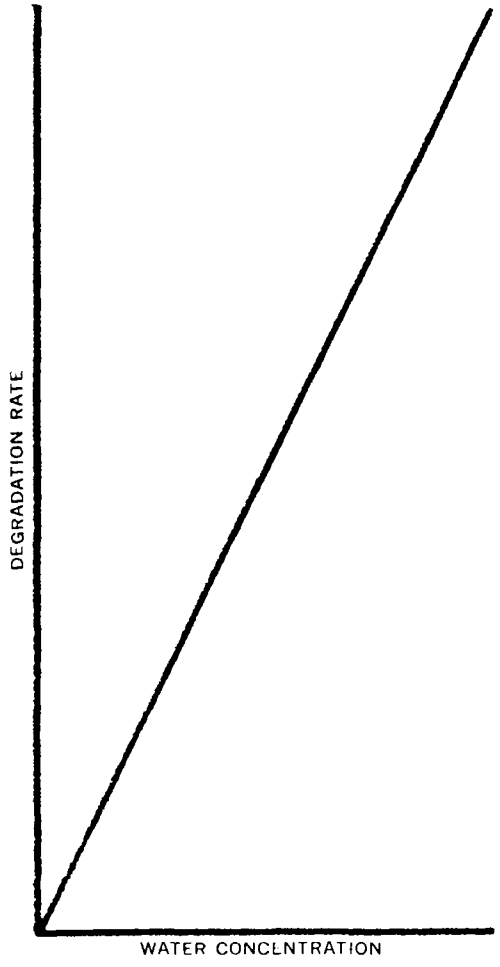

Figure 1—*Model plot showing the effect of water concentration on the stability of a relatively insoluble drug substance that degrades only in aqueous solution.*

vail and equal to k_0 when zero-order kinetics dominate. This concept was touched on by others (5, 11) and will be discussed later.

In Fig. 3, the drug substance is relatively insoluble and subject to both oxidation in the solid phase and hydrolysis in solution. At point A, with no water present, the effect of oxidation is evident; there is appreciable degradation in the absence of water. From A to B, hydrolysis enters the picture, but its effects are partially hidden because the two reactions are antagonistic. That is, the presence of water reduces the effects of oxidation (*e.g.*, by adsorbing on and

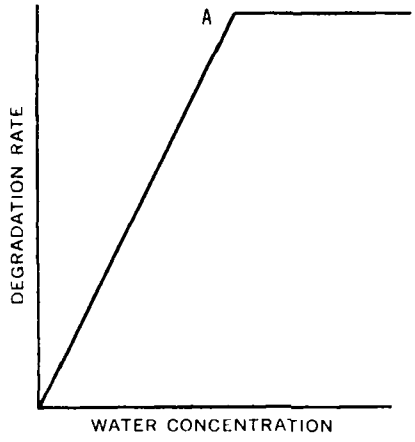

Figure 2—*Model plot showing the effect of water concentration on the stability of a relatively soluble drug substance that degrades only in aqueous solution. At point A, all of the drug substance is in solution.*

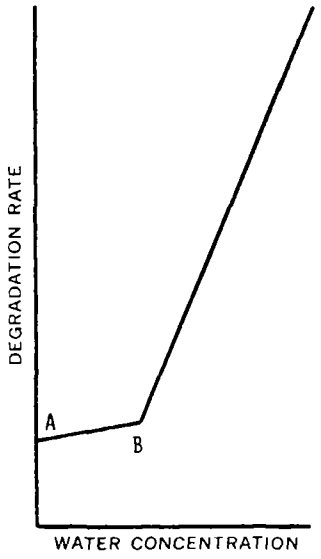

Figure 3—*Model plot showing the effect of water concentration on the stability of a relatively insoluble drug substance that degrades both in the solid state and in aqueous solution. See text for explanation.*

partially protecting the surface of the solid). After point B, the effects of oxidation become relatively constant and the situation more closely resembles that in Fig. 1. If the drug substance in Fig. 3 was water soluble, the plot would eventually plateau as in Fig. 2. Because a nonhydrolytic reaction is partially involved, the slope of the second portion of the plot is less likely to equal k_0. If the two reactions were simply additive, or if the hydrolytic reaction was much faster than the oxidative, the AB portion of the plot would be insignificant. The effect of hydrolysis alone could be determined by eliminating oxygen from the system.

In some situations, the data will not fit the models, but this is not unusual for theoretical models representing complex systems. The report on thiamine hydrochloride (10) is a case in point, but even here a good portion of the data fits the theoretical model. Examples from the literature and these laboratories can be used to illustrate the utility of the three models presented in Figs. 1–3.

Maulding *et al.* (11) obtained a plot identical to that in Fig. 1 using aspirin, a compound that fits the requirements of: (*a*) relatively low solubility, and (*b*) degradation primarily by hydrolysis. The zero-order nature of aspirin degradation in these systems is illustrated in that report, as well as in Fig. 4, based on data from these laboratories. In addition, the data of Leeson and Mattocks (1) can be plotted zero order, assuming an initial lag time (Fig. 5). Figure 6,

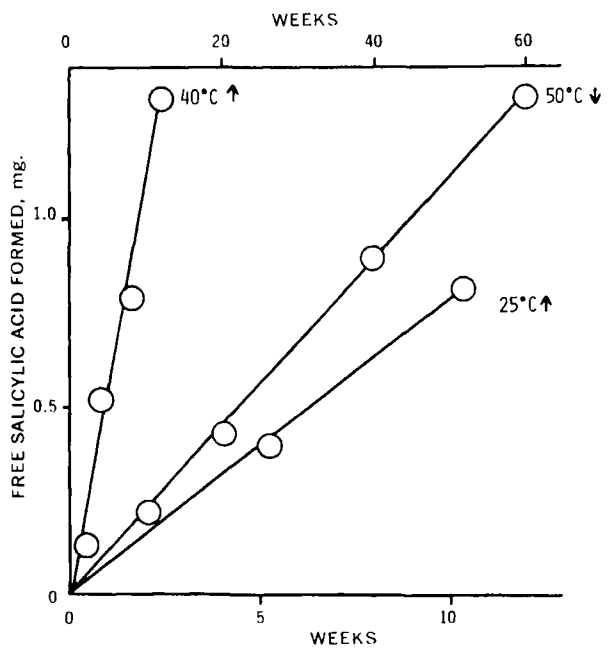

Figure 4—*Plot showing the zero-order nature of aspirin degradation in a solid system. The arrows show to which abscissa the plots refer.*

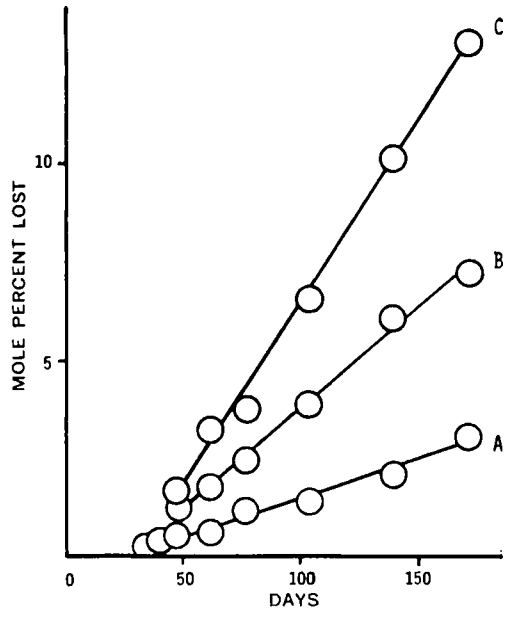

Figure 5—*Plot showing the zero-order nature of aspirin degradation in a solid system [50° data of Leeson and Mattocks (1)]. Key: A, 46.02 mm. vapor pressure of water; B, 68.30 mm.; and C, 74.20 mm.*

representing data from an experimental drug substance in these laboratories, also closely resembles Fig. 1.

The degradation of vitamin A in tablets was found to be first order rather than zero (2) but, as noted earlier, degradation involves more than simple hydrolysis. While the data of Tardif (3) were plotted first order, some of the plots (*e.g.*, thiamine and ascorbic acid at 50°) appear to exhibit zero-order characteristics. Furthermore, if all the thiamine was in solution (possible, especially at the higher temperatures), this would give first-order kinetics. These examples illustrate that many situations do fit the theory when examined in this way.

Thiamine hydrochloride meets the general criteria for compounds yielding the plot seen in Fig. 2. However, the situation is complicated by equilibrium phenomena and other factors, as discussed by Carstensen *et al.* (10). Nevertheless, a significant portion of the reaction follows zero-order kinetics (Fig. 7), and the plot in Fig. 4 of their report suggests that, under ideal conditions (*i.e.*, assuming no chemical equilibrium effects), a plot similar to that in Fig. 2 of this paper would result.

The situation represented in Fig. 3 finds a close parallel in the report of Carstensen *et al.* (5) on vitamin A acetate. Figure 8 is a plot of their data, and it is practically identical to the ideal case depicted in Fig. 3. The ordinate in Fig. 8 is the sum total of the vitamin A lost at all temperatures at a given water concentration. Data from 55°, 85° (4 days only), and 70° (8 days only) were not used because: (*a*) in some cases the concentration of vitamin A reached zero, and it is not known at which point in that time interval the value became zero; and (*b*) the second data points at 70 and 85° showed a drastic reduction in degradation rate, which raises questions about their validity (these data were also rejected by the authors in their calculations).

From Fig. 8 it is quite evident that in their system vitamin A

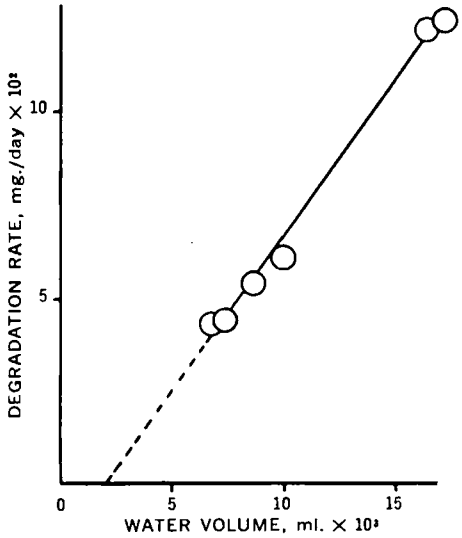

Figure 6—*Plot of actual data for experimental drug substance (confirms the validity of the model in Fig. 1).*

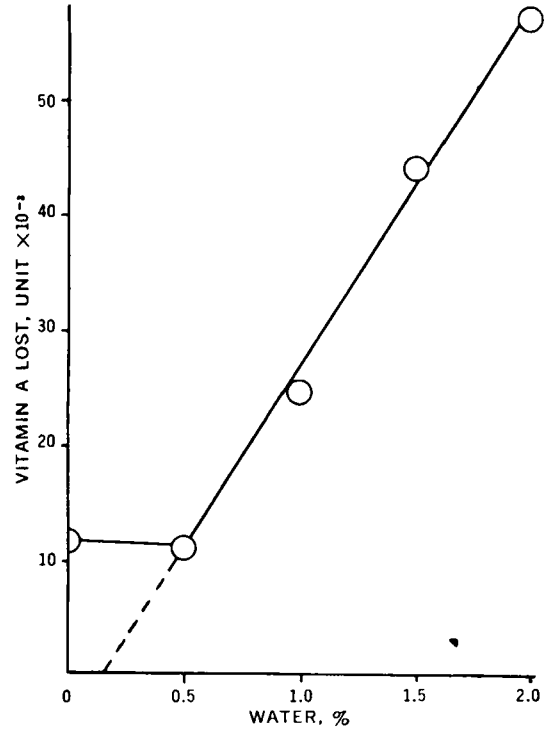

Figure 8—*Plot showing the effect of water concentration on the stability of vitamin A acetate in a solid system [data of Carstensen* et al. *(5)]. See text for explanation.*

acetate degrades significantly in the absence of water. When 0.5% water is added, the stability picture remains essentially the same, indicating that the water's contribution to degradation is offset by the partial protection it affords against solid-state oxidation. As more water is added, however, the degradation rate increases linearly with water concentration, indicating that the contribution of solid-state oxidation has plateaued and the effects of hydrolysis are becoming more evident.

The vitamin A acetate report (5) provides another example of the usefulness of the concepts and models presented in this paper. In discussing the theory behind their presentation, the authors (5) stated: "If vitamin A degrades by functional dependence of water content, then a $(1 + a)$ order reaction may be expressed as $dC_a/dt = -K \cdot C_A \cdot C^a_{H_2O}$ [their Eq. 1] where C denotes concentration and the subscripts denote vitamin A acetate and water." From their data, they reached the conclusion that the apparent value of a is 2–3, a relatively high order.

If one assumes that zero-order kinetics prevail for the water-dependent degradation (a reasonable assumption, since vitamin A acetate is relatively water insoluble), then their Eq. 1 reduces to our Eq. 1 when the value of a is unity. A slightly different interpretation of their data yields values of a that are close to unity and confirm the validity of the model in Fig. 3. That interpretation is as follows.

From the sharp break in the slope in Fig. 8, it is evident that the 0–0.5% range of water concentration is atypical. That is, their Eq. 1 assumes a continuous function and, for their system, the function can be considered continuous only between 0.5 and 2.0% added water. Therefore, the "water added" concept should, in our opinion, start from their 0.5% mark. Thus, their 0.5, 1.0, 1.5, and 2.0 values for "percent water added" should (more correctly) be taken as 0, 0.5, 1.0, and 1.5%, respectively. For example, their 1.5% is, more correctly, 1.0% (*i.e.*, 1.5 − 0.5). Recalculating their data using the corrected values of water added yields the following values for a: 85°, 0.90; 70°, 0.87; 55°, 1.45; 25°, 1.46; and 5°, 1.42. Considering the complexity of the system, experimental values of 0.87–1.46 (average = 1.2) against a theoretical value of unity is good confirmation of the validity of the model in Fig. 3.

CONCLUSION

Stability data for solid dosage forms, gathered under suitably controlled conditions, can often be successfully interpreted using the schematic models presented in Figs. 1–3.
