Carbocyclic Analogs of 6-Substituted Purine Ribonucleosides and of Adenosine Ribonucleotides

Y. FULMER SHEALY▲ and JOE D. CLAYTON

Abstract □ New analogs of 6-substituted purine ribonucleosides in which the furanose ring is replaced by a cyclopentane ring were synthesized. The cyclopentane (carbocyclic) analog of 6-chloropurine ribonucleoside was obtained in pure form and was used to prepare analogs having a methylamino, dimethylamino, hydroxylamino, or methoxy group at position 6 of the purine ring. The availability of the pure 6-chloropurine derivative also permitted improved syntheses of the adenosine and 6-(methylthio)purine ribonucleoside analogs, which had been prepared previously. The ribonucleoside analogs having the chloro, methylamino, hydroxylamino, or methoxy group at position 6 were cytotoxic to neoplastic cells (human epidermoid carcinoma No. 2) in culture, but these compounds were less active than the adenosine analog. In tests against leukemia L-1210 in mice, all of the new and the previously synthesized 6-substituted purine ribonucleoside analogs were administered in a single dose (Day 1 or 2), and most were also administered daily (*q.d.* 1–9) at several dose levels. There was no evidence of activity in these tests. The racemic carbocyclic analogs of adenylic acid and of 3′,5′-adenosine monophosphate (cyclic) were prepared from the adenosine analog. These nucleotide analogs were also cytotoxic.

Keyphrases □ Cyclopentane analogs of 6-substituted purine ribonucleosides and adenosine ribonucleotides—synthesis, cytotoxicity □ Carbocyclic analogs of 6-substituted purine nucleosides and adenosine ribonucleotides—synthesis, cytotoxicity □ Purine ribonucleosides, 6-substituted—synthesis of cyclopentane analogs, cytotoxicity □ Adenosine ribonucleotides, 6-substituted—synthesis of cyclopentane analogs, cytotoxicity □ Cytotoxicity—synthesis, evaluation of cyclopentane analogs of 6-substituted purine ribonucleosides and adenosine ribonucleotides

Nucleoside analogs in which a cyclopentane ring replaces the furanose ring may be termed carbocyclic analogs. The racemic[1], carbocyclic analog (II, C-Ado[2]) of adenosine (I) has been synthesized (1) by a multistep route from norbornadiene. The carbocyclic analogs (III–V) of inosine and of the anticancer agents 6-mercaptopurine ribonucleoside and 6-(methylthio)purine ribonucleoside were also prepared (2) from the precursors of II. The carbocyclic analogs of 2′- and 3′-deoxyadenosine were synthesized by similar routes (3); the analog of a pyrimidine deoxyribonucleoside, thymidine, had been prepared earlier by a different method (4).

Carbocyclic analogs, having a stable carbon–nitrogen bond instead of a glycosidic bond at position 9 of the purine ring, should not be subject to cleavage by purine nucleoside phosphorylases or hydrolases, but the similarity of their structures to nucleosides endows the carbocyclic analogs with the potential to function either as substrates for, or as inhibitors of, other enzymes that metabolize nucleosides. Biochemical studies show that this potential can, in fact, be realized. Bennett and co-

[1] Structures II–XVI depict one enantiomer of the racemic form that was actually obtained.

[2] (±)-*trans*-3-(6-Amino-9*H*-purin-9-yl)-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol. For the sake of brevity, the term C-Ado was employed in reports of biochemical studies (5, 6). In earlier publications (1, 2), C-Ado was designated (±)- or DL-9-[β-(2α,3α-dihydroxy-4β-(hydroxymethyl)cyclopentyl)] adenine.

workers (5, 6) showed that II can serve as a substrate for adenosine kinase and for adenosine deaminase and as an inhibitor, presumably after it is phosphorylated, of an early step in the biosynthesis *de novo* of inosinic acid. Hill *et al.* (7) found that II-phosphate (XV), the preparation of which is reported here, is a potent inhibitor of guanylic acid kinase. Furthermore, an analog of vitamin B_{12} coenzyme prepared from II can act as a coenzyme in the reaction catalyzed by dioldehydrase (8). Of added interest are the findings that II is a moderate inhibitor of the protozoan *Tetrahymena pyriformis* (9) and that aristeromycin (10), an antibiotic for certain plant pathogens, is one enantiomeric form of II (11, 12). These biochemical and biological studies show that alteration of the nucleoside structure by replacement of the furanose oxygen atom with a methylene group can produce biologically active compounds. The preparation of carbocyclic analogs of other bio-

chemically significant or biologically active 6-substituted purine ribonucleosides and ribonucleotides is now described.

CHEMISTRY

(±)-*trans*-3-(5-Amino-6-chloropyrimidin-4-yl)-*trans*-(5-hydroxymethyl)-*cis*-1,2-cyclopentanediol (XI) is the immediate precursor of the purine ring of carbocyclic analogs of 6-substituted purine ribonucleosides (1, 2). The pyrimidine (XI) was treated with triethyl orthoformate and concentrated hydrochloric acid to form the 6-chloropurine ring (VI), and the crude syrup obtained from the acid-catalyzed reaction was converted with anhydrous hydrogen chloride to a solid consisting of a mixture of hydrochlorides of VI and its derivatives (2). Such crude 6-chloropurine hydrochloride preparations, used previously (2) for the preparation of II and the inosine carbocyclic analog (III), furnished the 6-(methylamino)-purine (VII) and the 6-(dimethylamino)purine (VIII) derivatives by nucleophilic displacement of the 6-chloro substituent.

However, acid-catalyzed reactions of ribonucleosides with *ortho*-esters produce 2',3'-alkoxymethylene derivatives (13–16), which may be hydrolyzed under mildly acidic conditions to formate esters (14–16). Mass spectral studies of crude VI-hydrochloride specimens showed, as expected, the presence of derivatives of these types in addition to VI. Strongly acidic (and subsequent basic) conditions employed during the isolation and purification of II, VII, and VIII and during the preparation of the inosine analog (III) ensured liberation of the cyclopentyl hydroxyl groups. However, strongly acidic or basic conditions are detrimental to some 6-substituted purines, including 9-substituted 6-chloropurines. For this reason and because VI was desired as a target compound for biological evaluation, the preparation and purification of VI were investigated further. By omitting hydrochloride formation after the reaction of XI with triethyl orthoformate and by treating the reaction product successively with aqueous acetic acid and methanolic ammonia, pure VI was obtained. Mass spectral analyses at each stage indicated that: (*a*) the initial reaction product obtained from XI and triethyl orthoformate contained predominantly the formylethoxymethylene derivative (XII*a*), together with small amounts of XII*b* (or XII*c*) and VI; (*b*) the product after the aqueous acetic acid treatment consisted principally of a mixture of VI, monoformate esters (XII*d*), and diformate esters (XII*c*); and (*c*) the product after methanolic ammonia treatment was almost pure VI. TLC or the mass spectrum indicated that small amounts of II, III, X, and the 6-ethoxypurine analogous to X were formed by the sequence of treatments that began with XI. Pure VI could be obtained by recrystallization.

The 6-(hydroxyamino)purine derivative (IX) was obtained by replacement of the chloro group of purified specimens of VI with hydroxylamine by a procedure similar to that used for the ribonucleoside (17). The 6-methoxypurine (X) was prepared by treating pure VI with sodium methoxide in methanol. Previously (2), the 6-(methylthio)purine derivative (V) had been prepared by methyla-

[a] ED_{50} determined for H.Ep.-2 cells unless otherwise indicated. H.Ep.-2 = human epidermoid carcinoma cells, No. 2, growing in cell culture. KB = Eagle's KB cells growing in cell culture and derived from a carcinoma of the human nasopharynx. ED_{50} = concentration of a compound that inhibits cell growth, measured by protein determinations, to 50% of the growth of untreated cells. [b] Mice were implanted intraperitoneally on Day 0 with 10^6 L-1210 cells. For single-dose treatment, a compound was injected intraperitoneally on Day 1 (about 24 hr.) or on Day 2 (about 48 hr.) after implantation; *q.d.* 1–9 means that daily injections at the specified dose were initiated on Day 1 and continued through Day 9 or until the death of the animal. Average weight change = average weight change of host animals. Weight changes were determined 4 days after the first (for daily treatment) or only injection. *T* = treated mice; *C* = control mice. [c] Treatment on Day 1 unless otherwise indicated. [d] $T/C < 85\%$ and a difference in weight change ($T-C$) greater than 4 g. are criteria of toxicity to the host animals. [e] Approximate average of several tests. ED_{50} determined by the clone-colony method = 0.7 μmole/ml. (6). [f] Single-dose treatment with this compound was performed on Day 2. [g] Half of the treated animals died on or before Day 5. [h] The treatment schedule was Days 1, 5, and 9 rather than *q.d.* 1–9. [i] Average of three tests.

tion of the purine-6-thione (IV). The availability of pure VI permitted the synthesis of V by methylmercaptide ion generated from sodium methoxide and hydrogen sulfide in methanol (18). Proton magnetic resonance analysis of recrystallized V showed that it contained no more than 1% of the 6-methoxypurine (X). The 6-(methylamino)purine (VII) and the adenine (II) derivatives were also obtained more conveniently and in superior yields from purified VI.

The following derivatives of II were synthesized: the tetrabutyryl (XIII) and tributyryl (XIV) derivatives; the 5-dihydrogen phosphate (XV), which is the (±)-analog of adenylic acid; and the cyclic 1,5-phosphate (XVI), which is the (±)-analog of cyclic 3′,5′-adenosine monophosphate. The phosphate (XV) was obtained in 67% yield by phosphorylating isopropylidene II with phosphorus oxychloride in trimethyl phosphate (19, 20), isolating the product as the ammonium salt, and converting the salt to the free acid. After this work had been completed, the preparation of aristeromycin phosphate was reported by Imai *et al.* (21). The cyclic phosphate (XVI) was synthesized from XV by the method of Smith *et al.* (22) for the preparation of cyclic adenosine monophosphate; a simplified isolation procedure afforded a good yield of XVI.

BIOLOGICAL EVALUATION

Most purine ribonucleosides are not active *per se;* observed biological effects are caused by ribonucleotides formed from the ribonucleosides (23). Since it is generally accepted that nucleotides do not penetrate cell walls, activity is dependent on intracellular activation by kinases or by the sequential action of phosphorylases and phosphoribosyl transferases (23). Some new derivatives (VI–VIII and X) were selected, therefore, because the analogous ribonucleosides are good substrates for adenosine kinase from human epidermoid carcinoma (H.Ep.-2) cells (24), and these derivatives might also be phosphorylated by this enzyme. Additionally, the 6-(hydroxyamino)purine derivative (IX) is the analog of a nucleoside having anticancer activity (17, 25), and the cyclic phosphate (XVI) is the analog of cyclic adenosine monophosphate which may, in some degree, be transported intact into cells (26, 27).

The adenine derivative (II) is a highly cytotoxic compound (5, 6). The 6-chloropurine (VI), 6-(methylamino)purine (VII), and 6-(hydroxyamino)purine (IX) derivatives and the two nucleotide analogs (XV and XVI) also proved to be cytotoxic to neoplastic cells growing in culture (Table I), and the 6-methoxypurine (X) was modestly inhibitory. There is no evidence to indicate whether XV and XVI are cytotoxic as such or whether the observed activity is due to cleavage to II. As mentioned in the introduction, XV was found to be a potent inhibitor of guanylic acid kinase (7).

The results shown in Table I summarize tests of carbocyclic analogs of 6-substituted purine ribonucleosides against leukemia L-1210 in mice. All of the nucleoside analogs (II–X) were tested on a single-dose schedule (Day 1 or 2) at 400 mg./kg. If toxic symptoms appeared at this dose, testing was continued at lower doses. The 6-chloropurine (VI), 6-aminopurine (II), 6-(methylamino)purine (VII), 6-(hydroxyamino)purine (IX), and 6-methoxypurine (X) derivatives and the hypoxanthine (III) were administered at several

doses on a *q.d.* 1–9 schedule. These doses ranged from an upper, toxic dose (indicated by host weight loss or T/C <85%) to lower doses that caused little, or no, weight loss. The remaining compounds shown in Table I received more limited testing *in vivo*. None of the tests performed gave evidence of activity. The results in Table I indicate the degree of toxicity of these compounds *in vivo* (to leukemia-bearing mice) and show the scope of the evaluation.

EXPERIMENTAL[3]

(±)-*trans*-3-(6-Chloro-9*H*-purin-9-yl)-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (VI)—A solution of 500 mg. of XI, 15 ml. of triethyl orthoformate, and 0.15 ml. of 12 *N* hydrochloric acid was stirred at room temperature for 19 hr. The solution was concentrated *in vacuo* at 25° to a syrup, and several portions of toluene were similarly evaporated from the residue to aid in the removal of traces of volatile components. The mass spectrum (direct-probe inlet temperature 395°) of the residue indicated that it was composed principally of derivatives of VI formed by the reaction of triethyl orthoformate with the hydroxyl groups, along with trace amounts of VI and other components[4,5]: *m/e* 368 (M^+ of XII*a*, weak), 340 (M^+ of XII*b* or XII*c*, very weak), 339 (XII*a* − CHO), 323 (XII*a* − OC_2H_5, very strong), 295 (XII*b* − OC_2H_5 or 323 − CO), 284 (M^+ of VI, very weak), 235 (XII*a* − $OCHOC_2H_5$ − CH_2OCHO, very strong), 155 (P + 2H), 154 (P + H), and 153 (P); relative peak heights above 150 mass units, *m/e* 155 > 323 > 235 > 153. The fact that the peak of *m/e* 323 was the second strongest in the spectrum indicates that the crude product was mostly XII*a*; the strong peak at *m/e* 235 is consistent with this interpretation, but it also might have arisen partly from XII*b* (340 − $OCHOC_2H_5$ − CH_2OH).

To hydrolyze the ethoxymethylene group of XII*a* and XII*b* and other *ortho*-ester groups that might be present, a solution of the crude product in 10 ml. of 50% acetic acid was stirred at room temperature for 5.5 hr. and then concentrated to a syrup. To remove residual acetic acid, a solution of the syrup in water was lyophilized, yielding 553 mg. An IR spectrum showed strong ester absorption at 1710 $cm.^{-1}$ (—OCHO), and the mass spectrum[4,5] (direct-probe inlet temperature 390°) indicated that the product was chiefly a mixture of VI and its formate esters: *m/e* 340 (M^+ of XII*c*), 312 (M^+ of XII*d*, stronger than 284 and 340), 311 (XII*c* − CHO), 294 (XII*d* − H_2O), 284 (M^+ of VI), 283 (XII*d* − CHO), 253 (VI − CH_2OH or XII*d* − CH_2OCHO), 235 (XII*d* − CH_2OCHO − H_2O or VI − CH_2OH − H_2O), 181 (P + C_2H_4), 155 (P + 2H, base peak), 154 (P + H), and 153 (P); relative peak heights above 100 mass units, 155 > 157 > 181 > 154 ~ 235 > 156 > 119 > 183. The peak of *m/e* 235 must have been derived chiefly from XII*d*, because it was much stronger than the molecular ion peak of VI and it was much weaker than *m/e* 284 in the spectra of pure specimens of VI. Weak peaks of *m/e* 368 (XII*a*), 358, 330, 323 (XII*a* − OC_2H_5), and 302 showed the presence of other minor components.

A solution of 353 mg. of the gummy solid in 10 ml. of 10% ammonia–methanol was kept at room temperature for 4 hr. to remove the formyl groups. After evaporation of the solvent and of several portions of ethanol from the reaction product, it was stirred with a mixture of ethyl acetate (7 ml.) and ethanol (3 ml.) until solidification occurred, yielding 227 mg. (68% yield from XI), m.p. 152–170° dec. UV data and the mass spectrum (compared with spectra of pure specimens of VI) indicated that this material was almost pure VI; TLC showed that it was VI contaminated with small amounts (less than 3–5%) of both II and the hypoxanthine derivative (III). These impurities must have been introduced by displacement of the 6-chloro group by ammonia and *via* acidic hydrolysis, respectively. Also, weak peaks of *m/e* 280 and 294 in the mass spectrum correspond to the molecular ions of the 6-methoxypurine (X) and the analogous 6-ethoxypurine derivative, respectively, and suggest that slight displacement of the 6-chloro group by methanol and ethanol occurred. Recrystallization of such specimens from a small volume of ethanol–ethyl acetate or from ethanol–hexane (1:1) gave pure VI, m.p. 171–175° dec.; TLC, 1 spot [20 mcg., chloroform–methanol (4:1)]; UV: λ_{max} 265 (ϵ 9400) at pH 1 and 7; mass spectrum[4,5] (direct-probe inlet temperature 390°): *m/e* 284 (M^+), 267 (M − OH), 266 (M − H_2O), 256 (M − CO), 255, 253 (M − CH_2OH), 237, 235 (M − CH_2OH − H_2O), 225 (M − CH_2OH − CO), 219, 209, 197, 181 (P + C_2H_4), 167, 155 (P + 2H), 154 (P + H), and 153 (P). The peak of *m/e* 155 was the base peak in the spectra of purified specimens of VI. The peaks of *m/e* 157 (due to the ^{37}Cl-fragment analogous to *m/e* 155) and *m/e* 181 were the next strongest; other strong peaks above 100 mass units were 156, 154, 183, 119, 284, and 209.

Anal.—Calc. for $C_{11}H_{13}ClN_4O_3$: C, 46.40; H, 4.60; Cl, 12.45; N, 19.75. Found: C, 46.35; H, 4.69; Cl, 12.72; N, 19.51.

Crude 6-chloropurine (VI) hydrochloride specimens were used for preparing some 6-substituted purine derivatives. These very hygroscopic, white specimens were prepared by the previously described procedure (2) from XI, triethyl orthoformate, and concentrated hydrochloric acid, followed by treatment of the crude syrup with hydrogen chloride to obtain a solid product. Several specimens of the crude mixture of hydrochlorides gave similar (weak) mass spectral patterns. Dissolution of such specimens in water to dissociate the hydrochloride salts, followed by lyophilization, increased the volatility of the crude products; mass spectra were improved but not appreciably changed. Typical mass spectra showed peaks corresponding to the molecular ions of VI, XII*b* or XII*c*, XII*d*, and fragments derived from these compounds. Since the crude hydrochloride preparations are very hygroscopic, hydrolysis of some ethoxymethylene and formyl groups may have occurred during handling. Weak molecular ion peaks of *m/e* 358, 348 and 330, and 302 in the spectra correspond to by-products in which one or two hydroxyl groups of XII*b* or XII*c*, XII*d*, and VI, respectively, are replaced by chloro groups. These minor by-products may have been introduced during the preparation of the crude mixture of hydrochlorides or during one of the two preceding steps (2) and, because of their greater volatility, may have been detectable in trace amounts.

(±)-*trans*-3-(Hydroxymethyl)-*trans*-5-[6-(methylamino)-9*H*-purin-9-yl]-*cis*-1,2-cyclopentanediol (VII)—A solution of 1.0 g. of crude VI hydrochloride (2) and 60 ml. of liquid methylamine was heated in a glass-lined, stainless steel bomb at 70° for 18 hr. and then concentrated to a syrup. A solution of the syrup, 30 ml. of water, 30 ml. of ethanol, and 3 ml. of 12 *N* HCl was heated at 45° for 0.5 hr. The solvents were evaporated *in vacuo*, and several portions of water were evaporated from the residue. A solution of the residue in 150 ml. of water was stirred with 10 g. of an anion-exchange resin[6] for 0.5 hr., the resin was removed by filtration and washed several times with 50-ml. portions of warm water, and the residue remaining after evaporation *in vacuo* of the combined filtrate and wash solutions was dried further by evaporating several portions of ethanol from it. A solution of the amorphous residue in 50 ml. of ethanol deposited 693 mg. (80%) of crude VII free base (m.p. 103–106° dec.). A solution of 670 mg. of the crude free base, 25 ml. of ethanol, and 15 ml. of ether was treated with anhydrous hydrogen chloride. A white precipitate, with the approximate composition of a dihydrochloride, was recrystallized from methanol–ether, yielding 555 mg. of the monohydrochloride of VII, m.p. 177–

[3] UV spectra were recorded with a Cary model 17 or 14 spectrophotometer. UV maxima are in nanometers; sh = shoulder. Solutions for UV determinations were prepared by diluting a 5-ml. aliquot of a water or ethanol solution of the compound to 50 ml. with 0.1 *N* HCl, phosphate buffer (pH 7), or 0.1 *N* NaOH; absorption maxima are reported at pH 1, 7, and 13. IR spectra were recorded with a Perkin-Elmer model 621 or 521 spectrometer from samples in KBr disks. Mass spectral data were taken from low-resolution spectra determined with a Hitachi-Perkin-Elmer RMU-7 double-focusing instrument; the peaks listed are those due to the molecular ion (M^+), those attributable to the loss of certain fragments from the molecular ion (M − a fragment), and other prominent peaks due to fragments heavier than the purine moiety (minus the cyclopentyl group). Proton magnetic resonance (PMR) spectra were determined with a Varian model XL-100-15 spectrometer for observing proton resonance at 100 MHz. Chemical shift data (δ) are in parts per million downfield from tetramethylsilane, the internal reference; s = singlet, and m = multiplet. Melting temperatures were determined in capillary tubes heated in a Mel-Temp apparatus. Unless otherwise indicated, TLC was performed on plates of silica gel, and spots were detected by UV light (254 nm.) after spraying the chromatogram with an optical whitening agent (Ultraphor WT, BASF Colors and Chemicals, Inc., Charlotte, N. C.) and by spraying with a basic solution of potassium permanganate. The quantity applied and the developing solvent are shown parenthetically at the appropriate places in the procedures.

[4] The chlorine-containing fragments listed contain ^{35}Cl; the corresponding fragments (heavier by 2 mass units) containing ^{37}Cl are not listed unless the peaks were stronger than expected from the isotope ratio.

[5] P = the purine ring fragment without a 9-substituent.

[6] Dowex 1-X8, OH^- form.

179° dec.; UV: λ_{max} 263 (ε 17,200) at pH 1 and 267 (ε 16,800) at pH 7 and 13.

Anal.—Calc. for $C_{12}H_{17}N_5O_3 \cdot HCl$: C, 45.65; H, 5.74; N, 22.17. Found: C, 45.74; H, 5.79; N, 22.26.

Pure VI (500 mg.) was treated with 30 ml. of methylamine according to the procedure already described for crude VI hydrochloride. Concentration of the reaction mixture to dryness left a white solid. The product was recrystallized twice from ethanol and dried *in vacuo* at 78°, yielding 440 mg. (77%), m.p. 110–112° dec.; TLC, 1 spot [60 mcg., chloroform–methanol (3:1)]; mass spectrum (direct-probe inlet temperature 240°): *m/e* 279 (M^+), 262 (M − OH), 248 (M − CH_2OH), 232, 230 (M − CH_2OH − H_2O), 220 (M − CH_2OH − CO), 204, 192, 176 (P + C_2H_4), 150 (P + 2H, base peak), 149 (P + H), and 148 (P).

Anal.—Calc. for $C_{12}H_{17}N_5O_3 \cdot C_2H_5OH$: C, 51.68; H, 7.12; N, 21.53. Found: C, 51.72; H, 7.43; N, 21.36.

(±)-*trans*-3-[6-(Dimethylamino)-9*H*-purin-9-yl]-*trans*-(5-hydroxymethyl)-*cis*-1,2-cyclopentanediol (VIII)—A solution of 350 mg. of crude VI hydrochloride (2) in 12 ml. of 25% aqueous dimethylamine was heated under reflux for 3 hr., allowed to stand at room temperature for 5 days, and evaporated *in vacuo* to a syrup. By a procedure similar to that described for the preparation of VII from crude VI, the dihydrochloride of VIII was obtained from a chilled mixture of ethanol, ether, and dry hydrogen chloride, yielding 130 mg. (32%), m.p. 98–105° with premature softening; UV: λ_{max} 268 (ε 17,700) at pH 1 and 277 (ε 18,000) at pH 7 and 13.

Anal.—Calc. for $C_{13}H_{19}N_5O_3 \cdot 2HCl$: C, 42.63; H, 5.78; N, 19.12. Found: C, 42.78; H, 5.52; N, 18.84.

trans-3-[6-(Hydroxyamino)-9*H*-purin-9-yl]-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (IX)—A solution of 854 mg. of pure VI, 6 ml. of methanol, 6 ml. of ethanol, and 2.5 g. of hydroxylamine (prepared from the hydrochloride and sodium methoxide in methanol) was heated under reflux for 3 hr. and then allowed to stand at room temperature for 18 hr. A white precipitate was separated by filtration, washed with ethanol, and dried *in vacuo* at 78°, yielding 655 mg., m.p. 204–220° dec. The crude product was dissolved in 50% aqueous ethanol, the solution was concentrated to a syrupy consistency, ethanol was added, and the solution was chilled. The first crop (357 mg.) of IX was stirred with water, washed with ethanol, and dried *in vacuo* at 78°, yielding 313 mg., m.p. 225° dec.; TLC, 1 spot [40 mcg., butanol–water–acetic acid (5:3:2)]; UV: λ_{max} 266 (ε 16,700) at pH 1 and 267 (ε 13,700) at pH 7.

Anal.—Calc. for $C_{11}H_{15}N_5O_4$: C, 46.97; H, 5.37; N, 24.90. Found: C, 46.64; H, 5.65; N, 24.89.

A second crop of IX, obtained by concentrating the filtrate and cooling it to −20°, was recrystallized from aqueous ethanol, yielding 73 mg., m.p. 224° dec.; UV: λ_{max} 266 (ε 16,500) at pH 1.

(±)-*trans*-3-(Hydroxymethyl)-*trans*-5-(6-methoxy-9*H*-purin-9-yl)-*cis*-1,2-cyclopentanediol (X)—A solution prepared from 600 mg. of pure VI, 14 ml. of anhydrous methanol (dried with molecular sieves), and 6 ml. of 1 *N* sodium methoxide in methanol was heated under reflux for 2 hr., allowed to stand at room temperature for 48 hr., and evaporated to dryness *in vacuo*. A solution of the residue in 10 ml. of water was acidified with 1 ml. of 6 *N* HCl and then neutralized with solid sodium bicarbonate. The mixture, containing a precipitate, was allowed to stand at 5° and was then filtered to separate white crystals, yielding 490 mg., m.p. 203–210° dec. The crude product was recrystallized from water and dried *in vacuo* at 78°, yielding 387 mg. (65%), m.p. 210–212° dec.; TLC, 1 spot [40 mcg., chloroform–methanol (3:1)]; UV: λ_{max} 252 (ε 10,800) and 262 (sh) at pH 1 and 250–254 (ε 11,400) and 262 (sh) at pH 7 and 13; mass spectrum[5] (direct-probe inlet temperature 250°): *m/e* 280 (M^+), 263 (M − OH), 262 (M − H_2O), 252 (M − CO), 249 (M − CH_2OH), 233, 231 (M − CH_2OH − H_2O), 221 (M − CH_2OH − CO), 205, 193, 177 (P + C_2H_4), 163, 151 (P + 2H, base peak), 150 (P + H), and 149 (P); PMR[7] (dimethyl sulfoxide-d_6): δ 1.6–about 2.5 (m, H*a*H*a*H*b*), 3.4–3.63 (m, H*c*H*c*), 3.78–3.96 (m, H*d*), 4.1 (s, CH_3O), 4.24–4.5 (m, H*e*), 4.56–4.98 (m, H*f* + 3OH), 8.44 (s, H_8 of purine ring), 8.50 (s, H_2 of purine ring), and 4.62–5.04 (after addition of D_2O, m, H*f*). A specimen for analysis was dried at 110°.

Anal.—Calc. for $C_{12}H_{16}N_4O_4$: C, 51.40; H, 5.75; N, 19.99. Found: C, 51.15; H, 5.48; N, 19.60.

(±)-*N*-{9-[*trans*-2,*trans*-3-Dihydroxy-*cis*-4-(hydroxymethyl)cyclopentyl]-9*H*-purin-6-yl}butyramide Tributyrate (XIII)—An anhydrous mixture of 500 mg. of II, 10 ml. of pyridine, and 7.5 ml. of butyric anhydride was stirred at room temperature for 2 days and then concentrated *in vacuo* to a solid residue. White crystalline XIII was obtained by triturating the residue with ethanol–hexane (1:9) and recrystallizing the crude product (821 mg.) from ethyl acetate–hexane (4:15), yielding 723 mg. (70%), m.p. 116–117°; UV: λ_{max} 282 (ε 17,800) at pH 1.

Anal.—Calc. for $C_{27}H_{39}N_5O_7$: C, 59.43; H, 7.21; N, 12.84. Found: C, 59.25; H, 7.24; N, 12.87.

(±)-*trans*-3-(6-Amino-9*H*-purin-9-yl)-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol Tributyrate (XIV) Picrate—A solution of 190 mg. of XIII, 229 mg. of picric acid, and 11 ml. of methanol was heated under reflux for 45 min. A yellow precipitate was collected by filtration, washed with methanol, and recrystallized from an ethanol–acetone mixture, yielding 180 mg. (73%), m.p. 190–195°.

Anal.—Calc. for $C_{23}H_{33}N_5O_6 \cdot C_6H_3N_3O_7$: C, 49.43; H, 5.17; N, 15.92. Found: C, 49.25; H, 5.03; N, 15.96.

(±)-*trans*-3-(6-Amino-9*H*-purin-9-yl)-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol 5-Dihydrogen Phosphate (XV)—A solution of 12 ml. of trimethyl phosphate (19, 20), 0.732 ml. (8 mmoles) of phosphorus oxychloride, and 1.188 g. (3.9 mmoles) of the isopropylidene derivative (2) of II was prepared at −10°, stirred for 3 hr. at from −5 to −10°, and poured into 350 ml. of water. The resulting solution was allowed to stand at 25° for 1 hr., neutralized with 2.5 *N* aqueous ammonia, and passed through a column of a cation-exchange resin[8] (20 g.). The column was washed with 300 ml. of water and then with 400 ml. of 1 *N* aqueous ammonia. The ammonia effluent was concentrated *in vacuo* to a low volume (about 10 ml.), and ethanol (100 ml.) was added and the evaporation continued. Then additional ethanol (100 ml.) was added, and a white precipitate was collected by filtration and dried *in vacuo* over phosphorus pentoxide, yielding 1.036 g. (70%, calculated as a monohydrate of the ammonium salt of XV[9]). A solution of 1 g. of this material in 2 ml. of water was neutralized with 0.5 ml. of 6 *N* hydrochloric acid, diluted with 5 ml. of ethanol, and cooled to −20°. The white precipitate was dried *in vacuo* at 78° over phosphorus pentoxide, yielding 901 mg. (adjusted yield 67%), m.p. 250–252° dec.; TLC, 1 spot [60 mcg. on cellulose, butanol–water–acetic acid (5:3:2), detection by UV light after spraying[10]]. A specimen was recrystallized from water–ethanol and dried as before, m.p. 251–253° dec.; UV: λ_{max} 258 (ε 14,500) and 212 (ε 21,000) at pH 1 and 261 (ε 15,100) and 204 (ε 21,900) at pH 7.

Anal.—Calc. for $C_{11}H_{16}N_5O_6P \cdot {}^1/_2H_2O$: C, 37.29; H, 4.84; N, 19.77; P, 8.74. Found: C, 37.43; H, 4.60; N, 19.56; P, 8.64.

(±)-*trans*-3-(6-Amino-9*H*-purin-9-yl)-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol Cyclic 1,5-Hydrogen Phosphate (XVI)—A solution of 353 mg. of II-phosphate (XV), 293 mg. of 4-morpholino-*N*,*N*′-dicyclohexylcarboxamidine, 25 ml. of pyridine, and 5 ml. of water was evaporated to dryness *in vacuo*, and three 15-ml. portions of pyridine were added and evaporated separately *in vacuo* to remove water. A solution of the residue in 100 ml. of anhydrous pyridine was added dropwise during 3 hr. to a refluxing solution of 412 mg. of dicyclohexylcarbodiimide in 100 ml. of anhydrous pyridine, and the mixture was heated under reflux for an additional hour and then evaporated to dryness *in vacuo*. A mixture of the residue and water (250 ml.) was allowed to stand at room temperature for about 2 hr. and then concentrated *in vacuo* to dryness. Equal volumes of water and ether (100 ml.) were added, the mixture was shaken and filtered to remove dicyclohexylurea (m.p. 222–227°), and the aqueous layer was evaporated *in vacuo* to a yellow syrup. A solution of the syrup in 25 ml. of water was stirred with 3 g. of a strongly basic ion-exchange resin[11] for 15 min., the resin was separated by filtration and washed with water (10 × 3 ml.), and the product was recovered by stirring the resin with 175 ml. of 25% acetic acid. The aqueous acetic acid filtrate was concentrated *in vacuo* to a small volume (10 ml.), diluted with ethanol (10 ml.), chilled, and filtered to remove the white precipitate which was dried *in vacuo* at 78°, yielding 259 mg. (79%). The cyclic phosphate (XVI) was recrystallized from water (40 ml.) and dried *in vacuo* at 110°, yielding 198 mg. (61%), m.p. 268–272° dec.; UV: λ_{max} 258

(ε 13,500) and 211 (ε 20,600) at pH 1 and 261 (ε 14,100) and 205 (ε 20,400) at pH 7; TLC [silica gel, detection by UV and spraying[10], propanol–water (3:1)], XVI moved similarly to II and faster than XV; TLC [butanol–water–acetic acid (5:3:2)], XVI moved slower than II and slightly faster than XV.

Anal.—Calc. for $C_{11}H_{14}N_5O_5P$: C, 40.37; H, 4.31; N, 21.44; P, 9.46. Found: C, 39.98; H, 4.47; N, 21.71; P, 9.37.

(±)-*trans*-3-(6-Amino-9*H*-purin-9-yl)-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (II)—This compound was obtained in better yield and by a simpler procedure by beginning with purified VI (*cf.* 2). A mixture of 1.215 g. of VI and 20 ml. of liquid ammonia was heated in a glass-lined, stainless steel bomb at 60° for 20 hr. and then at 80° for 1 hr. The residue obtained by evaporating the ammonia with a current of nitrogen was stirred with 20 ml. of warm 90% ethanol. Compound II (885 mg., m.p. 238–247° dec.) was separated by filtration, recrystallized from water (35 ml.), and washed with ethanol, yielding 768 mg. (white crystals), m.p. 245–247° dec. A second crop (113 mg., m.p. 231–240° dec.) of II from the 90% ethanol filtrate was recrystallized from water, yielding 86 mg., m.p. 244–248° dec. TLC and UV data showed that both portions (total yield 75%) were pure II.

(±)-*trans*-3-(Hydroxymethyl)-*trans*-5-[6-(methylthio)-9*H*-purin-9-yl]-*cis*-1,2-cyclopentanediol (V)—This compound was prepared by an improved procedure (*cf.* 2). A solution consisting of 780 mg. of purified VI, 30 ml. of anhydrous methanol (dried with molecular sieves), and 5.5 ml. of a 1 *N* methanol solution of sodium methoxide was saturated with methanethiol at 5°. The solution was heated at 100° in a glass-lined, stainless steel bomb for 18 hr. and then concentrated to dryness *in vacuo*. A water solution (25 ml.) of the residue was acidified to pH 3 with 1 *N* HCl, neutralized by the addition of solid sodium bicarbonate[12], and evaporated to dryness *in vacuo*. The residual solid was leached repeatedly (10 times) with a boiling ethyl acetate–acetone (4:1) mixture. The total extract was concentrated *in vacuo* to about 10 ml., and the precipitate (630 mg.) was separated by filtration. Recrystallization of the crude product from ethanol gave 605 mg. (74%) of white crystals, m.p. 179–181° dec.; mass spectrum (direct-probe inlet temperature 270°): *m/e* 296 (M^+), 279 (M − OH), 278 (M − H_2O), 265 (M − CH_2OH), 249, 247 (M − CH_2OH − H_2O), 237 (M − CH_2OH − CO), 231, 222, 221, 209, 193 (P + C_2H_4), 179, 167 (P + 2H, base peak), 166 (P + H), and 165 (P); PMR[7] (dimethyl sulfoxide-d_6): δ 1.64–about 2.5 (m, H*a*H*a*H*b*), 2.68 (s, CH_3S), 3.42–3.64 (m, H*c*H*c*), 3.8–3.96 (m, H*d*), 4.24–4.52 (m, H*e*), 4.58–5.06 (m, H*f* + 3OH), 8.53 (s, H_8 of purine ring), 8.7 (s, H_2 of purine ring), and 4.66–5.06 (after addition of D_2O, m, H*f*). A very weak singlet at 4.1 p.p.m. indicated that this sample contained about 1% of the 6-methoxypurine derivative (X).

Toxicological and Pharmacological Actions of Methacrylate Monomers II: Effects on Isolated Guinea Pig Ileum

G. N. MIR, W. H. LAWRENCE, and J. AUTIAN▲

Abstract □ Methacrylic acid and 12 methacrylate esters were tested for their effects upon contraction of the isolated guinea pig ileum. Each compound was employed at three concentration levels, ranging from 1:500 to 1:100,000 (v/v), depending upon activity and solubility of the compounds. Most of the compounds, except dimethylaminoethyl methacrylate, produced an inhibition of spontaneous contractions of the isolated ileum which antagonized the stimulant actions of both acetylcholine and barium chloride. Although most of the methacrylate effects were readily washed out, 1,3-butylene dimethacrylate produced a relatively irreversible response. Dimethylaminoethyl methacrylate stimulated the isolated ileum, an effect that was not blocked by 0.1–1 mcg. of atropine/ml. of tissue bath fluid. Those compounds producing inhibition were ranked in order of their relative activities in antagonizing acetylcholine- or barium-induced contraction by determining the approximate molar ratio (*i.e.*, molar concentration of methacrylate per molar concentration of acetylcholine or barium chloride) required to produce 50% inhibition of the stimulant effect of acetylcholine or barium chloride.

Keyphrases □ Methacrylate monomers—effects on isolated guinea pig ileum, acetylcholine- and barium-induced contractions □ Smooth muscle relaxation—effects of methacrylate monomers on isolated guinea pig ileum, acetylcholine- and barium-induced contractions

The polymerized acrylates, particularly methyl methacrylate, find a number of applications as biomedical materials, especially in dentistry and orthopedic surgery. Acute lethality of the various monomers shows considerable variability. The LD_{50} values in mice for the specific samples employed in this study were presented in a previous paper (1). Deichmann (2) and Spealman *et al.* (3) reported that the acute lethal effect in laboratory animals was due to respiratory depression for monomeric methyl methacrylate and some related esters. Various aspects relating to other potential toxicity problems with methacrylates were presented by a number of workers (4–9). Previous work on the methacrylate monomers conducted in these laboratories included investigations into the use of mathematical models to predict acute toxicity (10), alteration of drug biological half-life by methacrylate inhalation (11), embryo–fetal toxicity and teratogenic effects in rats (12), and effects upon the isolated, perfused rabbit heart (1).

MATERIALS AND METHODS

Materials—Methacrylic acid and 12 methacrylate esters were tested on the isolated guinea pig ileum. The following compounds were included: methacrylic acid[1], 1,3-butylene dimethacrylate[1], and the methyl[1], ethyl[1], *n*-butyl[1], isobutyl[1], isodecyl[1], lauryl[1] (dodecyl), hydroxyethyl[1], *tert*-butylaminoethyl[1], dimethylaminoethyl[1], *n*-propyl[2], and 2-ethylhexyl[2] methacrylates.

Methods—Guinea pigs (300–500 g.) of either sex were sacrificed and exsanguinated, and the intestine was promptly exposed *via* a midline incision. An actively contracting loop of ileum, 4–6 cm. in length, was removed and placed in oxygenated Tyrode's solution. A 1.5–2-cm. section of ileum was suspended in oxygenated (95% oxygen + 5% carbon dioxide) Tyrode's solution in a 25-ml. chamber of an isolated organ-tissue bath[3], which was maintained at a constant temperature of 37 ± 0.3°. One end of the intestine was attached to a glass holder and oxygenator; the other end was attached to a force-displacement transducer[4], which was electrically connected to a polygraph[5] to produce a permanent record of the response. To maintain uniform sensitivity, the polygraph was calibrated to produce a 1-cm. pen deflection/g. of tension applied to the transducer.

In all cases the spontaneous activity of the intestine in Tyrode's solution was recorded; the methacrylate was then added to the bath and thise response was recorded. The methacrylate was administered by forceably dispensing the measured quantity of test compound from a syringe with a small bore needle, the tip of which was placed below the liquid surface of the chamber. Preliminary experiments were conducted to determine the concentration of methacrylate that would produce a measurable effect upon the isolated ileum; the other concentrations employed were two and four times as great as the initially determined one.

RESULTS

The responses of the guinea pig ileum to treatment with nine of these 13 compounds are presented in Table I. Three of the other four compounds, isodecyl, 2-ethylhexyl, and lauryl methacrylates, were rather insoluble in Tyrode's solution; it was, therefore, not possible to obtain solutions sufficiently concentrated to produce an observable response. The other compound, 1,3-butylene dimethacrylate, tended to produce relaxation of the smooth muscle but, unlike the majority of these compounds, the effect was very slow in onset. This slow, relatively mild effect did not lend itself well to quantitative measurement.

Concentrations of 1:1000 and 1:500 (v/v) of 1,3-butylene dimethacrylate exhibited a latent period of about 5 min., which was followed during the next 5 min. or so by a gradual decrease in pendular movements and a slow relaxation of the muscle. After the maximum effect developed, it appeared to be irreversible since the muscle would not return to control levels of activity even after repeated washing with Tyrode's solution. The activity of 1,3-butylene dimethacrylate partially antagonized neurogenic stimulation by acetylcholine (0.1 mcg./ml.) and myogenic stimulation by barium chloride (30 mcg./ml.).

Eight of the other nine compounds produced prompt (within 15–30 sec.) and qualitatively rather uniform effects, consisting of inhibition of pendular movements and relaxation of the muscle. The effect of each compound could be terminated by promptly washing the ileum with fresh Tyrode's solution. All of these compounds produced a concentration-dependent inhibition of the usual effects of acetylcholine and barium chloride upon the isolated ileum.

Dimethylaminoethyl methacrylate acted differently, both qualitatively and quantitatively, from the other compounds tested. While the other compounds either produced an inhibition of smooth muscle activity or had no effect on its activity, dimethylaminoethyl methacrylate produced contraction of the ileum. This smooth

			(This contraction was not blocked by 1×10^{-7} or 10^{-6} atropine sulfate)				

[a] + = contraction; − = relaxation. 10 mm. ≈ 1 g. tension. [b] Acetylcholine concentration = 1:10,000,000; barium chloride concentration = 3:100,000 (w/v). [c] Number of observations in parentheses. [d] n/a = not applicable.

muscle stimulation was not blocked by 0.1 mcg./ml. of atropine sulfate. Of the other compounds tested, hydroxyethyl and *tert*-butylaminoethyl methacrylates were the most potent, inhibiting ileum contraction by about 11 mm. at a 1:10,000 dilution, while dimethylaminoethyl methacrylate produced about 23 mm. contraction at a dilution of 1:100,000 (v/v).

DISCUSSION

Most of the methacrylates examined produced a depressant effect upon spontaneous motility of the isolated guinea pig ileum, and generally a good dose-response (concentration-dependent) relationship was observed (eight of the nine compounds listed in Table I). These eight compounds also demonstrated a good concentration-dependent antagonism of the neurogenic and myogenic stimulant effects of acetylcholine and barium chloride upon the isolated ileum. With the concentrations used, from 5 to 100% of the stimulant effect of acetylcholine was blocked by prior administration of the methacrylate, and from 7 to 100% of the stimulant effect of barium chloride was blocked. These data suggest that the inhibitory effects of these methacrylates upon the isolated ileum are myogenic in origin. The effects of these eight methacrylates may be terminated by promptly washing the intestine with fresh Tyrode's solution.

1,3-Butylene dimethacrylate [1:1000 and 1:500 (v/v)] also produced a reduction in pendular movements and a relaxation of the intestine. Unlike those already discussed, where the effect occurred within 15–30 sec., this compound showed a latent period of about 5 min. before any effect could be observed, and then the effect developed very slowly over the next 5–10 min. When the effect had developed, it antagonized the stimulant effect of acetylcholine (0.1 mcg./ml.) and barium chloride (30 mcg./ml.) upon the muscle. Unlike the previously discussed compounds, the depressant effects of 1,3-butylene dimethacrylate were not dissipated by repeated washings with Tyrode's solution. This may be due to either a stronger binding of this compound to the receptor tissue of the muscle or a greater physical penetration (solubility related) of the compound into the tissue, since the onset of action was much slower with greater difficulty in "washing out" the effect.

The three least soluble members of the series, 2-ethylhexyl, isodecyl, and lauryl methacrylates, did not elicit a demonstrable effect by this procedure. Since the effects produced by a compound of limited solubility are dependent upon the quantity that will go into solution to reach its target site and the inherent activity of the compound at its target site, the combination of solubility and inherent activity must not have reached critical values in these experiments for the isolated ileum; thus, no effect was observed. Use of a more sensitive system for detection of the action of the methacrylates may lead to quantitative results for these compounds;

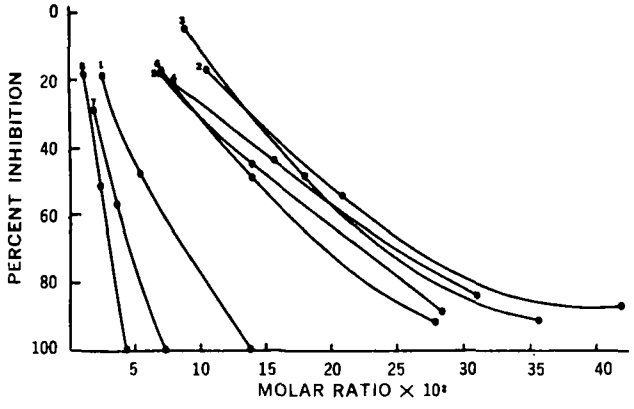

Figure 1—*Methacrylate inhibition of acetylcholine-induced contraction. Key: 1, methacrylic acid; 2, methyl methacrylate; 3, ethyl methacrylate; 4,* n*-propyl methacrylate; 5,* n*-butyl methacrylate; 6, isobutyl methacrylate; 7, hydroxyethyl methacrylate; and 8,* tert*-butylaminoethyl methacrylate.*

in the isolated heart, these compounds did demonstrate a measurable response (1).

These eight methacrylates may be grouped into two general orders of activity: (*a*) those in which the highest dilution used was 1:2000 (methyl, ethyl, *n*-propyl, *n*-butyl, and isobutyl methacrylates), and (*b*) those in which the highest dilution used was 1:10,000 (methacrylic acid and the "substituted" methacrylates, hydroxyethyl and *tert*-butylaminoethyl).

Figure 1 shows the antagonistic effect of the methacrylates upon acetylcholine-induced contraction of the isolated ileum. In this figure the molar ratio (molar concentration of the methacrylate per molar concentration of acetylcholine) is plotted against percent inhibition of the acetylcholine response. The standard concentration of acetylcholine bromide (0.1 mcg./ml.) employed in these studies represents 4.422×10^{-7} mole/l.

Figure 2 presents a similar graph showing the antagonistic effect of the methacrylates upon barium chloride-induced contraction of the isolated ileum. Again, the molar ratio (molar concentration of methacrylate per molar concentration of barium chloride) is plotted against percent inhibition of the barium chloride response. The standard concentration of barium chloride (30 mcg./ml.) used in these studies represented 1.228×10^{-4} mole/l.

The approximate molar ratios required for the compounds to produce 50% inhibition of the acetylcholine and barium chloride responses were estimated from Figs. 1 and 2, arranged in order of decreasing potency, and listed in Table II. The lower the molar ratio required to provide 50% inhibition, the more active is the compound in inhibiting contractions produced by the stimulant agent. Since these curves are constructed from only three data points, they must be considered as estimates; however, they do clearly represent the order of magnitude involved in the antagonism.

The activity of dimethylaminoethyl methacrylate was atypical of the series of compounds investigated by differing both in terms of

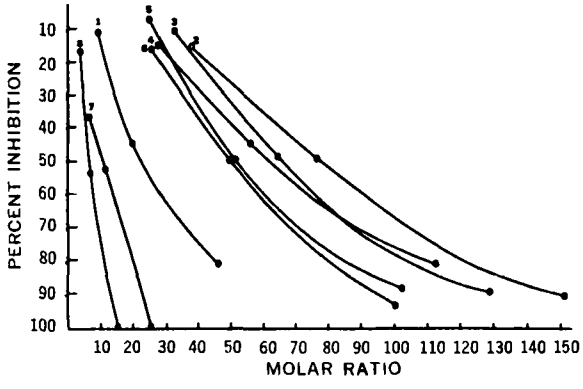

Figure 2—*Methacrylate inhibition of barium chloride-induced contraction. For key, see Fig. 1.*

Table II—Molar Ratio[a] to Produce 50% Inhibition of Induced Contraction

Compound	Acetylcholine	Barium Chloride
tert-Butylaminoethyl methacrylate	2,250	6.5
Hydroxyethyl methacrylate	3,250	10.0
Methacrylic acid	5,750	22.0
Isobutyl methacrylate	14,125	50.0
n-Butyl methacrylate	15,500	51.0
n-Propyl methacrylate	17,375	61.0
Ethyl methacrylate	18,125	65.0
Methyl methacrylate	19,375	76.5

[a] Molar ratio = molar concentration of methacrylate per molar concentration of stimulating agent at point where contraction is 50% of control contraction.

relative potency and type of action. Unlike the others, this compound produced contraction of the isolated ileum, and it was active in more dilute solutions than the others. At a concentration of 1:100,000 (v/v) (0.000059 mole/l.), dimethylaminoethyl methacrylate produced a significant contraction of the ileum. Pretreatment of the guinea pig ileum with atropine sulfate [1×10^{-7} and 10^{-6} (w/v) in the tissue bath] did not block or inhibit the contraction produced by this dimethylaminoethyl derivative. This would imply a myogenic effect, as suggested for the other homologs; but unlike the others, dimethylaminoethyl methacrylate stimulated the ileum to contract, while the other methacrylates inhibited such contractions.

SUMMARY AND CONCLUSIONS

The effects observed in this study, in which methyl methacrylate and most of the other monomers tested produced relaxation of the smooth muscle of the guinea pig ileum, are not inconsistent with the reports of Homsy *et al.* (9), who reported a fall in blood pressure of the dog by various concentrations of methyl methacrylate, or of Mir *et al.* (1), who observed a relative increase in coronary flow in the isolated rabbit heart following perfusion with methyl methacrylate and most of the other homologs included in this study. This latter response would suggest a direct vasodilator effect of the compounds upon the coronary circulation, although cardiac slowing *per se* may contribute to this effect by allowing more complete filling of coronary vessels prior to contraction. The work of Mir *et al.* (1) also showed that the pacemaker of the isolated heart was slowed and that the force of myocardial contraction was reduced when the heart was perfused with a solution containing the methacrylate monomer. While the hypotensive effect of methyl methacrylate on blood pressure in the dog (9) and possibly some hypotensive responses reported from the clinical use of self-curing acrylic cement (methyl methacrylate) in orthopedic surgery (8, 13, 14) may be due to a combination of effects, the reduction in tone of the smooth muscle of the arterioles, and hence vasodilation, must be considered as a possible primary or contributory factor in such hypotensive responses.

Tetracycline Binding to Bovine Serum Albumin Studied by Fluorescent Techniques

JOSEPH K. H. MA, H. W. JUN, and LOUIS A. LUZZI▲

Abstract □ Binding of demeclocycline and oxytetracycline to bovine serum albumin was studied using fluorescent methods. The mechanism of binding for tetracyclines is shown to be hydrophobic. The number of binding sites and the equilibrium constants were calculated over a range of protein concentrations. Two strong binding sites, at or near the tryptophan residues of bovine serum albumin, were found for both tetracyclines. The equilibrium constants for tetracyclines increased with increasing protein concentration, and the number of binding sites on the protein decreased with increasing protein concentration. These findings suggest the possibility of a sharing of one tetracycline molecule by more than one protein molecule at relatively high protein concentrations.

Keyphrases □ Demeclocycline—mechanism of binding to bovine serum albumin studied using fluorescent techniques □ Oxytetracycline—mechanism of binding to bovine serum albumin studied using fluorescent techniques □ Tetracyclines, demeclocycline and oxytetracycline—binding to bovine serum albumin, fluorescent techniques □ Serum protein binding—demeclocycline and oxytetracycline, fluorescent techniques □ Fluorescent techniques, probe and quenching titration—used to study mechanism of binding of demeclocycline and oxytetracycline to bovine serum albumin

The binding of drugs by plasma proteins has been recognized as an important factor in drug availability, drug efficacy, and drug transport for many years (1). Many experimental techniques have been employed to study drug–protein interactions (2–4). The fluorescence probe technique (5, 6) has recently been employed to study the mechanism of drug–protein binding and the nature of binding sites. This technique has also been very useful in biochemical research related to binding (7–9). The number of probes available at this time is limited; to explore the use of probes in binding studies more fully, it is necessary to search for new probe compounds. Therefore, the fluorescence studies of tetracyclines and bovine serum albumin were carried out in this laboratory.

Tetracyclines are fluorescent compounds with the excitation and emission maxima in the range of 390 and 520 nm., respectively. Ibsen and Urist (10) reported that the excitation maximum of tetracyclines varies with the presence of metal ions. They found that increasing metal concentration produced a bathochromic shift, indicating the formation of metal complexes. The quantum yields of several tetracyclines in various solvents and of their protein mixtures were reported by Popov *et al.* (11, 12). In a recent paper (13), they also studied the interaction of tetracyclines with bovine serum albumin using a fluorescence technique. The increase of the fluorescence of tetracyclines accompanied by an auxochromic shift of the fluorescence maxima in the presence of protein and in nonpolar solvents suggests that the tetracyclines exhibit the main features of fluorescence probes.

Fluorescence quenching titration is another sensitive method for the study of drug–protein molecular interactions. The procedure has been applied to many systems (14–16) and was best described by Chignell (17). It was found that the native fluorescence of bovine serum albumin was quenched by most of the tetracyclines. To examine the possible use of tetracyclines as probe compounds for drug–protein binding studies, the nature of binding of demeclocycline and oxytetracycline to bovine serum albumin was studied by both methods.

EXPERIMENTAL

Materials—Demeclocycline hydrochloride[1], oxytetracycline hydrochloride[2], and crystalline bovine serum albumin[3] were obtained from commercial sources. Methanol[4] was spectroscopic grade, and all other chemicals were reagent grade or of special purity. All chemicals were used without further purification.

Apparatus—Fluorescence measurements were made with a spectrophotofluorometer[5] equipped with a 150-w. xenon lamp and 1P21 photomultiplier tube. The relative fluorescence intensities were recorded directly from fluorometer readings.

Fluorescent Titration—The fluorescence and quenching titrations were performed manually with microsyringes[6]. Two milliliters of

each protein solution was titrated with successive additions of 2 μl. of drug solution (2×10^{-3} *M*) in methanol. Methanol did not affect the binding of the drug in the concentration range used. The protein solutions were prepared in pH 7.4 phosphate buffer. Concentrations of protein solutions were determined by measuring the absorbance at 280 nm. and using $a = 0.66$ (18); the molecular weight of 69,000 was used to determine the molar concentrations. All titrations were carried out at 25 ± 0.1°. The temperature was controlled by the use of thermostated cell compartments.

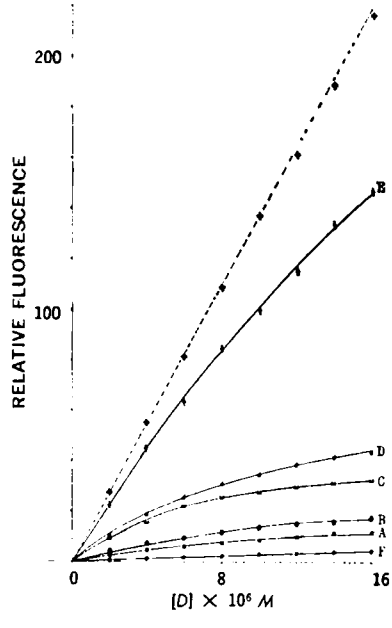

Figure 2—*Plots of oxytetracycline fluorescence intensities as function of oxytetracycline concentrations,* [D], *at (A) 1.436 × 10⁻⁶ M, (B) 7.436 × 10⁻⁶ M, (C) 14.18 × 10⁻⁶ M, (D) 21.62 × 10⁻⁶ M, and (E) 143.6 × 10⁻⁶ M bovine serum albumin, and (F) without bovine serum albumin. The values of* I_b *are plotted in dashed line.*

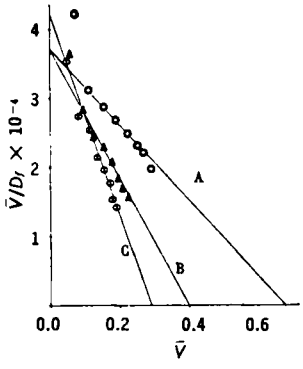

Figure 3—*Plots of* $\bar{V}/D_f$ versus $\bar{V}$ *for the demeclocycline-bovine serum albumin system in the demeclocycline concentration range of 2–16 × 10⁻⁶ M at (A) 5.095 × 10⁻⁶ M, (B) 7.99 × 10⁻⁶ M, and (C) 13.61 × 10⁻⁶ M bovine serum albumin.*

Treatment of Data—The fluorescence enhancement of the drug, upon addition to bovine serum albumin, was determined, and these data were used to calculate the binding constants for the albumin–drug complexes. The fraction of bound drug, X, was calculated from the following equation (7):

$$X = (I - I_f)/(I_b - I_f) \qquad \text{(Eq. 1)}$$

where I and I_f refer to the fluorescence intensities of a given concentration of drug in solutions of low protein concentration and in solutions without protein, respectively; I_b refers to the fluorescence intensity of the same concentration of drug in solutions of high protein concentration, which gives the fluorescence intensity of the drug in the presence of excess binding sites. In this study, the fluorescence titrations were carried out at several different protein concentrations, and the values of I_b were taken to be the extrapolated values of the plots of $1/I$ *versus* $1/[P]$, where $[P]$ represents the concentration of protein. After the value X is found for each point along the titration curve, the Scatchard equation (19) may be applied to determine the association constant of the drug:

$$\bar{V}/D_f = nK_a - \bar{V}K_a \qquad \text{(Eq. 2)}$$

where $\bar{V}$ is the number of moles of bound drug per mole of protein, D_f is the concentration of free drug, n is the number of binding sites on the protein, and K_a is the association constant of drug. The $\bar{V}$ is determined by multiplying the value for X by the ratio of the total drug concentration to the total protein concentration in solution. When $\bar{V}/D_f$ is plotted against $\bar{V}$, a straight line is obtained with a slope equal to $-K_a$. The ordinate and abscissa intercepts of this line give nK_a and n, respectively. The Scatchard equation assumes that the intrinsic association constants for all binding sites are equal.

In the fluorescence quenching titration method, titrations are made over a range of protein concentrations. The intensities, expressed as a percentage of the initial fluorescence of the protein, are then plotted as a function of the drug–protein ratio. Above a certain critical protein concentration, the titration curves are superimpos-

25.340[a]	8–80	0.775×10^4	2.00
44.330[a]	8–80	0.950×10^4	1.79

[a] Calculated from quenching data.

able since all the drug is bound. The concentration of bound drug (D_b) for a solution containing the protein below this critical concentration can be calculated by the equation:

$$D_b = (D_t)(R_h)/(R_l) \qquad \text{(Eq. 3)}$$

where D_t is the total drug concentration of the solution, and R_h and R_l are the drug–protein ratios at the same intensity for high and low protein solutions, respectively. The results can then be graphically treated using the Scatchard equation.

RESULTS AND DISCUSSION

The excitation and emission maxima, λ_{ex} and λ_{em}, for demeclocycline and oxytetracycline were found to be 382 and 520 nm. and 375 and 515 nm., respectively, in the concentration range used in this study. In the presence of bovine serum albumin, an auxochromic shift of about 20 nm. for the emission maxima was observed for both tetracyclines. Increasing protein concentration also produced a bathochromic shift for the excitation maxima. The fluorescence titrations were carried out over a range of protein concentrations, and the excitation and emission maxima used for demeclocycline and oxytetracycline were 390 and 504 nm. and 384 and 490 nm., respectively. The fluorescence data of the demeclocycline–bovine serum albumin and the oxytetracycline–bovine serum albumin systems, in which the fluorescence intensities are plotted as a function of drug concentration, are shown in Figs. 1 and 2, respectively. The dashed lines represent the I_b values.

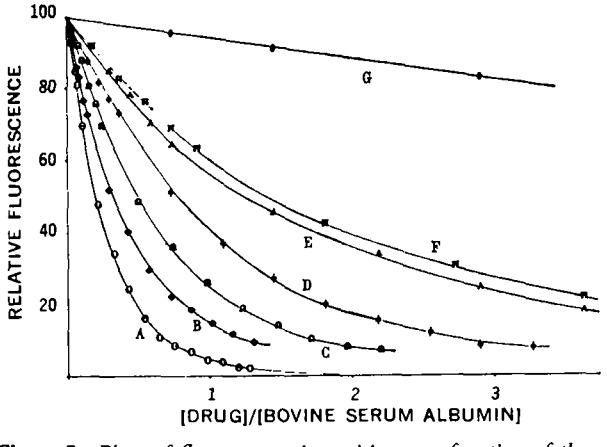

Figure 5—*Plots of fluorescence intensities as a function of the concentration ratios of demeclocycline and bovine serum albumin, where the bovine serum albumin concentrations for curves A, B, C, D, E, F, and G are 137.7 × 10⁻⁶ M, 68.87 × 10⁻⁶ M, 40.65 × 10⁻⁶ M, 27.54 × 10⁻⁶ M, 13.77 × 10⁻⁶ M, 11.02 × 10⁻⁶ M, and 1.377 × 10⁻⁶ M, respectively.*

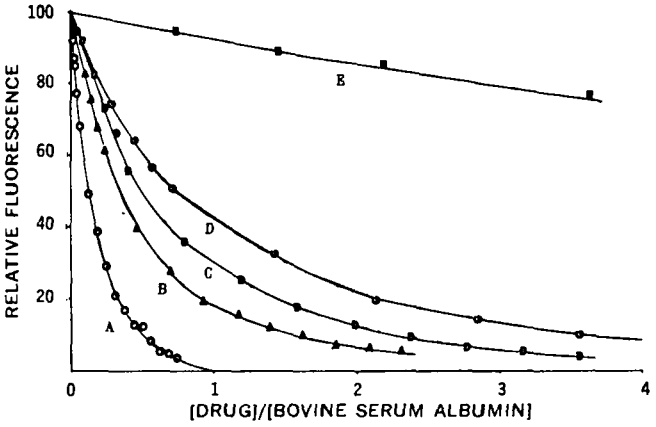

Figure 6—*Plots of fluorescence intensities as a function of the concentration ratios of oxytetracycline and bovine serum albumin where the bovine serum albumin concentrations for curves A, B, C, D, and E are 162.5 × 10⁻⁶ M, 44.33 × 10⁻⁶ M, 25.34 × 10⁻⁶ M, 14.06 × 10⁻⁶ M, and 1.377 × 10⁻⁶ M, respectively.*

The Scatchard plots for the binding of demeclocycline to bovine serum albumin are shown in Fig. 3. At different protein concentrations, the Scatchard plots gave straight lines corresponding to different n and K_a values. As shown in Table I, the equilibrium constant increased consistently with increasing protein concentration, whereas n decreased with increasing protein concentration. The same effect has also been observed in the binding of oxytetracycline to bovine serum albumin. The Scatchard plots of the oxytetracycline–bovine serum albumin system are shown in Fig. 4, with the corresponding n and K_a values listed in Table I.

The native fluorescence of bovine serum albumin was quenched by the addition of demeclocycline and oxytetracycline. The titration curves are shown in Figs. 5 and 6. The intensities, expressed as a percentage of the initial fluorescence of protein, are plotted as a function of the drug–protein ratio. The excitation and fluorescence maxima for all solutions were taken to be 285 and 354 nm., respectively. The concentration of bound drug and other parameters used for the Scatchard plot were calculated by the method previously described.

The plots of $\bar{V}/D_f$ *versus* $\bar{V}$ for the demeclocycline–bovine serum albumin system are shown in Fig. 7. Again, the equilibrium constant increased with increasing protein concentration, whereas the number of binding sites decreased with increasing protein concentration. The one exception is that a group of straight lines is superimposed

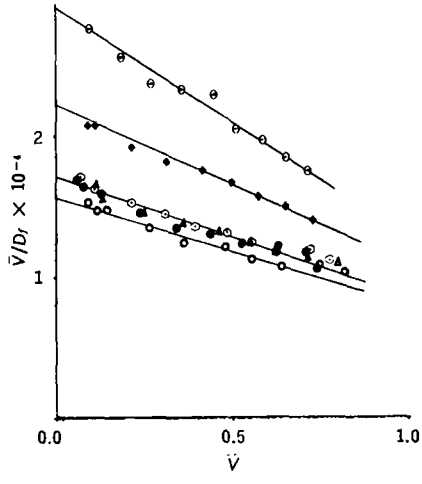

Figure 7—*Plots of* $\bar{V}/D_f$ versus $\bar{V}$ *for the demeclocycline–bovine serum albumin system in the demeclocycline concentration range of 8–80 × 10⁻⁶ M at various bovine serum albumin concentrations:* ○, *1.377 × 10⁻⁶ M;* △, *11.02 × 10⁻⁶ M;* ○, *13.77 × 10⁻⁶ M;* ○, *27.54 × 10⁻⁶ M;* Φ, *40.65 × 10⁻⁶ M; and* ⊙, *68.87 × 10⁻⁶ M.*

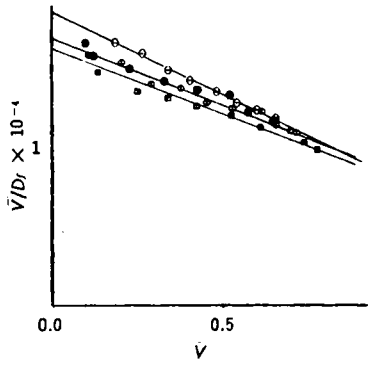

Figure 8—*Plots of* $\bar{V}/D_f$ versus $\bar{V}$ *for the oxytetracycline–bovine serum albumin system in the oxytetracycline concentration range of 8–80* $\times$ 10^{-6} M *at various bovine serum albumin concentrations:* ⊡, *1.377* $\times$ 10^{-6} M; ⊕, *14.06* $\times$ 10^{-6} M; ○, *25.34* $\times$ 10^{-6} M; *and* ⊙, *44.33* $\times$ 10^{-6} M.

upon each other in the protein concentration range of 11.02–27.54 $\times$ 10^{-6} *M*. Similar results were also found in the binding of tetracycline to bovine serum albumin. The values of n and K_a calculated from Figs. 7 and 8 are also shown in Table I; Fig. 8 shows the plots of $\bar{V}/D_f$ *versus* $\bar{V}$ for the binding of oxytetracycline to bovine serum albumin.

The binding information obtained from this study and the results recently reported by Popov *et al.* (13) show that the mechanism of binding for tetracyclines to bovine serum albumin is of a hydrophobic nature. The number of binding sites varies with varying tetracycline and protein concentrations, and the maximum number of strong or high affinity binding sites appears to be two. A quenching of tryptophan fluorescence, which is primarily responsible for the fluorescence of bovine serum albumin, by tetracyclines was also observed. Since bovine serum albumin is known to have two tryptophan binding sites per molecule (20), the quenching studies indicate that the binding sites are at or near the tryptophan residues. This is possible, since previous investigators (21, 22) showed that serum albumin has binding sites for small organic molecules which are located in the vicinity of the tryptophan residue. It is claimed that this is due to a clustering of hydrophobic apolar amino acids in the environment of tryptophan residues of these protein molecules.

The fact that the equilibrium constant is increasing with increasing protein concentration, together with the fact that n is concentration dependent, may suggest a sharing of one tetracycline molecule by more than one protein molecule in the binding. This observation is further substantiated by examination of Figs. 5 and 6, which show that at a certain drug–protein concentration ratio, the native fluorescence of protein is quenched more strongly at high protein concentration than at low protein concentration. In other words, the ratio of bound drug and total drug concentrations at high protein concentration is larger than that at low protein concentration.

The present studies show that the tetracyclines represent a class of compounds that can be used as probes for both techniques used in this investigation. The results also show that investigations at different protein concentrations are necessary to understand further the nature of binding.

Metabolism of Clindamycin I: Absorption and Excretion of Clindamycin in Rat and Dog

F. F. SUN▲ and R. S. P. HSI

Abstract □ Clindamycin hydrochloride, randomly labeled with tritium, was synthesized and used for animal metabolism studies. The drug was administered to rats (oral and intraperitoneal routes) and dogs (oral and intramuscular routes) at a dose of 50–150 mg./kg. In both species, after the oral or parenteral drug administration, the excretion of radioactive materials in the urine (approximately one-third of the dose) and in the feces (approximately two-thirds of the dose) was independent of the route of administration. The initial rate of excretion for the oral dose was significantly faster than the parenteral dose. In the dog, peak plasma radioactivity concentrations were observed at 2 and 4 hr. after oral and intramuscular administration, respectively. The slower rate of absorption and excretion following parenteral compared to oral administration was believed due to precipitation of the drug at the injection site or a difference in transport processes. Based upon the identical areas under the plasma total radioactivity *versus* time curves, plus the fact that the distribution of radioactivity excreted in urine and feces was independent of the route of administration, it was concluded that after oral administration the absorption of this drug into the bloodstream was almost complete and that little appeared to pass through the GI tract for direct elimination.

Keyphrases □ Clindamycin hydrochloride, radiolabeled—absorption and excretion after oral and parenteral administration, rats, dogs □ Absorption, radiolabeled clindamycin hydrochloride—after oral and parenteral administration, rats, dogs □ Excretion, radiolabeled clindamycin hydrochloride—after oral and parenteral administration, rats, dogs

Clindamycin[1] (I), a new antibacterial agent produced by chlorination of lincomycin, exhibits approximately four- to eightfold the *in vitro* antibacterial activity of lincomycin against Gram-positive organisms. *In vitro* clindamycin gave significantly lower CD_{50} values than lincomycin with a number of organisms tested. In addition, this drug has been shown to be a promising antimalarial agent in both mice and monkeys. The chemistry and biological activities were reported previously by Birkenmeyer (1), Magerlein *et al.* (2), and Birkenmeyer and Kagan (3).

Studies on the absorption, excretion, and half-life of clindamycin administered orally (4) or intramuscularly (5) to human subjects were also reported previously. Microbiological assays were used for end-point measurement. It was found that an orally administered dose was absorbed quantitatively and extremely fast in man. The maximal serum activity was achieved within 45 min. postadministration, with a clearance half-life of 2.38 hr. On the other hand, the intramuscularly injected dose was absorbed rather slowly. The maximal serum activity was achieved 2 hr. after administration, with an elimination half-life of 4.76 hr. Local precipitation of the drug at the injection site was believed to be the cause of this absorption delay. Since the bioassay measures only the algebraic sum of the antibacterial activities of the drug and its metabolites, the present study was undertaken to provide an overall understanding of the excretion of this antibiotic.

EXPERIMENTAL

Synthesis of Clindamycin-^{3}H Hydrochloride—Since extensive work had already been done on the tritiation of lincomycin hydrochloride (6), it was decided to prepare tritium-labeled lincomycin hydrochloride according to previously described methods and to use it as the starting material for conversion to clindamycin hydrochloride. Although the catalytic gas-exposure tritiation method gives a product of higher radiochemical purity and specific activity, it results in tritiation predominately in the propyl hygric acid portion of the molecule (6). Therefore, to achieve a more random distribution of the tritium label in the molecule, the Wilzbach gas-exposure tritiation method in the absence of catalyst was used.

Tritiation of Lincomycin—Three grams of lincomycin free base was submitted[2] for tritiation. The sample was exposed to 15 c. of carrier-free tritium gas for 2 weeks at 27° and 660 mm. Hg pressure. The crude material was twice dissolved in 25 ml. of water and freeze dried to give 2.922 g. of material with a specific activity of 19.26 μc./mg.

Purification of Lincomycin-^{3}H—A 2.8 × 57-cm. column of 200–400-mesh Dowex 50WX8 was washed with water, 2 *N* NH_4OH, water, 2 *N* HCl, and 0.1 *N* HCl in that order. The freeze-dried crude material was loaded onto the column, which was then eluted with 1.4 l. of 0.1 *N* HCl and 1.5 l. of water. Elution was continued with 1.5 l. of 2 *N* NH_4OH, which was collected in 17-ml. fractions at 12 min./fraction. Monitoring the radioactivity of the ammonium hydroxide eluate indicated that the desired product appeared in fractions 34–47. These fractions were combined and concentrated at water-aspirator pressure and 36°. The residue was recrystallized by dissolving in 1 *N* HCl (1 g./ml.) followed by the addition of 10 volumes of acetone. The resulting crystalline material was repeatedly recrystallized until constant specific activity was achieved on successive recrystallizations.

Two final samples were obtained. One sample, weighing 882 mg. with a specific activity of 2.45 μc./mg., was analyzed by paper chromatography with a solvent mixture of *n*-butanol–acetic acid–water (2:1:1). It was also analyzed by TLC on silica gel with the following solvent systems: I, methanol; II, *n*-butanol–acetic acid–water (2:1:1); and III, methyl ethyl ketone–acetone–water (3:1:1). Radioactivity analyses of the papergram and thin-layer plates showed that the material was radiochemically pure.

Table I—Recovery of Radioactivity of Clindamycin-^{3}H from Female Rats

	Percent of Administered Dose — Rat Number				
	1	2	3	4	Mean ± *SD*
Oral Administration					
Urine	20.76	33.30	26.93		27.04 ± 5.12
Feces	74.06	62.26	69.10		68.47 ± 4.84
^3H_2O in urine	0.91	1.06	1.63		1.20 ± 0.31
Total	94.96	95.56	96.03		95.51 ± 0.44
Intraperitoneal Injection					
Urine	31.37	21.49	29.30	28.56	27.73 ± 3.7
Feces	66.82	73.95	73.43	66.87	67.76 ± 3.5
^3H_2O in urine	1.20	0.61	0.86	1.42	0.89 ± 0.34
Total	98.40	85.44	102.73	95.43	95.50 ± 6.36

The second sample, weighing 447 mg. with a specific activity of 2.59 μc./mg., was shown to be identical to the first sample by TLC on silica gel with Solvent System III. These two samples were combined for use in the subsequent step.

Preparation of Clindamycin-^{3}H—Twenty milliliters of carbon tetrachloride was added to a stirred slurry of 1.315 g. (2.94 mmoles) of tritiated lincomycin hydrochloride, 3.86 g. (14.72 mmoles) of triphenylphosphine, and 16 ml. of acetonitrile. The mixture was stirred at room temperature under nitrogen for 18 hr. The resulting clear solution was concentrated at reduced pressure, and the residue was dissolved in 20 ml. of water. The insoluble triphenylphosphine oxide was removed by filtration. The filtrate was basified with 6 *N* NaOH solution, and the liberated free base was extracted into 2 × 15 ml. of chloroform. The combined extracts were washed and saturated with sodium chloride solution and concentrated at reduced pressure. The residual oil was dissolved in 20 ml. of methanol, and the solution was refluxed for 1 hr. and concentrated at reduced pressure. The residue was dissolved in about 20 ml. of 0.1 *N* HCl. The insoluble solids were removed by filtration, and the filtrate was extracted with carbon tetrachloride. The aqueous phase was then basified with 6 *N* NaOH and extracted with 2 × 15 ml. of chloroform. The combined chloroform extracts were washed with saturated sodium chloride solution and dried over magnesium sulfate. The dried chloroform solution was concentrated at reduced pressure, and the residual oil was dissolved in a mixture of 2 ml. of ethanol and 7 ml. of ethyl acetate and treated with anhydrous ethanolic hydrochloric acid.

Cooling the mixture in a refrigerator overnight gave the crystalline product, which was dried in a vacuum desiccator over phosphorus pentoxide. The product obtained, 488 mg. (37.2% yield), had

a specific activity of 2.386 μc./mg. This material was chromatographed on a silica gel thin-layer plate with lincomycin hydrochloride and clindamycin hydrochloride standards in Solvent System III (Fig. 1). Analyses of radioactivity on the thin-layer plate indicated that the material was 98.64% radiochemically pure, while 0.90% of the total radioactivity appeared in the same region as lincomycin hydrochloride. Its IR spectrum was identical to form I clindamycin hydrochloride standard.

Dosage and Collection of Samples—*Absorption and Excretion Studies in Rats*—Three female Sprague–Dawley (Upjohn strain) rats, with an average weight of 181 g., were used in the oral administration experiments. These rats were fasted for 12 hr. and loaded with 10 ml. of water before dosing. Each rat accepted, through a stomach tube, 1.5 ml. of the solution containing 1.54 mg. of the tritium-labeled clindamycin hydrochloride and 18.7 mg. of the carrier drug. The radioactivity dose was 3.6 μc./rat. The rats were then placed in stainless steel metabolism cages with free access to food and water, and urine and feces samples were collected.

In the intraperitoneal injection experiments, four female Sprague–Dawley rats (average weight 190 g.) were used. Each rat was loaded with 5 ml. of water before being injected with 0.5 ml. of an aqueous solution containing 1.85 mg. of the tritium-labeled drug and 28.40 mg. of the cold drug. The radioactivity dose was 4.42 μc./rat. Urine and feces samples were collected for 14 days in the same way as in the oral experiment.

Absorption and Excretion Studies in Dogs—Three male beagle dogs, weighing 11.7, 8.9, and 8.2 kg., respectively, were used. The labeled drug was given orally in hard filled capsules or intramuscularly as a solution. The intramuscular experiment was carried out 8 weeks after the oral experiment to ensure that the dogs retained no residual radioactivity from the first treatment.

In the oral experiment, both labeled and carrier drugs were weighed into hard-gelatin capsules individually for each dog. Ten milligrams of the labeled drug was also weighed into a volumetric flask for standardization of the radioactivity and correction for decay losses. Dogs were fasted for 18 hr. before dosing and were fed 4 hr. after dosing. Food[3] was given once a day and water was given *ad libitum* throughout the 2-week period. On the 1st and 2nd days, food wetted with water was given to increase the urine output.

Blood samples were collected from the jugular vein immediately before dosing and 0.5, 1, 2, 3, 4, 5, 6, 8, 12, 24, 36, and 48 hr. after dosing. Samples were obtained by using heparinized tubes[4], and plasma was prepared by centrifugation. Urine samples were collected every 4 hr. for the first 12 hr. by catheterization and once a day in stainless steel metabolism cages for the next 2 weeks. Fecal samples were collected as soon as they were seen or at least once a day. They were weighed and homogenized with water to make 20% homogenates. All samples were frozen immediately until analysis for radioactivity.

In the intramuscular experiment, 500 mg. of the drug containing 47.78 μc. of the labeled drug was dissolved in 2 ml. of sterile normal saline and the solution was injected as two split doses of 1 ml. each into the two hindlegs. The dogs were fed 1 hr. after dosing. The rest of the feeding schedules and the collections of blood, urine, and feces were the same as for the oral experiment.

Counting of Radioactivity—A counting medium[5] was used for direct counting of synthetic samples, urine, and tritiated water. A toluene–methanol–4% 2,5-diphenyloxazole/0.04% 1,4-bis-2-(4-methyl-5-phenyloxazolyl)-benzene mixture (9.25:5:0.72) was used for combusted samples. All solvents were reagent grade and were used without further purification.

Radioactivity in all samples was counted by the liquid scintillation technique, with the internal standard method to correct for quenching losses. Synthetic samples were dissolved in appropriate volumes of methanol, and 1.0-ml. aliquots were mixed with 15 ml. of counting solvent. Urine samples were counted directly after mixing 0.5-ml. aliquots with 15 ml. of counting solvent. Blood plasma (0.5-ml.) samples were dried in cellophane bags and combusted by the Schöniger oxygen flask procedure (7). The tritiated water generated from the combustion was collected in 17 ml. of counting solvent, and 15 ml. of the mixture was counted. Aliquots of fecal homogenate were weighed, dried, and combusted in the same way as the plasma samples. Tritiated water in the urine was separated by lyophilization, and 0.5 ml. of the condensate was counted directly as described for the urine samples.

All samples were analyzed in duplicate and counted twice to minimize any error in handling.

[3] Purina dog chow.
[4] Vacutainer.
[5] The Diotol counting solvent used is a mixture of 300 ml. of toluene, 210 ml. of methanol, 350 ml. of 1,4-dioxane, 73 g. of recrystallized naphthalene, and 50 ml. of 4% 2,5-diphenyloxazole and 0.04% 1,4-bis-2-(4-methyl-5-phenyloxazolyl)-benzene.

RESULTS

Absorption and Excretion of Clindamycin-^{3}H Radioactivity in Rats—Table I lists the total recovery from both experiments. When the drug was orally administered, a mean of 27.04% of the total radioactivity was excreted in the urine and 68.47% in the feces. The mean total recovery after 2 weeks was 95.51%. A very small amount of tritiated water was found in the urine (1.2%). Assuming that the same amount of tritiated water was eliminated in the expired air, the total quantity of tritiated water produced would be 2.4% of the dose.

The same excretion pattern was obtained when the drug was injected intraperitoneally. A mean of 27.73% of the total radioactivity was excreted through the kidney and 67.76% in the feces. The mean total recovery was 95.5%. Only 0.89% of the total radioactivity was found in the urine as tritiated water, corresponding to 1.78% if the expired air is included.

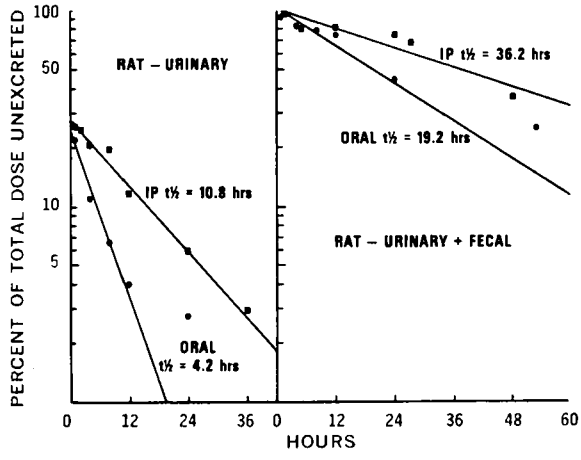

Figure 3—*Urinary and combined urinary and fecal excretion of clindamycin radioactivity by female rat.*

Table V—Parameters of Plasma Clindamycin-^{3}H Radioactivity in Male Beagle Dogs

	Dog B67-104		Dog G67-305		Dog G67-501		Mean ± *SD*	
	Oral	Intramuscular	Oral	Intramuscular	Oral	Intramuscular	Oral	Intramuscular
Maximum concentration (uncorrected), mg./ml.	43.577	18.70	61.245	43.26	63.178	41.01	56.00	34.32
Maximum concentration (corrected for dose level), (mcg./ml.)/(mg./kg.)	0.861	0.438	0.921	0.770	0.875	0.672	0.886 ± 0.026	0.627 ± 0.140

Area under the curve (corrected for dose level), (mcg.-hr./ml.)/(mg./kg.)	5.78	5.87	7.84	8.43	6.68	9.26	6.77 ± 0.85	7.85 ± 1.44
Relative absorption efficiency, %	98.45	100	93.03	100	72.21	100	87.90 ± 11.3	100

Since the intraperitoneally injected dose was presumably absorbed quantitatively, the identical distribution of radioactivity excreted after the two routes of administration suggested that oral absorption was also quantitative.

Figure 2 shows cumulative urinary, fecal, and total excretion of radioactivity after both routes of administration. Excretion was rapid in the urine but slow in the feces. Eighty-six percent of the radioactivity excreted in the urine was excreted in the first 48 hr. Fecal excretion was relatively slow and irregular. With both routes of administration, it took 120 hr. before 90% of the total fecal radioactivity was recovered.

During the first 24 hr. after administration, the percent urinary excretion of radioactivity from the oral (22.40 ± 4.0) and intraperitoneal (22.20 ± 2.37) doses was equivalent. During the same period, fecal excretion eliminated 29.68 ± 8.86% of the oral dose but only 8.79 ± 6.0% of the intraperitoneal dose. The difference apparently indicated that the transport of this drug to the bile was substantially slower after intraperitoneal than oral administration.

Although the different routes of drug administration did not appear to affect the distribution of total radioactivity in urine and feces, they did affect the initial rate of excretion (Fig. 3). The semilogarithmic plots clearly show that the initial rate of urinary excretion of the orally administered clindamycin radioactivity was twice as fast as the intraperitoneally injected dose. Table II lists the estimated half-lives for appearance of radioactivity in the excretions of each rat in this experiment. The average half-time for urinary excretion was 4.3 hr. for the oral dose in contrast to 9.45 hr. for the intraperitoneal dose. The half-times for the total elimination of the drug, as obtained by combining the urinary and fecal excretions of radioactivity at each time interval, also showed that the orally administered dose was excreted faster than the injected dose.

Absorption and Excretion of Clindamycin-^{3}H Radioactivity in Dogs—Two weeks after the administration of clindamycin-^{3}H, the average recoveries of radioactivity from three dogs in the oral experiment were 30.29 ± 2.56% from urine, 55.06 ± 1.85% from feces, and 85.35 ± 0.72% total. On the other hand, 27.74 ± 5.2% of the intramuscular dose appeared in the urine and 63.85 ± 8.5% in the feces. The total recovery in this case was 91.86 ± 3.31%. Recovery data for each individual dog are listed in Table III.

Figure 4 shows cumulative urinary, fecal, and total excretion of radioactivity after each route of administration. The identical distribution of radioactivity between urine and feces again suggested quantitative oral absorption. In all cases, only trace amounts of tritiated water were found in the urine. This indicated good stability of the radioisotope label in the drug during metabolic transformations.

Semilogarithmic plots for excretion of clindamycin-^{3}H radioactivity are presented in Fig. 5. The patterns in both urinary and overall excretion appear to be similar to that of the rat (Table IV). Both plots show that the dose of orally administered clindamycin was eliminated faster than the intramuscularly injected dose.

In the initial phase of the urinary excretion, the average elimination half-life after intramuscular administration was 8.64 ± 0.39 hr. compared with 4.10 ± 0.29 hr. after oral administration, which indicated that the drug and metabolites were eliminated 2.1 times more rapidly through the kidney after oral dosing. On the other hand, in the initial phase of the total excretion, the average elimination half-life after intramuscular administration was 11.20 ± 0.98 hr. compared to 8.0 ± 0.23 hr. *via* the oral route. This implies that the drug was eliminated 1.4 times more rapidly following oral than intramuscular administration. The delayed excretion following intramuscular administration was believed due to drug precipitation at the injection site or a difference in the transport process.

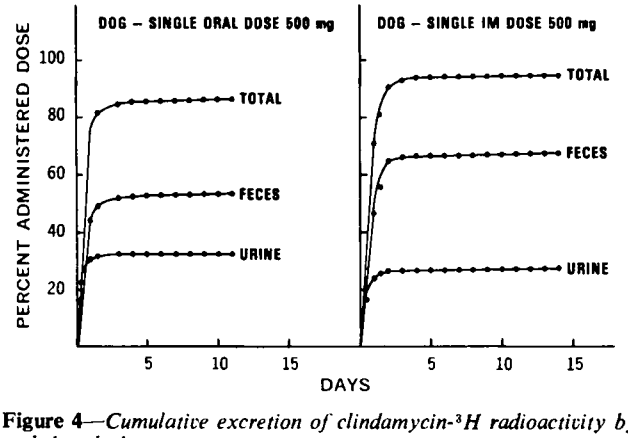

Figure 4—*Cumulative excretion of clindamycin-^{3}H radioactivity by male beagle dog.*

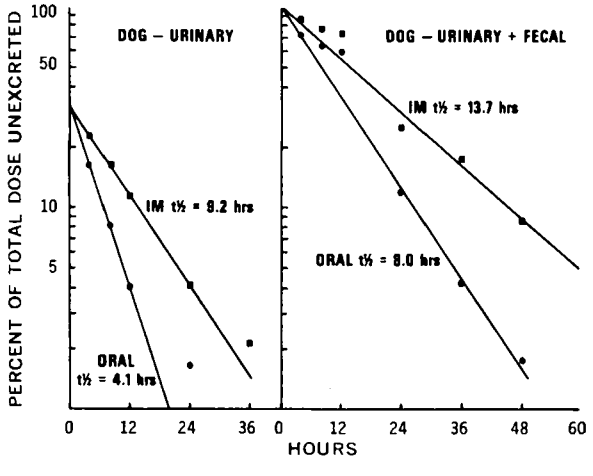

Figure 5—*Urinary and combined urinary and fecal excretion of clindamycin radioactivity by male beagle dog.*

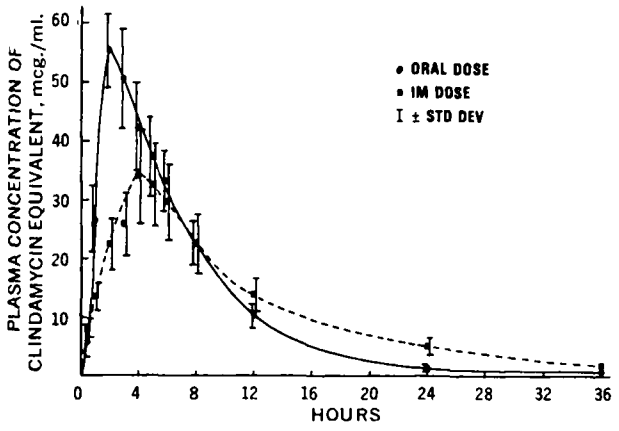

Figure 6—*Plasma concentration of clindamycin and metabolites (expressed as micrograms of clindamycin equivalent per milliliter of plasma) in dogs after oral (●) or intramuscular (■) administration of tritium-labeled clindamycin hydrochloride.*

Figure 6 shows the plasma levels of clindamycin radioactivity in dogs after two different routes of drug administration. When drug was administered orally, a peak concentration of 56-mcg. drug equivalents/ml. was observed at 2–3 hr. with a disappearance half-time of 3.8 hr. When drug was given intramuscularly, a peak concentration of 34-mcg. drug equivalents/ml. was observed at 4–5 hr. The disappearance half-time was estimated to be 5.5 hr.

Table V lists the parameters of plasma clindamycin concentration curves obtained for the three dogs. After the dosage levels were corrected to account for the slight differences in body weight, the mean areas under the plasma concentration curve per milligram dose per kilogram body weight were 6.77 ± 0.85 and 7.85 ± 1.44 mcg./hr./ml. for the oral and intramuscular doses, respectively. The ratio of the areas indicated that an average of 87.9 ± 11.3% of the drug was absorbed orally.

The plasma drug disappearance half-times were estimated graphically to be 3.87 ± 0.50 hr. for the orally administered dose and 5.55 ± 0.39 hr. for the intramuscularly injected dose. These values only represent the initial drug and/or metabolite disappearance in the first 12-hr. period since the curves deviate from the first-order kinetics after that period. A small secondary peak occurred after the animals were fed, strongly suggesting enterohepatic recirculation of drug and/or metabolites.

DISCUSSION

Based upon the described data it appears that orally administered clindamycin hydrochloride is rapidly and nearly quantitatively absorbed by rats and dogs. The drug is also rapidly excreted through both kidney and bile. However, the injected dose is absorbed and excreted much slower than the oral dose. These observations are consistent with the results of Novak *et al.* (5) in their study of absorption and excretion of intramuscularly administered clindamycin in man.

The absorption efficiencies of orally administered drug for each individual dog, as estimated by urinary excretion and areas under the plasma concentration curve, were not identical but were consistent. Both estimations show that orally administered drug was absorbed nearly quantitatively in Dogs B67-104 and G67-305 but only 70–90% in Dog G67-501. The difference is not considered significant.

The delayed absorption of the injected dose was suggested by Novak *et al.* (5) as being caused by the precipitation of the drug at the injection site. Since most of the drug at pH 7.4 (extracellular fluid pH) exists as the free base with low aqueous solubility and since the fluid volume in the injection site is limited, it is possible that the injected dose acts as if the drug were given in aqueous suspension. In addition, local swelling and irritation were observed at the injection site and persisted for 5–6 hr. This finding would be inconsistent with this postulation.

The lower plasma level and the slower initial rate of excretion of clindamycin radioactivity after intramuscular administration than after oral administration in dogs could also be caused by a difference in transport processes. The oral dose was absorbed and went through the portal system to the liver, where the entire dose was exposed to metabolism. On the other hand, the parenterally administered dose was absorbed into the venous system and delivered to the heart. Only a fraction of the cardiac output passes through the liver in each circulation.

However, the same argument cannot be used to explain the delayed excretion of the intraperitoneally administered clindamycin in the rat. Lukas *et al.* (8) recently showed that drugs administered intraperitoneally are absorbed primarily through the portal circulation and pass through the liver before reaching other organs. Therefore, the delay of excretion must be related to the slow absorption process through the peritoneal membrane, either due to local precipitation of the drug or other unknown reasons.

A similar case was reported by Burns *et al.* (9) in their study of phenylbutazone absorption. This drug was rapidly and completely absorbed from the GI tract in man but very slowly absorbed after intramuscular injection. The peak plasma concentration was reached 2 hr. after oral administration; but if an intramuscular dose was given, the peak was not observed until 6–10 hr. afterward. In this case, however, Burns *et al.* (9) proved that the cause of the delayed absorption was drug precipitation at the site of injection.

Correlation of Dissolution, Disintegration, and Bioavailability of Aminosalicylic Acid Tablets

R. E. SCHIRMER▲, J. W. KLEBER, and H. R. BLACK

Abstract □ Rank-order correlations are demonstrated among dissolution, disintegration, and several measures of bioavailability for tablets of aminosalicylic acid and its salts. The correlation between disintegration time and the percent of the dose excreted in the urine is examined quantitatively using both linear and quadratic models. The results support the use of either disintegration or dissolution tests to control the availability of this drug and suggest control limits for these tests. The suggested limits on the disintegration tests are shorter than those currently specified in USP XVIII monographs on these items.

Keyphrases □ Aminosalicylic acid and aminosalicylate tablets—rank-order correlations among dissolution, disintegration, and bioavailability □ Dissolution, disintegration, and bioavailability of aminosalicylic acid and aminosalicylate tablets—rank-order correlations □ Disintegration, dissolution, and bioavailability of aminosalicylic acid and aminosalicylate tablets—rank-order correlations □ Bioavailability, dissolution, and disintegration of aminosalicylic acid and aminosalicylate tablets—rank-order correlations

In 1956, Chapman *et al.* (1) reported a direct relationship between *in vitro* disintegration times and the biological availability of sodium aminosalicylate tablets. More recently, Middleton *et al.* (2) compared disintegration times and dissolution rates with the biological availability of tablets of aminosalicylic acid and sodium, potassium, and calcium aminosalicylate. Middleton *et al.* concluded, however, that disintegration times did not correlate with availability while dissolution rates gave good correlation. Neither paper supported its claims with a statistical evaluation of the data.

The doubt Middleton *et al.* (2) cast upon the value of disintegration tests for monitoring drug availability from aminosalicylate tablets, plus the fact that they did not use the USP–NF dissolution apparatus and presented only very limited data on tablets of aminosalicylic acid itself (our primary concern), led to this reevaluation of the relationship between *in vivo* and *in vitro* data for this product. Data available in the literature were used along with data available in this laboratory on a variety of aminosalicylic acid formulations exhibiting a wide range of dissolution and disintegration times. Significant rank-order correlations were found between several *in vivo* and *in vitro* parameters of availability, but only the data compiled on disintegration times and urinary excretion of drug were adequate for quantitative correlation.

EXPERIMENTAL

Tablets—Uncoated tablets and tablets with various enteric coatings were used. These tablets exhibited a wide range of dissolution and disintegration behavior. Suspensions of aminosalicylic acid powder were also administered to several subjects.

Dissolution Studies—Dissolution rates for uncoated tablets were measured in the USP–NF dissolution apparatus, using 900 ml. of pH 7.5 buffer (USP) in each vessel and a stirring speed of 165 r.p.m. Enteric-coated tablets were washed with pH 1.2 buffer for 1 hr. before placing them in the dissolution apparatus. Samples were collected at 5-min. intervals for rapidly dissolving tablets and at 20-min. intervals for all other tablets. The dissolution samples were analyzed for aminosalicylic acid using a modification of the automated analysis procedure reported by Wrightman *et al.* (3).

The results of the dissolution tests are reported as the average time required for 20% of the drug to go into solution from four or five tablets (T_{20}). This time was determined by a straight-line interpolation between the data points; in the case of enteric-coated tablets, it does not include the time spent in pH 1.2 buffer prior to the dissolution test. T_{20} was chosen rather than the more common T_{50} because several of the tablets tested dissolved so slowly that T_{50} could not be determined in a reasonable length of time; several T_{20} values were not determined for this same reason.

Disintegration—Disintegration times were determined using the USP apparatus. The disintegration times for enteric-coated tablets were determined in simulated intestinal fluid USP following 1 hr. in simulated gastric fluid USP. The disintegration times for nonenteric tablets were determined in simulated gastric fluid USP. Disks were used in both cases. The procedure differed from the USP procedure in that the tablets were observed continuously and a disintegration time for each tablet was recorded. The average of the observed disintegration times is reported rather than the time required for all the tablets to disintegrate, as specified in USP XVIII. This modification was expected to give better correlation with the clinical results, which are also reported as average plasma or urine concentrations from several subjects, each of whom ingested several tablets. In addition, a measure of tablet uniformity is available from data recorded in this manner.

Clinical Studies—All subjects were fasted overnight before receiving six 500-mg. tablets of aminosalicylic acid, which constitutes a normal therapeutic dose of this drug substance. Blood samples

were drawn at 0, 2, 4, 6, 8, and 12 hr. in early studies. In later studies, 1-, 3-, and 10-hr. samples were also drawn. Urine was collected for 12 hr. following drug administration.

Plasma and urine samples were analyzed by procedures adapted from Way *et al.* (4). The basic procedure consists of diazotization of the aminosalicylic acid followed by reaction with *N*-1-naphthylethylenediamine to form a rose-colored adduct whose absorbance is measured at 540 nm. This procedure measures the primary aromatic amines in the sample.

To precipitate plasma proteins, plasma samples were treated with trichloroacetic acid prior to developing the color. The reported plasma concentrations represent the sum of aminosalicylic acid and its metabolites that have a free amino group; aminosalicyluric acid, for example, is found in plasma in low but significant amounts (4–6) and would be included in the reported concentration. The major metabolite (4–7), *N*-acetyl-*p*-aminosalicylic acid, would not be included in the reported concentrations. However, the kinetics of elimination of aminosalicylic acid and its metabolites are very nearly linear up to a plasma concentration of approximately 110 mcg./ml. (8). Since the plasma concentrations encountered in this study did not exceed 85 mcg./ml. (Table I), which is well within the linear region, the area under the plasma level–time curve as determined by this method is a suitable measure of drug availability.

Urine samples were subjected to an acid hydrolysis before

Table II—*In Vivo* and *In Vitro* Availability of Aminosalicylic Acid from Tablets[a]

Tablet	Number of Subjects	Time of Plasma Peak, hr.	Plasma Peak, mcg./ml.	Area under Plasma Curve, mcg.-hr./ml.	Percent Recovered in Urine[b]	Mean Disintegration Time, min.	T_{20}, min.

I Enteric	5	—[d]	—[d]	—[d]	2 ± 4	73 ± 13	—[f]
J Enteric	5	—[d]	—[d]	—[d]	0.8 ± 0.5	53 ± 5	—[f]

[a] Ranges are ±1 *SD*. [b] Calculated as the percent of labeled potency of the tablet. [c] Two independent clinical trials were conducted on Tablet E. [d] Plasma level parameters could not be calculated because the plasma concentration had not passed its maximum at the time the last blood sample was drawn. The mean area under the plasma level curve up to 12 hr. was less than 8 mcg.-hr./ml. [e] A T_{20} value was not calculated because one out of four tablets showed no dissolution after 2 hr. in the pH 7.5 buffer. [f] There was no measurable dissolution after 3 hr. in the pH 7.5 buffer.

Table III—Rank-Order Correlation Coefficients for *In Vivo* and *In Vitro* Availability of Aminosalicylic Acid[a]

	Peak Plasma Level	Area under Plasma Level–Time Curve	Percent of Dose Excreted in Urine	Mean Disintegration Time	Dissolution, T_{20}
Time of plasma peak level	−0.77	−0.49	−0.71	+0.94 (0.02)	+1.00 (0.01)
Peak plasma level		+0.83 (0.1)	+0.83 (0.1)	−0.83 (0.1)	−0.77
Area under plasma level–time curve			+0.83 (0.1)	−0.60	−0.49
Percent of dose excreted in urine				−0.96 (0.01)	−0.93 (0.01)
Mean disintegration time					+0.95 (0.01)

[a] For correlations significant at the 0.1 level or below, the approximate confidence level is given in parentheses.

analysis. This procedure frees the amino group in the *N*-acetyl metabolite, so that the reported values are a measure of total aminosalicylic acid and metabolites and provide a good basis for comparing the relative bioavailability of aminosalicylic acid from various formulations.

DISCUSSION

The results of the *in vivo* and *in vitro* experiments are summarized in Table II. The entries in Table II are arranged in order of decreasing percentage of drug recovered in the urine, and a comparison of the columns suggests several rank-order correlations among the variables. The data suggest that longer disintegration times and T_{20}'s are associated with a greater delay before the peak plasma concentration is reached, a lowering of the peak concentration, a smaller area under the plasma concentration–time curve, and reduced amounts of drug excreted in the urine. The correlation coefficients and corresponding significance levels derived from the distribution of sums of squares of rank differences (9) are presented in Table III for these data. Several correlations are, in fact, significant, the most notable being the correlations between time of plasma peak, the percent of the dose excreted in the urine, and the disintegration and dissolution times.

Table IV summarizes the published data relating tablet disintegration time to the amount of drug excreted in the urine following the administration of tablets of aminosalicylic acid and its salts. A significant correlation between the *in vivo* and *in vitro* test results is also found with these data. However, the correlation coefficient calculated for the disintegration times and urine recoveries of the salts was only −0.72, while the correlation coefficient calculated from the data on tablets of the acid was −0.96. The lower correlation coefficient found for the salts is due to the existence of a range of disintegration times over which the bioavailability remains essentially at its maximum value (Fig. 1). A better evaluation of the correlation in this case is obtained from the regression analysis discussed below.

Although a rank-order correlation between *in vivo* and *in vitro* tests may be sufficient for establishing manufacturing controls to assure a lower limit on the availability of drug from manufactured lots of tablets, a more quantitative correlation is desirable because it allows the data to be summarized in a simple algebraic relation and also because it allows one to estimate the reliability of predictions made from the model equation. Therefore, the correlation between disintegration time (X) and percent of the dose excreted in the urine (Y) was examined using both a linear and a quadratic model, *i.e.*, ($Y = a_1 + b_1X$) and ($Y = a_2 + b_2X + c_2X^2$), respectively.

Table IV—Summary of Availability Data on Aminosalicylate Tablets from the Literature[a]

Tablet	Percent Recovered in Urine[a]	Mean Disintegration Time, min.	Reference
Sodium salt:			
A	74	19.5	1
B	72	58.0	1
C	72	67.0	1
D	72	63.5	1
E	61.5	91.1	1
F	50.0	111.5	1
G	2.1	200.4	1
H	78.3	10	2
I[b]	84.5	28	2
J[b]	76.4	45	2
Calcium salt:			
K	81.2	63	2
Free acid:			
L	85.9	1	2
M[b]	43.7	31	2

[a] Calculated as the percent of labeled potency of the tablet. The correlation between the tabulated urine recoveries and disintegration times for the sodium and calcium salts is significant at the 0.02 level when calculated from the distribution of sums of squares of rank differences (9). The correlation coefficient is −0.720. [b] Enteric-coated tablets.

Table V—Relation of Percent of Dose Excreted in the Urine (Y) to Tablet Disintegration Time (X)

	Linear Model	Quadratic Model
Aminosalicylic acid:		
Equation	$Y = 80.8 - 1.37X$	$Y = 87.1 - 2.34X + 0.0153X^2$
Multiple correlation coefficient	−0.94	−0.96
Standard error of estimate	13.1	10.6
Aminosalicylate salt:		
Equation	$Y = 94.1 - 0.412X$	$Y = 80.5 - 0.009X - 0.00194X^2$
Multiple correlation coefficient	−0.94	−0.98
Standard error of estimate	8.3	4.8

Only disintegration times and urine levels were used in this analysis, because these parameters covered a wider range of values than the other parameters, and more data pairs were available (Tables II and IV). The quadratic model was included in the analysis, because a plot of disintegration time against the percent drug recovered in the urine (Fig. 1) suggested a curvilinear relation between the variables. A curvilinear relation would be expected on theoretical grounds as well. If the rate of release of drug from the dosage form were much faster than the rate of absorption, the drug would be maximally available; a further increase in the rate of release would have no effect on the availability of the drug. Similarly, when the release is so slow that essentially no drug is absorbed, a further decrease in the rate of release would not affect the availability. These regions of maximal and minimal availability would be expected to be joined by some smooth function, $Y = Y(X)$. In the absence of a theory defining the functional form of $Y(X)$ more precisely, a simple polynomial is a reasonable choice for use in a study of the correlation between Y and X. The results of the analyses using these models are presented in Table V, and the regression curves are plotted in Fig. 1.

As indicated in Table V, the regression analyses of the data on aminosalicylic acid and its salts were carried out separately. The experimental points in Fig. 1 suggest that the acid and its salts do not fall on the same regression curve, and subsequent statistical treatment confirmed that the difference is significant. This difference in behavior is probably not an artifact generated by interlaboratory assay differences, because the data of Middleton *et al.* (2) on aminosalicylic acid are consistent with the present results, while their data on the salts are consistent with the results of Chapman *et al.* (1). Three possible sources of this difference are: (*a*) differences between the acid and its salts with respect to physical-chemical properties, such as solubility or rate of dissolution of the crystals; (*b*) the fact that most of the slow disintegrating tablets of aminosalicylic acid were enteric coated, whereas most tablets of the salts were not; or (*c*) the difference in the disintegration tests used for enteric tablets as opposed to nonenteric tablets (see *Experimental* section). The available data are not sufficient to decide among these alternatives.

The multiple correlation coefficients in Table V show that 92 or 96% of the variance in the urinary excretion of drug following the administration of aminosalicylic acid or an aminosalicylate salt, respectively, can be ascribed to the effect of tablet disintegration time when the quadratic model is assumed. Only 88% of the variance can be ascribed to tablet disintegration time when the linear model is assumed.

The standard error of the estimate for the quadratic model indicates that 95% of the time the experimental urine recovery of aminosalicylic acid should lie within ±21% of the value predicted by the regression line. The 95% confidence limits for urine recovery values predicted for the salts of aminosalicylic acid are ± 10%. The confidence limits for the linear model are broader than those for the quadratic model for both groups of tablets. While the confidence limits are not as tight as one would like, they are reasonable in view of the large intersubject variability normally encountered in clinical studies.

The constant terms in the equations in Table V represent the maximum availability of the drug predicted by the model. The values of 87.1 and 80.5% obtained for the quadratic model are in good agreement with the values reported in the literature, which range from 70 to 85% (1, 2, 4–6, 10, 11).

CONCLUSIONS

The correlations between disintegration times and bioavailability (Table V) show that it is possible to use disintegration tests to control the availability of drug from aminosalicylate tablets. Tablets of aminosalicylic acid and sodium and potassium aminosalicylates are official in USP XVIII. The USP requires that uncoated tablets disintegrate within 30 min. and that enteric-coated tablets disintegrate within 150 min. As can be seen from Fig. 1, only the limits set for uncoated tablets of the sodium and potassium salts are adequate to ensure drug availability; tablets of the salts disintegrating within 30 min. are as available as a suspension of the drug (80.5%). The USP tests would pass uncoated tablets of aminosalicylic acid, which were only 30.4% available, and enteric-coated tablets of aminosalicylic acid and aminosalicylates, which were 0.0 and 35.5% available, respectively. The results indicate that the time limits for enteric-coated tablets should be the same as the time limit for uncoated tablets and that the limit on the disintegration time for aminosalicylic acid tablets should be reduced from 30 to approximately 10 min.

The data in Tables II and III, as well as the data of Middleton *et al.* (2), show that dissolution tests may also be used to control drug availability from tablets of aminosalicylic acid and its salts. In principle, dissolution tests are more likely to give valid comparisons of drug availability from different formulations than are disintegration tests, because availability could be limited by the rate of dissolution from the tablet fragments rather than by the rate of disintegration of the tablet. The available data indicate, however, that the possible discrepancy between dissolution and disintegration times does not, in fact, occur for typical formulations of tablets of aminosalicylic acid and its salts. Middleton *et al.* (2) probably failed to find a correlation between disintegration times and bioavailability because they studied tablets of both aminosalicylic acid and its salts, and these fall on different correlation lines. Their data were not sufficient to make the existence of two lines obvious, and the resulting distribution of points was interpreted as a lack of correlation. The open symbols in Fig. 1 represent the data of Middleton *et al.* and clearly show the apparent lack of correlation.

In the present study, a problem was encountered in attempting to correlate dissolution time with urinary excretion of drug because T_{20}'s for the least available tablets were too long to be conveniently measured, whereas the T_{20}'s for the most available tablets were too short to be measured accurately. This situation made a full regression analysis of the data impossible, although it did not obscure the rank-order correlation existing between these variables. The data in Table II show that T_{20} must be limited to 15 min. or less, when the test is conducted as described in the *Experimental* section, to ensure at least 50% drug availability.

GLC Determination of 7-Trifluoromethyl-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4-(3*H*,5*H*)-dione in Plasma

LEONARD C. BAILEY and ARVIN P. SHROFF▲

Abstract □ A GLC assay method is described for the determination of 7-trifluoromethyl-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4-(3*H*,5*H*)-dione in the plasma or serum of dogs, rabbits, or humans. After extraction with hexane from acidified plasma or serum, the compound is analyzed by GLC using a flame-ionization detector. Quantitation is accomplished using a standard curve, which was found to be linear over the 0.002–3.5-mcg. range. The analysis is sensitive to amounts of the drug above 0.1 mcg./ml. Recovery of the title compound added to human plasma averaged 98.7%, with a variation of approximately 7.1% (*RSD*). Plasma data are presented to demonstrate the utility of the method.

Keyphrases □ 7-Trifluoromethyl-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4-(3*H*,5*H*)-dione—GLC analysis in plasma □ 1,5-Benzodiazepine compounds—GLC analysis of 7-trifluoromethyl-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4-(3*H*,5*H*)-dione in plasma □ GLC—analysis, 7-trifluoromethyl-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4-(3*H*,5*H*)-dione in plasma

A recently synthesized member of the benzodiazepine class of compounds, 7-trifluoromethyl-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4-(3*H*,5*H*)-dione[1] (I), is currently being evaluated for its activity as a minor tranquilizer. It differs significantly from other benzodiazepine psychotropic agents in that the carbon and nitrogen atoms in the 4- and 5-positions of the diazepine ring are reversed, giving rise to the 1,5-benzodiazepine structure. The pharmacological action of Compound I on the CNS of various test animals has been reported (1, 2), as well as the metabolism of the drug in animals and man (3).

To assist in correlating pharmacological activity with blood levels of Compound I, it was necessary to develop a sensitive, specific method of analysis that would permit processing of a large number of samples in a relatively short time. Various methods have been described for the determination of benzodiazepines, notably diazepam and chlordiazepoxide, in physiological fluids. In some cases, quantitation is achieved by making use of the UV-absorbing properties of the compound (4), while in others it depends upon hydrolysis of the drug followed by colorimetric determination of a Bratton–Marshall adduct (5–8). Cathode ray polarography has been successfully applied to plasma determinations (9). The most sensitive and specific methods use GLC, either of the intact compounds or of their hydrolysis products, and electron-capture detection (4, 10–12). However, these methods require extensive, time-consuming manipulations to produce an extract clean enough for chromatography.

The method described here used GLC followed by flame-ionization detection for the determination of Compound I in plasma or serum to levels of 0.1 mcg./ml. The analysis is specific for Compound I in the presence of its known metabolites and is applicable to human or animal samples after administration of therapeutic doses.

EXPERIMENTAL

Reagents—The purity of Compound I used was 100% as determined by GLC and TLC. All other materials were analytical reagent quality. The hexane was purified further by shaking with sulfuric acid, washing with water until neutral, and redistilling

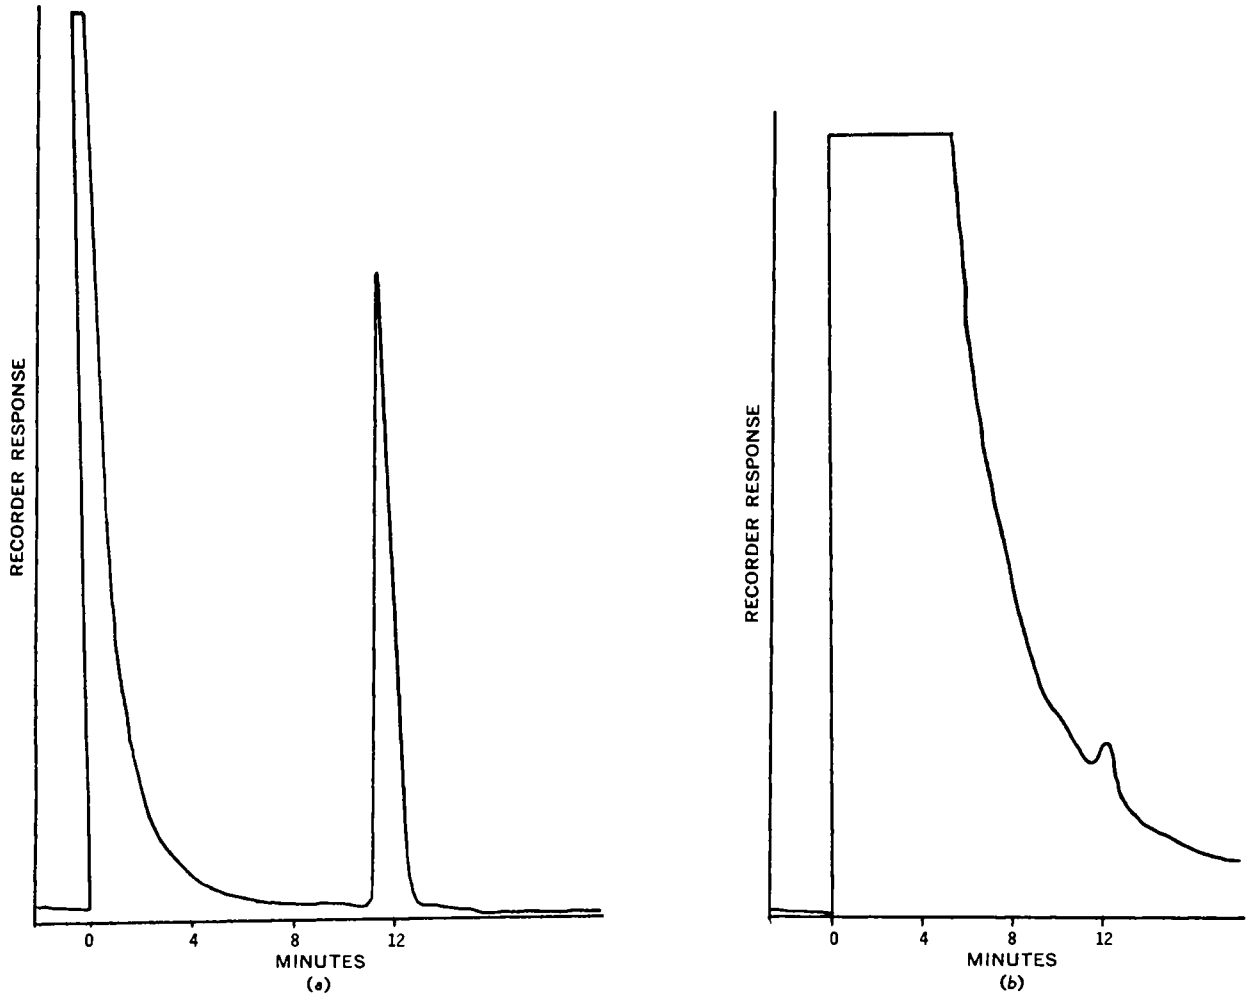

Figure 1—*Representative chromatograms of Compound I:* (a) *0.27 mcg. (attenuation* × *16), and* (b) *0.8 ng. (attenuation* × *1).*

twice through a 30.48-cm. (12-in.) Vigreux column. This was necessary to eliminate interferences which became significant after concentration of the hexane.

Apparatus—A gas chromatograph[2] with a dual flame-ionization detector was used. The output of the chromatograph was recorded on a recorder[3] with a full-scale range of 1.0 mv.

Analyses were performed using a glass column, 0.61 m. (2 ft.) × 4 mm. i.d., packed with 6% Carbowax 20M on Gas Chrom Q (100–120 mesh). The column was conditioned for 24 hr. at 250° with a helium flow of 60 ml./min. The inner surface of the column and the glass wool used to retain the packing were previously deactivated by treatment with dichlorodimethylsilane (13).

The analytical parameters used were: oven temperature, 240°; injector and manifold temperature, 230°; hydrogen inlet pressure, 1 kg./cm.^{2}; oxygen inlet pressure, 2 kg./cm.^{2}, and helium flow, 60 ml./min. With these conditions, Compound I was eluted as a symmetrical peak at 12.03 min. (Fig. 1*a*). The minimum detectable quantity of standard is less than 1 ng. (Fig. 1*b*).

Procedure—The glassware was washed with detergent and water, rewashed with chromic acid cleaning solution, rinsed with water and methanol, and dried overnight at 110°.

Blood samples were routinely collected in heparinized tubes, and the plasma was separated by centrifugation. However, in the case of human samples, it was found that less contamination occurred and greater sensitivity was possible if serum was analyzed instead of plasma. Either plasma or serum samples could be stored at 5° for at least 2 months without adversely affecting the analysis.

Exactly 1 ml. of serum was pipeted into a 25-ml. glass-stoppered extraction tube, and 0.05 ml. of concentrated hydrochloric acid was added. The tube was agitated to redissolve the small precipitate, 7 ml. of hexane was added, and the sample was extracted with vigorous shaking for 5 min. The layers were allowed to separate for 5 min., and the hexane layer was transferred with a Pasteur pipet to another extraction tube containing 2 ml. of 10% aqueous sodium carbonate. This was shaken for 1 min. and then allowed to separate for 1 min.; the hexane layer was transferred to a 12-ml. centrifuge tube for evaporation to dryness at 50° under a gentle stream of nitrogen.

The sample was extracted twice more with 6-ml. portions of hexane. These, in turn, were back-extracted with the carbonate solution and transferred to the centrifuge tube. After evaporation of the hexane, the residue was concentrated at the tip of the centrifuge tube with the aid of small portions of hexane–methylene chloride (50:50). The residue was quantitatively transferred to a tube[4] and concentrated in the tip. Exactly 20 μl. of hexane was added, and an accurately measured quantity (~2.5 μl.) was injected into the chromatograph. Figures 2*a* and 2*b* show representative chromatograms of control blood and of a sample containing 0.3 mcg./ml., respectively.

A calibration curve prepared by injecting known amounts of standard Compound I was found to be linear over the range of interest (0.002–3.5 mcg.) and to pass through the origin. To minimize the effects of variations in instrument parameters, standards were run on a daily basis.

Quantitation of the samples was achieved by drawing the baseline and determining the area by multiplying the height times the width at half-height. Sample areas were normalized by dividing by the volume injected, and the quantity of Compound I per microliter

injected was determined by interpolation of the standard values. This result was multiplied by 20 to arrive at the final concentration in micrograms per milliliter.

RESULTS AND DISCUSSION

Sadée and Van der Kleijn (14) reported that certain diazepine compounds are decomposed during GLC as indicated by GLC–mass spectrometry. To verify the identity of the species being analyzed, mass spectra were obtained on a solid sample of Compound I and on the material eluted from the GLC column. Both mass spectra were identical, indicating the stability of Compound I to GLC.

Although Compound I does not form salts with mineral acids, it was determined in this investigation that recoveries of the drug were enhanced if the plasma or serum was acidified before extraction. Interfering substances that are also extractible from acid solution are removed by the carbonate back-extraction.

Table II—Plasma Levels[a] of Compound I in Humans

Dose, mg./day	Patient					
	R.E.B.	R.H.	R.B.	J.D.	M.K.	P.A.
10	0.169	0.182	0.099	0.176	0.107	0.193
20	0.286	0.300	0.300	0.414	0.214	0.375
30	0.371	0.376	0.403	0.442	0.328	0.470

[a] Values are micrograms per milliliter.

It was reported[5] that Compound I undergoes hydrolytic degradation in strong acid to form N^1-acetyl-N^1-methyl-N^2-phenyl-(4-trifluoromethyl)-2,1-phenylenediamine (II). However, the rate constants indicate that a negligible amount of hydrolysis should occur at room temperature during the time necessary to extract the plasma. Residues from sample analyses were chromatographed on silica gel thin-layer plates using various solvent systems. Comparison with concurrently chromatographed authentic Compound II indicated no degradation of Compound I. Elution of the sample zone and subsequent GLC confirmed this observation.

The accuracy and precision of the analysis, determined by adding known amounts of Compound I to plasma or serum, are shown in Table I.

To demonstrate the suitability of the method for actual biological samples, rabbits were dosed intravenously with 5, 10, or 20 mg. of Compound I and plasma samples were taken at appropriate intervals for analysis. The plasma concentrations (mean ± *SE*) shown in Fig. 3 illustrate the applicability of the method.

Blood levels were also determined in human plasma samples obtained from a group of patients participating in a clinical study. Plasma concentrations ranging from 0.099 to 0.47 mcg./ml. were found in samples taken 24 hr. after successive daily doses of 10, 20, and 30 mg. (Table II). These results confirm the utility of the GLC analysis for clinical samples.

Intraamniotic Prostaglandin $F_{2\alpha}$ Dose–Twenty-Four-Hour Abortifacient Response

W. E. BRENNER[A], C. H. HENDRICKS, J. I. FISHBURNE, Jr., L. STAUROVSKY, J. BRAAKSMA, and R. TAFT

Abstract □ Prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) was administered intraamniotically to 132 midtrimester gravidas by one of six dose schedules to determine the dose–24-hr. abortifacient response. Single doses between 15 and 50 mg. and multiple doses between 15 and 25 mg. were administered to three groups each, the latter regimen at 6-hr. intervals. Dose–response relationships with both the single- and multiple-injection methods were different in patients of different parities and gestational ages. Interpretation of the dose–response relationships indicated that: (*a*) no one-dose schedule will obtain maximum rates of abortion in all types of patients; (*b*) single injections of greater than 50 mg. of $PGF_{2\alpha}$ are indicated in multiparas of greater than 16 weeks' gestational age, (*c*) in patients at 16 weeks' gestation or less, the low dose multiple-injection schedule attains high abortion rates that probably cannot be achieved by higher multiple-injection methods or any single-injection method; (*d*) it is unlikely that any significant increase in effectiveness can be obtained by multiple injections in excess of 25 mg. initially and repeating an identical dose in 6 hr. in patients greater than 16 weeks' gestation; and (*e*) it is unlikely that any increase in effectiveness will result from single doses in excess of 25 mg. in multiparas of 16 weeks' gestation or less. Complications were not of such severity or frequency as to limit the practicability of these schedules.

Keyphrases □ Prostaglandin $F_{2\alpha}$—intraamniotic dose–24-hr. abortifacient response □ Intraamniotic prostaglandin $F_{2\alpha}$ administration—dose–24-hr. abortifacient response □ Abortion—24-hr. response after intraamniotic prostaglandin $F_{2\alpha}$ administration □ Dose–response relationships—prostaglandin $F_{2\alpha}$ intraamniotic administration and 24-hr. abortifacient response

Although the intraamniotic administration of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) has been demonstrated to be an effective means of aborting pregnancies after 14 weeks' gestation (1, 2), the dose schedule safely resulting in the greatest frequency of abortion within the shortest period of time remains to be demonstrated. In an effort to make the search for this dose less arduous for both the subjects and investigators, the dose–24-hr. abortifacient response relationships were studied.

MATERIALS AND METHODS

One hundred thirty-two physically healthy gravidas between 10 and 23 menstrual weeks' gestation received $PGF_{2\alpha}$ intraamniotically by one of six dose schedules to induce therapeutic abortion[1]. There were no significant differences in the compared characteristics between the groups (Table I).

Prostaglandin $F_{2\alpha}$ in a concentration of 5 mg./ml. of diluent was injected through a polyethylene catheter[2] inserted into the amniotic cavity *via* an 18-gauge, thin-wall needle by either the transabdominal or transvaginal approach. The initial 5 mg. $PGF_{2\alpha}$ was injected over 5-min., while the remainder of the dose was injected over the following 5-min. period.

One of six $PGF_{2\alpha}$ dose schedules was used. The single-dose schedules were:

Group I (15 mg.)—Twenty gravidas were injected with 15 mg.

Group II (25 mg.)—Thirty-one gravidas were injected with 25 mg.

Group III (50 mg.)—Twenty-four gravidas were injected with 50 mg. at the initiation of the study, with no further $PGF_{2\alpha}$.

The multiple-dose schedules were:

Group IV (15–15 mg.)—Ten gravidas were injected with 15 mg. at the initiation of the study and an identical dose 6 hr. later.

Group V (25–25 mg.)—Twenty-two gravidas were injected with 25 mg. at the initiation of the study and an identical dose 6 hr. later if abortion had not occurred.

Group VI (25–25–25 mg.)—Twenty-five gravidas were injected with 25 mg. at the initiation of the study with an identical dose 6 and 12 hr. later if abortion had not occurred.

For this study, all trials were declared a failure if abortion (either complete or incomplete) did not occur within 24 hr. of the initial injection. Abortion was classified complete when both the fetus and placenta were completely expelled from the uterus; it was considered incomplete when the placenta was not completely expelled from the uterus. Abortion interval was the period of time from the initial injection to expulsion of the fetus from the uterus. Gestational age was calculated as the nearest number of whole weeks from the first day of the patient's last normal menstrual period. A subject was classified as multiparous if she had one previous delivery after 20 weeks of gestation. Differences at the $p < 0.05$ level were considered statistically significant.

RESULTS

Single-Dose Schedules—Although there was an increase in effectiveness when the dose was raised from 15 mg. (Group I) to 25 mg. (Group II), there was an insignificant increase when the dose was raised from 25 to 50 mg. (Group III) (Fig. 1 and Table II). Increases in frequency of abortion (9%) and in the mean abortion time (3.1 hr.) and differences in the rates of incomplete abortions noted when the dose was raised from 25 to 50 mg. were statistically insignificant.

Different dose–response relationships were noted for patients of different parities and gestational ages (Fig. 2). As the dose was progressively increased in nulliparous patients, increasing rates of abortion were observed. In contrast, as the dose was progressively increased in multiparous patients, decreasing rates of abortion were observed.

Differences were also observed between patients of greater than 16 weeks' gestation (>16 weeks) and 16 weeks' gestation or less (≤16 weeks). In gravidas >16 weeks' gestation, significantly higher rates of abortion were observed with each increase in dose. Higher

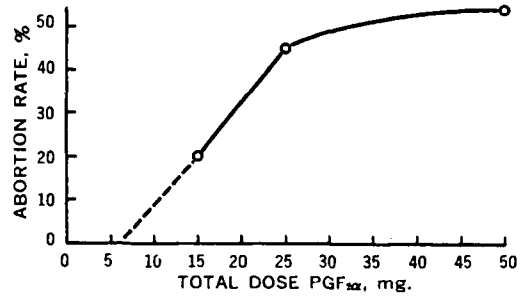

Figure 1—*The 24-hr. abortion rate in percent with three single-injection dose schedules of intraamniotic prostaglandin $F_{2\alpha}$ detailed in the text. The dashed line is extrapolated as the best fitting line between existing frequencies.*

Mean	64.6	64.0	64.0	63.7	63.3	65.0
(Range)	(52–70)	(59–69)	(59–71)	(58–68)	(59–67)	(60–72)

abortion rates were not obtained with single injections in excess of 25 mg. in patients ≤16 weeks' gestation. In nulliparous patients and in patients >16 weeks' gestation, the abortifacient response was higher when the dose was increased from 25 to 50 mg. In patients ≤16 weeks' gestation, the 50-mg. dose was no more effective than the 25-mg. dose, and in multiparas the 50-mg. dose was less effective.

Multiple-Dose Schedules—Although the overall results indicated no increase in the frequency of abortion within the 24-hr. period for dosage levels higher than 15 mg. repeated in 6 hr. (Group IV) (Fig. 3), differences in abortion rates were noted for patients of different parities and gestational ages (Fig. 4). Nulliparas and patients ≤16 weeks' gestation had significantly lower rates of abortion when the dose was increased above that of Group IV. However, in multiparas and patients ≤16 weeks' gestation, higher rates of abortion were noted to the Group V level (25 mg. repeated in 6 hr.). Although the mean abortion time of Group V was shorter and the rates of incomplete abortion were higher for Group VI, these differences were not statistically significant.

Single-Dose Compared to Multiple-Dose Schedules—All multiple-dose schedules resulted in higher abortion rates than the single-dose schedules (Fig. 5). The multiple-injection schedule of Group VI, however, did not result in a statistically significant increase over the single injection of 50 mg. (Group III).

When the differences in dose schedules were analyzed for patients of different parities and gestational ages (Fig. 6), the multiple-injection schedules were as effective, if not more effective, in comparable total doses. In both nulliparas and patients ≤16 weeks' gestation, the Group IV dose schedule was the most effective. In contrast, in multiparas and patients >16 weeks' gestation, the Group V (25–25 mg.) schedule was the most effective. Single doses of 50 mg. (Group III) appeared equally as effective as the 50-mg. dose administered in two separate 25-mg. doses (Group V) in nulliparas and patients >16 weeks' gestation.

Complications—Although the minor complications were frequent, no serious complications were observed (Table III). The frequency

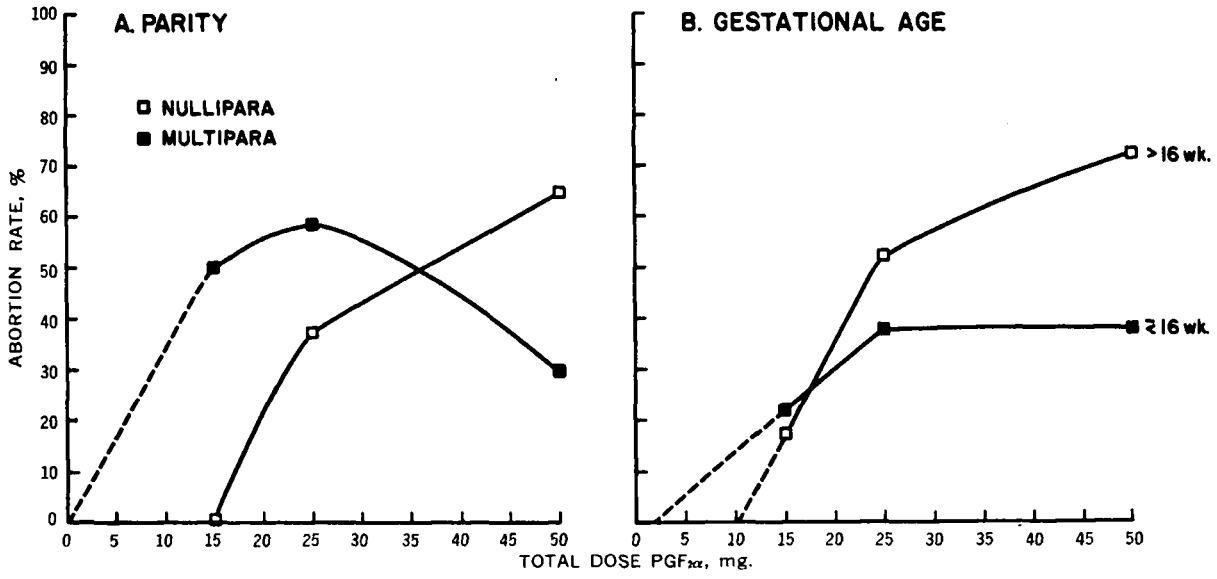

Figure 2—*The 24-hr. abortion rate in percent with three single intraamniotic prostaglandin $F_{2\alpha}$ dose schedules (detailed in the text) for: A, nulliparas and multiparas; and B, patients 16 weeks' gestation or less (≤16 wk.) and patients greater than 16 weeks (>16 wk.). The dashed line is extrapolated as the best fitting line between existing points.*

of complications did not appear to correlate with dose, parity, or gestational age.

DISCUSSION

In an effort to develop practicable methods of midtrimester abortion, investigators have pursued both multiple- and single-intraamniotic $PGF_{2\alpha}$ injection techniques (3–7). If intraamniotic injection is as effective as intravenous infusion, high abortion rates within 24 hr. are possible (8). Search for the most effective dose schedules has been conducted by administering progressively increasing amounts in an increasing number of injections. Results from these studies indicate that more than 50% of the patients can be aborted without serious complications within 24 hr. by a variety of unaugmented $PGF_{2\alpha}$ dose schedules. Initially, only small groups of patients were necessary to demonstrate differences in effectiveness between these schedules because there were large differences in the rates of abortion. However, single- and multiple-injection dose schedules with smaller differences in rates of abortion have been developed which require large numbers of patients to demonstrate differences with any statistical certainty. Therefore, the progressively-increasing-the-dose method is no longer a practical means for determining the dose schedule with the highest rates of abortion and tolerable side effects.

Because most therapeutic agents have certain characteristics in common, by determining one of these characteristics, the dose–response relationship, one should be able to use it to make the search for the most effective dose schedule less arduous for patients and investigators. Although dose–response relationships are constant for a drug under identical conditions (9), in this study the midtrimester patients differ from each other in many variables, some of which greatly influence the dose–response relationships. Two of these variables are parity and gestational age.

Single-Injection Techniques—Although doses of greater than 25 mg. of $PGF_{2\alpha}$ do not appear warranted from the results in the whole group (Fig. 1), parity and gestational age are important variables in

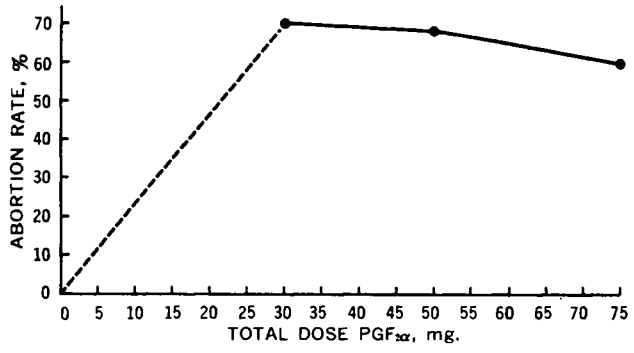

Figure 3—*The 24-hr. abortion rate in percent with three intraamniotic prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) multiple-injection dose schedules (detailed in the text). The dashed line is an extrapolation to zero abortion rate at zero dose of $PGF_{2\alpha}$.*

significant variable, two conclusions appear justified: (*a*) doses greater than 15 mg. initially with an identical dose repeated 6 hr. later probably will not increase the 24-hr. abortion rate in nulliparas ≤16 weeks' gestation, and (*b*) doses greater than 25 mg. repeated in 6 hr. will probably not improve the 24-hr. abortion rate in multiparas ≤16 weeks' gestation.

Comparison of Single- and Multiple-Dose Schedules—Overall, these multiple-dose schedules achieved higher 24-hr. abortion rates than the single-injection schedules (Fig. 5). However, when parity and gestational age were considered, the single-dose abortifacient response curves had not reached a plateau (no further increase in frequency of abortion with further increase in dose) at the 50-mg. (Group III) dose in nulliparas and patients >16 weeks' gestation. Rates in multiparas receiving a single injection of 25 mg. (Group II) were not significantly different from those in multiparas receiving multiple injections of 25 mg. (Groups V and VI), and rates greater than about 65% probably cannot be achieved for all multiparas with either type of dose schedule. The multiple-injection technique appears definitely superior for patients ≤16 weeks' gestation. Although the single-dose schedule curve reached a plateau after 25 mg. for these patients at less than a 50% abortion rate, the multiple-injection schedule used in Group IV (15–15 mg.) resulted in a 100% abortion rate. Whether the dose–response curve for single doses higher than 50 mg. in nulliparas and patients >16 weeks' gestation will reach a plateau or surpass the rates achieved with multiple injections remains to be demonstrated. Finally, it does not appear that any one dose, whether it is administered by single-injection or multiple-injection methods, will be maximally effective in patients of all gestational ages and parities.

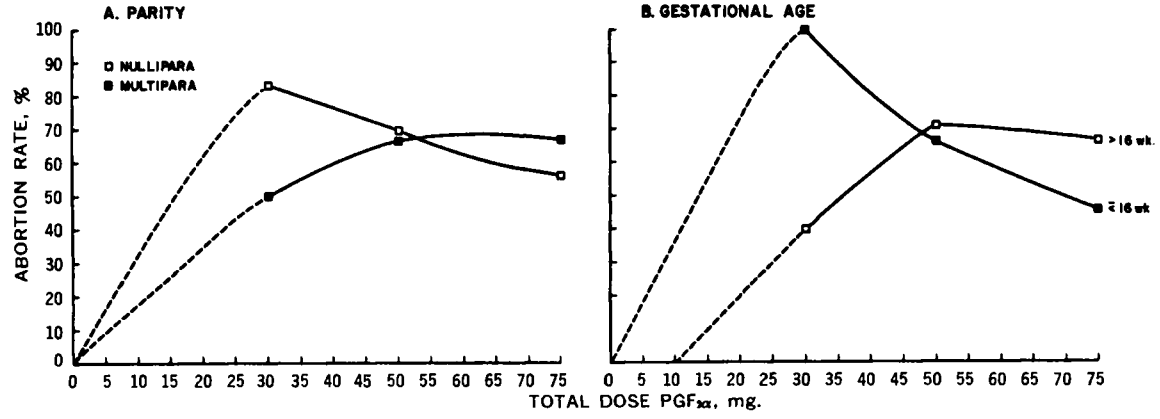

Figure 4—*The 24-hr. abortion rate in percent with three multiple intraamniotic prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) dose schedules (detailed in the text) for: A, nulliparas and multiparas; and B, patients 16 weeks' gestation or less (≤16 wk.) and patients greater than 16 weeks' gestation (>16 wk.). The dashed line is the extrapolation of either the best fitting line between existing points or to zero abortion rate at zero dose of $PGF_{2\alpha}$.*

the dose–response relationship (Fig. 2). Two conclusions appear warranted as a means of increasing the 24-hr. abortifacient efficiency: (*a*) doses in excess of 25 mg. in multiparas ≤16 weeks' gestation probably will not increase the rate, and (*b*) investigation of single injections greater than 50 mg. in nulliparas >16 weeks' gestation may improve the rate.

Multiple-Injection Schedules—Within the limits of these dose schedules, it appears from the overall results that there is no benefit to increasing the dose schedule above an initial injection of 15 mg. and repeating an identical dose in 6 hr. However, parity and gestational age are significant variables (Fig. 4). Interpretation of multiple-injection dose–response relationships is even more limited than that of single-dose schedules because of the many dose combinations possible. Although there were not enough patients in this series to determine whether parity or gestational age was the more

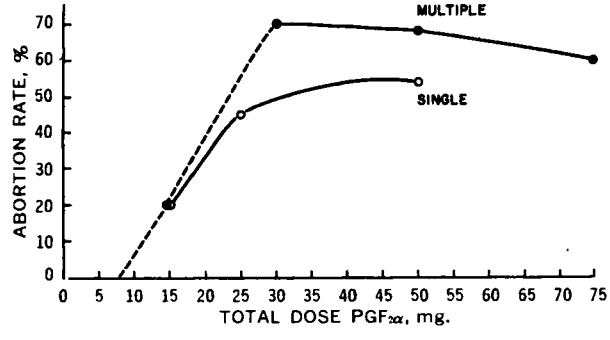

Figure 5—*The 24-hr. abortion rate in percent for three single and three multiple intraamniotic prostaglandin $F_{2\alpha}$ dose schedules (detailed in the text). The dashed lines are extrapolations.*

Complications—Because the dose schedules investigated were not associated with any serious complications and minor complications were of minimal severity, the effective schedules can be used clinically. Chlorpromazine and diphenoxylate hydrochloride/atropine sulfate[3] were demonstrated to be effective in decreasing the frequency and severity of vomiting and diarrhea, respectively (1, 10). One can only speculate upon whether premedicating patients to prevent minor complications will be advisable with the most effective dose schedule when it is identified.

Even though one can make certain hypotheses from dose–response curves, comparative series of different dose schedules will be necessary to verify these hypotheses. Dose–response relationships are absolutely reproducible only when all conditions are equal —a situation unimaginable in clinical medicine. However, once the significant variables are identified, the dose–response relationships are within ranges useful for clinical purposes. Two variables significantly modifying the dose–response relationship have been identified: parity and gestational age. As the information expands, the relative importance of these and other conditions should be specified.

[3] Lomotil, Searle. (Each tablet contains 2.5 mg. diphenoxylate hydrochloride and 0.025 mg. atropine sulfate.)

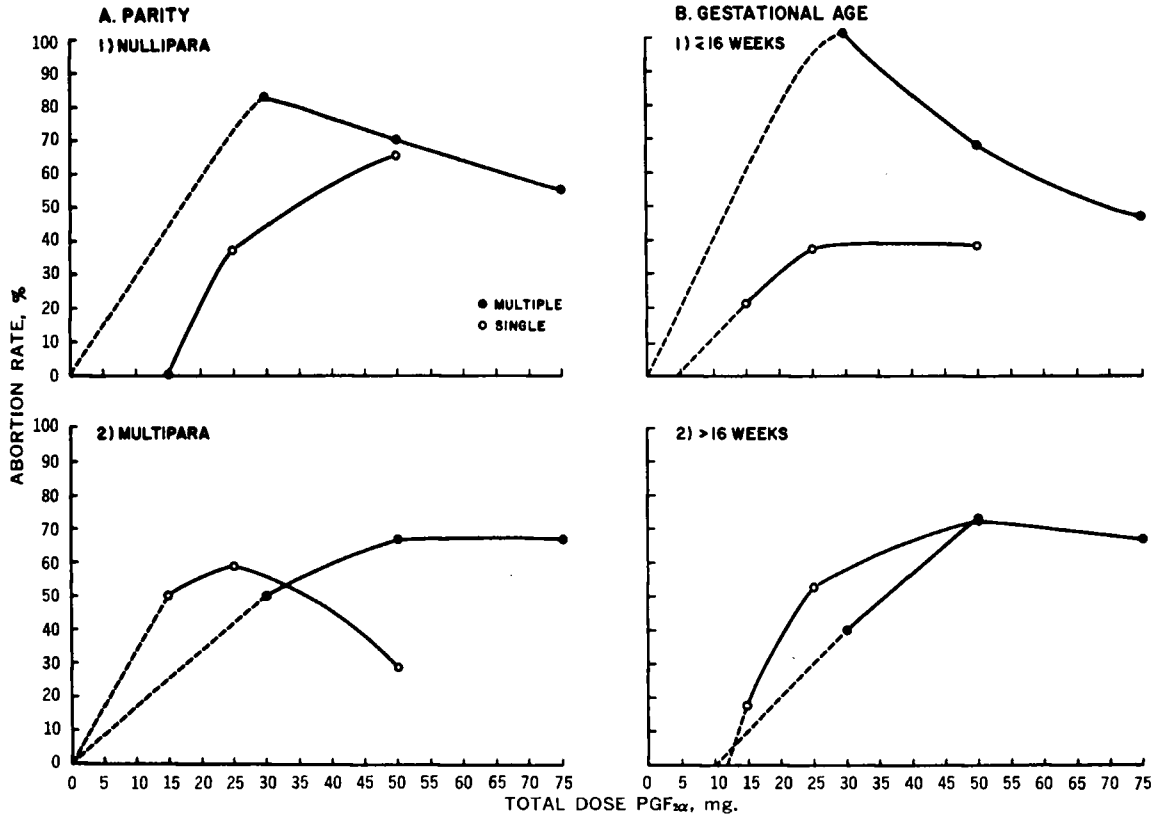

Figure 6—*The 24-hr. abortion rates in percent with three single- and three multiple-dose intraamniotic prostaglandin $F_{2\alpha}$ schedules (detailed in the text) for: A, patients of different parities (nulliparas and multiparas); and B, patients of different gestational ages [16 weeks' gestation or less (≤16) and greater than 16 weeks' gestation (>16)]. The dashed lines are extrapolations.*

Interpretation of the dose-response relationships indicates that further study of the following is desirable to improve the abortion rates: (*a*) single doses greater than 50 mg. in nulliparas and patients >16 weeks' gestation, (*b*) single doses in the range of 25 mg. in multiparas and patients <16 weeks' gestation, (*c*) multiple doses in the range of 15 mg. repeated in 6 hr. for nulliparas and patients >16 weeks' gestation, and (*d*) multiple doses in the range of 25 mg. repeated in 6 hr. for multiparas and patients >16 weeks' gestation. Although these interpretations of the dose-response relationships appear to be logical, extensive clinical trials will be necessary to confirm these hypotheses.

Nonsolvolytic Acetylation of Homatropine by Aspirin

E. SHAMI[▲], J. DUDZINSKI, L. LACHMAN, and J. TINGSTAD*

Abstract □ A nonsolvolytic (solid-state) reaction between aspirin and homatropine, yielding acetylhomatropine and free salicylic acid, is reported. A GC assay for homatropine is described. In the presence of excess aspirin, the kinetics are pseudo first order with respect to homatropine. The apparent heat of activation is estimated and a possible mechanism of the reaction is discussed.

Keyphrases □ Homatropine—kinetics and possible mechanism of nonsolvolytic (solid-state) acetylation by aspirin □ Aspirin—kinetics and possible mechanism of nonsolvolytic (solid-state) acetylation of homatropine □ Acetylhomatropine and salicylic acid—products of solid-state acetylation of homatropine by aspirin, kinetics □ Acetylation, nonsolvolytic (solid state)—reaction of aspirin and homatropine □ Solid-state (nonsolvolytic) acetylation reactions—aspirin and homatropine

Compared to the literature on aqueous solutions, there are relatively few publications on kinetics and mechanisms of reactions in the solid state. The nonsolvolytic (solid-state) acetylation of drugs containing alcoholic, aminic, or phenolic groups by aspirin has been reported (1–3). This article describes the kinetics and possible mechanism of a nonsolvolytic reaction between aspirin and homatropine, yielding acetylhomatropine and free salicylic acid.

EXPERIMENTAL

Aspirin USP (containing less than 0.05% free salicylic acid) was used. The homatropine base employed assayed 100.3% by nonaqueous titration. The two drugs were mixed in a 12:1 (aspirin–homatropine) molar ratio and were allowed to react at the desired temperatures. The 12:1 ratio was chosen because of assay convenience and because it would simplify reaction kinetics by eliminating aspirin concentration as a significant factor (4). It was felt that this experimental procedure was valid because the ratio of the two in the tablet formulation under study was even greater than 12:1.

Homatropine Assay—A gas chromatograph[1] utilizing a flame-ionization detector was used with a 1.2-m. (4-ft.) × 3-mm. i.d. glass column, using Diatoport S (80–100 mesh) coated with UC-W-98 silicone rubber (3.8%). The column temperature was 215°, and both the detector temperature and the injection port temperature were 270°. Gas flow rates were: helium, 75 ml./min.; hydrogen, 35 ml./min.; and air, 350 ml./min. Codeine was used as the internal standard.

About 1.4 g. of the aspirin–homatropine mixture was accurately weighed and dissolved in 100.0 ml. of chloroform. A 25.0-ml. aliquot was taken and extracted three times with an equal volume of distilled water adjusted to pH 11–12 with ammonia. A 20.0-ml. aliquot of the chloroform layer was pipeted into a 250-ml. distilling flask, the internal standard was added, and the solution was evaporated to dryness *in vacuo*. A standard homatropine solution was similarly treated. Ten milliliters of chloroform was pipeted into each of the sample and standard flasks and, after solution was complete, 1.8 μl. was injected into the gas chromatograph with a 1.0-μl. solvent flush. The peak height of homatropine relative to codeine was determined in both the sample and reference standard.

Free Salicylic Acid Assay—Approximately 1.4 g. of the aspirin–homatropine mixture was accurately weighed and dissolved in 100.0 ml. of methanol. An aliquot was taken and assayed by the standard ferric nitrate procedure (5).

Tropine Assay—The same procedure was used as for homatropine except that the column temperature was 115° and the detector and flash heater were both at 190°.

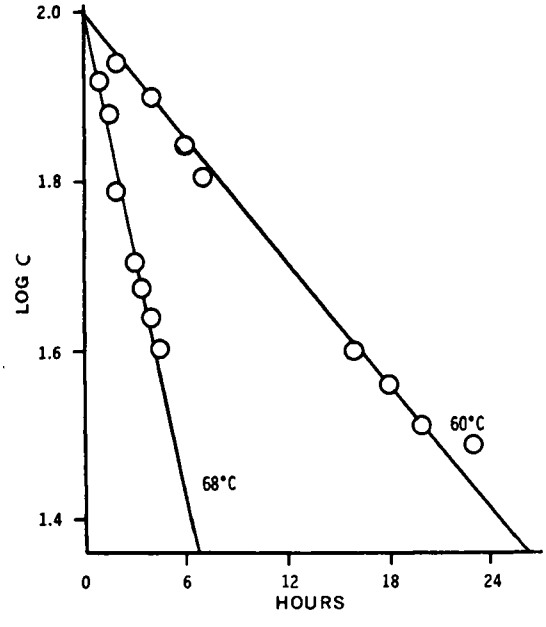

Figure 1—*Disappearance of homatropine at 60 and 68°.*

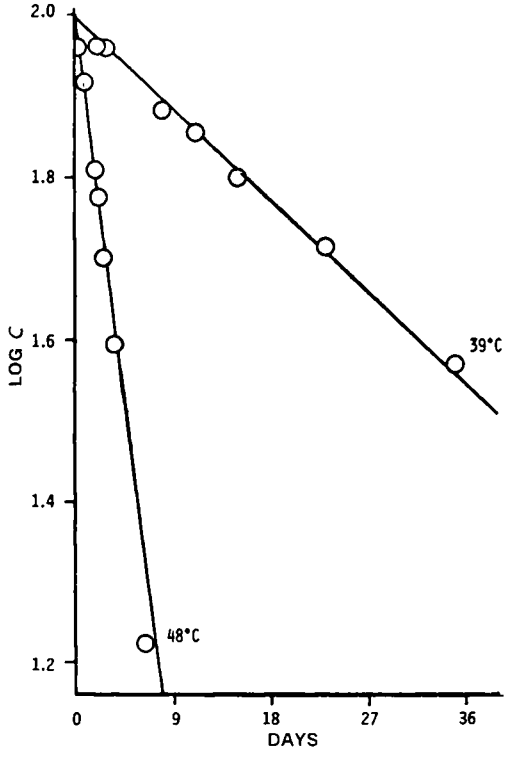

Figure 2—*Disappearance of homatropine at 39 and 48°.*

Table I—Reaction Rate Constants and Half-Lives for Homatropine Disappearance

Temperature	Reaction Rate Constant, hr.$^{-1}$	Half-Life, hr.
68°	0.209	3.32
60°	0.0531	13.0
48°	0.0105	65.8
39°	0.00120	577

Table II—Reaction Rate Constants and Half-Lives for Free Salicylic Acid Formation

Temperature	Reaction Rate Constant, hr.$^{-1}$	Half-Life, hr.
60°	0.0532	13.0
48°	0.0105	65.8

Kinetic Studies—Aspirin and homatropine base (12:1) were gently mixed in a glass mortar and placed in preweighed glass ampuls. Weights were accurately determined and the ampuls were sealed. Samples were stored at 39, 48, 60, and 68°, periodically removed, and assayed. Because a eutectic forms after a period of time, the entire contents of the ampul were used for each assay to ensure no loss of material. The 68° samples were maintained in a constant-temperature bath (±0.2°) while the rest were stored in hot air ovens (±1°). To ensure proper temperature control in the ovens, a recording thermal probe was placed near the samples.

Synthesis of Acetylhomatropine—Homatropine base was dissolved in a 1:1 mixture of pyridine and acetic anhydride and stored at room temperature (in the dark to prevent color formation) for 24 hr. Methanol was added to destroy the acetic anhydride; the solution was then evaporated on a flash evaporator until there was no odor of pyridine. The resulting oil was difficult to purify; consequently, the picrate salt was made. One-half gram of the oil was dissolved in 5 ml. of methanol, 5 ml. of a saturated solution of picric acid was added, and the resulting precipitate was recrystallized from boiling methanol.

Anal.—Calc. for $C_{15}H_{21}NO_4$: C, 52.75; H, 4.80; N, 10.25. Found: C, 52.79; H, 4.80; N, 10.23.

TLC System—A chamber[2] with a saturation pad was used for all chromatograms. Precoated aluminum oxide plates[3] were activated for 0.5 hr. at 100° prior to use. The developing solvent system was chloroform–methanol–diethylamine (200:10:1). For color development the plates were sprayed with Dragendorff's reagent followed by an overspray of 5% sodium nitrite.

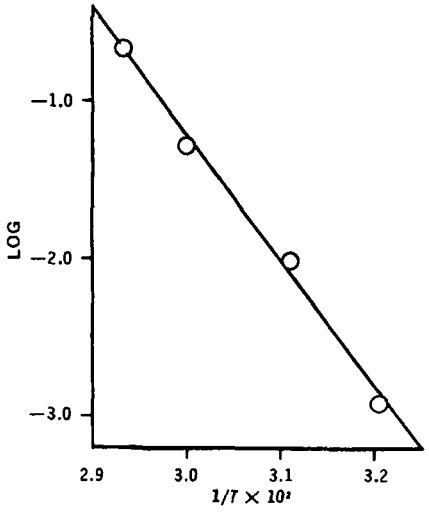

Figure 3—*Arrhenius plot for homatropine disappearance.*

[2] Gelman.
[3] Brinkmann T250μ.

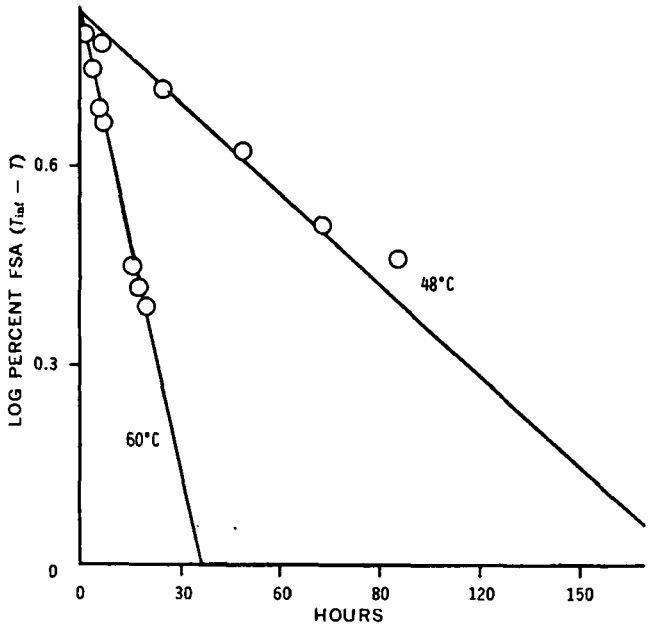

Figure 4—*Appearance of free salicylic acid (FSA) at 48 and 60°. See text for explanation.*

RESULTS

TLC and GLC analyses indicated that the partially reacted mixtures contained only homatropine, aspirin, salicylic acid, and acetylhomatropine, with trace amounts of acetic acid. The completely reacted mixtures (at time infinity) contained only aspirin, salicylic acid, and acetylhomatropine, with trace amounts of acetic acid. No tropine was found in any of the reaction mixtures; consequently, hydrolysis of homatropine can be ignored (6, 7).

Disappearance of Homatropine—Based on the kinetic plots shown in Figs. 1 and 2, the reaction appears to be pseudo first order. An Arrhenius plot (Fig. 3) yields an activation energy of 36.4 kcal./mole. The reaction rate constants and half-lives at the various temperatures are given in Table I.

Appearance of Free Salicylic Acid—The rates of appearance of free salicylic acid, plotted as percentage free salicylic acid at time infinity minus percentage at time t for 48 and 60°, are shown in Fig. 4. The experimentally determined values of the free salicylic acid infinity term (6 days, 60° = 6.93% and 8 weeks, 48° = 6.50%) are in good agreement with the theoretical value of 6.39%. Based

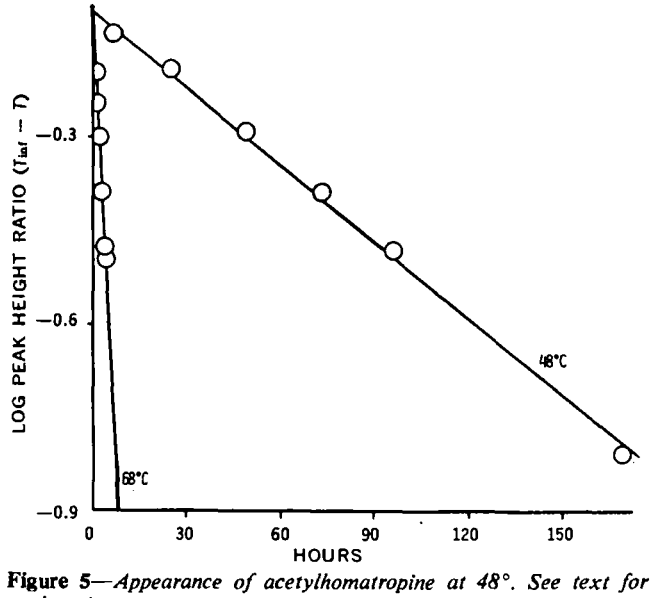

Figure 5—*Appearance of acetylhomatropine at 48°. See text for explanation.*

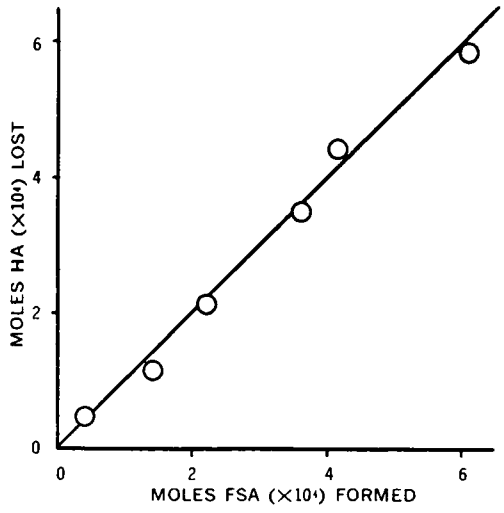

Figure 6—*Correlation of disappearance of homatropine (HA) with appearance of free salicylic acid (FSA) at 48°.*

upon the appearance of acetylhomatropine and the disappearance of homatropine, the reaction seemed to be complete at 48° in at least 5 weeks. The fact that 3 additional weeks at this temperature did not produce significant amounts of excess free salicylic acid indicates that degradation of aspirin to salicylic acid apart from its reaction with homatropine was not a significant factor in these studies. This is further confirmed by the fact that the reaction rate constants and half-lives for the disappearance of homatropine (Table I) are in good agreement with those found for the appearance of salicylic acid (Table II).

Appearance of Acetylhomatropine—The rate of acetylhomatropine formation, plotted as the peak height ratio (acetylhomatropine–codeine after normalizing all sample weights to 1 g.) at time infinity minus that at time t for 48 and 68°, is shown in Fig. 5. The infinity value was taken as the average normalized peak height ratio at 5 and 8 weeks at 48°, and the two values agreed within 3%. These figures were confirmed by the fact that at 5 weeks, at 48°, no homatropine could be detected in the reaction mixture. The reaction rate constants and half-lives for acetylhomatropine appearance are given in Table III; they are in good agreement with those of Tables I and II.

Correlation of Homatropine Loss and Free Salicylic Acid Formation—The tabular data indicate a 1:1 molar relationship in the reaction. This is further emphasized in Fig. 6 where, at 48°, the moles of free salicylic acid formed is plotted against moles of homatropine lost; the correlation coefficient is 0.99. Similar plots of 39 and 60° data yield coefficients of 1.06 and 0.96, respectively. The coefficient for 68° is 0.87, indicating some possible variations in the reaction not observed at lower temperatures.

Confirmation of Acetylhomatropine Synthesis—NMR analysis of the synthesized homatropine picrate showed the disappearance of the alcohol proton and the appearance of three methyl protons on the acetate group. TLC results for the "known" acetylhomatropine base (the oil resulting from the reaction mixture) and unknown samples (the heat-treated mixtures of aspirin and homatropine base) were identical (no tropine present in the unknown). The following R_f values were obtained: acetylhomatropine, 0.64; homatropine, 0.42; and tropine, 0.20.

Table III—Reaction Rate Constants and Half-Lives for Acetylhomatropine Formation

Temperature	Reaction Rate Constant, $hr.^{-1}$	Half-Life, hr.
68°	0.202	3.43
48°	0.00946	73.3

DISCUSSION

There are two probable mechanisms for the reaction. In the first version, there is liquefaction followed by subsequent reaction. The low water content (less than 0.05%) and the absence of excess free salicylic acid in the reaction mixture eliminate water as a factor, either in liquefaction or in the reaction kinetics. The eutectic contains no solid homatropine (as shown by differential scanning calorimetry); aspirin is present both in the liquid phase and as a crystalline solid. The "saturated" solution with respect to aspirin (with excess solid phase present) accounts for the pseudo-first-order character of the reaction.

The second version of the proposed mechanism is identical to the first except that after liquefaction the reaction (probably intramolecular transesterification) is preceded by salt formation. A similar "solid-state" salt formation between aspirin and antipyrine has been reported (8). The second version, involving salt formation, seems more likely for the following reasons:

1. If a 1:1 molar mixture of aspirin and homatropine is dissolved in a chloroform–methanol mixture and evaporated to dryness, the resulting oil is soluble in water.
2. When a 1:1 molar mixture of the two is gently heated, an oily liquid results which does not solidify upon cooling. IR scans of this oil and of a solid 1:1 mixture indicate salt formation.
3. The relatively high heat of activation (36.4 kcal./mole) points toward a possible contribution from heat of ionization and/or fusion.

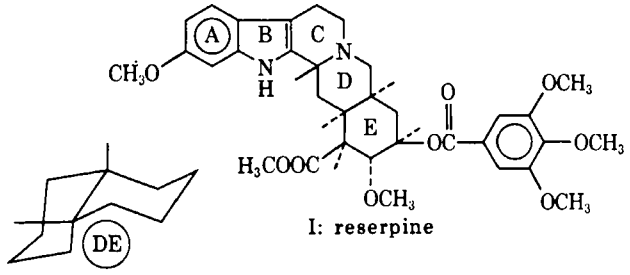
Cardiovascular Effects of Reserpine, Yohimbine, and Reserpine–Yohimbine Mixtures on Intact Anesthetized Dog

MARK M. LUCKENS[▲] and MARVIN H. MALONE*

Abstract □ Cardiovascular and respiratory parameters plus responses to periodically injected epinephrine were monitored for 5 hr. in the anesthetized dog after single intravenous injections of saline, reserpine, yohimbine, or reserpine–yohimbine mixtures. Whole root *Rauwolfia serpentina* contains reserpine-like and yohimbine-like alkaloids and is widely used and classified as a reserpine-like agent. However, qualitative results in the present study indicate interactions between reserpine and yohimbine when administered concurrently, with end results incorporating the time–response profiles of both agents when given singly.

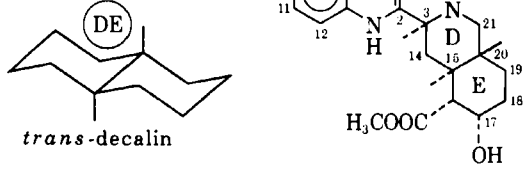
Keyphrases □ Reserpine, yohimbine, and reserpine–yohimbine mixtures—cardiovascular effects on intact anesthetized dog □ Yohimbine, reserpine, and yohimbine–reserpine mixtures—cardiovascular effects on intact anesthetized dog □ Cardiovascular effects—reserpine, yohimbine, and reserpine–yohimbine mixtures, dogs □ Rauwolfia whole root preparations—cardiovascular effects of reserpine, yohimbine, and reserpine–yohimbine mixtures, dogs

Reserpine (I) and yohimbine (II) are naturally occurring pentacyclic tertiary alkaloids whose basic ring systems present a number of similarities. In the former, the D and E rings have a *cis*-decalin conformation; in the latter compound, these rings are *trans*-decalin. Reserpine is esterified with a trimethoxybenzoic moiety on the E ring. The methyl ester grouping at position 16 on the E ring is in a *trans*-position in the reserpine compound, while it is in a *cis*-position in yohimbine. Both compounds possess the α-configuration at the C-15 position. Since the proton at this site does not appear to exhibit a facile epimerization, it may well be that some pharmacological properties of these alkaloids may be due partly to this configuration. Cursory examination indicates that "flipping" with respect to the D and E rings could exist in reserpine, but this would not be the case for the yohimbine molecule. This may also contribute to the different pharmacological profiles of these compounds.

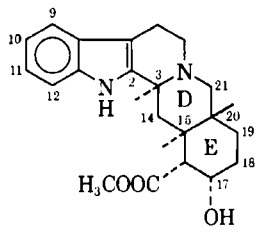


cis-decalin

I: reserpine



trans-decalin



II: yohimbine

Both compounds occur together in many rauwolfia species of the family Apocynaceae. The isolation of reserpine from *Rauwolfia serpentina* Benth may be considered a landmark in the development of modern psychopharmaceuticals. Its isolation also spurred productive investigations in antihypertensive therapy and provoked a general revival of interest in plants as a source of useful and potent therapeutic agents. Our interest in studying selected cardiovascular effects of reserpine, yohimbine, and mixtures of these alkaloids in the intact animal stemmed from the fact that they are concurrently administered therapeutically in medicinals prepared from, or containing, whole root *R. serpentina*. Such whole root preparations antagonize the pressor response to epinephrine (1).

Yohimbine is a classic α-adrenergic blocking agent. It blocks the pressor response to epinephrine and, in sufficient doses, induces "epinephrine reversal" (2). Reserpine is presumed to have no effect on adrenergic receptors, but it depletes central and peripheral stores of catecholamines. This depletion has been reported to hypersensitize adrenergic receptors and potentiate the effect of exogenously administered norepinephrine (3, 4). Yohimbine does not deplete either serotonin or epinephrine centrally (5), but there is evidence that it reduces or depletes norepinephrine in the brain (5). It has also been reported (6) to be an antimetabolite of serotonin. Malone and Roth (7) reported that yohimbine potentiates reserpine-induced blepharoptosis in mice without altering the slope of the dose–response curve. Blepharoptosis is a manifestation of hypothalamic depression and is seen in Horner's syndrome in man (8).

A number of clinical and animal studies demonstrated that preparations made from the whole root of rau-

wolfia exhibit greater sedative–hypotensive potency than would be expected from reserpine alone or simply the additive effects of a combination of the various reserpine-like alkaloids (9–15). To date, no experimental study has investigated the cardiovascular dynamics of reserpine–yohimbine mixtures in the intact animal. The reserpine content of *R. serpentina* Benth, collected in the Himalayan foothills, was documented at 0.14% (16). The yohimbine content of such roots has not been reported to date. The ratios of reserpine–yohimbine tested in this cardiovascular study varied from 1.0:1.0 to 1.0:0.1 based on the assumption that the actual content of yohimbine in rauwolfia whole root neither exceeds that of reserpine nor is less than one-tenth that of reserpine.

MATERIALS AND METHODS

Thirty-two mongrel dogs of both sexes, weighing 9.5–40.0 kg., were randomly divided into eight experimental groups (Table I).

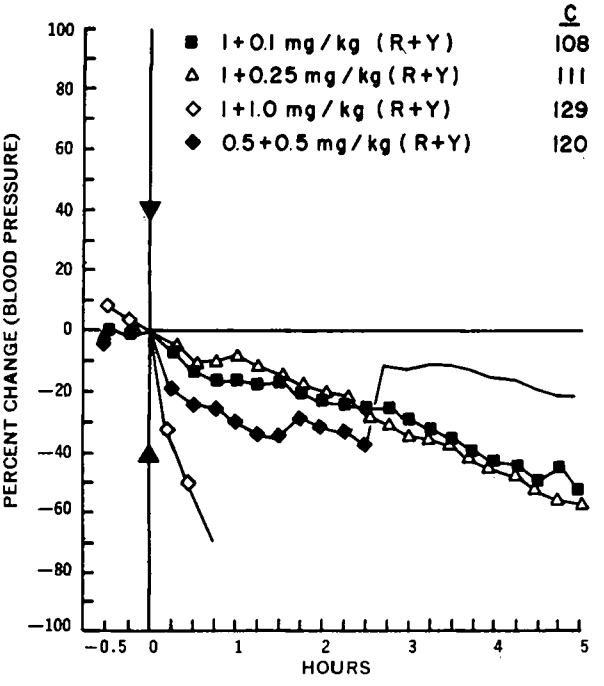

Figure 2—*Blood pressure changes after intravenous administration of nonhypotensive doses of reserpine and yohimbine (R + Y) mixtures expressed as percent change from control (C) values (mm. Hg).*

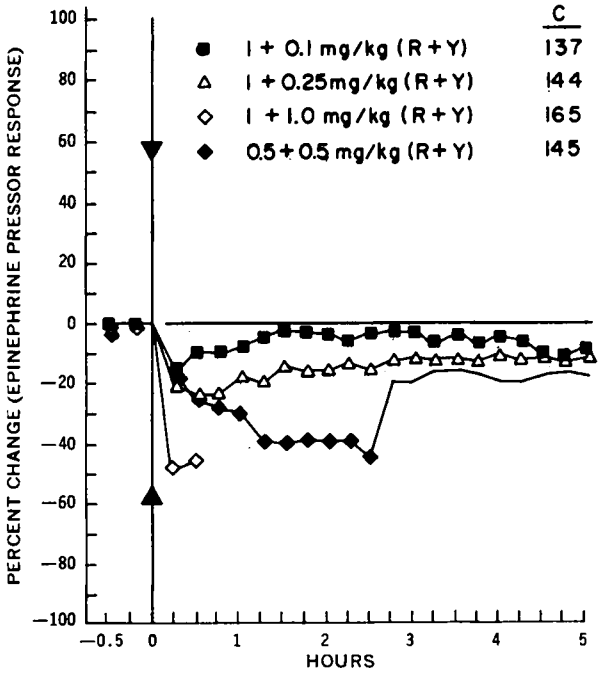

Figure 4—*Changes in epinephrine pressor response after intravenous administration of reserpine and yohimbine (R + Y) mixtures expressed as percent change from control (C) values (mm. Hg).*

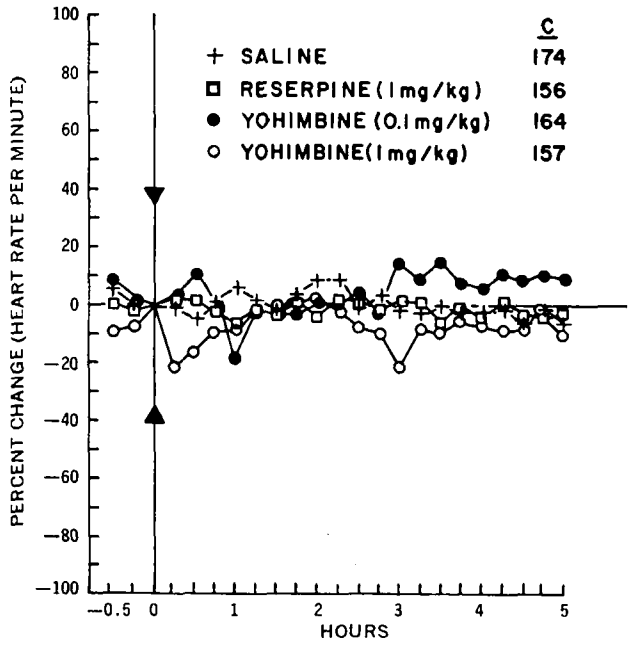

Figure 7—*Heart rate changes after intravenous administration of isotonic saline, reserpine, or yohimbine expressed as percent change from control (C) values (mm. Hg).*

Test animals were taken off feed 12 hr. prior to the start of the experiment with water allowed *ad libitum*. Each animal was anesthetized to the point of blockade of the corneal reflex by slow intravenous titration of a 30% solution of urethan, at a rate of approximately 1 ml./min., *via* the cephalic vein in the left foreleg. Direct femoral arterial blood pressure, heart rate, and respiratory rate were recorded kymographically. After a stabilization period of 15–30 min., a standard dose of epinephrine was determined, intravenously, for each animal. The standard injection (30-sec. duration, with saline wash) was defined as one that would be reproducible at 15-min. intervals and would show a clear biphasic response of pressor–depressor activity. After two control injections of the standard dose of epinephrine, one of the eight treatments was administered at a uniform rate *via* the femoral vein at "zero time." Each injection was of 5-min. duration, followed by a 3-ml. wash of isotonic saline, over 3 min. The total injection time was 8 min.

Reserpine and yohimbine combinations were not administered as a single solution. Reserpine acetate was injected first and washed in with saline. The yohimbine hydrochloride was then injected, followed by a saline wash. The total injection time, for this procedure, also totaled 8 min. Recording of blood pressure, other physiological parameters, and the response to periodic injections of epinephrine was continued throughout the 300-min. observation period unless the test animal died. The control dose of reserpine used (1 mg./kg.) has been shown in this laboratory to produce unequivocal and characteristic effects without lethality.

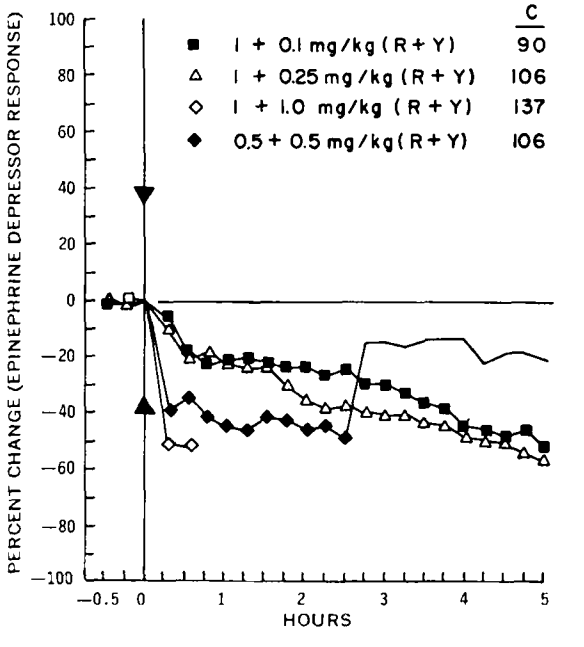

Figure 6—*Changes in epinephrine depressor response after intravenous administration of reserpine and yohimbine (R + Y) mixtures expressed as percent change from control (C) values (mm. Hg).*

RESULTS AND DISCUSSION

Figures 1 through 11 summarize the percent change from control values (preinjection levels of the parameters measured) for each set of treatments. Figure 1 clearly shows the percent change in blood pressure seen after the administration of 1.0 mg./kg. of reserpine as compared to isotonic saline. This dose elicited a slowly developing, progressive hypotension which amounted to a 37% fall at the end of the 5-hr. observation period. This may be contrasted with the absence of such an effect in the salinized animals or those receiving 0.1 mg./kg. of yohimbine. A dose of 1.0 mg./kg. of yohimbine, however, elicited a prompt 32% fall in mean blood pressure. This hypotensive response was maintained throughout the 5-hr. observation period, reaching a maximum of 43% of the control values at the end of the 5th hr.

Concurrent administration of nonhypotensive doses of yohimbine combined with reserpine accentuates the hypotensive effect of reserpine and may cause death. Figure 2 illustrates the effects of such combinations on the percent change in blood pressure as compared to control levels. Injections of 0.1 or 0.25 mg./kg. of yohimbine combined with 1 mg./kg. of reserpine induced essentially equivalent responses, which appeared reserpine-like in onset. However, the effects seen at the end of 5 hr. (54–58%) were considerably lower than the 37% reduction seen with reserpine only (Fig. 1). One animal died during each of these treatments, both in the latter half of the experiment. The combination of 1 mg./kg. each of reserpine and yohimbine was uniformly fatal for two dogs. Both died of respiratory arrest shortly after injection. In the two surviving animals, the resting blood pressure fell to 50% of the control values at the end of 30 min. and respiratory arrest occurred shortly thereafter. Of the four animals treated with 0.5 mg./kg. of each of the two alkaloids, one died after 75 min. and two expired after 150 min.

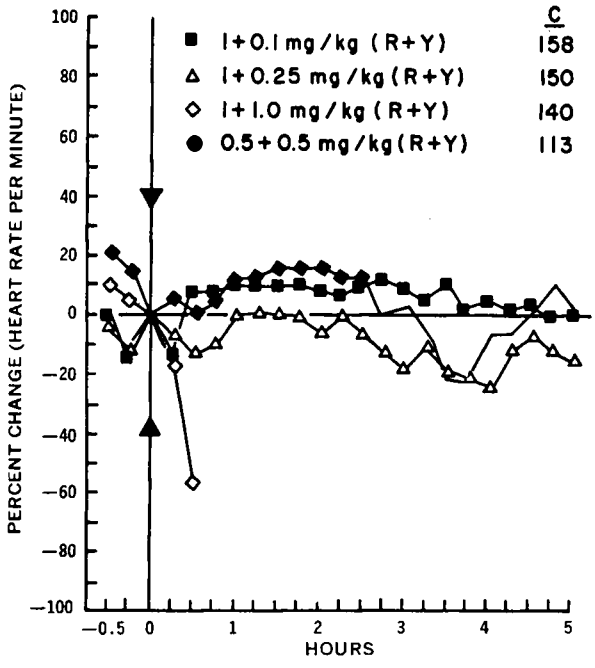

Figure 8—*Heart rate changes after intravenous administration of reserpine and yohimbine (R + Y) mixtures expressed as percent change from control (C) values (mm. Hg).*

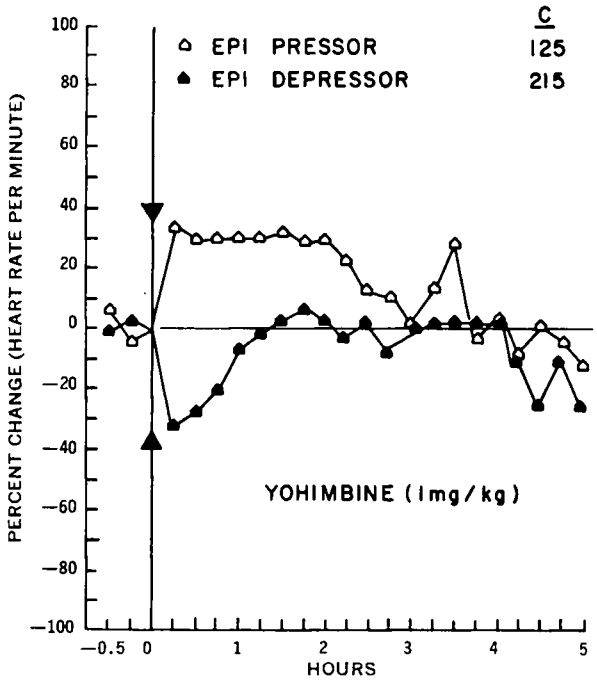

Figure 9—*Changes in epinephrine (EPI) pressor and depressor responses after intravenous administration of yohimbine expressed as percent change from control (C) values (mm. Hg).*

Only one dog survived the full 5-hr. observation period. Its tracing is shown in Fig. 2 as a line without markers. In this test group, the fall in blood pressure was rapid (30% of control levels at 1 hr. and 41% of the controls at the end of 2 hr.).

The effect of the test treatments on exogenous epinephrine is illustrated in Fig. 3. These data indicate that both physiological saline and reserpine enhance the pressor effects of epinephrine about 10% over control values. Bein (17) and Bein *et al.* (18) originally reported a significant enhancement of the epinephrine pressor response after the administration of 0.1 mg./kg. i.v. of reserpine under allobarbital[1] anesthesia. The quantitatively modest results of the present study may be due to species differences or, more probably, the continued repetitive challenges of intravenous epinephrine every 15 min. Such repetitive challenges may prevent the sensitization of adrenergic receptors suggested by Bein. In any event, a dose of 1 mg./kg. of yohimbine has a prompt, unequivocal α-adrenolytic effect which was sustained throughout the 5-hr. experimental period. A dose of 0.1 mg./kg. produced a similar but lesser effect.

Figure 4 illustrates the effects elicited by combinations of reserpine and yohimbine upon the epinephrine pressor response. In all treatments, the effect appears to be what one would expect from yohimbine alone. The effect of the combination of 0.5 mg./kg. reserpine and 0.5 mg./kg. yohimbine is essentially the same as that seen at the lower levels. Even when the lethal combination of 1.0 mg./kg. reserpine and 1.0 mg./kg. yohimbine was used, the α-adrenolytic effect of the combination matched that of yohimbine alone.

Figure 5 illustrates the effect of reserpine on epinephrine's secondary phase. An attenuation of this depressor phase slowly developed over the 5-hr. observation period, at the end of which time a mean value of −34% had been documented. Yohimbine, at a dosage of 1 mg./kg., rapidly attenuated the depressor response by −53% within 15 min. This dramatic effect was sustained in a plateau-like fashion throughout the rest of the observation period. This could be interpreted as β-blocking activity; however, when one considers that the response curves seen here parallel the effects previously presented for resting blood pressure, another conclusion presents itself. From this work and other studies in this laboratory, one can generalize that nonspecific and nonmusculotropic agents which lower the resting blood pressure tend to dampen epinephrine's depressor effect and accentuate the pressor response. Conversely, a nonspecific and nonmusculotropic agent which raises the resting blood pressure tends to accentuate epinephrine's depressor effect and dampen the pressor response.

Figure 6 also shows a direct and passive correlation between the percent decrease in the epinephrine depressor response and the percent decrease in resting blood pressure. Therefore, it was concluded that neither reserpine, yohimbine, nor mixtures of these alkaloids pharmacologically affect the depressor response to exogenous epinephrine.

Figure 7 is concerned with the effects of these alkaloids on the resting heart rate. Treatment with 1 mg./kg. of reserpine did not produce a significant bradycardic effect during the 5-hr. observation

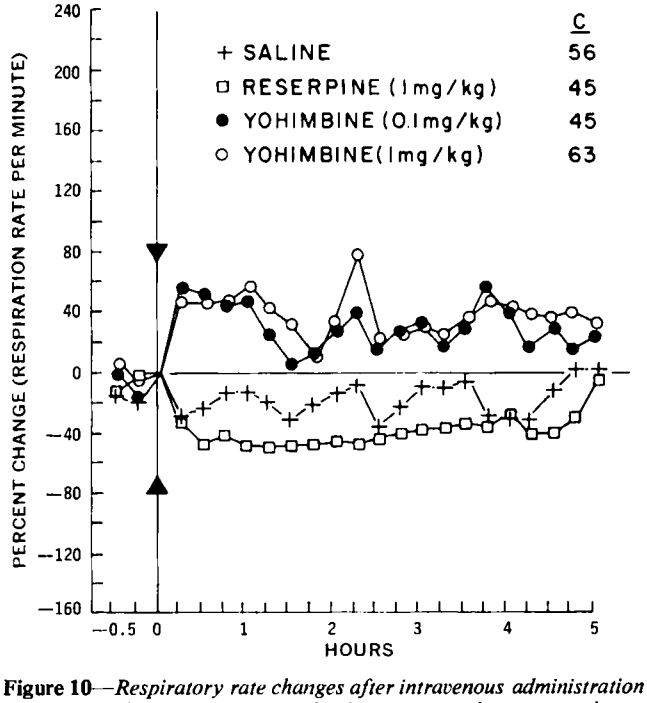

Figure 10—*Respiratory rate changes after intravenous administration of isotonic saline, reserpine, or yohimbine expressed as percent change from control (C) values (mm. Hg).*

[1] Dial.

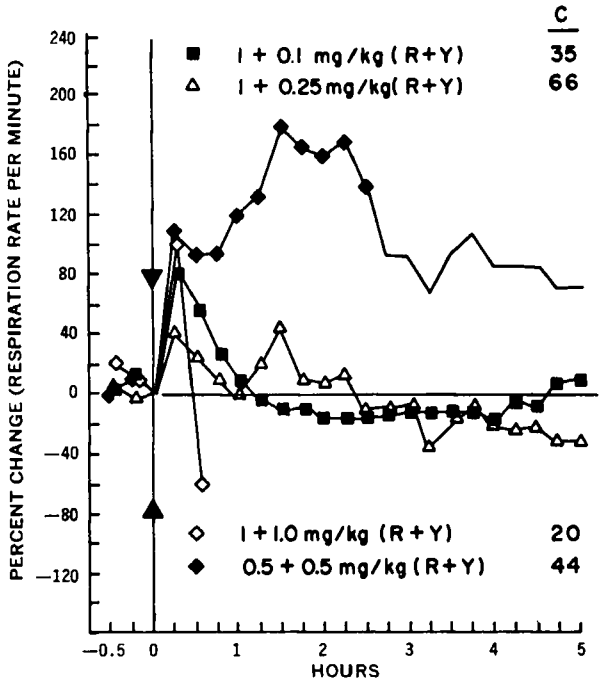

Figure 11—*Respiratory rate changes after intravenous administration of reserpine and yohimbine (R + Y) mixtures expressed as percent change from control (C) values (mm. Hg).*

period. However, 1 mg./kg. of yohimbine produced a prompt 22% slowing of the heart rate, with recovery at the end of the 1st hr. At the 3-hr. interval of the experiment, there was a second period of bradycardia.

Figure 8 exhibits no distinct dose–response pattern. However, a profound and unequivocal bradycardia was seen with the lethal combination of 1.0 mg./kg. of reserpine and 1.0 mg./kg. of yohimbine.

The combination of 1.0 mg./kg. of reserpine and 0.25 mg./kg. of yohimbine elicited a somewhat cyclical bradycardia, which one would not expect considering the effects of reserpine alone (Fig. 7). The effects produced by the combination of 0.5 mg./kg. each of reserpine and yohimbine is shown by the line without markers and is characterized by some equivocal tachycardia seen between 1 and 2 hr. and the bradycardia seen between 3 and 4 hr. Except for the steepness of parts of the first portion of the curve, it bears some similarity to the response seen with the combination of 1.0 mg./kg. reserpine and 0.25 mg./kg. yohimbine.

Figure 9 clearly shows that yohimbine (1 mg./kg.) blocks the vagal slowing seen during the pressor phase of the response to epinephrine. Likewise, it tends to block the tachycardia seen during the depressor phase. This phenomenon was observed with all reserpine–yohimbine combinations and is pharmacologically most interesting. In 1930, Heymans and Bouckaert (19) reported that yohimbine could suppress carotid sinus vasomotor reflexes.

Percentage shifts in respiration were more pronounced than the other parameters measured. Isotonic saline appeared to produce some cyclic depression of the resting respiratory rate, whereas 1 mg./kg. of yohimbine was uniformly depressant (Fig. 10). This depression appeared to be overcome at the end of the 5-hr. observation period. There was some evidence of cyclic stimulation of the respiratory rate in the animals treated with either 1 mg./kg. of reserpine or 0.1 mg./kg. of yohimbine. From Fig. 11, it can be seen that all alkaloid combinations produced a transient stimulation of respiratory rate at the 15-min. interval. Subsequently, the combination of 1 mg./kg. reserpine and 1 mg./kg. yohimbine induced a profound respiratory depression, resulting in the death of all test animals before the end of the 1st hr. of observation. Although it appears in Fig. 11 that treatment with the combination of 0.5 mg./kg. each of reserpine and yohimbine produced only respiratory stimulation, three test animals plunged into respiratory depression during the middle of the observation period and died. Only one dog in this group survived the entire 5-hr. period (its response is noted by the line without markers). After the initial stimulation, the treatment consisting of 1 mg./kg. reserpine and 0.1 mg./kg. yohimbine elicited respiratory responses much like predrug levels. The pattern for the combination of reserpine and yohimbine (1 and 0.25 mg./kg., respectively) showed some evidence of cyclization during most of the observation period.

SUMMARY

It is evident from the data presented that preparations made from the whole root of *R. serpentina* cannot be considered as just other "reserpine-like" drugs. It appears that yohimbine and/or yohimbine-like alkaloids can contribute significantly to the pharmacological–therapeutic profile of rauwolfia whole root.

Opium Alkaloids XIV: Biosynthesis of Aporphines—Detection of Orientaline in Opium Poppy

E. BROCHMANN-HANSSEN▲, C. H. CHEN, H.-C. CHIANG*, C.-C. FU†, and H. NEMOTO

Abstract □ Orientaline was detected in the opium poppy by an isotope dilution method based on its biosynthesis from norlaudanosoline. Administration of labeled orientaline revealed that this alkaloid was not a precursor of isoboldine, and the experimental results provided no evidence for a pathway involving norprotosinomenine. No conclusion was possible relative to the origin of magnoflorine in the opium poppy.

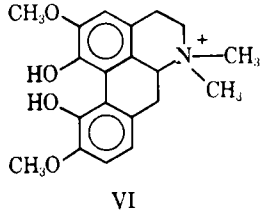
Keyphrases □ Opium alkaloids—biosynthesis of aporphines, detection of orientaline in opium poppy □ Orientaline—detection in opium poppy by isotope dilution method, biosynthesis from norlaudanosoline □ Biosynthesis of opium alkaloids—orientaline from norlaudanosoline □ Aporphine biosynthesis—detection of orientaline in opium poppy □ Isotope dilution technique—determination, orientaline in opium poppy

An earlier paper in this series (1) reported that isoboldine (III) is biosynthesized in the opium poppy by direct oxidative coupling (*ortho–para*) of reticuline (II), whereas a direct pathway could not be ascertained for magnoflorine (VI). At the same time, it was pointed out that an alternative pathway *via* orientaline (IV) and orientalinone (V) might also exist for isoboldine (Scheme I). Orientaline and orientalinone are present in *Papaver orientale* and *P. bracteatum* (2, 3), where they are involved in the biosynthesis of the aporphine isothebaine (2, 4, 5), but they have not yet been isolated from opium or the opium poppy. Biosynthesis of aporphines by direct *ortho–ortho* coupling of reticuline has been demonstrated for bulbocapnine in *Corydalis cava* (6, 7) and for magnoflorine in Columbine plants (aquilegia, McKana hybrid) (8). Battersby *et al.* (9) were unable to show either type of direct coupling for the biosynthesis of corydine (X), glaucine (XI), and dicentrine (XII) in *Dicentra eximia*. Instead, they found evidence of an indirect mechanism involving norprotosinomenine (VII) and the dienones VIII and IX. This opened a new possibility for the biosynthesis of isoboldine and magnoflorine in the opium poppy.

The present study was undertaken to discover alternative pathways for the biosynthesis of these alkaloids.

RESULTS AND DISCUSSION

Enzymes catalyzing biosynthetic reactions show a great deal of configurational specificity. Yet, they will often interact with substances foreign to the organism and transform them along normal metabolic routes, provided these foreign compounds are sufficiently similar to the normal metabolites. Thus, codeine 6-methyl ether has been converted to codeine by the opium poppy (10) and 1,3-dimethyl-1-pyrrolinium chloride to 3′-methylnicotine by the tobacco plant (11). Incorporation of a potential precursor into an alkaloid is, therefore, not sufficient evidence of its participation in the normal biosynthesis. It is also necessary to demonstrate that the proposed precursor actually exists in the living plant.

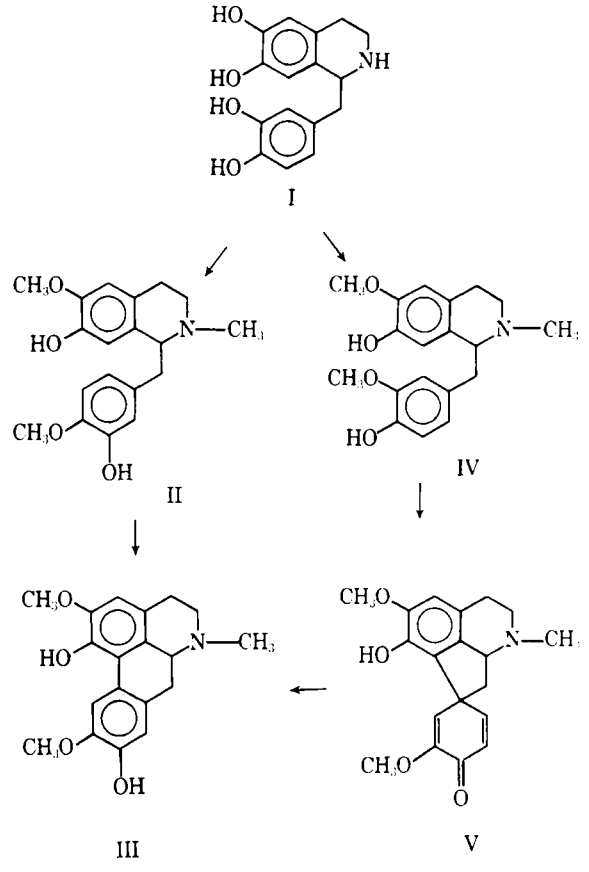


VI

In the anticipation of an alternative pathway for biosynthesis of isoboldine by way of orientaline, a scheme was developed for detection of orientaline based on its biosynthesis from norlaudanosoline (I). (±)-Norlaudanosoline-3-^{14}C was administered to opium poppies, and (±)-orientaline was added as cold carrier during the extraction. Isolation and purification of orientaline, first as the perchlorate and then as *O,O*-diacetylorientaline picrate, gave a radioactive compound. Based on the amount of orientaline added as a carrier, the incorporation of radioactivity amounted to 0.54%.

Orientaline (IV) and reticuline (II) are position isomers and difficult to separate. It was, therefore, conceivable that the radioactivity might be due to a small amount of reticuline present as an impurity. This possibility was tested by diluting a sample of the purified, radioactive diacetylorientaline picrate with 2.5 times its weight of diacetylreticuline picrate. Fractional crystallization of the mixture gave diacetylreticuline picrate of negligible specific activity.

Feeding experiments with (±)-orientaline-*N*-$^{14}CH_3$ gave no incorporation of radioactivity into isoboldine. In view of the apparent role of norprotosinomenine in the biosynthesis of apor-



Scheme I—Potential pathways for biosynthesis of isoboldine

phines (9), (±)-norprotosinomenine-3-^{14}C-7-*O*-methyl-^{3}H was administered to opium poppies, and isoboldine and magnoflorine were isolated after dilution with "cold" carriers. Neither alkaloid showed any incorporation of radioactivity.

It may be concluded that orientaline is a normal alkaloid constituent of the opium poppy. However, it does not participate in the biosynthesis of isoboldine. No definite conclusions may be drawn from these experiments about the biosynthesis of magnoflorine in the opium poppy, since both reticuline and norprotosinomenine have given negative results. There are great quantitative variations in the alkaloid composition of different varieties of the opium poppy. It is, therefore, quite possible that the variety used in these experiments (Noordster) may not have contained detectable amounts of magnoflorine.

EXPERIMENTAL

The methods used for the determination of radioactivity, cultivation of plants, and administration of labeled precursors were described previously (12). *Papaver somniferum*, Noordster variety, was used in these experiments. The radioactive purity of labeled, potential precursors was determined by radioactivity scanning of thin-layer chromatograms[1].

Alkaloids for Carrier Dilution—*Magnoflorine Iodide*—This alkaloid was used as supplied.

(±)-*Isoboldine*—This compound was synthesized as described by Kametani *et al.* (13). The product was identified by TLC and by comparison of its UV and NMR spectra with those of natural isoboldine (14).

(±)-*Orientaline*—This compound was synthesized by conventional methods (15, 16). It was purified as the perchlorate, m.p. 127° [lit. (16) m.p. 127°]. The base was further characterized by NMR (17) and mass spectrometry (18).

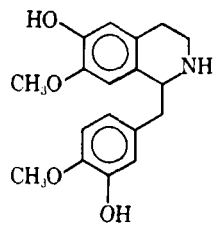
Synthesis of Labeled Precursors—(±)-*Norlaudanosoline-3-^{14}C Hydrochloride*—This compound was prepared by demethylation of (±)-tetrahydropapaverine-3-^{14}C as described by Battersby *et al.* (19), m.p. 278–281° [lit. (19) m.p. 278–281°], specific activity 0.36 mc./mmole.

(±)-*Orientaline*-N-$^{14}CH_3$—This compound was synthesized in the same way as the "cold" material, except that radioactive methyl iodide was distilled into the reaction vessel in a vacuum manifold system as described previously for (±)-reticuline-*N*-$^{14}CH_3$ (12). The intermediates in the synthesis and the final product were compared with the corresponding nonradioactive compounds by TLC on silica gel with two solvent systems (20) and by GLC on silicon rubber OV-1 and OV-225. The specific activity of (±)-orientaline-*N*-$^{14}CH_3$ was 1.68 mc./mmole.

(±)-*Norprotosinomenine-3-^{14}C-7-O-methyl-^{3}H Hydrochloride*—

1. (±)-*O,O*-Dibenzylnorprotosinomenine-3-^{14}C was prepared by standard methods as described for (±)-*O,O*-dibenzylnorreticuline-3-^{14}C (21), specific activity 0.24 mc./mmole.

2. (±)-*O,O*-Dibenzylnorprotosinomenine-7-*O*-methyl-^{3}H was prepared by dissolving catechol (55 g.) and benzyl chloride (63.3 g.) in 120 ml. of absolute ethanol. A solution of 11.5 g. of sodium in 170 ml. of absolute ethanol was added, and the mixture was refluxed for 2 hr. under a stream of nitrogen. The reaction mixture was allowed to cool and was then acidified with hydrochloric acid and placed in a refrigerator overnight. Sodium chloride and dibenzylcatechol crystallized out and were removed by filtration. The filtrate was evaporated to an oil, which was extracted with ether. The combined ether extracts were washed with water and evaporated to dryness. The oily residue was distilled under reduced pressure (10 mm. Hg). Unchanged catechol distilled over first, followed by the monobenzyl ether as a pale-yellow oil, boiling range 168–173°. To a well-stirred solution of *O*-benzylcatechol (5 g.) and potassium hydroxide (9 g.) in ethanol (40 ml.) and water (20 ml.) was added dropwise 10 ml. of chloroform while the solution was kept under an atmosphere of nitrogen. After 2 hr. at room temperature, the reaction mixture was refluxed for 30 min. Ethanol and unreacted chloroform were removed under reduced pressure. The residue was acidified with hydrochloric acid and extracted with ether. The combined ether extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness. The brown,



VII

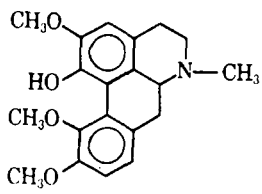
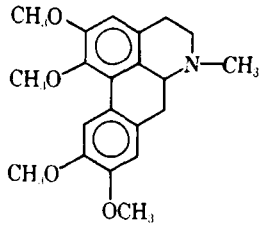
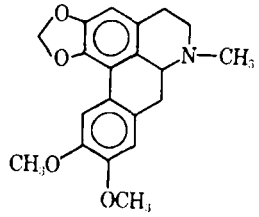
IX



X



XI



XII

oily residue was chromatographed on silica gel[2], first with chloroform and then with chloroform containing 3% of methanol. The fractions containing 3-benzyloxy-4-hydroxybenzaldehyde were combined, evaporated to dryness, and crystallized from benzene, m.p. 113–114°, yield 0.288 g. NMR data agreed well with the structure. Mixed melting point with 4-benzyloxy-3-hydroxybenzaldehyde (m.p. 121–123°) showed great melting-point depression.

3-Benzyloxy-4-hydroxybenzaldehyde (22.8 mg., 0.1 mmole) was dissolved in 3 ml. of anhydous benzene, and 0.095 mmole of freshly prepared sodium ethoxide solution in 0.5 ml. of absolute ethanol was added. Radioactive iodomethane-^{3}H (10 mc., 0.01 mmole)[3] was distilled into the solution in a vacuum transfer system (21). The tube containing the reaction mixture was sealed and left at room temperature for 3 days with frequent shaking. The contents were transferred to a flask and evaporated to dryness. The residue was mixed with 330 mg. of 3-benzyloxy-4-methoxybenzaldehyde (*O*-benzylisovanillin) and dissolved in chloroform; the solution was washed with 10% potassium hydroxide solution (2 × 10 ml.) and then with water, dried over potassium carbonate, and evaporated to dryness. The residue was crystallized from ethanol.

O-Benzylisovanillin-*O*-methyl-^{3}H was converted to *O,O*-dibenzylnorprotosinomenine-7-*O*-methyl-^{3}H by conventional methods (21), specific activity 4.45 μc./mmole.

A mixture of 100 mg. of (±)-*O,O*-dibenzylnorprotosinomenine-3-^{14}C and 200 mg. of (±)-*O,O*-dibenzylnorprotosinomenine-7-*O*-methyl-^{3}H was debenzylated with hydrochloric acid (12) and purified by crystallization of the hydrochloride. Specific activity: ^{14}C, 80 μc./mmole; ^{3}H, 2.97 μc./mmole; and a ratio ^{14}C/^{3}H = 26.9.

Detection of Orientaline—(±)-Norlaudanosoline-3-^{14}C hydrochloride (10 mg.) was dissolved in 5 ml. of water, and the solution was administered to 10 plants. Two weeks later the plants were extracted by maceration with methanol in a high-speed blender[4]. (±)-Orientaline perchlorate (265 mg.) was dissolved in 100 ml. of 70% methanol and mixed with the plant material. The suspension was poured into a glass percolator and extracted with methanol until the extract gave negative tests for alkaloids. The extract was concentrated to about 500 ml. in a rotary vacuum evaporator at a temperature maintained below 40° and shaken in a separator with

[3] Most of the iodomethane decomposed before use.

[4] Waring Products Co.

2 × 150 ml. of ethyl acetate. The ethyl acetate extract was back-extracted with 3 × 50 ml. of 0.5 *N* hydrochloric acid, and the washings were combined with the original aqueous solution (total alkaloids). The aqueous, acidic solution of total alkaloids was extracted with chloroform to remove weakly basic alkaloids, the pH was adjusted to 9 with ammonium hydroxide, and the solution was extracted with a mixture of chloroform and isopropyl alcohol (3:1). The extract was evaporated to dryness under reduced pressure, and the residue (2.2 g.) was chromatographed on a column of silica gel[5] with a mixture of chloroform and methanol (97:3). The fractions containing orientaline, as indicated by micro-TLC, were combined and evaporated to dryness. The residue (63 mg.) was converted to the perchlorate (16) and crystallized from ethanol. The specific activity decreased slowly with each recrystallization and was not yet constant after six crystallizations (930 d.p.m./mg.). The remainder of the sample (about 30 mg.) was converted to the base, dissolved in about 1 ml. of a mixture of pyridine and acetic anhydride (1:1), and left at room temperature. After 2 days, 1.05-mole equivalents of picric acid in a minimum volume of absolute ethanol were added gradually to the reaction mixture and the picrate was allowed to crystallize in a refrigerator. The crystals were collected and recrystallized from 75% ethanol to constant radioactivity, 338 d.p.m./mg., m.p. 216–217°.

To prove that the radioactivity was not due to an impurity of reticuline, 3 mg. was mixed with 7.5 mg. of *O,O*-diacetylreticuline picrate and the mixture was crystallized from 75% ethanol. The crystals, consisting mainly of *O,O*-diacetylreticuline picrate, had a specific activity that was considerably lower than that calculated for the mixture, and it decreased with each recrystallization. After six recrystallizations, when the sample was exhausted, the specific activity was 13 d.p.m./mg.

Isolation of Isoboldine and Magnoflorine—The aqueous, acidic solution of total alkaloids from the plants to which (±)-isoboldine and magnoflorine iodide had been added as cold carriers was extracted with chloroform to remove the weakly basic alkaloids. The aqueous phase was basified to pH 8–9 with sodium bicarbonate and extracted with several portions of ether. The combined ether extracts were washed with water and evaporated to dryness. The residue was chromatographed on silica gel[2] with chloroform–methanol (100:1). The fractions containing isoboldine were combined, evaporated to dryness, and crystallized from methanol to constant radioactivity; (±)-orientaline-*N*-$^{14}CH_3$ feeding: 3 d.p.m./mg.; norprotosinomenine feeding: 5 d.p.m./mg.

The aqueous, alkaline solution remaining after extraction with ether was acidified with glacial acetic acid. Magnoflorine was isolated as the iodide as described by Doskotch and Knapp (22) and crystallized from methanol to constant radioactivity; norprotosinomenine feeding: 2 d.p.m./mg.

Reactions of 2,2-Dimethylaziridine-Type Alkylating Agents in Biological Systems I: Colorimetric Estimation and Stability in Physiological Media

DAVID LALKA and T. J. BARDOS▲

Abstract □ Procedures were developed for the quantitative estimation of 2,2-dimethylaziridine containing alkylating agents in blood and urine. Rapid alkalinization of the biological samples, followed by protein precipitation and extraction of the compounds at high salt concentration into acetophenone, resulted in good recoveries. The use of a nonaqueous solvent (acetophenone) and the adoption of *N*-phenylpiperazine as the proton-accepting reagent significantly improved the sensitivity and reproducibility of the colorimetric assay with 4-(*p*-nitrobenzyl)pyridine. These improvements appear to be generally applicable to the quantitative determination of aziridine-type alkylating agents. The 2,2-dimethylaziridine agents were shown to undergo extremely rapid hydrolysis under neutral or acidic conditions and were stable only in alkaline solution. The half-lives of tris(2,2-dimethyl-1-aziridinyl)phosphine oxide, bis(2,2-dimethylaziridinyl)phosphinylurethan, and ethyl bis(2,2-dimethyl-1-aziridinyl)phosphinate in whole blood, at 37°, pH 7.38, were 7, 11, and 18 min., respectively; the corresponding half-lives in plasma were approximately four times longer.

Keyphrases □ 2,2-Dimethylaziridine-type alkylating agents—stability and colorimetric estimation in blood and urine, half-lives □ Aziridine-type alkylating agents, 2,2-dimethyl analogs—stability and colorimetric estimation in blood and urine, half-lives □ pH dependence—hydrolysis rates of 2,2-dimethylaziridine-type alkylating agents □ *N*-Phenylpiperazine—used as base reagent for colorimetric estimation of 2,2-dimethylaziridine-type alkylating agents in urine and blood □ Colorimetry—analysis and stability of 2,2-dimethylaziridine-type alkylating agents in blood and urine

Bis(2,2-dimethylaziridinyl)phosphinylurethan[1] (I), one of a series of "dual antagonists" synthesized and studied in this laboratory (1–8), has been undergoing extensive clinical trials[2] as an anticancer agent (9–18). It appears that this drug potentiates the antitumor effects of X-rays clinically (14–19) as well as in animal experiments (20). In man, relatively small doses of X-rays produced short-term remissions of solid tumors when administered with Compound I (14–17). Furthermore, a recently concluded study of the treatment of bronchogenic carcinoma with this compound in combination with radiotherapy showed some encouraging long-term therapeutic effects (18, 19). These results suggest continuing interest in the clinical study of this agent. In the meantime, several other compounds containing the 2,2-dimethylaziridine moiety were synthesized and found to be effective against a spectrum of transplanted tumors in rodents (21–26). Two of these agents, ethyl bis(2,2-dimethyl-1-aziridinyl)phosphinate (II) (23, 24) and tris(2,2-dimethyl-1-aziridinyl)phosphine oxide (III) (25), which showed particularly potent activities against leukemia L-1210 in mice, passed through the preclinical pharmacology stage (24) and are presently undergoing preliminary evaluation against solid tumors in man.

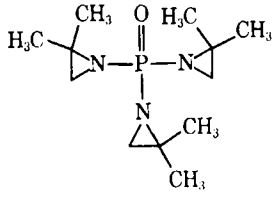
II



III

In view of the unique chemical and pharmacological properties (2, 7, 8, 22, 26) of these 2,2-dimethylaziridine derivatives as compared to their ring-C-unsubstituted aziridine analogs [*i.e.*, the conventional "ethyleniminetype" alkylating agents, bis(1-aziridinyl)phosphinylurethan (IV), triethylenemelamine (V), tris(1-aziridinyl)-phosphine oxide (VI), *etc.*] and in view of their apparently selective chemotherapeutic effects (26), it appeared worthwhile to investigate the reactions of these compounds in biological systems. Such studies may lead to a better understanding of the chemical, metabolic, and pharmacokinetic processes influencing the chemotherapeutic activities of these unusually "water-labile" alkylating agents. Therefore, the results of these studies may facilitate the design of optimally effective agents and may aid in establishing optimal conditions for their therapeutic application. The present paper describes studies to determine the *in vitro* stabilities of these agents in various aqueous and physiological media and to establish an assay methodology applicable to subsequent studies of their metabolism and distribution *in vivo*.

4-(*p*-Nitrobenzyl)pyridine (N, Scheme I) (27) is the most widely used analytical reagent for the assay of alkylating agents. Many procedures have been reported for the determination of various alkylating agents in blood and tissues using this reagent (28–35). However, the unusually rapid hydrolysis of the 2,2-dimethylaziridine derivatives in acidic or neutral aqueous media, as well as their relatively low chemical alkylating activities, necessitated the development of procedures that would provide: (*a*) rapid alkalinization followed by efficient extraction into nonaqueous media and (*b*) increased sensitivity of the colorimetric assay.

EXPERIMENTAL

Materials—Acetophenone and acetic acid were distilled before use. 4-(*p*-Nitrobenzyl)pyridine[3] and *N*-phenylpiperazine[4] were used as supplied. Compound V[5] and 2,2-dimethylaziridine[6] (VII) were purified before use. Compounds I, II, III, and VI were synthesized in this laboratory[7]. Since some of the aziridine derivatives may hydrolyze or polymerize during storage, IR and NMR spectra were taken periodically. TLC examination was also performed to check the purity and identity of the samples.

Colorimetric Determination of Alkylating Agents Using Nonaqueous Medium (Procedure A)—Reagent solutions were prepared by adding 1.0 ml. of glacial acetic acid (for I, III, VI, and VII) or 1.6 ml. of glacial acetic acid (for II and V) to 20 ml. of 25% 4-(*p*-nitrobenzyl)pyridine in acetophenone. These reagent solutions should be used within 30 min. after the addition of the acetic acid because the acetate salt precipitates upon standing longer. One milliliter of the reagent solution was added to 1.0 ml. of the sample, *i.e.*, an acetophenone solution containing the alkylating agent. The mixture was heated for 35 min. on an oil bath at 85° (55° in the case of the volatile Compound VII). To terminate the reaction, the tubes were placed into cold tap water. The color was developed by addition of 0.50 ml. of *N*-phenylpiperazine. The volume was then made up to 3.0 ml. with acetophenone. This mixture was transferred to a cell, and the absorbance at 575 nm. was measured spectrophotometrically against a blank prepared exactly as the sample except that the alkylating agent was omitted. The absorbance of the colored product is stable for at least 5 min.

Extraction of Alkylating Agents from Fresh Heparinized Blood (Procedure B)—Eight milliliters of human or dog blood was drawn into a 10-ml. syringe containing about 0.1 ml. of heparin injection USP (1000 units/ml.). The contents of the syringe were quickly emptied into a centrifuge tube containing the given amount of alkylating agent. After a few seconds of mixing[8], the centrifuge tubes were placed into an ice water bath. Then 0.5 ml. of 0.5 *M* NaOH was slowly added while vigorously shaking the tube on a mixer[8] (excessively high local concentrations of sodium hydroxide cause hemolysis). The tubes were kept in an ice water bath until they were centrifuged for the separation of the plasma. This was carried out at 1500×*g* for 10 min. at 10°. The preceding steps should be accomplished in less than 15 min. from the time the blood is drawn, and the temperature of the samples should be maintained at 0–10°.

Subsequently, 1.5-ml. aliquots of plasma were further alkalinized by the addition of 0.25 ml. of 50% NaOH. After this alkalinization, the tubes can be kept in ice water for at least 2 hr. without significant loss of activity. To each aliquot was added, in the following sequence, 1.5 ml. of 5% $ZnSO_4$, 1.5 ml. of 0.3 *N* $Ba(OH)_2$, 4.5 ml. of saturated ammonium sulfate, and 1.5 ml. of acetophenone. At least 30 sec. of vigorous agitation on a mixer[8] was applied after the addition of each reagent. This mixture was centrifuged (1500×*g*) for 35 min. at 10°, and about 1.1 ml. of an acetophenone phase was obtained. The colorimetric assay already described was then employed to determine the amount of alkylating agent in 1.0 ml. of the acetophenone phase. Contaminating traces of the aqueous phase or precipitated protein do not significantly affect the accuracy of the procedure.

Extraction of Alkylating Agents from Cellular Fraction of Blood—*Procedure C-1*—After separation of the plasma from formed elements as described for *Procedure B*, the cell fraction was kept in ice water except when otherwise stated. An aliquot of the cell fraction (1.5 ml.) was extracted with 2.0 ml. of 1.5% $NaHCO_3$ (adjusted to pH 8.4 with sodium hydroxide). The cells were resuspended by shaking on a mixer[8] and then centrifuged again. A 1.5-ml. aliquot of the supernate was treated in the same manner as was the plasma in *Procedure B*.

Procedure C-2—The cell fraction (1.5 ml.) was alkalinized with 0.2 ml. of 0.5 *M* NaOH. To this (under thorough mixing) was added, in rapid succession, 1.5 ml. of 5% $ZnSO_4$, 1.5 ml. of 0.3 *N* $Ba(OH)_2$, 0.2 ml. of 50% NaOH, 4.5 ml. of saturated ammonium sulfate, and 1.5 ml. of acetophenone. The sample was then centrifuged (1500×*g*, 10°) for 55 min. and about 1.1 ml. of an acetophenone phase was obtained. A 1.0-ml. aliquot of this phase was then treated as described in *Procedure A*.

Extraction of Alkylating Agents from Aqueous Buffers and Urine (Procedure D)—Buffer solution or urine (1.5 ml.) containing the alkylating agent was alkalinized with 0.2 ml. of 50% NaOH; then 1.5 ml. of saturated ammonium sulfate solution and 1.5 ml. of acetophenone were added. The mixture was agitated for about 30 sec. on a mixer[8] and then centrifuged (1500×*g*) for 10 min. at 10°. A 1.0-ml. aliquot of the acetophenone phase was spectrophotometrically assayed according to *Procedure A*. When the concentration of drug was too low, it was possible to extract 20 ml. of urine with 3.0 ml. of acetophenone by alkalinizing the urine with 2.0 ml. of 50% NaOH, adding 20 ml. of saturated ammonium sulfate (to salt-out drug and precipitated protein), and then adding 3.0 ml. of acetophenone. After mixing and centrifugation, about 2.5 ml. of an acetophenone phase was obtained. Duplicate 1.0-ml. aliquots

Table II—Determination of Alkylating Agents by *Procedure A*

Compound	Concentration Range Studied, mcg./ml. of Sample	Slope[a] Absorbance/ mcg./ml. of Sample	Slope[a] Absorbance/ μmoles/ml. of Sample
I	0.64–32.3	0.021	5.79
II	0.63–62.5	0.024	5.59
III	0.43–42.6	0.031	7.69
V	0.22–11.1	0.054	11.02
VI	0.13–13.1	0.038	6.61
VII	0.30–30.0	0.066	4.69

[a] The "slopes" of the Beer's law plots were calculated from quadruplicate absorbance measurements taken at five different concentrations in the range indicated, utilizing an Olivetti Programma 101 (least-squares fit through the origin). The precision and accuracy of the absorbance measurements were comparable to the values shown in Table III.

[3] 4-(*p*-Nitrobenzyl)pyridine was purchased from the Aldrich Chemical Co.

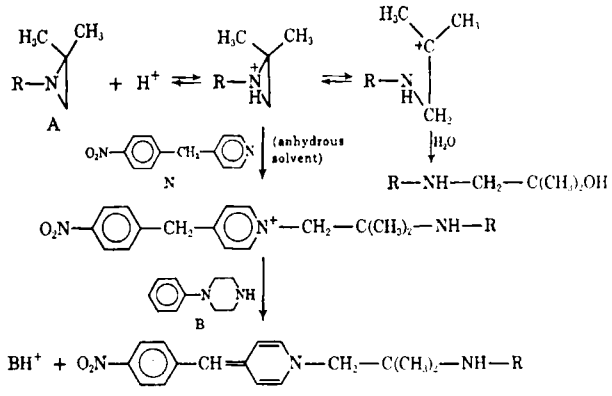
[4] *N*-Phenylpiperazine was obtained at 99% purity from the Aldrich Chemical Co. A practical grade (95% purity) was purchased from Eastman Organic Chemicals. Both products were equally satisfactory in the assay.

[5] Product of the American Cyanamid Co., purified by recrystallization from chloroform.

[6] Purchased from Fike Chemicals (through Columbia Organic) and redistilled before use.

[7] Thanks are due to Dr. Z. F. Chmielewicz and Dr. Y. Y. Hsiao for preparation of these materials.

[8] Vortex.



Scheme I—A = 2,2-dimethylaziridine-type alkylating agent (I–III, VII), N = nucleophilic reagent [4-(p-nitrobenzyl)pyridine], and B = base reagent (N-phenylpiperazine)

of this phase were then spectrophotometrically assayed according to *Procedure A*.

Chromatography (Procedure E)—TLC[9] was conducted, using two solvent systems: A, chloroform–absolute ethanol (1:1); and B, ethyl acetate. The alkylating agents were located on the chromatogram with a spray reagent. The most satisfactory reagent was a mixture of 9 ml. of 15% 4-(*p*-nitrobenzyl)pyridine in acetone and 1 ml. of glacial acetic acid (which were combined less than 5 min. before use). After spraying, the chromatogram sheets were heated to 95° in a hot air oven for 15 min. Color development was achieved by spraying with a 15% solution of *N*-phenylpiperazine in acetone (this solution is stable for about 2 days). The alkylating agents appeared as dark-blue spots on a yellow background. The R_f values are listed in Table I. Alkylating agents were extracted from plasma by adding, with vigorous shaking, in this order: 20 ml. of plasma, 3.0 ml. of 50% NaOH, 20 ml. of saturated ammonium sulfate, and 5.0 ml. of methylene chloride. Centrifugation (1500×*g*) for 35 min. at 10° yielded 1–2 ml. of a methylene chloride phase, which was then suitable for spotting.

This method permits the detection of 1–2 mcg. of alkylating agent.

RESULTS AND DISCUSSION

Assay Procedures—By using *Procedure A*, linear absorbance *versus* concentration plots (colorimetric assay standards) were obtained for 2,2-dimethylaziridine (VII), for the three agents (I–III) containing the 2,2-dimethylaziridine moiety, and for the two "conventional" alkylating agents (V and VI) containing C-unsubstituted aziridine functions. For all these compounds, good agreement with Beer's law was observed throughout the entire concentration range studied. The "slopes," given in Table II, reflect the sensitivity of the colorimetric assay. On a molar concentration basis, the slopes of the 2,2-dimethylaziridine derivatives are comparable to those of the corresponding analogous unsubstituted aziridine agents (see III *versus* VI) and are related to the number of alkylating moieties in the molecule. Thus, on a molar basis, the slopes obtained for the two bifunctional agents (I and II) are almost identical but are smaller than those obtained for the analogous trifunctional agents (III and VI) and are larger than that of the monofunctional agent (VII).

By using a nonaqueous solvent for the reaction with 4-(*p*-nitrobenzyl)pyridine, *Procedure A* eliminates the competing hydrolysis reactions for the aziridines. These reactions were particularly significant with the 2,2-dimethylaziridine derivatives (Scheme I). Rapid hydrolysis probably caused the unsatisfactory results obtained when previously published methods (using 50% aqueous buffers, usually at pH 4.5) were applied to the determination of Compound I. Acetophenone was previously employed as a solvent (36) for the colorimetric assay of alkyl halides with 4-(*p*-nitrobenzyl)pyridine; however, in the latter case, no acid was needed for the reaction to occur. In contrast, the reactions of aziridines require an appreciable

acid concentration (see *Procedure A*), because protonation of the aziridine ring is the rate-determining step. The addition of acid to the reagent solution increases the color (absorbance) of the "blank" tubes (after alkalinization). This may be due to stabilization of the 4-(*p*-nitrobenzyl)pyridinium salt of the acid (*via* formation of a charge-transfer complex), which could favor the removal of a benzyl proton upon addition of the base. The nature of the base was a critical factor. Among a large series of bases studied, *N*-phenylpiperazine was unique in producing the maximal amount of colored product from the alkylated 4-(*p*-nitrobenzyl)pyridine in the sample tubes and, at the same time, causing very little color formation in the blanks.

Because of its overall structural similarity to 4-(*p*-nitrobenzyl)-pyridine, it is possible that the *N*-phenylpiperazine is capable of "discharging" the acid-salt complex; alternatively, *N*-phenylpiperazine is a sufficiently strong base to serve as an efficient proton

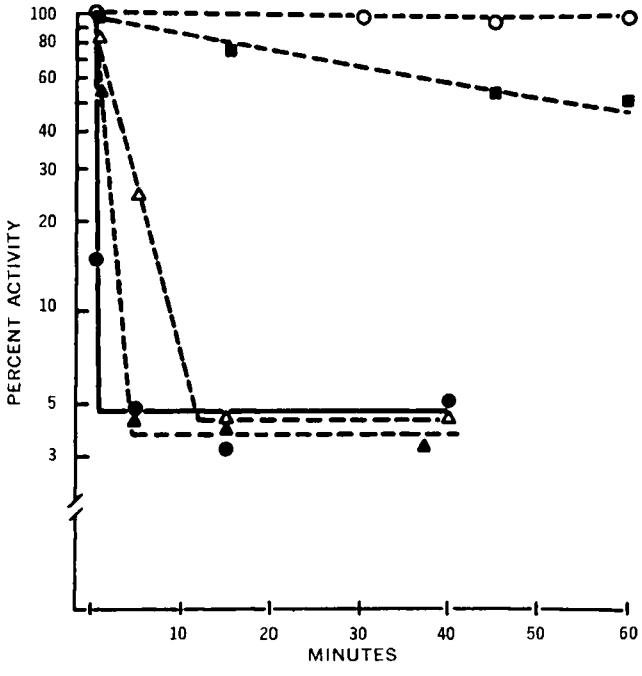

Figure 1—*Rate of hydrolysis of III in buffers of various composition (at 25°). Key: ○, pH 10.9 (0.6 M Na_2CO_3); ■, pH 7.5 (0.6 M $NaHCO_3$); △, pH 6.0 (10^{-3} M potassium hydrogen phthalate); ▲, pH 6.0 (10^{-1} M potassium hydrogen phthalate); and ●, pH 5.0 (10^{-3} M potassium hydrogen phthalate). The ordinate is the remaining alkylating activity, expressed as a percent of the t = 0 alkylating activity; t = 0 activity was calculated on the basis of an absorbance of 0.030/mcg. of III (Table III).*

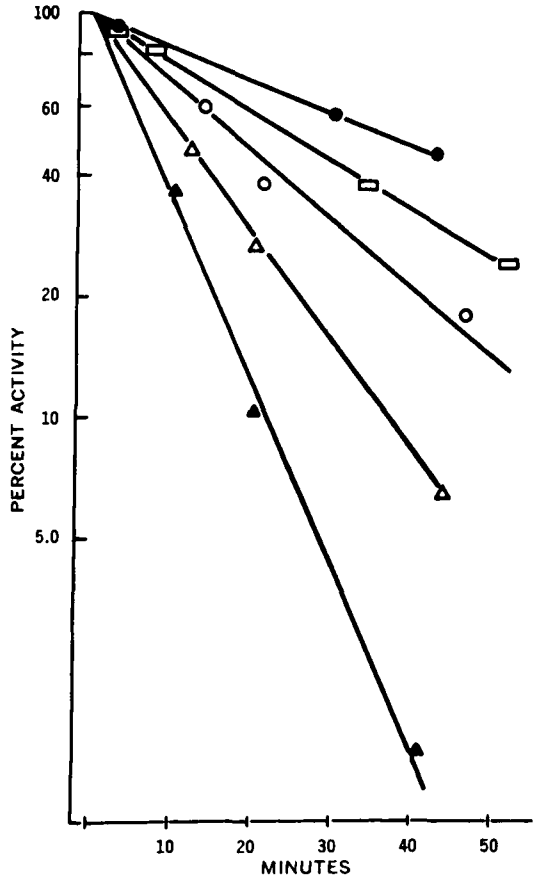

Figure 2—*Disappearance of reactivity with 4-(p-nitrobenzyl)pyridine in fresh human heparinized blood and plasma (pH 7.36). Key: ▲, III in blood at 37°; △, I in blood at 37°; ○, II in blood at 37°; □, III in plasma at 37°; and ●, III in blood at 25°.*

acceptor for a benzyl proton of the alkylated reagent but not for that of its acetate salt. The adoption of *N*-phenylpiperazine as the base reagent greatly increases the sensitivity of the colorimetric assay (Scheme I).

For the determination of 2,2-dimethylaziridine derivatives in blood samples according to *Procedure B*, it is advantageous to use another set of standard curves that already include the "recovery factor" of each agent, *i.e.*, the yield of extraction into the nonaqueous phase. Data for such curves were determined for Compounds I–III (Table III), and these data show good adherence to Beer's law. In other words, the absorbance measurements obtained in the acetophenone phase show a linear relationship to the theoretical concentrations (*i.e.*, the amount of drug per milliliter of blood added immediately before extraction) for each agent. This means that the percent recovery from blood (based on micrograms per milliliter concentration) for any given agent is constant throughout the concentration range studied, its value being dependent on the partition of the agent between the aqueous (salt) phase and the acetophenone phase (see *Procedure B*). Comparison of the data in Table III with those in Table II gives the "recovery factors": 60% for I, 95% for II, and 95% for III. The data in Table III also give some indication of the reproducibility and sensitivity of the assay procedure.

These recoveries were obtained by adding the compounds to whole blood immediately prior to separation of the plasma phase according to *Procedure B*. Virtually identical recoveries (absorbance per microgram per milliliter of biological fluid) and standard curves were obtained when the drugs were added directly to plasma. This suggests that the drugs rapidly equilibrate between the cellular fraction and plasma.

When the drugs added to the whole blood were extracted from the cell fraction, according to *Procedure C*, the percent recoveries (per milliliter of cell fraction) were somewhat lower (Table IV). This may be due to increased contact time of these reactive agents with the cells, resulting in binding and/or degradation.

Table IV—Recovery of Compounds I–III from Blood

Compound	Concentration Prepared in Whole Blood, mcg./ml.[a]	Recovery from Plasma, mcg./ml.[b,e]	Recovery from Cellular Fraction, mcg./ml.[c,e]	Recovery from Cellular Fraction, mcg./ml.[d,e]
I	78	71	49	38
II	88	76	64	39
III	68	63	46	27

[a] The alkylating agent was added to blood at 25°. [b] Results obtained utilizing *Procedure B* after the blood and alkylating agent had been incubated for 10 min. at room temperature. [c] Using *Procedure C-1*. [d] Using *Procedure C-2*. [e] The values in these columns were corrected for the 60% recovery of Compound I and the 95% recovery of Compounds II and III.

The recoveries of Compounds I–III, either from urine or from aqueous buffers, by *Procedure D* were virtually identical with the corresponding recovery factors obtained by the application of *Procedure B* to whole blood or plasma. This is significant, because it shows that the different proteins present in these biological fluids do not affect the results obtained with these assay procedures.

Stability Studies—Figure 1 shows the rates of hydrolysis of III in buffers and infusion vehicles at various pH values. The corresponding hydrolysis rates of I and II are slightly lower but show the same pH dependence. It is evident that III is stable in alkaline solution (pH 10.9) but that it loses 50% of its alkylating activity[10] in 1 hr. at pH 7.5 and in 1–3 min. at pH 6.0. At pH 5.0, about 85% of the drug is hydrolyzed in 30 sec. A 100-fold increase of the buffer concentration (at pH 6) further increases the rate of hydrolysis. Dependence of the rates of hydrolysis upon both hydrogen-ion and buffer concentrations has also been observed in the case of unsubstituted aziridine (37) and its derivatives (V and VI) (38). However, the corresponding hydrolysis rates are more than an order of magnitude lower for the latter compounds (*e.g.*, VI has a half-life of 15 hr. at pH 7.0) than for the 2,2-dimethylaziridine-containing agents. Therefore, the vehicle and rate of administration are much more critical factors in the clinical application of I–III than in the case of the conventional alkylating agents.

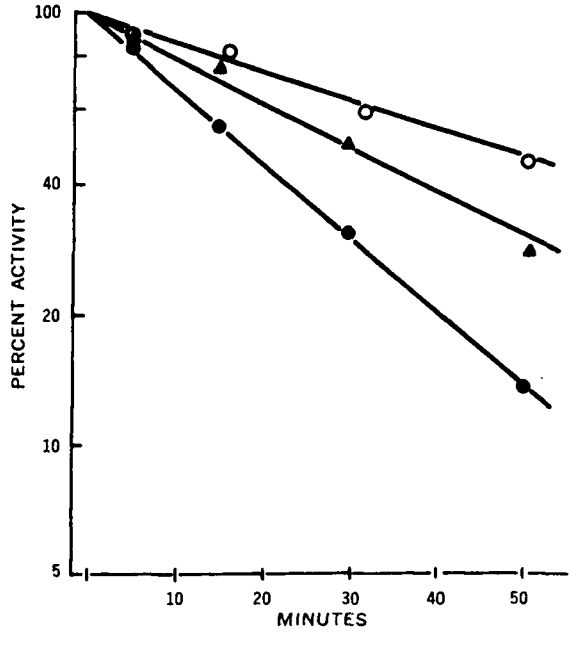

Figure 3—*Hydrolysis of Compounds I (▲), II ○, and III (●) in fresh human urine adjusted to pH 7.8 at 37°.*

[10] That is, reactivity with 4-(*p*-nitrobenzyl)pyridine, usually referred to in the literature as "NBP-reactivity."

It can be observed in Fig. 1 that about 4.5% of the zero-time alkylating activity remains after a time interval corresponding to many times the half-life of the parent compound. This suggests that the hydrolysis products contain some reactive material which is relatively stable to further hydrolysis. TLC (*Procedure E*) shows the presence of two such components, one having the same R_f values as Compound VII (Table I).

Figure 2 shows the rate of disappearance of the alkylating activities of Compounds I–III upon incubation with human blood or plasma. (Similar results were obtained with canine blood.) It is apparent that solutions of all three agents lose their alkylating activities very rapidly; the half-lives, in whole blood, at 37° are 11, 18, and 7 min. for Compounds I, II, and III, respectively. Comparison of the rates of loss of the alkylating activity for Compound III in whole blood and in plasma (half-life of 7 *versus* 26 min., respectively, at 37°) indicates that the blood cells contribute significantly to the loss of reactive material. The rate of loss was much lower at 25° than at 37° (half-life of 39 *versus* 7 min., respectively, in whole blood) (Fig. 2).

TLC analysis (*Procedure E*) of samples taken at various time points confirmed that at least 95% of the substances reacting with 4-(*p*-nitrobenzyl)pyridine were, in each case, identical with the parent compounds. Trace amounts of the two above-mentioned hydrolysis products (VII and unknown) were also detected.

The rates of hydrolysis of these agents in urine (Fig. 3) are comparable to those in blood plasma; however, substantial variations may be expected if such studies are conducted with urine samples of different compositions and pH's.

CONCLUSIONS

These studies demonstrated that the alkylating agents containing 2,2-dimethylaziridine moieties show a very rapid loss of recoverable alkylating activity when incubated with whole blood under physiological conditions. Since the half-lives of these agents in blood plasma are significantly longer, it appears that the blood cells provide effective binding sites and/or reactive nucleophilic targets for these agents. However, the possibility that some cellular enzymes (*e.g.*, phosphoramidases) may catalyze the degradation of these agents cannot be ruled out entirely.

For clinical chemotherapy, it is important to consider the extreme pH dependence of the hydrolysis rates of 2,2-dimethylaziridine-containing alkylating agents (Fig. 1). These drugs should be administered in an alkaline vehicle; otherwise, the actual dose of active drug introduced into the patient cannot be controlled.

In view of: (*a*) the relatively high and reproducible recovery of these agents from body fluids after rapid alkalinization, (*b*) the increased sensitivity of the modified colorimetric assay using nonaqueous solvent and *N*-phenylpiperazine as the base reagent, and (*c*) the relatively large doses employed clinically with the 2,2-dimethylaziridine agents, the application of these assay procedures to the study of the pharmacokinetics of these agents is feasible.

Cellophane as a Dialysis Membrane for Studying Nonionic Surfactants

S. J. A. KAZMI and A. G. MITCHELL▲

Abstract □ The permeability of cellophane membranes to the nonionic surfactant cetomacrogol 1000 was investigated using equilibrium dialysis, dynamic dialysis, and an ultrafiltration technique. Cellophane and silicone rubber membranes were compared in an equilibrium dialysis study of the interaction of chlorocresol with cetomacrogol. The permeability and interaction studies showed that the cellophane membranes were permeable to the surfactant. In addition, errors were introduced into the calculation of the binding constants unless changes in volume and in surfactant concentration, which occur as a result of the osmotic differential across the membrane, were taken into account.

Keyphrases □ Cellophane dialysis membranes—permeability to nonionic surfactant, used to study interaction of chlorocresol with cetomacrogol, compared to silicone rubber membranes □ Dialysis membrane permeability to nonionic surfactant, interaction with preservative—cellophane and silicone rubber compared □ Surfactant (nonionic) interaction with preservatives—studied using cellophane dialysis membranes, effect of osmosis on binding constants

Cellophane membranes are widely used in equilibrium (1–7) and dynamic (7–9) dialysis studies involving the interaction of preservatives and drugs with nonionic surfactants. Cellophane has also been used to study the effects of surfactants on the diffusion of drugs across membranes (8–12). Ideally, such investigations require that the membrane be impermeable to the nonionic surfactant while allowing diffusion of the drug and that the osmotic differential across the membrane is negligible.

There is some controversy concerning the permeability of cellophane dialysis membranes to nonionic surfactants. Patel and Kostenbauder (13) reported that Visking cellophane membrane was permeable to polysorbate 80, and they considered this membrane unsatisfactory for equilibrium dialysis work. This observation was supported by Nishida *et al.* (14). Breuninger and Goettsch (2) found that, although Visking cellophane membrane was permeable to polysorbate 80, Fisher cellophane membrane was impermeable to the same surfactant. Matsumoto *et al.* (4) studied the permeability of polysorbate 80 and a polyoxyethylene lauryl ether through Visking cellophane membrane, using dynamic dialysis (without stirring the solutions) under sink and nonsink conditions. They found that Visking cellophane membrane was practically impermeable to the nonionic surfactants and that only impurities, such as low molecular weight polyethylene glycols, passed through it.

Patel (5) compared Fisher cellophane membrane with nylon and rubber membranes in equilibrium dialysis studies, involving the interaction of several preservatives with cetomacrogol 1000 and polysorbate 80. Since close agreement was found between data obtained using Fisher cellophane membrane and those obtained using the rubber or nylon membranes, it was assumed that the cellophane membrane was impermeable to cetomacrogol and polysorbate 80. Ikeda *et al.* (7) used Visking cellophane membrane in equilibrium and dynamic dialysis techniques to study the interaction of barbiturates with a polyoxyethylene ether surfactant. Although the surfactant permeated through the cellophane membrane, the amount passed during 48 hr. was below the CMC of the surfactant.

Short *et al.* (10) reported that Visking cellophane membrane was impermeable to polyoxyethylene surfactants and that only small traces of nonsurface-active impurities passed through it.

Although the permeability of cellophane to polyethylene glycols has been studied less extensively than the nonionic surfactants, it has been shown that cellophane is permeable to polyethylene glycols with a molecular weight less than 20,000 (3, 15). Polyethylene glycols permeate cellophane membranes more readily than nonionic surfactants of similar molecular weight.

Rubber (16) and nylon (17) membranes were used in equilibrium dialysis studies of the interaction of various preservatives with the nonionic surfactant cetomacrogol, since qualitative tests showed that cellophane is permeable to the nonionic surfactant and that volume changes occurred as a result of osmosis. Apart from Matsumoto *et al.* (4), few workers using cellophane appear to have corrected for the volume changes. In view of the continued use of cellophane, it seemed desirable to make quantitative measurements of the permeability of cellophane membranes to cetomacrogol and to assess the effects of surfactant permeation and osmosis on the binding constants for the interaction between the surfactant and a preservative determined using the equilibrium dialysis technique.

EXPERIMENTAL

Materials—Cetomacrogol 1000 BPC[1] of the general formula $CH_3(CH_2)_m(OCH_2CH_2)_nOH$, where m may be 15 or 17 and n may be 19–23, was used. The molecular weight was taken as 1300. The preservative selected was chlorocresol, reagent grade[2]. Three membranes were used: Membrane 1, cellophane, dialysis tubing 3.6-cm. ($1^{47}/_{64}$-in.) flat width[3]; Membrane 2, cellophane, dialysis tubing 2.4-cm. ($^{15}/_{16}$-in.) flat width[4]; and Membrane 3, silicone rubber (silastic sheeting, nonreinforced 0.01 cm. (0.005 in.)[5]. All membranes were washed thoroughly with distilled water before use. Deionized glass-distilled water was used in all studies.

Analysis of Cetomacrogol—The presence of surface-active material in the "surfactant-free" compartment of the dialysis cell was readily detected by the formation of foam on agitation and by the

precipitation of a phosphomolybdic acid complex in a barium chloride–hydrochloric acid medium (18).

Quantitative analysis of surfactant was made using a polarograph[6]. The analysis was based on the suppression of the oxygen maximum by surfactants. Potassium chloride solution (0.002 *N*) gives a very pronounced oxygen maximum. A comparison of the heights of the maxima in the presence and absence of cetomacrogol and reference to a calibration curve permitted the determination of surfactant down to 1.0 mg./l. (19, 20). Since the method is not specific for cetomacrogol, the results are expressed as apparent cetomacrogol concentrations.

Permeability of Membranes to Cetomacrogol—*Equilibrium Dialysis*—Dialysis cells similar to those described by Patel and Foss (21) were used. The two chambers of the cell were separated by a cellophane or silicone rubber membrane. Twenty milliliters of cetomacrogol solution was pipeted into one chamber, and 20 ml. of distilled water was pipeted into the other. The cells were tumbled in a temperature-controlled water bath; at 12-hr. intervals, equal volumes were pipeted from both chambers and analyzed for cetomacrogol.

Dynamic Dialysis—Twenty-five milliliters of 10% cetomacrogol was transferred to membrane 1 suspended in 200 ml. of distilled water in a jacketed beaker. The solution in the jacketed beaker was stirred with a magnetic stirrer, while the cetomacrogol solution in the cellophane bag was stirred with a glass stirrer. One hundred milliliters of the solution was pipeted from the jacketed beaker at 12-hr. intervals and analyzed for cetomacrogol. The volume of solution in the jacketed beaker was immediately made to 200 ml. with fresh distilled water to maintain sink conditions.

Ultrafiltration—Membrane 2 was cut and fitted into an ultrafiltration cell[7]. Thirty-five milliliters of 1.8% cetomacrogol solution was placed in the cell, and a pressure of 18.2 kg. (40 lb.)/in.^{2} was applied until complete filtration of the liquid was attained. The filtrate was analyzed for cetomacrogol.

Interaction of Chlorocresol with Cetomacrogol—The equilibrium dialysis technique was used to study the interaction of chlorocresol with cetomacrogol. The dialysis membrane was either Membrane 1 or 3. An aqueous solution of chlorocresol in cetomacrogol was placed in one side of the cell, and water or water plus chlorocresol was placed in the other. Two glass beads were added to each compartment to ensure continuous mixing, and the cells were rotated in the water bath at 25°. The cholorocresol in both chambers was analyzed spectrophotometrically at 280 nm. after 4 days, and the volume of solution in each chamber was measured.

Table I—Change of Surfactant Concentration in Equilibrium Dialysis with Cellophane as a Semipermeable Membrane

Cetomacrogol Concentration, $M \times 10^3$			
M_1, Initial	M_2, Calculated from Volume Change[a]	M_3, Calculated Using Eq. 2[b]	M_4, Permeated at 96 hr.[c]
38.46	33.88	31.60	2.19
76.92	62.06	55.42	7.23

[a] Each value represents the mean of five readings. [b] Values were obtained by substituting n_1K_1 and n_2K_2, calculated from the binding curve obtained using the silicone rubber membrane (Fig. 3), and $[D_b]$ and $[D_f]$, obtained using the cellophane membrane (Fig. 3), into Eq. 2. Each value represents the mean of five readings. [c] From Fig. 1.

RESULTS AND DISCUSSION

Permeability of Membranes to Cetomacrogol—Figure 1 shows the fraction of cetomacrogol dialyzed through Membranes 1 and 2 as a function of time in equilibrium dialysis. Both membranes are permeable to cetomacrogol at approximately the same rate. The silicone rubber membrane, Membrane 3, was completely impermeable to the nonionic surfactant. Figure 2 shows the permeability of Membrane 1 to cetomacrogol using dynamic dialysis under sink conditions. Increases in the volume of solution in the surfactant chamber of the equilibrium dialysis cell and the cellophane bag used in the dynamic dialysis technique showed that osmosis had occurred.

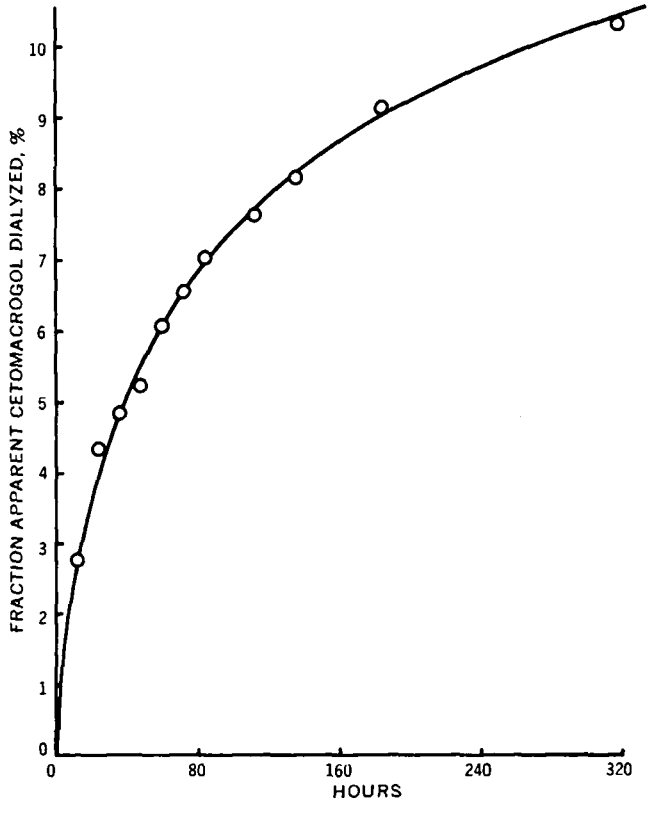

Figure 2—*Permeability of Membrane 1 to cetomacrogol in dynamic dialysis under sink conditions. Initial cetomacrogol concentration was 76.92* × *10*$^{-3}$ M. *The fraction dialyzed was not corrected for changes in surfactant concentration due to osmosis.*

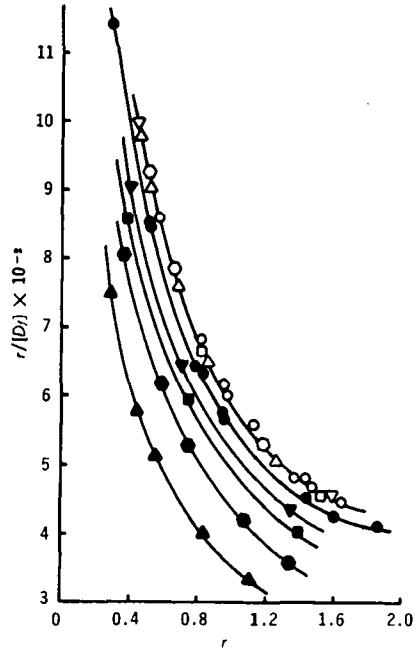

Figure 3—*Scatchard plot for the interaction of chlorocresol with cetomacrogol. Initial cetomacrogol concentrations were:* ○, *7.69* × *10⁻³* M; ▽, *15.3* × *10⁻³* M; □, *23.07* × *10⁻³* M; ○, *38.46* × *10⁻³* M; *and* △, *76.92* × *10⁻³* M. *Closed and open symbols represent data obtained using Membranes 1 and 3, respectively.*

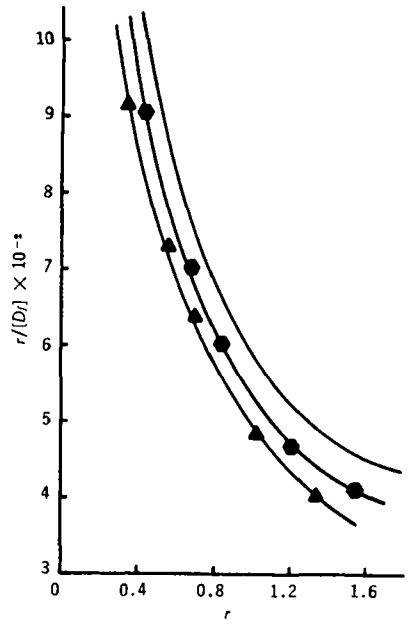

Figure 4—*Scatchard plot for the interaction of chlorocresol with cetomacrogol. The upper binding curve was obtained using the silicone rubber membrane as in Fig. 3. Cellophane membrane data were corrected for changes in surfactant concentrations due to osmosis. Initial concentrations were as listed in Fig. 3; corrected concentrations are shown in Table I.*

Ultrafiltration of cetomacrogol solution (1.8%) through Membrane 2 showed that 2.7% of the total surfactant passed through the membrane.

Interaction of Chlorocresol with Cetomacrogol—The binding results in the form of a Scatchard plot (22) are shown in Fig. 3. The binding of chlorocresol with cetomacrogol is independent of surfactant concentration when silicone rubber is used as the dialysis membrane. Similar independence of surfactant concentration was reported previously for the binding of several other preservatives with cetomacrogol when nylon was used as the dialysis membrane (17). The binding constants were estimated from the slope of the curve in the region of interest. In this work, however, the curve was characterized according to Eq. 1 on the assumption that two classes of binding sites are involved in the interaction:

$$\frac{[D_b]}{[M]} = r = \frac{n_1K_1[D_f]}{1 + K_1[D_f]} + \frac{n_2K_2[D_f]}{1 + K_2[D_f]} \qquad \text{(Eq. 1)}$$

where:

$[D_f]$ = concentration of free preservatives in the aqueous phase
$[D_b]$ = concentration of preservative bound to surfactant
$[M]$ = concentration of surfactant
n_1 = number of independent binding sites of Class I on the surfactant molecule
n_2 = number of independent binding sites of Class II on the surfactant molecule
K_1 = intrinsic association constant for the binding of a molecule of preservative to one of the binding sites of Class I
K_2 = intrinsic association constant for the binding of a molecule of preservative to one of the binding sites of Class II

The experimental data are indicated by points, while the solid lines were fitted according to the n and K values computed from Eq. 1 using a nonlinear regression program.

Figure 3 shows that when a cellophane dialysis membrane was used, the binding is apparently not independent of cetomacrogol concentration and a series of curves are obtained. Theoretically, such results indicate that an increase in the concentration of cetomacrogol results in a decrease in the number of binding sites on the cetomacrogol molecule. However, since the results obtained with the silicone rubber membrane are independent of surfactant concentration, it is suggested that changes in cetomacrogol concentration due to dilution as a result of osmosis and/or to permeation of surfactant through the cellophane membrane provide a more likely explanation. Permeation of sufficient cetomacrogol into the surfactant-free chamber of the dialysis cell would lead to an increase in the apparent value of $[D_f]$ due to micellar interaction with the chlorocresol and, therefore, decrease the ratio $r/[D_f]$ for a given r value. Moreover, loss of surfactant by permeation through the membrane would also decrease r due to the uncorrected decrease in the value of $[M]$ and the decrease in $[D_b]$. Thus, a plot of $r/[D_f]$ *versus* r for different concentrations of cetomacrogol would result in a series of curves, each representing a given surfactant concentration. Dilution of cetomacrogol as a result of osmosis would produce a similar displacement of the binding curves.

The surfactant concentration required to produce the observed displacement of the binding curves was calculated from a rearrangement of Eq. 1:

$$[M] = \frac{[D_b](1 + K_1[D_f] + K_2[D_f] + K_1K_2[D_f]^2)}{[D_f](n_1K_1 + n_2K_2 + n_1K_1K_2[D_f] + n_2K_1K_2[D_f])} \qquad \text{(Eq. 2)}$$

where $[D_b]$ and $[D_f]$ are the experimental values for the cellophane membrane (Fig. 3) and n_1, K_1, n_2, and K_2 are the binding constants obtained using the silicone rubber membrane. The data in Table I show that the changes in surfactant concentration (*i.e.*, differences between the initial and calculated cetomacrogol concentrations, $M_1 - M_3$) were considerably greater than could be accounted for solely by loss of surfactant as a result of permeation through the cellophane membrane, M_4. However, when the binding curves are replotted using surfactant concentrations corrected for volume changes in the chambers of the dialysis cell, M_2, the discrepancies between the curves determined using the silicone rubber membrane and the cellophane membrane are markedly reduced (Fig. 4).

Since the difference between M_2 and M_3 is of the same order of magnitude as M_4, the residual displacement of the binding curves can be attributed to the decrease in $[M]$ due to permeability of the cellophane membrane to cetomacrogol.

Hence, it can be concluded that the observed displacement of the binding curves obtained in the equilibrium dialysis study using cellophane membranes is due both to osmosis and to permeability of the membrane to the surfactant, with dilution of surfactant as a result of the osmotic differential across the membrane being the major factor. The use of cellophane as a membrane will introduce appreciable errors into interaction and transport studies involving nonionic surfactants unless corrections are made for osmosis.

Tremor Induction by Intracaudate Injections of Bretylium, Tetrabenazine, or Mescaline: Functional Deficits in Caudate Dopamine

P. M. LALLEY*‡, G. V. ROSSI*, and W. W. BAKER†▲

Abstract □ Tremor responses were evoked by intracaudate injections of tetrabenazine, bretylium, or mescaline in cats with chronically implanted recording electrodes and microinjection cannulas. The characteristics of the maximal tremors with each agent closely resembled those induced by increased levels of cholinergic activity in the caudate (previously reported). These maximal tremors, like the cholinergic tremors, were suppressed by local injections of catecholamines (dopamine and epinephrine), scopolamine, or hemicholinium but were intensified by intracaudate serotonin. Although local acetylcholine had no effect on established tremor activity, tremors abolished by hemicholinium were reestablished by small doses of acetylcholine. These results suggested that interference with local dopamine inhibitory mechanisms ("functional dopamine deficiency") was the basis for the tremorgenic actions of bretylium, tetrabenazine, and mescaline; the findings also indicated that sustained endogenous acetylcholine activity in the caudate was a necessary condition for the development and maintenance of tremor activity. These data lend support to the hypothesis that an imbalance in the caudate between dopamine inhibition and acetylcholine excitation in favor of the latter results in tremors.

[a] (−) = tremor activity abolished; (+) = tremor activity intensified. [b] Doses of dopamine, epinephrine, or serotonin represent their respective bases (mean ± standard error). [c] Activity ratio = number of tremor inhibitions (or intensifications)/total number of trials.

pyramidal symptoms developing after systemic administration of neuroleptic drugs have been attributed to reduced dopamine functioning (7, 8).

The present investigation was undertaken to explore the relationship between dopamine and acetylcholine in tremor, utilizing tetrabenazine, bretylium, and mescaline as pharmacological tools. The purposes were to ascertain whether interference with caudate dopamine mechanisms was tremorgenic and to determine whether acetylcholine was involved in this tremorgenic process.

EXPERIMENTAL

Thirty-two male cats (3.0–4.5 kg.) were used in these studies. Under pentobarbital anesthesia, permanent bipolar assemblies[1], consisting of microinjection cannulas and recording electrodes, were implanted stereotaxically in both caudate nuclei (R. and L. Caud.) at Horsley-Clarke coordinates A_{15}, R_5, and L_5, D + 5 (9). Bipolar twisted electrodes were also positioned in the cortex and other subcortical recording sites. All electrodes were externalized to a 15-pin plug[2], which was fixed to the skull with acrylic dental cement and hard wax. Details of the assembly and microinjection technique were described previously (2, 10, 11).

After a recovery period of at least 2 weeks, the unanesthetized cat was suspended in a canvas hammock and positioned so that its hindlimbs were extended. Motor and electrographic responses were monitored on an oscilloscope and recorded on an electroencephalograph. Tremor activities were detected by a phonocartridge transducer[3] affixed to the dorsal surface of one hindfoot. Tremor responses were analyzed in terms of amplitude, percent tremor time, tremor frequency, and number of tremor bursts per minute, which provided an accurate assessment of relative tremor intensity (1, 10). The maximal tremor response is characterized in terms of the amplitude of the recorded involuntary movement oscillations (microvolts) for any given dose of drug.

All microinjections were made into the head of the right or left caudate through the bipolar assemblies[1] by way of a delivery cannula coupled to a calibrated micrometer-driven hypodermic syringe. Only one caudate nucleus was utilized for drug injection in any given experiment. Concentrations (0.1–1.5%) of drug solutions for intracaudate injections were adjusted so that microinjected volumes usually did not exceed 10 μl. Pilot experiments showed that alterations in pH and tonicity of drug solutions over a wide range produced no discernible effect on tremorgenesis or on other drug responses. Solutions of the following compounds prepared in distilled water were employed: bretylium tosylate, mescaline hydrochloride, tetrabenazine methanesulfonate, acetylcholine chloride, physostigmine sulfate, epinephrine bitartrate, dopamine hydrochloride, serotonin creatinine sulfate, hemicholinium-3 hydrobromide, and scopolamine hydrochloride. Drug quantities specified in the text refer to those of their respective bases.

Animals were rested at least 1 week between experiments. At the end of the study, after each brain was fixed in formalin, placements of the electrodes and permanent bipolar assemblies[1] were verified by examination of their tracts and the electrolytic lesions at the electrode tips.

	Activity ratio	6/6	6/6	7/7
	Duration[e]			

[a] (−) = tremor activity abolished; (0) = no effect on tremor activity. [b] Doses of acetylcholine or scopolamine represent their respective bases (mean ± standard error). [c] Activity ratio = number of tremor inhibitions/total number of trials. [d] Duration not followed; tremors reestablished by intracaudate injection of acetylcholine chloride (15–30 mcg.). [e] Duration of inhibition not followed; higher doses of scopolamine, after initially blocking tremors, evoked behavioral effects and involuntary movements, distinguishable from the test tremors elicited by tetrabenazine, bretylium, or mescaline.

RESULTS

Tremor Characteristics—Tetrabenazine, bretylium, and mescaline were tremorgenic over a range of doses (50–175 mcg.); the intensity and duration of tremor responses were proportional to the dose. Only the tremor responses to the higher doses of each drug were quantified; only in these higher doses was maximal tremor maintained throughout the entire experimental period of 5–6 hr.

As indicated in Table I, the tremors generated by these agents were more intense and of longer duration than the cholinergic tremors evoked by 150 mcg. intracaudate physostigmine (2). Bretylium had the most rapid onset of action, mescaline was intermediate, and tetrabenazine exhibited the longest latencies for onset and development of maximal tremor. The mean intracaudate doses required for comparable maximal tremor responses and duration were: tetrabenazine, 161 mcg.; bretylium, 112 mcg.; and mescaline, 64 mcg. Tremor characteristics (bursts per minute, tremor frequency, and percent tremor time) were similar for these three compounds and did not differ appreciably from those recorded during physostigmine (cholinergic) tremors. Neither autonomic nor behavioral changes were observed with any of the drugs while the animals were tremoring.

Effect of Intracaudate Monoamines on Tremors—The effects of microinjected dopamine, epinephrine, or serotonin when superimposed on ongoing maximal tremors induced by intracaudate tetrabenazine, bretylium, or mescaline are summarized in Table II. Intracaudate injections of the catecholamines (dopamine and epinephrine) temporarily abolished all three types of maximally developed tremors. Figure 1 illustrates the progressive changes in the development of tremors to maximal intensities, their subsequent inhibition by dopamine, and recovery with the return of tremor activity. Based on the doses required for maximal tremor suppression, epinephrine was six to seven times more potent than dopamine, but their respective latencies and durations of tremor inhibition were comparable. Mescaline tremors required appreciably higher doses of the catecholamines than the other two tremorgenic agents for complete suppression. Tetrabenazine tremors, although the most susceptible to suppression with dopamine, recovered to maximal intensities more rapidly than those of bretylium or mescaline.

In contrast to the catecholamines, intracaudate injection of serotonin, even at relatively low doses, intensified all three types of tremors, as evidenced by significant increases in essentially all tremor parameters (*i.e.*, amplitude, percent tremor time, and duration of tremor). However, these tremor intensities declined steadily to preserotonin levels within 25–60 min.

Intracaudate Cholinergic Agents on Tremors—Intracaudate acetylcholine, at a dose of 32 mcg., produced no discernible changes in tremor activity or electrograph patterns when injected during periods of maximal tremors induced by each of the three tremorgenic agents (Table III); this dose of acetylcholine is substantially below that (>500 mcg.) shown to be tremorgenic in the caudate (10). Comparable small doses of acetylcholine injected during the declining phases of these tremors also failed to alter existing tremor intensities. By contrast, local injections of hemicholinium, an agent known to interfere with acetylcholine synthesis, abolished all three types of tremors within 33–45 min., with no evidence of spontaneous recovery with the reestablishing of tremor activity during the experimental period. This inhibition of tremor was accompanied by bilateral synchronous slow waves in the caudate nuclei and postcruciate (frontal) cortex (Fig. 2). Parallel changes in behavior, autonomic functioning, or respiration were not evident. In all experiments, tremor suppressed by hemicholinium was readily restored (within 8–20 min.) by minimal supplemental doses (12–24 mcg.) of acetylcholine. This reestablished tremor activity usually persisted for less than 30 min. before declining. Nontremorgenic doses (6–13 mcg.) of physostigmine, when added to the acetylcholine injection, extended the duration of the reestablished tremor well beyond 1 hr.

Scopolamine, when microinjected into the caudate, also abolished the maximal tremors evoked by each of the three tremorgenic agents within 13–30 min. (Table III). The relatively high doses of scopolamine (>120 mcg.) required in the present study to suppress tremor (contrasting with scopolamine doses of less than 25 mcg. that suppress cholinergic tremors) produced another type of involuntary motor activity. These movements were slower (10–20 c.p.s.) rotational excursions of the hindlimb and were readily distinguished from the characteristic maximal tremor (21–25 c.p.s.).The involuntary movements generated by large doses of scopolamine were accompanied by pronounced autonomic (mydriasis), behavioral (apparent disorientation and distress), and electrographic (caudate-localized and projected synchronous slow waves) changes. In contrast to the inhibitory action of hemicholinium, tremor suppression by scopolamine was not reversed by intracaudate acetylcholine.

DISCUSSION

Although significant differences exist in their neuropharmacological actions (12), several lines of evidence support the position that tetrabenazine, bretylium, and mescaline share a common basis for their local tremorgenic actions in the caudate, namely interference with the level of dopamine functioning. The characteristics of their tremor responses (frequencies, bursts per minute, and tremor time) were strikingly similar; however, there were appreciable differences in their tremorgenic potencies (mescaline > bretylium > tetrabenazine) and in their onset and time sequences for reaching peak activity. It is significant that their tremor activities were quite comparable to the tremor type characterized previously during increased cholinergic activity in the caudate (10) and also that the catecholamines (dopamine and epinephrine) and hemicholinium were highly effective in suppressing cholinergic tremor (1, 2) as well as "dopamine-deficiency" tremors described in the current investigation. Because of its putative neurotransmitter role (13), attention

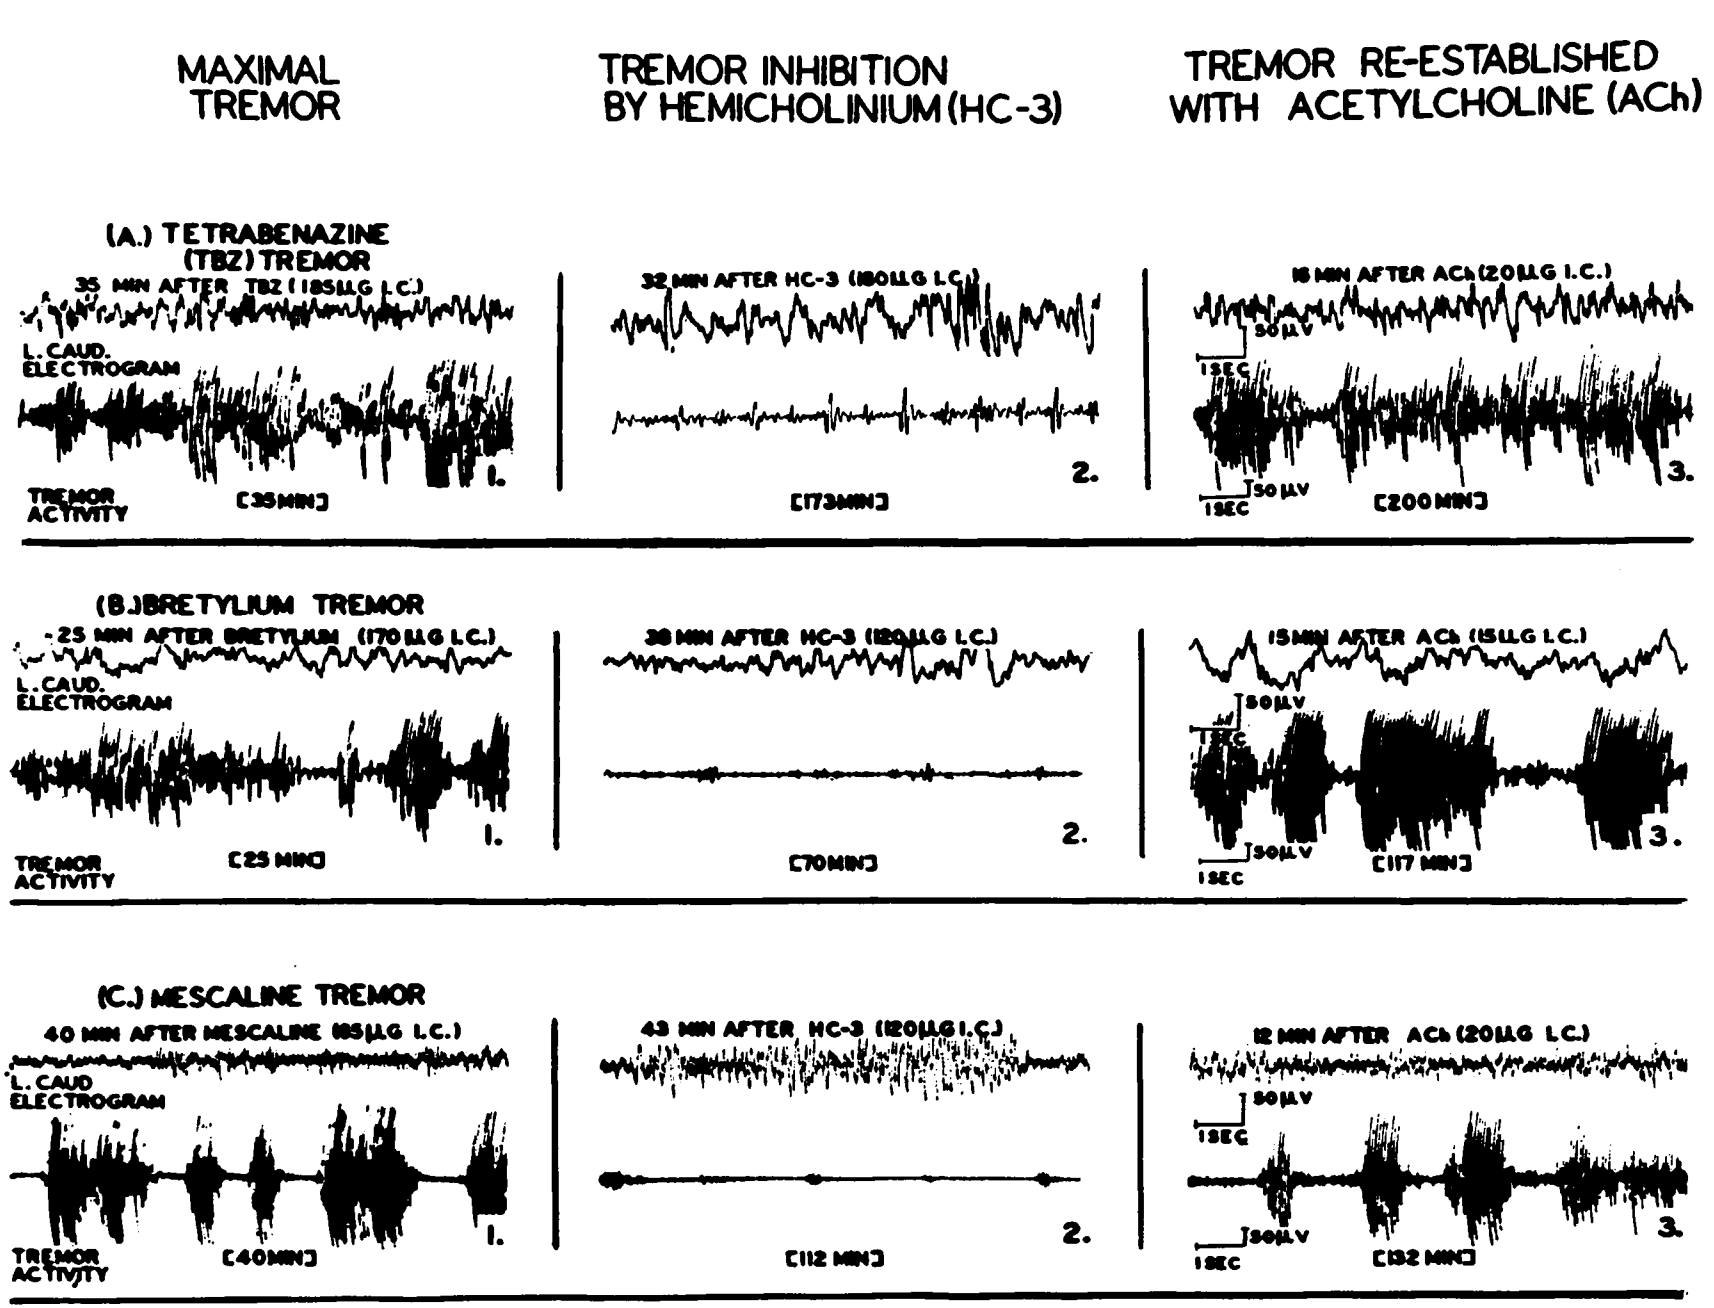

Figure 2—*Inhibition of maximal tetrabenazine (TBZ), bretylium, and mescaline tremors by intracaudate injections of hemicholinium-3 (HC-3). Tremors were reestablished temporarily by intracaudate supplemental injections of acetylcholine (ACh). Doses of acetylcholine represent its chloride salt.*

was directed to the functional status of dopamine (rather than epinephrine) in the caudate. The interpretation that seems most consistent with the present data and previous findings with cholinergic tremor is that interference with local dopamine functioning results in a relative increase (or imbalance) in favor of acetylcholine activity, which then causes tremors. In keeping with this is the proposal that the effects of acetylcholine in the caudate are excitatory and that, under stable conditions, these effects are offset by the local inhibitory action of dopamine (3, 14).

Since levels of dopamine in the caudate were not determined chemically, evidence is lacking to substantiate this interpretation directly. However, a consideration of the neuropharmacology of the three agents may establish a relationship to their ability to impair the functioning of endogenous dopamine. Bretylium, by virtue of its quaternary structure, is limited in its access to the brain; but when administered systemically, bretylium is taken up by tissues having a relatively high concentration of dopamine (15). Thus, it would be reasonable to expect that microinjected bretylium might be localized in dopamine-containing axon terminals of the caudate nucleus and, by analogy with its peripheral antiadrenergic actions (16), that it may elicit tremors by interfering with the release of intracaudate dopamine. Along parallel lines, tetrabenazine, like reserpine, depletes catecholamines (as well as serotonin) in the CNS by blocking ATP-dependent uptake of monoamines into storage granules (17). Of the monoamines in question, a deficiency of serotonin is ruled out as the basis for the tremors in these studies, since supplemental microinjected serotonin intensified tetrabenazine tremor responses whereas dopamine suppressed them. It thus appears that tetrabenazine tremor can be linked more appropriately to a deficiency of dopamine.

Mescaline and other *O*-methylated derivatives of dopamine were reported (18, 19) to produce tremors experimentally. Tremorgenic effects of intracaudate mescaline in cats demonstrated in this study essentially parallel the findings by Little and Dill (19) of dyskinesias after injection of mescaline into the caudate–putamen complex in rats. Dill (14) attributed mescaline dyskinesias in part to blockade of adrenergic inhibitory receptors, which in turn upsets a hypothesized local acetylcholine–dopamine balance. Results of the present studies tend to support this general proposition. Apparently, mescaline also exerts an "intrinsic," nonadrenergic, tremorgenic action since various other adrenergic receptor blocking agents (chlorpromazine and propranolol) neither suppress the dyskinetic excitatory effects of mescaline (14) nor are themselves tremorgenic when injected into the caudate (1). Significantly, on brainstem neurons, microinjected mescaline blocked only the inhibitory actions of the catecholamines without affecting the excitatory ones (20). The higher doses of dopamine required to suppress mescaline tremors, in comparison to doses that suppressed bretylium or tetrabenazine tremors, might be explained by the effective dopamine receptor blocking action of mescaline.

The data also underscore the key role of local acetylcholine in the development and maintenance of tremor activities with all three agents. This is evidenced not only by hemicholinium suppression of tremor and by restoration of this activity with acetylcholine but also by antagonism with scopolamine. However, since neither tetrabenazine nor bretylium nor mescaline had an apparent anticholinesterase action (no potentiation of low doses of microinjected acetylcholine), the involvement of acetylcholine as a necessary condition for these tremors may be attributed to a resulting predominance of endogenous cholinergic mechanisms. This appears to have a bearing on the increased cholinergic hyperactivity secondary to decreased dopamine functioning noted in clinical Parkinsonism (21).

It is concluded that tetrabenazine, bretylium, and mescaline are tremorgenic because they each produce, by somewhat different mechanisms, a functional dopamine deficiency in the caudate. Yet, for the development and maintenance of these tremors, a sustained endogenous acetylcholine activity in the caudate is essential. The data thus add support to the hypothesis that the excitatory effects of acetylcholine and the inhibitory actions of dopamine in the caudate are critically balanced and, as such, represent an important local system for regulating motor activity.

Use of Thermal Gravimetric Analysis, GLC, and Mass Spectrometry in Sorption Studies III: Evaluation of Clustering Functions of Ethanol–Water–Polyurethane System

G. W. C. HUNG*, L. J. NUNEZ, and J. AUTIAN▲

Abstract □ An equilibrium sorption study on the ethanol–water–polyurethane system over an extended ethanol concentration range was conducted by means of thermal gravimetric analysis, GLC, and mass spectrometry. From a single dynamic experiment, the equilibrium solubility in and the activation energy of desorption from the polymer matrix were evaluated simultaneously. The equilibrium sorption behavior of ethanol and water in the polymer matrix was interpreted in terms of the modified Zimm–Lundberg clustering theory applied to the liquid phase. The results indicate that the activation energy for desorption of ethanol decreases to a minimum and then increases with an increasing amount of sorption. The clustering function suggests that there is a greater tendency for ethanol molecules to cluster in the polymer matrix at lower ethanol activity but that there is no tendency for water molecules to cluster together. Water molecules show ideal sorption behavior at high water content and localized sorption on specific polymer sites at lower water content. Below 43% by weight or 0.51 activity, ethanol demonstrates ideal behavior; but at higher ethanol compositions, localized sorption takes place. There is also a great tendency for ethanol and water molecules to cluster together in the polymer matrix. The mean cluster size for ethanol is 1.4–2.5 molecules, while that for ethanol–water is 2.5–3.9 molecules.

Keyphrases □ Ethanol–water–polyurethane system—clustering functions evaluated using thermal gravimetric analysis, GLC, and mass spectrometry □ Polyurethane–water–ethanol system—clustering functions evaluated using thermal gravimetric analysis, GLC, and mass spectrometry □ Polymer–solute (solvent) interactions—clustering functions of ethanol–water–polyurethane system □ Clustering of penetrant molecules in polymer matrix—studied using thermal gravimetric analysis, GLC, and mass spectrometry, Zimm–Lundberg theory □ Sorption of solvent molecules in polymer matrix—clustering functions of ethanol–water–polyurethane system □ Thermal gravimetric analysis—determination of clustering functions for ethanol–water–polyurethane system □ GLC—determination of clustering functions for ethanol–water–polyurethane system □ Mass spectrometry—determination of clustering functions for ethanol–water–polyurethane system

Previous studies in these laboratories demonstrated the usefulness of thermal gravimetric analyses in sorption studies of selected liquid compounds with nylon (1) and with the diffusion and solubility of a series of aliphatic alcohols in polyurethane (2). This report continues these studies, exploring the clustering effects of sorbed molecules in a specific polyurethane using thermogravimetry, GLC, and mass spectrometry. Since polyurethanes have a wide range of applications in medicine, pharmacy, and dentistry, the information presented here should be of fundamental value in understanding aspects of solute (or solvent)–polymer interactions.

The tendency for penetrant molecules or solvent molecules to cluster in the polymer matrix can be interpreted by the Zimm–Lundberg clustering theory. Zimm (3) and Zimm and Lundberg (4) modified the formulas for the theory of solutions proposed by Kirkwood and Buff (5) and applied them to solvent vapor–high polymer systems.

The Zimm–Lundberg clustering theory was developed on the basis of statistical mechanical considerations employing molecular distribution functions. This theory has one advantage over others in that it gives a direct measurement of nonrandom mixing of penetrant molecules in the polymer phase without the use of any preconceived model. It thus shows how the sorption process changes with increasing solvent content from one of sorption on a few highly specific sites to a diffuse swelling phenomenon. It has been found useful and applicable to the treatment of vapor phase sorption data of solvent–high polymer systems (4, 6–9) in molecular terms at isothermal conditions. However, the present report is concerned with equilibrium sorption measurements of the ethanol–water–polyurethane system in the liquid phase as a function of widely varying concentrations or activities of ethanol at 25 ± 0.1°. The possible mechanism of sorption behavior of penetrant molecules in the polymer matrix is also discussed.

The amount of equilibrium sorption of penetrant molecules (included are ethanol and water molecules) in the polyurethane film was measured by thermal gravimetric analysis. From a single dynamic (nonisothermal) thermal gravimetric analysis experiment, the solubility (equilibrium sorption value) of penetrant molecules in and the activation energy for desorption of penetrant molecules from the polyurethane film were determined simultaneously at a specific ethanol activity. The amount of sorption of individual water molecules was obtained from thermal gravimetric analysis sorption data by assuming a constant amount of water sorbed in the polyurethane film independent of the amount of ethanol sorbed in the film. Mass spectrometry was also used to estimate the ethanol–water composition of the sorbed material. The activity of ethanol in the vapor phase at equilibrium with the ethanol–water–polyurethane system was measured by GLC. Then the clustering functions for penetrant molecules in the polyurethane film at each different ethanol activity were evaluated from the activity *versus* volume fraction sorption isotherms of the ethanol–water–polyurethane system.

THEORETICAL

Mathematical Derivatives of Clustering Functions—The original equation of Kirkwood and Buff (Eq. 19 of *Reference 5*) for a two-component system is:

$$G_{11}C_1 = kT\left(\frac{\partial C_1}{\partial P}\right)_{T,\mu_2} - 1 \qquad \text{(Eq. 1)}$$

Table I—Physical Properties of Ethanol and Water at 25°

where G_{11} and C_1 are the cluster integral and molecular concentration for type 1 molecules, respectively, k is the Boltzmann constant, T is the absolute temperature, P is the vapor pressure, and μ_2 is the chemical potential for component 2.

On the basis of some thermodynamic properties and relationships and by further mathematical modifications, Zimm (3) transformed Eq. 1 into:

$$\frac{G_{11}}{V_1} = -\phi_2\left[\frac{\partial(a_1/\phi_1)}{\partial a_1}\right]_{P,T} - 1 \qquad \text{(Eq. 2)}$$

or:

$$\frac{G_{11}}{V_1} = -(1-\phi_1)\left[\frac{\partial(a_1/\phi_1)}{\partial a_1}\right]_{P,T} - 1 \qquad \text{(Eq. 3)}$$

where a_1, ϕ_1, and V_1 are the activity, volume fraction, and partial molecular volume of type 1 molecules, respectively, and ϕ_2 is the volume fraction of component 2 (polymer material); G_{11}/V_1 is called the clustering function. It denotes a tendency for type 1 molecules to cluster in the polymer matrix. Three physical meanings may be considered:

Case I—If values of $G_{11}/V_1 > -1$, there will be a tendency for type 1 molecules to cluster together. In other words, the concentration of type 1 molecules is higher than average in the neighborhood of a given type 1 molecule. This is due to the fact that the first type 1 molecule enters the polymer structure, loosens the structure, and makes it easier for subsequent molecules to enter in the neighborhood of the first one than to go elsewhere.

Case II—If values of $G_{11}/V_1 = -1$, this shows ideal solution behavior. A particular type 1 molecule in such a system excludes its own volume to the other molecules but otherwise does not affect the distribution.

Case III—If values of $G_{11}/V_1 < -1$, this is interpreted in terms of localized sorption of type 1 molecules on specific sites.

Equation 3 is very useful, since the right-hand side of the equation is in terms of experimentally measurable quantities, activity (a_1), and volume fraction (ϕ_1) of type 1 molecules.

The quantity $\phi_1 G_{11}/V_1$ is a measure of the mean number of type 1 molecules in the neighborhood of a given type 1 molecule in excess of the mean concentration of type 1 molecules. The mean size of a cluster is given by $(\phi_1 G_{11}/V_1 + 1)$. This cluster size represents an overall average of the penetrant species (type 1 molecules).

Thermodynamic Activity of Type 1 Molecules—Thermodynamically, it is always true that at equilibrium at constant temperature and pressure the chemical potential of component 1 in the liquid phase, $\mu_1(L)$, is equal to the chemical potential of the same component in the vapor phase, $\mu_1(V)$. That is:

$$\mu_1(L) = \mu_1(V) \qquad \text{(Eq. 4)}$$

However, at pressures of a few atmospheres or less, the vapor phase obeys the ideal gas law, so that the chemical potential of component 1 in the vapor phase can be represented by Eq. 5:

$$\mu_1(V) = \mu_1^\circ + RT \ln P_1 \qquad \text{(Eq. 5)}$$

where μ_1° is the chemical potential of pure component 1 at the standard state of pure gas at $P = 1$ atm. and temperature T; R is the universal gas constant.

If component 1 in the liquid phase obeys Raoult's law, it is true that:

$$P_1 = P_1^\circ N_1 \qquad \text{(Eq. 6)}$$

and Eq. 5 can be rewritten as:

$$\mu_1(V) = \mu_1^\circ + RT \ln N_1 \qquad \text{(Eq. 7)}$$

where N_1 is the mole fraction of component 1 in the liquid phase, and μ_1° is the chemical potential of pure component 1 at the standard state of pure liquid at $N_1 = 1$ and temperature T.

If component 1 in the liquid phase deviates from Raoult's law, then:

$$P_1 \neq P_1^\circ N_1 \qquad \text{(Eq. 8}a\text{)}$$

but:

$$P_1 = P_1^\circ a_1 \qquad \text{(Eq. 8}b\text{)}$$

Therefore, Eq. 5 may be rewritten as:

$$\mu_1(V) = \mu_1^\circ + RT \ln a_1 \qquad \text{(Eq. 9)}$$

where a_1 is the activity of component 1 (that is, type 1 molecules) in the vapor phase in terms of the relative pressure, and μ_1° now represents the chemical potential at the standard state of pure liquid at $a_1 = 1$ or $N_1 = 1$ and temperature T. In this study, pure liquid ethanol at the mole fraction $N_E = 1$ or $a_E = 1$ and pure liquid water at the mole fraction $N_W = 1$ or $a_W = 1$ were taken as the standard states for type 1 molecules at a temperature of 25.0°.

Therefore, the activity of type 1 molecules in the liquid phase may be evaluated from measurements of the relative pressure, P_1/P_1°; these data, in turn, can be used in Eq. 3 to calculate the clustering functions.

EXPERIMENTAL

Materials—The solvent was reagent grade absolute ethanol, obtained commercially, and it was used without further purification. Doubly distilled water was used in all equilibrium sorption measurements. Table I summarizes some physical properties of ethanol and water.

The polyurethane was obtained[1] as a thin film. It is a thermoset solid polyurethane prepared by reacting a polyurethane prepolymer with 4,4′-methylenebis(2-chloroaniline). Its general properties are those of an elastomer (Table II).

Preparation of Samples—Test samples were punched from the polyurethane film with a paper punch, No. 1, 0.63-cm. diameter. Cylindrical-shaped samples were cut of 0.62-cm. diameter, 0.0770–0.0778-cm. thickness, and 25.5–27.2-mg. weight. All test samples for each different ethanol concentration or activity were as uniform as possible, and variation never exceeded 0.5% (thickness or weight) from sample to sample. The test samples were soaked in 95% ethanol for 48 hr. and then rinsed repeatedly with distilled water. An additional soaking in 50% ethanol for 24 hr., with subsequent rinsing with distilled water, was performed. Finally, the test samples were rinsed with acetone, dried to constant weight, and stored in a desiccator until ready for use.

Thirteen different aqueous ethanol solutions were prepared volumetrically. The concentrations of these solutions varied from 0 to 100% ethanol by volume. Eight pieces of approximately the same initial dry weight of polyurethane film were placed in an all-glass sorption tube containing 20.0 ml. of ethanol solution. The tubes were then stoppered (screw cap with Teflon-faced rubber liner) and immersed in a thermally controlled water bath adjusted to 25.0 ± 0.1°.

Preliminary measurements indicated that the equilibrium sorption occurred within several weeks. For uniformity, the sorption tubes with samples were kept in the water bath for exactly 30 days. After this time, the plastic sample was removed from the test ethanol solution and excess liquid was blotted with tissue paper. Immediately (within 70 sec.) the plastic sample was introduced into the thermal gravimetric analysis instrument, the sample weight was recorded, and a thermogram was run.

Thermal Gravimetric Analysis for Desorption Studies—Descriptions of the thermal gravimetric analysis instrument and the method of running a desorption experiment were presented previously (2); in the present study the desorption runs were made in a dynamic manner by increasing the temperature at a constant rate.

A stream of nitrogen was passed through concentrated sulfuric acid and then into the chamber containing the test sample, at a constant flow rate of 200 ml./min., to flush and remove any adhering gases or decomposed gaseous products evolved during the desorption experiment. The nitrogen gas, in turn, was led out of the chamber into a series of gas-washing bottles. After the sorbed plastic sample was placed in the thermal gravimetric analysis system, the instrument run was initiated and the weight loss *versus* temperature (and time) was recorded on chart paper until a constant weight was obtained. This thermogram was used for evaluation of the solubility of solvent molecules in and the activation energy for desorption of solvent molecules from the polymer film. The solubility was determined from the difference between the initial reading (equilibrium sorption value) and the constant weight reading on the thermogram after complete desorption. The activation energy for desorption was evaluated from the corresponding thermogram by employing Broido's method (1, 10). To ensure reproducibility, at least two test samples for each different group of ethanol solutions were run. The relative precision of the calculated solubility for each group of test samples was 2.5% or less. The reproducibility for activation energy of desorption was about 1.0–3.0%.

[1] Code No. MP950, Molded Products Co., Easthampton, Mass.

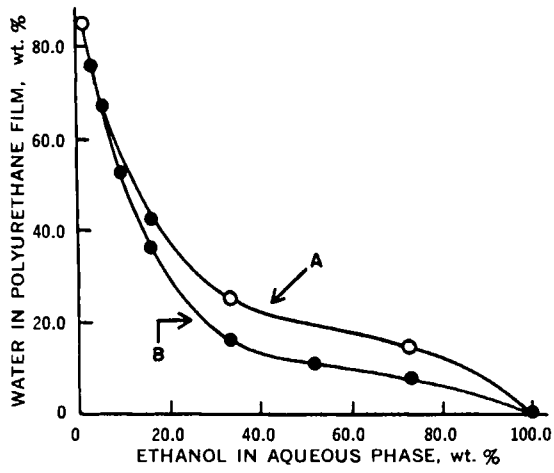

Figure 1—*Weight percent water in polyurethane film* versus *weight percent ethanol in aqueous phase at 25°. Key: A, mass spectrometry; and B, thermal gravimetric analysis.*

Determination of Ethanol Activity in Vapor Phase—The activity of ethanol, a_1, in the vapor phase above various concentrations of ethanol solutions can be determined in terms of relative pressure, P_1/P_1°, by GLC. Furthermore, at equilibrium at constant temperature and pressure, the following relations are true:

$$a_1 = \frac{P_1}{P_1^\circ} = \frac{\text{mole}_1}{\text{mole}_1^\circ} = \frac{(\text{mass/mol. wt.})_1}{(\text{mass/mol. wt.})_1^\circ} = \frac{\text{mass}_1}{\text{mass}_1^\circ} \quad \text{(Eq. 10)}$$

However, the area of the peak in GLC with a flame-ionization detector (FID) is:

$$\text{area}_1 = K_{\text{FID}}\text{mass}_1 \quad \text{(Eq. 11)}$$

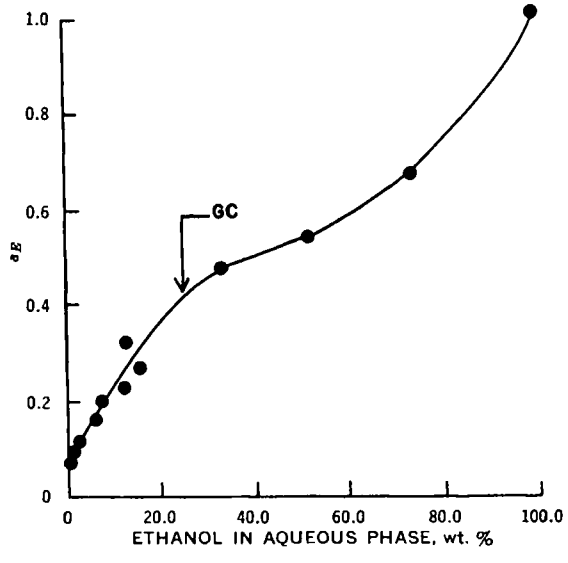

Figure 2—*Ethanol activity in vapor phase as a function of aqueous phase ethanol composition at 25°.*

Table IV—Volume Fraction Data for Ethanol–Water–Polyurethane System at 25 ± 0.1°

Initial Concentration of Aqueous —Ethanol Solutions— wt. %	moles/l.	ϕ_E	ϕ_W	ϕ_P
3.16	0.682	0.0066	0.0224	0.971
16.2	3.41	0.0468	0.0212	0.932
33.2	6.92	0.123	0.0190	0.858
52.1	10.2	0.192	0.0180	0.790
73.4	13.6	0.241	0.0160	0.743
100.0	17.0	0.271	0.0000	0.729

where K_{FID} is a proportionality constant for type 1 molecules.

Equation 11 shows that for a detector responding to the mass flow rate, the peak area is proportional to the total mass of the eluted component (11).

Similarly, for a pure component of type 1 molecules:

$$\text{area}_1^\circ = K_{FID}\text{mass}_1^\circ \qquad \text{(Eq. 12)}$$

Dividing Eq. 11 by Eq. 12, one gets:

$$\frac{\text{area}_1}{\text{area}_1^\circ} = \frac{K_{FID}\text{mass}_1}{K_{FID}\text{mass}_1^\circ} = \frac{\text{mass}_1}{\text{mass}_1^\circ} \qquad \text{(Eq. 13)}$$

Comparison of Eqs. 10 and 13 gives:

$$a_1 = \frac{P_1}{P_1^\circ} = \frac{\text{area}_1}{\text{area}_1^\circ} \qquad \text{(Eq. 14)}$$

Therefore, by simply measuring GLC peak areas for type 1 molecules in the vapor phase and then dividing by the peak area of pure type 1 molecules in the vapor phase, the activities of type 1 molecules were determined.

Determination of Volume Fraction of Type 1 Molecules in Polymer Film—Experimentally, the volume fraction, ϕ_1, for type 1 molecules can be evaluated from the following:

$$\phi_1 = \frac{V_1}{V_1 + V_p} = \frac{V_1}{V_{\text{total}}} \qquad \text{(Eq. 15)}$$

But:

$$V_1 = \frac{\text{wt.}_1}{D_1} \qquad \text{(Eq. 16a)}$$

$$V_p = \frac{\text{wt.}_p}{D_p} \qquad \text{(Eq. 16b)}$$

$$\phi_1 + \phi_p = 1 \qquad \text{(Eq. 16c)}$$

where V_1, wt.$_1$, and D_1 are equilibrium sorption volume, equilibrium sorption weight, and density, respectively, of type 1 molecules at the same temperature; V_p, wt.$_p$, and D_p are volume, weight, and density of the polymer film in that order; and ϕ_1 and ϕ_p are volume fractions of type 1 molecules and the polymer film, respectively.

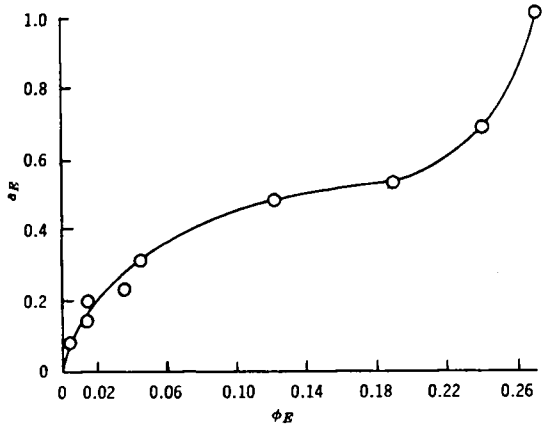

Figure 3—*Ethanol activity as a function of volume fraction of sorbed ethanol in polyurethane film at 25°.*

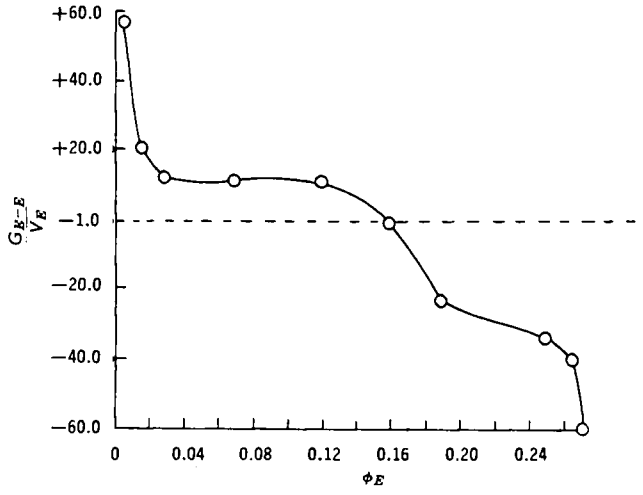

Figure 4—*Clustering function for ethanol in ethanol–water–polyurethane system at 25°.*

The equilibrium sorption weight of type 1 molecules was determined by thermal gravimetric analysis, and the density of type 1 molecules in the liquid state at the same temperature was obtained from the literature. The density of the polymer film was measured by the water or solvent displacement method with a pycnometer. Finally, ϕ_1 was calculated from the measured V_1 and V_p. By knowing ϕ_1, ϕ_p can be computed from Eq. 16c.

RESULTS AND DISCUSSION

Table III summarizes the sorption data and activation energy of desorption for the ethanol–water–polyurethane system at 25°. The total amount of sorption increases with increasing concentration of ethanol. The amount of sorption of pure water is about 7.0% of the amount of sorption of pure ethanol. The activation energy of desorption of solvent molecules from the polymer film decreases with an increasing amount of total sorption to a minimum and then increases again. This suggests a possible change in the sorption mechanism. The activation energy of desorption of pure water from the polymer film is a little higher than that of pure ethanol.

Figure 1 shows the plot of weight percent of water in the polyurethane film *versus* weight percent of ethanol in the liquid phase. The weight percent of water in the polyurethane film was differentiated from the total amount of sorbed solvent molecules in the film by mass spectrometry (open circles in Fig. 1). The other curve of Fig. 1 (black circles) was obtained from thermal gravimetric analysis sorption data by assuming a constant amount of water

sorbed in the polyurethane film independent of the amount of ethanol sorbed in the film. It is obvious that the two curves are very close. At higher concentrations of ethanol, the amount of sorption of water estimated by mass spectrometry is higher than that determined by thermal gravimetric analysis. Possibly, ethanol molecules may enhance the sorption of water molecules in the polymer film by breaking the hydrogen bonds in liquid water clusters and carrying more free water molecules into the polymer matrix.

Figure 2 shows the plot of ethanol activity as a function of weight percent of ethanol in the aqueous phase for the ethanol–water–polyurethane system. The activity of ethanol is directly proportional to the concentration of ethanol in the liquid phase. However, the activity of water, although not shown here, was computed from the partial vapor pressure of water in the ethanol–water binary system at 25.0° obtained from the literature (12).

Table IV lists some volume fraction data for the ethanol–water–polyurethane system at 25.0°. In general, the volume fraction of ethanol in the polyurethane film, ϕ_E, increases with an increasing concentration of ethanol in solution. The volume fraction of the polymer film, ϕ_P, shows opposite behavior, while ϕ_W for water does not vary significantly.

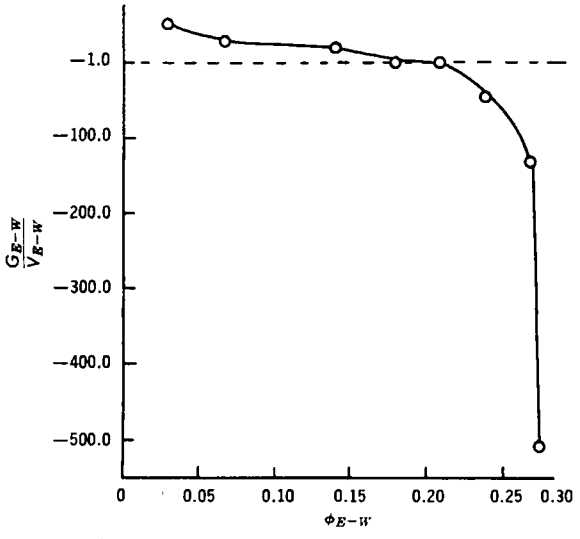

Figure 6—*Clustering function for ethanol and water mixtures in ethanol–water–polyurethane system at 25°.*

A typical plot of ethanol activity, a_E, *versus* volume fraction of ethanol, ϕ_E, is shown in Fig. 3. From this sorption isotherm, the clustering functions for ethanol molecules in the polyurethane film were evaluated. Similar treatments were performed for the evaluation of clustering functions of water molecules and of ethanol–water molecules in the polymer matrix.

The clustering function for ethanol molecules in the polyurethane film is plotted in Fig. 4 (numerical values are listed in Table V). It is obvious that there is a greater tendency for ethanol molecules (compared to water molecules) to cluster together at the smaller volume fractions of sorption (or at the lower concentrations or activities of ethanol, as can be seen from Table V), then pass through ideal behavior at a volume fraction of 0.16 (or activity of 0.51), and finally demonstrate localized sorption on specific polyurethane segment sites. The mean number of clustering is from 0.4 to 1.5, whereas the mean cluster size is about 1.4–2.5 molecules.

Figure 5 shows the clustering function for water molecules. Water molecules would not cluster together in this particular system. As can also be seen from Table VI, water molecules show a wide range of ideal sorption behavior from a low to a high ethanol concentration of 73.4% by weight and then show a localized sorption phenomenon.

By assuming that ethanol and water molecules may also cluster together in this particular system, the clustering functions for ethanol–water molecules were evaluated (Fig. 6 and Table VII). However, the activity of ethanol–water molecules, a_{E-W}, was taken from the square root of the product of the activities of ethanol and water molecules, and additive properties of the volume fractions were assumed. In general, the clustering phenomena for ethanol–water molecules are very similar to those of ethanol molecules themselves, except that the ideal behavior of ethanol–water molecules shifts from 43.4 to 52.1% by weight. The mean cluster number ranges from 1.5 to 2.9, and the mean cluster size ranges from 2.5 to 3.9 molecules.

In summary, the Zimm–Lundberg clustering theory was applied to the treatment of sorption data of the ethanol–water–polyurethane system in the liquid phase at 25 ± 0.1°. The results indicate that there is a greater tendency for ethanol molecules to cluster together than for water molecules. Water molecules in this particular system do not appear to cluster together, even though the evaluation of clustering functions for water molecules is only an approximation approach. The tendency for ethanol–water molecules to cluster together is high.

The mechanism or sorption behavior of ethanol and water molecules in the polyurethane film may be interpreted as follows. At the lower ethanol concentration or activity, the first ethanol or water

molecule enters the polyurethane chain structure, loosens the structure, and makes it easier for subsequent ethanol or water molecules to enter in the neighborhood of the first one than to go elsewhere; therefore, they cluster together. As the concentration or activity of ethanol increases, the amount of sorption increases. However, because the polyurethane film cannot swell enough for accommodation of excess penetrant molecules, ethanol and water molecules diffuse out from the initial position and become a homogeneously localized sorption phenomenon under the driving forces of concentration or chemical potential gradient. The binding forces for the ethanol–water–polyurethane system are through hydrogen-bond formation between ethanol and/or water molecules and the polar groups (such as urethane groups) of polyurethane segments. However, the hydrophobic properties of ethanol molecules play an important role in the interpretation of stronger affinity for ethanol molecules toward the polyurethane chain structure. The formation of water clusters (13) between liquid water molecules in the liquid phase gives a consistent explanation for the lower content of water sorbed in the polyurethane film.

Acceleration of Peritoneal Dialysis with Minimal *N*-Myristyl-β-aminopropionate

EMAD A. EL-BASSIOUNI* and ALBERT M. MATTOCKS▲

Abstract □ A single short-term exposure of the peritoneal membrane to *N*-myristyl-β-aminopropionic acid solution (0.25%) gave an accelerating effect on the peritoneal clearance of salicylate, barbiturate, and diphenylhydantoin, which lasted throughout several subsequent exchanges with standard dialysis fluid. A brief kinetic study on *N*-myristyl-β-aminopropionate was done, and its intraperitoneal absorption and urinary and peritoneal clearances are reported. The LD_{50} of this wetting agent in mice and its hemolytic threshold were also estimated.

Keyphrases □ Peritoneal dialysis of salicylate, barbiturates, and diphenylhydantoin—acceleration with *N*-myristyl-β-aminopropionate □ Salicylate, peritoneal clearance—acceleration with *N*-myristyl-β-aminopropionate □ Barbiturates, peritoneal clearance—acceleration with *N*-myristyl-β-aminopropionate □ Diphenylhydantoin, peritoneal clearance—acceleration with *N*-myristyl-β-aminopropionate □ *N*-Myristyl-β-aminopropionate—intraperitoneal absorption, urinary and peritoneal clearances, used to accelerate peritoneal dialysis of salicylate, barbiturates, and diphenylhydantoin

Previous work in this laboratory (1, 2) showed that the wetting agent *N*-myristyl-β-aminopropionic acid[1], when added to a standard dialysis fluid, accelerated the peritoneal removal of barbiturates, diphenylhydantoin, and salicylate. Since absorption of *N*-myristyl-β-aminopropionate from the peritoneum might occur during its use in dialysis and a hazard of added toxicity from this chemical might arise, an effort was made to attain its beneficial effects with minimum exposure. A priming lavage technique, devised in this laboratory and proven successful in accelerating peritoneal removal of urea (3), was used.

EXPERIMENTAL

Materials—Radioactive drugs were used to facilitate measurement of drug concentration. ^{14}C-Diphenylhydantoin was synthesized and purified by a published method (4). Solutions for injection were freshly prepared to contain 10 mg. diphenylhydantoin as the sodium salt and 1 μc./ml. and were injected at the level of 10 mg./kg. ^{14}C-Phenobarbital was obtained commercially[2], and the injection was prepared to contain 50 mg. phenobarbital as the sodium salt and 0.1 μc./ml. It was injected at the level of 50 mg./kg. ^{14}C-Pentobarbital was obtained commercially[2], and the injection contained 18 mg. pentobarbital as the sodium salt and 4 μc./ml. The pentobarbital dose was 18 mg./kg. ^{14}C-Amobarbital and ^{14}C-butabarbital were synthesized from ^{14}C-urea and the appropriate malonic esters (5). Their identity and purity were checked by IR spectrometry and paper chromatography, and their injections were prepared and used in the same manner as pentobarbital. ^{14}C-Salicylic acid was obtained commercially[2], and the injection contained 50 mg. salicylic acid as the sodium salt and 1 μc./ml. It was injected at the level of 100 mg./kg.

The control dialysis fluid was a typical formula with 377 milliosmoles/l. It contained dextrose (1.5%), sodium lactate (0.5%), sodium chloride (0.56%), calcium chloride (0.025%), and magnesium chloride hexahydrate (0.015%). *N*-Myristyl-β-aminopropionic acid dialysis fluid was prepared simply by dissolving 0.25% of the commercial solution in the control fluid. The only exception was in phenobarbital experiments where the concentration of the surfactant was increased to 0.5%. This change came as a result of preliminary work in which weaker solutions were used and the clearances obtained showed high variations.

Intermittent Dialysis—Healthy, mature, male albino rabbits were used as the experimental animals. They were administered ^{14}C-tagged drug intravenously *via* the marginal ear vein, and 1 hr. was allowed for drug distribution in the body before beginning dialysis. At that time a blood sample was taken and 60 ml./kg. of dialysis fluid was rapidly injected intraperitoneally *via* a pediatric-size catheter. At the end of the prescribed dwell time, the dialysate was drained by gravity, over 10 min., through the same catheter into a graduated cylinder. At the end of drainage, another blood sample was taken and the next exchange of fluid was rapidly injected. The volume of return dialysate was measured for each exchange, it was mixed thoroughly, and a sample was taken for measurement of drug concentration.

Preliminary work showed that a single short-term exposure of the peritoneum to a 0.25% *N*-myristyl-β-aminopropionate solution gave an accelerated dialysis effect which lasted throughout several subsequent exchanges with ordinary control fluid. A similar short-term exposure to control fluid had no significant effect on subsequent exchanges. On this basis, the test animals were given a priming lavage with *N*-myristyl-β-aminopropionate fluid, in which the dialysis fluid was allowed to remain in the peritoneum for 5 min. and then was drained for 10 min., giving a 15-min. first cycle. Then five 30-min. exchanges were run with control fluid, each consisting of a 20-min. dwell period and a 10-min. drainage. Control tests consisted of the same procedure except for elimination of the 15-min. exposure to *N*-myristyl-β-aminopropionate fluid.

Measurement of Drug Concentration—For salicylate and phenobarbital, since the amount of drug metabolized in the 3-hr. experiment is negligible (1, 2), 0.5-ml. samples of plasma and dialysate were added directly to the counting fluid [0.01% 1,4-bis-2-(phenyloxazolyl)benzene and 0.4% 2,5-diphenyloxazole in a solvent of 33% nonionic surfactant[3] and 67% toluene]. Samples thus prepared were counted in a liquid scintillation spectrometer[4] using the channels ratio method for quench correction.

A new procedure was developed for pentobarbital assay in which a sample of 1.0 ml. plasma or 2.0 ml. dialysate was transferred to a centrifuge tube, acidified with 0.4 ml. of 0.5 *N* HCl, and extracted four times with 3-ml. portions of ether. The ether extracts, containing all the unchanged pentobarbital and small amounts of metabolites, were evaporated to dryness. The residue was dissolved in about 0.05 ml. of ether and quantitatively spotted on a 20 × 20-cm. sheet of Whatman No. 2 chromatography paper. The chromatogram was developed in a chromatography chamber[5] with *n*-amyl alcohol–concentrated ammonium hydroxide (90:10 v/v). This system gave average R_f values of 0.90 for pentobarbital and 0.10 for metabolites. After drying, the chromatograms were viewed under UV light to locate the pentobarbital spots. The spots were cut out, placed in counting vials containing 10 ml. scintillation cocktail, shaken well, and counted. Application of this method to samples of known concentrations gave recoveries of 97% or better.

[a] Each entry represents the average clearance for five exchanges on one animal. [b] From previous work (1). [c] Average ± standard error of the mean. [d] From previous work (2).

Amobarbital and butabarbital were extracted completely from acidified samples with 4 × 5 ml. ether. Contamination by metabolites was less than 3%, as determined by paper chromatography. Extracts were evaporated in counting vials, scintillation fluid was added, and they were then counted.

For diphenylhydantoin, the samples were acidified with 0.5 *N* HCl, extracted with 2 × 5 ml. chloroform, which was evaporated in counting vials, and counted in the usual manner.

In each case, an exact dilution of radioactive injection was counted with the samples as a standard.

Studies on *N*-Myristyl-β-aminopropionic Acid—Absorption of the wetting agent *N*-myristyl-β-aminopropionate from the peritoneum might occur during its use in dialysis. High blood levels coupled with low excretion rate might prove hazardous to the health of the patient undergoing dialysis as a result of accumulation of this chemical in the body. Therefore, it was thought pertinent to determine whether this agent is absorbed during its passage across the peritoneum and, if so, to what degree and how rapidly it would be removed in subsequent exchanges. From these data, it would be possible to estimate the likelihood of toxicity.

Since a reliable method for quantitative determination of *N*-myristyl-β-aminopropionic acid could not be found, ^{14}C-tagged compound was used to measure its concentration in body fluids. The synthesis was performed in this laboratory. The first step involved the preparation of ^{14}C-tetradecanitrile by the method of Friedman and Shechter (6), using 1-bromotridecane and ^{14}C-sodium cyanide in dimethyl sulfoxide. The nitrile was reduced to tetradecylamine-1-^{14}C by sodium butoxide in toluene (7). *N*-Myristyl-β-aminopropionate was then prepared by reacting the amine with 20% excess of methyl acrylate. The product was saponified with an equivalent amount of 50% NaOH solution after the excess methyl acrylate was removed at 100° under vacuum (8). The identity and purity of each intermediate compound and the final product were checked with TLC and IR spectrometry. The overall yield of *N*-myristyl-β-aminopropionate was 42%, with a specific activity of 0.373 μc./mg.

To estimate the amount of wetting agent that might be absorbed in a single peritoneal lavage, absorption was measured over a longer period than just a 15-min. cycle. This afforded measurements useful even if lavages of different cycle times were used. The rabbits were prepared for the experiment in the same manner as mentioned previously. The dialysis fluid, containing 0.125% radioactive *N*-myristyl-β-aminopropionate (equivalent in concentration to 0.25% of the commercial solution) was injected at the same level and using the same procedure as before, except that the fluid was left in the peritoneum for 3 hr. Samples of blood and dialysate were taken 5 min. after injection, at 10-min. intervals for the 1st hr., at 20-min. intervals for the 2nd hr., and at 30-min. intervals for the 3rd hr. The samples were counted directly for total radioactivity.

To determine the rate of disappearance from plasma and the urinary clearance of *N*-myristyl-β-aminopropionate, two rabbits were given an intravenous dose of 30 mg. radioactive compound in normal saline. Plasma and urine samples were collected every 10 min. for the 1st hr. and every 20 min. for the following 2 hr. The samples were counted directly.

To determine the peritoneal clearance of *N*-myristyl-β-aminopropionate, a rabbit was injected intravenously with ^{14}C-labeled compound at the level of 10 mg./kg. A 30-min. period was allowed for distribution in the body before commencing dialysis. Five dialysis cycles with control fluid were carried out, each consisting of a 20-min. dwell time and a 10-min. draining period. Plasma, dialysate, and urine samples were collected and directly counted in the liquid scintillation spectrometer.

To determine the hemolytic threshold and the concentration of *N*-myristyl-β-aminopropionate producing 50% hemolysis, a series of dilutions of the surfactant in normal saline, ranging from 2 to 74 mcg./ml., was prepared. Normal saline was used as the negative control (no hemolysis), and a 1% solution of sodium carbonate in saline was used as a positive control (100% hemolysis). Ten milliliters of each solution was placed in a centrifuge tube and kept in a water bath at 37° for 30 min. to provide temperature equilibration. Then 0.1 ml. of heparinized rabbit whole blood was added to each tube and incubated at the same temperature. At the end of 1 hr., the tubes were centrifuged for 10 min. at 60,000 r.p.m. and the supernatant solutions were carefully removed and measured in a spectrophotometer at 540 nm.

To obtain an estimate of the LD_{50} of *N*-myristyl-β-aminopropionate in mice, young, healthy, male albino animals (15–28 g.) were used. They were divided into five groups, each containing five mice.

	Total	1.30	Av. 0.16	

[a] Experiment on Animal E-27, which weighed 2.30 kg. The dialysis cycle time was 30 min.

Four doses of commercial *N*-myristyl-β-aminopropionate, ranging from 250 to 1000 mg./kg., were selected due to a pilot experiment. These doses were administered intraperitoneally as a 1% solution in normal saline to four test groups, and the control group received 2 ml. normal saline. The animals were put under observation for 24 hr.

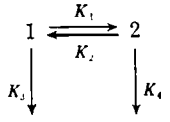
RESULTS

Results of intermittent dialysis of the drugs tested are shown in Table I, where each entry represents the average clearance of five exchanges on one animal. Previously reported results for control fluid were added for comparison. It can be seen that a 15-min. lavage with *N*-myristyl-β-aminopropionate fluid accelerated the peritoneal removal of all drugs tested. The highest increases in clearance were observed with salicylate and diphenylhydantoin, where clearance values about 2.5 times control were obtained. With the barbiturates, clearances ranged between 1.4 and 1.9 times control.

The high affinity of diphenylhydantoin for plasma protein appears to be the underlying cause for its low clearance. If the unbound diphenylhydantoin is considered to be 14% of the total plasma concentration over the range studied (1), the calculated average dialysate–plasma ratio of free drug is found to be 0.50 with control dialysis and 0.99 with the priming lavage technique. In this case, the protein binding of diphenylhydantoin seems to be the rate-limiting step during dialysis and equilibrium between drug in plasma and dialysate is rapidly attained. Therefore, peritoneal removal of diphenylhydantoin could be further accelerated by much shorter dwell periods.

Typical plasma and peritoneal fluid curves demonstrating intraperitoneal absorption of *N*-myristyl-β-aminopropionate are illustrated in Fig. 1. The plasma level did not exceed 2.7 mcg./ml. in the first 5 min., corresponding to the dwell period in a lavage. After 15 min., a period that would allow absorption to continue during drainage, the level did not exceed 7 mcg./ml. The absorption of wetting agents was quite rapid, as reflected in the dialysate curve, with about 30–50 mg./kg. being absorbed in a 15-min. period.

The plasma curves following intravenous injection were biexponential, indicating a two-compartment model. Of several two-compartment models possible, only one gave an acceptable fit to the urine curve as shown in Scheme I, where 1 is the central compartment including the plasma, 2 is a peripheral tissue compartment (possibly largely the liver), K_1 and K_2 are distribution constants between the two compartments, K_3 is the urinary excretion constant, and K_4 represents direct elimination from the tissue compartment (possibly elimination *via* the bile). The constants may be found by solving a biexponential equation obtained from the plasma curve alone, but it was considered preferable to solve it with an analog computer which would utilize the cumulative urine curve as well



Scheme I

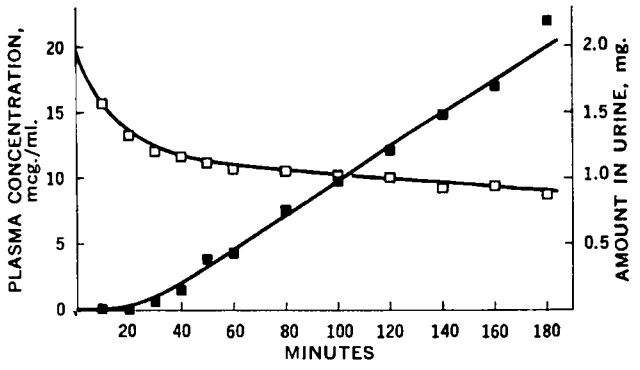


Figure 2—*Plasma and urine curves following intravenous administration of* N-*myristyl-β-aminopropionate to Animal E-24. The lines are computer drawn. Key:* □, *plasma; and* ■, *urine.*

as plasma data. This was done with the data of Animal E-24, as illustrated in Fig. 2, and the rate constants were estimated to be as follows: $K_1 = 1.60 \times 10^{-2}$ min.$^{-1}$, $K_2 = 2.08 \times 10^{-2}$ min.$^{-1}$, $K_3 = 1 \times 10^{-5}$ min.$^{-1}$, and $K_4 = 1.25 \times 10^{-3}$ min.$^{-1}$. These constants demonstrate the relatively low rate of urinary excretion as compared to the presumed biliary excretion. Also, the high distribution volumes, 152% for the central compartment and 380% for the equilibrium distribution volume, explain the relatively low plasma concentrations found in these experiments. The model fitted to these data should not be accepted as an established one for this compound, since it is based on limited data, but it was the only one that satisfactorily fit the data available.

The removal of *N*-myristyl-β-aminopropionate from the body by peritoneal dialysis with control fluid is summarized in Table II. Once absorbed, the wetting agent is slowly removed by peritoneal dialysis. The peritoneal clearance was only 0.16 ml./min., as compared to a urinary clearance of 0.58 ml./min. measured in the same experiment.

The data for the hemolysis experiment are illustrated in Fig. 3, where the results, as percentage hemolysis, were plotted against the concentrations of *N*-myristyl-β-aminopropionate used, to give a dose-response curve. The concentration giving 50% hemolysis was estimated to be 63.2 mcg./ml. It was also found that below 15 mcg./ml. no hemolysis occurred. The plasma level of *N*-myristyl-β-aminopropionate remained below 7 mcg./ml. for the first 15 min. during the intraperitoneal absorption experiment, thus being well below the hemolytic threshold.

The results of the LD_{50} experiment were plotted (Fig. 4) as the logarithms of the doses administered against the probit effects according to the method of Miller and Tainter (9). The best fitting line was calculated by the least-squares method, and the LD_{50} of *N*-myristyl-β-aminopropionate in mice was estimated to be 620 mg./kg. with a standard error of ±136.

DISCUSSION

The data obtained in this study clearly confirm the earlier findings in this laboratory (1, 2) that *N*-myristyl-β-aminopropionic acid has an accelerating effect on the peritoneal clearance of salicylate, barbiturates, and diphenylhydantoin. Of particular interest is the

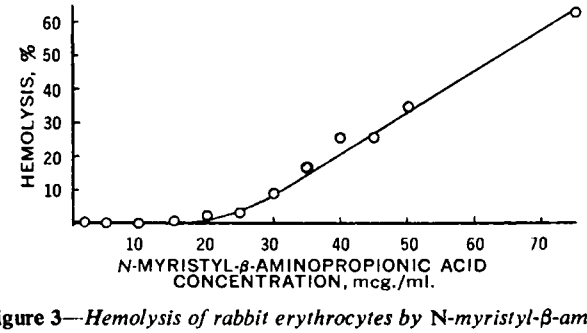

Figure 3—*Hemolysis of rabbit erythrocytes by* N-*myristyl-β-aminopropionate.*

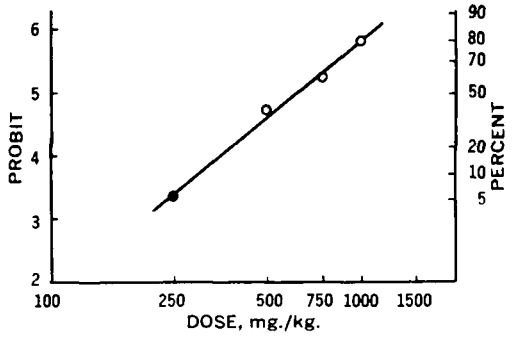

Figure 4—*LD_{50} of N-myristyl-β-aminopropionate in mice.*

finding that a single short-term exposure of the peritoneal membrane to *N*-myristyl-β-aminopropionate solution gave an accelerated dialysis effect which lasted throughout at least five subsequent exchanges with standard dialysis fluid. This would make possible the effective use of this accelerator with minimum exposure to the patient. The absorption tests also demonstrated that, although *N*-myristyl-β-aminopropionate is rapidly taken up from the dialysis fluid, the resulting plasma levels are quite low and appear to be well below concentrations that would result in acute toxicity. With its comparatively short 5-hr. biological half-life (as calculated from the terminal phase of the blood curves), practically all surfactant absorbed into the circulation should be eliminated from the blood in less than 48 hr. These findings should enhance the potential for the clinical use of *N*-myristyl-β-aminopropionate as an accelerator during peritoneal dialysis. Further toxicological studies are essential, of course, before this substance might be tested in man.

The mechanism of action of the surfactant is not yet known. Studies to determine the mechanism are being conducted but are not yet conclusive.

Survival of *Staphylococcus aureus* on Pharmaceutical Oral Solid Dosage Forms

ROBERT F. WATERMAN, EDWARD D. SUMNER▲, JACK N. BALDWIN, and FLYNN W. WARREN

Abstract □ The relationship of temperature, relative humidity, size of inoculum, and duration of storage on survival of *Staphylococcus aureus* inoculated onto surfaces of 17 commercial tablets and one gelatin capsule was determined. The data were analyzed using a two-way factorial analysis of variance. Decreased survival was associated with an increase in each of the variables, within limits of the experiment; within those limits, size of inoculum and storage time were the least significant factors and storage environment appeared to be the most significant.

Keyphrases □ *Staphylococcus aureus* inoculation—surface of commercial tablets and capsules, effects of temperature, relative humidity, size of inoculum, and storage time on survival □ Tablet and capsule surface inoculated with *Staphylococcus aureus*—effects of temperature, relative humidity, size of inoculum, and storage time on survival □ Sterility testing, tablets and capsules inoculated with *Staphylococcus aureus*—effects of size of inoculum, storage time, and environmental conditions on survival

The necessity for sterility of parenteral products has long been recognized. NF V was the first official compendium in the United States to require sterility for such products (1). With respect to distribution and use of nonsterile pharmaceuticals, it is now recognized that microbial contamination must be minimal; with respect to certain species, it is totally unacceptable. Kallings *et al.* (2) focused attention on microbial content of nonsterile products when they reported infections resulting from the use of contaminated medications. The Swedish National Board of Health is restricting levels of microbes that may be present in liquid and tableted preparations (3), and a policy of not allowing an excess of 100 colonies/g. for practically all medical preparations was adopted (4). Czechoslovakia adopted statutory microbiological standards for tablets (5).

Numerous studies (6–12) confirmed existence of microbial contamination in some products. Hirsch *et al.* (13) reported that 82% of 57 oral liquid products tested contained microorganisms, and other researchers (14) found more than 100 microorganisms/ml. in 40 of 489 samples of such preparations. USP XVIII now includes a statement regarding microbial contamination of nonsterile pharmaceutical products (15).

The purposes of this study were to: (*a*) determine the ability of solid pharmaceutical dosage forms to carry bacteria; and (*b*) investigate the effect of temperature, relative humidity, size of inoculum, and storage time on

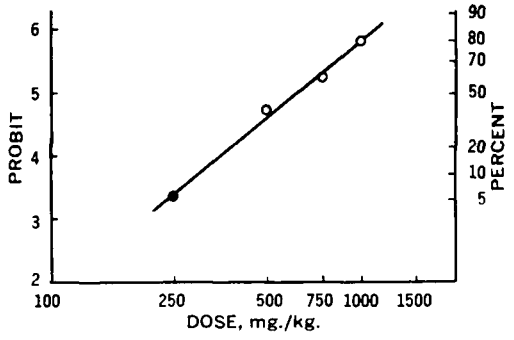

Figure 4—*LD_{50} of N-myristyl-β-aminopropionate in mice.*

finding that a single short-term exposure of the peritoneal membrane to *N*-myristyl-β-aminopropionate solution gave an accelerated dialysis effect which lasted throughout at least five subsequent exchanges with standard dialysis fluid. This would make possible the effective use of this accelerator with minimum exposure to the patient. The absorption tests also demonstrated that, although *N*-myristyl-β-aminopropionate is rapidly taken up from the dialysis fluid, the resulting plasma levels are quite low and appear to be well below concentrations that would result in acute toxicity. With its comparatively short 5-hr. biological half-life (as calculated from the terminal phase of the blood curves), practically all surfactant absorbed into the circulation should be eliminated from the blood in less than 48 hr. These findings should enhance the potential for the clinical use of *N*-myristyl-β-aminopropionate as an accelerator during peritoneal dialysis. Further toxicological studies are essential, of course, before this substance might be tested in man.

The mechanism of action of the surfactant is not yet known. Studies to determine the mechanism are being conducted but are not yet conclusive.

Survival of *Staphylococcus aureus* on Pharmaceutical Oral Solid Dosage Forms

ROBERT F. WATERMAN, EDWARD D. SUMNER▲, JACK N. BALDWIN, and FLYNN W. WARREN

Abstract □ The relationship of temperature, relative humidity, size of inoculum, and duration of storage on survival of *Staphylococcus aureus* inoculated onto surfaces of 17 commercial tablets and one gelatin capsule was determined. The data were analyzed using a two-way factorial analysis of variance. Decreased survival was associated with an increase in each of the variables, within limits of the experiment; within those limits, size of inoculum and storage time were the least significant factors and storage environment appeared to be the most significant.

Keyphrases □ *Staphylococcus aureus* inoculation—surface of commercial tablets and capsules, effects of temperature, relative humidity, size of inoculum, and storage time on survival □ Tablet and capsule surface inoculated with *Staphylococcus aureus*—effects of temperature, relative humidity, size of inoculum, and storage time on survival □ Sterility testing, tablets and capsules inoculated with *Staphylococcus aureus*—effects of size of inoculum, storage time, and environmental conditions on survival

The necessity for sterility of parenteral products has long been recognized. NF V was the first official compendium in the United States to require sterility for such products (1). With respect to distribution and use of nonsterile pharmaceuticals, it is now recognized that microbial contamination must be minimal; with respect to certain species, it is totally unacceptable. Kallings *et al.* (2) focused attention on microbial content of nonsterile products when they reported infections resulting from the use of contaminated medications. The Swedish National Board of Health is restricting levels of microbes that may be present in liquid and tableted preparations (3), and a policy of not allowing an excess of 100 colonies/g. for practically all medical preparations was adopted (4). Czechoslovakia adopted statutory microbiological standards for tablets (5).

Numerous studies (6–12) confirmed existence of microbial contamination in some products. Hirsch *et al.* (13) reported that 82% of 57 oral liquid products tested contained microorganisms, and other researchers (14) found more than 100 microorganisms/ml. in 40 of 489 samples of such preparations. USP XVIII now includes a statement regarding microbial contamination of nonsterile pharmaceutical products (15).

The purposes of this study were to: (*a*) determine the ability of solid pharmaceutical dosage forms to carry bacteria; and (*b*) investigate the effect of temperature, relative humidity, size of inoculum, and storage time on

the survival of *Staphylococcus aureus* on the surfaces of commercial products.

EXPERIMENTAL

Materials and Methods—The products (and their strength if applicable) were as follows: aspirin[1] (325 mg.), buffered aspirin[2] (325 mg.), sodium butabarbital[3] (100 mg.), chewable multiple vitamins[4], digitalis USP[5] (100 mg.), chlorothiazide[6] (500 mg.), a nasal decongestant[7], meprobamate[8] (400 mg.), a barbiturate–analgesic combination[9], a gelatin capsule[10], magnesia hydroxide[11] (325 mg.), tolbutamide[12] (500 mg.), pentaerythritol tetranitrate[13] (20 mg.), quinidine sulfate[14] (200 mg.), magaldrate[15] (400 mg.), methocarbamol with aspirin[16] (400 mg.), an antiasthmatic[17], and ethinamate[18] (500 mg.).

Survival tests were performed with *S. aureus* FDA 209[19] as the test organism, cultured in trypticase soy broth or on trypticase soy agar as appropriate. Relative humidity in the test chambers was maintained at 33, 52, or 85% (at 25°) by means of saturated solutions of magnesium chloride, magnesium nitrate, or potassium chloride, respectively (16). Potassium thiocyanate was employed as an indicator (17).

Sterilization—Products to be tested were placed in cotton-plugged erlenmeyer flasks (25 or 50 ml.) or culture tubes (25 × 130 mm.) and exposed to ethylene oxide[20] in a sterilizer[21] for 6 hr. at 55°. The efficiency of the sterilization cycle was determined by means of *Bacillus subtilis* indicator strips[22]. Sterility was rechecked after 1 week at ambient temperature by incubating control samples in 10 ml. sterile broth for 24 hr. at 37°.

Inoculation of Samples—Following the rechecking of sterility, samples were placed in humidity chambers and were inoculated after 1 week with 50 μl. of a suspension of the test organism prepared as follows:

1. Incubate broth culture 20 hr. at 37°.
2. Centrifuge.
3. Wash cells in 10 ml. sterile water.
4. Recentrifuge.
5. Resuspend in 10 ml. sterile water.

Capsules were inoculated by placing inoculum into one of the two parts, and tablets were inoculated by distributing the inoculum on the surface. All procedures were conducted in a laminar flow hood.

One, 3, and 7 days after inoculation and storage under the respective conditions, samples were placed in sufficient sterile water to make a final volume of 10 ml. They were permitted to stand for 1 hr. and then shaken. Then 50 μl. of the dispersion was streaked on agar plates; these plates were incubated at 37° for 48 hr., at which time colonies were counted.

Maintenance of sterility was verified by inoculating tablets (digitalis, chlorothiazide, and magaldrate) with sterile saline and subjecting them to the experimental conditions used in the study. To determine the basal survival rate of the microorganisms, filter paper disks[23] (12.7 mm. diameter) were inoculated because they are porous and nonbactericidal.

Contamination in Commercial Products—Commercial preparations were tested to determine the presence of microbial contaminants by transferring them aseptically from the original packages to tubes containing 10 ml. of broth. Six samples of each product were prepared. Following incubation at 37° for 24 hr., the tubes were examined for evidence of bacterial growth.

Effect of pH on Survival—To study the effect of pH on survival rates, tubes containing 10 ml. of distilled water, adjusted with acid or base to pH values of 2.5–10, were sterilized and inoculated with *S. aureus* (17.18×10^6 organisms). After 1 hr., 0.1-ml. samples were removed and streaked on agar plates. The plates were examined after incubation at 37° for 24 hr.

pH of Aqueous Dispersions of Tablets—Triplicate samples of products were placed in sufficient water to make 30 ml. After the tablets disintegrated, the pH of the resulting dispersions was measured.

Statistical Analysis—The data were analyzed using a two-way factorial analysis of variance. The variables involved were time

[a] Each value reported represents the average from counts of two tablets or capsules. (L) = 1.47×10^6 bacteria/sample. (H) = 13.57×10^6 bacteria/sample. [b] Group 4, 33% relative humdity; Group 5, 52% relative humidity; and Group 6, 85% relative humidity.

(three categories), level of inoculum concentration (two categories), and environmental storage conditions (three categories). The *F*-distribution was used as the test of significance in the analysis of variance.

RESULTS

The survival of *S. aureus* on solid dosage forms under conditions where storage time, temperature, and relative humidity were varied is reported in Table I. The data reveal decreased survival with increased temperature and storage time. *S. aureus* did not survive on eight samples (aspirin, the nasal decongestant, the barbiturate–analgesic combination, methocarbamol with aspirin, magnesia hydroxide, buffered aspirin, quinidine, and pentaerythritol tetranitrate tablets). There was a high frequency of survival on the gelatin capsules (8%) and magaldrate (5%) after 7 days under conditions that resulted in no survivors on 15 of the products.

Table II shows the percent survival of *S. aureus* after storage at a constant temperature of 25° when relative humidity and size of inoculum varied. Decreased survival rates were noted when relative humidity, storage time, and inoculum concentration were increased.

Tests on unsterilized pharmaceuticals revealed contamination of 12. Contaminants were not identified. Bacterial growth was not observed in the tubes containing aspirin, buffered aspirin, sodium butabarbital, the nasal decongestant, magnesia hydroxide, and methocarbamol with aspirin.

The pH of aqueous dispersions of the tablets ranged from 2.7 to 9.8. *S. aureus* did not survive in water outside the pH range of 4.0–8.6. Maximum survival was observed in the pH range of 7.0–8.6.

DISCUSSION

Sterility is not a requirement in official compendia for oral pharmaceutical dosage forms. However, contamination may occur during manufacturing, packaging, and handling by the consumer. This causes concern, since some dosage forms, if stored in favorable environments, can serve as substrates for microorganisms. Not all of the dosage forms studied supported bacterial (staphylococcal) contamination under the experimental conditions, suggesting that some pharmaceuticals are less likely than others to support bacterial survival (or at least survival of staphylococci).

Many factors determine whether a microorganism will survive on a solid dosage form. Active ingredient and formulation additives may have a profound effect on bacteria; in certain formulations, they may act as bactericidal agents. Environmental conditions such as humidity, temperature, and absence or presence of oxygen may give rise to unfavorable conditions for survival of bacteria. Other factors involved may be size of inoculum and length of storage (18).

Using aqueous solutions adjusted to varying pH's with acid or base, it was found that *S. aureus* did not survive except in the pH range of 4.0–8.6. Because the pH of aqueous dispersions of aspirin, the nasal decongestant, the barbiturate–analgesic combination, methocarbamol with aspirin, and magnesia hydroxide was outside the range of 4.0–8.6, pH was considered a major factor for *S. aureus* not surviving. However, lack of survival cannot be explained solely on the basis of pH since the other three tablets (buffered aspirin, quinidine, and pentaerythritol tetranitrate) did not permit survival even though aqueous dispersions were in the favorable pH range of 4.0–8.6. The formulation ingredients may be the reason for zero survival of *S. aureus* on these tablets, since bacteria survived on the filter paper disk control under the same experimental conditions.

At high relative humidities, the survival rate was reduced (Table II). A thin aqueous film may form on the surface of the solid dosage forms and, as the humidity increases, this aqueous film formation should increase. Not only would more water be available for the organism, but additional quantities of the soluble ingredients would be dissolved in the film and a greater bactericidal action would be exerted. The existence of a critical moisture content at which a bacterial cell becomes more susceptible to toxic agents has been postulated (19).

Table I shows that there were fewer survivors at 37° than at 28° where the relative humidities were similar. This may be due in part to increased solubility of tablet ingredients in the surface film at the higher temperature and the fact that the bactericidal action of chemical agents is greater at higher temperatures (18). Consequently, there would be a greater bactericidal effect on *S. aureus*.

The frequency of survivors on nine samples after storage for 7 days at 25° and 33% relative humidity was 100–1000-fold higher than on the control filter paper disks, indicating that ingredients in the samples protected the *S. aureus*.

High and low concentrations of inoculum were used to determine the effect on survival rates, because some medications may be more contaminated than others. Differences between percent survivals were noted; in general, the highest survival rate was observed with the lower inoculum concentrations. The differences were not statis-

tically significant, and no explanation can be offered for these results.

The size of inoculum and storage time (within the limitations of the experiment) were less significant factors. Storage conditions appeared to be the most significant factor.

Numerous variables were inherent in the study, and the data are inconclusive. Future studies may provide data to explain the differences in survival rates of *S. aureus* on solid dosage forms.

Physical–Chemical Properties of Substituted Amides in Aqueous Solution and Evaluation of Their Potential Use as Solubilizing Agents

PATRICK P. DeLUCA▲, LEON LACHMAN*, and HANS G. SCHROEDER

Abstract □ The tetramethyl-substituted amides of pimelamide, suberamide, azelamide, and sebacamide markedly enhance the solubility of glutethimide in aqueous solution. Partition studies, surface tension measurements, and light-scattering measurements strongly suggest that the amides are associating at infinitely dilute concentrations and further aggregation of these associated molecules occurs with the possible formation of micelles at concentrations slightly higher than that observed for surfactants. The CMC's were identified at 0.41, 0.20, 0.031, and 0.11 *M* for pimelamide, suberamide, azelamide, and sebacamide, respectively. The solubility of glutethimide was increased significantly above the critical concentrations and, from the nature of the solubility curves, a micellar type of solubilization appears to be dominant.

Keyphrases □ Amides, tetramethyl substituted—partitioning, surface tension, and light-scattering measurements in aqueous solution, potential solubilizing agents (solubilization of glutethimide) □ Pimelamide, tetramethyl, as potential solubilizing agent—partitioning, surface tension, and light-scattering measurements in aqueous solution, solubilization of glutethimide □ Suberamide, tetramethyl, as potential solubilizing agent—partitioning, surface tension, and light-scattering measurements in aqueous solution, solubilization of glutethimide □ Azelamide, tetramethyl, as potential solubilizing agent—partitioning, surface tension, and light-scattering measurements in aqueous solution, solubilization of glutethimide □ Sebacamide, tetramethyl, as potential solubilizing agent—partitioning, surface tension, and light-scattering measurements in aqueous solution, solubilization of glutethimide □ Solubilizing agents, potential—tetramethyl-substituted amides □ Glutethimide solubility—effect of tetramethyl-substituted amides

The formulation of a suitable dosage form for administration *via* the oral, parenteral, and topical routes is often a problem with drugs that have only limited water solubility. For oral administration, a solution would preclude the requirement for dissolution as in the case of suspensions or solid dosage forms and facilitate passage of the drug across the lipid membrane. For topical preparations, a homogeneous system would facilitate percutaneous absorption; for parenteral administration, a solution is generally desirable, especially *via* the intravenous route.

Nonaqueous solvents are often combined with water to dissolve a sparingly soluble drug even for injectable preparations (1), and the solvent selected must be free of toxic and irritating effects and not give rise to pharmacological responses. Two-component solvent systems

tically significant, and no explanation can be offered for these results.

The size of inoculum and storage time (within the limitations of the experiment) were less significant factors. Storage conditions appeared to be the most significant factor.

Numerous variables were inherent in the study, and the data are inconclusive. Future studies may provide data to explain the differences in survival rates of *S. aureus* on solid dosage forms.

Physical–Chemical Properties of Substituted Amides in Aqueous Solution and Evaluation of Their Potential Use as Solubilizing Agents

PATRICK P. DeLUCA▲, LEON LACHMAN*, and HANS G. SCHROEDER

Abstract □ The tetramethyl-substituted amides of pimelamide, suberamide, azelamide, and sebacamide markedly enhance the solubility of glutethimide in aqueous solution. Partition studies, surface tension measurements, and light-scattering measurements strongly suggest that the amides are associating at infinitely dilute concentrations and further aggregation of these associated molecules occurs with the possible formation of micelles at concentrations slightly higher than that observed for surfactants. The CMC's were identified at 0.41, 0.20, 0.031, and 0.11 *M* for pimelamide, suberamide, azelamide, and sebacamide, respectively. The solubility of glutethimide was increased significantly above the critical concentrations and, from the nature of the solubility curves, a micellar type of solubilization appears to be dominant.

The formulation of a suitable dosage form for administration *via* the oral, parenteral, and topical routes is often a problem with drugs that have only limited water solubility. For oral administration, a solution would preclude the requirement for dissolution as in the case of suspensions or solid dosage forms and facilitate passage of the drug across the lipid membrane. For topical preparations, a homogeneous system would facilitate percutaneous absorption; for parenteral administration, a solution is generally desirable, especially *via* the intravenous route.

Nonaqueous solvents are often combined with water to dissolve a sparingly soluble drug even for injectable preparations (1), and the solvent selected must be free of toxic and irritating effects and not give rise to pharmacological responses. Two-component solvent systems

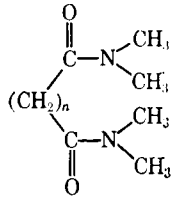
and hydrotropic agents have been employed and, more recently, surfactants have been used extensively.

The subject of micellar solubilization was dealt with thoroughly in two recent reviews by Mulley (2) and Swarbrick (3); and while hydrotropic solubilization (4) has received less attention, the literature on this type of solubilization has increased. Hydrotropes differ from surface-active agents in that they presumably do not possess surface activity or do not form micelles at low concentrations. Monosubstituted and disubstituted α-hydroxy acid amides, which are effective solubilizers, have been classified as hydrotropes.

N,N-Dimethylacetamide has been employed in the preparation of many dosage forms containing poorly soluble drugs (5). Specifically, the solubilities of tetracycline and oxytetracycline have been increased in nonaqueous systems by the addition of *N,N*-dimethylacetamide (6) and other amides of β-hydroxybutyric acid, succinic acid, adipic acid, tartaric acid, glycolic acid, and salicylic acid (7). A comprehensive study of the solubility of a number of drugs in acid amide solutions was undertaken by Samejima (8). The increase in solubility of the drugs studied was of relatively low order.

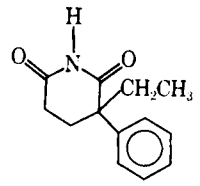
The excellent solvent properties of amides can be attributed in part to the strong dipole of the amide function and to the good electron-donating properties of the carbonyl group. Kostenbauder and Higuchi (9, 10) studied the molecular complexing tendencies of *N,N,N',N'*-tetramethylphthalamide series and some lower dicarboxylic acid amides and found increased solubility for chloramphenicol and *p*-hydroxybenzoic acid derivatives.

In light of these findings and on the basis of preliminary data for *N,N*-dimethylacetamide, *N*-methylpyrrolidone, and *N*-methylacetamide as solubilizing agents for poorly soluble drugs[1], it was felt that the higher homologs of *N,N,N',N'*-tetramethyl-substituted dicarboxylic acid amides were worthy of study. The general structure for the compounds selected is shown here. Hereafter these compounds will be referred to periodically simply as "amides."



pimelamide: $n = 5$
suberamide: $n = 6$
azelamide: $n = 7$
sebacamide: $n = 8$

The higher homologs were preferred because the inductive effect of the terminal amide groups upon each other would be negligible beyond succinamide where the functional groups are separated by three or more methylene groups. This type of structure would provide two, essentially independent, electron-donating groups



glutethimide

on a single molecule. Alkylation of the nitrogen groups was necessary to increase the solubility of the amides.

In this investigation, the properties of the amides in aqueous solution were studied and the potential solubilizing action of the amides was evaluated. Since the carbonyl group of an amide is a good electron donor, attraction for electron-accepting groups exists. Compounds possessing acidic hydrogen(s) such as alcohols, phenols, amines, xanthines, sulfonamides, and barbiturates should interact with the substituted amides. Glutethimide (2-ethyl-2-phenylglutarimide) is soluble to the extent of only 1 mg./ml. in water and it was selected for study.

Although glutethimide is a weak acid, having a pKa of approximately 11.8, it was felt that the hydrogen of the imide grouping would be sufficiently acidic to accept electrons. The tendency of the amides to associate or aggregate in aqueous solution was determined by partition studies and light-scattering measurements, and the surface activity of the amides was determined by surface tension measurements.

EXPERIMENTAL

Preparation of Amides[2]—The tetramethyl-substituted amides were prepared by reacting the corresponding acid chlorides with dimethylamine in alkaline media. Since only the azelaoyl and sebacoyl chlorides were commercially available, pimeloyl and suberoyl chlorides were prepared by reacting thionyl chloride with the dicarboxylic acids. Purification of the amides involved either vacuum distillation for the odd-carbon amides, pimelamide and azelamide, or recrystallization from acetone and hexane for the even-carbon amides, suberamide and sebacamide.

The purity of the amides was determined by vapor phase chromatography[3] and checked by differential scanning calorimetry[4] and elemental (C,H,N) analysis[5]. In all cases, the amides were found to be greater than 99% pure.

Solubility of Amides—The solubility of the amides was determined in distilled water at 30° in a constant-temperature water bath using the phase solubility technique (11). The amides were added to 20 ml. of distilled water in 30-ml. glass-stoppered bottles and agitated for 24 hr. The amide concentration in solution was determined by reaction with hydroxylamine (12); where excess amide was employed, the amount undissolved was weighed. The effect of added electrolyte on solubility was determined by adjusting the ionic strength of the solutions to 0.1 and 0.75 with potassium chloride.

Partitioning Studies—The amides were partitioned between organic and aqueous phases using chloroform–isooctane (12.5:87.5 v/v) as the organic phase and water as the aqueous phase. Twenty milliliters of the water phase of known amide concentration was placed in a special shaker tube (13), and 20 ml. of the organic phase was added. The tubes were agitated for 10 hr. at ambient condition at a rate of 1 c.p.m. The amount of amide partitioning into the organic phase was determined by GC employing the

Compound	Distilled Water	—Potassium Chloride— 0.1 *M*	0.75 *M*
Tetramethylpimelamide	Mixes in all proportions	Mixes in all proportions	Mixes in all proportions
Tetramethylsuberamide	2.52	2.50	1.14
Tetramethylazelamide	3.90	3.85	3.72
Tetramethylsebacamide	0.527	0.344	0.170

following conditions: 1.25% OV-225 on Chromosorb G, 1.8-m. × 0.635-cm. (6-ft. × 0.25-in.) column, column temperature 225°, detector temperature 280°, and injector temperature 285°.

Surface Tension Measurements—Surface tension measurements were made with a surface tensiometer[6] employing a platinum–iridium ring. The measurements were made at ambient conditions using 10 ml. of solution contained in a 5.1 × 1.3-cm. (2 × 0.5-in.) Petri dish. The ring had a circumference of 6.060 cm. and was thoroughly rinsed with 95% alcohol and heated to incandescence in a bunsen flame between measurements. Readings were allowed to stabilize, and an average of three readings was recorded for each concentration. The effect of sodium chloride and urea on the surface tension measurements was determined by adding sodium chloride or urea to the amide solutions. No correction was made for volume changes with sodium chloride, but with urea it was necessary to account for the volume change to correct the amide concentration.

Light-Scattering Measurements—A photometer[7] was utilized for light-scattering measurements at a wavelength of 436 nm. While the instrument measures absolute turbidity, the calibration was checked periodically with a polystyrene fraction of known molecular weight (105,000). The scattering cell was a sinter-fused optical glass cell which permitted readings at angles of 0, 45, 90, and 135° to the direction of the transmitted beam. The method employed was essentially the same as that used by Brice *et al.* (14) for the determination of absolute turbidity. The scattering intensities at an angle of 90° were used to determine the absolute turbidity. The turbidity due to the solvent was subtracted from the total values, and the difference represented the excess turbidity. It was necessary to filter the solutions several times through a 0.45-μ cellulose ester membrane filter[8] and to allow sufficient time for stabilization of the readings to occur.

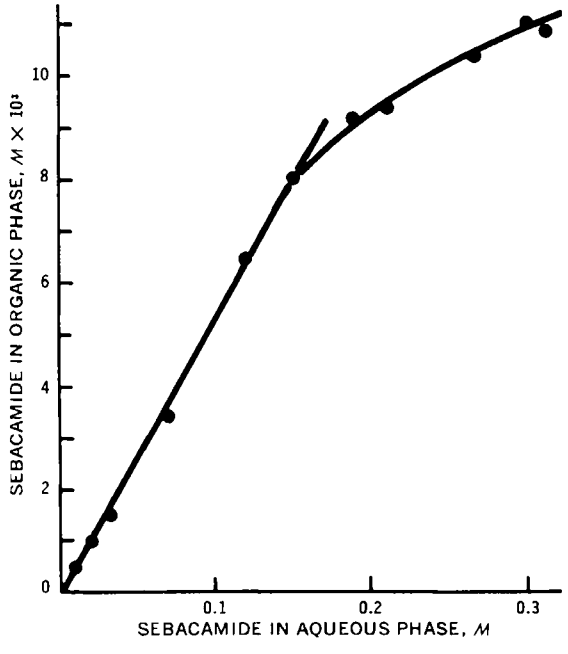

Figure 1—*Partitioning of tetramethylsebacamide between an organic phase of 12.5% chloroform in isooctane and an aqueous phase of water at room temperature.*

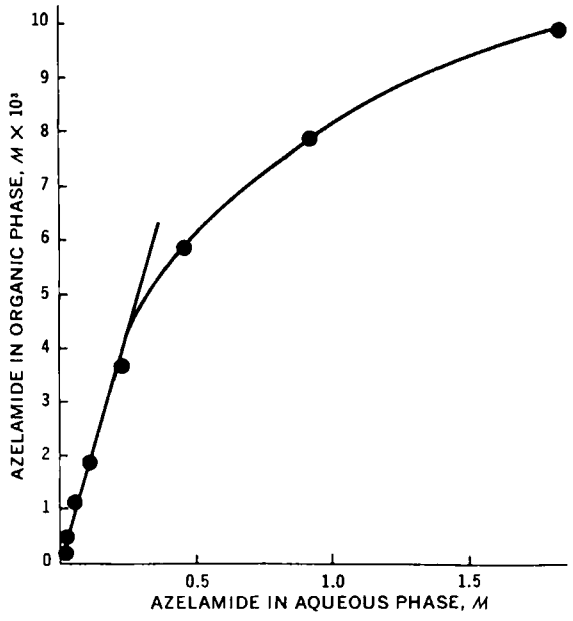

Figure 2—*Partitioning of tetramethylazelamide between an organic phase of 12.5% chloroform in isooctane and an aqueous phase of water at room temperature.*

The specific refractive index increments, *dn/dc*, were determined with a differential refractometer[9] at a temperature of 25° and a wavelength of 436 nm., using water as the solvent at five concentrations between 0 and 2.5%. Potassium chloride was used as a reference standard.

Solubilization of Glutethimide—Excess quantities of glutethimide[10], m.p. 84°, were placed into 30-ml. glass-stoppered bottles, and 20 ml. of solution of varying amide concentration was added. The bottles were tightly sealed and agitated in a constant-temperature water bath at 30° for at least 24 hr. until equilibration occurred. Equilibrium was determined by repetitive sampling, and it was found that 24 hr. of agitation was sufficient. The glutethimide concentration was determined spectrophotometrically using a spectrophotometer[11] with a recorder attachment at a wavelength of 257.6 nm. Anhydrous reagent methanol was used as the diluent for the drug samples.

RESULTS AND DISCUSSION

Aqueous Solubility—The tetramethyl-substituted amides were found to be extremely soluble in water. Table I lists the aqueous solubility values of the amides and the influence of ionic strength at a temperature of 30°. The solubility was not strictly a function of the chain length but was greater for the odd-carbon chain length amides. The C_5 compound, tetramethylpimelamide, is a liquid and mixes with water in all proportions. The C_7 compound, tetramethylazelamide, was soluble to the extent of 3.9 *M*.

The ionic strength of the solution appears to have a greater influence on the solubility of the even-carbon amides. At an ionic strength of 0.1, the solubility of tetramethylsuberamide was not altered; at an ionic strength of 0.75, the solubility was reduced by more than one-half. The solubility of tetramethylsebacamide was lowered by one-third at 0.1 and by two-thirds at 0.75. For the odd-carbon amides, tetramethylpimelamide and tetramethylazelamide, there was no apparent lowering of the solubility at either concentration of potassium chloride.

The salting-out effect of potassium chloride on the even-carbon amides indicates that solutions of these compounds might be less polar than the odd-carbon amides. However, to make a comparative assessment of polarity, dielectric constants of the amide solutions would have to be determined. Closer packing of the even-carbon chain has been demonstrated for dicarboxylic acids using X-ray analysis (15). Such behavior with the amides may give rise to a less polarizable compound, and the decrease in solubility of the even-carbon amides might be attributed to a preferential orientation of the polarizable water molecules around the ions of the added electrolyte.

Construction of molecular models shows that the odd-carbon amides favor a *cis*-configuration while the even-carbon compounds prefer a *trans*-orientation. The carbonyl groups for the odd-carbon amides are *cis* and in a parallel plane, while the nitrogen groups are *cis*-antiparallel; this type of orientation gives rise to a compound with a high dipole moment. The even-carbon amides have *trans*-antiparallel carbonyl groups and *trans*-parallel nitrogen groups; this symmetrical type of orientation results in a lower dipole and lower solubility.

Partition Studies—Partition isotherms for the amides are illustrated in Figs. 1–3. A linear relationship exists at low concentrations of the amides, but deviation from linearity occurs at higher concentrations, with more amide partitioning into the aqueous phase. Deviation of the partition isotherms at higher amide concentrations indicates increased association between amide molecules in aqueous solution. The break in the curve occurred at 0.15, approximately 0.25, and 0.22 *M* for sebacamide, azelamide, and suberamide, respectively.

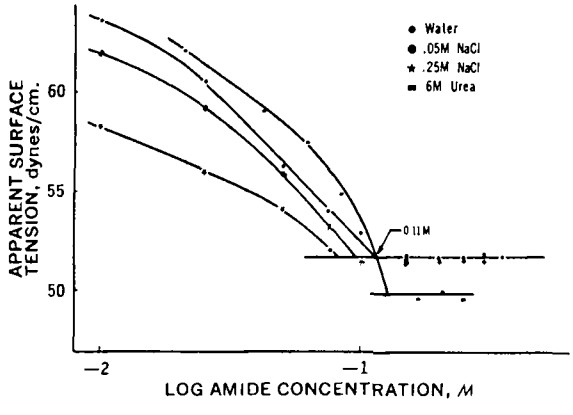

Figure 4—*Apparent surface tension as a function of tetramethylsebacamide concentration in water, 0.05* M *NaCl, 0.25* M *NaCl, and 6* M *urea.*

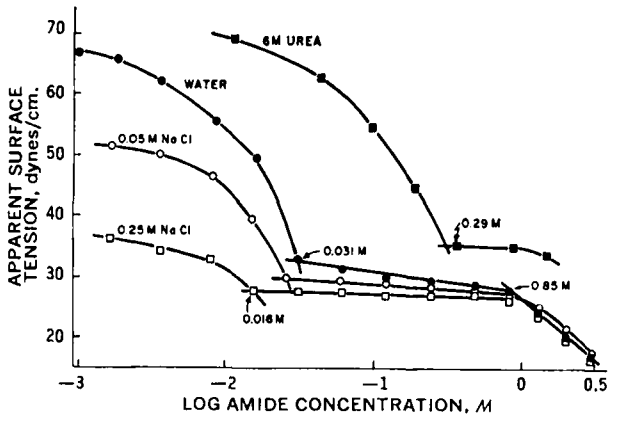

Figure 5—*Apparent surface tension as a function of tetramethylazelamide concentration in water, 0.05* M *NaCl, 0.25* M *NaCl, and 6* M *urea.*

Surface Tension Measurements—The results of the surface tension measurements are represented in Figs. 4–7 as plots of apparent surface tension *versus* the logarithm of the molar concentration. The curves show that the amides possess surface activity and that a critical concentration is associated with each amide.

For sebacamide, the break in the surface tension curve (Fig. 4) occurred at approximately 0.11 *M*. The addition of electrolyte suppressed the critical concentration only slightly. This effect is consistent with the findings of previous workers who studied the effect of electrolytes on nonionic association colloids (16–19) and found a decrease in the CMC.

Urea was included in the surface tension studies because of its ability to disaggregate nonpolar units within a molecule by weakening hydrophobic bonding (20, 21). Aside from the occurrence of a slight lowering of surface tension at the critical concentration, 6 *M* urea had no significant effect on the measurements. Due to the limited solubility of sebacamide, it was not possible to follow the surface tension beyond 0.5 *M* amide.

For azelamide, the break in the surface tension curve (Fig. 5) occurred at 0.031 *M*. In the presence of electrolyte, the surface tension was lowered and the break in the curve occurred at slightly lower concentrations. Urea at 6 *M* concentration had a profound effect on the surface tension, delaying the lowering and shifting the break in the curve to a concentration 10-fold higher than that in water. A second break in the surface tension curve was observed at a concentration of approximately 0.85 *M* amide, and a further lowering of the surface tension occurred with an increase in amide concentration. Much research has been done on the properties of

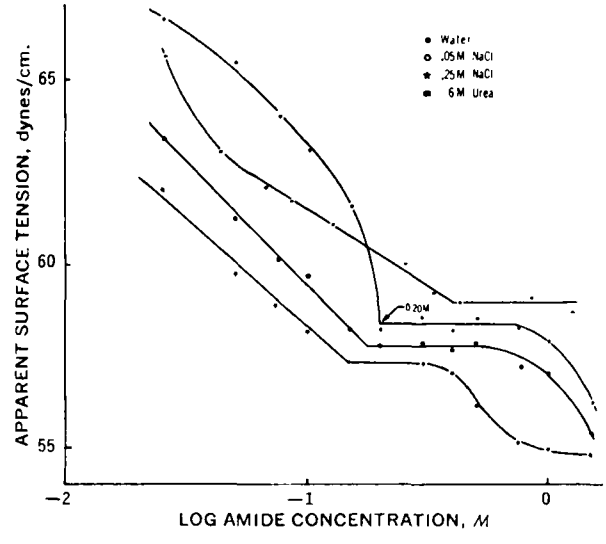

Figure 6—*Apparent surface tension as a function of tetramethylsuberamide concentration in water, 0.05* M *NaCl, 0.25* M *NaCl, and 6* M *urea.*

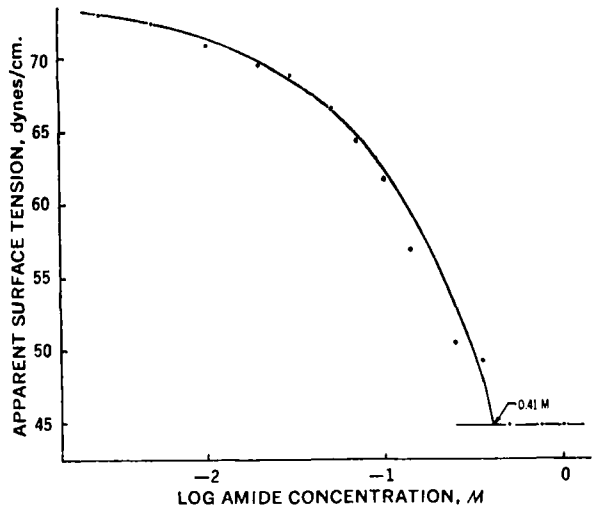

Figure 7—*Apparent surface tension as a function of tetramethylpimelamide concentration in water.*

surfactant solutions above the CMC, and several workers have identified a second CMC (22–24). While little has been done to explain this phenomenon, it has been postulated that an increase in size and asymmetry was associated or responsible for the second CMC.

Figure 6 shows the surface tension curves for tetramethylsuberamide, with the initial break in the curve occurring at 0.2 *M* amide in water; the lowering of the surface tension with suberamide is not as pronounced as with the other amides. The surface tension was found to be stable up to approximately 0.9 *M*, where the second break in the curve occurred. Added electrolyte enhanced the lowering of the surface tension and caused the break in the curve to occur at slightly lower concentrations. Urea delayed the break in the curve.

In the surface tension curve for pimelamide (Fig. 7), the break in the curve occurred at approximately 0.41 *M* amide concentration. Because of the limited amount of pimelamide available, no attempt was made to study the effect of urea or electrolyte, but it is

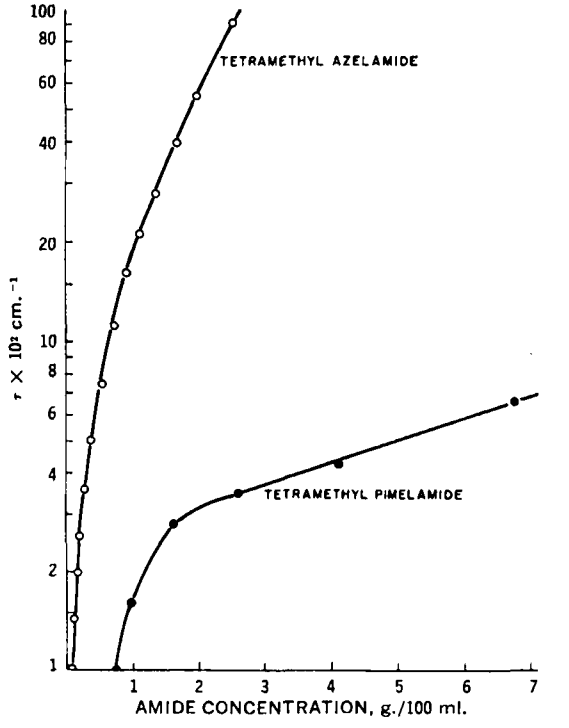

Figure 8—*Excess turbidity as a function of amide concentration for tetramethylazelamide and tetramethylpimelamide in water.*

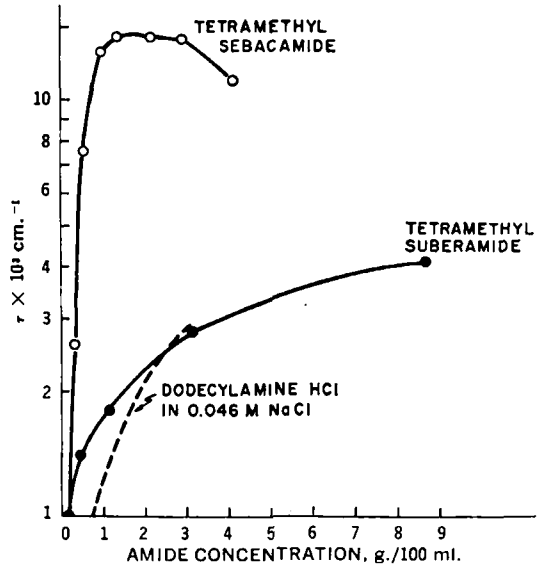

Figure 9—*Excess turbidity as a function of amide concentration for tetramethylsuberamide and tetramethylsebacamide in water. The dotted line is for dodecylamine hydrochloride in 0.046 M NaCl (27).*

believed that the effects would be the same as those observed for the other amides.

The surface tension lowering with the increase in amide concentration indicates that the amides have surface activity, and the break in the curve with a subsequent plateau suggests that saturation at the surface has been achieved in a manner closely resembling that for surfactants. Such behavior is well recognized for surfactant or detergent molecules; but to our knowledge, nothing has been reported on the possibility of a compound with two similar polar groups, one on each end of the molecule, such as the substituted dicarboxylic acid amides, behaving in this manner.

The apparent formation of micelles of the amides is not as spontaneous as one would expect for ionic surfactants. Additionally, it is suspected that some premicellar aggregation is occurring because of the necessity to "age" the solution to obtain stable surface tension readings. The effect of electrolyte in lowering the CMC has been well documented for ionic and nonionic surfactants. In addition to a simple dehydrating effect, Schick (18) postulated a salting-out effect for the lowering of CMC's by electrolytes.

Urea, by virtue of its two bonding centers on each molecule, undergoes hydrogen bonding with water; at high enough concentrations, it reduces the structure of water. This effect was studied with dodecylpyridinium salts (20), proteins (25), and alkyltrimethylammonium alkyl sulfates (21). As a result of the lowering of the interfacial energy between the hydrocarbon and water, the free energy differences between the hydrophobic groups and the water would be reduced and, therefore, the CMC would increase. Urea was found to have a profound effect with azelamide, elevating the CMC 10-fold, while with suberamide and sebacamide the CMC was increased only slightly.

Light-Scattering Measurements—To obtain estimates of weight average molecular weights of associated molecules and aggregates, *i.e.*, polymers and micelles, light-scattering measurements have been employed (26). Light scattering depends largely upon the microscopic heterogeneity of the solution due to fluctuations in concentration. The extent of these spontaneous fluctuations in concentration is a measure of the osmotic work; therefore, a relationship exists between the intensity of the scattered light and the osmotic pressure of the solution. Light scattering offers the advantage that the property being measured increases with an increase in molecular weight, whereas the reverse is true for osmotic pressure.

In Figs. 8 and 9, the excess turbidity at 90° of the amide solutions over that of water is plotted on a log scale as a function of amide concentration. The turbidity was found to increase rapidly from zero concentration in a manner resembling the behavior of high polymer solutions (27).

The odd-carbon amides, azelamide and pimelamide, showed unusually high scattering intensities, and the values obtained for

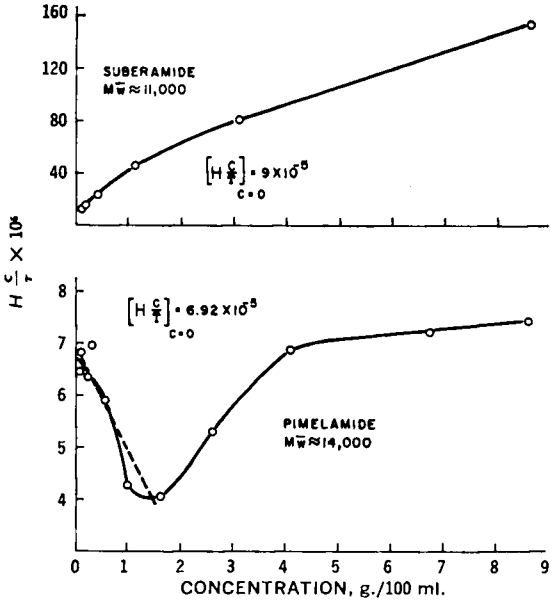

Figure 10—*Specific reciprocal turbidity as a function of amide concentration for tetramethylsuberamide and tetramethylpimelamide in water.*

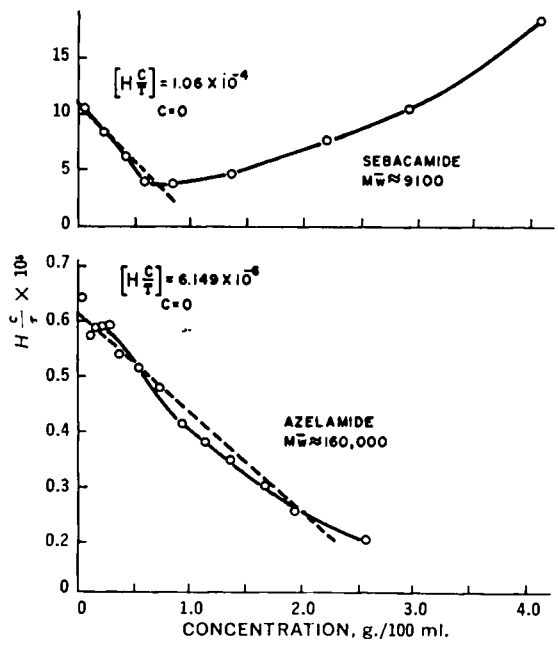

Figure 11—*Specific reciprocal turbidity as a function of amide concentration for tetramethylazelamide and tetramethylsebacamide in water.*

azelamide are in the order of at least 10 times those found for polymer solutions at similar concentrations. It was difficult to carry light-scattering measurements beyond 2 g./100 ml. because a high amount of scattering occurred at 0°. The turbidity of the pimelamide solution was lower than that for azelamide but was still higher than that found for most polymer solutions.

The intensity of scattering for the even-carbon amides was approximately one order of magnitude less than that for the previous odd-carbon amides. The turbidity of the sebacamide solution increased rapidly and reached a plateau at about 1.5 g./100 ml. Herrmann *et al.* (28), in their studies on the micellar properties of alkyl dimethylphosphine oxide solutions, observed maxima in the turbidity–concentration curves. The curve for suberamide closely resembles that found for polymers but is still of higher magnitude than that found for soap solutions above the CMC. The dotted line represents the curves for dodecylamine hydrochloride in 0.046 *M* sodium chloride solution above the CMC (26). It was not possible to plot the curves for the detergent in water on the graph since the turbidity reached a maximum value at approximately 0.3×10^{-3} cm.$^{-1}$. The influence of chain length on the turbidity is clearly evident for the even- and odd-carbon amides, with the higher homologs in each case showing greater scattering.

To determine average molecular weights from turbidity measurements, the refractive index increment must be determined since the refractive index of the solution is also a function of concentration. Debye (29) transformed Van't Hoff's law for high polymer solutions into the following equation:

$$H\frac{c}{\tau} = \frac{1}{MW} + 2Bc + \ldots \qquad \text{(Eq. 1)}$$

which, at high dilutions, would be a good linear approximation for the reciprocal specific turbidity as a function of concentration; τ is the experimentally measured excess turbidity of the solution, c is the concentration in grams per milliliter, and MW is the average molecular weight. The constant B depends on the solvent, and H can be calculated from refraction measurements using the following equation:

$$H = \frac{32\pi^3}{3}\frac{\eta_0^2}{N\lambda^4}\left(\frac{\eta - \eta_0}{c}\right)^2 \qquad \text{(Eq. 2)}$$

where η_0 and η are the refractive indexes of the solvent and solution, respectively; N is Avogadro's number (6.023×10^{23}); and λ is the wavelength of light employed for the light-scattering measurements. A plot of $H(c/\tau)$ *versus* concentration generally produces a straight line at low concentrations, where the Van't Hoff equation is valid. The intercept is equal to the reciprocal of the average molecular weight.

In Figs. 10 and 11, $H(c/\tau)$ is plotted as a function of the amide concentration. As shown in Fig. 10, the curve for pimelamide decreases, passes through a minimum, and then increases. Such nonideal behavior was reported by Robins and Thomas (24) for dodecylaminoethanol salts and by Herrmann *et al.* (28). Extrapolation of the data below 1 g./100 ml. using least-squares treatment results in an average molecular weight of approximately 14,000. For suberamide, the curve closely resembles that obtained for polymers and extrapolation of the data gives an average molecular weight of 11,000.

As shown in Fig. 11, the plot for azelamide has a negative slope with considerable fluctuations in the turbidity values at dilute concentration. The curve resembles that for bovine serum albumin in water (30), with the curvature and "scattering" of points at dilute concentrations considered to be routine occurrences and attributed to the activity of the solvent and various charge factors. The average molecular weight for azelamide appears to be in the range of 160,000.

For sebacamide, extrapolation of the data below 1 g./100 ml. gives a molecular weight of 9100, which is similar to that for suberamide at infinite concentration. However, unlike suberamide, further association of aggregation appeared to occur as the concentration of sebacamide was increased. An initial negative slope was found, with a minimum in the curve occurring at approximately 0.8 g./100 ml. The results of the light-scattering measurements are listed in Table II.

The deviation from linearity of the light-scattering curves was discussed previously for polymers (27, 31, 32) and can be attributed to one or more of the following:

1. Interparticulate interference, giving rise to dissymmetry; *i.e.*, the ratio of the intensity scattered at two angles symmetrical about 90° (33).
2. A distribution of molecular weights, giving rise to depolarization (34); *i.e.*, the molecules are no longer isotropic.
3. The presence of an impurity.
4. Continued association of polymer molecules.
5. The equation is valid only at very dilute concentrations.

Dissymmetry became a problem above a concentration of 1.5–2.0 g./100 ml. Because of the disproportionate increase of scattering intensities at angles of 45 and 135° as the amide concentrations were increased, it was not possible to extend the light-scattering measurements to a concentration where the breaks in the apparent surface tension curves, partition isotherms, and glutethimide solubility profiles occurred.

Table II—Light-Scattering Results for Tetramethyl-Substituted Amides at 436 nm.

	dn/dc[a]	$\left[H\frac{c}{\tau}\right]_{c=0}$	$\overline{MW}$	N[b]

It was felt that, at the dilute concentrations, dissymmetry would be negligible and the depolarization caused by large molecules, a mixture of different molecular sizes, or concentration effects would not be significant. While it may not be possible to estimate average molecular weights by such treatment, the significance of the light-scattering data is that the amides appear to exist as associated molecules at very dilute solutions. To gain insight into the orientation and size of these aggregates, the influence of time, temperature, and electrolytes on the light-scattering measurements must be considered. Without such measurements, it is possible only to conjecture when trying to explain the light-scattering curves. The presence of maxima, minima, and curvature in the light-scattering curves was reported by several researchers (24, 28, 30, 32, 35). Robins and Thomas (24) showed that, for the iodide and nitrate salts of 2-dodecylaminoethanol, maxima in the curves occurred at a salt concentration of approximately 1.5% followed by a broad minimum at approximately 3% concentration. The hypothesis proposed for this behavior was that, at just above the CMC, the micelles were spherical in shape and the positive slope was due to solvent–solute interactions. At the inflection point in the curve, the micelles became more asymmetrical in shape and the negative slope was attributed to solute–solute interaction, *i.e.*, growth of the micelles. The increase in turbidity over this range was greater than the solute–solvent interaction effect and, consequently, the slope was negative. The upward curvature in the curves following the minima was believed to be due to a less rapid growth in the size of the micelles to the extent that the solute–solvent interaction had greater influence.

Curves for sebacamide, azelamide, and pimelamide show negative slopes, with the sebacamide and pimelamide curves exhibiting minima at approximately 1.0% concentration followed by an increase in the specific reciprocal turbidity function. On the basis of this hypothesis, it is possible that association of the amides continues to occur at dilute amide concentration due to strong solute–solute interaction. The inflection in the curve occurs when the solute–solvent interaction becomes greater than the affinity of the amide molecules to associate further.

No attempt was made in this study to correct for dissymmetry or depolarization, even though the data show that dissymmetry was occurring and became significant as the concentration of amide was increased. Consequently, the data in this study are subject to error, but this should be of a low order of magnitude at the dilute concentration. It is unlikely that this behavior can be attributed to the presence of an impurity since GC, thermal, and elemental analyses show the amides to be at least 99% pure.

Table III—Solubilization of Glutethimide with Tetramethyl-Substituted Amides at 30°

Amide Concentration, M	—Glutethimide Solubility ($M \times 10^3$) in Presence of— Pimelamide, $M \times 10^3$	Suberamide, $M \times 10^3$	Azelamide, $M \times 10^3$	Sebacamide, $M \times 10^3$

[a] Solubility of 2-ethyl-2-phenylglutarimide in water (1.0 mg./ml.).

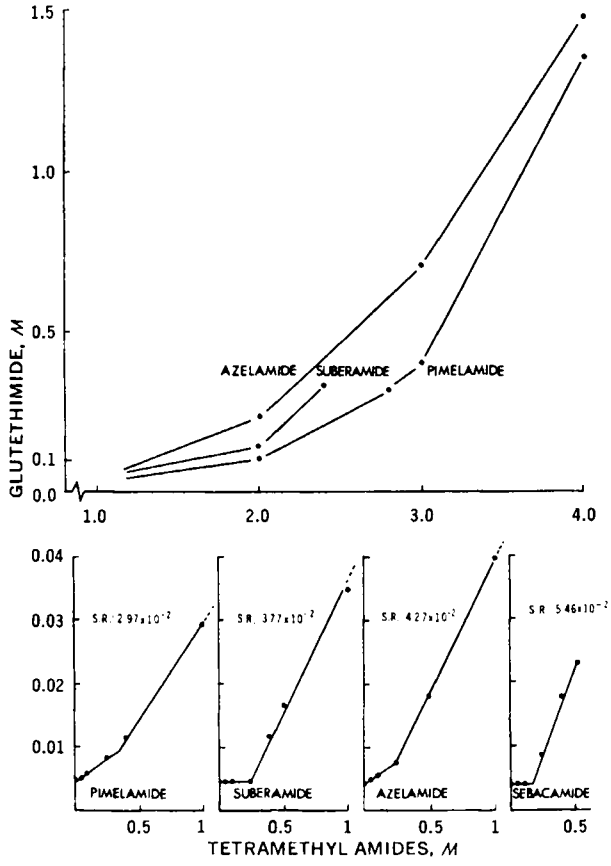

Figure 12—*Solubility curves for glutethimide with tetramethyl-substituted amides at 30°. Lower curves show the solubility over an amide concentration of 0–1* M, *and the upper curves show the solubility above 1* M.

Solubilization of Glutethimide—The data presented in Table III illustrate the influence of the substituted amides on the solubility of glutethimide. For the even-carbon amides below a concentration of 0.25 *M*, there appeared to be no significant increase in glutethimide solubility; with the odd-carbon amides, interaction did occur. However, a substantial increase in the solubility of the drug was not observed until above 0.4 *M* concentration of the amides. The increase in solubility of glutethimide parallels the increase in chain length of the amides but, because of the greater solubility of the odd-carbon amides, it is possible to attain higher levels of glutethimide with pimelamide and azelamide.

The data in Table III are represented graphically in Fig. 12, where the amount of glutethimide solubilized is plotted as a function of amide concentration. To permit the full range of glutethimide levels reached to be plotted on a single graph, the *y* axis is broken. The solubilization at low amide concentrations is shown by the lower curves for the four amides, while the upper curves depict what occurs at higher amide concentrations. With the possible exception of sebacamide, it is evident from the nonlinearity of the plots that glutethimide solubility is not directly proportional to the amide concentration over the entire solubility range. However, for all the amides there appears to be a linear relationship over an amide concentration of 0.2–1.0 *M*.

The solubilizing capacity of the amides for glutethimide is represented on the lower graphs by the saturation ratios, *i.e.*, moles of glutethimide per mole of amide, over the concentration range from the break in the curve up to 1.0 *M* amide. It was not possible to calculate saturation ratios above 1 *M* amide concentration due to the nonlinearity of the curves. Above 1 *M* amide concentration, the amount of glutethimide solubilized increased significantly with an increase in amide concentration. At 3.9 *M* azelamide, a concentration of 320 mg./ml. of glutethimide was attained, representing

a 320-fold increase from that in water; for pimelamide at the same concentration, 292 mg. of glutethimide was solubilized per milliliter.

The shape of the solubility curves suggests that two types of interactions are involved; one type occurs below some critical concentration of amide and a second, more pronounced interaction, predominates above the critical concentration. The interaction that occurs between glutethimide and azelamide and pimelamide prior to the break in the curve was found to be of low order. The fact that the even-carbon amides, sebacamide and suberamide, do not interact with glutethimide below the critical point might be attributed to either a preferred orientation of the odd-carbon amides or, as indicated by light-scattering data, the existence of larger aggregates for the odd-carbon amides giving rise to a greater hydrophobic center.

Of greater significance is the interaction with glutethimide occurring at higher amide concentrations. The nature of the interaction and the break in the surface tension curves suggest micelle formation with higher order complexes forming above the critical point. It appears that at higher amide concentrations, above 1.0 *M*, the drug may be participating in or influencing the aggregate structure or that further aggregation of the amides occurs which gives rise to larger or more densely oriented hydrophobic centers. In any event, the solubility of glutethimide in azelamide and suberamide was enhanced significantly at a concentration where the second break in the surface tension curves occurred.

Preliminary toxicity screening of the amides revealed that the toxicity by the intravenous route for pimelamide and suberamide was similar or slightly less than that for dimethylacetamide and *N*-methylacetamide, while azelamide and sebacamide appeared to be slightly more toxic. However, due to the existence of large associated molecules at low concentration, passage across the lipid membrane may be restricted and the amides may find application for solubilizing drugs for oral and topical administration. Absorption studies are presently being contemplated, but an oil–water partition study revealed that the oil–water partition coefficient is extremely low and both the toxicity and oil partitioning appear to increase with an increase in chain length. Further toxicity and tissue tolerance experimentation will be conducted.

SUMMARY AND CONCLUSIONS

The tetramethyl-substituted amides of sebacamide, azelamide, suberamide, and pimelamide appear to possess the potential of solubilizing hydrophobic molecules due to their strong association tendencies, as indicated by partitioning studies, surface tension measurements, light-scattering measurements, and solubility studies. The nature of the partition isotherms, surface tension curves, and solubility curves for glutethimide suggests the existence of aggregates or micelles of the amides, and possibly the solubilization of glutethimide can be attributed to a micellar type of interaction.

While it is conceivable, as indicated by surface tension measurements, that a micellar type of aggregation occurs at some critical concentration, the light-scattering measurements strongly suggest the existence of large associated molecules at very dilute concentrations. The scattering intensity was of a magnitude similar to that for polymer solutions, and the intensity increased significantly with an increase in amide concentration. The odd-carbon amides, azelamide and pimelamide, show greater light-scattering intensity, greater lowering of surface tension, and higher solubility in water than the even-carbon amides, suberamide and sebacamide. Additionally, unlike the solubility observed for the even-carbon amides, the solubility of the odd-carbon amides was not reduced by an increase in ionic strength and they interacted slightly with glutethimide at low concentration. The further lowering of surface tension following a plateau area in the surface tension curves for two of the amides, azelamide and suberamide, suggests either that the aggregates formed are surface active or that a reorientation at the surface is occurring.

If the amides are of a size that hinders penetration of semipermeable membranes, they may find application in drug delivery systems as implants as well as being used as dialysis solutions in cases of glutethimide intoxication. Considerably more work is needed to determine the potential value of the amides as solubilizing agents and vehicles in drug delivery systems.

Assay of Quaternary Ammonium Compounds in Various Dosage Forms by Acid-Dye Method

L. G. CHATTEN[▲] and K. O. OKAMURA

Abstract □ An organic dye salt partition technique was employed to estimate quantitatively some medicinally important quaternary ammonium compounds. Methyl orange, bromthymol blue, and orange IV were used as color-forming agents for the quaternary ammonium agents. The intensity of the color was measured spectrophotometrically. Linear relationships between concentration and absorbance were obtained for the majority of quaternary ammonium substances investigated. By using the calibration curves obtained, a quantitative procedure was developed for pharmaceutical dosage forms. Satisfactory results were obtained with the majority of dosage forms investigated. The tablet excipients studied had negligible effects on the procedure. The results obtained with this method were compared to results by an official procedure or the manufacturer's method, where possible.

Keyphrases □ Quaternary ammonium compounds (16) in 23 dosage forms—analysis, acid-dye technique □ Acid-dye technique—analysis, 16 quaternary ammonium compounds in 23 dosage forms □ Colorimetry—use of acid dyes as color-forming agents for analysis of quaternary ammonium compounds □ Complex formation—acid dyes–quaternary ammonium compounds, spectrophotometric analysis in dosage forms

In 1943, Auerbach (1) described a colorimetric method of analysis in which buffered solutions of quaternary ammonium compounds were treated with bromphenol blue and the ion-pair was extracted with ethylene dichloride. Colichman (2) analyzed two surfactants by a direct photometric titration, while Ballard *et al.* (3) determined several quaternary ammonium compounds by colorimetric measurement of the salt that the drugs formed with bromthymol blue.

Two photometric methods were presented by Helgren *et al.* (4) in 1957 for the analysis of hexocyclium methosulfate. Bromthymol blue was used as the color-producing agent in one instance, and ammonium cobaltothiocyanate was used in the other. Santoro (5) selectively determined isopropamide iodide in the presence of amine bases by treating it with methyl orange in a buffer at pH 10.2.

The most intensive work in this field has been by Schill and his coworkers. They published a series of papers on the photometric determination of amines and quaternary ammonium compounds with bromthymol blue (6–8). Results also were published on the determination of quaternary ammonium compounds with hexanitrodiphenylamine (9) and by their picrates (10). However, these methods were nonspecific because amines would react under the same conditions. In a more recent investigation, Irving and Markham (11) utilized bromcresol green as a color-forming agent in the analysis of long-chain, tertiary alkylamines and quaternary ammonium salts. Unfortunately, the blank is dependent both on pH and on concentration of the excess reagent.

UV spectroscopy has been employed by several authors as a means of analyzing certain quaternary ammonium salts and some of their dosage forms (12–15). In addition, the BP (16), USP XVIII (17), and NF XIII (18) employ this technique for a limited number of quaternary compounds.

In 1954, Carkhuff and Boyd (19) assayed cetylpyridinium chloride by titrating it with sodium lauryl sulfate in a two-phase system. NF XIII (18) describes a similar titrimetric method for benzethonium and cetylpyridinium chlorides, which also employs a two-phase system with sodium tetraphenylboron as titrant and bromphenol blue as indicator. NF XIII (18) also extensively employs nonaqueous titrimetry in glacial acetic acid as a means of assaying a substantial number of quaternary ammonium salts. In addition, a variety of titrimetric techniques are employed for various dosage forms. Billow and Baker (20) proposed a procedure for benzethonium chloride which is similar to that of NF XIII but which was carried out in a one-phase system. Eksborg *et al.* (21) reported the determination of emepronium bromide in urine by an ion-pair extraction method.

Although several methods have been employed in the analysis of quaternary ammonium substances, disadvantages were found to exist in all of them. The UV method is sensitive and rapid; however, interferences from tablet excipients occur in many instances. Most volumetric and gravimetric methods require large samples and cannot be applied to many dosage forms.

Therefore, the purpose of this investigation was to employ a sensitive and rapid method of analysis that could be applied to a large number of dosage forms whose active ingredient contains the quaternary ammonium functional group. A colorimetric method involving reaction of the medicinal agents with various acid dyes was selected.

EXPERIMENTAL[1]

Chemicals—The following were used: chloroform, methylene chloride, glacial acetic acid, ether, hydrochloric acid, potassium chloride, potassium acid phthalate, sodium hydroxide, potassium phosphate, and boric acid. All were ACS grade.

[1] A Beckman model B spectrophotometer, a Beckman model DB spectrophotometer, a Beckman Zeromatic II pH meter, magnetic stirring apparatus, and conventional laboratory glassware were used.

Table I—Conditions for Quantitative Assay of Commercial Quaternary Ammonium Dosage Forms by the Organic Dye Salt Partition Method

Quaternary Ammonium Compound	Molecular Weight	Amount of Compound in Assay Solution Aliquot, μmoles	Dye Used	Optimum pH	Optimum Wavelength for Measurement, nm.	Procedure Used	Modification of General Procedure for Dosage Forms
Ambenonium chloride	608.5	0.24	Orange IV	6.0	410	B (tablets)	None
Benzethonium chloride	466.1	0.36	Methyl orange	8.0	415	A (solution)	See text
Cetylpyridinium chloride	358.0	0.42	Methyl orange	7.0	405	A (solution)	See text
Demecarium bromide	716.6	0.21	Orange IV	10.0	415	B (solution)	None
Domiphen bromide	414.5	0.36	Methyl orange	8.0	415	A (tablets)	Lozenges assayed by tablet method, powder treated as calibration curve
Edrophonium bromide	246.2	0.60	Bromthymol blue	7.0	410	C (solution)	None
Hexocyclium methosulfate	428.0	0.35	Methyl orange	8.0	410	A (tablets)	None
Isopropamide iodide	480.4	0.31	Methyl orange	8.0	415	A (tablets)	None
Methantheline bromide	420.3	0.35	Methyl orange	8.0	415	A (tablets)	None
Oxyphenonium bromide	428.4	0.35	Methyl orange	8.0	415	A (tablets)	None
Penthienate bromide	420.4	0.35	Orange IV	6.0	405	B (tablets)	None
Penthienate bromide			Orange IV	6.0	405	B (solution)	None
Pentolinium tartrate	538.6	0.27	Bromthymol blue	7.0	410	C (tablets)	See text
Pentolinium tartrate			Bromthymol blue	7.0	410	C (solution)	See text
Pipenzolate bromide	434.4	0.34	Orange IV	8.0	410	B (tablets)	None
Propantheline bromide	448.4	0.33	Methyl orange	8.0	410	A (tablets)	See text
Propantheline bromide			Methyl orange	8.0	410	A (solution)	See text
Pyridostigmine bromide	259.1	0.57	Bromthymol blue	7.0	410	C (tablets)	None
Trimethidinium methosulfate	490.7	0.30	Bromthymol blue	7.0	410	C (tablets)	None

Reagents—The following were used: 0.0001 *N* methyl orange[2], 0.0001 *N* orange IV[2] (tropaeolin OO), 0.0001 *N* orange II[2], 0.0001 *N* bromphenol blue[2], 0.0001 *N* bromthymol blue[2], 0.05 *N* perchloric acid in dioxane (standardized against potassium acid phthalate), 0.02 *M* sodium tetraphenylboron, 6% mercuric acetate, crystal violet indicator (0.5% in glacial acetic acid), methyl red indicator (0.1% in glacial acetic acid), and bromphenol blue solution (1 in 2000).

Quaternary Ammonium Substances—See Table I.

Analysis of Crystalline Quaternary Ammonium Materials—The purity of most of the crystalline materials was determined by a well-recognized, nonaqueous titrimetric technique.

The following substances were analyzed by a method similar to that employed in USP XVIII (17) for demecarium bromide: bethanechol chloride, demecarium bromide, isopropamide iodide, mepenzolate bromide, penthienate bromide, pentolinium tartrate, and pipenzolate bromide. For edrophonium bromide, methyl red was a more suitable indicator than crystal violet.

For the following substances, chloroform was the solvent and methyl red the indicator: benzethonium chloride, cetylpyridinium chloride, domiphen bromide, hexocyclium methosulfate, methantheline bromide, oxyphenonium bromide, propantheline bromide, pyridostigmine bromide, and valethamate bromide.

Ambenonium chloride and trimethidinium methosulfate were assayed by their respective NF XIII (18) procedures.

Selection of Color-Forming Agent—Solutions of 0.0001 *N* were prepared from each dye and were buffered at pH values of 2, 4, 6, 8, and 10, respectively. Five milliliters (0.5 mmole) of the quaternary ammonium substance was added to 10 ml. of each buffered dye solution contained in a 250-ml. separator. The ion–ion colored species was extracted with 10 ml. of methylene chloride, and the organic layer was drawn into a cell. The cells were stoppered, and absorbance measurements were taken at regular intervals for 120 min., at the wavelength of maximum absorbance. This wavelength was employed for all subsequent determinations of that particular substance.

[2] These dye solutions were buffered with Clark and Lubs phosphate buffers to the appropriate pH.

Calibration Curves—*General Procedure*—Fifty milligrams of the quaternary ammonium compound was accurately weighed into a 100-ml. volumetric flask and dissolved in distilled water. The solution was made up to volume with distilled water, and 10 ml. of it was diluted to 100 ml. to produce a 0.05-mg./ml. solution.

To five 250-ml. separators, each containing 10 ml. of a 0.0001 *N* solution of the dye, were added 1, 2, 3, 4, and 5 ml. of the 0.05-mg./ml. solution of the quaternary ammonium compound. Sufficient distilled water was added to make the volume constant in each separator. Twenty-five milliliters of methylene chloride was then added to each separator from a 50-ml. buret. The separator was shaken vigorously for 1 min., and the system was allowed to equilibrate for 10 min. The inside of the stem was wiped clean with adsorbent paper. The organic phase was then drawn into a cell, and the absorbance was measured at the optimum wavelength, using a methylene chloride blank. The procedure was repeated five times and the calibration curve was constructed from the average.

Procedure A—The general procedure was employed at pH 8.0 with methyl orange as the color-forming agent for those substances so designated in Table I. For cetylpyridinium chloride and propantheline bromide, only 20 ml. of methylene chloride was used to extract the colored species.

Procedure B—This procedure employed orange IV as the color-forming agent and was followed for those substances so designated in Table I. For ambenonium, 20 ml. of orange IV at pH 6.0 was used. The equilibration time, however, was 30 min. and the organic phase was drawn into a 25-ml. volumetric flask and the contents were shaken.

Demecarium required a 20-min. equilibration time and also 10 min. to stabilize the color in the cell prior to taking absorbance measurements. The general procedure was followed for penthienate, and again a 10-min. period was allowed for color stabilization prior to measuring the absorbance.

Procedure C—The general procedure was employed with 20 ml. of bromthymol blue at pH 7.0 as the color-forming agent for the substances so designated in Table I.

Analysis of Pharmaceutical Dosage Forms—*General Procedure for Tablets*—Ten tablets were weighed and finely powdered. A sample of powder equivalent to 5 mg. of the quaternary ammonium compound was weighed into a 150-ml. beaker and stirred magnetically

for 15 min. with 40 ml. distilled water. This solution was suction filtered through Whatman No. 1 paper into a 125-ml. flask. The beaker and residue were washed with a further 30 ml. of distilled water, and the filtrate was made to volume in a 100-ml. volumetric flask. Three milliliters of this solution (theoretically 0.05 mg./ml.) and 2 ml. of distilled water were added to the dye solution employed in the preparation of its calibration curve. The remainder of the procedure was identical to that described for the calibration curve of each particular substance.

General Procedure for Injections and Solutions—A suitable volume of the injection was diluted to yield a theoretical concentration of 0.05 mg./ml. Three milliliters of this solution was added to the appropriate dye solution. The remainder of the procedure was identical to that described for the calibration curve of each particular substance.

For many of the dosage forms, the general procedures, as previously outlined, can be followed. The conditions regarding dye, pH, wavelength, *etc.*, are presented in Table I. The following are modifications required for the assay of certain pharmaceuticals.

Benzethonium Chloride—Ten milliliters of benzethonium chloride tincture (1:500) was pipeted into a 150-ml. beaker containing 10 ml. of distilled water. This solution was heated on a water bath to evaporate the acetone and alcohol. After cooling, this solution was made to 100 ml. in a volumetric flask. Twenty-five milliliters of the resulting solution was diluted to 100 ml., yielding a theoretical concentration of 0.05 mg./ml. of benzethonium. Three milliliters of this solution and 2 ml. of distilled water were added to 10 ml. of 0.0001 *N* methyl orange (pH 8.0). The remainder of the procedure was identical to that described for the calibration curve beginning with: "Twenty-five milliliters of methylene chloride. . . ."

Cetylpyridinium Chloride—

1. Ten milliliters of cetylpyridinium chloride solution (1:2000) was pipeted into a 150-ml. beaker and heated over a steam bath to evaporate the ethanol. The solution was cooled to room temperature and then made to 100 ml. in a volumetric flask. Three milliliters of this solution and 2 ml. of distilled water were added to 10 ml. of 0.0001 *N* methyl orange at pH 8.0 in a 250-ml. separator. The remainder of the procedure was identical to that described for the calibration curve beginning with: "Twenty-five milliliters of methylene chloride. . . ."

2. Five cetylpyridinium chloride lozenges were weighed and finely powdered. A sample equivalent to 2.5 mg. of cetylpyridinium chloride was weighed in a beaker and stirred magnetically for 30 min. with 25 ml. distilled water. The solution was made to volume in a 50-ml. volumetric flask. Three milliliters of this solution and 2 ml. of distilled water were added to 10 ml. of 0.0001 *N* methyl orange at pH 8.0 in a separator. The remainder of the procedure was identical to that described for the calibration curve beginning with: "Twenty-five milliliters of methylene chloride. . . ." A blank was also determined, replacing the dye solution with 10 ml. of distilled water.

Pentolinium Tartrate—

1. The general procedure for tablets was used for pentolinium tartrate tablets (40 mg.), except a solution of theoretical concentration 0.5 mg./ml. was prepared first.

2. Five milliliters of pentolinium tartrate injection was pipeted into a 250-ml. volumetric flask and made to volume with distilled water. To 20 ml. of 0.0001 *N* bromthymol blue at pH 7.0 were added 1.5 ml. of the diluted injection and 3.5 ml. of distilled water. The remainder of the procedure was identical to that described for the calibration curve beginning with: "Twenty-five milliliters of methylene chloride. . . ."

Propantheline Bromide—

1. Ten propantheline bromide tablets (7.5 mg.) were weighed and finely powdered. Fifty milligrams of the powdered material was weighed in a 150-ml. beaker and stirred magnetically for 30 min. with 25 ml. of methylene chloride. The solution was filtered through Whatman No. 1 paper, and the residue was washed with a further 10 ml. of methylene chloride. The filtrate was evaporated to dryness and the residue was dissolved in water and made to volume in a 100-ml. volumetric flask. The remainder of the procedure was identical to that described for its calibration curve.

2. The procedure for 15-mg. propantheline bromide tablets was identical to that described for the 7.5-mg. tablets, except that only 25 mg. of the powdered tablets was used.

3. The general procedure for tablets was used for 30-mg. propantheline bromide tablets.

Table II—Analysis of Commercial Pharmaceutical Dosage Forms

Compound	Average Recovery, %	Average Recovery, % Comparative Method
Ambenonium chloride tablets		
10 mg.	102.9 ± 0.9	95.20[a]
25 mg.	100.2 ± 1.3	94.52[a]

[a] Analytical data supplied by manufacturer. [b] Analysis by official procedure. [c] Analysis by nonaqueous titration.

4. The contents of the propantheline bromide injection ampul were transferred to a beaker and weighed. Distilled water was added to dissolve the powder, and the solution was transferred to a 100-ml. volumetric flask and made to volume. Appropriate dilutions were made to ensure that the absorbance would fall within the limits of the calibration curve. The remainder of the procedure was identical to that described for its calibration curve.

RESULTS AND DISCUSSION

The results for the analyses of the crystalline materials indicated that they were of high purity, and all were used without further purification.

The dyes chosen for the investigation were bromphenol blue, bromthymol blue, orange IV, orange II, and methyl orange. In most instances, the wavelength of maximum absorbance was the same for all ion-ion-pairs involving one particular dye. Methyl orange was found generally to give colored species with high absorbances and greatest stability. Therefore, it was employed where possible.

Methylene chloride was found to be a more suitable solvent than chloroform. In most instances, 25 ml. was found to be a sufficient volume to extract completely the ion-ion-pair species. Blank determinations on the dyes alone indicated negligible absorbances.

When the most suitable dye for each quaternary compound was selected, the optimum wavelength for each colored species and the optimum pH of the aqueous media were determined (Table I). Linear calibration curves were obtained for all pure substances except bethanechol, isopropamide, and mepenzolate.

Table III—Molar Absorptivities of Quaternary Ammonium Compounds

Compound	Molecular Weight	$M \times 10^{-5}$	Absorbance	Absorptivity ($\times 10^4$)

[a] Reacted with methyl orange. [b] Reacted with bromthymol blue. [c] Reacted with orange IV.

Before the pharmaceutical dosage forms were analyzed, a study on the effect of common tablet excipients was performed. In this investigation, a quantity of the tablet excipient was added to 10 ml. of the appropriate dye and extracted with methylene chloride. The absorbance of the organic phase was measured, and the results showed that the absorbance due to these tablet excipients was negligible. Other common ingredients used as tablet excipients are kaolin, starch, magnesium stearate, and talc. However, all of these compounds are water insoluble and would be filtered out in the procedure. One of the products contained phenobarbital as an active constituent. This drug was also treated with the appropriate dye (methyl orange) and extracted with methylene chloride. The result produced negligible absorbance.

The results for the analysis of the dosage forms are presented in Table II. Where official procedures existed, they were used as a comparative means of analysis. Good results were obtained with the majority of dosage forms, and generally good agreement was noted with the comparative method.

A general procedure could be employed for most analyses, but slight modifications were required in some instances. For the majority of tablets, extraction of the powdered material was made by distilled water. For 7.5- and 15-mg. propantheline bromide tablets, which are sugar coated, methylene chloride was utilized as the extracting solvent, since extraction with distilled water gave poor recoveries.

In some analyses, blank determinations of the sample without the dye were required because the sample was colored. Both benzethonium chloride tincture and penthienate bromide elixir gave no absorbance when extracted with methylene chloride. This indicated that the absorbance would be entirely due to the colored species formed between the quaternary ammonium and the dye in these instances.

Satisfactory results could not be obtained with the dosage forms of demecarium, isopropamide, and trimethidinium. The high results obtained for the dosage forms of isopropamide may be attributed to the calibration curve, which was not entirely linear, or to decomposition of the drug.

The high recoveries obtained for demecarium bromide ophthalmic solution (0.25%) can be explained by the fact that this preparation contained benzalkonium chloride as a preservative[3]. Since this method cannot differentiate between quaternary ammonium compounds, the benzalkonium would also react with the dye. The result would be overestimation.

An explanation for the low recoveries obtained with trimethidinium methosulfate tablets is not apparent, because the calibration curve for the crystalline material was linear and reproducible.

[3] D. F. Solometo, Merck Sharp & Dohme Laboratories, Philadelphia, Pa., personal communication.

A study of the molar absorptivities of the quaternary ammonium compounds shown in Table III gave more indication of the stoichiometry of the reaction. In those instances where methyl orange was the dye of choice, the cationic portion contains one quaternary nitrogen and shows approximately the same molar absorptivity. With bromthymol blue and orange IV, the bisquaternary compounds show molar absorptivities that are approximately twice that of the monoquaternary compounds. This would, therefore, indicate a dye–quaternary stoichiometry of 2:1 for the bisquaternary compounds.

SUMMARY AND CONCLUSIONS

1. A study on various acid dyes as color-forming agents for quaternary ammonium compounds was presented. Methyl orange, orange IV, and bromthymol blue were the most satisfactory.

2. Linear and reproducible calibration curves were obtained for 16 quaternary compounds. Of the compounds investigated, only bethanechol, isopropamide, and mepenzolate failed to show a linear relationship.

3. The effect on the procedure by common tablet excipients was found to be negligible.

4. A quantitative method of analysis was developed for 23 pharmaceutical dosage forms containing a quaternary ammonium compound. The procedure is very sensitive and was adaptable to the various types of dosage forms investigated.

5. On the basis of the present investigation, it is concluded that the proposed method is generally superior to existing methods. It is recognized that the UV method is equally satisfactory except that it is more prone to error by interferences than is the colorimetric technique.

Microdetermination of Hyoscyamine and Scopolamine in Mixtures

SAWSAN EL-MASRY and SALEH A. H. KHALIL▲

Abstract □ Following the acid-dye technique, hyoscyamine (or atropine) could be selectively determined in the presence of scopolamine, using bromcresol purple at pH 6.6. Total alkaloids were determined using bromthymol blue at pH 5.6. By referring to calibration curves of the two alkaloids with the appropriate dye, the concentration of each alkaloid in the mixture could be computed. The suggested procedure was adopted to analyze the two alkaloids in synthetic mixtures. As low as 0.05 mg. of each alkaloid could be estimated, with average percentage recoveries of 98.6 and 101.5 for hyoscyamine and scopolamine, respectively. Tincture of belladonna was assayed following a modification of the suggested method. The results obtained were comparable with those obtained following the BP method.

Keyphrases □ Hyoscyamine mixtures with scopolamine—acid-dye analysis without prior separation, effect of pH and dye type □ Scopolamine mixtures with hyoscyamine—acid-dye analysis without prior separation, effect of pH and dye type □ Tropane alkaloid mixtures—acid-dye analysis of hyoscyamine and scopolamine □ Acid-dye technique—analysis of hyoscyamine and scopolamine in mixtures

Most reported methods for the determination of tropane alkaloids present in mixtures necessitate separation of the individual alkaloids (1–3). The acid-dye technique reported for the estimation of microquantities of atropine (4, 5) can be adopted to determine the individual alkaloids, without preliminary separation, if a proper choice is made regarding the dye used and the pH of the medium. Khalil and El-Masry (6) found that tropine did not interfere in the assay of atropine when using bromthymol blue at pH 3. The present article examines the effects of pH and selection of the dye on the assay of microquantities of hyoscyamine and scopolamine without prior separation.

EXPERIMENTAL

Materials—Both hyoscyamine sulfate[1] and scopolamine hydrobromide[1] were BP quality. For the dye solutions, bromcresol purple and bromthymol blue were separately dissolved in chloroform to produce 2×10^{-4} *M* solutions. For the buffer solutions, McIlvaine's buffer solutions of various pH values (3–7.5 ± 0.05) were used. Chloroform was reagent grade[1] and freshly distilled. Two lots[2] of belladonna tincture BP were used.

Method—The procedure described by Khalil and El-Masry (6) was followed. Into a 50-ml. separator containing 10 ml. of the buffer solution, a volume of the sample corresponding to about 0.05–0.1 mg. of either alkaloid was added. Then 10 ml. of the chloroformic dye solution was added. After manual shaking for 1 min., the layers were left for complete separation and the chloroformic layer was transferred into a 25-ml. volumetric flask. The aqueous layer was further extracted with 10 and 5 ml. of chloroform, and the color intensity of the combined chloroform extracts was measured at 420 nm. using a spectrophotometer[3] and a blank similarly prepared.

RESULTS AND DISCUSSION

Figure 1 shows the effect of pH on the extractability of the alkaloid–bromcresol purple complex. At all pH values studied, the hyoscyamine–dye complex gave comparatively higher absorbance values at 420 nm. compared with scopolamine. The latter was not assayable at pH values higher than 6.6 since the chloroformic phase was colorless. Due to the relatively high absorbance readings obtained at pH 6.6, hyoscyamine was thus selectively determined at this pH using bromcresol purple. A linear relationship was obtained over the concentration range used (Fig. 2). When using bromthymol blue, both alkaloids were complexed at all pH values studied. However, the calibration curve for hyoscyamine using bromthymol blue at pH 5.6 and that with bromcresol purple at pH 6.6 were almost identical. The slopes were 2.564 and 2.578, respectively (Fig. 2). Therefore, to simplify calculation, pH 5.6 was chosen for the

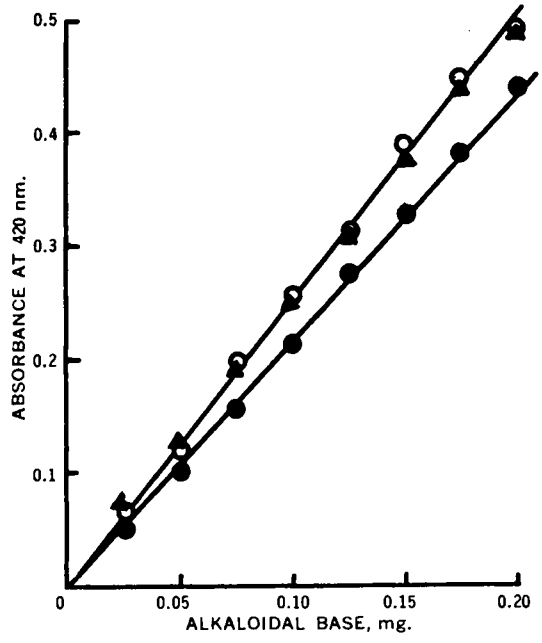

Figure 2—*Calibration curves of hyoscyamine (▲) and scopolamine (●) using bromthymol blue at pH 5.6 and of hyoscyamine (○) using bromcresol purple at pH 6.6.*

analysis of both alkaloids using bromthymol blue. From the slopes of the calibration curves shown in Fig. 2 for the two alkaloids, and since the absorbance values obtained for hyoscyamine complex were almost identical when using either dye, the following equations can be derived:

$$\text{milligrams hyoscyamine in mixture} = A/2.57 \quad \text{(Eq. 1)}$$

$$\text{milligrams scopolamine in mixture} = B - (A/2.18) \quad \text{(Eq. 2)}$$

where:

A = absorbance at 420 nm. of hyoscyamine-bromcresol purple complex at pH 6.6

B = absorbance at 420 nm. of complexes of both alkaloids with bromthymol blue at pH 5.6; 2.57 and 2.18 are the slopes of the curves (Fig. 2) for hyoscyamine and scopolamine, respectively, as determined by the method of least squares

The validity of Eqs. 1 and 2 was tested by assaying synthetic mixtures containing known amounts of hyoscyamine sulfate and scopolamine hydrobromide (Table I). As low as 0.05 mg. of either alkaloid could be determined, with percentage recoveries of 98.6 and 101.5 for hyoscyamine and scopolamine, respectively.

Determination of Hyoscyamine Content of Tincture of Belladonna—An improved procedure, suitable for the determination of hyoscyamine content in tincture of belladonna, was found. About 0.1–0.2 ml. of the tincture was added to a 50-ml. glass-stoppered separator containing 10 ml. of buffer solution (pH 6.6). A 10-ml.

Table I—Results of Analysis of Synthetic Mixtures of Hyoscyamine and Scopolamine[a]

Mixture Number	Compositions, mg. %[b] Hyoscyamine	Scopolamine	Found, mg. % Hyoscyamine	Found, mg. % Scopolamine

Table II—Results of Analysis of Two Batches of Belladonna Tincture BP by the BP Procedure and the Suggested Method

Batch	BP Method[a], mg. %	Suggested Method, Hyoscyamine, mg. %
A	30.1	29.6
B	28.8	28.2

[a] Total alkaloids calculated as hyoscyamine.

portion of chloroformic solution of bromcresol purple was added, and the mixture was manually shaken for 1 min. and left for complete separation (15 min.). After separation of the chloroformic phase, the aqueous layer was further extracted with 10 and 5 ml. of chloroform. The combined chloroformic extracts were treated with 0.1 *N* NaOH, and the liberated dye was measured at 580 nm. In this way, sensitivity was increased by a factor of about 2.4 (Fig. 3). Interference due to chlorophyll was also eliminated through the measurement of the violet color of the liberated dye. Tropine, one of the hydrolytic products of hyoscyamine, did not interfere in the assay following the above-mentioned procedure. This is an advantage over the procedure of Durick *et al.* (7), who used bromcresol purple at pH 5.3. Under this condition, it was found that tropine (6) and scopolamine (Fig. 1) interfered.

Two batches of belladonna tincture BP were assayed following the suggested method. The results obtained are compared in Table II with the data obtained following the BP procedure for the assay of belladonna tincture. The hyoscyamine contents of both batches, as determined by the suggested method, are in good agreement with the results obtained following the BP procedure for the total alkaloidal content. The application of Eqs. 1 and 2 failed to show any scopolamine in the tinctures, apparently because of the relatively minute amounts of scopolamine in the two tinctures studied; TLC testing[4] of the tinctures revealed no spots corresponding to scopolamine. The suggested method for the determination of hyoscyamine content in tincture of belladonna couples both simplicity and sensitivity, and only a small volume (0.1–0.2 ml.) is required.

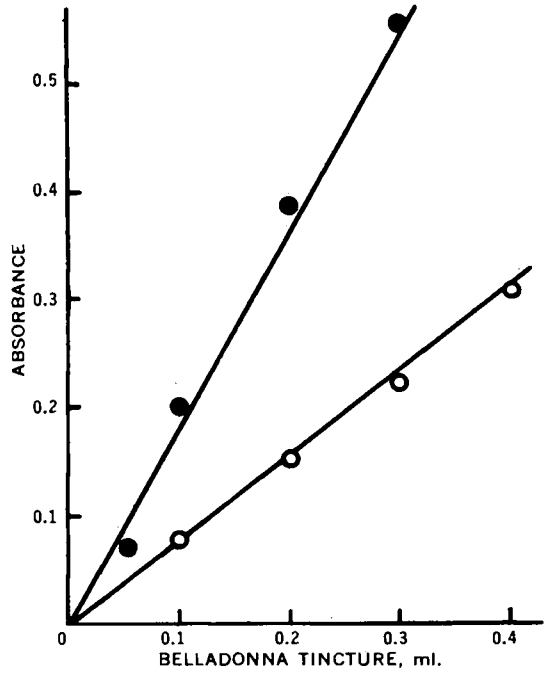

Figure 3—*Calibration curves of belladonna tincture (Batch A): (○) absorbance at 420 nm. of the yellow complex, and (●) absorbance at 580 nm. of the liberated dye after treatment with 0.1 N NaOH. The dye used was bromcresol purple at pH 6.6.*

[4] Using silica gel H as the adsorbent and a system of methanol (100 ml.) and ammonia 0.88 (1 ml.).

SUMMARY

1. Bromcresol blue at pH 6.6 forms a chloroform-extractable complex with hyoscyamine (atropine); tropine and scopolamine do not interfere.

2. Both hyoscyamine and scopolamine form chloroform-extractable complexes using bromthymol blue at pH 5.6. In this way, mixtures of both alkaloids can be determined without preliminary separation.

3. The hyoscyamine content in belladonna tincture can be accurately and selectively determined using as little as 0.1–0.2 ml. of the tincture. Bromcresol purple is used at pH 6.6 and the complex formed is treated with 0.1 *N* NaOH and measured at 580 nm. Neither tropine nor scopolamine interferes.

NMR Quantitative Analysis of Quinidine in Mixtures of Quinidine and Hydroquinidine

THO HUYNH-NGOC and GERARD SIROIS▲

Abstract □ A new procedure for the rapid quantitative analysis of quinidine in mixtures of quinidine and hydroquinidine is described. The method is based upon measurement of the NMR spectrum of these compounds in deuterated chloroform, using 2,3,5-tribromothiophene as an internal standard. The signal chosen is from the vinyl group of quinidine. The great advantage of this procedure is that it permits the determination of the percentage of hydroquinidine in commercial bulk quinidine.

Keyphrases □ Quinidine in mixtures with hydroquinidine—NMR analysis □ Hydroquinidine as impurity in quinidine bulk—NMR analysis □ NMR spectroscopy—analysis, quinidine and hydroquinidine mixtures

Commercial bulk quinidine, the base and its salts, contains variable amounts of hydroquinidine. The USP identification test for quinidine by TLC (1) does not separate these two cinchona alkaloids (2). Many analytical procedures for quinidine have been reported, including UV spectrophotometric (3, 4), colorimetric (5), fluorometric (6), titrimetric (1), and gravimetric (7, 8) determinations. All of these procedures determine the total mixture of alkaloids: quinidine and hydroquinidine. Work in this laboratory indicates that the UV and visible absorptivity and the quantum efficiency of fluorescence are the same for quinidine and hydroquinidine.

A method for their separation and identification by TLC was described previously (2, 9). NMR spectroscopy affords a suitable method of distinguishing between the $-CH{=}CH_2$ and $-CH_2{-}CH_3$ groups present in quinidine and hydroquinidine, respectively. The quinidine spectrum (10) in deuterated chloroform possesses signals that are absent in the hydroquinidine spectrum and are thus available for use in quantitative analysis. A specific NMR quantitative analytical method for quinidine is described here.

EXPERIMENTAL

Spectra were obtained at 60 MHz. using an analytical NMR spectrometer[1]. All spectra were taken at 8 Hz., and a chart width of 72 Hz. was used for all integrals. Tetramethylsilane in deuterated chloroform[2] was used as an internal reference to measure chemical shifts.

Assay Procedure—Pure quinidine base was obtained from quinidine sulfate[3] by eliminating hydroquinidine by the method of Thron and Dirscherl (11).

Approximately 60 mg. of quinidine and 65 mg. of the internal reference 2,3,5-tribromothiophene[4] were accurately weighed and dissolved in a volumetric flask of 1 ml. of deuterated chloroform containing tetramethylsilane. The NMR spectrum was obtained and integrated five times through the region of interest. The mean of the integrated values was used for quantitative calculations.

Calculation—

$$W_{quin} = \frac{EW_{quin}}{EW_{std}} \times \frac{A_{quin}}{A_{std}} \times W_{std} \times F \qquad \text{(Eq. 1)}$$

where:

W_{quin} = weight of quinidine in milligrams
EW_{quin} = molecular weight of quinidine divided by the number of protons in the signal chosen, 324.45/1 = 324.45
EW_{std} = molecular weight of standard divided by the number of protons in the signal chosen, 320.84/1 = 320.84
A_{quin} = integral value of quinidine signal at 5.16 p.p.m.
A_{std} = integral value of standard signal at 6.93 p.p.m.

SUMMARY

1. Bromcresol blue at pH 6.6 forms a chloroform-extractable complex with hyoscyamine (atropine); tropine and scopolamine do not interfere.

2. Both hyoscyamine and scopolamine form chloroform-extractable complexes using bromthymol blue at pH 5.6. In this way, mixtures of both alkaloids can be determined without preliminary separation.

3. The hyoscyamine content in belladonna tincture can be accurately and selectively determined using as little as 0.1–0.2 ml. of the tincture. Bromcresol purple is used at pH 6.6 and the complex formed is treated with 0.1 *N* NaOH and measured at 580 nm. Neither tropine nor scopolamine interferes.

NMR Quantitative Analysis of Quinidine in Mixtures of Quinidine and Hydroquinidine

THO HUYNH-NGOC and GERARD SIROIS▲

Abstract □ A new procedure for the rapid quantitative analysis of quinidine in mixtures of quinidine and hydroquinidine is described. The method is based upon measurement of the NMR spectrum of these compounds in deuterated chloroform, using 2,3,5-tribromothiophene as an internal standard. The signal chosen is from the vinyl group of quinidine. The great advantage of this procedure is that it permits the determination of the percentage of hydroquinidine in commercial bulk quinidine.

Keyphrases □ Quinidine in mixtures with hydroquinidine—NMR analysis □ Hydroquinidine as impurity in quinidine bulk—NMR analysis □ NMR spectroscopy—analysis, quinidine and hydroquinidine mixtures

Commercial bulk quinidine, the base and its salts, contains variable amounts of hydroquinidine. The USP identification test for quinidine by TLC (1) does not separate these two cinchona alkaloids (2). Many analytical procedures for quinidine have been reported, including UV spectrophotometric (3, 4), colorimetric (5), fluorometric (6), titrimetric (1), and gravimetric (7, 8) determinations. All of these procedures determine the total mixture of alkaloids: quinidine and hydroquinidine. Work in this laboratory indicates that the UV and visible absorptivity and the quantum efficiency of fluorescence are the same for quinidine and hydroquinidine.

A method for their separation and identification by TLC was described previously (2, 9). NMR spectroscopy affords a suitable method of distinguishing between the $-CH{=}CH_2$ and $-CH_2{-}CH_3$ groups present in quinidine and hydroquinidine, respectively. The quinidine spectrum (10) in deuterated chloroform possesses signals that are absent in the hydroquinidine spectrum and are thus available for use in quantitative analysis. A specific NMR quantitative analytical method for quinidine is described here.

EXPERIMENTAL

Spectra were obtained at 60 MHz. using an analytical NMR spectrometer[1]. All spectra were taken at 8 Hz., and a chart width of 72 Hz. was used for all integrals. Tetramethylsilane in deuterated chloroform[2] was used as an internal reference to measure chemical shifts.

Assay Procedure—Pure quinidine base was obtained from quinidine sulfate[3] by eliminating hydroquinidine by the method of Thron and Dirscherl (11).

Approximately 60 mg. of quinidine and 65 mg. of the internal reference 2,3,5-tribromothiophene[4] were accurately weighed and dissolved in a volumetric flask of 1 ml. of deuterated chloroform containing tetramethylsilane. The NMR spectrum was obtained and integrated five times through the region of interest. The mean of the integrated values was used for quantitative calculations.

Calculation—

$$W_{quin} = \frac{EW_{quin}}{EW_{std}} \times \frac{A_{quin}}{A_{std}} \times W_{std} \times F \qquad \text{(Eq. 1)}$$

where:

W_{quin} = weight of quinidine in milligrams
EW_{quin} = molecular weight of quinidine divided by the number of protons in the signal chosen, 324.45/1 = 324.45
EW_{std} = molecular weight of standard divided by the number of protons in the signal chosen, 320.84/1 = 320.84
A_{quin} = integral value of quinidine signal at 5.16 p.p.m.
A_{std} = integral value of standard signal at 6.93 p.p.m.

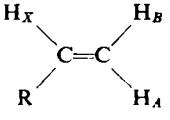
F = correction factor

RESULTS AND DISCUSSION

The NMR spectra of quinidine and hydroquinidine[4] in deuterochloroform solutions are shown in Figs. 1 and 2, respectively. The solvent contains about 1% tetramethylsilane, which produces the reference signal at zero on the parts per million or δ scale on the charts. The concentrations of quinidine and hydroquinidine are 50.72 and 57.60 mg./ml., respectively.

The positions of the observed chemical shifts are located at lower fields than reported by Dega-Szafran and Mitura (10). The results were confirmed by recording these spectra on another spectrometer[5]. Peaks at 5.88 and 6.13 p.p.m. (δ) for quinidine and hydroquinidine, respectively, were also reported in saturated solutions and attributed to the hydroxylic proton (10). In this study, saturated solutions at room temperature also presented these peaks at δ values of 6.24 and 6.70 p.p.m. for quinidine and hydroquinidine, respectively. The rise in concentration of these solutes in $CDCl_3$ increases the extent of intermolecular hydrogen bonding. Hydrogen bonding decreases the electron density around the proton and thus moves the proton absorption to lower field. For instance, when the concentration of hydroquinidine is weak, the proton shift is presumably located at a δ value of 5.60 p.p.m. However, when this concentration is increased above 125 mg./ml., work in this laboratory shows that the peak starts moving gradually to lower field.

Quinidine is an *ABX* system:



in which the protons H_A, H_B, and H_X are presumably located in Fig. 1 at 4.90, 5.14, 5.76, 5.90, 6.05, 6.20, and 6.32 p.p.m. (10). The 2,3,5-tribromothiophene (12) was chosen as an internal standard for quantification of quinidine, because its NMR spectrum in deuterated chloroform presents a singlet at 6.90 p.p.m. and does not interfere with the spectrum obtained from a mixture of quinidine and hydroquinidine (Fig. 3).

The singlet at 5.16 p.p.m. was chosen for quantification of quinidine because of its high intensity of integration and its absence in the hydroquinidine spectrum. A correction was made on the integral value of this peak, because a resonance peak (or peaks) of some protons on the substance studied having a chemical shift in the close proximity of the chosen resonance signal for integration interferes in a constant ratio with this signal. The relative intensity of the integrals of each peak depends on the couplage of the protons (13). In the NMR analysis of mixtures of aspirin, phenacetin, and caffeine, a correction was made by Hollis (14) for the carbon-13 sideband from the aspirin peak which falls beneath the analytical methyl peak of caffeine at 3.4 p.p.m. Such carbon-13 sidebands could also contribute to the interference with the integral of the singlet at 5.16 p.p.m. Furthermore, in some cases, spinning sidebands can interfere with integration. In this work, the spinning rate of the sample tube was adjusted between one-fifth and three-fifths of the maximum speed position of the spinner air control valve on the spectrometer. For this range of spinning rate, the integral value of the chosen signal is constant. It does appear then that, in these conditions, spinning sidebands do not interfere with the integral of the chosen signal, because the intensity and displacement of these sidebands from a resonance peak are recognized to be proportional to the spinning speed (15). The correction factor that must be applied to the integral of the chosen analytical resonance signal is determined experimentally with the internal standard.

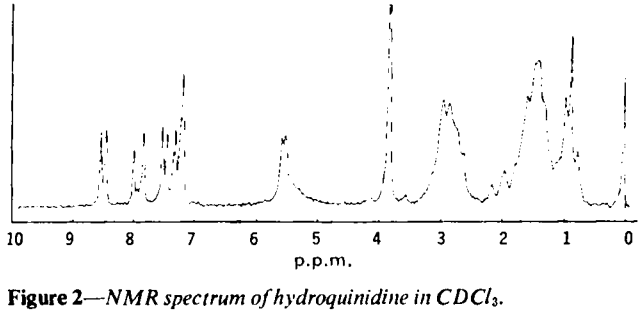


Figure 2—*NMR spectrum of hydroquinidine in $CDCl_3$.*

[5] Varian A-60.

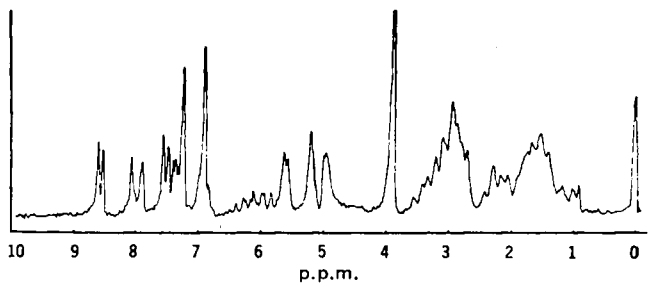

Figure 3—*NMR spectrum of quinidine and hydroquinidine mixture in $CDCl_3$.*

The results obtained from the analysis of 11 known samples of purified quinidine are shown in Table I. The correction factor, F, was calculated from Eq. 1 for each sample. The mean value of F was then used to evaluate the amount of quinidine found by Eq. 1. The mean of percent found is 100.04 and the standard deviation from the mean is 0.972. Synthetic mixtures of purified quinidine and hydroquinidine were made to detect the influence of hydroquinidine on the quinidine spectrum, particularly on the singlet at 5.16 p.p.m. Table II shows five different mixtures containing up to 40.97% of hydroquinidine. The mean of percent found and the standard deviation from the mean are not statistically different from those of Table I. For Student's t test and Fisher's F test, the level of significance, p, is less than 0.01 for differences of the means and standard deviations from the mean, respectively.

					Mean percent found: 100.10%	
					SD: 0.912	
					Average deviation from mean: 0.748%	

The precision, reproducibility, and specificity of this NMR method make it useful as a rapid procedure for the determination of quinidine in the absence or presence of hydroquinidine. However, because of the displacement of the chemical shift of the hydroxyl proton in the region of the internal standard at very high concentration, the weight of the sample must be kept as low as possible. Excellent results were obtained for samples of 40–80 mg./ml. Preliminary work indicates that this method can also be applied to the analysis of quinidine in mixtures of the salts of these two alkaloids.

Complete Analysis of Levodopa Capsules and Tablets by GLC

B. L. CHANG, B. F. GRABOWSKI▲, and W. G. HANEY, Jr.

Abstract □ A GLC assay was developed for the determination of levodopa in both capsule and tablet preparations. The procedure also allows for the quantification of closely related amino acids that might be present, as a consequence of either the natural or synthetic production of levodopa, in these dosage forms. The method is based on the assay of the trimethylsilyl derivatives of the constituents of the dosage form, using α-methyldopa as the internal standard for the analysis of levodopa and α-methyldopate as the internal standard for the related amino acid contaminants. This procedure has been applied to the analysis of several commercial capsule and tablet preparations containing levodopa with reproducible results ranging from 97.6 to 101.8% of the labeled amount of levodopa. In addition, several closely related amino acids in these commercial preparations were identified and quantified.

Keyphrases □ Levodopa capsules and tablets—GLC–flame-ionization analysis after silylation, quantitation of companion amino acid impurities □ Amino acids as impurities in levodopa formulations—GLC analysis after silylation □ α-Methyldopa and α-methyldopate—used as internal standards in GLC analysis of levodopa formulations containing amino acid impurities □ GLC–flame-ionization detection—analysis, levodopa and amino acid impurities in levodopa capsules and tablets

Interest in the analysis (1–3) of levodopa [(−)-3-(3,4-dihydroxyphenyl)-L-alanine] has increased considerably since the initial demonstration of its effectiveness in the treatment of some patients afflicted with Parkinson's disease (4). The development of a reliable procedure for the analysis of levodopa has been complicated because of the wide range of possible contaminants that might be present in the drug as a result of the numerous methods used for its preparation (5–7). In addition, the large daily dose of the drug suggests that a patient may be exposed to a significant daily intake of these impurities even when they are present in relatively small amounts.

DISCUSSION

Since it is the immediate precursor of dopamine, levodopa occupies an important position in the biosynthesis of bioactive aromatic amines. Its metabolism, through dopamine, results in the production of 3-methoxytyramine, norepinephrine, or dihydroxyphenylacetic acid (8), and each of these products may, in turn, be further metabolized in the body. Likewise, amino acids closely related to levodopa, such as tyrosine and 3-aminotyrosine, follow qualitatively similar routes of metabolism.

The metabolism of levodopa and of closely related amino acids, therefore, gives rise to a multiplicity of products, each with its own pharmacological activity. While the metabolism of levodopa has been implicated in its beneficial biological activity (9), the metabolism of closely related amino acids in a pharmaceutical preparation containing levodopa may introduce needless therapeutic complexities into the activity of the drug preparation. Therefore, it is important to identify and quantify these amino acids in the preparation.

While these considerations may apply to the analysis of most drugs and drug products, they are particularly important in the case of levodopa because of its large daily dose (6–8 g.). As a result of this large dose, an impurity that comprises only 1% of the preparation would result in an intake of 60–80 mg./day of extraneous material. Hence, the large therapeutic dose of levodopa increases the likelihood that impurities present in the preparation will give rise to untoward effects and makes their determination critical.

Some assay procedures proposed for levodopa do not possess sufficient specificity to differentiate levodopa from products closely related to it. For example, the spectrophotometric assay designed by Nedergaard (10) does not allow for the unequivocal determination of the drug but determines the presence of tyrosine, 3-methoxytyrosine, and 3,4,6-trihydroxyphenylalanine in addition to levodopa.

A specific assay for levodopa would, however, not be satisfactory if the procedure gave information pertaining only to the quantity of levodopa in the drug preparation. The data from an assay of levodopa must allow for the identification of related amino acids and their quantification, even when they are present in relatively small quantities (0.1–1%). Unless such data are available for the drug preparation, it is impossible to make an intelligent judgment as to its therapeutic efficacy.

While a series of different assays might give a range of information, analysis time for such a scheme would, of necessity, be substantial. Hence, a single assay procedure would be desirable. The procedure should give reliable data for substances present in concentrations ranging over several orders of magnitude. Also, it should be specific in the sense that no one component can interfere with the determination of any other component, and it should be nonselective in the sense that each component in the sample should be identified and quantified.

Currently, chromatographic procedures are the only methods capable of providing the needed information; one can isolate, identify, and quantitate many components in a single rapid procedure. In particular, the use of a flame-ionization detector in conjunction with GLC offers an appealing combination of both linear range and nonspecificity of response. Hence, a procedure for the complete characterization of levodopa-containing pharmaceutical preparations was developed based on the flame-ionization detection of levodopa and related amino acids separated by GLC.

[a] Mean of n determinations.

Because of their low volatility, amino acids have chromatographic characteristics unsuitable for precise quantification. Prior to analysis, therefore, it is necessary to form derivatives of the amino acids. While several procedures are available (11, 12), almost all rely on two or more reaction steps. Since the formation of trimethylsilyl derivatives is rapid and a one-step procedure, silylation was chosen for derivatization of the amino acids. In addition, the reaction process leading to these trimethylsilyl derivatives is relatively nonspecific, giving products with acids, amines, alcohols, *etc.* (13).

EXPERIMENTAL

Materials—*N,O*-Bis(trimethylsilyl)acetamide[1] was used as the silylating solvent. 3-Methoxytyrosine[2], 3,4,6-trihydroxyphenylalanine[2], levodopa[2], α-methyldopa[2], and α-methyldopate[2] were obtained. Alanine[3], phenylalanine[4], and *l*-tyrosine[4], each of which melted at literature values after recrystallization, were used. Commercial capsules and tablets containing levodopa were used in the analysis.

				0.54[d]	0.008	
				—[f]		

[a] Expressed as percent of labeled amount of levodopa. [b] 3-Aminotyrosine. [c] 3-Methoxytyrosine. [d] 3,4,6-Trihydroxyphenylalanine. [e] Tyrosine. [f] Phenylalanine.

Standard Solution—α-Methyldopate was used as a solution (1.0 mg./ml.) in 0.1 *N* HCl.

Apparatus—A gas chromatograph[5] with isothermal control and a flame-ionization detector was used for the analysis. The columns were 3.04 m. (10 ft.) in length, spiral-shaped, borosilicate glass tubing of 0.61 cm. (0.125 in.) inner diameter and packed with 2% methyl silicone and 6% phenyl methyl silicone on 80–100-mesh, silanized, acid-washed, flux-calcined diatomite[6]. Prior to use, the column was conditioned at 250° for 30 hr. The injector port (fitted with a glass injector sleeve), column, and detector temperatures were 225, 198, and 245°, respectively. The gas flow rates were: hydrogen, 40 ml./min.; compressed air, 226 ml./min.; and nitrogen, as the carrier gas, 40 ml./min. Column peak areas were determined using a fully automatic electronic digital integrator with printout[7].

Determination of Reaction Time and Product Stability—Ten milligrams each of 3-methoxytyrosine, levodopa, 3-aminotyrosine, 3,4,6-trihydroxyphenylalanine, and the internal standards α-methyldopa and α-methyldopate was placed in cone-shaped vials[1] fitted with Teflon septums. A 0.6-ml. sample of the silylating agent, *N,O*-bis(trimethylsilyl)acetamide, and 0.6 ml. of the silylating solvent, dry pyridine, were added to each vial. The vials were maintained in a water bath at 80°, and aliquots were taken for analysis from each vial at 10-min. intervals. After 3 hr., heating was discontinued, and the vials were protected from light and moisture. Aliquots for analysis were then taken at 4-hr. intervals for 24 hr.

Preparation of Calibration Curves—*Levodopa*—α-Methyldopa (20.0 mg.) was placed in each of six separate cone-shaped vials fitted with Teflon septums. A weight of levodopa calculated to give weight ratios of levodopa to reference standard over the range 0–2.5 at 0.5 increments was then added to the respective vials. Dry pyridine (0.6 ml.) and the silylating agent (0.6 ml.) were added to each vial, which was then heated in a water bath at 80° for 1 hr. The reaction mixture was then cooled to room temperature, and 1.0 μl. of the mixture was injected into the chromatographic system. The peak area ratios of the trimethylsilyl derivative of levodopa to the trimethylsilyl derivative of the α-methyldopa derivative were plotted *versus* the weight of levodopa, and the line of best fit was determined.

Related Amino Acids—Solutions (2.0 mg./ml. in 0.1 *N* HCl) of each amino acid included in the study were prepared. A volume of the standard solution of α-methyldopate (internal standard) equivalent to 0.2 mg. of α-methyldopate was added to each of six vials. A volume of each amino acid solution calculated to give weight ratios over the range 0–2.5 (related amino acid to internal standard) at 0.5 increments was added to the vials. Each sample was then evaporated to dryness at 60° with a stream of dry nitrogen and treated as described under *Levodopa*, beginning: "Dry pyridine . . ."

Analysis of Commercial Products—Tablets containing levodopa were sampled by selecting four tablets at random from each sample lot. These tablets were then weighed and finely powdered. In the

[5] Varian model 575.
[6] OV-1 (2%) and OV-17 (6%) on Chromosorb G, A-W, DMCS, from Varian Aerograph, Walnut Creek, Calif.
[7] Varian model 475.

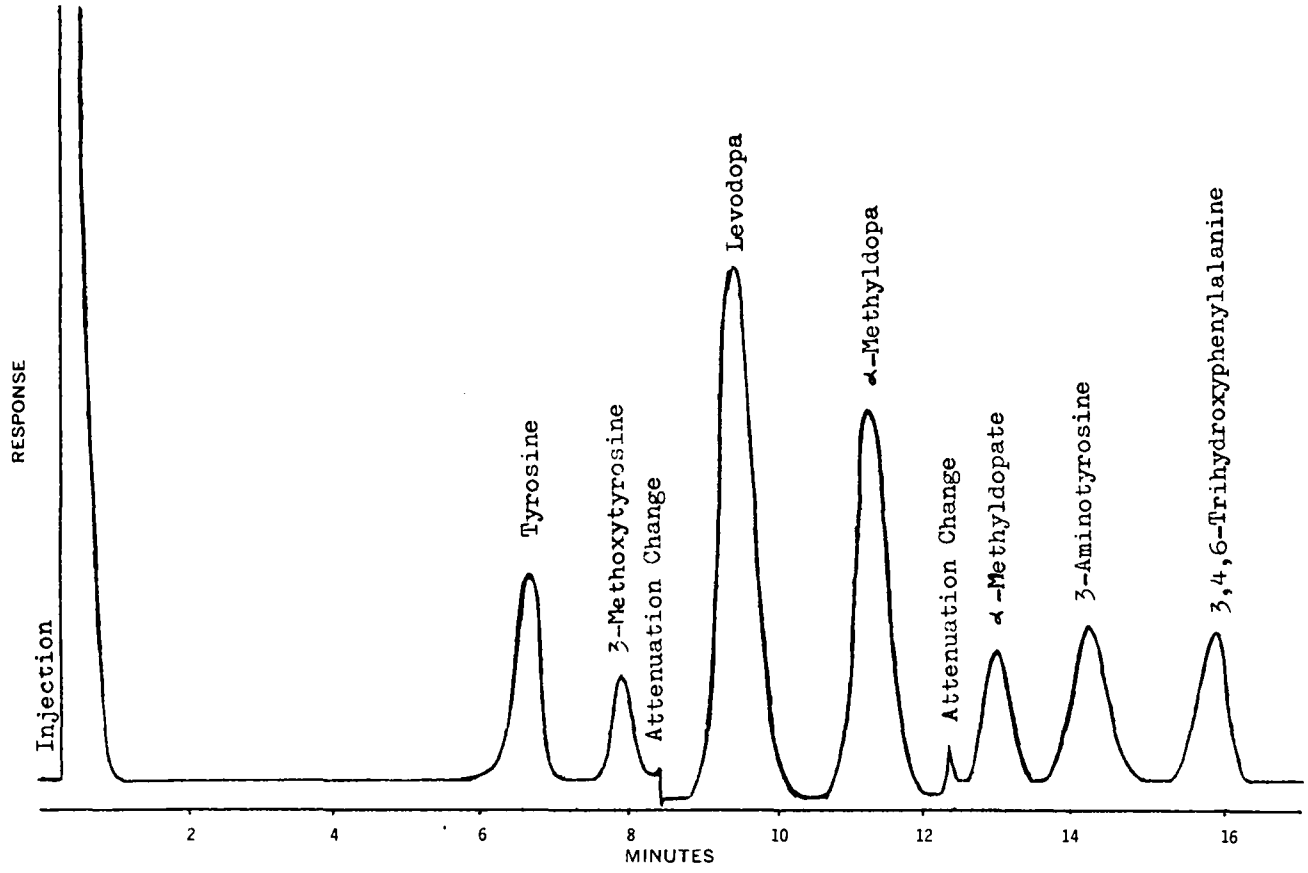

Figure 3—*Chromatographic trace of the trimethylsilyl derivatives of a synthetic mixture of levodopa, related substances, and internal standards. See text for conditions.*

case of the capsules, four capsules were weighed and emptied and their contents were weighed and then thoroughly mixed.

A volume of the α-methyldopate standard solution equivalent to 0.2 mg. of α-methyldopate was added to a vial, and the solution was evaporated to dryness at 60° with a stream of dry nitrogen. A sample of dosage form equivalent to about 25 mg. of levodopa was weighed accurately and placed in the vial along with 20.0 mg. of α-methyldopa. Dry pyridine (0.6 ml.) and the silylating agent (0.6 ml.) were added to the mixture, and the vial was capped and heated in a water bath at 80° for 1 hr. A volume of the solution (1.0–3.0 μl.) was injected into the chromatographic system, and the peak area ratio of the trimethylsilyl derivative of levodopa to the trimethylsilyl derivative of α-methyldopa was determined. The quantity of levodopa in the sample was then determined graphically from the calibration curve. Any related amino acids present in the sample were quantified, using the trimethylsilyl derivative of α-methyldopate as the internal standard. The percentage of levodopa or related amino acids in the product was calculated as the percentage of the claim of levodopa.

RESULTS AND DISCUSSION

Results of the study of the relative silylation rate of levodopa and the internal standard at 80° are illustrated in Fig. 1. From the curve, it can be seen that a stable ratio of the trimethylsilyl derivatives of levodopa to α-methyldopa is obtained after 40 min. For the related amino acids, a qualitatively similar curve showed the stable ratio of trimethylsilyl derivatives of related amino acids to α-methyldopate to occur after 30 min. However, alanine does not appear to give a response in this system. While no explanation for this anomaly is offered, a similar result was pointed out by Gehrke *et al.* (14).

Generally, trimethylsilyl derivatives are known to be sensitive to moisture (15). In these studies, however, the ratios of the trimethylsilyl derivatives of levodopa or related amino acids to their internal standards were stable for at least 24 hr. if the trimethylsilyl derivatives were protected from light and moisture. This implies that degradation of the derivatives does not occur or that it occurs at the same rate for all substances in the study.

The calibration curve for the trimethylsilyl derivatives of levodopa and α-methyldopa is shown in Fig. 2. This relationship was linear over the concentration range studied, and the slope was computed from the formula for least squares to be 1.086, with a coefficient of variation of ±1.16%. However, continued use of the chromatographic system over 2 months gave rise to a decreased slope, which was 0.31% in excess of the mean slope error. This decrease occurred despite the fact that the detector was cleaned weekly. Hence, it is necessary to prepare calibration curves periodically and to calculate the quantity of levodopa in the sample graphically.

Calibration curves for the trimethylsilyl derivatives of α-methyldopate and the related amino acids were linear and passed through the origin. One exception to this generality was *l*-tyrosine, which gave a calibration curve having negative deviation from linearity at ratios greater than 1.5. Nonlinearity might be expected in this case due to the rather large difference between the retention time of the trimethylsilyl derivatives of *l*-tyrosine and α-methyldopate. However, the precision and accuracy of the assay were not greatly affected as long as calibration curves were used.

The precision and accuracy of the assay procedure were examined by assaying prepared standard mixtures composed of levodopa and the related substances in varying ratios (Table I). Even when the ratio of levodopa to related amino acid was greater than 300:1, the method gave reliable data for both levodopa and the related amino acid. While the deviation for *l*-tyrosine was larger than that for the other substances, the deviation was still within the range required for an acceptable assay.

The selectivity of the method is exemplified in Fig. 3, which illustrates a chromatographic trace of the trimethylsilyl derivatives of levodopa, related amino acids, and the internal standards. Although levodopa and α-methyldopa are very closely related in physicochemical properties, the resolution factor for their trimethylsilyl derivatives (16) is 1.68. In addition, each peak from the trimethylsilyl derivatives of the related amino acids is relatively symmetrical and well separated. The chromatographic parameters used in the deter-

mination are necessary for the complete separation of all the components used in the study. However, once an initial determination of the constituents present in the sample has been made, the column temperature may be increased to shorten the analysis time without affecting the precision and accuracy of the results.

Table II illustrates the results of the application of this procedure to the analysis of several commercial capsule and tablet preparations. The route of preparation of levodopa (synthetic or natural) may be determined by examining the related amino acids present. TLC (17) was used to identify the amino acid phenylalanine found in Tablet VI.

Since the procedure did not employ any cleanup or extraction procedures prior to analysis, diluents and binders used to formulate the dosage forms of levodopa could offer a potential source of interference. However, since there were no extraneous peaks observed in the chromatograms of any dosage form analyzed in this study, these materials apparently do not interfere with the assay procedure.

In conclusion, a GLC determination of levodopa has been developed and is proposed as an assay for the drug contained in both capsules and tablets. Related amino acids which were present as possible contaminants were also separated, identified, and quantified. In addition, these results indicate that analysis of α-methyldopa by the same or a closely related procedure may be feasible.

This procedure was applied to several commercial tablet and capsule preparations containing levodopa, with satisfactory results.

GLC Determination of Meclizine Hydrochloride in Tablet Formulations

C. K. WONG, J. R. URBIGKIT, N. CONCA, D. M. COHEN, and K. P. MUNNELLY▲

Abstract □ A method was developed for the quantitative determination of meclizine hydrochloride in tablet formulations by GLC after a suitable separation technique.

Keyphrases □ Meclizine hydrochloride tablets—GLC analysis after chloroform extraction □ GLC—analysis, meclizine hydrochloride tablets

Meclizine hydrochloride is an antihistamine which shows marked protective activity against nebulized histamine. It is indicated in the management of nausea, vomiting, and dizziness associated with motion sickness, and it has been found useful in the management of vertigo associated with diseases affecting the vestibular system. Various methods for the determination of meclizine hydrochloride have been reported, including TLC (1–4), polarography (5), NMR (6), fluorometry (7), nonaqueous titration (8), and UV spectroscopy (9–11). However, these methods do not have the rapidity, simplicity, and degree of sensitivity found in GLC methods.

Papers (12–15) published on the GLC determination of meclizine hydrochloride lack quantitative data or include chromatograms showing serious peak tailing. This paper describes a simple and direct GLC procedure for the quantitative determination of meclizine hydrochloride after extraction from a tablet formulation with chloroform.

EXPERIMENTAL

Equipment—A gas chromatograph[1], equipped with a dual flame detector and an electronic integrator[2], was used throughout this study. The column was 1.82-m. × 4-mm. (6-ft. × 0.25-in.) stainless steel tubing packed with diatomaceous earth[3], 80–100 mesh, coated with 3% OV-17. The operating temperatures were: column, 290°; de-

GLC Determination of Meclizine Hydrochloride in Tablet Formulations

C. K. WONG, J. R. URBIGKIT, N. CONCA, D. M. COHEN, and K. P. MUNNELLY▲

Abstract □ A method was developed for the quantitative determination of meclizine hydrochloride in tablet formulations by GLC after a suitable separation technique.

Keyphrases □ Meclizine hydrochloride tablets—GLC analysis after chloroform extraction □ GLC—analysis, meclizine hydrochloride tablets

Meclizine hydrochloride is an antihistamine which shows marked protective activity against nebulized histamine. It is indicated in the management of nausea, vomiting, and dizziness associated with motion sickness, and it has been found useful in the management of vertigo associated with diseases affecting the vestibular system. Various methods for the determination of meclizine hydrochloride have been reported, including TLC (1–4), polarography (5), NMR (6), fluorometry (7), nonaqueous titration (8), and UV spectroscopy (9–11). However, these methods do not have the rapidity, simplicity, and degree of sensitivity found in GLC methods.

Papers (12–15) published on the GLC determination of meclizine hydrochloride lack quantitative data or include chromatograms showing serious peak tailing. This paper describes a simple and direct GLC procedure for the quantitative determination of meclizine hydrochloride after extraction from a tablet formulation with chloroform.

EXPERIMENTAL

Equipment—A gas chromatograph[1], equipped with a dual flame detector and an electronic integrator[2], was used throughout this study. The column was 1.82-m. × 4-mm. (6-ft. × 0.25-in.) stainless steel tubing packed with diatomaceous earth[3], 80–100 mesh, coated with 3% OV-17. The operating temperatures were: column, 290°; de-

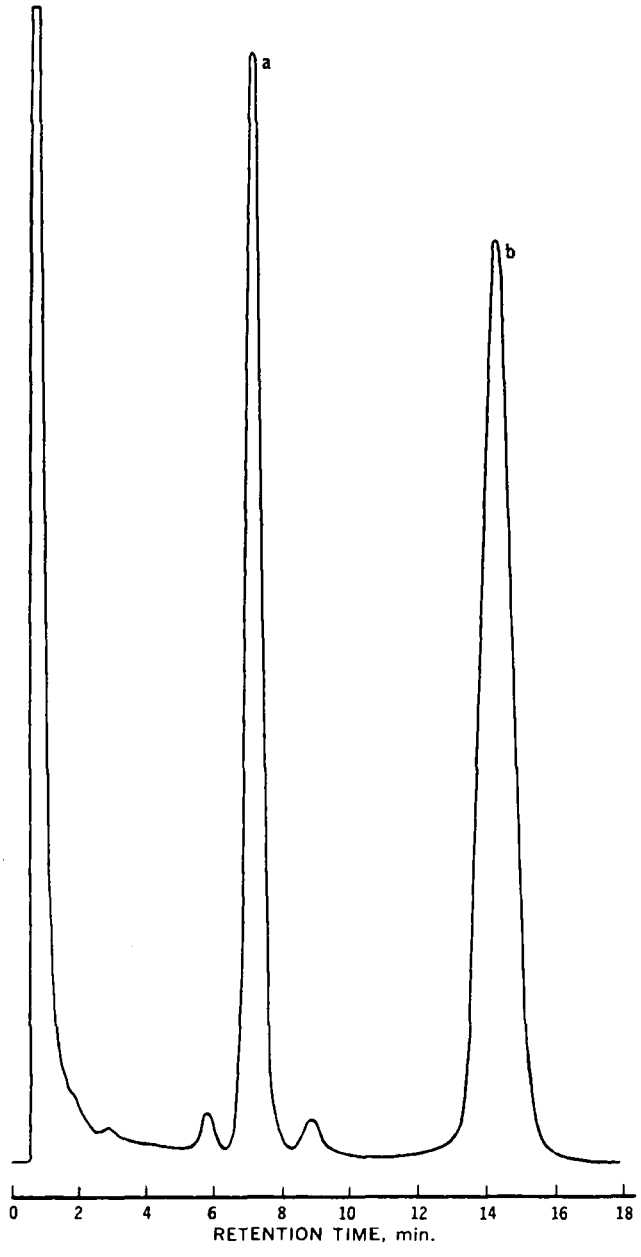

Figure 1—*Representative chromatograms. Key: a, dinonyl phthalate; and b, meclizine.*

tector, 330°; and injection port, 320°. Helium, with a flow rate of 75 ml./min., was the carrier gas. The hydrogen flow rate was adjusted to optimum sensitivity without causing high noise background in the electronic integrator. Oxygen was maintained at 30 psig. head pressure.

Reagents—Meclizine hydrochloride USP XVIII reference standard was dried at 100° for 2 hr. before use. Dinonyl phthalate[4], practical grade, was the internal standard. Chloroform[5] was GC spectrophotometric quality.

Preparation of Standard Solution—Dissolve approximately 500 mg. of dinonyl phthalate in 500 ml. chloroform. Accurately weigh approximately 100 mg. of meclizine hydrochloride standard and transfer to a 125-ml. conical flask. Pipet 50 ml. of the dinonyl phthalate solution into the conical flask containing the meclizine hydrochloride and swirl to make a uniform solution.

Preparation of Sample Solution—Determine the average tablet weight of 20 tablets. Pulverize the tablets, weigh an amount equivalent to 100 mg. of meclizine hydrochloride, and transfer the powder to a 125-ml. conical flask. Pipet 50 ml. of the dinonyl phthalate solution into the conical flask and shake for 30 min. Centrifuge the solution and use the supernate for the GLC determination.

Table I—Percent Recovery of Meclizine Hydrochloride

Day	Weight Number	Injection 1	Injection 2	Injection 3
1	1	100.9	102.8	102.9
	2	99.5	100.2	100.1
2	3	99.0	100.8	101.1
	4	100.9	101.6	101.7
3	5	99.4	98.4	99.2
	6	99.0	99.0	100.7
		Overall average	100.4%	

Table II—Estimates of Precision for Determination of Meclizine Hydrochloride in a Pharmaceutical Formulation

Number of Days	Number of Weights per Day	Number of Injections per Weight	Estimates of Precision[a], %
1	1	1	±2.8
1	1	3	±2.4
1	2	3	±1.9
2	1	3	±1.7
Injection to injection within a weight on a day			±1.7

[a] Ninety-five percent of individual results or average of three or six results will not vary from each other by more than the percentages quoted. These estimates include variability due to days, weights, aliquots, and injections.

Chromatography—After conditioning the column with four injections of the sample solution, approximately 5 μl. each, inject 5 μl. of the standard solution followed by three 5-μl. injections of the sample solution and one 5-μl. injection of the standard solution. The peak areas obtained from the electronic integrator are used for the calculation.

Calculations—Calculate the potency of meclizine hydrochloride in milligrams per tablet according to the following formula:

$$\text{milligrams per tablet} = \frac{R_{spl} \times \text{standard weight (mg.)} \times \text{average tablet weight (mg.)}}{R_{std} \times \text{sample weight (mg.)}} \quad \text{(Eq. 1)}$$

where R_{spl} is the ratio of meclizine peak area to dinonyl phthalate peak area in the sample solution, and R_{std} is the average ratio of

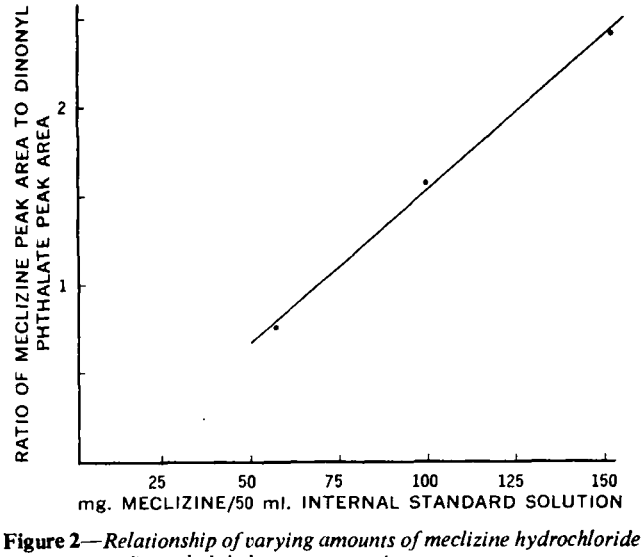

Figure 2—*Relationship of varying amounts of meclizine hydrochloride to a constant dinonyl phthalate concentration.*

the meclizine peak area to the dinonyl phthalate peak area in the standard solution before and after sample injections.

RESULTS AND DISCUSSION

A typical chromatogram of meclizine and dinonyl phthalate is shown in Fig. 1. Figure 2 shows the linear relationship of various amounts of meclizine to a constant amount of dinonyl phthalate.

The accuracy and precision of the method were tested by the following experiment. Two weights of a placebo blend in which known quantities of meclizine hydrochloride had been added were assayed per day for 3 consecutive days. The average recovery (Table I) was 100.4%. The estimate of precision (Table II) for injection to injection within a weight on a day, excluding variability due to days and weights, was ±1.7%. The standard error for the average of three injections is ±2.4%.

Meclizine hydrochloride yields a symmetrical peak, identical with meclizine base. A possible explanation for this phenomenon is that two HCl molecules are thermally removed from the meclizine molecule inside the injection port (16). By taking advantage of this effect, sample preparation is simplified since a two-phase liquid extraction step is eliminated.

Spectrophotometric Determination of Thyroxine Iodine in Thyroid Preparations

DAVID L. SONDACK

Abstract □ An improved quantitative determination of thyroxine iodine in USP thyroid preparations is described. The iodine-containing proteins are dissolved in 8 *M* urea and separated from cell debris and excipient materials by centrifugation and filtration. One aliquot of the clear yellow filtrate is adjusted to pH 9.0, and a second aliquot is adjusted to pH 5.0. The difference in absorbance between the two is observed at 325, 350, and 360 nm. These values are inserted into an equation utilizing the appropriate absorptivities of the iodoamino acids and dilution factors, and the amount of thyroxine iodine is calculated. The relative standard deviation of the method is ±6.0%. Data are presented to demonstrate the application of this method to several thyroid formulations, thyroid powder USP, tablets, and enteric-coated tablets. Correlation with biological data is shown.

Keyphrases □ Thyroxine iodine—UV titrimetric analysis in thyroid preparations □ Thyroid preparations—UV titrimetric analysis of thyroxine iodine □ UV spectrophotometric titration—analysis, thyroxine iodine in thyroid preparations

Thyroxine contained in pure proteins can be determined by spectrophotometric titration, taking advantage of the unique ionization and absorption properties of the iodoamino acids (1, 2). Various other methods to measure chemically both thyroxine and triiodothyronine (liothyronine) in pharmaceutical thyroid preparations have been described (3–13). These methods involve: chemical or enzymic hydrolysis of the thyroproteins; extraction of the released iodoamino acids; separation of these acids by paper chromatography, TLC, or gel permeation chromatography; and quantitation by iodometry. The methods are time consuming and the stability of the iodoamino acids in solution also has been a problem (14–16). The USP

Table I—Precision of Measurement of Thyroxine in Thyroid Preparations

Spectrophotometric Determination of Thyroxine Iodine in Thyroid Preparations

DAVID L. SONDACK

Abstract □ An improved quantitative determination of thyroxine iodine in USP thyroid preparations is described. The iodine-containing proteins are dissolved in 8 *M* urea and separated from cell debris and excipient materials by centrifugation and filtration. One aliquot of the clear yellow filtrate is adjusted to pH 9.0, and a second aliquot is adjusted to pH 5.0. The difference in absorbance between the two is observed at 325, 350, and 360 nm. These values are inserted into an equation utilizing the appropriate absorptivities of the iodoamino acids and dilution factors, and the amount of thyroxine iodine is calculated. The relative standard deviation of the method is ±6.0%. Data are presented to demonstrate the application of this method to several thyroid formulations, thyroid powder USP, tablets, and enteric-coated tablets. Correlation with biological data is shown.

Keyphrases □ Thyroxine iodine—UV titrimetric analysis in thyroid preparations □ Thyroid preparations—UV titrimetric analysis of thyroxine iodine □ UV spectrophotometric titration—analysis, thyroxine iodine in thyroid preparations

Thyroxine contained in pure proteins can be determined by spectrophotometric titration, taking advantage of the unique ionization and absorption properties of the iodoamino acids (1, 2). Various other methods to measure chemically both thyroxine and triiodothyronine (liothyronine) in pharmaceutical thyroid preparations have been described (3–13). These methods involve: chemical or enzymic hydrolysis of the thyroproteins; extraction of the released iodoamino acids; separation of these acids by paper chromatography, TLC, or gel permeation chromatography; and quantitation by iodometry. The methods are time consuming and the stability of the iodoamino acids in solution also has been a problem (14–16). The USP

Table I—Precision of Measurement of Thyroxine in Thyroid Preparations

Preparation	Average Value	Range	*RSD*, %
Powder USP, mcg./g.	207.0	191.0–222.0	±6
120-mg. tablets USP, mcg./tablet	24.2	22.7–25.3	±5
200-mg. enteric-coated tablets USP, mcg./tablet	32.8	30.2–33.9	±6

Table II—Thyroxine Iodine and Total Organic Iodine Contents of Thyroid Preparations from the Same Starting Material

Preparation	Thyroxine Iodine, mcg./Tablet Spectrophotometric	Bioassay[a]	Total Organic Iodine, mcg./Tablet
120-mg. enteric-coated tablets USP	22.7	30.8	253.0
60-mg. enteric-coated tablets USP	12.0	14.9	120.0
120-mg. tablets USP	22.5	29.5	242.0
60-mg. tablets USP	11.5	14.9	120.0
30-mg. tablets	6.1	7.2	61.5
Precursors to above preparations:			
Powder USP	209.0 mcg./g.	258.0 mcg./g.	2120.0 mcg./g.
Desiccated crude material	NA[b]	914.0 mcg./g.	7500.0 mcg./g.

[a] Bioassay values were calculated by reducing the value obtained for the desiccated crude material in proportion to the total organic iodine. [b] NA = not available.

XVIII method measures the total iodine content (17), which is not truly reflective of the physiological activity of the preparation (10, 18, 19).

This report presents the application of spectrophotometric titration to pharmaceutical thyroid preparations. The data are compared with data obtained by bioassay. The rapidity of the method and the parallel data to bioassay should make this a useful method for control of thyroid preparations in conjunction with biological or chemical evaluation of the raw material.

EXPERIMENTAL

Thyroxine Iodine—An amount of the thyroid preparation, equivalent to 500–1000 mg. of USP material, is transferred to a centrifuge tube. The material is suspended in 10 ml. 8 *M* urea containing 1 *M* guanidine hydrochloride, as described by Covelli *et al.* (2), and is mixed intermittently for 1 hr. The tubes are then centrifuged for 15 min. at 2000 r.p.m. The yellow, slightly turbid supernate is filtered with gentle suction through a Whatman glass fiber pad on a Gooch crucible with the aid of a bell jar microfiltration assembly. The clear yellow liquid is collected in a small conical flask. Equal amounts (2 ml.) of the filtrate are pipeted into each of two test tubes. To one tube an equal volume of 8 *M* urea–1 *M* guanidine hydrochloride, buffered to pH 5.0 with 0.2 *M* acetate, is pipeted. To the other tube an equal volume of 8 *M* urea–1 *M* guanidine hydrochloride, buffered to pH 9.0 with 0.2 *M* tromethamine, is similarly added. After mixing, the solutions are transferred to matched silica cells and the difference in absorbance (ΔA) between them is measured at 325, 350, and 360 nm.

The concentration of thyroxine iodine in the cell is given by the following equation[1]:

$$\text{mcg. thyroxine iodine/ml.} = \frac{(\Delta A_{350} - \Delta A_{360})5960 - \Delta A_{325} \times 280}{10.6 \times 10^3} \times 507.6 \frac{\text{mg. iodine}}{\text{mmole thyroxine}} \quad \text{(Eq. 1)}$$

The amount of thyroxine iodine per unit of the thyroid preparation is obtained by applying the appropriate dilution factors.

The thyroid preparations tested were: desiccated crude thyroid glands, thyroid powder USP, ground tablets, and enteric-coated tablets (decoated with dilute acid and then cracked to expose the interior).

[1] For the derivation of this expression, see *Reference 2.*

Table III—Thyroxine Iodine and Total Organic Iodine of Thyroid Preparations at Various Stages of Manufacture

Preparation	Thyroxine Iodine—Spectrophotometric	Thyroxine Iodine—Bioassay	Total Organic Iodine
A:			
200-mg. enteric-coated tablets USP, mcg./tablet	33.0	44.0	380.0
Powder USP, mcg./g.	178.0	232.0	2000.0
Desiccated crude material, mg./g.	680.0	927.0	8000.0
B:			
200-mg. enteric-coated tablets USP, mcg./tablet	35.0	51.5	380.0
Powder USP, mcg./g.	213.0	292.0	2200.0
Desiccated crude material, mcg./g.	NA[a]	983.0	7400.0
C:			
Powder USP, mcg./g.	209.0	333.0	2100.0
Powder USP, mcg./g.	198.0	333.0	2100.0
Desiccated crude material, mcg./g.	NA	1250.0	7900.0

[a] NA = not available.

Bioassay—Bioassay was performed by either a mouse anoxia method (20) or a rat goiterogenic method (21).

Total Iodine—Total iodine was determined by the USP XVIII method (17).

RESULTS AND DISCUSSION

To obtain the precision of the method, five replicate analyses were run on composite samples of the various thyroid formulations. The results are shown in Table I.

Tablets and enteric-coated tablets of various dose sizes, prepared from the same lot of desiccated crude thyroid, were assayed (Table II). As expected, the spectrophotometric results are consistently lower than biological activity calculated from the value measured for the desiccated crude material in proportion to the total iodine content of the tablet or enteric-coated tablets.

Table III also displays the relation between thyroxine iodine and bioassay values. The first line in each section shows the values obtained or calculated for the preparation. The material represented on the first line was made from the powder represented on the second line which, in turn, was made from the desiccated crude material shown on the third line.

The presence of triiodothyronine is ignored by this method, since it is not measured spectrophotometrically (1, 2). This compound is reported to be at least five times as active as thyroxine (22). The deviation between the spectrophotometric and bioassay values in Tables II and III can thus be accounted for by an amount of triiodothyronine representing 5–10% of the thyroxine level.

This method may prove useful as a control assay in the manufacture of thyroid formulations. It is probably best used in conjunction with biological or chemical assay of the desiccated crude thyroid glands entering the process as raw material.

GLC of Cycloserine

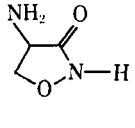
DAVID L. SONDACK▲, FRANK E. GAINER, and HAROLD J. WESSELMAN

Abstract □ A GLC assay is described for cycloserine (D-4-amino-3-isoxazolidinone). The sample is dissolved in pyridine–water (2:1), an aliquot is evaporated, and the residue is treated with *N,O*-bis(trimethylsilyl)acetamide and trimethylchlorosilane. After heating for a few minutes, chromatography is performed using a column containing methyl vinyl silicone, a relatively nonpolar liquid phase. Favorable quantitation is achieved by using hexamethylbenzene as the internal standard. The observed peak is the *N,N'*-bistrimethylsilyl derivative of cyloserine. The procedure eliminates interference from the cycloserine dimer, which does not chromatograph under these conditions.

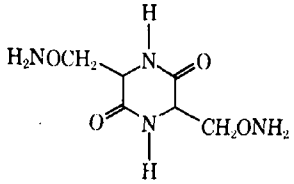
Keyphrases □ Cycloserine—GLC analysis using trimethylsilyl derivatives □ GLC—analysis of cycloserine trimethylsilyl derivatives □ Trimethylsilyl derivatization—GLC analysis of cycloserine

Cycloserine (D-4-amino-3-isoxazolidinone, I) equilibrates with its dimer, (+)-*cis*-3,6-bis(aminoxymethyl)-2,5-piperazinedione (II) even in the solid state (1, 2). In solution, pH extremes cause degradation of the dimer to 3,6-dimethylene-2,5-piperazinedione and to β-aminoxyalanine (3, 4). At or near neutral pH, dimerization predominates (4).

Quantitative determination of cycloserine in pharmaceutical preparations has been done by the nitroprusside method (5), titrimetrically and by UV spectrophotometry (6), or microbiologically against suitably susceptible microorganisms. The chemical treatment and solvents required for these assays cause formation of degradation products (1–4), which may interfere with the assay or give inaccurate results. This report presents a more specific GLC method for the quantitative analysis of cycloserine.



I



II

EXPERIMENTAL

Equipment—A gas chromatograph[1], equipped with a flame-ionization detector, was used. The detector signal was fed to a computer[2] for peak integration and to a 1-mv. recorder[3] with a chart speed of 15 in./hr. and a 1-sec. fullscale response. Samples were injected with a 10-μl. syringe[4]. Helium was used as the carrier gas, and electrolytic hydrogen and oxygen were used in the detector. The stationary phase was 3.8% UC W98 on Diatoport S[5] (80–100 mesh) packed in borosilicate glass columns 0.91-m. × 0.64-cm. o.d. All chemicals used were reagent grade or the best quality available.

Operating Conditions—The column was operated isothermally at 115° with the detector block and injection port at 150°. The helium flow rate was 55 ml./min. with an inlet pressure of 40 p.s.i. The electrometer range was 100 with an attenuation of 32. Sample injections of between 1 and 5 μl. were made.

Internal Standard—Hexamethylbenzene, 1 mg./ml., in chloroform was used.

Cycloserine Analysis—Solutions of cycloserine (I) reference standard or samples were prepared with pyridine–water (2:1) mixed prior to use and cooled to room temperature. Enough material was dissolved to provide a 1-mg./ml. solution. After mixing, excipient material was allowed to settle for 15 min. A 1-ml. aliquot of each was transferred by pipet to small screw-capped vials with Teflon septa. A stream of filtered dry air was used to evaporate the solvent. A 1-ml. portion of the internal standard solution was pipeted into each vial. The caps were screwed on firmly, and 100 μl. of *N,O*-bis(trimethylsilyl)acetamide and 10 μl. of trimethylchlorosilane[6] were added with a tuberculin syringe. After heating the vials for 10 min. on a heating block at 80°, the samples were ready for chromatography.

UV Spectra—Solutions of cycloserine reference standard and of 3,6-bis(aminoxymethyl)-2,5-piperazinedione (II) were prepared

according to the procedure described in the British Pharmacopoeia (6). Since this treatment converts II to 3,6-bismethylene-2,5-piperazinedione, solutions of II were also prepared in 0.1 *N* hydrochloric acid. UV spectra were obtained on a recording spectrophotometer[7].

GLC–Mass Spectrometry—Mass spectra of the peak observed on GLC were obtained on a mass spectrometer[8] coupled with a gas chromatograph[9] by means of a separator[10]. The sample was ionized under the influence of 70 ev.

RESULTS AND DISCUSSION

The UV spectra of cycloserine monomer (I) and dimer (II), after treatment with sodium hydroxide as described in the British Pharmacopoeia (6), are presented in Fig. 1. Obviously, a mixture of the two would not yield valid data for the assay of cycloserine using the 219-nm. reading. Also shown is the spectrum of an equivalent concentration of II not treated with base. Although significantly less absorbance at 219 nm. is exhibited, readings taken on mixtures of monomer and dimer would not be completely free of error.

A typical gas chromatogram is presented in Fig. 2. The first peak is a by-product of silylation. The second peak is the trimethylsilyl derivative of cycloserine, which was identified as *N,N'*-bis-(trimethylsilyl)-cycloserine by GLC–mass spectrometry. The fragmentation pattern was analogous to that described for various cycloserine derivatives (7). The third peak in the chromatogram is hexamethylbenzene, the internal standard. Relative to hexamethylbenzene, the retention time of cycloserine is 0.67.

Accuracy and precision were determined by analyses of five replicate samples. A residual standard deviation of ±0.5% and a relative error of +2.0% were obtained.

Samples of II and of 3,6-bismethylene-2,5-piperazinedione were taken for GLC under conditions identical to those for I. An insoluble residue remained after treatment with silylating reagents, and no peaks were detectable on chromatography even after extended time periods and temperature elevation. These compounds interfere with UV analysis of I.

A sample of β-aminoxyalanine, treated in the same manner as I, gave a peak with a relative retention time of 4.0 compared to hexamethylbenzene. Thus, the known degradation products of I have been shown not to interfere with GLC analysis.

Aged and degraded samples of cycloserine capsules were evaluated by this method. The assay values showed a decrease *versus* the age of the sample and were in agreement with microbiological data. No interferences or extraneous peaks were observed on the chromatograms.

SUMMARY

A GLC procedure for the specific determination of cycloserine was developed. The method is precise to within ±0.5%. The determination of cycloserine in a pharmaceutical preparation and in

Selective Determination of Belladonna Alkaloids by GLC

RALPH S. SANTORO▲, PATRICIA P. PROGNER, EDWARD A. AMBUSH, and DAVID E. GUTTMAN

Abstract □ Atropine/hyoscyamine and scopolamine, in dosage forms in which the scopolamine represented less than 9% of the total belladonna alkaloids, were isolated as free bases from phenylpropanolamine, chlorpheniramine, and interfering excipients by a series of pH- and solvent-controlled extractions and were quantitated by GLC. Homatropine was used as the internal standard. Precision and accuracy data are represented, along with assay results on three commercial capsule lots.

Keyphrases □ Belladonna alkaloid mixtures with phenylpropanolamine and chlorpheniramine, low scopolamine content—GLC analysis, atropine/hyoscyamine and scopolamine □ Atropine/hyoscyamine and low-content scopolamine—GLC analysis in mixtures with phenylpropanolamine and chlorpheniramine □ Scopolamine (low content) and atropine/hyoscyamine—GLC analysis in mixtures with phenylpropanolamine and chlorpheniramine □ GLC—analysis, atropine/hyoscyamine and scopolamine in mixtures with phenylpropanolamine and chlorpheniramine

Because of its specificity, sensitivity, and resolving properties, GLC has been increasingly used for belladonna alkaloid analysis (1–6). The USP collaborative study for the assay of atropine and scopolamine dosage forms by GC (7) indicated that these two substances, when found individually in tablet dosage forms, could be assayed in this manner with an acceptable degree of precision.

However, the case becomes less clear, even with the high resolving power of GC, when belladonna is found in the presence of a preponderant concentration of other amines and/or in dosage forms with high background contributions. The problem is further complicated when both atropine and scopolamine must be determined together with, as is many times the case, the scopolamine only a small fraction of the atropine.

This paper describes a GLC procedure in which hyoscyamine sulfate, atropine sulfate, and scopolamine hydrobromide in dosage forms are determined in the presence of chlorpheniramine maleate and phenylpropanolamine hydrochloride, and also where the scopolamine content is less than 9% of the total belladonna present.

EXPERIMENTAL

Materials—*Buffer*—Dissolve 34.8 g. of dibasic potassium phosphate in 900 ml. of water, adjust to pH 9.0 with 1 *N* hydrochloric acid or sodium hydroxide, and dilute to 1 l. with water.

Methylene Chloride—Distill reagent grade methylene chloride and store in a tightly closed container.

Atropine Sulfate Standard Solutions—Prepare solutions of USP Atropine Sulfate Reference Standard (or NF Hyoscyamine Sulfate Reference Standard), dried at 105° for 4 hr., in 0.01 *N* sulfuric acid with concentrations of 0.70, 0.65, and 0.60 mg./ml.

Scopolamine Hydrobromide Standard Solutions—Prepare solutions of USP Scopolamine Hydrobromide Reference Standard, dried at 105° for 4 hr., in 0.01 *N* sulfuric acid with concentrations of 0.070, 0.065, and 0 060 mg./ml.

Internal Standard Solution—Prepare a solution of USP Homatropine Hydrobromide Reference Standard, dried at 105° for 4 hr., in 0.01 *N* sulfuric acid with a concentration of 0.50 mg./ml.

Procedure—For this study, the contents of six capsules, each containing 50 mg. of phenylpropanolamine hydrochloride, 4 mg. of chlorpheniramine maleate, and 0.25 mg. of combined belladonna alkaloids (0.0375 mg. atropine sulfate, 0.0219 mg. scopolamine hydrobromide, and 0.1906 mg. hyoscyamine sulfate) were triturated with 0.01 *N* sulfuric acid. The slurry was quantitatively transferred to a 50-ml. volumetric flask, 2.0 ml. of internal standard was added, and it was diluted to volume with 0.1 *N* sulfuric acid. The contents of the flask were transferred to a 50-ml. centrifuge bottle and centrifuged at 2000 r.p.m. for 15 min., and 25.0 ml. of clear supernatant solution was transferred to a 150-ml. separator.

The solution was extracted twice with 25-ml. portions of chloroform, and the chloroform extracts along with any emulsion were discarded. Vigorous shaking was avoided in this step to prevent excessive emulsion formation, so losses of belladonna alkaloids and internal standard were minimized. The pH of the solution was adjusted to 8.0 ± 0.1 by the addition of 25 ml. of pH 9.0 buffer and the dropwise addition of 1 *N* sodium hydroxide; then the solution was extracted with three 25-ml. portions of cyclohexane, and the cyclohexane extracts were discarded. The solution was further

the presence of degradation products was performed. The method may also find application in kinetic studies of cycloserine degradation.

Selective Determination of Belladonna Alkaloids by GLC

RALPH S. SANTORO▲, PATRICIA P. PROGNER, EDWARD A. AMBUSH, and DAVID E. GUTTMAN

Abstract □ Atropine/hyoscyamine and scopolamine, in dosage forms in which the scopolamine represented less than 9% of the total belladonna alkaloids, were isolated as free bases from phenylpropanolamine, chlorpheniramine, and interfering excipients by a series of pH- and solvent-controlled extractions and were quantitated by GLC. Homatropine was used as the internal standard. Precision and accuracy data are represented, along with assay results on three commercial capsule lots.

Keyphrases □ Belladonna alkaloid mixtures with phenylpropanolamine and chlorpheniramine, low scopolamine content—GLC analysis, atropine/hyoscyamine and scopolamine □ Atropine/hyoscyamine and low-content scopolamine—GLC analysis in mixtures with phenylpropanolamine and chlorpheniramine □ Scopolamine (low content) and atropine/hyoscyamine—GLC analysis in mixtures with phenylpropanolamine and chlorpheniramine □ GLC—analysis, atropine/hyoscyamine and scopolamine in mixtures with phenylpropanolamine and chlorpheniramine

Because of its specificity, sensitivity, and resolving properties, GLC has been increasingly used for belladonna alkaloid analysis (1–6). The USP collaborative study for the assay of atropine and scopolamine dosage forms by GC (7) indicated that these two substances, when found individually in tablet dosage forms, could be assayed in this manner with an acceptable degree of precision.

However, the case becomes less clear, even with the high resolving power of GC, when belladonna is found in the presence of a preponderant concentration of other amines and/or in dosage forms with high background contributions. The problem is further complicated when both atropine and scopolamine must be determined together with, as is many times the case, the scopolamine only a small fraction of the atropine.

This paper describes a GLC procedure in which hyoscyamine sulfate, atropine sulfate, and scopolamine hydrobromide in dosage forms are determined in the presence of chlorpheniramine maleate and phenylpropanolamine hydrochloride, and also where the scopolamine content is less than 9% of the total belladonna present.

EXPERIMENTAL

Materials—*Buffer*—Dissolve 34.8 g. of dibasic potassium phosphate in 900 ml. of water, adjust to pH 9.0 with 1 *N* hydrochloric acid or sodium hydroxide, and dilute to 1 l. with water.

Methylene Chloride—Distill reagent grade methylene chloride and store in a tightly closed container.

Atropine Sulfate Standard Solutions—Prepare solutions of USP Atropine Sulfate Reference Standard (or NF Hyoscyamine Sulfate Reference Standard), dried at 105° for 4 hr., in 0.01 *N* sulfuric acid with concentrations of 0.70, 0.65, and 0.60 mg./ml.

Scopolamine Hydrobromide Standard Solutions—Prepare solutions of USP Scopolamine Hydrobromide Reference Standard, dried at 105° for 4 hr., in 0.01 *N* sulfuric acid with concentrations of 0.070, 0.065, and 0 060 mg./ml.

Internal Standard Solution—Prepare a solution of USP Homatropine Hydrobromide Reference Standard, dried at 105° for 4 hr., in 0.01 *N* sulfuric acid with a concentration of 0.50 mg./ml.

Procedure—For this study, the contents of six capsules, each containing 50 mg. of phenylpropanolamine hydrochloride, 4 mg. of chlorpheniramine maleate, and 0.25 mg. of combined belladonna alkaloids (0.0375 mg. atropine sulfate, 0.0219 mg. scopolamine hydrobromide, and 0.1906 mg. hyoscyamine sulfate) were triturated with 0.01 *N* sulfuric acid. The slurry was quantitatively transferred to a 50-ml. volumetric flask, 2.0 ml. of internal standard was added, and it was diluted to volume with 0.1 *N* sulfuric acid. The contents of the flask were transferred to a 50-ml. centrifuge bottle and centrifuged at 2000 r.p.m. for 15 min., and 25.0 ml. of clear supernatant solution was transferred to a 150-ml. separator.

The solution was extracted twice with 25-ml. portions of chloroform, and the chloroform extracts along with any emulsion were discarded. Vigorous shaking was avoided in this step to prevent excessive emulsion formation, so losses of belladonna alkaloids and internal standard were minimized. The pH of the solution was adjusted to 8.0 ± 0.1 by the addition of 25 ml. of pH 9.0 buffer and the dropwise addition of 1 *N* sodium hydroxide; then the solution was extracted with three 25-ml. portions of cyclohexane, and the cyclohexane extracts were discarded. The solution was further

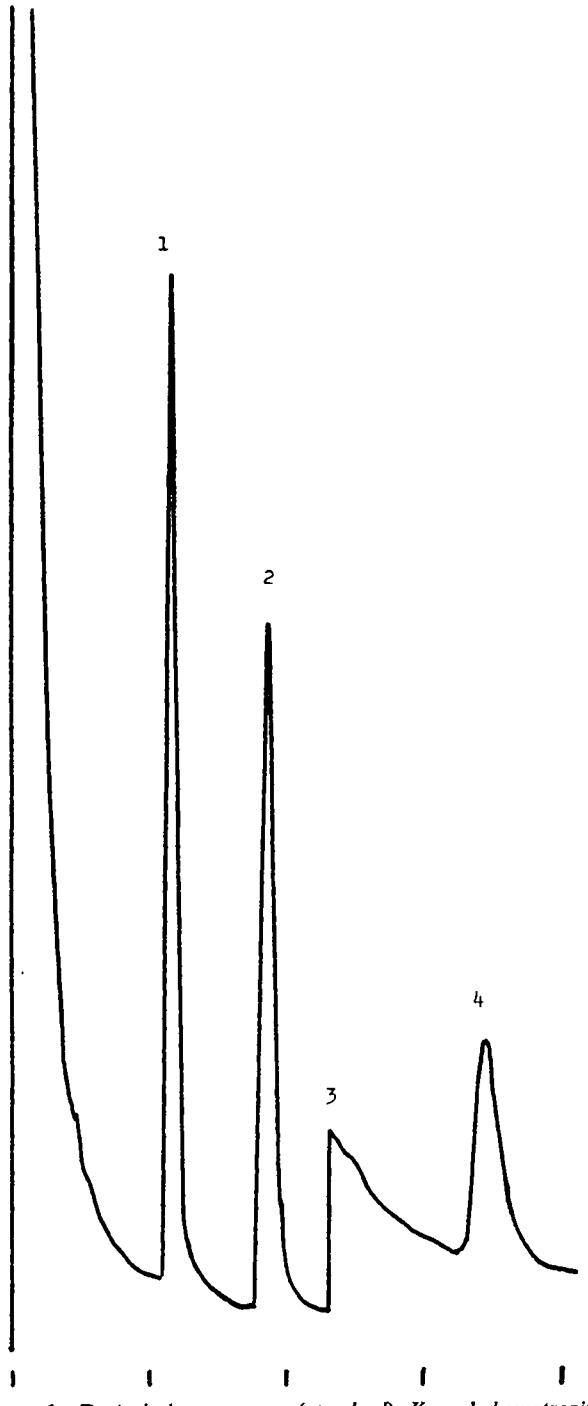

Figure 1—*Typical chromatogram (standard). Key: 1, homatropine; 2, atropine/hyoscyamine; 3, attenuation change; and 4, scopolamine.*

adjusted to pH 9.0 ± 0.1 with 1 *N* sodium hydroxide and extracted with two 10-ml. portions of methylene chloride. Then the methylene chloride extracts were combined and allowed to stand to permit as much of the emulsion to break as practical. The clear extract was filtered through a cotton–anhydrous sodium sulfate filter, previously wetted with methylene chloride into a 25-ml. graduated cylinder, transferred to a 19 × 36-mm. glass vial equipped with a plastic liner cap, and evaporated to dryness under nitrogen and mild heat. The residue was dissolved in 0.9 ml. of methylene chloride and used for GLC. A series of combined standards was prepared by pipeting 1.0 ml. of each atropine and scopolamine standard solution into each of three 150-ml. separators containing 25 ml. of 0.1 *N* sulfuric acid, so that combined standards of 0.70 and 0.070, 0.65 and 0.065, and 0.60 and 0.060 mg. of atropine and scopolamine, respectively, were obtained. A 1.0-ml. of aliquot of the internal standard solution was pipeted into each separator, and the combined standards were then carried through the procedure as already described, beginning with: "The solution was extracted twice with 25-ml. portions of chloroform. . . ."

GLC—The analysis was performed on a gas chromatograph[1] equipped with a 1.22-m. (4-ft.) × 4-mm. glass column packed with 3% (w/w) methyl phenyl silicone oil on 100–120-mesh silanized, acid-washed, flux-calcined diatomite[2] and also equipped with a flame-ionization detector. The column was conditioned at 250° for 1 hr. with helium flowing to remove oxygen and solvents, stopping the flow of helium and heating at about 340° for 4 hr., and finally lowering the temperature to 250° and conditioning with helium flowing until a stable baseline was obtained (7, 8). Weekly injections[3]

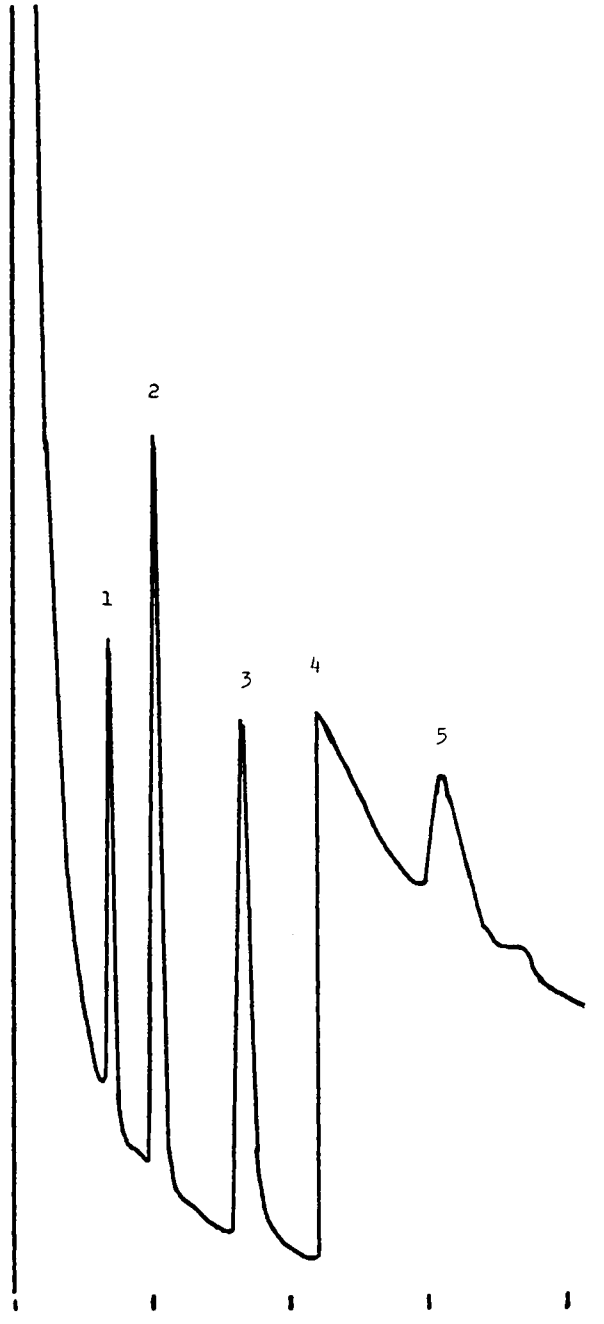

Figure 2—*Typical chromatogram (capsule). Key: 1, chlorpheniramine; 2, homatropine; 3, atropine/hyoscyamine; 4, attenuation change; and 5, scopolamine.*

[1] Perkin-Elmer 900.

maintained column efficiency. The analysis was carried out isothermally at 210°, with the helium carrier gas flow rate at about 50 ml./min. and the temperature of the injection port not more than 25° above that of the column.

Appropriate volumes of the standard and sample preparations were injected into the chromatograph, and the peaks were obtained at a convenient attenuation. The attenuation was decreased by a factor of 8 about halfway between the hyoscyamine/atropine peak and the scopolamine peak to increase the height of the scopolamine peak. The heights were measured for the first (homatropine), second (hyoscyamine and atropine), and third (scopolamine) components for each standard injection, and the values were recorded as P_1, P_2, and P_3, respectively. The standard hyoscyamine/atropine ratio, R_a, and standard scopolamine ratio, R_s, were calculated by:

$$R_a = P_2/P_1 \qquad \text{(Eq. 1)}$$

$$R_s = P_3/P_1 \qquad \text{(Eq. 2)}$$

The average factors for hyoscyamine/atropine, F_a, and scopolamine, F_s, were determined by dividing each R_a and R_s into its respective standard concentration and averaging the individual factors obtained. The peak heights were measured for the sample preparations in the same manner as above and recorded as p_1, p_2, and p_3, respectively. The hyoscyamine/atropine ratio, r_a, and scopolamine ratio, r_s, were calculated by:

$$r_a = p_2/p_1 \qquad \text{(Eq. 3)}$$

$$r_s = p_3/p_1 \qquad \text{(Eq. 4)}$$

The hyoscyamine/atropine (A_1) and scopolamine (A_2) assay was calculated by:

$$A_1 = \frac{F_A \times r_a \times 1.023}{3} \qquad \text{(Eq. 5)}$$

$$A_2 = \frac{F_s \times r_s \times 1.12}{3} \qquad \text{(Eq. 6)}$$

The factors 1.023 and 1.12 convert anhydrous hyoscyamine/atropine and scopolamine to the USP hydrated form.

Table I—Belladonna Alkaloid Recovery

Average	100	102
Sigma	0.8	3.7
Standard error	0.3	1.5

[a] Each recovery sample contained 150 mg. phenylpropanolamine hydrochloride, 12 mg. chlorpheniramine maleate, and 0.75 mg. belladonna alkaloids (atropine sulfate, 0.1125 mg.; hyoscyamine sulfate, 0.5700 mg.; and scopolamine hydrobromide, 0.0675 mg.) plus placebo.

Table II—Belladonna Alkaloid Assay of Commercial Capsule Lots

Lot	Percent Claim[a] Hyoscyamine/Atropine	Scopolamine
1	97	97
2	100	97
3	100	102

[a] Claim per capsule: 50 mg. phenylpropanolamine hydrochloride, 4 mg. chlorpheniramine maleate, and 0.25 mg. belladonna alkaloids (atropine sulfate, 0.0375 mg.; hyoscyamine sulfate, 0.1906 mg.; and scopolamine hydrobromide, 0.0219 mg.).

RESULTS AND DISCUSSION

Figures 1 and 2 are typical chromatograms obtained from standards and samples with a 10-μl. injection, preliminary attenuation of 256, and a final attenuation for scopolamine of 32. The system does not differentiate the isomers, hyoscyamine and atropine, which are eluted as one peak. The peak before the internal standard, homatropine, in the sample chromatogram (about 3 4 min.) is a trace of chlorpheniramine not removed by the cyclohexane extraction at pH 8.0. The dissolution of atropine/hyoscyamine in some dosage forms was followed, and Fig. 3 is a representative standard curve obtained in these experiments. The curve shows good linearity throughout the required range.

Table I lists recoveries of known amounts of the belladonna alkaloids mixed with placebo, which contained phenylpropanolamine hydrochloride and chlorpheniramine maleate in the ratio of 200 and 16 times, respectively, the concentration of the total belladonna content. Recoveries were quantitative, with the standard deviation for scopolamine significantly higher than that for hyoscyamine/atropine, reflecting the fact that its peak was measured at a much lower attenuation because it represented less than 9% of the total belladonna present. Furthermore, a small error in measurement produced a proportionately greater error in the final calculation.

Three different commercial lots of capsules were assayed (Table II). The reproducibility was checked in Lot 1, and the standard deviations were found to be 1.4 and 3.4 atropine/hyoscyamine and scopolamine, respectively. These values were of the same order of magnitude as reported in the recovery experiments.

Control of pH was important for obtaining correct results and acceptable precision limits. The initial extraction with chloroform from acid was to remove interfering wax excipients that chromatograph with similar retention times as the internal standard and belladonna alkaloids. The adjustment to pH 8.0 for the cyclohexane extraction was carefully controlled, since a higher pH would entail significant loss of belladonna while a lower value would leave too much chlorpheniramine behind. The chlorpheniramine would be extracted in the next step and interfere with the internal standard peak. Similarly, careful adjustment to pH 9.0 for the methylene chloride extraction of the belladonna was required because phenylpropanolamine would begin to partition at a higher pH. Distilled methylene chloride was necessary for extraction because reagent grade and spectrograde material contained additives that chromatographed with a similar retention time as that of scopolamine.

Throughout the extractions, vigorous shaking was avoided to control emulsion formation.

SUMMARY

A GLC procedure was presented that is capable of determining atropine/hyoscyamine and scopolamine in the presence of phenylpropanolamine and chlorpheniramine, and also where the scopolamine is less than 9% of the belladonna present. Interfering excipients were removed with chloroform from acid, adjustment to pH 8.0 and extraction with cyclohexane removed chlorpheniramine, and further adjustment to pH 9.0 with methylene chloride extraction isolated the belladonna alkaloids. The final extract was concentrated and gas chromatographed. Homatropine was used as the internal standard. The method was sensitive, highly specific, and reasonably precise.

PHARMACEUTICAL TECHNOLOGY

Sensory Assessment of Spreadability of Hydrophilic Topical Preparations

B. W. BARRY▲ and M. C. MEYER

Abstract □ The rheological conditions operative during spreading of topical preparations on the skin were determined for series of aqueous gels and oil-in-water emulsions. Master curves were derived from the rheological data obtained using a sensory test with a panel of 24 members. Rates of shear varied from 350 to 10,000 sec.$^{-1}$, depending on the consistency and the type of preparation being spread. Two preference scoring techniques were used to assess the series of preparations in terms of spreadability. From the preference data, the shearing conditions with optimum patient acceptance potential were derived. An indication is given for the use of such master curves with their preferred regions for the determination of instrumental rheological conditions for use in routine and innovative industrial control procedures. Where relevant, all results were compared with previously reported work on lipophilic formulations.

Keyphrases □ Spreadability—sensory tests correlated to rheological conditions, hydrophilic topical preparations □ Rheological master curve—shear rate variation, spreadability of hydrophilic topical preparations, sensory tests □ Skin, sensory perception of spreadability of hydrophilic topical preparations—correlation of rheological conditions, master curves derived

In the pharmaceutical and cosmetic industries, it is important that formulations, besides possessing the correct physicochemical and biopharmaceutical properties, should have maximum patient and consumer acceptability. Spreadability plays an important role in the patient's assessment of a topical product. The correct consistency for such a preparation helps to ensure that a suitable dose is applied to the skin. This is particularly important with vehicles that incorporate potent drugs such as corticosteroids; excessive doses may lead to collagen atrophy and other undesirable side effects. Previous authors have assessed spreadability in terms of shear rate, either by a correlation with non-Newtonian viscosities (1–4) or by assuming that the spreading procedure can be likened to plane laminar flow between parallel plates (5–7) and thus can be described by the equation:

$$\dot{\gamma} = V/d \qquad \text{(Eq. 1)}$$

where $\dot{\gamma}$ is the rate of shear, V is the relative velocity of the plates or skin surfaces, and d is the distance between them. *Estimates* of V and d were used to find the shearing conditions operative during spreading.

In contrast, Wood (8) developed a method which involved comparing Newtonian liquids with pseudoplastic liquids to determine the approximate rate of shear developed in the mouth. This procedure, which has the advantage that V and d need not be known to determine the shearing conditions occurring *in vivo*, was modified by Barry and Grace (9) to investigate the rheological conditions that operate during the spreading of lipophilic preparations on the skin.

In the present work, the techniques used by Barry and Grace (9) were extended to investigate the shearing con-

Throughout the extractions, vigorous shaking was avoided to control emulsion formation.

Where relevant, all results were compared with previously reported work on lipophilic formulations.

Keyphrases □ Spreadability—sensory tests correlated to rheological conditions, hydrophilic topical preparations □ Rheological master curve—shear rate variation, spreadability of hydrophilic topical preparations, sensory tests □ Skin, sensory perception of spreadability of hydrophilic topical preparations—correlation of rheological conditions, master curves derived

In the pharmaceutical and cosmetic industries, it is important that formulations, besides possessing the correct physicochemical and biopharmaceutical properties, should have maximum patient and consumer acceptability. Spreadability plays an important role in the patient's assessment of a topical product. The correct consistency for such a preparation helps to ensure that a suitable dose is applied to the skin. This is particularly important with vehicles that incorporate potent drugs such as corticosteroids; excessive doses may lead to collagen atrophy and other undesirable side effects. Previous authors have assessed spreadability in terms of shear rate, either by a correlation with non-Newtonian viscosities (1–4) or by assuming that the spreading procedure can be likened to plane laminar flow between parallel plates (5–7) and thus can be described by the equation:

$$\dot{\gamma} = V/d \qquad \text{(Eq. 1)}$$

where $\dot{\gamma}$ is the rate of shear, V is the relative velocity of the plates or skin surfaces, and d is the distance between them. *Estimates* of V and d were used to find the shearing conditions operative during spreading.

In contrast, Wood (8) developed a method which involved comparing Newtonian liquids with pseudoplastic liquids to determine the approximate rate of shear developed in the mouth. This procedure, which has the advantage that V and d need not be known to determine the shearing conditions occurring *in vivo*, was modified by Barry and Grace (9) to investigate the rheological conditions that operate during the spreading of lipophilic preparations on the skin.

In the present work, the techniques used by Barry and Grace (9) were extended to investigate the shearing con-

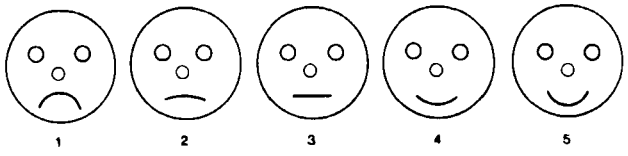

Figure 1—*Preference Scoring System 2. Faces represent degrees of agreeableness during spreading, with numerical scores as shown.*

ditions that operate during the spreading of aqueous gels. Oil-in-water emulsions were similarly tested to ascertain whether an internal lipophilic phase affected these conditions.

Preference scaling techniques were used to obtain the optimum consistency for spreading and, thus, the maximum patient acceptability potential for a preparation.

The formulations investigated varied in consistency from mobile liquids to stiff and, in some cases, highly elastic semisolids and, therefore, encompassed the range of consistencies found in hydrophilic topical applications.

EXPERIMENTAL

In general, the theory used and experimental procedures applied were as reported previously (9). Only the essential details and variation in procedure are reported here.

Preparations Used—Fifteen gels, ranging in consistency from mobile liquids to elastic semisolids, were prepared by neutralizing aqueous solutions of carboxypolymethylene 940 or 941[1] with triethanolamine (Table I). Sample 1 was a mixture of starch and Carbopol gel. Samples 17–22 were liquid paraffin in water emulsions stabilized by the mixed emulsifier cetrimide–cetostearyl alcohol in various concentrations. All materials were of BP or BPC quality, except the Carbopols which were commercial samples. Prior to use, samples were stored at 25 ± 1°.

Instrumental Rheology—A range of silicone oils [viscosities determined[2] by Barry and Grace (9) at 34 ± 0.2°] were used as standards. A cone and plate viscometer[3] with automatic flow curve recorder unit and *X–Y* plotter was used in two modes to obtain rheograms for the test preparations at 34 ± 0.2° (approximate skin temperature).

Instrumental Method 1—The samples were continuously sheared from 0.0 to 1754.0 to 0.0 sec.$^{-1}$ in 120 sec. When necessary, the shear rate range was changed either by alteration (by a factor of 10) of the gear train in the cone drive unit or by using cones of different angles.

Instrumental Method 2—The viscometer (with *X–Y* plotter measuring torque as a function of time) was used to determine shear stresses at various constant rates of shear. The "fast-up" control applied the rate of shear within about 1 sec., and the "hold speed" control maintained the shear rate. From the plot obtained at each shear rate, the shear stresses at zero time and after 20 sec. [estimate of average time of spreading (9)] were determined.

Instrumental Method 2 is relevant when the material being tested exhibits time-dependent behavior on shearing. For Carbopol gels, time-dependent effects were negligible (programmed shearing provided negligible hysteresis loops); thus, the data obtained by Method 2 agreed with those from Method 1 and are not included. Since the oil-in-water emulsions provided large hysteresis loops, both sets of data are shown.

Sensory Tests—From a panel of 24, a minimum of 14 and a maximum of 24 persons were selected for any one test. The untrained panel contained both sexes, with an age range of 18–50 years. The panel members were asked to assess the preparations critically, according to the relevant scaling procedure, while spreading the materials onto the inner surface of the forearm. In all sensory tests, three or four samples were presented to each panel

member at each session according to a scheme designed to eliminate the sample sequence affecting the results. The reliability of the panel members was confirmed using the method of circular triads (10–12) with Samples 5–12.

Shear Conditions during Spreading—Panel members were asked to indicate for each sample the Newtonian silicone oil that appeared

The data are numbered to identify the samples; in parentheses are the coefficients of variation of the Newtonian viscosity values used to obtain the data.*

Table I—Formulations of Preparations Used (by Weight)

Sample Number	Carbopol 940 or 941	Starch	Cetrimide	Cetostearyl Alcohol	Water	Liquid Paraffin
1	5	50	—	—	45	—
2–16	20–0.025	—	—	—	80–99.975	—
17	—	—	6.4	57.6	100	300
18	—	—	4.8	43.2	100	300
19	—	—	4.0	36.0	100	300
20	—	—	3.2	28.8	100	300
21	—	—	2.4	21.6	100	300
22	—	—	0.8	7.2	100	300

most similar while spreading on the skin. The shearing conditions operative during spreading are assumed to be those located at the intersection of the rheogram obtained by Instrumental Method 1 or 2, and the flow curve for the Newtonian silicone oil, judged by the panel to be of similar spreadability to the sample under test.

Preference Testing—Panel members were asked to evaluate Samples 4–22 taken in groups of three or four according to two scoring systems (only one scoring system was used per session).

System 1 [Five-Point Semantic Hedonic Scale (5, 8, 9)]—

Score	Sensation during Spreading
1	Too fluid, disagreeable
2	Fluid but all right
3	Agreeable
4	Stiff but all right
5	Too stiff, disagreeable

System 2 [Five-Point Facial Hedonic Scale (13, 14)]—Panel members were asked to indicate the face that most closely agreed with their feeling with regard to the spreadability of each sample. Scores were allocated to their decision (Fig. 1). The faces depict the degree of agreeableness or disagreeableness experienced by the subject, the neutral face being the median interval. System 2 was developed (13) to overcome problems in semantics, which can arise with the use of descriptive rating scales such as System 1. A score of 1 or 5 in System 1 corresponds approximately to a score of 1 in System 2. A score of 2 or 4 in System 1 corresponds approximately to a score of 2 in System 2, and a score of 3 is approximately the same for both systems. Scores of 4 and 5 in System 2 represent degrees of agreeableness not present in System 1; hence, System 2 was considered by one worker to be more sensitive than System 1 when used for tasting tests (13).

Data Analysis[4]—A computer program was used to fit the best straight line or curve to the data obtained from the two preference scoring methods, according to the least-squares criterion. A second program was used to calculate the means, standard deviations, coefficients of variation, and other statistical data used in this work.

[4] Using an I.C.L. 4130 computer with computer instrumentation plotter C4600.

RESULTS

The rheological conditions operative during spreading of the aqueous gels were similar whether derived by Instrumental Method 1 or 2. These conditions, when used in a double-logarithmic plot of shearing stress against shear rate, showed a distinct trend (dotted lines in Fig. 2). The double-logarithmic plot of the oil-in-water emulsions showed a similar trend to the gels but, in general, the oil-in-water emulsions were assessed at lower rates of shear (Fig. 3). The Newtonian viscosity, used to determine the rheological conditions for any sample, was the arithmetic mean of the silicone oil viscosities considered by each panel member to be similar to the topical product during spreading. The coefficients of variation of the panel data are indicated in Figs. 2 and 3.

The data derived from the two preference scaling procedures are listed in Table II. The apparent viscosities quoted were obtained from Instrumental Method 1 data at the rate of shear indicated approximately by the master curve. The mean panel scores were compared graphically with their respective instrumental viscosities. For Scoring System 1, linear plots were obtained using semi- and double-logarithmic axes; for Scoring System 2, parabolic plots were obtained using the same axes (Figs. 4–7). The equations for these lines are listed in Table III. The use of higher order polynomials in the computer analysis gave better fitting curves but were not used owing to the limited accuracy of the experimental data.

The data from Scoring System 2 for Samples 4 and 16 were not included in the computer analysis, because these points would have

[a] Equations for Figs. 4 and 5 are derived from Preference Scoring System 1; those for Figs. 6 and 7 are derived from Preference Scoring System 2.

unrealistically distorted the curve. This situation arises because the minimum preference score is 1, whereas apparent viscosities may range from near zero to infinity. If such extreme data are added to the graph, the resulting extended tails seriously widen the curve apex. This makes the curve a less sensitive means for assessing the range of acceptable apparent viscosities. For Scoring System 1, the optimum apparent viscosity for spreading corresponded to a score of 3 and the range of acceptable apparent viscosities was given by the score of 2–4. For Scoring System 2 the optimum was given by the highest score obtained and corresponded to the maximum of the parabola; the range was given by a score of 3 or greater. These values were obtained from the plots (Figs. 4–7) and checked by substituting the appropriate scores in the respective equations (Table III). The optimum viscosities were plotted, in terms of shear rate–shear stress, on the master curves, and the intersection of the two plots defined the shearing conditions with maximum patient acceptability for the class of preparations under consideration (Fig. 8). The range of acceptable values were similarly plotted (shaded areas in Fig. 8).

DISCUSSION

Figure 2 shows the approximate rheological conditions that operate during the spreading of aqueous gels on the skin. The master curve obtained for these hydrophilic preparations approximates to a mirror image, about the figure's diagonal axis, of the master curve for lipophilic materials (9). This suggests that there is a large general region defining the shear stress–shear rate conditions which operate during spreading of topical preparations and that exact conditions depend on the class of preparations applied.

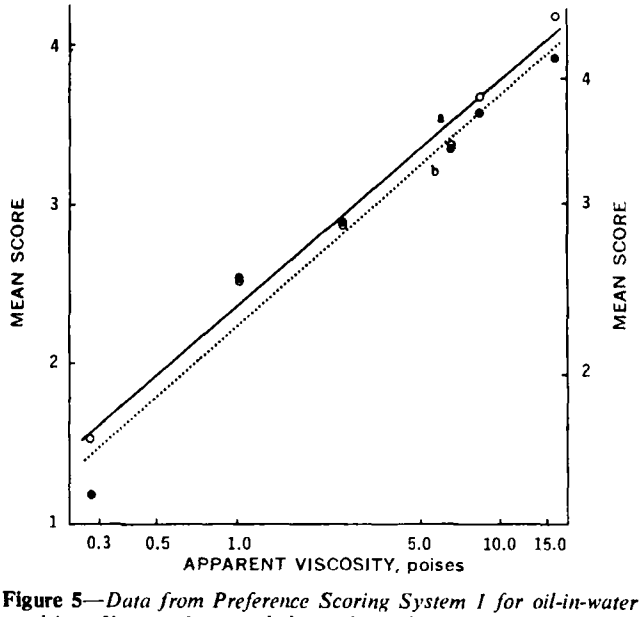

Figure 5—*Data from Preference Scoring System 1 for oil-in-water emulsions. Key: —, ○, a, single-logarithmic plot; and . . . , ●, b, double-logarithmic plot.*

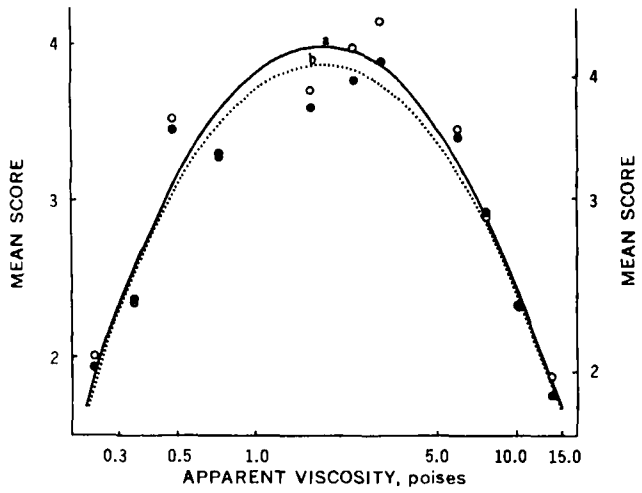

Figure 6—*Data from Preference Scoring System 2 for gels. Key: —, ○, a, single-logarithmic plot; and . . . , ●, b, double-logarithmic plot.*

The Carbopol gels containing more than 5% polymer (Samples 2–4) were highly elastic semisolids, which tended to roll up rather than to spread when applied to the skin. It was considered possible that this dominant elasticity was mainly responsible for the shape of the curve at high stress values and that very viscous preparations which lacked substantial elastic properties would not fit on the curve. To resolve this point, it was necessary to prepare and test a hydrophilic preparation of high consistency but minimal elastic recoil. This was achieved by blending starch with gel (Sample 5) to provide Sample 1. The position of the experimental point for this sample (Fig. 2) confirms the general curvature of the graph. In addition, gels containing 5% polymer or less (Samples 5–12), although they exhibited little rolling-up behavior, still defined the curved portion of the graph. Thus, it was considered valid to use elastic gels (Samples 2–4) as aids in defining the general shape of the curve, which then would be applicable to hydrophilic, elastic, and nonelastic gels.

The master curve for aqueous gels is approximately vertical at high shear rates, indicating that mobile materials are applied to the skin at a constant high rate of shear, with shear stress being the variable assessed subjectively by the patient. However, as consistency increased, the applied shear rate decreased so that both rheological

[a] Corresponding to a preference mean score of 3 (Figs. 4 and 5). [b] Corresponding to a preference mean score of 2–4 (Figs. 4 and 5). [c] Corresponding to parabola maximum (Figs. 6 and 7). [d] Corresponding to a preference mean score of 3 (Figs. 6 and 7). [e] Derived from *Reference 9*.

parameters varied from gel to gel. The shear rate variation was caused by two factors: (*a*) the more mobile the gel, the faster the rubbing cycle used (V increases in Eq. 1); and (*b*) the stiffer the material, the thicker the layer applied (d increases in Eq. 1).

The master curves for lipophilic and hydrophilic preparations diverge widely over much of their lengths. This suggests that panel members consciously or unconsciously consider the extent of oiliness of a preparation when assessing its spreadability. This phenomenon is less important at the extremes of the consistency range where the master curves converge at high and low stress values; *i.e.*, at these consistencies, rheological parameters are much more important than a tactile stimulus such as oiliness. If it is true that, for the major portion of the consistency range, patients are influenced in a judgment of spreadability by the proportion of lipophilic material present, it follows that if an oil phase is introduced into a preparation but its overall nature is maintained as hydrophilic, the resulting master curve should lie between the lipophilic and gel curves. As can be seen from Fig. 3, the curve for such materials formulated as oil-in-water emulsions has the same general shape as the gel curve but it is shifted towards the lipophilic curve, thus confirming this view.

When master curves such as those shown in Figs. 2 and 3 have been constructed, it is possible to define preferred areas of acceptability by using the data derived from preference testing (Table IV). Optimum apparent viscosities for spreading, together with the acceptable ranges, are plotted on the master curves. (Figure 8 illustrates arithmetic average values for the two preference scoring methods calculated from both semi- and double-logarithmic plots.) As can be seen from Table IV, both preference scoring procedures gave similar results. However, compared to lipophilic preparations, the preferred regions for gels and oil-in-water emulsions were enlarged, caused mainly by the low limit corresponding to the "fluid but all right" rating. The difficulty that the panel experienced in scoring hydrophilic preparations as "too fluid, disagreeable" was possibly because they were conditioned from birth to accept very mobile, aqueous solutions for spreading on the skin (*i.e.*, washing with soap and water). Such conditioning would not significantly affect the rating for oily preparations; hence, a definite, relatively high, limit was obtained for lipophilic preparations. This conditioning effect is also illustrated in the way in which the optimum apparent viscosity for spreading increases in the order of: gels, oil-in-water emulsions, and lipophilic preparations, *i.e.*, in the order of decreasing hydrophilicity (Table IV). The upper limits for lipophilic and hydrophilic formulations were similar, although shearing conditions were higher in the latter case (*i.e.*, higher shear stresses and shear rates operate for hydrophilic materials).

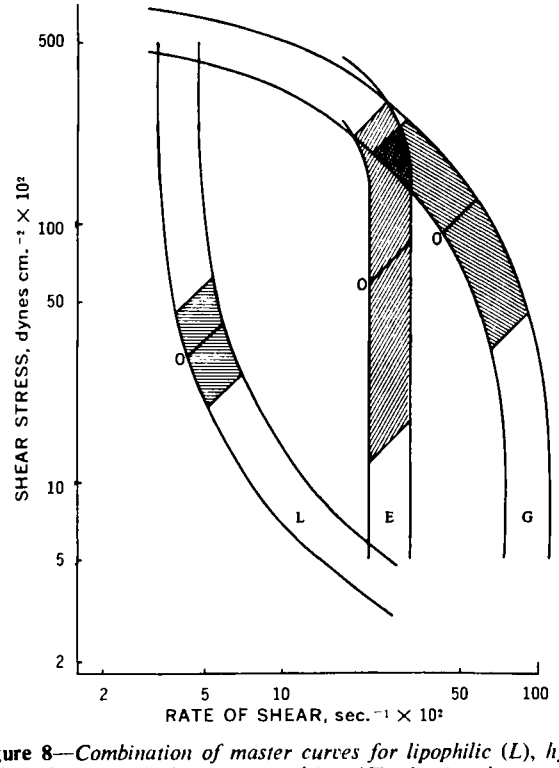

Figure 8—*Combination of master curves for lipophilic (L), hydrophilic gels (G), and oil-in-water emulsions (E), showing the acceptable range of viscosities for spreading on the skin (shaded area) and the optimum values (solid line 0).*

In the context of this conditioning effect, it was thought possible that there might be a difference in the location and extent of the preferred regions, based on whether these were derived using an all male or all female panel. For example, it might be that women, due to their experience with cosmetics, would be more critical than men of the spreadability of a preparation and would report a more condensed preferred region. Therefore, the preference results were divided into two subsets, male and female; the data were computed and graphed as before; and the subsets were compared with each other and with the total panel. However, any differences based on sex were found to be nonsignificant when compared by an F test and, thus, only total panel results have been reported here.

The data obtained from Scoring System 1 for hydrophilic preparations are similar to those obtained for lipophilic preparations (9), in that the regression lines derived from the data can equally well be represented by either single- or double-logarithmic equations as proposed by Weber and Fechner (15) and Stevens (16). In addition, the data obtained by Scoring System 2 (represented by second-order polynomials) provide similar curves when plotted on either single- or double-logarithmic axes (Figs. 6 and 7). According to Stevens' definition of stimuli (16), preference testing should be metathetic (qualitative—agreeable or disagreeable) and should thus be represented by a single logarithmic equation of the type:

$$\theta = K \log S \qquad \text{(Eq. 2)}$$

where θ is the sensory response to a stimulus, S, and K is a constant. Thus, as pointed out by Barry and Grace (9), the classification proposed by Stevens is probably invalid for the type of test considered in this paper. Treisman (17, 18) questioned Stevens' work and claimed that no experiment can distinguish between the two equations and that the relationship obtained will be a function of the method of scaling.

The correlation coefficients and the other data quoted tend to suggest that individual panel members react similarly when evaluating spreadability. However, the data used in the diagrams are arithmetic means. The coefficients of variation (Figs. 2 and 3 and Table II) show the variability of a sensation produced by the same stimulus on different people. One main disadvantage of preference testing in this case is that only a limited number of samples can be tested on a single occasion and no really effective means of cross-linking the data exists (20). The types and causes of other such variable factors were fully discussed by other authors (15, 20, 21).

The present work gives a broad picture of the type of laboratory screening procedure that may be utilized in innovative work on topical preparations prior to field trials. The new formulation, whether it be lipophilic (anhydrous or water-in-oil emulsion) or hydrophilic (aqueous gel or oil-in-water emulsion) can be tested using Instrumental Method 2 to obtain its rheogram. The instrumental data are then plotted onto the combined master curves (Fig. 8). Depending on the type of formulation under test, the new product curve should intersect the appropriate master curve in the preferred region. To achieve the maximum patient acceptance potential, this intersection should occur at the optimum value of the preferred region.

In addition, manufacturers often wish to standardize a product by a simple rheological test involving a single shear rate. At present, this parameter is often selected arbitrarily. It would be an improvement if selection were made relevant to the individual consistency of the product, taking into account its nature as an ointment, cream, gel, *etc*. This could be done as discussed here, and a shear rate between 350 and 10,000 sec.$^{-1}$ would be obtained. The particular shear rate, selected from such a wide range, would at least be relevant as a quality control parameter in that it would approximate that used by the patient when applying the medicament.

SUMMARY

The work reported here is an extension of that performed by Barry and Grace (9) on the rheological conditions operative during spreading of topical preparations. A master curve for aqueous gels was obtained, which was an approximate mirror image of that obtained previously for lipophilic preparations. To investigate the effect of the introduction of a lipophilic phase into an aqueous preparation, a master curve was similarly obtained for oil-in-water emulsions. This curve, although similar in shape to the gel master curve, was displaced toward the lipophilic plot.

The gels and emulsions were assessed for spreadability by two preference scoring techniques. These data gave the optima and ranges of acceptable apparent viscosities for spreading of the topical preparations used. These values were superimposed on the master curves to show the "preferred regions" (shearing conditions with maximum patient acceptance potential). A combination of these master curves and preferred regions may be used in the design of instrumental tests for industrial quality control procedures concerned with preparations for topical use.

Automated Assay of Single Tablets of Methdilazine and Methdilazine Hydrochloride

RHYS BRYANT▲, F. J. BURGER, D. E. MANTLE, D. L. TIMMA, F. B. TRENK, and D. S. YODER

Abstract □ An automated analytical system was used to determine the amount of methdilazine base or methdilazine hydrochloride in a single tablet. Tablets were sampled at a rate of 20/hr., with observed coefficients of variation of 2.8 and 3.4% for methdilazine base and methdilazine hydrochloride, respectively. Blending of methdilazine hydrochloride tablets was improved by presoaking the tablets in the sample cups. Interference from ascorbic acid was overcome by first blending the tablet in a basic solution containing copper (II) ion followed by acidification to solubilize the methdilazine hydrochloride prior to sampling.

Keyphrases □ Methdilazine and methdilazine hydrochloride single tablets—automated UV analysis □ UV spectrophotometry—analysis, automated, single methdilazine and methdilazine hydrochloride tablets

Methdilazine[1] (1), as the base or as the hydrochloride (I), is a potent long-acting antipruritic agent, reportedly effective in relieving a variety of itching conditions (2, 3). In this study, it was determined in two different formulations by an automated analysis system.

EXPERIMENTAL[2]

Reagents—The following were used:

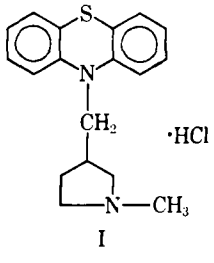
Phosphoric Acid Solution—Phosphoric acid[3], 0.1 and 2 *M* in distilled water.

Cupric Chloride Solution—Cupric chloride dihydrate[3], analytical reagent grade, 0.001% in 0.1 *M* aqueous ammonia[3], analytical reagent grade.

Alcohol Reagent—Methanol[3], analytical reagent grade, and ethanol[3], analytical reagent grade, mixed in the ratio of 3:1 v/v.

Standards—For methdilazine tablets, solutions of methdilazine base were prepared in 0.1 *M* phosphoric acid at three levels of concentration (0.333, 0.392, and 0.450 g./l.). Ten-milliliter aliquots of each solution were equivalent to 3.03, 3.56, and 4.09 mg. of methdilazine, respectively, when diluted in the Solidprep sampler.

For methdilazine hydrochloride tablets, aqueous solutions of methdilazine hydrochloride were prepared at three levels of concentration (0.748, 0.880, and 1.012 g./l.). Ten-milliliter aliquots of each solution were equivalent to 6.8, 8.0, and 9.2 mg. of methdilazine hydrochloride, respectively, when diluted in the Solidprep sampler.



I

Samples—Production lots of tablets were used in this study. Theoretical tablet content was 3.6 mg. for the methdilazine tablets and 8.0 mg. for the methdilazine hydrochloride tablets.

Procedure—Schematics of the automatic analyzer systems are shown in Figs. 1 and 2.

Methdilazine tablets were disintegrated in the presence of 0.1 *M* phosphoric acid, sampled, and dialyzed. The intensity of the absorbance at 252 nm. was then measured and recorded (Fig. 3).

Methdilazine hydrochloride tablets, after pretreatment with alcohol, were disintegrated in the presence of basic cupric chloride. After 45 sec., the sample was acidified with 2 *M* phosphoric acid. This resultant solution was then sampled and dialyzed, and the drug content was measured and recorded as previously indicated. The steady-state curve of the system is shown in Fig. 4.

Tablets were sampled at a rate of 20/hr. Standard solutions were analyzed several times during the day to check for any variation in absorbance. No significant variation was observed.

Calculation—The average absorbance for each standard was plotted *versus* tablet equivalent to give a standard curve. Reference to the appropriate standard curve for each sample yielded the milligrams of methdilazine or methdilazine hydrochloride per tablet.

DISCUSSION

Methdilazine tablets contained no interfering excipient. Disinte-

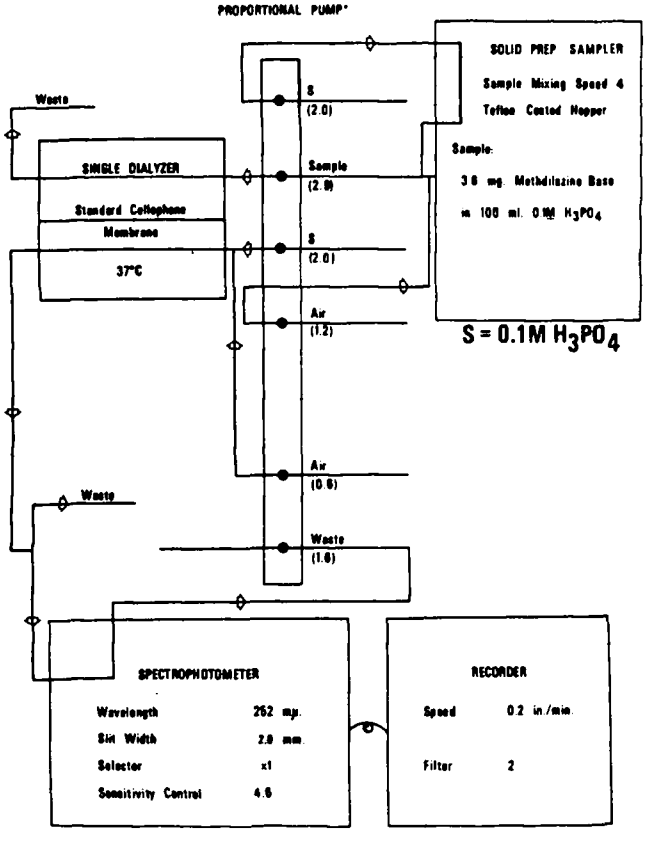


Figure 1—*Schematic for methdilazine tablets. (*Values in parentheses are flow rates in milliliters per minute. All pump tubing is Tygon.)*

[1] Tacaryl Chewable and Tacaryl Hydrochloride Tablets, Mead Johnson Laboratories, Division of Mead Johnson and Co.

[2] The analytical train consisted of the following Technicon modules (Technicon Corp., Tarrytown, N. Y.): (*a*) Solidprep sampler, (*b*) proportioning pump (model I), and (*c*) dialyzer (model I), in conjunction with a Hitachi Perkin-Elmer model 139 spectrophotometer using a microflow cell, 9120 No. 5, a Sargent model TR-05 recorder, and a Brewer model 40 automatic pipeting machine, equipped with a 50-ml. syringe (BBL, Division of BioQuest, Cockeysville, Md.).

[3] Mallinckrodt.

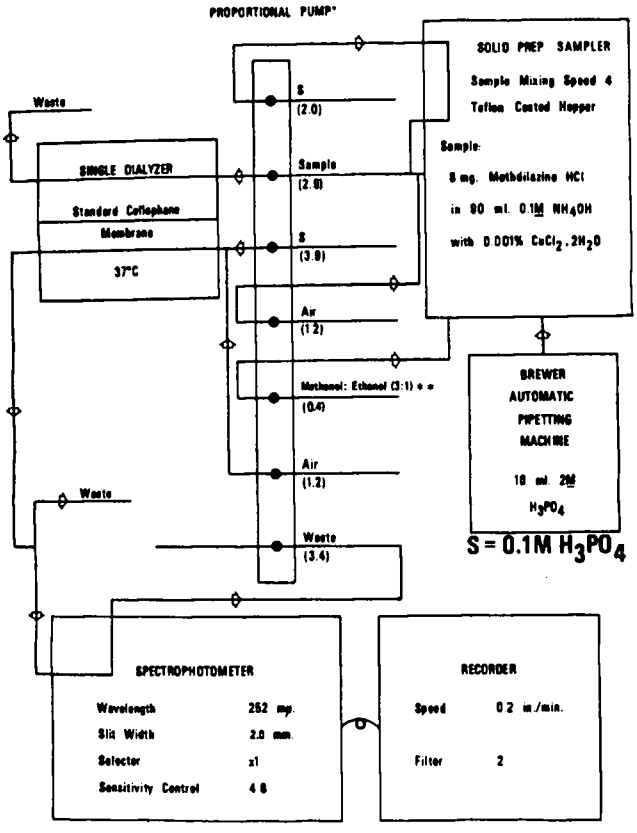

Figure 2—*Schematic diagram for methdilazine hydrochloride, 8 mg. tablets. (*Values in parentheses are flow rates in milliliters per minute. **Solvaflex tubing; all other tubing is Tygon.)*

gration in phosphoric acid followed by dialysis was sufficient to measure the drug absorbance at 252 nm.

Methdilazine hydrochloride tablets gave somewhat erratic results when assayed by the procedure developed for methdilazine tablets. Investigation indicated two factors contributing to this observation: (*a*) incomplete disintegration of the tablet in the Solidprep sampler, and (*b*) a tablet excipient that interfered in the UV measurement of drug.

Methdilazine hydrochloride tablets are manufactured as coated tablets, with a center drug-containing core. Pretreatment of individual tablets at position one on the sampler tray with 1.2 ml. of

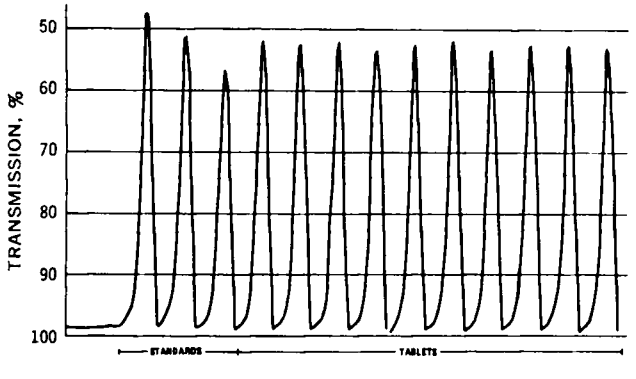

Figure 3—*Typical curve for methdilazine tablets and standards.*

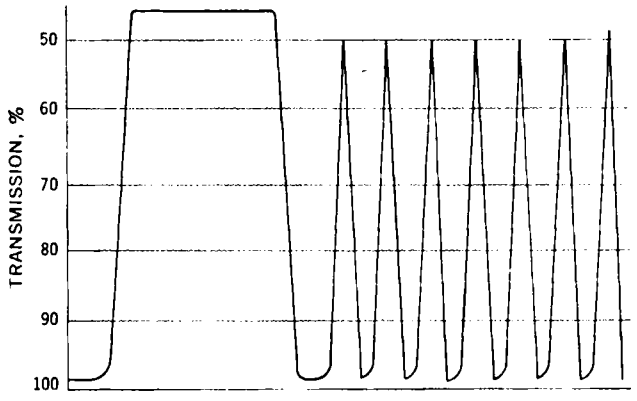

Figure 4—*Steady-state response of methdilazine hydrochloride.*

alcohol for 3 min. prior to disintegration in the sampler was sufficient to loosen the outer tablet coating.

The presence of ascorbic acid (2 mg./tablet) in methdilazine hydrochloride tablets resulted in assay values 13% above theory. This was overcome by oxidative destruction of the ascorbic acid using a cupric chloride–ammonia solution. However, methdilazine precipitated in basic solution, necessitating the addition of a sufficient amount of phosphoric acid to redissolve the methdilazine.

This requirement was met by using an automatic pipet in conjunction with the Solidprep sampler. Utilization of the cam system in the sampler allowed the addition of 2 *M* phosphoric acid 45 sec. into the analysis cycle.

Using the described analytical systems, linearity of absorbance values obtained for standards was satisfactory from 0 to 200% of declared tablet potency for both methdilazine and methdilazine hydrochloride.

RESULTS

Standard Curve—The average absorbance for each of the three standards was determined. A plot of the values gave a straight line in accordance with Beer's law.

Reproducibility of Standards—The reproducibility of the method was checked by the analysis of 30 standards (three levels of concentration) for both methdilazine and methdilazine hydrochloride. The coefficient of variation ranged from 0.3 to 0.9%.

Accuracy and Precision—The accuracy and precision of the method were ascertained by spiking a product placebo with the theoretical amount of drug prior to sampling. Data generated in this manner indicated the accuracy to be 1% with a coefficient of variation of 2.4%.

Synthesis and Biological Activity of 9-Substituted Acridines

JAMES T. STEWART

Abstract □ Various 9-substituted acridine derivatives, *i.e.*, carbamic and thiocarbamic acid esters, urea, and thioureas, were synthesized and tested for potential biological activity. Some compounds were found active in antibacterial, metabolic, parasitologic, and GI screening procedures. The screening results indicate that acridine derivatives of these types possess biological activity similar to other known acridines, especially in the areas of antibacterial action and parasitology. The antisecretory action of one carbamate is a new potential use of acridines which has not been reported previously.

Keyphrases □ Acridines, 9-substituted—synthesis and biological screening □ Biological screening—9-substituted acridine derivatives

Interest in this laboratory in the use of acridines as potential medicinal agents resulted in the synthesis of some 9-substituted acridines, *i.e.*, carbamic acid esters (I), urea (II), thiourea (III), and thiocarbamic acid esters (IV). The antineoplastic activity of acridine derivatives of types I, II, and III was reported previously (1). A search of the scientific literature revealed that little or no information was available concerning additional biological activity of these types of structures. The carbamate, thiocarbamate, urea, and thiourea derivatives described are of special interest since some were found active in antibacterial, metabolic, parasitologic, and GI screening procedures. Compounds I*a*, I*c*, and II were also active in a preliminary virology screen involving a nonspecific nucleic acid polymerase, but the results are only qualitative at this time.

The syntheses of I*a*, I*b*, II, and III*a* were reported previously (1). The benzyl (I*c*) and 2-methylpropyl (I*d*) esters of 9-acridinecarbamic acid were prepared in one-step, high yield reactions starting with 9-aminoacridine. Compounds III*b* and IV also were not reported previously. Synthetic steps leading to these compounds are described in the *Experimental* section.

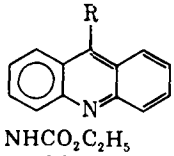
SCREENING RESULTS[1]

Compounds III*a* and III*b* were evaluated for antibacterial activity by a medicated agar dilution technique. In this test, the compounds are added to the agar and the test organisms are inoculated on the agar surface. The end-point is the level of compound that prevents emergence of visible growth. At 400-mcg./ml. levels, Compounds III*a* and III*b* were effective in inhibiting strains of *Staphylococcus aureus* (ATCC 6538), *Proteus vulgaris*[2], *Salmonella pullorum*[2], *Salmonella typhimurium*[2], *Escherichia coli*[2], *Klebsiella pneumoniae*[2], and *Diplococcus pneumoniae*[2]. Compound III*b* also inhibited *Proteus mirabilis*[2], *Streptococcus pyrogenes*[2], and *Pasteurella multocida*[2]. In comparison, 9-aminoacridine is effective at 40-mcg./ml. levels (2). Compound IV was also tested in an antibacterial screen (3) involving a variety of Gram-positive and Gram-negative bacteria and fungi of industrial importance. It was active against *Aerobacter aerogenes* (IPC 500)[3], *Bacillus mycoides* (IPC 509), and *S. aureus* (ATCC 6538) at 100-p.p.m. level, but it failed against these organisms at 5 p.p.m. 9-Aminoacridine is active against these organisms at 6–7-p.p.m. levels (4).

The activity of Compounds I*b* against certain other organisms was assessed by measuring inhibition of metabolic acitivity. One such test for anaerobic microorganisms is an assessment of reduction in formation from carbon dioxide and hydrogen by *Methanobacterium ruminantium*[2] at 39° for 2.5 hr. The level of methane is quantitated by passing a sample of the gas phase through a gas partitioner. Compound I*b* inhibited methane formation completely at 250 mcg./ml. and by 50% at 5 mcg./ml. However, under these same conditions, a 29.4-mcg./ml. level exhibited only a 20% inhibition after a 48-hr. incubation. This loss of effectiveness on continued incubation seems to be characteristic of a number of acridines[4].

Compound IV was active in an *in vitro* parasitology screen. Larvae or eggs of trichostrongyle nematodes were exposed to the test drug *in vitro*, initially at 100-mcg./ml. concentration. Efficacy was determined by direct microscopic inspection of the conditions of the parasites. Active compounds were retested in 10-fold serial dilutions to determine the end-point (5). The thiocarbamate (IV) was active against the eggs at 0.01 mg./ml., but it was inactive in the *in vivo* parasitology screen (6). In contrast, 9-aminoacridine has only shown effectiveness against parasites in *in vitro* testing at 2.5-mg./ml. levels (7). It is also inactive *in vivo*.

Compound I*a* was effective in inhibiting gastrin-stimulated acid secretion in an animal with a chronic gastric fistula. The carbamate (I*a*) in 50 ml. of aqueous methylcellulose (1%) was administered directly into the stomach of an unanesthetized chronic gastric fistula dog. One hour later, the gastric contents were drained and gastrin tetrapeptide (0:064 mg./kg. s.c.) was administered. Gastric secretions were collected over 2 hr., and the volume of secretions and total acid (meq./l.) were measured. The percent inhibition of volume and acid response were calculated using control values obtained in the same animal in an earlier experiment. Compound I*a*,



I*a*: R = $NHCO_2C_2H_5$
I*b*: R = $NHCO_2$-*n*-C_4H_9
I*c*: R = $NHCO_2CH_2C_6H_5$
I*d*: R = $NHCO_2CH_2CH(CH_3)CH_3$

II: R = NHCONH— —OCH_3

III*a*: R = $NHCSNHC_6H_5$
III*b*: R = $NHCSNHCH_2C_6H_5$
IV: R = $NHCSOC_2H_5$

[1] Tests for the various biological activities were carried out at Merck Sharp & Dohme Research Laboratories, Rahway, N. J. Only those acridine derivatives that showed activity in the testing are discussed.

[2] Identified by Dr. Eugene L. Dulaney, Merck Sharp & Dohme Research Laboratories, Rahway, N. J.

[3] IPC, Institute of Paper Chemistry, Appleton, Wis.

[4] H. B. Woodruff, Merck Sharp & Dohme Research Laboratories, personal communication, 1972.

at a dose of 16.1 mg./kg., reduced the volume of secretions and total acid content by approximately 35%.

The screening results indicate that acridine derivatives of the I, II, III, and/or IV types possess biological activity similar to 9-aminoacridine, especially in the areas of antibacterial action and parasitology. The antisecretory action of Compound Ia is a new potential use of acridine derivatives which has not been reported previously.

EXPERIMENTAL[5]

9-Acridinecarbamic Acid Esters (Ic and Id)—9-Aminoacridine (0.02 mole) and 0.02 mole of the necessary chloroformate ester were refluxed for 1 hr. in 300 ml. of acetone in the presence of 4 g. of sodium bicarbonate. The hot suspension was filtered, followed by evaporation of the acetone to yield a residue. The residue was recrystallized from ethanol or ethanol–water to give a solid, 80% yield.

The melting point for Ic was 210–213°.

Anal.—Calc. for $C_{21}H_{16}N_2O_2$: C, 76.81; H, 4.91; N, 8.53. Found: C, 76.91; H, 4.95; N, 8.46.

The melting point for Id was 152–154°.

Anal.—Calc. for $C_{18}H_{18}N_2O_2$: C, 73.44; H, 6.16; N, 9.51. Found: C, 73.29; H, 6.13; N, 9.59.

1-(9-Acridinyl)-3-benzyl-2-thiourea (IIIb)—*Method A*—9-Aminoacridine (0.02 mole) and 0.02 mole of benzyl isothiocyanate were refluxed for 1 hr. in 300 ml. of acetone.The acetone was evaporated, and the residue was recrystallized from ethanol–water to give a yellow solid, m.p. 178–180°, in 90% yield.

Method B—9-Isothiocyanatoacridine (0.02 mole) and 0.02 mole of benzylamine in 100 ml. of ethanol were heated on a water bath for 30 min. When the reaction mixture cooled to room temperature, the precipitate was collected and dried. Two recrystallizations from 25% ethanol–water gave a yellow powder, m.p. 178–180°, in 80% yield.

Anal.—Calc. for $C_{17}H_{17}N_3S$: C, 73.44; H, 4.99; N, 12.23. Found: C, 73.15; H, 5.15; N, 12.05.

Ethyl-N-(9-acridinyl)thiocarbamate (IV)—9-Isothiocyanatoacridine (0.02 mole) and 50 ml. of absolute ethanol were refluxed for 10 hr. The ethanol was evaporated to yield a residue, which was recrystallized from ethanol–water to give an orange solid, m.p. 160–162°, in 90% yield.

Anal.—Calc. for $C_{16}H_{14}N_2OS$: C, 68.06; H, 4.99; N, 9.92. Found: C, 68.16; H, 5.02; N, 10.04.

[5] Melting points were taken in capillary tubes on a Thomas-Hoover apparatus and are uncorrected. Elemental analyses were obtained from Atlantic Microlabs, Atlanta, Ga. IR spectra were recorded on a Perkin-Elmer model 237B spectrophotometer and were as expected. 9-Isothiocyanatoacridine was obtained from Eastman Organic Chemicals.

Isolation of β-Amyrin and Ellagic Acid from *Couroupita amazonica*

B. O. SOWEMIMO, F. H. SEGELMAN, M. TIN-WA, H. WAGNER*, G. J. PERSINOS†, and N. R. FARNSWORTH▲

Abstract □ A phytochemical examination of *Couroupita amazonica* (Lecythidaceae) led to the isolation of β-amyrin and ellagic acid.

Keyphrases □ *Couroupita amazonica* (Lecythidaceae)—isolation, identification of β-amyrin and ellagic acid □ β-Amyrin—isolated and identified from *Couroupita amazonica* □ Ellagic acid—isolated and identified from *Couroupita amazonica*

The Amazonian plant *Couroupita amazonica* was selected for investigation because no phytochemical studies have as yet been reported on this genus of plants. These studies resulted in the isolation of β-amyrin and ellagic acid, which are commonly encountered plant principles.

EXPERIMENTAL

Plant Material[1]—The trunk bark of *Couroupita amazonica* Kunth. (Lecythidaceae) was collected during July 1969 in the vicinity of Iquitos, Perú.

Extraction—The coarsely milled plant material (1.1 kg.) was extracted continuously for 24 hr. in a soxhlet apparatus with petroleum ether (b.p. 30–60°). The petroleum ether extract yielded 6 g. of a semicrystalline residue. The defatted plant material was then air dried and extracted with 95% ethanol, which afforded 67 g. of residue following evaporation of the solvent. This residue was partitioned between equal volumes of chloroform and water, and the aqueous fraction was extracted four times with ethyl acetate.

[1] Voucher specimens (2331 and 2342) were identified by Dr. J. Wurdack, Smithsonian Institution, Washington, D. C., and are deposited at this address.

Isolation of β-Amyrin and Ellagic Acid from *Couroupita amazonica*

B. O. SOWEMIMO, F. H. SEGELMAN, M. TIN-WA, H. WAGNER*, G. J. PERSINOS†, and N. R. FARNSWORTH▲

Abstract □ A phytochemical examination of *Couroupita amazonica* (Lecythidaceae) led to the isolation of β-amyrin and ellagic acid.

Keyphrases □ *Couroupita amazonica* (Lecythidaceae)—isolation, identification of β-amyrin and ellagic acid □ β-Amyrin—isolated and identified from *Couroupita amazonica* □ Ellagic acid—isolated and identified from *Couroupita amazonica*

The Amazonian plant *Couroupita amazonica* was selected for investigation because no phytochemical studies have as yet been reported on this genus of plants. These studies resulted in the isolation of β-amyrin and ellagic acid, which are commonly encountered plant principles.

EXPERIMENTAL

Plant Material[1]—The trunk bark of *Couroupita amazonica* Kunth. (Lecythidaceae) was collected during July 1969 in the vicinity of Iquitos, Perú.

Extraction—The coarsely milled plant material (1.1 kg.) was extracted continuously for 24 hr. in a soxhlet apparatus with petroleum ether (b.p. 30–60°). The petroleum ether extract yielded 6 g. of a semicrystalline residue. The defatted plant material was then air dried and extracted with 95% ethanol, which afforded 67 g. of residue following evaporation of the solvent. This residue was partitioned between equal volumes of chloroform and water, and the aqueous fraction was extracted four times with ethyl acetate.

[1] Voucher specimens (2331 and 2342) were identified by Dr. J. Wurdack, Smithsonian Institution, Washington, D. C., and are deposited at this address.

Isolation and Identification of β-Amyrin—The semicrystalline precipitate from petroleum ether was crystallized from methanol to yield 0.592 g. of colorless needles, m.p. 197–199° [lit. (1) m.p. 194–200°]. The UV spectrum showed only end-absorption at λ_{max}^{MeOH} 206 nm. (log ε 3.48) and $[\alpha]_D^{25}$ + 89.4° (0.5, $CHCl_3$) [lit. (1) $[\alpha]_D^{25}$ + 87°]. An IR spectrum (KBr) was superimposable with that of an authentic sample of β-amyrin. An acetate derivative was prepared in the usual manner and exhibited m.p. 237–238° [lit. (1) m.p. 237–242°]. The identity of the isolate as β-amyrin was confirmed by a direct comparison with an authentic sample (mixed melting point, TLC, and IR).

Isolation and Identification of Ellagic Acid—On standing, a yellow compound (180 mg.) precipitated from the ethyl acetate fraction. This compound was insoluble in all common organic solvents; it was slightly soluble in hot pyridine but would not crystallize from this solvent. It did not melt below 350°, and it gave a green color with ferric chloride (phenolic). The compound was soluble in alkaline solution, giving a yellow color after the addition of alkali. It gave a positive Greissmayer test, indicating the presence of the 4,4′-dihydroxydiphenyl moiety (2). The UV spectrum of an impure sample showed absorption bands at λ_{max}^{MeOH} 366 and 255 nm. In the presence of sodium acetate, a new band appeared at 280 nm., with a corresponding weakening of the band at 255 nm. These UV data are in agreement with those published for ellagic acid (2). The IR spectrum (KBr) showed absorption bands at 3520 (OH), 1720 (unsaturated lactone), and 1601 (aromatic character) cm.$^{-1}$. An NMR spectrum in dimethyl sulfoxide showed only two aromatic protons in symmetric position at δ 7.5. A comparison by paper chromatography showed the isolate and a reference sample of ellagic acid to be identical.

A 30-mg. sample of the impure ellagic acid was heated under reflux with an excess of acetic anhydride for 15 hr. The resulting product was crystallized from dioxane to obtain colorless crystals, which began to sinter at 331° and melted at 338–341° [lit. (3) m.p. 343–346°]. A second 30-mg. sample was methylated in the usual manner with diazomethane. The product was crystallized from dioxane to yield pale-yellow crystals, m.p. 338–340° [lit. (4) m.p. 342–344°]. The IR spectrum (KBr) corresponded with published data for the tetramethyl ether of ellagic acid (4).

Isolation of Daphnetin-8-β-glucoside from *Daphne papyracea*

RITEN NASIPURI and EGIL RAMSTAD▲

Abstract □ Daphnetin occurs free and bound as β-glucoside in the roots of *Daphne papyracea* Wall. ex Steud. The bound form, however, is not in the form of daphnin, as found in several Thymelaceae, but in the form of daphnetin-8-β-glucoside.

Keyphrases □ Daphnetin-8-β-glucoside—isolated from *Daphne papyracea* □ *Daphne papyracea*—isolation of daphnetin-8-β-glucoside

The isolation of three flavone glycosides was reported by Basu and Nasipuri (1) in their preliminary investigation of the roots of *Daphne papyracea* Wall. ex Steud., collected from Ranikshet, India. Later, Sharma *et al.* (2) reported the isolation of daphnin from the roots of the same plant. The present authors found that daphnetin occurs free and bound as 8-β-glucoside in the roots of the same plant[1] collected in Nepal.

[1] The plant was identified by Mr. P. Joshi, Pharmaceutical Expert to the Government of U.P., India, and the late Prof. N. K. Basu of Banaras Hindu University, Banaras, India. A specimen of the plant was deposited in the Department of Pharmaceutics, Banaras Hindu University, Banaras, India.

DISCUSSION

Two crystalline compounds were isolated: A, m.p. 255–256° dec.; and B, m.p. 229–230°, $[\alpha]_D^{25}$ −92° (solvent: 50% alcohol).

Acid hydrolysis of Compound B provided A_1, identical to Compound A, as shown by its chromatographic behavior, no depression of melting point by admixture with Compound A, and identical UV and IR spectra. The hydrolysate of B contains glucose, identified by chromatography and chromogenic tests. Emulsin hydrolyzed B into A and glucose, showing B to be a β-glucoside of A.

Compound A, giving color reactions for phenols, has the elementary composition of $C_9H_6O_4$ (mol. wt. 178.0282; theoretical 178.0266), and the UV spectral characteristics of a coumarin: λ_{max}^{EtOH} 224 (log ε 4.2), 262 (log ε 3.9), and 326 nm. (log ε 4.05) [literature (3) data for 7,8-dihydroxycoumarin: λ_{max}^{EtOH} 260 (log ε 3.8) and 327 nm. (log ε 4.1)].

Compound A was identified as 7,8-dihydroxycoumarin (daphnetin) from the mass spectrometry, IR, and NMR data.

Mass spectral findings can be rationalized as follows (Scheme I). The fragmentation pattern and relative mass peak abundance are very similar to those of umbelliferone (4), each corresponding *m/e* having an additional value of 16 (for the added oxygen).

The IR spectrum shows absorptions at 3360 (OH), 1665 (lactone), 1580, and 1490 (aromatic) cm.$^{-1}$.

A comparison of the chemical shifts and splitting pattern of the

Isolation and Identification of β-Amyrin—The semicrystalline precipitate from petroleum ether was crystallized from methanol to yield 0.592 g. of colorless needles, m.p. 197–199° [lit. (1) m.p. 194–200°]. The UV spectrum showed only end-absorption at λ_{max}^{MeOH} 206 nm. (log ε 3.48) and $[\alpha]_D^{25}$ + 89.4° (0.5, $CHCl_3$) [lit. (1) $[\alpha]_D^{25}$ + 87°]. An IR spectrum (KBr) was superimposable with that of an authentic sample of β-amyrin. An acetate derivative was prepared in the usual manner and exhibited m.p. 237–238° [lit. (1) m.p. 237–242°]. The identity of the isolate as β-amyrin was confirmed by a direct comparison with an authentic sample (mixed melting point, TLC, and IR).

Isolation and Identification of Ellagic Acid—On standing, a yellow compound (180 mg.) precipitated from the ethyl acetate fraction. The hydrolysate of B contains glucose, identified by chromatography and chromogenic tests. Emulsin hydrolyzed B into A and glucose, showing B to be a β-glucoside of A.

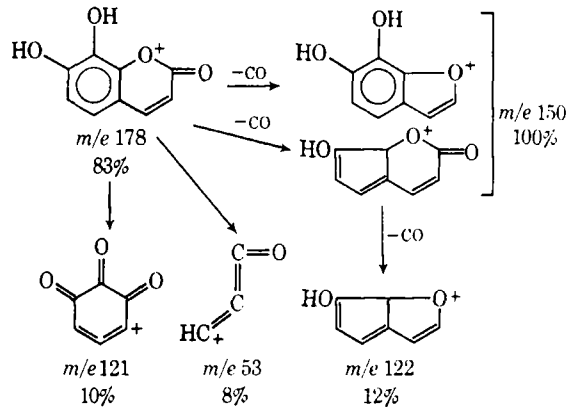
Compound A, giving color reactions for phenols, has the elementary composition of $C_9H_6O_4$ (mol. wt. 178.0282; theoretical 178.0266), and the UV spectral characteristics of a coumarin: λ_{max}^{EtOH} 224 (log ε 4.2), 262 (log ε 3.9), and 326 nm. (log ε 4.05) [literature (3) data for 7,8-dihydroxycoumarin: λ_{max}^{EtOH} 260 (log ε 3.8) and 327 nm. (log ε 4.1)].

Compound A was identified as 7,8-dihydroxycoumarin (daphnetin) from the mass spectrometry, IR, and NMR data.

Mass spectral findings can be rationalized as follows (Scheme I). The fragmentation pattern and relative mass peak abundance are very similar to those of umbelliferone (4), each corresponding *m/e* having an additional value of 16 (for the added oxygen).

The IR spectrum shows absorptions at 3360 (OH), 1665 (lactone), 1580, and 1490 (aromatic) cm.$^{-1}$.

A comparison of the chemical shifts and splitting pattern of the



Scheme I

three coumarins reported in the literature supports the structure as being dihydroxycoumarin (Table I).

The splitting of two aromatic protons into doublets (J = 9.5 Hz.) in the NMR spectrum shows them to be *ortho* to each other. Proton 4 in coumarins without substitution at C-5 resonates at δ7.65–7.77 [umbelliferone (5), herniarin (6), 7-geranyl-8-hydroxycoumarin (7), and scoparone (8)]. Substitution at C-5 with oxygen would have caused a downfield shift of proton 4 as in limettin (δ7.95) (9) and sibricin (δ7.95) (9); since the two aromatic protons of A (5 and 6) are coupled, the only positions left for the two hydroxyl groups are 7 and 8. Compound A is, therefore, 7,8-dihydroxycoumarin (daphnetin).

Several species of daphne have been found to contain daphnin, which is 7-daphnetin-β-glucoside (10, 11). Compound B, however, melts sharply at 229–230° compared to 215–217° (12) or 223–224° dec. (13, 14) for daphnin. Also, $[\alpha]_D^{24}$ is −92° compared to $[\alpha]_D^{22}$ −123.9° for daphnin (13). It must be concluded that in B the glucosidic linkage is at C-8 rather than at C-7. For verification, Compound B was peracetylated. The NMR spectrum of the acetate showed five acetyl groups and a downfield shift of proton C-6 by δ0.35, identical in magnitude to the shift experienced by the same proton in salicylic acid upon acetylation.

EXPERIMENTAL[2]

Isolation of A and B—Powdered dry root of *D. papyracea* was extracted with alcohol (95%), the extract was concentrated under reduced pressure, and the concentrate was poured in a thin stream into a large volume of water. The precipitated mass was separated by filtration and the filtrate was concentrated under reduced pressure. A 10% solution of neutral lead acetate was added to the concentrated liquid. A yellow precipitate (a) was filtered from the solution (b). Substance A was isolated from the yellow precipitate (a) by treatment of its aqueous alcoholic suspension with hydrogen sulfide gas, concentration of the resulting solution, and subsequent crystallization.

Filtrate (b) was treated with a 10% solution of basic lead acetate, yielding a pale-yellow precipitate (c) from which Compound B was isolated in the same way as was A from precipitate (a).

Hydrolysis of Compound B—Fifty milligrams of B was refluxed for 1 hr. with 20 ml. of 1% sulfuric acid, and the solution was then neutralized with barium carbonate and filtered.

TLC of the filtrate revealed a phenolic compound identical to that of Compound A. The adsorbent was silica gel G. The solvent systems were: (*a*) ethyl acetate–pyridine–water (3.6:1.0:1.15), (*b*) chloroform–methanol (60:40), and (*c*) butanol–acetic acid–water (4:1:1). The detectors were: (*a*) ferric chloride solution and (*b*) Pauly's reagent (15).

Chromatograms of the same filtrate gave spots of identical chromatographic behavior and color reactions as those of glucose. Two systems were used: (*a*) absorbent: silica gel G; solvent system: chloroform–methanol (60:40); and (*b*) absorbent: silica gel G buffered with sodium acetate; solvent system: acetone–water (90:10). The detector was aniline–diphenylamine–phosphoric acid (15). The nonaromatic portions of the NMR spectra of peracetylated Compound B and peracetylated glucose were virtually identical except for the presence of three protons at δ2.36 (aromatic acetyl group) in Compound B and three protons at δ2.10 (C-1 acetyl group) in peracetylated glucose.

Compound A was isolated from the filtrate. Admixture of this and A originally isolated from the plant gave no melting-point difference.

The presence of the β-glucosidic linkage in Compound B was shown by hydrolyzing B with emulsin at 24° for 2 hr. and identifying the released glucose.

Table I—NMR Spectral Data

Compound	Chemical Shift (δ) and Splitting Pattern H-3	H-4	H-5	H-6
Compound A ($CDCl_3$ + 30% dimethyl sulfoxide) (100 MHz.)	6.18 d	7.67 d	6.92 d	6.88 d
Umbelliferone ($CDCl_3$) (5)	6.26 d	7.77 d	7.42 m	6.89 m
Herniarin ($CDCl_3$) (6)	6.23 d	7.65 d	7.40 m	6.87 m
7-Geranyl-8-hydroxycoumarin ($CDCl_3$) (7)	6.25 d	7.65 d	7.38 m	6.88 m

Simplified Method for Determining Chemical Stability of Drug Substances in Pharmaceutical Suspensions

J. TINGSTAD▲, J. DUDZINSKI, L. LACHMAN, and E. SHAMI

Abstract □ A simplified method for determining the chemical stability of drug substances in pharmaceutical suspensions is described. The applicable theory is discussed, and a suitable example from the literature is presented. The value of the method is confirmed experimentally using aspirin.

Keyphrases □ Stability, chemical—drugs in suspensions, simplified method, calculations using aspirin □ Suspensions—simplified method for determining chemical stability of drug substances □ Drug stability in pharmaceutical suspensions—simplified method for determination of chemical stability □ Preformulation studies—simplified method for determining chemical stability of drug substances in pharmaceutical suspensions, example using aspirin, equations

One of the most common and important preformulation studies is the determination of a drug substance's chemical stability in aqueous systems. The usual procedure is to dissolve the compound in suitably buffered water or, if necessary, in a mixed solvent system and then to perform classical kinetic experiments. However, many drug substances have low aqueous solubilities, and it is often desirable to determine the chemical stability of the compound suspended in water. In addition, it is often important to perform accelerated chemical stability studies on suspension formulations. Relatively few such experiments have been reported (1–5), primarily because: (*a*) kinetic studies on drug substances in solution are easier to perform and lend themselves to more sophisticated treatment, and (*b*) with suspensions the kinetic calculations are complicated by the change in drug solubility with temperature. This report describes a simplified method for determining the chemical stability of drug substances in aqueous suspension, one that does not require solubility determinations and yet lends itself to classical mathematical treatment.

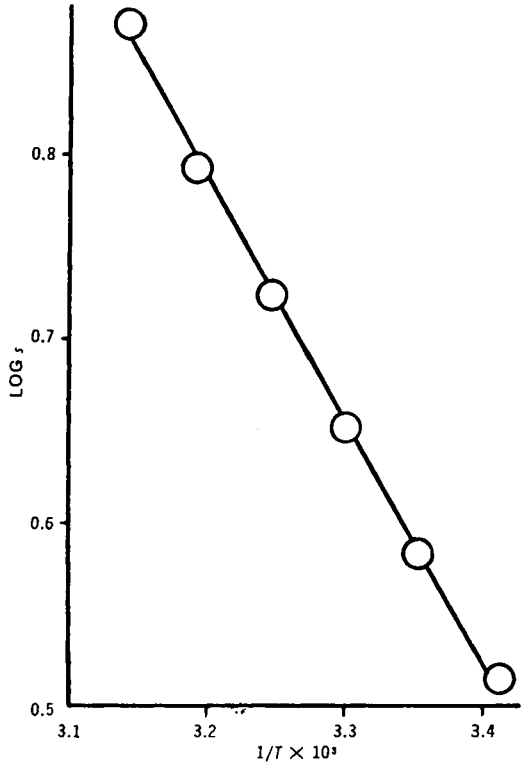

Figure 1—*Plot of log solubility of undissociated aspirin* versus *the reciprocal of the absolute temperature from data of Edwards* (6).

THEORY

Many drug substances in solution degrade according to first-order kinetics:

$$-dc/dt = kc \qquad \text{(Eq. 1)}$$

where c is the concentration of reactant, t is time, k is the rate constant, and dc/dt is the rate at which the concentration decreases. When the system involves a drug substance in suspension, the concentration in solution usually remains constant because, as the reaction proceeds, solid drug substance dissolves and the solution remains saturated with respect to undegraded reactant. Equation 1 then becomes:

$$-dc/dt = k_0 \quad \text{or} \quad -dc/dt = ks \qquad \text{(Eq. 2)}$$

where k_0 is the apparent zero-order rate constant (equal to ks), k is the first-order rate constant of Eq. 1, and s is the solubility of the

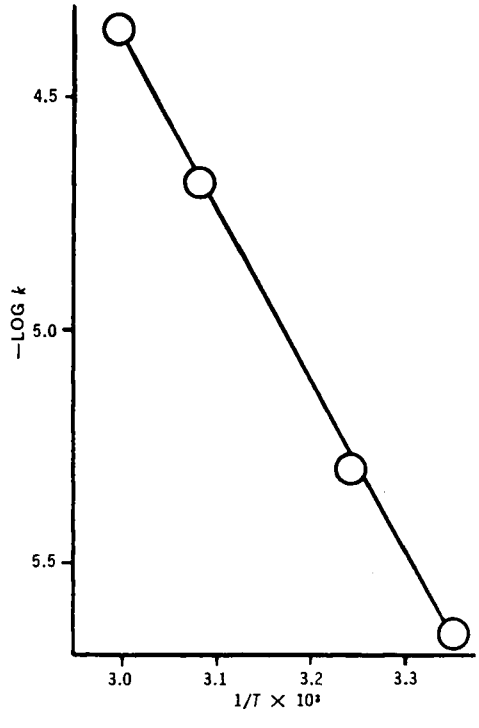

Figure 2—*Plot of log reaction rate constant of undissociated aspirin* versus *the reciprocal of the absolute temperature from data of Garrett* (7).

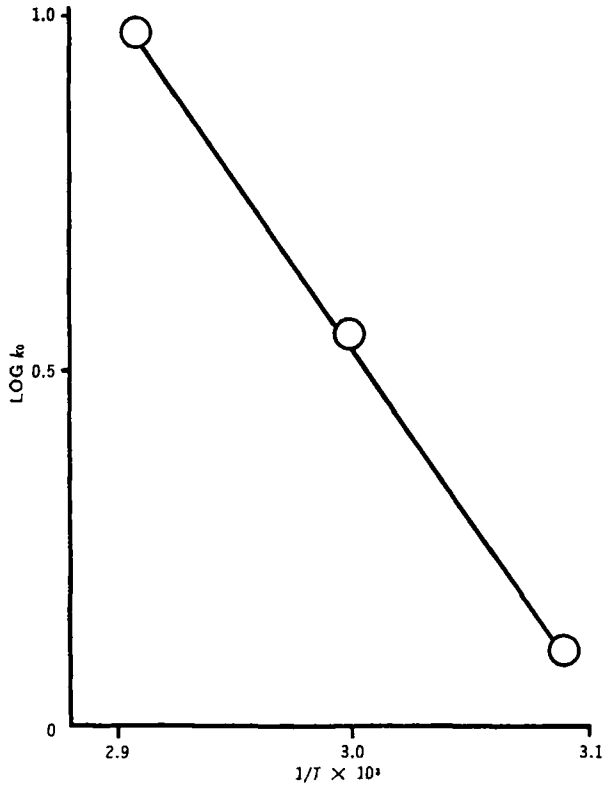

Figure 3—*Plot of log (apparent) zero-order reaction rate constant* versus *the reciprocal of the absolute temperature from data of James (2) for aspirin suspension.*

drug substance at the given temperature (and equal to c of Eq. 1).

When the reaction is studied at various temperatures, the apparent zero-order rate constant (k_0) will vary because of the temperature effect on the first-order rate constant and on the solubility of the drug substance in the solvent. One way to proceed is to determine its solubility at the various reaction temperatures, calculate k from the experimentally determined values of k_0 and s, and then estimate the room temperature stability from the heat of activation and the solubility at 25° (1).

Under certain conditions, room temperature stability can be estimated without determining the solubility of the drug substance at any temperature. These conditions are: (*a*) drug substance degradation takes place only in solution and according to first-order kinetics, (*b*) the drug substance–solvent system obeys the classical relationships to temperature with respect to solubility and rate of reaction, and (*c*) the dissolution–degradation kinetics are not dissolution rate limited.

From Eq. 2 it can be said that:

$$k_0 = ks \qquad \text{(Eq. 3)}$$

Taking logs of both sides yields:

$$\log k_0 = \log k + \log s \qquad \text{(Eq. 4)}$$

The classical relationship between reaction rate and temperature is:

$$\log k = -\frac{\Delta H_a}{2.303RT} + \text{a constant} \qquad \text{(Eq. 5)}$$

where k is the reaction rate constant, ΔH_a is the molar energy of activation, R is the gas constant, and T is the absolute temperature. Similarly, the relationship between solubility and temperature is:

$$\log s = -\frac{\Delta H_f}{2.303RT} + \text{a constant} \qquad \text{(Eq. 6)}$$

where s is the solubility at absolute temperature T, and ΔH_f is the molar heat of fusion.

Substituting from Eqs. 5 and 6 into Eq. 4 gives:

$$\log k_0 = -\frac{\Delta H_a + \Delta H_f}{2.303RT} + \text{a constant} \qquad \text{(Eq. 7)}$$

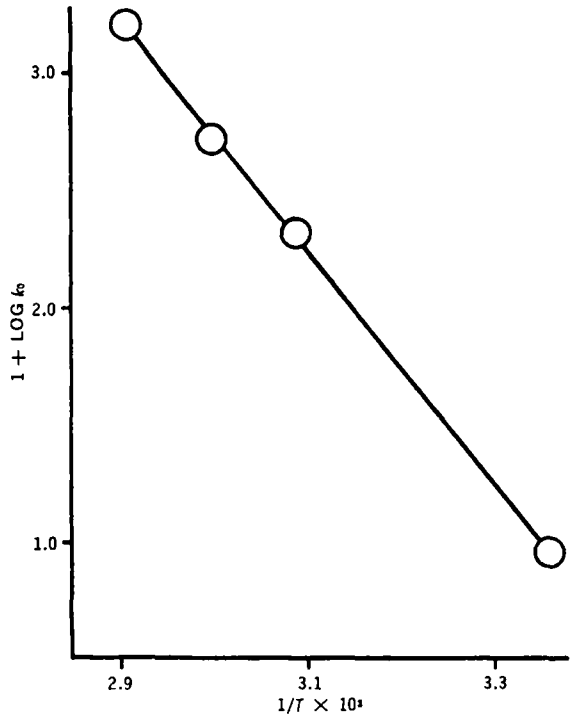

Figure 4—*Plot of log (apparent) zero-order reaction rate constant* versus *the reciprocal of the absolute temperature for experimental aspirin suspension.*

Thus, a plot of log k_0 *versus* $1/T$ should yield a straight line with a slope of $-(\Delta H_a + \Delta H_f)/2.303R$. By this method, room temperature stability can be estimated from studies at elevated temperatures without determining solubilities or first-order rate constants for the drug substance in solution.

EXAMPLE

An example from the literature, involving several unrelated sources, will help clarify the method and indicate its usefulness. Edwards (6) determined the solubility of aspirin as the undissociated acid (pH 1) at various temperatures, and a plot of log s *versus* $1/T$ (Fig. 1) yields a straight line with a slope of -1327. Garrett (7) determined the first-order rate constants for aspirin degradation in solution at pH 1.1 at various temperatures, and a plot of log k *versus* $1/T$ (Fig. 2) gives a straight line with a slope of -3698. Thus, $(\Delta H_a + \Delta H_f)/2.303R$ for this system is estimated to be $-(1327 + 3698)$ or -5025 kcal./mole. Therefore, a plot of log k_0 *versus* $1/T$ (see Eq. 7) for a suspension of aspirin at pH $\sim$ 1 should result in a straight line with a slope of approximately -5000 kcal./mole. Plotting the data of James (2) in such a manner (Fig. 3) results in a straight line whose slope is -4817 kcal./mole. Only data from 50, 60, and 70° were used because only those data were obtained on the same suspension formula.

EXPERIMENTAL

Because only three points were used to determine the slope in Fig. 3, a limited stability study on aspirin in suspension was performed to confirm the usefulness of the abbreviated method. Twelve hundred milligrams of aspirin USP (80 mesh) was placed in 50-ml. vials containing 20 ml. of 0.1 *N* sulfuric acid, which had been preheated to the experimental temperature. The vials were stoppered and stored at 70, 60, 50, and 24.5°. Duplicate samples were removed at appropriate times and quenched in an ice bath, and the entire contents were assayed for salicylic acid by the method of Tinker and McBay (8).

RESULTS AND DISCUSSION

The pH of both the fresh and degraded suspensions was 1.4. Plotting the stability data according to Eq. 7 yields a straight line

(Fig. 4) with a slope of −5002 kcal./mole, confirming the usefulness of the method.

Four points should be emphasized concerning kinetic studies on drug substances in suspension.

1. Data should be reported as "amount degraded" rather than "amount remaining" or "percentage lost," since (for example) for a given drug substance a suspension having a potency of 20 mg./ml. will degrade at the same rate as one containing 10 mg./ml. but the "percentage lost" is one-half as much.

2. If the drug substance under study is acidic or basic, it will often act as the primary buffer in the system, since solid drug substance is always in excess.

3. Because the solvent system is saturated with drug substance, concentrations of degradation products may reach a point where they affect the reaction rate, causing deviations from zero-order kinetics as the reaction proceeds.

4. In those cases where the simplified method fails because the system is dissolution rate limited, it may help to: (*a*) use a batch of drug substance with smaller particle size, and (*b*) agitate the stored samples. Estimations of room temperature stability based upon such conditions will err on the safe side.

CONCLUSION

Using the simplified procedure (for systems obeying the underlying assumptions stated under *Theory*), the room temperature stability of a drug substance in suspension can be estimated from elevated temperature studies (measuring amount degraded at various times) without determining solubilities or first-order rate constants. When the assumptions are not valid for a particular system, the abbreviated method will not work. The procedure is being presented here so that its applicability can be tested by investigators concerned with evaluating the stability of drug substances in suspension or suspension formulations.

Hydrindene Derivatives as Potential Oral Hypoglycemic Agents: *N*-Alkyl 1,2,3,3a,4,8b-Hexahydroindeno[1,2-*b*]pyrroles

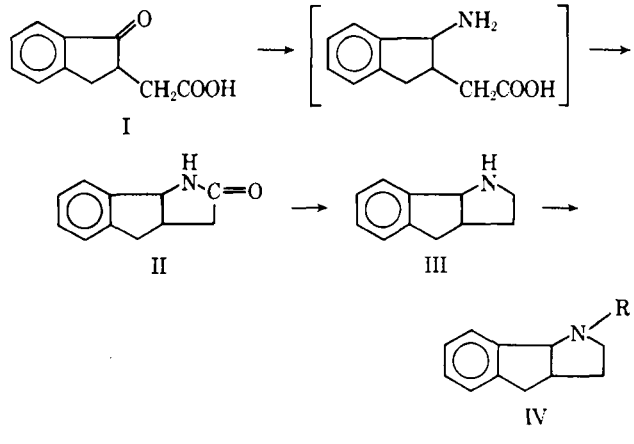
A. U. DE▲ and B. P. SAHA

Abstract □ A number of hexahydroindeno[1,2-*b*]pyrroles were synthesized and biologically evaluated. Only two compounds of this series showed some weak oral hypoglycemic activity. However, one compound inhibited epinephrine biosynthesis *in vitro* appreciably.

Keyphrases □ Hydrindene derivatives—*N*-alkyl 1,2,3,3a,4,8b-hexahydroindeno[1,2-*b*]pyrroles synthesized and screened as potential oral hypoglycemic agents □ *N*-Alkyl 1,2,3,3a,4,8b-hexahydroindeno[1,2-*b*]pyrroles—synthesized and screened as potential oral hypoglycemic agents □ Hypoglycemic agents, oral, potential—synthesis and screening of *N*-alkyl 1,2,3,3a,4,8b-hexahydroindeno-[1,2-*b*]pyrroles □ Heterocyclic compounds—synthesis of new class of hydrindene derivatives

In continuation of an investigation on hydrindene derivatives as potential oral hypoglycemic agents (1), it was considered worthwhile to synthesize isomeric indeno[1,2-*b*]pyrroles and test their activity. This new type of heterocyclic compound, although prepared earlier by different routes without any alkyl substitution at the nitrogen atom (2–4), was synthesized, in high yield (Scheme I), by a novel route by way of reductive amination.

1-Keto-2-indanylacetic acid (I) (5, 6), on being subjected to reductive amination with hydrogen and dry ammonia gas in absolute ethanol in the presence of Raney nickel catalyst, yields the corresponding pyrrolidone (II) in one step. Pyrrolidone (II), after reduction with lithium aluminum hydride in dry tetrahydrofuran, gives indeno[1,2-*b*]pyrrole (III). The pyrrolidone (II) shows the characteristic C=O and N—H stretching vibrations, while the indenopyrrole (III) shows only the N—H stretching vibrations. The indenopyrroles were



Scheme I

(Fig. 4) with a slope of −5002 kcal./mole, confirming the usefulness of the method.

treated with the appropriate alkyl halide and purified by tosylation to furnish the respective *N*-alkyl indenopyrroles (IV).

ACTIVITY

Four compounds were synthesized in this series; only *n*-propylhexahydroindeno[1,2-*b*]pyrrole (IV: R = *n*-propyl) caused a 12% blood sugar lowering at a dose level of 250 mg./kg. body weight in normal, overnight fasted rabbits while the butyl derivative (IV: R = *n*-butyl) caused a 10% lowering. The blood sugar was estimated at 0, 2, and 4 hr. Tolbutamide was a standard in this test, and it caused a reduction of about 40% of the blood sugar at a dose of 250 mg./kg.

In another test, inhibition of epinephrine biosynthesis *in vitro* from norepinephrine, the hydrochloride of 1,2,3,3a,4,8b-hexahydroindeno[1,2-*b*]pyrrole (III), caused a 73.1% inhibition of phenylethanolamine-*N*-methyltransferase activity (7) at a concentration of 1×10^{-4} *M*.

EXPERIMENTAL[1,2]

2-Oxo-1,2,3,3a,4,8b-hexahydroindeno[1,2-*b*]pyrrole (II)—1-Keto-2-indanylacetic acid (I, 0.3 mole) was subjected to reductive amination in the presence of absolute ethanol (300 ml.) containing dry ammonia gas (16%) and Raney nickel (10 g.) at a hydrogen pressure of 150 atm. at 125°. After the reaction, which required nearly 8 hr., the mass was separated from the catalyst by filtration, ethanol was removed by distillation, and the residual mass was repeatedly washed with water and finally crystallized from hot water as shining white crystals, m.p. 191–193°; ν_{max} 1652 (C=O) and 2975 (NH) $cm.^{-1}$.

Anal.—Calc. for $C_{11}H_{11}NO$: C, 76.32; H, 6.36; N, 8.09. Found: C, 76.02; H, 6.58; N, 7.88.

1,2,3,3a,4,8b-Hexahydroindeno[1,2-*b*]pyrrole (III)—Pyrrolidone (II, 1 mole) was reduced with lithium aluminum hydride (0.6 mole) in dry tetrahydrofuran for 10–12 hr. and worked up in the usual way. The indenopyrrole distilled at 99–101°/0.6 mm. as a colorless liquid; ν_{max} 2950 $cm.^{-1}$ (NH). Picrate darkens at 182° and melts at 224–226° dec.

Anal.—Calc. for $C_{11}H_{13}N$: C, 83.04; H, 8.18; N, 8.80. Found: C, 82.87; H, 8.42; N, 9.03.

***N*-Alkyl 1,2,3,3a,4,8b-Hexahydroindeno[1,2-*b*]pyrrole (IV)**—Indenopyrrole (III, 1 mole) was heated in a sealed tube with the appropriate alkyl halide (1.1 moles) on a water bath for 8–12 hr. and then poured into water and extracted with benzene. It was then tosylated with *p*-toluenesulfonyl chloride (1 mole) in benzene solution under stirring at 40° with simultaneous addition of sodium hydroxide (10%) to keep the mass alkaline. The benzene layer was separated out, and the tertiary amine was repeatedly extracted with hydrochloric acid (6 *N*). The combined acid extracts were basified with sodium hydroxide under cooling, extracted with ether, and dried over anhydrous sodium sulfate, and the amine was distilled under reduced pressure to furnish colorless liquids (Table I).

[1] All melting points are uncorrected.
[2] IR spectra were recorded in mineral oil mulls using a Perkin-Elmer spectrophotometer.

Kinetics of Acid-Catalyzed Hydrolysis of Dexoxadrol

LEO W. BROWN and ARLINGTON A. FORIST▲

Abstract □ The kinetics of the hydronium-ion-catalyzed hydrolysis of the ketal group in dexoxadrol hydrochloride [*d*(+)-2,2-diphenyl-4-(2′-piperidyl)-1,3-dioxolane hydrochloride], an orally active analgesic agent, were determined as functions of acid concentration, ionic strength (μ), and temperature. Pseudo-first-order kinetics were observed. Specific reaction rate constants increased with increasing μ; log $k'/[H^+]$ was linearly related to $\sqrt{\mu}$ at $\mu \leq 0.03$. The energy (ΔE_a), enthalpy ($\Delta H^{\ddagger}$), and entropy ($\Delta S^{\ddagger}$) of activation were 16.8 kcal./mole, 16.2 kcal./mole, and −18.8 e.u., respectively. The rate of dexoxadrol hydrolysis was about 2% of that reported in the literature for 2,2-diphenyl-1,3-dioxolane, indicating a marked retardation due to the protonated piperidyl moiety. For a 60-min. residence time at pH 2.0 in the stomach, it was estimated that more than 91% of orally ingested dexoxadrol would remain intact.

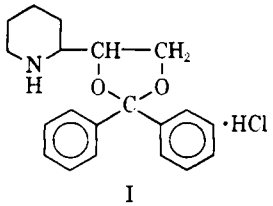
Keyphrases □ Dexoxadrol—kinetics of acid-catalyzed hydrolysis □ Hydrolysis, acid catalyzed—dexoxadrol, kinetics □ Kinetics of hydrolysis—dexoxadrol, acid catalyzed

Dexoxadrol hydrochloride [*d*(+)-2,2-diphenyl-4-(2′-piperidyl)-1,3-dioxolane hydrochloride, I][1] is a potent, orally active analgesic agent in man (1–4). The synthesis (5), physicochemical properties (6), and pharmacology (7–9) of I were reported previously. The known instability of ketals in acid solution made it important to determine the extent of possible degradation of orally administered I in the stomach. Therefore, the kinetics of the acid-catalyzed hydrolysis of I were determined and are the subject of this report.

EXPERIMENTAL

Acid hydrolysis of I yields *l*-2-(2-piperidyl)-1,2-ethanediol (II) (10) and benzophenone (III). Production of III was confirmed in the present study by: (*a*) the UV spectra of reaction mixtures at completion of hydrolysis which were identical to the spectrum of III, and (*b*) TLC of a chloroform extract of the reaction mixture which showed only one UV-absorbing product, identical to III [TLC used silica gel G and the plates were developed with isooctane–chloroform (80:35), $R_f \sim 0.3$].

In the kinetic studies, aqueous solutions of I and of hydrochloric acid were preequilibrated to the desired temperature and rapidly mixed to yield the final concentrations shown in Table I. Each reaction mixture was placed in a UV spectrophotometer equipped with a constant-temperature cell compartment. Absorbances (A_t) were determined at appropriate times at 247 nm., the absorption maximum of III (ϵ = 11,570), until no further absorbance increases occurred (A_∞). Pseudo-first-order reaction rate constants, k', were obtained from the slopes of plots of log $(A_\infty - A_t)$ *versus* time. The analytical wavelength chosen was highly sensitive to the production of III, since neither I (λ_{318}, ϵ = 10,700; λ_{247}, ϵ < 300) nor II absorbs significantly at 247 nm. Based on observed A_∞ values and the molar absorptivity of III, determined under the same conditions, hydrolysis of I was complete (mean yield of III in all studies at 37° was 102.7%).



I

RESULTS AND DISCUSSION

The generally accepted mechanism for the acid-catalyzed hydrolysis of acetals and ketals involves a rapid protonation of the substrate molecule followed by a unimolecular rate-determining decomposition to an alcohol and a resonance-stabilized carbonium ion (11, 12, and references cited therein). Thus, the reaction should show first-order dependence on the acetal or ketal and hydronium ion.

In the present study, plots of log $(A_\infty - A_t)$ *versus* time were strictly linear, confirming first-order dependence on I (Fig. 1). Pseudo-first-order reaction rate constants, k', obtained from the slopes of these plots are shown in Table I along with the resulting values of $k'/[H^+]$. Hydronium-ion concentrations were converted to activities by interpolation of the data of Harned and Owen (13) and were used to calculate the specific reaction rate constants, k_H - (Table I).

Inspection of the data shows that $k'/[H^+]$ and k_{H^+} increased with acid concentration and, therefore, with ionic strength (μ), since the latter was permitted to vary with the acid concentration. For hydrolysis of a neutral species, k_{H^+} should be essentially independent of μ. However, the pKa of I is approximately 8.9 (6). As a consequence, I was completely in the cationic form in the systems studied, and the hydronium-ion-catalyzed hydrolysis involved a reaction between like-charged ions. In such a case, an increase in the rate constant with increasing μ would be predicted, with log $k'/[H^+]$ linearly related to $\sqrt{\mu}$ at low values for μ (14). To test this relationship for the present system, linear least-squares regression of log $k'/[H^+]$ *versus* $\sqrt{\mu}$ (for $\mu \leq 0.03$) was conducted with predetermined theoretical slopes of 1.00, 0.97, and 0.93 at 30, 37, and 44°, respectively (14). The resulting curves (Fig. 2) provided convincing evidence for the predicted effects of μ on the rate constants. Accord-

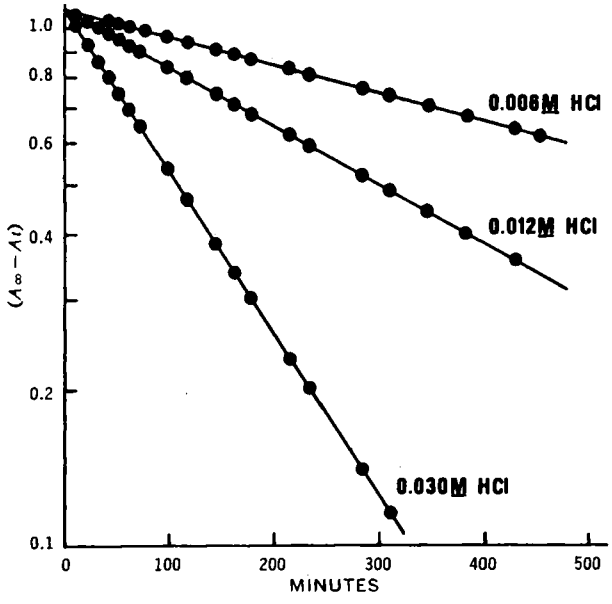


Figure 1—*Pseudo-first-order reaction rate curves for dexoxadrol hydrolysis at 44°.*

[1] Dexoxadrol hydrochloride has also been referred to in the literature as U-22,559A (The Upjohn Co.) and CL-911-C (Cutter Laboratories). USAN chemical name is (+)-2-(2,2-diphenyl-1,3-dioxolan-4-yl)piperidine hydrochloride.

[a] $k_{H^+} = k'/a_{H^+}$. [b] Intercept from log $k'/[H^+]$ *versus* $\sqrt{\mu}$ for $\mu \leq 0.03$ (Fig. 2).

ingly, k_0 (specific reaction rate constant at infinite dilution) was obtained from the intercept of each curve in Fig. 2 and is shown in Table I.

Parameters of activation for the hydrolysis of I were determined from k_0 at 30, 37, and 44° and appropriate linear regressions (Fig. 3). Similar determinations were made utilizing k_{H^+} values obtained at the three temperatures in 0.006, 0.012, and 0.030 M HCl solutions. From the summary in Table II, it may be seen that the classical Arrhenius activation energy (ΔE_a) is in good agreement with the value of 17.2 kcal./mole reported by Ceder (15) for the hydrolysis of 2,2-diphenyl-1,3-dioxolane under similar conditions. The enthalpy of activation ($\Delta H\ddagger$) is somewhat larger than that reported by De Wolfe *et al.* (16) for the hydrolysis of 2,2-diphenyl-1,3-dioxolane in 30% dioxane ($\Delta H\ddagger$ = 14.6 kcal./mole). Fife and Hagopian (12) suggested that steric inhibition of resonance in the incipient carbonium ion should make $\Delta H\ddagger$ more positive. The differences in $\Delta H\ddagger$ may, therefore, reflect such an inhibition by the piperidyl moiety present in I. The entropy of activation ($\Delta S\ddagger$) is considerably more negative than values reported for the hydrolysis of 2,2-diphenyl-1,3-dioxolane in 30% dioxane ($\Delta S\ddagger$ = −8.3 e.u.) (16) and for a series of 2-phenyl-2-alkyl-1,3-dioxolanes in 50% dioxane ($\Delta S\ddagger$ = −8.6 to −8.9 e.u.) (12). Although the magnitude of $\Delta S\ddagger$ is typical of those observed for bimolecular reactions (17), there is no reason to conclude that the mechanism of reaction for I differs

Table II—Activation Parameters for Dexoxadrol Hydrolysis

Basis for Calculation	ΔE_a, kcal./mole	$\Delta H‡$, kcal./mole	$\Delta S‡$, e.u.
k_0	16.9 ± 0.6	16.3 ± 0.6	−19.1 ± 1.9
k_{H^+}, 0.006 *M* HCl	17.2 ± 0.5	16.6 ± 0.5	−17.3 ± 1.7
k_{H^+}, 0.012 *M* HCl	16.6 ± 1.0	15.9 ± 1.0	−19.3 ± 3.2
k_{H^+}, 0.030 *M* HCl	16.4 ± 0.8	15.8 ± 0.8	−19.4 ± 2.7
Mean	16.8 ± 0.8	16.2 ± 0.8	−18.8 ± 2.5

from that generally accepted for ketal hydrolysis. Rather, it appears that I represents a case where steric hindrance in the transition state produces an increase in $\Delta H‡$ and a decrease in $\Delta S‡$ (17).

The data of De Wolfe *et al.* (16) allow a comparison of the hydrolysis rates for I and 2,2-diphenyl-1,3-dioxolane. These investigators found $k_{H^+} = 7.50 \times 10^{-2}\ M^{-1}$ sec.$^{-1}$ for the latter compound at 30° (0.0197 *M* HCl in 1.3% dioxane–98.7% water). Interpolation of the data for I from Fig. 2 gave $k_{H^+} = 1.29 \times 10^{-3}\ M^{-1}$ sec.$^{-1}$ at 30° (0.0197 *M* HCl in water). Presence of the protonated piperidyl group in I, therefore, produced a greater than 98% reduction in hydrolysis rate, reflecting the less favorable entropy of activation.

De Wolfe *et al.* (16) found that hydrolysis of a number of benzophenone ketals was susceptible to general acid catalysis. The catalytic constants for acids other than the hydronium ion were small but significant. For example, dichloroacetic acid (HA) catalyzed the hydrolysis of 2,2-diphenyl-1,3-dioxolane (30°, 20% dioxane) such that $k_{H^+}/k_{HA} = 40$. No attempt was made in the present studies to determine the role of general acid catalysis in the hydrolysis of I. However, it may be concluded from the data in Table I (37°, 0.03 *M* HCl) that the protonated substrate (a Bronsted acid) did not make a significant catalytic contribution to its own hydrolysis, since observed rate constants were independent of initial I concentration.

Oral doses of I in man have ranged from 10 to a maximum of 150 mg. (1–4). Since the solubility of I is high (11.66 mg./ml. at 23°) (6), rapid and complete dissolution should occur in the stomach. Gastric pH and emptying times vary widely. To provide a reasonable estimate of the stability of I during its transit through the stomach, a pH of 2.0 (corresponding to the data for 0.012 *M* HCl in Table I) and a residence time of 60 min. (approximately three half-lives for the stomach emptying process) (18) were assumed. Under those conditions, more than 91% of orally ingested I would survive hydrolysis. This estimate is consistent with the high order of oral activity observed in clinical studies.

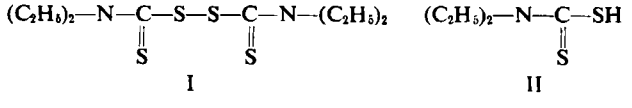
Colorimetric Assay of Disulfiram

RAINER FRIED*▲, ASAAD N. MASOUD†, and FRANCIS M. KLEIN‡

Abstract □ A quantitative assay for disulfiram was developed based on color formation during the interaction of disulfiram, ethanol, and cyanide. A linear curve is obtained over a wide range of disulfiram concentrations. Metabolites of disulfiram do not interfere in this assay. The color reaction is suitable for identification of small aliphatic alcohols and ketones.

Keyphrases □ Disulfiram—colorimetric assay using ethanol and cyanide, used to identify small aliphatic alcohols and ketones □ Alcohols and ketones, aliphatic—identification, colorimetric reaction with disulfiram and cyanide □ Colorimetry—analysis of disulfiram using ethanol and cyanide, used to identify aliphatic alcohols and ketones

During a study of the metabolic effects of disulfiram[1] [bis(diethylthiocarbamoyl) disulfide, I], attention was directed to a color reaction, quoted in the manual of drug identification of Clarke (1). This reaction is found in older manuals and its original discoverer is not known[2]. The color produced by mixing an alcoholic disulfiram solution with aqueous cyanide was listed as a colorimetric spot test for disulfiram. Further investigation showed that this assay could be suitably adapted to a sensitive quantitative method for disulfiram determination. The mechanism and specificity of this reaction were examined further, since the strong blue color, produced rapidly at room temperature, was very puzzling. An examination of a large list of organic compounds proved that the reaction with cyanide and disulfiram could be used as a sensitive class reaction for aliphatic alcohols and ketones and that it may serve as a tool for identification of unknown compounds. Some of the present results were presented as a preliminary communication (2).



I

II

EXPERIMENTAL

Color was developed by mixing a freshly prepared solution of disulfiram (50 mg./5 ml.) in ethanol or other solvents with 1 ml. of 1 *M* NaCN at room temperature. For quantitative determinations, the reaction mixture was let stand for 30 min. at room temperature. TLC was carried out on silica gel GF[3] (3). Disulfiram showed R_f 0.67 in chloroform and R_f 0.24 in benzene, and it could be identified by quenching UV light and by a yellow spot when sprayed with ethanol and cyanide.

Absorption and IR spectra were obtained in spectrophotometers[4]. GC was carried out[5] using stainless steel columns, 1.8 m. × 1.3 cm. (6 ft. × 0.5 in.), with Chromosorb W (100–120 mesh) and 0.5% SE-30 as the liquid phase between 70 and 190°. The reaction mixture with ethanol was investigated further and was tested for diethyl dithiocarbamate (II) and carbon disulfide by colorimetric methods (4, 5). Sulfur was identified as barium sulfate after wet-ashing with concentrated nitric acid, and thiocyanate was identified by reaction with ferric chloride (6).

RESULTS AND DISCUSSION

An ethanolic solution of disulfiram treated with 1 *M* sodium cyanide rapidly forms an intense yellow color, which quickly passes to green and blue, with a broad maximum between 520 and 580 nm. and a minimum at 450–460 nm. (Fig. 1). The blue color fades on standing, reverting to yellow; neither the intensity of colors nor the rate of color formation is affected by the order of addition. The blue color can be extracted into ether but does not pass into petroleum ether.

When the graded levels of disulfiram are used for color development, a straight line is obtained over a wide concentration range. This can be used as a convenient colorimetric assay for disulfiram (Fig. 2). Eventual interference by other colored compounds, as found in urine, can be eliminated by extracting the blue color into ether and determining the color of the organic phase. Diethyl dithiocarbamate (II) and carbon disulfide, important metabolites of disulfiram (7–11), do not give a color reaction with cyanide, nor are they formed in the reaction of disulfiram with cyanide. The present method is, therefore, suitable for studies of metabolic transformations of disulfiram.

Color formation only takes place with oxygenated compounds that act not only as solvents but also participate in the reaction (Table I). Best results are obtained with small primary aliphatic alcohols, of which butanol forms an intense blue color at the interphase. The blue color is most stable and intense when methoxyethanol or *tert*-butanol is used as a reactant. Acetaldehyde could

not be tested, because acetaldehyde and cyanide alone (in absence of disulfiram) form an intense brown color in a strongly exothermic reaction. An intense yellow color is formed by acetone, dioxane, dimethyl sulfoxide, and methylcellulose. Contrary to the reaction with alcohols, this color is stable and does not pass to blue nor fade on standing.

Acetone also serves as a suitable reagent for quantitative determination of disulfiram (Fig. 2). Dimethyl sulfoxide gives an exothermic reaction in which gas and precipitate formation are observed. When the reaction is carried out in this reagent, the yellow color is not converted to blue on addition of ethanol.

To identify the products of this reaction, a large batch was prepared with ethanol using the same proportions of reagents as for the routine color development. Several compounds were isolated, and the presence of others was detected by TLC. The new reaction products were found not to be disulfiram or its known derivatives by using TLC, GC, and UV and IR spectrophotometry. In view of the rapid formation and great intensity of color, a clarification of the reaction mechanism would be of considerable theoretical interest.

A proposed mechanism (12, 13) may be pertinent, in which a disulfide bridge is split by cyanide, with the formation of a thioether and free thiocyanate. However, no color formation has been reported (13). Thiocyanate could not be detected in the present study by reaction with ferric chloride; the reasons for these discrepancies are not clear. Similar interactions of cyanide with disulfide bridges occur not only with simple organic compounds but also with biological compounds. Cyanide causes cleavage of protein chains at the cystine bridges (14, 15) with the liberation of thiocyanate (16). Xanthine oxidase is irreversibly inactivated by cyanide, which forms a covalent bond with the enzyme (17, 18), and thiocyanate is liberated from the persulfide group, which is essential for enzyme activity (19).

The present procedure was used to determine disulfiram in urine of chronic alcoholics receiving disulfiram therapy. The drug could not be identified in urine or urine extracts, which is in agreement with previous reports (4, 20, 21).

SUMMARY

The interaction of disulfiram, cyanide, and organic solvents was studied. A simple colorimetric assay of disulfiram was developed, which gives a linear response over at least a 20-fold range. The reaction can be used as a type reaction for alcohols.

Table I—Color Reaction of Disulfiram with Organic Reagents[a]

Reagent	Color	Reaction Rate[b]
Methanol	Blue	Fast
Ethanol	Blue	Fast
Isopropanol	Green	Fast
1-Butanol	Blue	Fast
Methoxyethanol	Blue	Fast
2-Butanol	Light green	Slow
tert-Butanol	Blue	Fast
Acetaldehyde[c]	(Brown)	(Fast)
1-Octanol	Light orange	Very slow
Isoamyl alcohol	Yellow	Slow
Acetone	Lemon yellow	Fast
Dioxane	Brown	Fast
Formamide	Yellow	Slow
Dimethylformamide	Yellow	Slow
Dimethyl sulfoxide[c]	Yellow	Fast

[a] Fifty milligrams of disulfiram was dissolved in 5.0 ml. of solvent, and 1.0 ml. of 1 *M* NaCN was added. [b] Negative reactions were obtained with cyclohexanol, benzyl alcohol, phenol, acetic acid, ethyl acetate, butyraldehyde, hexane, benzene, ether, chloroform, carbon tetrachloride, and carbon disulfide. Fluorometric Determination of Primary and Secondary Aliphatic Amines by Reaction with 9-Isothiocyanatoacridine

ANDRÉ DeLEENHEER*, J. E. SINSHEIMER▲, and J. H. BURCKHALTER

Abstract □ An improved procedure was developed for the analysis of primary and secondary aliphatic amines based upon the fluorescence of a cyclized product derived from isothiourea derivatives of amines and 9-isothiocyanatoacridine. Initial isothiourea formation as well as its cyclization is carried out in toluene, which results in the formation of highly fluorescent 2-alkylamino-1,3-thiazino-[4,5,6-*kl*]acridine with a minimum of by-products. The fluorescence of these thiazinoacridine compounds is determined either directly in solution after dilution with acidified alcohol or after TLC separation and direct scanning of the TLC plate. For example, amphetamine could be determined with a sensitivity of 0.12 nl./ml. in solution or at a 3-pl. level by the TLC procedure.

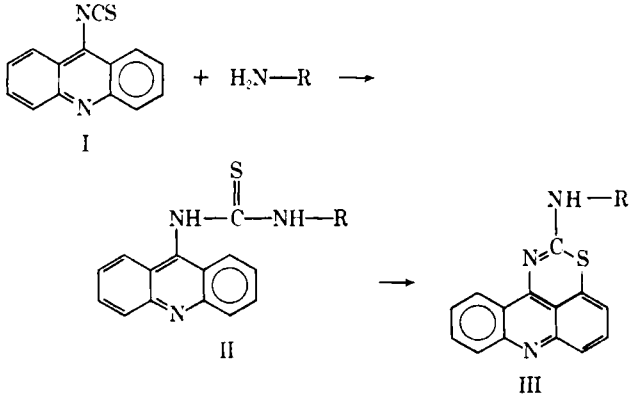
Keyphrases □ Amines, primary and secondary aliphatic—fluorescent analysis with 9-isothiocyanatoacridine □ Fluorescent analysis—primary and secondary aliphatic amines using 9-isothiocyanatoacridine, TLC fluorometry □ Amphetamine—fluorescent analysis using 9-isothiocyanatoacridine □ 9-Isothiocyanatoacridine—used as a reagent in fluorometic determination of primary and secondary aliphatic amines

The use of 9-isothiocyanatoacridine (I) as a reagent for the fluorometric determination of primary amines was previously reported from these laboratories (1). In that reaction (Scheme I), the thiourea (II) that formed was found to undergo a photochemical oxidation to yield a cyclized product (III), whose fluorescence can be related to the concentration of the original amine present (2). Knowledge of this cyclization has led to modification of the original analytical procedure (1), which has increased its sensitivity as well as permitted the analysis of secondary aliphatic amines.

This paper describes the modified procedure and its application to primary and secondary amines, with special emphasis on amphetamine analysis.

EXPERIMENTAL

Fluorometric Procedure—Solutions of 10–50 nl. (nanoliters) of liquid amines or of 10–50 mcg. of *p*-anisidine in 5.00 ml. of toluene were allowed to react with 2 ml. of 9-isothiocyanatoacridine reagent (80.0 mg. of 9-isothiocyanatoacridine in 100.0 ml. of toluene). Liquid amines were distilled over zinc dust, and *p*-anisidine was recrystallized from *n*-hexane prior to use. These solutions were allowed to react in 15-ml. glass-stoppered centrifuge tubes overnight (15 hr.) on the laboratory desk. These conditions permitted exposure to indirect morning sunlight after an initial reaction period in the dark. Fluorometric measurements[1] were made directly on the toluene solutions as well as on dilutions of 0.5 ml. of the toluene solution with 4.5 ml. of alcohol and of 0.5 ml. of the toluene solution with 4.5 ml. of alcohol and 0.1 ml. of concentrated hydrochloric acid. Reagent solutions without amine present were allowed to stand under the same conditions and were measured as controls.



Scheme I

TLC Separation and Fluorometry—Aliquots (15 μl.) of the toluene reaction mixtures from butylamine, amphetamine, and the reagent control described under *Fluorometric Procedure* were chromatographed on commercial[2] 250-μ precoated silica gel G plates (20 × 20 cm.), which were scored in 0.5-cm. channels prior to use. Development was in benzene–methanol (140:40) with detection under UV light. Quantitative fluorometric measurements were made directly from thin-layer plates with the aid of a scanner[3] as previously described (2).

RESULTS AND DISCUSSION

Reaction of 9-isothiocyanatoacridine with amines in alcoholic solutions leads to a mixture of fluorescent compounds (1). The fluorescence of one of these products could be related to the amount of amine present. It was subsequently recognized (2) that this fluorescent product was a cyclized compound (III) produced by photooxidation of thiourea II. Therefore, a study was undertaken to develop an analytical procedure with an increased yield of cyclized product in a minimal background of fluorescent by-products. The use of toluene in place of alcohol produced a more stable reagent solution and eliminated the interaction of reagent and solvent. Experiments to establish a maximum yield of cyclized product by exposure of the initial reaction mixture of amine and excess reagent to UV light in a photochemical reactor[4] were unsuccessful. While individual thioureas such as *N*-butyl-*N'*-(9-acridinyl)thiourea could be cyclized under these conditions, the procedure could not be applied to the analytical reaction mixture. Under these conditions, the required excess of the reagent, 9-isothiocyanatoacridine, was readily converted into acridone [λ (activation) 320 nm.; λ (emission) 440 nm.] by exposure to UV radiation. This resulted in excessive background fluorescence.

The most convenient reaction condition for the present study was to allow the amine and a 10–70-fold molar excess of reagent to react overnight at room temperature in the dark. This was followed by a limited morning exposure to indirect sunlight. An alternative procedure was to allow the amine sample and excess reagent to react in the dark at 60° before exposure to sunlight. In either case, care was taken to expose all sets of reaction mixtures containing increasing concentrations of amines and control reagent solutions to the same conditions.

Progress of the reaction can be monitored by TLC as described in the *Experimental* section. For example, a 15-μl. aliquot of a typical overnight reaction mixture of 0.05 ml. of *n*-butylamine and 1.6 mg. of 9-isothiocyanatoacridine in 7 ml. of toluene showed fluorescent spots corresponding to the R_f values and conditions of the following reference compounds: 0.02, blue, trace (9-aminoacridine);

Table I—Analysis of Amines

	Fluorescence		
	Activation, nm.	Emission, nm.	Intensity/ Concentration[a]
n-Butylamine	300	525	14.0
Cyclohexylamine	300	515	14.4
Benzylamine	300	520	12.2
β-Phenylethylamine	300	520	12.8
Amphetamine	300	520	8.6
Diethylamine	300	520	17.6
N-Methylpiperazine	310	525	12.8

[a] Slope of linear range: given as the difference in fluorescence over the reagent blank (calculated for a meter multiplier reading of 1 at a sensitivity of 25) and divided by concentration of amine (in nanoliters per milliliter). The average value for the acidic, alcoholic dilution of reagent blank was 60 at 465 nm. at a meter multiplier reading of 0.1. This value was reduced to about 12 in the wavelength range of maximum fluorescence of the test compounds.

0.16, yellow-green (cyclized product: 2-butylamino-1,3-thiazino[4,-5,6-*kl*]acridine); and 0.36, blue (excess reagent: 9-isothiocyanatoacridine). While a reagent control solution showed the spot at R_f 0.66 and those corresponding to trace quantities of aminoacridine and acridone, there was no fluorescence in the region of the thiourea or the cyclized compound.

When the final reaction mixture was measured in an alcoholic solution, especially an acidic alcoholic solution, there was a pronounced increase in the difference between fluorescence of the amine reaction solution and the control solution. Thus, while alcoholic solutions were avoided in original reaction mixtures, they could be employed to advantage just before determination of fluorescence. However, there is a decrease in stability of such solutions, with a change in fluorescence appearing in about 6 hr., as opposed to no appreciable change in fluorescence of the more concentrated reaction mixtures in toluene after 3 days.

The final analytical procedure was performed as outlined in the *Experimental* section. This included the acidic, alcoholic dilution of the original toluene reaction mixture just prior to measurement of fluorescence. Of particular importance in this procedure are the facts that the final reaction product has fluorescent characteristics that permit its direct determination in the presence of excess reagent and that this fluorescence is proportional to the amount of amine originally present.

Table I is a summary of compounds that were successfully analyzed by the modified technique. Included are the wavelengths of activation and emission used to obtain a maximum difference in fluorescence between the reaction mixture and its corresponding reagent blank. Table I also includes a summary of the intensity of this difference in fluorescence.

In addition to the compounds listed in Table I, aniline, *p*-toluidine, *p*-anisidine, and *N*-ethylaniline were subjected to the procedure but did not yield satisfactory results. Failure to achieve positive results with these compounds, which is consistent with the nucleophilicity of the amines involved, suggests that the rate of thiourea formation (Compound II) is a critical consideration. Thus, by using the basicity of amines as a measure of nucleophilicity, it was found that all amines that were successfully determined have a pKa $\geq$ 9.33 (benzylamine), while no compound with a pKa $\leq$ 5.34 (*p*-anisidine) (3) could be measured.

The procedure is applicable to amines of biological significance such as amphetamine. A detection limit down to a concentration of 0.12 nl./ml. was established for quantitative results for amphetamine solutions. The results for six samples in the range from 0.2 to 0.5 nl./ml. gave a mean recovery of 97% with a standard deviation of 3.3%. The sensitivity of the solution procedure could be greatly enhanced by combination with TLC followed by direct fluorometric scanning of the plates. The fluorescence scanning procedure was conducted as previously described (2) after chromatography on silica gel G with benzene–methanol (140:40). Measurement of the cyclized product derived from amphetamine was at an activation of 355 nm. and an emission of 518 nm. The recorder response was linear to the original volume of amphetamine over a range of samples of 3, 6, 9, 20, and 25 pl. (picoliters). The results for eight samples over this range gave a mean recovery of 98.9% with a standard deviation of 9.9%. The TLC scanning procedure thus results in a loss in precision but a great increase in sensitivity and it eliminates the interfering fluorescence of products and excess reagent.

Stability of Aspirin in Liquid and Semisolid Bases II: Effect of Fatty Additives on Stability in a Polyethylene Glycol Base

C. W. WHITWORTH[A], L. A. LUZZI, B. B. THOMPSON, and H. W. JUN

Abstract □ Aspirin decomposes rapidly when incorporated into mixtures of polyethylene glycols, but aspirin incorporated into fatty-type suppository bases is much more stable. Fats of vegetable origin were incorporated into a polyethylene glycol base in an attempt to inhibit the decomposition of aspirin in this type of mixture. The process is temperature dependent and refrigeration of the mixture greatly slows decomposition. Degradation was retarded at 26°, but little effect was noted at 4 and 45° within the time limits of this study.

Keyphrases □ Aspirin—effect of fatty additives on stability of polyethylene glycol base suppositories □ Fatty additives—effect on decomposition of aspirin in polyethylene glycol base suppositories □ Degradation—effect of fatty additives on aspirin stability in polyethylene glycol base suppositories □ Polyethylene glycol–aspirin formulations—effect of fatty additives on aspirin stability □ Additives, fatty—effect on aspirin stability in polyethylene glycol base suppositories

Aspirin has been found to degrade in polyethylene glycol mixtures. The process has been shown to be due in part to transesterification (1). The process is greatly temperature dependent, with refrigeration at 4° markedly slowing the rate of decomposition.

Aspirin is commercially available in suppository form in a cocoa butter base. Under refrigeration, these suppositories are sufficiently stable, although an expiration date is necessary. Aspirin is likewise much more stable in other fatty vehicles than in the polyethylene glycols. A product composed of distilled acetylated monoglycerides was tested as a vehicle for aspirin and found to inhibit greatly the degradation process (Fig. 1). It was then decided that fatty additives might have an inhibiting effect on aspirin decomposition in a polyethylene glycol base. The purpose of this study was to formulate a stable aspirin suppository using a polyethylene glycol base without altering the desirable characteristics of the base. A 10% concentration of additive was used in the study, and no compatibility problems were encountered with the formulation. Six different additives were utilized.

Polyethylene glycol mixtures serve as excellent suppository bases for some drugs (2). Their main advantages are water solubility, an innocuous nature, the ability to release a drug for absorption (3), and firmness at room temperature. Since the polyethylene glycols dissolve in the body secretions rather than melting, they do not require refrigeration with most drugs; in this respect, they have a great advantage over the fatty-type bases such as cocoa butter.

Unfortunately the polar and perhaps also the hygroscopic nature of these glycols tends to allow certain drugs such as aspirin to degrade when incorporated into this type of base.

One aspect of the study was to determine if packaging and storage procedures contributed significantly to the degradation process. Commercially, polyethylene glycol base suppositories are packaged unwrapped in jars and stored at room temperature until dispensed. In this project, the control batch of aspirin suppositories was divided into groups and some were wrapped in aluminum foil and stored both with and without a desiccant in the container. The degradation of these suppositories was compared with another batch stored without either wrapping or desiccant. There were no appreciable differences in the degradation curves for these batches. Throughout the study, however, a desiccant was present in all containers to reduce the effect of moisture on the decomposition process.

EXPERIMENTAL

Materials—The formula for the polyethylene glycol base used in the study was as follows:

polyethylene glycol 400[1]	24.8%
polyethylene glycol 1540[1]	30.4%
polyethylene glycol 6000[1]	40.0%
polysorbate 60[2]	4.8%

The additives used in the project were:

1. Hard butter containing lauric fats[3]. Free fatty acids, 0.1% max. Iodine value, 3 max. Used in confections and candies as coatings.
2. A coating butter made from domestic vegetable oils[4]. Free fatty acids, 0.1% max. Iodine value, 58–63. Used in confections and candies.
3. Hard butters obtained from lauric oils[5]. Free fatty acids, 0.05% max. Used in candies and confections.
4. Distilled, fully acetylated monoglycerides[6]. Acid value, 4. Iodine value, 44. Made from edible fats. Used in cosmetics as emulsifiers.
5. Oil expressed from roasted seeds of *Theobroma cacao*[7]. A mixture of glycerides. Iodine value, 35–43. Used as a suppository base.
6. Hydrogenated glycerides of fatty acids from palm oils[8]. Acid value, 1. Iodine value, 2. Used as suppository base.

Procedure—The additives were added in quantities equivalent to 10% of the amount of base used. The ingredients were then melted at 55° with stirring, and aspirin equal to 12% of the base–additive mixture was stirred into the melted mixture. The mixture was poured with stirring into suppository molds and allowed to congeal. The batch of suppositories was divided into three quantities for storage at the temperatures reported in this study. All suppositories were stored in airtight containers containing a desiccant.

Aspirin was added with stirring to the acetylated monoglyceride product in the same ratio as with all the other formulations and stored under similar conditions.

Analytical Method—Assays were performed at short intervals for the first part of the study, and the intervals gradually lengthened

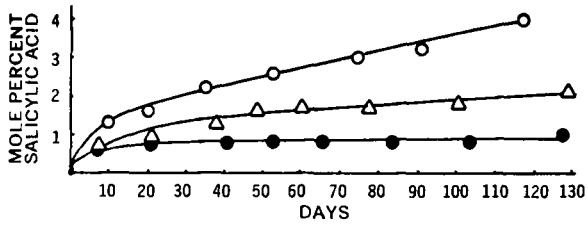

Figure 1—*Mole percent decomposition of aspirin with time in a vehicle composed of acetylated monoglycerides. Key: ○, 45°; △, 26°; and ●, 4°.*

as decomposition slowed down. When the percent decomposition reached 30–35%, assaying was discontinued. The assay procedure consisted of dissolving each suppository (approximately 2.4 g.) in 100 ml. of a solution of chloroform containing 1% acetic acid. A 1:50 dilution was made, and the absorbance of the dilution was read at 278 nm. for aspirin and 308 nm. for salicylic acid on a spectrophotometer[9]. From a standard curve the moles of each drug were determined and mole percent of salicylic acid (percent decomposition) was calculated.

RESULTS AND DISCUSSION

Figure 1 shows the degradation of aspirin in acetylated monoglycerides. The graphs are all plots of mole percent salicylic acid against time. The ordinates likewise represent mole percent decomposition of aspirin. Figure 2 represents the control, which was the polyethylene glycol mixture without additives. Since all additives yielded essentially identical results, only one curve at each temperature is shown in Fig. 3. For purposes of comparison, the control curves appear as broken lines in Fig. 3.

A comparison of Figs. 1 and 2 shows a drastic difference in the rate of decomposition of aspirin in a fatty-type vehicle compared to a polyethylene glycol base. In acetylated monoglycerides the decomposition after about 130 days at 45, 26, and 4° had reached

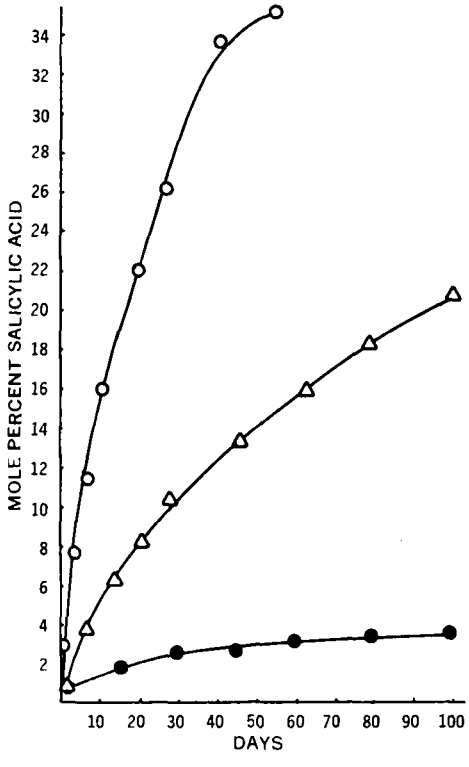

Figure 2—*Mole percent decomposition of aspirin with time in a polyethylene glycol base (control). Key: ○, 45°; △, 26°; and ●, 4°.*

[9] Beckman DU.

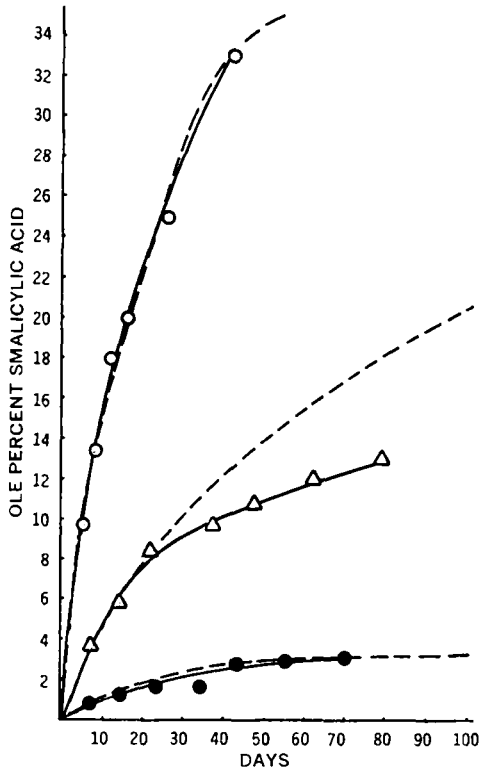

Figure 3—*Mole percent decomposition of aspirin with time in a polyethylene glycol base containing 10% acetylated monoglycerides. Broken lines represent control. Key: ○, 45°; △, 26°; and ●, 4°.*

only approximately 5, 2, and 1%, respectively; in the polyethylene glycol base, the decomposition was much greater.

The effect of temperature on aspirin degradation in many different types of vehicles is well documented. However, no study heretofore has dealt with aspirin stability in a polyethylene glycol-type suppository base. In practice, polyethylene glycol-type suppositories are stored at room temperature. This study shows this procedure should not be followed with aspirin.

As could be expected and as may be seen from Fig. 3, degradation was drastically inhibited in all the mixtures by reducing the temperature of storage. At 45°, both the control and the bases with additives reached the range of 30–35% decomposition in about 40–50 days, at which time sampling was discontinued. It is readily apparent that the fatty additives used in this study had no significant effect on aspirin degradation in the polyethylene glycol base at 45°. This is probably due to the rapid rate of the reaction at this temperature.

Figure 3 also shows that storage of suppositories at 26° drastically reduced the rate of decomposition of both the control and additive bases. For comparable time periods, the percent decomposition at 26° was less than half that at 45°. It may be seen that the additives had an inhibiting effect on aspirin degradation at this temperature. The difference in stability becomes apparent after about 20 days when the curves diverge.

Refrigeration of the suppositories at 4° reduced the decomposition of aspirin to less than 4% within the time limits of this study, for both the control and the additive bases. There was no apparent difference between the results from the control and the treated bases. It is possible that the additive would show an inhibiting effect on the degradation of aspirin after a much longer storage period.

The aims of this project were to study aspirin decomposition in polyethylene glycol mixtures and to devise means of stopping or reducing this degradation. As previously reported, the degradation is partly due to a transesterification mechanism (1).

It was felt that fatty additives might render a polyethylene glycol suppository base suitable as a vehicle for aspirin. From this study, it is concluded that while the fatty additives have an inhibiting effect at a room temperature of 26°, the percent of decomposition is still prohibitively high. Furthermore, the results showed temperature

effect to be much more pronounced than additive effect. Refrigeration dramatically slows the rate of decomposition.

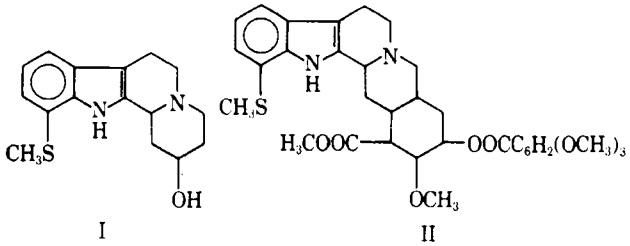
Synthesis of (±)-*trans*-11-Methylthio-1,2,3,4,6,7,12,12b-octahydrohydroxyindolo[2,3-*a*]quinolizine

GARY E. DUGAN* and KARL A. NIEFORTH†▲

Abstract □ (±)-*trans*-11-Methylthio-1,2,3,4,6,7,12,12b-octahydrohydroxyindolo[2,3-*a*]quinolizine was synthesized as a cardiovascular agent. Biological evaluation of the title compound and several precursors (7-methylthiotryptamine formate, 7-methylthiotryptamine formamide, 8-methylthio-3,4-dihydro-β-carboline, *trans*-11-methylthio - 1,2,3,4,6,7,12,12b - octahydro - 2 - oxoindolo[2,3 - *a*] quinolizine) showed no activity.

Keyphrases □ (±)-*trans*-11-Methylthio-1,2,3,4,6,7,12,12b-octahydrohydroxyindolo[2,3-*a*]quinolizine—synthesis, pharmacological evaluation □ Thioindole derivatives—synthesis and pharmacological evaluation of (±)-*trans*-11-methylthio-1,2,3,4,6,7,12,12b-octahydrohydroxyindolo[2,3-*a*]quinolizine

The title compound, (±)-*trans*-11-methylthio-1,2,3,4,-6,7,12,12b - octahydrohydroxyindolo[2,3 - *a*]quinolizine (I), was prepared as an extension of the authors' interest in thioindole derivatives and the reported (1) activity of methiopidine (II). Unsubstituted octahydroindolo[2,3-*a*]-quinolizine has been synthesized (2) and reported to be a hypotensive agent. Synthesis (Scheme I) of I was achieved by first preparing 7-methylthiotryptamine through a sequence described by Abramovitch and Shapiro (3). Preparation of the phenylhydrazone (III) was carried out *via* the Japp-Klingemann reaction of S-methyl - 2 - aminobenzenethiol and 3 - carbethoxy - 2-piperidone. Cyclization of III into the β-carboline (IV) was smooth in hot acetic acid–hydrogen chloride gas. Hydrolysis of the β-carboline (IV) to the amino acid (V) was quantitative in 5% alcoholic potassium hydroxide. Decarboxylation to 7-methylthiotryptamine (VI) was accomplished with difficulty in refluxing 2 *N* hydrochloric acid–acetic acid. Synthesis of the octahydroindolo[2,3-*a*]quinolizine (X) followed a procedure described previously (4–6). Addition of ethyl acetate–90% formic acid (1:1) to an ethyl acetate solution of 7-methylthiotryptamine afforded the formate salt (VII) which, upon heating, was converted to the formyl derivative (VIII). The *N*-formyl derivative was treated under Bischler–Napieralski conditions to form the Schiff base (IX), which was converterted to the *trans*-indolo[2,3-*a*]-quinolizine (X) by warming with methyl vinyl ketone and a catalytic amount of ethanol saturated with hydrogen chloride gas. Assignment of the *trans*-configuration was based on the presence of a Bohlman band between 2700 and 2800 cm.$^{-1}$ (KBr) on the IR spectrum (7). Reduction of X with lithium aluminum hydride afforded the title compound, I.



I II

PHARMACOLOGICAL RESULTS

The compounds were tested[1] in a variety of *in vitro* and *in vivo* assays: antibacterial, antifungal, antiparasitic, and antiviral assays. In some cases they were checked for activities of potential interest in the cardiovascular and behavioral fields. A total of 114 individual bioassays was run.

The compounds were tested in chicks (8) for possible anticoccidal activity and for *in vitro* anthelmintic activity against larvae or eggs of trichostrongyle nematodes (9). Antiviral screening (10) was conducted at sample concentrations up to 400 mcg./ml. in cell cultures.

Activity was demonstrated only by Compound VII in any of the screening procedures. Compound VII was active in a concentration of 400 p.p.m. against the organism *Bacillus megaterium* (ATCC 7056). The compound was tested by the medicated agar dilution technique, in which the compound is added to the agar and the test organism is inoculated (about 3 × 10^5 cells) on the surface. The end-point is the level of compound that prevents emergence of visible growth. Since Compound VII was active against only a single organism, lower dose levels were not run.

EXPERIMENTAL[2]

7-Methylthiotryptamine Formate (VII)—To a vigorously stirred solution of 19.4 g. (0.094 mole) of crude VI (11) in ethyl acetate (100 ml.) was slowly added a solution of 1:1 ethyl acetate–90% formic

[1] In the Merck Sharp & Dohme Research Laboratories.

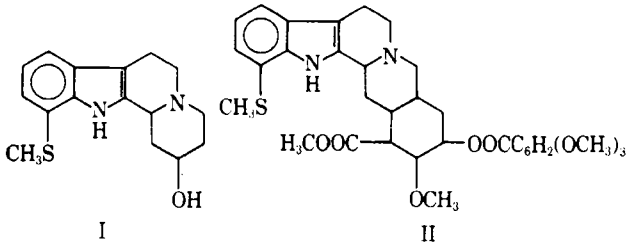
Cyclization of III into the β-carboline (IV) was smooth in hot acetic acid–hydrogen chloride gas. Hydrolysis of the β-carboline (IV) to the amino acid (V) was quantitative in 5% alcoholic potassium hydroxide. Decarboxylation to 7-methylthiotryptamine (VI) was accomplished with difficulty in refluxing 2 *N* hydrochloric acid–acetic acid. Synthesis of the octahydroindolo[2,3-*a*]quinolizine (X) followed a procedure described previously (4–6). Addition of ethyl acetate–90% formic acid (1:1) to an ethyl acetate solution of 7-methylthiotryptamine afforded the formate salt (VII) which, upon heating, was converted to the formyl derivative (VIII). The *N*-formyl derivative was treated under Bischler–Napieralski conditions to form the Schiff base (IX), which was converterted to the *trans*-indolo[2,3-*a*]-quinolizine (X) by warming with methyl vinyl ketone and a catalytic amount of ethanol saturated with hydrogen chloride gas. Assignment of the *trans*-configuration was based on the presence of a Bohlman band between 2700 and 2800 cm.$^{-1}$ (KBr) on the IR spectrum (7). Reduction of X with lithium aluminum hydride afforded the title compound, I.



I II

PHARMACOLOGICAL RESULTS

The compounds were tested[1] in a variety of *in vitro* and *in vivo* assays: antibacterial, antifungal, antiparasitic, and antiviral assays. In some cases they were checked for activities of potential interest in the cardiovascular and behavioral fields. A total of 114 individual bioassays was run.

The compounds were tested in chicks (8) for possible anticoccidal activity and for *in vitro* anthelmintic activity against larvae or eggs of trichostrongyle nematodes (9). Antiviral screening (10) was conducted at sample concentrations up to 400 mcg./ml. in cell cultures.

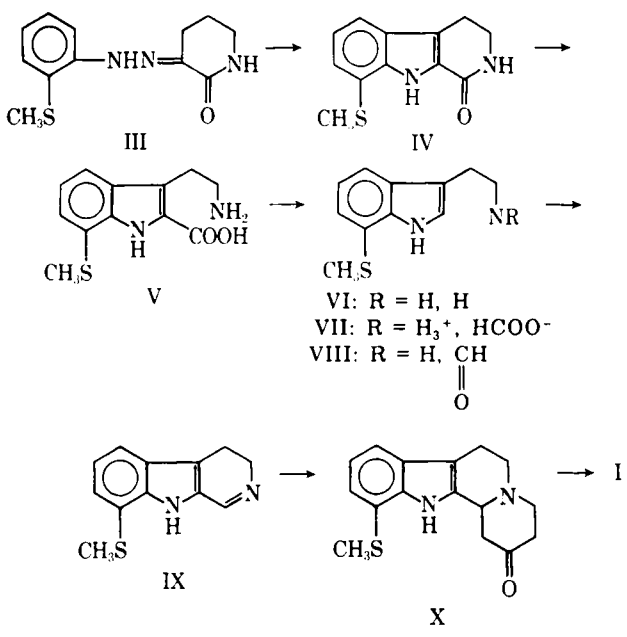
Activity was demonstrated only by Compound VII in any of the screening procedures. Compound VII was active in a concentration of 400 p.p.m. against the organism *Bacillus megaterium* (ATCC 7056). The compound was tested by the medicated agar dilution technique, in which the compound is added to the agar and the test organism is inoculated (about 3 × 10^5 cells) on the surface. The end-point is the level of compound that prevents emergence of visible growth. Since Compound VII was active against only a single organism, lower dose levels were not run.

EXPERIMENTAL[2]

7-Methylthiotryptamine Formate (VII)—To a vigorously stirred solution of 19.4 g. (0.094 mole) of crude VI (11) in ethyl acetate (100 ml.) was slowly added a solution of 1:1 ethyl acetate–90% formic

[1] In the Merck Sharp & Dohme Research Laboratories.

[2] All melting points were determined in open glass capillaries on a Thomas–Hoover apparatus and are corrected.



Scheme I

acid. The solid was collected and recrystallized from ethanol to give 19.5 g. (82%) of white crystals, m.p. 152–153°.

Anal.—Calc. for $C_{12}H_{16}N_2O_2S$: C, 57.10; H, 6.39; N, 11.11; S, 12.69. Found: C, 56.80; H, 5.21; N, 11.43; S, 12.71.

***N*-Formyl-7-methylthiotryptamine (VIII)**—A test tube containing 7 g. (0.038 mole) of the formate salt VII was heated in an oil bath at 185° for 45 min. After cooling, a small portion of ethanol was added to the thick gummy residue. Vigorous stirring of the mixture yielded white crystals; 5.35 g. (82%) was collected and recrystallized from a minimal amount of hot water, m.p. 109–110°.

Anal.—Calc. for $C_{12}H_{14}N_2OS$: C, 61.51; H, 6.02; N, 11.95; S, 13.68. Found: C, 61.51; H, 6.14; N, 11.97; S, 13.45.

8-Methylthio-3,4-dihydro-β-carboline (IX)—A mixture of 7 g. (0.03 mole) of VIII and of anhydrous benzene (126 ml.) was heated until solution was nearly complete. The solution was allowed to cool slightly and then 21 g. (0.137 mole) of freshly distilled phosphorus oxychloride was added dropwise. When spontaneous boiling ceased, the solution was heated for 30 min. on an oil bath. Upon cooling, the hydrochloride salt of the desired product precipitated. The hydrochloride, 6.8 g. (90.5%), m.p. 242–243°, upon neutralization yielded the free amine as white crystals, m.p. 87–88°.

Anal.—Calc. for $C_{12}H_{11}N_2S \cdot HCl$: C, 57.02; H, 5.18; N, 11.08; S, 12.86. Found: C, 56.72; H, 5.33; N, 10.84; S, 12.68.

***trans*-11-Methylthio-1,2,3,4,6,7,12,12b-octahydro-2-oxoindolo-[2,3-*a*]quinolizine (X)**—To a warmed solution of 34 g. (0.136 mole) of IX in absolute ethanol (75 ml.) were added 38 g. (0.544 mole) of methyl vinyl ketone and a catalytic amount of absolute ethanol saturated with hydrogen chloride. The solution was allowed to reflux for 6 hr. and then to cool overnight, and the solvent was removed *in vacuo*. The residue, on crystallization from ethanol, gave 4.5 g. (9.9%) of the crude ketone X. A pure sample of the ketone X, m.p. 164–166°, was obtained *via* preparative TLC using chloroform–methanol (1:9) as the solvent. The 2,4-dinitrophenylhydrazone derivative had a melting point of 148–150°.

Anal.—Calc. for $C_{22}H_{22}N_6O_4S$: C, 56.64; H, 4.75; N, 18.01; S, 6.87. Found: C, 56.75; H, 4.91; N, 17.78; S, 6.93.

(±)-*trans*-11-Methylthio-1,2,3,4,6,7,12,12b-octahydro-2-hydroxyindolo[2,3-*a*]quinolizine (I)—A solution of 0.9 g. (0.003 mole) of crude X in 100 ml. of anhydrous dioxane–anhydrous ether (1:1) was slowly added to 0.12 g. (0.003 mole) of lithium aluminum hydride in 100 ml. of the same solvent. After the addition was completed, the solution was allowed to reflux overnight and then to cool, and the solvent was removed *in vacuo*. The residue, on crystallization from chloroform–acetone, yielded 0.4 g. (43%) of the crude I, m.p. 250–252° dec. Preparative TLC using chloroform–acetic acid (95:5) as solvent afforded an analytical sample of the alcohol IX, m.p. 262–264°.

Anal.—Calc. for $C_{16}H_{20}N_2OS$: C, 66.63; H, 6.99; N, 9.72. Found: C, 66.48; H, 7.24; N, 9.51.

GLC Determination of 1-(2,6-Dimethylphenoxy)-2-aminopropane in Urine

NAOMI SZINAI*, ROBERT J. PERCHALSKI*, RICHARD H. HAMMER†▲, B. JOE WILDER*, and RICHARD R. STREIFF*

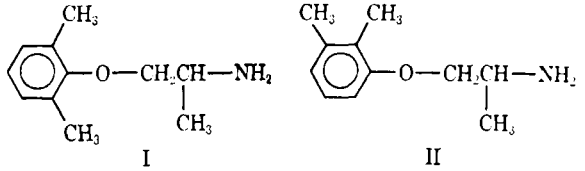
Abstract □ A rapid, sensitive, and accurate GLC method of analysis of a new anticonvulsant drug, 1-(2,6-dimethylphenoxy)-2-aminopropane, was developed, utilizing an acid hydrolysis procedure to increase its degree of recovery from urine and employing one of its isomers, 1-(2,3-dimethylphenoxy)-2-aminopropane, as an internal standard.

Keyphrases □ 1-(2,6-Dimethylphenoxy)-2-aminopropane—GLC analysis in urine □ GLC—analysis, 1-(2,6-dimethylphenoxy)-2-aminopropane in urine

A new anticonvulsant drug, 1-(2,6-dimethylphenoxy)-2-aminopropane[1] (I), is presently undergoing clinical testing and metabolic studies in humans (1, 2). Significant anticonvulsant activity has been demonstrated in patients with psychomotor seizures or temporal lobe epilepsy when receiving divided daily doses of 4–8 mg./kg. (1). To evaluate its rate of elimination and other kinetic parameters, a rapid and accurate method of analysis in urine of I was sought. Due to the structural similarity of I to amphetamine and its congeners, several GLC methods of analysis of amphetamine in biological fluids were evaluated from the literature (3–7). The method of Ramsey and Campbell (7) was found to be a simple, accurate, and rapid GLC method which was modified to accommodate the urinary analysis of I. This paper describes a fast (50 samples/day/technician), sensitive, and accurate GLC method of analysis for measuring urinary levels of I in humans.

EXPERIMENTAL

Extraction Procedure—Two milliliters of patient or standard urine was accurately measured and pipeted into a 15-ml. ground-glass conical centrifuge tube, and 1.0 ml. hydrochloric acid solution was added. The tube was stoppered and the mixture was heated in a constant-temperature bath at 100° for 1 hr. After cooling to room temperature, the pH was adjusted to 12 (Hydrion E paper) with a saturated solution of sodium hydroxide. To the alkaline solution, 0.5 ml. of internal standard (II)[2] solution (300 mcg./ml. water) and 0.1 ml. chloroform were accurately measured and added. The free bases were extracted into the chloroform layer by vigorous shaking for 1 min., followed by centrifugation for 4 min. After separation of the two layers, 1.0 μl. of the lower chloroform phase was injected into the gas chromatograph.



GLC—GLC experiments were performed on a dual-channel instrument[3] equipped with four hydrogen flame detectors. The 1.83-m. (6-ft.) long, U-shaped column (2-mm. i.d.) was packed with 3% OV-17 on Gas Chrom Q, 100–120 mesh. Operating temperatures were: injector port, 340°; column, 125° (isothermal); and detector, 260°. Flow rates (milliliters per minute) were: nitrogen, 60; air, 300; and hydrogen, 50.

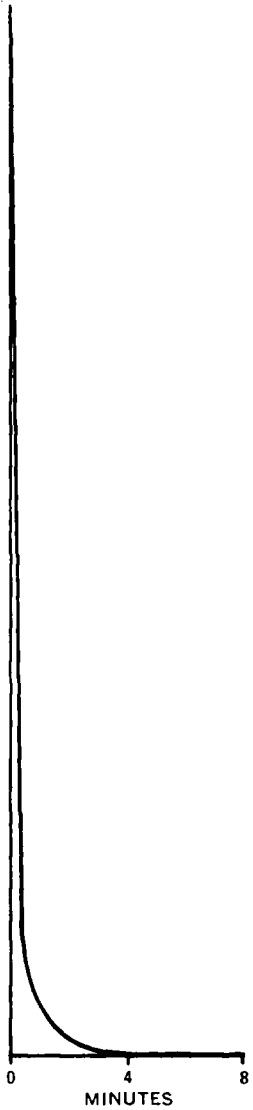


Figure 1—*Chromatogram of hydrolyzed normal urine.*

[1] Designated as KÖ 1173 and supplied as the hydrochloride salt by C. H. Boehringer Sohn, Ingelheim, Germany. Amounts and levels of KÖ 1173 and KÖ 1398 are designated throughout the paper in milligrams of free base rather than hydrochloride salt (1.0 g. KÖ 1173-HCl or KÖ 1398-HCl = 0.83 g. KÖ 1173 or KÖ 1398 free base, respectively).

[2] Designated as KÖ 1398 (II) [1-(2,3-dimethylphenoxy)-2-aminopropane] (isomer of KÖ 1173-I) and furnished as the hydrochloride salt by C. H. Boehringer Sohn, Ingelheim, Germany.

[3] Varian 2100.

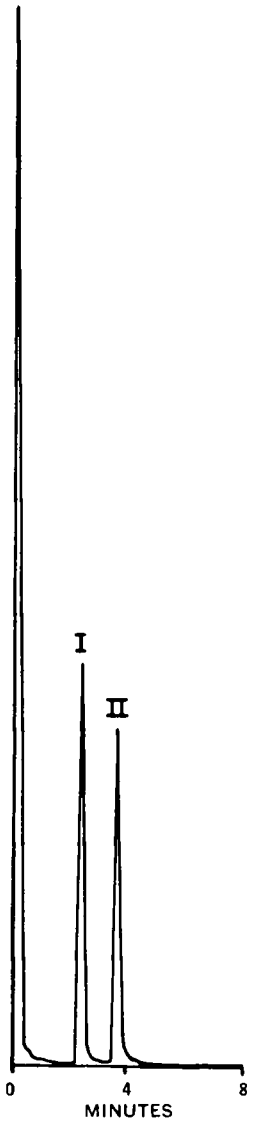

Figure 2—*Chromatogram of hydrolyzed normal urine with drug (I) and internal standard (II) added.*

The standard calibration curve was prepared by measuring the peak height at seven different concentration levels of I (5.06–150.90 mcg./ml. urine) and II (75 mcg./ml. urine) *via* GLC in normal urine after acid hydrolysis and extraction (Figs. 1–3). The mean of the peak height ratio of I:II of six determinations at each concentration level was plotted *versus* its respective concentration level of I (micrograms per milliliter urine). The least-squares method, employed to obtain the best fit for the seven concentration levels, indicated that the peak height ratios of I:II were linear with respect to the concentration of I (Fig. 4).

RESULTS AND DISCUSSION

GLC analysis of urine of epileptic patients who were taking I showed an increase in the chromatographic peak height of I when the urine was hydrolyzed in acid media *versus* the peak height of I measured in nonhydrolyzed urine. Apparently, I exists partly conjugated in urine and acid hydrolysis released the free drug, producing a larger peak height on the chromatogram. The optimum length of time for the urinary acid hydrolysis step was 1 hr. Additional hydrolysis time did not increase the amount of free unconjugated I in urine.

Amphetamine, 2,3-II, and 2,4- and 2,5-dimethyl isomers of I were evaluated as internal standards. Amphetamine had an undesirable short retention time, with its chromatographic peak occurring in front of I close to the solvent front. The most favorable

Table I—Typical Urinary Levels of I in Humans

Patient	Daily Dose, mg.	24-hr. Urine: Volume, ml.	24-hr. Urine: Concentration, mcg./ml.	24-hr. Urine: Total Amount Excreted, mg.
L.J.F.	100	3260	13.5	44.0
J.W.	100	1600	29.7	47.5
L.F.	200	1500	42.3	63.5
F.C.	200	1930	13.5	26.1
L.S.	300	1900	24.1	45.8
T.S.	300	1360	29.8	40.6

marker appeared to be II. It was completely separated from I and possessed a longer retention time than I. Both drugs (I and II) gave sharp, well-defined peaks with no tailing (Figs. 2 and 3). Initially, II was added as an internal standard before acid hydrolysis and then was hydrolyzed along with I for 1 hr. However, the results were erratic and inconsistent, and the standard calibration curve was not reproducible. GLC analysis of I added to standard urine before and after hydrolysis indicated that no acid degradation had taken place in either case. Therefore, the erratic quantitative results were not

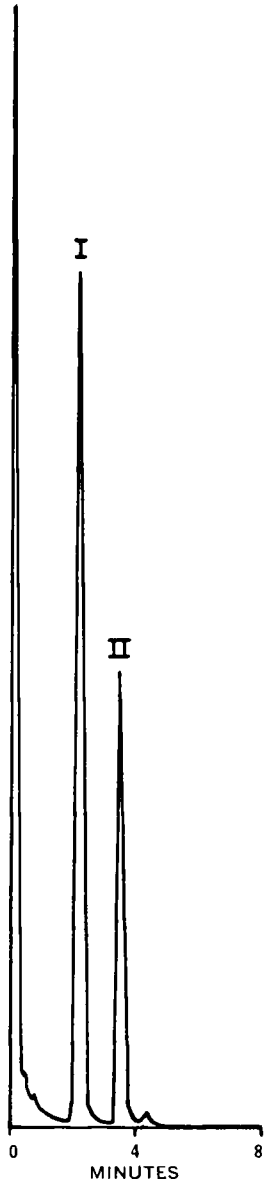

Figure 3—*Chromatogram of hydrolyzed patient urine with internal standard (II) added.*

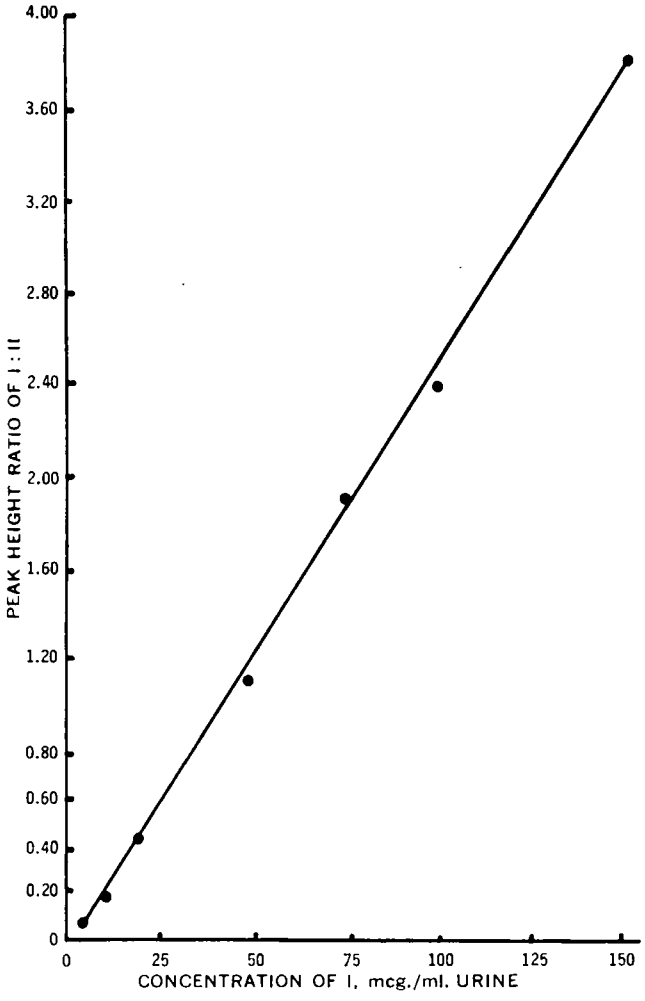

Figure 4—*Standard calibration curve.*

due to degradation of I. Similar studies of II revealed some acid degradation when it was added before hydrolysis. The problem of erratic quantitative results was, therefore, traced to acid degradation of II during the hydrolysis step.

One can postulate that I is stable to acid degradation through steric hindrance imposed by the 2,6-dimethyl groups shielding the ether oxygen to protonation. However, II, with its 2,3-dimethyl group substitution, cannot provide the same degree of steric hindrance as I and would be expected to degrade partially in acid media. In the case of amphetamine, the quantitative results were the same whether it was added before or after the acid hydrolysis, indicating acid stability. When II was added after the acid hydrolysis step, the results were consistent with the values obtained when using amphetamine either before or after hydrolysis. Therefore, the 2,3-dimethyl isomer (II) of I was chosen as the internal standard rather than amphetamine or one of the other isomers of I. The addition of II after the acid hydrolysis step led to reproducible and accurate results, as indicated by the linearity of the standard calibration curve (Fig. 4, mean standard deviation = ±5.9%).

The advantage in using small volumes of extracting solvent (*e.g.*, 0.1 ml. chloroform) *versus* larger volumes is in the reduction of impurities that would normally be extracted with larger volumes (Figs. 2 and 3; note absence of impurities). An additional advantage is that only one centrifuge tube is used in the extraction.

Several examples of urinary levels of I in humans are cited in Table I. The complete results of the clinical trial and kinetic studies in humans will be published at a later date.

Synthesis and Pharmacological Activity of 1-(Arylsulfonyl)-3,5-dialkyl-*s*-triazine-2,4,6-(1*H*,3*H*,5*H*)-triones

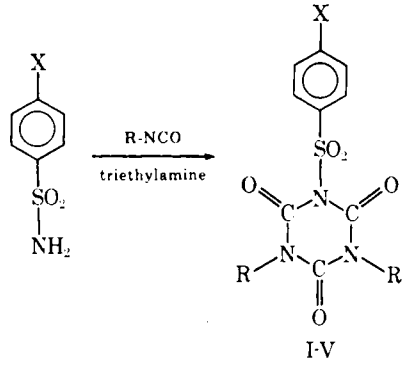
GEORGE N. HOLCOMB*▲, LORRAINE A. KLEMM*, THOMAS J. SILHAVY*‡, and RAYMOND E. COUNSELL†

Abstract □ A series of five 1-(arylsulfonyl)-3,5-dialkyl-*s*-triazine-2,4,6-(1*H*,3*H*,5*H*)-triones was synthesized by the base-catalyzed reaction of arylsulfonamides with alkyl isocyanates. The compounds were tested for apomorphine antagonism in mice, diuretic activity in fasted rats, antiviral activity in mice, antiviral activity in infected cell cultures, CNS stimulant activity in mice, and hypoglycemic activity in rats. The only biological activity exhibited by these compounds was a slight tendency to lower blood sugar levels in glucose-primed, fasted rats. This activity may be attributable to their structural similarity to the sulfonylurea hypoglycemics.

Keyphrases □ 1-(Arylsulfonyl)-3,5-dialkyl-*s*-triazine-2,4,6-(1*H*,3*H*,5*H*)-triones—synthesized and screened as potential hypoglycemic agents □ Triazine derivatives—synthesis as potential hypoglycemic agents and screening of 1-(arylsulfonyl)-3,5-dialkyl-*s*-triazine-2,4,6-(1*H*,3*H*,5*H*)-triones □ Hypoglycemic agents, potential—synthesis and screening of 1-(arylsulfonyl)-3,5-dialkyl-*s*-triazine-2,4,6-(1*H*,3*H*,5*H*)-triones

Recently it was reported that 1-(*p*-iodobenzenesulfonyl)-3,5-di-*n*-propyl-*s*-triazine-2,4,6-(1*H*,3*H*,5*H*)-trione (I) is formed when *p*-iodobenzenesulfonamide reacts with an excess of *n*-propyl isocyanate in the presence of triethylamine (1). This represents the first example of a 1-(arylsulfonyl)-3,5-dialkyl-*s*-triazine-2,4,6-(1*H*,3*H*,5*H*)-trione; however, this compound has certain structural features in common with a number of sulfonamides with known biological activity. Of particular interest in this regard is the structural similarity between I and the sulfonylurea hypoglycemics. In fact, I actually contains a sulfonylurea moiety within its structure.

The sulfonylureas are known to exert a wide variety of extrapancreatic effects (2). However, most investigators currently feel that the primary mode of action of these compounds is the stimulation of insulin release from pancreatic β-cells (3). Because of the structural similarities between I and the sulfonylureas, it seemed quite possible that I could interact with β-cell receptors in much the same way as the sulfonylureas and, thereby, it could be an active hypoglycemic.



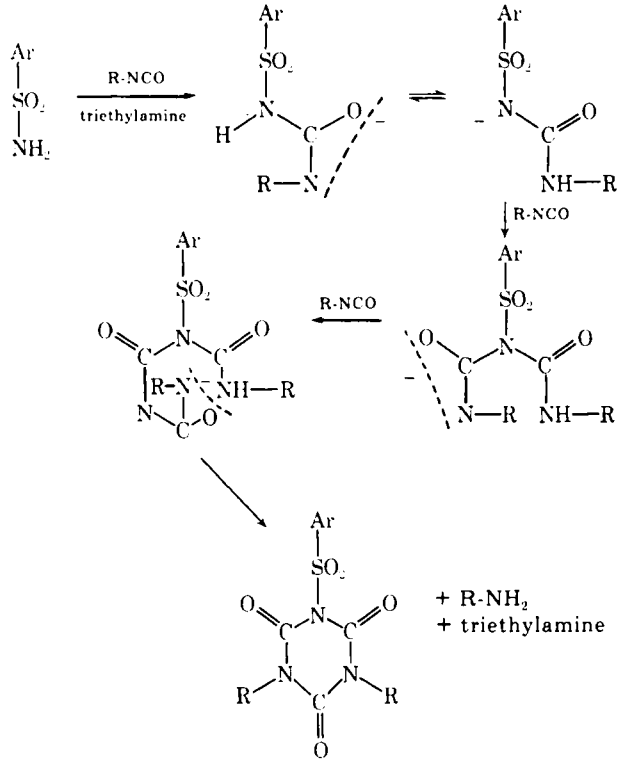
Scheme I

In addition to their hypoglycemic effects, sulfonamides are known to have various other pharmacological activities (4, 5). Some biological effects that have been attributed to sulfonamides are bacteriostatic (6), diuretic (7), hypotensive (8), anti-inflammatory (9), and CNS depressant effects (10).

The present studies were designed to determine if I and certain of its analogs possess sulfonylurea-like hypoglycemic activity and also to ascertain whether these compounds exert other significant biological effects.

The arylsulfonamides were prepared by treating the appropriate sulfonyl chloride with ammonium hydroxide as described in the *Experimental* section. The arylsulfonyl-*s*-triazine derivatives (I–V) were synthesized (Scheme I) by treating the arylsulfonamides with an excess of the appropriate alkyl isocyanate, with triethylamine as the catalyst.

Attempts to synthesize *s*-triazine derivatives from several isocyanates (*tert*-butyl, cyclohexyl, isopropyl, and isobutyl isocyanates) were unsuccessful, thus suggesting that the reaction is subject to steric hindrance. This is in agreement with a previous proposal that the *s*-triazines are formed by the base-catalyzed reaction of the arylsulfonamide with a threefold excess of the alkyl



Scheme II

Table I—Physical Data

isocyanate, with the subsequent elimination of an alkyl amine (1). These observations are consistent with the mechanism proposed in Scheme II. The transient existence of the anionic intermediates can be justified by the delocalization of the developing charge as proposed by Ulrich (11) for similar reactions.

EXPERIMENTAL[1]

Arylsulfonamides—The appropriate arylsulfonyl chloride (0.085 mole) was dissolved in ether (300 ml.), and ammonium hydroxide (100 ml.) was added to the reaction dropwise over 20 min. The mixture was stirred for 30 min., and 1 *N* NaOH (250 ml.) was added. The aqueous layer was filtered, and the pH of the filtrate was adjusted to 6 with 1 *N* HCl. The arylsulfonamide precipitated on cooling and was isolated by suction filtration. Yields and melting points were as follows: *p*-iodobenzenesulfonamide, 91.4%, 191–192° [lit. (12) m.p. 190–191°]; and *p*-bromobenzenesulfonamide: 92.4%, 169–170° [lit. (12) m.p. 165°].

*1-(p-Iodobenzenesulfonyl)-3,5-di-*n*-propyl-*s*-triazine-2,4,6-(1H,3H,5H)-trione (I)*—This compound was prepared as described previously (1).

*1-(Arylsulfonyl)-3,5-dialkyl-*s*-triazine-2,4,6-(1H,3H,5H)-triones (II-V)*—A mixture of the appropriate arylsulfonamide (0.02 mole), the corresponding alkyl isocyanate (0.20 mole), and triethylamine (1 ml.) was heated at 70° with stirring for 120 hr., and the excess alkyl isocyanate was removed under vacuum. The residual solid was washed with ether (25 ml.) and 1 *N* NaOH (20 ml.) and then recrystallized from ethanol–water. Yields and physical constants are reported in Table I.

Biological—The animals used for hypoglycemic testing were glucose-primed, fasted, pathogen-free, male rats[2]. The test compounds were administered orally in 0.5 ml. of carboxymethylcellulose vehicle. Immediately prior to administration of the test compound, the animals were injected subcutaneously with 100 mg. of glucose. The rats were bled *via* the jugular vein 2 hr. after the injection of the test compound. Blood glucose concentrations were determined[3] by a modification of the method of Hoffman (13).

RESULTS AND DISCUSSION

Although significant hypoglycemic activity was detected in some compounds, they were not as potent as tolbutamide (Table II). Compound I (X = I, R = n-C_3H_7) exhibited the greatest degree of hypoglycemic activity. However, this compound only depressed blood glucose levels by 10.1% when it was administered at a dose of 100 mg./kg., whereas tolbutamide produced a 34.0% decrease in blood sugar when administered at a dose of only 25 mg./kg. Compounds II (X = Cl, R = n-C_3H_7) and IV (X = Cl, R = C_2H_5) exhibited a slight tendency to lower blood sugar levels in glucose-primed, fasted rats. Compounds III (X = Br, R = n-C_3H_7) and V (X = Cl, R = n-C_4H_9) did not exhibit any significant hypoglycemic activity in this test system.

[a] Standard error of the mean.

The hypoglycemic activity exhibited by some compounds may be attributable to their structural similarity to the sulfonylurea hypoglycemics. No definite reason can be stated for their low order of potency, although it could be due to the presence or absence of certain structural features which interfere with their ability to interact with pancreatic β-cell receptors and stimulate insulin release. Alternatively, the diminished activity of these compounds could be a result of altered absorption and/or distribution characteristics arising from their extremely low aqueous solubility. The limited aqueous solubility observed in these compounds may be attributable to the fact that, unlike most other sulfonamides with demonstrated biological activity, they do not contain an acidic hydrogen.

All five compounds were also tested for apomorphine antagonism in mice, diuretic activity in fasted rats, antiviral activity (Influenza A_2 virus) in mice, antiviral activity in infected cell cultures, CNS stimulant activity in mice, and CNS depressant activity in mice. They did not exhibit significant activity in any of these tests.

[1] All melting points were determined on a Fisher-Johns melting-point apparatus and are corrected. The structures of all compounds were supported by IR and NMR spectra. IR spectra were taken on a Perkin-Elmer 337 spectrophotometer using KBr pellets. NMR spectra were determined on a Varian A-60 spectrometer in $CDCl_3$ at a concentration of 10%, with trimethylsilane as an internal reference. Elemental analyses were performed by Spang Microanalytical Laboratories, Ann Arbor, Mich. Chromatogram strips (K301R) were used for TLC, and the spots were detected with UV light.

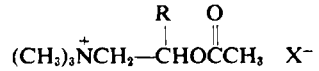
Ketoxime Acetates: Substrates for Cholinesterases

GEORGE M. STEINBERG▲, NORMAN C. THOMAS, MORTON L. MEDNICK, and VERNON BALTHIS

Abstract □ Ketoxime acetates function as typical substrates for acetylcholinesterase. Several 3-pyridinium ketoxime esters have potential utility for spectrophotometric studies with the enzyme. Each is highly water soluble and gives a large change in absorbance upon hydrolysis. With each, the acylation step is rate limiting. They bind to the enzyme strongly; the lowest $K_{m(app)}$ observed is 1.5×10^{-5} *M*. The substrates are hydrolyzed by butyrylcholinesterase. Several show great selectivity for butyrylcholinesterase over acetylcholinesterase.

Keyphrases □ Ketoxime acetates—as cholinesterase (acetyl and butyryl) substrates, binding constants, hydrolysis, absorbance changes, selectivity □ Cholinesterase substrates, acetyl and butyryl —ketoxime acetates, binding constants, hydrolysis, absorbance changes, selectivity □ Acetylcholinesterase—1-alkyl 3-pyridinium ketoxime halide esters as substrates □ Butyrylcholinesterase—1-alkyl 3-pyridinium ketoxime halide esters as substrates

A recent publication (1) reported the activity of aldoxime acetates as substrates for acetylcholinesterase (acetylcholine hydrolase, E.C. 3.1.1.7). The two principal purposes of that study were: (*a*) to gain information on the kinetic specificity and selectivity of the enzyme, and (*b*) to widen the range of spectrophotometrically useful substrates for studying enzyme properties. This note extends the work to ketoxime esters.



I: R = H
II: R = CH_3

Acetylcholinesterase is generally insensitive to bulking on the alcohol portion of the ester molecule. For example, methacholine (II) is hydrolyzed nearly as rapidly as acetylcholine (I) (2). The reverse pattern is observed with butyrylcholinesterase (acylcholine arylhydrolase, E.C. 3.1.1.8), where bulking near the ester linkage in a test substrate may markedly reduce or even completely abolish response to the enzyme (2). This study was initiated to learn if these characteristics extend to the oxime esters and to determine whether appreciable changes in K_m could be provided by the simple expedient of changing the size (bulk) of the alkyl group attached to the pyridine nitrogen atom.

EXPERIMENTAL

The oxime acetates (III–VII) were prepared in conventional manner by oximation of the corresponding aldehydes or ketones, acetylation with acetic anhydride, and finally alkylation of the pyridine nitrogen atom with methyl iodide or benzyl bromide (3–7).

NMR spectra[1] of the oxime acetates were determined in approximately 10% solutions containing internal standards. For the aromatic compounds, the solvent was $CDCl_3$ and the standard was tetramethylsilane. For the pyridine derivatives, D_2O was used as the solvent and sodium 3-trimethylsilyl-1-propanesulfonate was the standard. The chemical shifts (δ) reported are in parts per million.

The integration of peaks together with the sharpness of spectra indicates the absence of impurities. Hence, the purity of each compound is greater than 96–97% and *each exists as a single isomer* (1). For several compounds, elemental analyses were performed (C, H, N, O, and halogen, Table I).

Pertinent data[2] on the studied compounds are as follows: acetophenone oxime acetate, m.p. 56 57° [lit. (6) m.p. 55°], with NMR chemical shifts at 2.23 and 2.34 (acetate and C-methyl, respectively); *syn*-benzaldoxime acetate, m.p. < room temperature [lit. (7) m.p. 21°], with an NMR chemical shift at 2.12 (acetate methyl); IV, glass, with NMR chemical shifts at 2.43 (acetate methyl), 5.99 (C-methyl), 7.59 (benzene), 9.48 (H_a), 8.28 (t or 2d, H_c), 8.99 (d), and 9.13 (d, one is H_b and the other H_d); 3-acetylpyridine oxime acetate, m.p. 37.8°, with NMR chemical shifts at 2.36 and 2.39 (acetate methyl and C-methyl, respectively), 7.55 (m, H_c), 8.18 (d, H_b), 8.69 (d, H_d), and 8.85 (H_a); III, m.p. 116–119° dec. [lit. (3) m.p. 115°], with NMR chemical shifts at 2.39 (acetate methyl), 2.60 (C-methyl), 4.55 ($^+$N-methyl), 8.25 (m, H_c), 9.00 (m, H_b and H_d), and 9.35 (H_a); V, m.p. 112–115° dec., with NMR chemical shifts at 1.04 (C-methyl), 2.38 (acetate methyl), 3.08 (m, methylene), 4.54 ($^+$N-methyl), 6.95 (m, H_c), 7.64 and 7.77 (H_b and H_d, respectively), and 8.06 (H_a); and VI, m.p. 126–128°, with NMR chemical shifts at 2.40 (acetate methyl), 6.02 (methylene), 7.65 (benzene), 8.30 (m, H_c), 8.90 (aldehydic proton), 9.10 (m, H_b and H_d), and 9.46 (H_a).

Absorption Spectra[3]—All measurements were made at 25.0 ± 0.1°, pH 6.61, in 0.1 *M* 2-(*N*-morpholino)ethanesulfonic acid, using buffer solution in the reference compartment (Table II). The oximes were obtained by enzymatic hydrolysis of the corresponding esters. Oxime configuration probably remains unchanged.

For the difference spectra, the ketoxime esters were placed in the reference beam. Hence, the positive values of $\Delta\epsilon$ represent an increase in absorbance upon hydrolysis. With *syn*-benzaldoxime acetate, the reverse is true; hydrolysis results in a reduction in absorbance. At pH 6.61, the oximes listed in Table II exist in the protonated form, since all have pKa values greater than 9 (3, 4).

Enzyme Kinetics—*Acetylcholinesterase*—Measurements were made spectrophotometrically as previously described (1). The enzyme source[4] and its storage were identical. Runs were made at 25 ± 0.1° in 0.1 *M* 2-(*N*-morpholino)ethanesulfonic acid, pH 6.61. Computation of $K_{m(app)}$ and V_{max} (or k_{cat}) was made by computer using the Wilkinson (8) weighted regression method. Estimates of the 95% confidence limits of the computed constants were calculated from their standard errors using the Student *t* table ($n - 2$ degrees of freedom). The number of experimental points taken varied from seven to 15, using a minimum of seven different concentrations of substrate. In each case, double-reciprocal plots (Lineweaver–Burk) gave good straight lines. With Compounds V and VI, the Beer–Lambert relationship was examined and the plots of both substrate and products, in each case, were linear (Table III).

syn-Benzaldoxime acetate	257	5.8	253	4.8	262	−12.4

[a] Ester is reference beam, $\Delta\epsilon = \Delta A/[\text{substrate}]$.

Butyrylcholinesterase[5]—A standard solution of the enzyme was prepared in potassium chloride-gel (1), which gave one-seventieth the activity of the acetylcholinesterase concentrate (E_w) when assayed with phenyl acetate, 7.71×10^{-3} *M*, at pH 6.61 in the standard buffer. Comparative hydrolysis rates were determined for the two enzymes using appropriately diluted solutions to give the same hydrolysis rate with phenyl acetate.

Phenyl acetate was chosen as the basis of comparison instead of acetylcholine because its hydrolysis could be measured spectrophotometrically. However, the hydrolysis rates of the two substrates by these enzymes are closely similar, so extrapolation to the more conventional acetylcholine can be made[6].

Measurements were made at pH 6.61 in the standard buffer using the concentrations of the substrates indicated in Table IV.

RESULTS AND DISCUSSION

Comparison of the kinetic constants of the 1-methylpyridinium Compounds III and V (Table III) with those of *syn*-3-formyl-1-methylpyridinium iodide oxime acetate, VIII (1), indicates that the bulking methyl and ethyl groups have little effect on either $K_{m(app)}$ or V_{max} for the enzyme acetylcholinesterase. Elimination of the positive charge, as in VII, resulted in an increase in $K_{m(app)}$ without change in V_{max}. Replacement of the 1-methyl group by the larger 1-benzyl group, as in Compounds IV and VI, decreased $K_{m(app)}$ by one order of magnitude and produced a corresponding reduction in V_{max}. The decrease in $K_{m(app)}$ may be attributed to increased hydrophobic binding in the region just beyond the anionic binding site (9). The decrease in V_{max} cannot clearly be attributed to any specific parameters. Speculation on its cause at this point seems unwarranted.

The hydrolytic stability of the pyridinium ketoxime acetate, III, is approximately twice that of the corresponding aldoxime ester, VIII (Table III). The hydrolysis rates of the pairs III and IV and VI and VIII are probably very similar, since the effect of increased bulk at the remote *meta*-position should be very small. Similarly, Compound V, with the bulkier ethyl group in place of the methyl group in Compound III, may be expected to be equal to or even a bit more resistant to hydrolysis than III. Elimination of the charge, as in VII, considerably reduces the hydrolysis rate of this oxime ester.

[5] Worthington horse serum cholinesterase, code CHE.
[6] H. Michel, unpublished. Using acetylcholine, pH 7.4, 0.224 *M* KCl, 0.1% gelatin, 25°, titrimetrically, acetylcholinesterase had a $K_m = 3 \times 10^{-4}$ *M* and $V_{max} = 1.63 \times 10^{-4}$ meq./min. and horse serum cholinesterase had a $K_m = 1.85 \times 10^{-3}$ *M* and $V_{max} = 1.4 \times 10^{-4}$ meq./min. Using phenyl acetate, pH 7.2, 0.01 *M* morpholinopropanesulfonic acid, 0.01 *M* magnesium sulfate, 0.01% gelatin, 10^{-3} *M* Versene, 25°, spectrophotometrically, acetylcholinesterase had a $K_m = 1.8 \times 10^{-3}$ *M* and $V_{max} = 1.4 \times 10^{-4}$ meq./min. and horse serum cholinesterase had a $K_m = 1.6 \times 10^{-3}$ *M* and $V_{max} = 3.2 \times 10^{-4}$ meq./min.

Table III—Ester Hydrolysis by Eel Acetylcholinesterase[a]

[a] 25.0°, 0.1 *M* 2-(*N*-morpholino)ethanesulfonic acid, pH 6.61. [b] $V_{max(s)}$ and $V_{max(p)}$ refer, respectively, to V_{max} values of the individual substrates and of phenyl acetate. [c] *Reference 3.* [d] *Reference 4.* [e] *Reference 1.*

Table IV—Comparative Hydrolysis Rates: Butyrylcholinesterase *versus* Acetylcholinesterase[a]

Substrate	v_{ChE}/v_{AChE}	Concentration of Substrate, $M \times 10^3$
Phenyl acetate	1.0	7.71
III	20.8	8.35
IV	15.4	6.0
V	6.7	9.03
VI	57	5.89

[a] v_{ChE} and v_{AChE} refer, respectively, to the substrate hydrolysis rates catalyzed by horse serum cholinesterase and eel acetylcholinesterase.

Following the discussion in *Reference 1* for the three-step mechanism involved in substrate hydrolysis by acetylcholinesterase, the data in Table III lead to the conclusions that acylation is the rate-limiting step and that the $K_{m(app)}$ values are closely similar to K_s for the compounds examined here. A comparison of the reaction rates of Compounds III and VII shows that VII, the uncharged ester, reacts equally rapidly with acetylcholinesterase while its reaction rate with hydroxide ion is only one-twentieth that of III. With Compound VII, kinetic specificity is reflected in loss of affinity (increased K_m) and with a relative increase in reaction rate.

The pyridinium ketoxime esters have similar kinetic constants to the corresponding pyridinium aldoxime esters. They are more resistant to aqueous hydrolysis. Furthermore, experience has shown that the ketoximes are substantially more stable during storage than the aldoximes, and it is assumed that this property extends to the oxime esters. Hence, in the absence of other considerations, the ketoxime esters would be preferred.

Table IV indicates the comparative ease of hydrolysis of Compounds III–VI by butyrylcholinesterase and acetylcholinesterase, using phenyl acetate as the reference standard. The oxime acetates are considerably more selective than phenyl acetate as substrates for butyrylcholinesterase. Compound VI is particularly outstanding in this regard, and the corresponding butyrate might be even more useful as a highly selective substrate for serum (butyryl) cholinesterase.

syn-Benzaldoxime acetate is hydrolyzed by acetylcholinesterase. However, the spectra of ester and oxime are quite similar. Thus, at 262 nm., the wavelength of maximum absorbance change, the ester absorbance is very high, $\epsilon = 5.7 \times 10^3$. At longer wavelengths where the ester absorbance falls, $\Delta\epsilon$ falls correspondingly. Thus, this compound is not particularly useful for spectrophotometric purposes and its properties were not studied further.

SUMMARY

1. 3-Substituted 1-alkyl pyridinium ketoxime acetates are useful substrates for acetylcholinesterase.

2. Among the 1-alkyl pyridinium compounds, replacement of the methyl group by the benzyl group decreases $K_{m(app)}$ approximately 10-fold and reduces V_{max} (k_{cat}) to approximately the same extent.

3. The oxime acetates are good substrates for butyrylcholinesterase. 1-Benzyl-3-formylpyridinium halide oxime acetate is hydrolyzed considerably more rapidly by butyrylcholinesterase than by acetylcholinesterase. This compound or the corresponding butyrate might be useful as a highly selective substrate for butyrylcholinesterase.

Biochemical Interactions of Dimethyl Sulfoxide II: Lactate Dehydrogenase-Catalyzed Reactions

ROBERT L. BEAMER▲, JAMES E. WYNN, JANET R. ROLLINS, and RAFAEL E. LEDESMA*

Abstract □ The effect of dimethyl sulfoxide upon the reactions catalyzed by lactate dehydrogenase was studied. Both the forward (lactate to pyruvate) and the reverse (pyruvate to lactate) reactions were investigated using dimethyl sulfoxide concentrations lower than those used by previous investigators. An aldol-type condensation of dimethyl sulfoxide with pyruvate is proposed as an explanation for the observation that the forward reaction is accelerated and the reverse reaction is slowed by the presence of dimethyl sulfoxide in the reaction medium. A product of the aldol-type condensation was identified in the enzyme reaction medium. The aldol condensation product was synthesized and determined to be 2-hydroxy-2-methyl-3-methylsulfinylpropanoic acid.

Keyphrases □ Dimethyl sulfoxide—effect on lactate dehydrogenase-catalyzed reactions, aldol-type condensation with pyruvate proposed, synthesis and identification of condensation product □ Lactate dehydrogenase-catalyzed reactions—effect of dimethyl sulfoxide, 2-hydroxy-2-methyl-3-methylsulfinylpropanoic acid proposed as dimethyl sulfoxide–pyruvate aldol-type condensation product and synthesized □ 2-Hydroxy-2-methyl-3-methylsulfinylpropanoic acid—synthesis, proposed as aldol-type condensation product of dimethyl sulfoxide–pyruvate in lactate dehydrogenase-catalyzed reactions □ Enzyme systems—effect of dimethyl sulfoxide on lactate dehydrogenase-catalyzed reactions (lactate to pyruvate and pyruvate to lactate)

In the previous paper of this series, the inhibition of the respiration of rabbit liver homogenates by dimethyl sulfoxide was reported (1). The effects of dimethyl sulfoxide upon isolated enzyme systems have received little attention in the literature. Ramler (2) studied the effects of high concentrations of dimethyl sulfoxide upon glutamate dehydrogenase- and lactate dehydrogenase-catalyzed reactions. He concluded that the observed inhibition resulted from a change in the secondary and tertiary structures of the enzyme protein.

L-Glutamic acid oxidation, catalyzed by glutamate dehydrogenase, was not affected by dimethyl sulfoxide concentrations of 10–20% (2), but there was a rapid lowering of reaction rate with increasing dimethyl sulfoxide concentrations above 10–20%.

L-Alanine also was reported (3) to be a substrate for glutamate dehydrogenase. L-Alanine oxidation, catalyzed by glutamate dehydrogenase, was observed to increase with increasing dimethyl sulfoxide concentrations (2).

The work described in this paper concerns the effects of dimethyl sulfoxide upon lactate dehydrogenase-catalyzed reactions. Ramler (2) showed an increase in the forward reactions (lactate to pyruvate) with dimethyl sulfoxide concentrations up to 30%. Dimethyl sulfoxide concentrations above 30% produced a marked decrease in the reaction rate.

Ramler did not investigate the effects of dimethyl sulfoxide upon the reverse reaction (pyruvate to lactate), nor did he study the effects of dimethyl sulfoxide at the concentration levels usually employed for enzyme inhibitors. His studies were conducted at pH 9 rather than at pH 7.4.

Therefore, it was decided to study the effects of dimethyl sulfoxide upon the lactate dehydrogenase-catalyzed reactions in less concentrated dimethyl sulfoxide solutions (10^{-3}–10^{-1} *M*) than those employed by Ramler. Both the forward and the reverse reactions were studied at pH 7.4. A product study was conducted on the enzyme reaction mixture to help establish the mechanism of the interaction of dimethyl sulfoxide with the lactate dehydrogenase-catalyzed reaction.

EXPERIMENTAL[1]

Reagents—The following were used: experimental drug grade dimethyl sulfoxide[2], redistilled under reduced pressure (100°/2 torr.); sodium lactate parenteral solution[3]; sodium pyruvate[4]; lactate dehydrogenase[5]; nicotinic adenine dinucleotide[6]; and methyl-*n*-propyl sulfide[7].

Enzyme Rate Studies—These studies were carried out using a spectrophotometer[8] equipped with a linear recorder[9] and a constant-temperature chamber set at 37°. The lactate dehydrogenase-catalyzed reactions were studied by assessing the rate of appearance or disappearance of nicotinic adenine dinucleotide by measuring the change in absorbance at 340 nm.

Lactate to Pyruvate Reaction—Studies of the forward reaction were conducted in a 0.06 *M* sodium phosphate buffer at pH 7.4. The initial reaction mixture was 8.0 m*M* in sodium lactate and 2.4 m*M* in nicotinic adenine dinucleotide. The dimethyl sulfoxide concentrations ranged from 0.00 to 10^{-1} *M*. In all studies, a constant lactate dehydrogenase concentration (0.001 mg. protein/ml., representing 0.147 unit of lactate dehydrogenase activity) was maintained. All materials, except the coenzyme, were placed in a cell and allowed to equilibrate to 37°. After 3 min., the reaction was initiated by adding the coenzyme. The coenzyme solution was added to the bottom of the cell and air was introduced to ensure mixing. The volume of each cell was 3 ml. Reaction rates were determined by comparing the absorbance at the end of 1 min. with standards of known concentrations.

Pyruvate to Lactate Reaction—The reverse reaction was run in a similar manner to that described for the forward reaction. The reaction was carried out in a 0.06 *M* sodium phosphate solution buffered at pH 7.4 and was 2 m*M* in sodium pyruvate and 0.6 m*M* in reduced nicotinic adenine dinucleotide; the enzyme concentration was 0.008 mg. protein/ml. (0.840 unit of lactate dehydrogenase activity).

Product Study—*Isolation of Aldol-Type Condensation Product from Enzyme Reaction*—In each of five 50-ml. conical flasks were placed 0.0032 ml. of an 8 m*M* sodium lactate solution, 5.27 ml. (0.1 *M*) of dimethyl sulfoxide, 0.001 ml. (0.003 mg. protein) of lactate dehydrogenase, and 5.63 ml. of 0.06 *M* sodium phosphate

[1] IR spectra were determined with a Beckman IR 20A. NMR spectra were determined using a Varian A60 NMR spectrometer. Carbon–hydrogen analyses were determined using a Hewlett-Packard model 185 C, H, and N analyzer. GC data were obtained using a Beckman GC-2A gas chromatograph. All temperatures are uncorrected.

Table I—Rates of the Lactate to Pyruvate Reaction

Dimethyl Sulfoxide Concentration, *M*	Mean Rate, mmoles/min.	Standard Error[a] (±)	*p*[b]
0.00	4.8×10^{-2}	7.8×10^{-4}	—
10^{-3}	5.0×10^{-2}	5.5×10^{-4}	0.038
10^{-2}	5.5×10^{-2}	7.5×10^{-4}	<0.0005
10^{-1}	5.9×10^{-2}	1.2×10^{-3}	<0.0005

[a] Degrees of freedom ≥ 40. [b] A one-tailed *t*-test was used.

Table II—Rates of the Pyruvate to Lactate Reaction

Dimethyl Sulfoxide Concentration, *M*	Mean Rate, mmoles/min.	Standard Error[a] (±)	*p*[b]
0.00	3.72×10^{-4}	1.88×10^{-5}	—
10^{-3}	1.90×10^{-4}	1.25×10^{-5}	<0.0005
10^{-2}	1.01×10^{-4}	4.10×10^{-6}	<0.0005
10^{-1}	0.31×10^{-4}	5.50×10^{-6}	<0.005

[a] Degrees of freedom ≥ 40. [b] A one-tailed *t*-test was used.

buffer, pH 7.4. The flasks were placed in a shaker water bath at 37° and allowed to equilibrate for 5 min. The reaction was started by adding 16 mg. of nicotinic adenine dinucleotide from a 2.4 m*M* solution. The reaction was run for 4 days, after which the flask contents were pooled, cooled in an ice bath, and adjusted to pH 1.4 with cold 15% sulfuric acid. The acidified mixture was extracted with ether in a continuous extractor for 48 hr. The extract was dried over anhydrous magnesium sulfate and the ether was removed *in vacuo*, leaving a small quantity of liquid residue which was subjected to TLC.

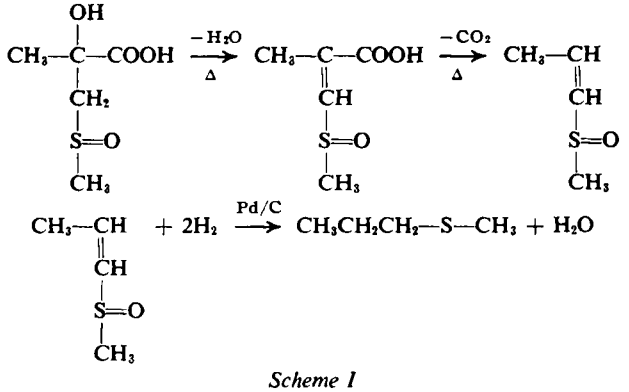
TLC—Ten microliters of the lactate to pyruvate reaction mixture or the residue from the continuous ether extraction was removed and applied to TLC plates[10]. The plates were developed using methanol–chloroform (75:25). The dried plates were treated with iodine vapors for visualization of the spots.

Synthesis of Proposed Intermediate (2-Hydroxy-2-methyl-3-methylsulfinylpropanoic Acid)—To 0.073 mole of potassium pyruvate or sodium pyruvate in 60 ml. of distilled water was added 9.33 ml. (10.30 g., 0.132 mole) of dimethyl sulfoxide. The pH of the mixture was adjusted to 7.5 using a 0.4 *N* sodium hydroxide solution, and the mixture was stirred at room temperature for 24 hr. Following the reaction period, the pH of the mixture fell to 6.5–7.0. The reaction mixture was cooled in an ice water bath to 0°, acidified to pH 2 with cold 15% sulfuric acid, and extracted with ether in a continuous extractor for 48 hr. The extract was dried over anhydrous magnesium sulfate for 48 hr. The ether was removed *in vacuo*, leaving 9.10 g. (75%) of a colorless to light-yellow corrosive liquid possessing a sour odor, b.p. 58°/0.6 torr. IR (neat on sodium chloride cells): 3400 (OH), 2900 [CH(sh)], 1650 (COOH carbonyl), and 1025 [—(O=)S—] cm.$^{-1}$; NMR (60 MHz., dimethyl sulfoxide-d_6): δ 2.6 (s, 3), 4.35 (m, 5), 1.9 (broad, 1), and 7.35 (broad, 1).

Anal.—Calc. for $C_5H_{10}O_4S$: C, 36.14; H, 6.07. Found: C, 36.10; H, 6.04.

The 2-hydroxy-2-methyl-3-methylsulfinylpropanoic acid was subjected to TLC as described, and the chromatogram was compared with that from the enzyme reaction mixture.

Chemical Degradation of 2-Hydroxy-2-methyl-3-methylsulfinylpropanoic Acid—Chemical degradation of the product of the aldol-type condensation was studied according to Scheme I. A solution of 2-hydroxy-2-methyl-3-methylsulfinylpropanoic acid (0.02 mole in toluene) was placed in a flask equipped with a Dean-Starke trap and a condenser. The top of the condenser was fitted with a delivery tube leading to a saturated solution of barium hydroxide. The toluene solution was refluxed overnight. A copious precipitate of barium carbonate formed in the barium hydroxide solution, and 0.5 ml. (0.0278 mole) of water was collected in the Dean-Starke trap.



Scheme I

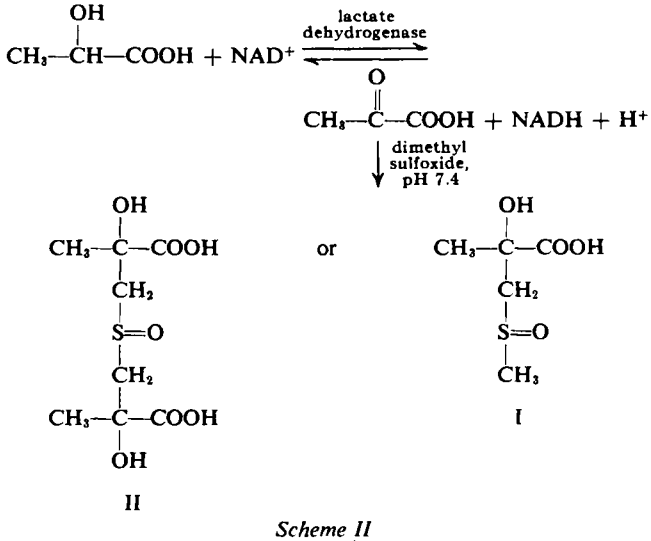
A second degradation was conducted using 0.06 mole of the 2-hydroxy-2-methyl-3-methylsulfinylpropanoic acid in 25 ml. of absolute ethanol. To this solution was added 2 drops of concentrated sulfuric acid. The solution was refluxed for 14 hr. under a nitrogen atmosphere, and the reaction was followed using the barium hydroxide solution described previously.

Following the reaction, the total mixture was hydrogenated on a low-pressure Parr hydrogenator at an initial hydrogen pressure of 65 p.s.i. and using 1 g. of palladium-on-charcoal (100 mg. palladous chloride/1 g. of charcoal) as the catalyst. After 12 hr. of hydrogenation, an additional 1 g. of catalyst was added and the hydrogenation was continued for another 12 hr. The catalyst was removed by filtration and the solution was distilled. The impure methyl-*n*-propyl sulfide fraction was collected at 32°/20 torr.

The methylpropyl sulfide fraction was subjected to vapor phase chromatography using a 1.8-m. (6-ft.) metal column packed with 1.15% silicone rubber SE-30 on Gas Chrom P (100–140 mesh). A thermal conductivity detector was employed. The helium carrier gas was maintained at a flow rate of 20 ml./min., and the column temperature was 70°. The sample volume was 10 μl. The retention time of the peak identified as methyl-*n*-propyl sulfide was 6.5 min. and corresponded to that of a commercial sample determined under identical conditions. An IR spectrum of the hydrogenation product was identical with that of commercial methyl-*n*-propyl sulfide containing 1 ml. of 95% ethanol/100 ml. of sulfide.

RESULTS

The rates of the forward reaction in the presence of varying concentrations of dimethyl sulfoxide are presented in Table I. The rates of the reverse reaction in the presence of varying concentrations of dimethyl sulfoxide are concentration dependent. This concentration dependence is statistically significant (Table II).



Scheme II

[10] Absorbasil-3, Applied Science.

TLC showed the presence of a compound in the enzyme reaction mixture and the ether extract which was neither lactate nor pyruvate nor dimethyl sulfoxide. The R_f value for this compound was identical with that for 2-hydroxy-2-methyl-3-methylsulfinylpropanoic acid. No intermediate spot could be detected in the absence of dimethyl sulfoxide in the reaction medium.

DISCUSSION

Baker *et al.* (4) showed that the lactate dehydrogenase reaction sites are the same. Therefore, inhibition at the reaction site should decrease the rates of both the forward and the reverse reactions. The increase in the forward reaction rate and the decrease in the rate of the reverse reaction could be explained by the presence of a concentration gradient on the reversible reaction in a direction favoring pyruvate formation. Such a concentration gradient could result from a complexation or condensation of dimethyl sulfoxide with pyruvic acid, thus removing that species from the reaction medium. A possible reaction that could remove effectively the keto acid salt (pyruvate) is an aldol-type condensation between the methyl groups of dimethyl sulfoxide and the carbonyl function of the pyruvate. Such a condensation may involve either a single methyl group or both methyl groups of the dimethyl sulfoxide (Scheme II). The effect on the enzyme-catalyzed reaction would be concentration dependent (Tables I and II).

The presence of 2-hydroxy-2-methyl-3-methylsulfinylpropanoic acid in the enzyme mixture leads to the conclusion that dimethyl sulfoxide interferes with the lactate dehydrogenase-catalyzed reaction by condensing with pyruvate in an aldol-type condensation.

Cinchona Alkaloids on Ion-Exchange Resins V: Ammonium Form of Resins

A. H. VYAS, C. V. BHAT, B. R. KAMATH, and S. L. BAFNA▲

Abstract □ Equilibrium exchange of cinchona alkaloid sulfates and column runs of cinchona bark were carried out with the ammonium form of sulfonic acid cation-exchange resins. The results indicate that, for 100 meq. of the resin capacity, the amounts of the alkaloid-containing material extracted from cinchona bark are 15 and 8 g. for the ammonium forms of two commercially available ion-exchange resins. Dilute aqueous sulfuric acid was used as the extraction solvent, and ammonical ethanol was used as the eluant.

Keyphrases □ Cinchona alkaloids—separation from cinchona bark using ion-exchange resins in ammonium form, comparison of two commercially available resins, separation capacity □ Alkaloids, cinchona—separation from cinchona bark using ion-exchange resins in ammonium form, comparison of two commercially available resins, separation capacity □ Resins, ion exchange, in ammonium forms—comparison of separation capacities of two commercially available resins, cinchona alkaloids □ Ion-exchange chromatography—comparison of separation capacities of two commercially available resins, cinchona alkaloids □ Chromatography, ion exchange—comparison of separation capacities of two commercially available resins, cinchona alkaloids

A previous paper (1) reported the effect of the particle size of styrene divinylbenzene copolymer-based sulfonic acid cation-exchange resins on equilibrium exchange and column studies for cinchona alkaloid sulfates. The work suggested that a fine mesh resin with a relatively low degree of cross-linking (Resin I[1]) or with an expanded structure (Resin II[2]) in ammonium form could be suitable for recovery of cinchona alkaloids, with aqueous sulfuric acid as the solvent for the exchange run and ammoniacal ethanol as the solvent for the elution run. The present work includes a study of equilibrium exchange of cinchona alkaloid sulfates and column runs of cinchona bark with the ammonium form of sulfonic acid cation-exchange resins.

EXPERIMENTAL

Resins—The resins were conditioned and converted into hydrogen form. The experimentally estimated values of percent moisture content and capacity in milliequivalents per gram of air-dried resin were: Resin I (50–100), 24.0, 3.89; Resin I (100–200), 22.0, 3.72; and Resin II (20–50), 26.0, 3.53.

The ammonium form of the resin was prepared by treating the hydrogen form with excess aqueous ammonia. The moisture content of the air-dried resin in the ammonium form was estimated, and its capacity was calculated by taking the oven-dried capacity of the resin in hydrogen and ammonium forms to be the same.

Chemicals and Materials—Chemicals were from earlier stocks. Cinchona bark[3] was powdered below 60 mesh, and samples were estimated for alkaloid content (2). The value was 6.5%. Samples of extracted alkaloid material were analyzed (3), and the mixture of quinine and cinchonidine obtained was estimated for each by UV absorption (4). The percent analysis was: quinine, 18.0; quini-

Table I—Equilibrium Exchange[a] of Aqueous Quinine Sulfate and Cinchonidine Sulfate with Cation-Exchange Resins in Ammonium Form

Resin	Quinine Sulfate			Cinchonidine Sulfate		
	$[\bar{A}]_e$	P_A	P_R	$[\bar{A}]_e$	P_A	P_R
Resin I (50–100)	0.49	20.5	49.0	0.45	21.0	68.1
	0.79	33.5	50.1	0.80	37.5	68.8
	1.30	55.0	51.4	1.26	59.0	69.3
	1.74	73.5	52.1	1.62	76.0	69.6
Resin II (20–50)	0.63	28.5	26.3	0.52	25.0	29.0
	0.89	40.5	25.3	0.76	37.0	27.4
	1.29	58.5	23.9	1.10	53.5	25.1
	1.76	80.0	22.6	1.56	76.0	22.3

[a] $[\bar{A}]_e$ = Milliequivalents of alkaloid in the resin phase per liter of solution, at equilibrium; P_A = percent exchange of alkaloid sulfate at equilibrium; and P_R = percent resin capacity exchanged at equilibrium. Effective capacity = (capacity of the resin) (average value of P_R).

dine, 17.5; cinchonine, 29.0; cinchonidine, 9.0; and the rest (by difference), 26.5.

Procedure—The procedure for equilibrium exchange of cinchona alkaloid (quinine, quinidine, cinchonine, and cinchonidine) sulfates with ammonium forms of Resin I (50–100) and Resin II (20–50) was same as given earlier (5, 6).

Columns, each containing 100 meq. of the resin in the ammonium form, were set up (1).

The values of bed length (cm.) and bed volume (ml.) were: for Resin I (100–200), 44.1, 75.0; and for Resin II (20–50), 35.0, 59.5.

The procedure for carrying out a run was as follows. A weighed amount of the powdered cinchona bark was stirred with 0.01 *N* aqueous sulfuric acid solution (4 l.), allowed to stand overnight, and filtered. The filtrate was transferred to an overhead aspirator and passed through the column at a flow rate of 10 ml./min. The effluent was collected, and its acid strength was adjusted to about 0.01 *N* by pH measurement; then it was returned to the container of bark, stirred well, and filtered. The filtrate was transferred to the overhead aspirator and thus the run was continued. The run was discontinued when the alkaloids were almost completely extracted from cinchona bark, as indicated by absence of fluorescence, or when the alkaloid content of the effluent and influent was almost same, as indicated by fluorescence when exposed to UV radiation. Then the column was washed with distilled water and backwashed to remove extraneous materials from the resin bed. Fifty percent aqueous ethanol (50 ml.) was passed through the column.

The alkaloid material was eluted with 0.1 *N* ammoniacal ethanol at a flow rate of 1.5 ml./min. The effluent containing alkaloids was concentrated by distillation, evaporated on a water bath, dried at 100 ± 1°, weighed, and analyzed.

The resin in the column was then replaced by an equivalent amount of resin from stock, backwashed, and allowed to settle under gravity. The column then was ready for the next run.

RESULTS AND CONCLUSIONS

Equilibrium Exchange Study—The equilibrium exchange study was carried out for the cinchona alkaloid (quinine, quinidine, cinchonine, and cinchonidine) sulfates with Resin I (50–100) and Resin II (20–50) in the ammonium form. Table I gives the results for quinine sulfate and cinchonidine sulfate. From the results obtained, it may be concluded that:

Table II—Data for Column Runs with Cinchona Bark

	Resin I	Resin II
Weight, g.[a]	1000	357
Amount of acid[b] solution passed, l.	44	24
Amount of eluant[c] used, l.	6	3
Weight of extracted material, g.	15	8

[a] Weight (grams) = weight (grams) of cinchona bark taken for the run. [b] Acid = 0.01 *N* sulfuric acid. [c] Eluant = 0.1 *N* ammoniacal ethanol.

1. The value of P_R (the percent resin capacity exchanged at equilibrium) for the optical isomers (quinine and quinidine or cinchonine and cinchonidine) is not measurably different.
2. The value of P_R for quinine sulfate is lower than that of cinchonidine sulfate.
3. The value of P_R for Resin II decreases as the value of P_A (the percent exchange of alkaloid sulfate at equilibrium) increases.

These results are similar to those obtained earlier (5, 6).

Column Study—Runs were carried out starting with different amounts of powdered cinchona bark. From the results obtained, it is concluded that:

1. When the alkaloid content (milliequivalents) of the powdered cinchona bark is lower than the capacity (milliequivalents) of the resin in the column, the alkaloid material present in the bark is extracted.
2. When the alkaloid content of the powdered cinchona bark is much greater than the capacity of the resin in the column, the amount of extracted alkaloid-containing material is 15 g. for Resin I and 8 g. for Resin II (capacity of the resin in the column being 100 meq.). Thus, the amount of the alkaloid-containing material obtained is close to the effective capacity of the column (7). Table II gives the data for runs with excess powdered cinchona bark.

The results indicate that for the extraction of alkaloids from cinchona bark with the ammonium form of the resin, dilute aqueous sulfuric acid may be used as the extraction solvent and ammoniacal ethanol may be used as the eluent. It would be desirable to assess the stability of the resins for repeated use over time.

Clemmensen Reduction of Mannich Bases: Potential Ganglionic and Nicotinic Agents

R. R. ISON▲ and M. M. A. HASSAN*

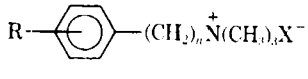
Abstract □ An attempt was made to prepare *p*-aminophenylpropyltrimethylammonium iodide (a potential ganglionic stimulant) by a route involving the Clemmensen reduction of 3-dimethylamino-1-*p*-nitrophenylpropan-1-one. The main product was the *trans*-isomer of 1-*p*-aminophenyl-3-dimethylaminoprop-1-ene, but this could be converted to the required trimethylammonium derivative by hydrogenation and methylation. The Clemmensen reduction of other Mannich bases also was investigated. 3-Dimethylamino-1-arylprop-1-enes are of particular interest because of the reported nicotinic activity of the methosalts. Several products were formed, however, including an azeotropic mixture of the aminoalkane and the aminoalkene. The azeotrope could be converted smoothly to the pure 1-aryl-3-dimethylaminopropane by catalytic hydrogenation. This route can, therefore, be used to prepare 1-arylpropyltrimethylammonium halides, which are potentially nicotine-like. Other methods for reducing the carbonyl group of Mannich bases completely are discussed.

Keyphrases □ *p*-Aminophenylpropyltrimethylammonium iodide—synthesis and screening as a potential ganglionic stimulant □ Ganglionic stimulants, potential—synthesis and screening of *p*-aminophenylpropyltrimethylammonium iodide, Clemmensen reduction of Mannich bases □ Clemmensen reduction of Mannich bases—synthesis of potential ganglionic and nicotinic agents □ Mannich bases—use of Clemmensen reduction to synthesize potential ganglionic and nicotinic agents

Some aralkyltrimethylammonium salts (I) were highly active on the isolated frog rectus abdominis muscle (1). The most active agonists were *m*-hydroxyphenethyltrimethylammonium iodide (leptodactyline iodide) (I*a*, $n = 2$), *m*-hydroxyphenylpropyltrimethylammonium bromide (I*a*, $n = 3$), and *p*-aminophenethyltrimethylammonium iodide (I*b*, $n = 3$), which were 20–50 times as potent as nicotine on this preparation. *p*-Aminophenethyltrimethylammonium iodide was found later to be the most specific as a ganglionic stimulant (2), and it was decided to prepare *p*-aminophenylpropyltrimethylammonium iodide for pharmacological evaluation. A number of arylpropenyltrimethylammonium halides (VI), which are structurally similar to the aralkyltrimethylammonium series (I), also were reported (3, 4) to possess high nicotinic activity.

DISCUSSION

A three-stage synthesis was designed (II*a* → III*b* → I*b*, $n = 3$) to prepare *p*-aminophenylpropyltrimethylammonium iodide (Scheme I). The first step involved the Clemmensen reduction (5) of 3-dimethylamino-1-*p*-nitrophenylpropan-1-one (II*a*) to the corresponding *p*-aminophenylpropylamine (III*b*). This produced the *trans*-*p*-aminophenylpropenylamine (IV*b*) in 24% yield, together with a large quantity of intractable material. The product (IV*b*) was identified by its PMR spectrum, which showed a vinylic multiplet (ABX_2, $J_{AB} = 16$ Hz.) characteristic of *trans*-1-aryl-3-tertiary-aminoprop-1-enes (6). Catalytic hydrogenation of IV*b* gave 1-*p*-aminophenyl-3-dimethylaminopropane (III*b*), from which *p*-aminophenylpropyltrimethylammonium iodide (I*b*, $n = 3$) was prepared.



I*a*: R = *m*-OH
I*b*: R = *p*-NH$_2$

The formation of olefinic by-products in the Clemmensen reaction is well established (7), but there appears to be no report relating to the reduction of β-aminoketones (II). The isolation of *trans*-1-*p*-aminophenyl-3-dimethylaminoprop-1-ene (IV*b*) from the reaction, however, was of much interest, because the quaternary methiodide derivatives (VI) of such aminoalkenes have been reported (3, 4) to be highly active nicotinic agents. It was, therefore, decided to see whether aminoalkenes were consistently formed with other Mannich bases (Table I), three of which (II*c*, II*d*, and II*e*) were studied in detail. The Clemmensen reduction gave two products in low yield[1]: (*a*) an azeotropic mixture of the appropriate aminoalkane[2] (III) and aminoalkene[2] (IV), and (*b*) a high boiling liquid which could be crystallized. The solid product appeared to be a mixture of the *meso*- and *dl*-forms of the dimer[3] (V) and was probably formed by the addition of two electrons and protons from the Clemmensen reagent (8) to the Mannich base.

With the three other β-aminoketones (II*f*, II*g*, and II*h*), no attempt was made to isolate the corresponding dimers. Only the low boiling distillate was collected, and it was again found to be a mixture of aminoalkane and aminoalkene[2]. The formation of pure aminoalkene (IV*b*) in the initial reaction seems to depend on the presence of the nitro group, which may prevent complete reduction. The exact mechanism of the Clemmensen reduction of β-aminoketones is obscure, but the formation of aminoalkenes may involve a monomeric alcohol[4] intermediate (7).

The carbonyl group in Mannich bases appears to be very difficult to reduce to methylene; treatment of both the phenyl and *o*-tolyl aminoketones with the lithium aluminum hydride–aluminum

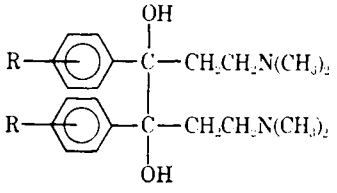
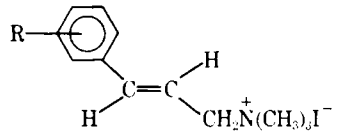
Scheme I

[1] A large amount of intractable resinous material was evident after distillation of each crude Clemmensen product.
[2] Proton magnetic resonance evidence.
[3] Mass spectral total ion-current evidence.
[4] When one reaction with II*c* was terminated by basification after 3 hr., a sample of 3-dimethylamino-1-phenylpropan-1-ol hydrochloride (3%) was isolated, m.p. 135°, identical to authentic material (6), but the ratio of the other products remained unchanged.



V



VI

chloride reagent, which has been suggested as an alternative to the Clemmensen reduction (15), gave only the corresponding secondary alcohols. Both the carbonyl and the *p*-nitro groups of the Mannich base (II*a*) could be reduced, however, when the compound was suspended in ethanolic hydrogen chloride and hydrogenated at room temperature and atmospheric pressure for 14 days with palladium-on-carbon as catalyst[5]. This method provided another route to *p*-aminophenylpropyltrimethylammonium iodide (I*b*, n = 3).

PHARMACOLOGY

p-Aminophenylpropyltrimethylammonium iodide showed no hypotensive effects in the pithed rat and acted as a weak blocker[6]. It was only one-tenth as active as *p*-aminophenethyltrimethylammonium iodide (I*b*, n = 2) when tested for ganglionic stimulant activity on the isolated guinea pig ileum.

EXPERIMENTAL[7]

β-Aminoketone Hydrochlorides (II)—The hydrochloride salts of II*a*–II*h* were prepared by the usual method (16) from the appropriately substituted acetophenones. The melting points of II*a* (17), II*c* (9), II*d* (10), II*e* (11), II*f* (12), II*g* (13), and II*h* (14) were in agreement with literature values.

***trans*-1-*p*-Aminophenyl-3-dimethylaminoprop-1-ene (IV*b*)**—A solution of mercuric chloride (5 g.) in 10% HCl (100 ml.) was shaken (5 min.) with granulated zinc (60 g.) as previously described (5), and the amalgam was rinsed with water. 3-Dimethylamino-1-*p*-nitrophenylpropan-1-one hydrochloride (17) (II*a*) (38 g., 0.147 mole) was dissolved in 35% HCl (150 ml.), and the solution was added dropwise to the amalgam. The vigorous reaction was kept under control by cooling under the tap before a further portion of 35% HCl (100 ml.) was added and the mixture was refluxed overnight. The solution was basified with enough ammonium hydroxide to redissolve the zinc hydroxide precipitate and was then extracted with ether and dried (sodium sulfate). Evaporation of the extracts gave an oil (14 g.) which, when distilled *via* a Vigreux head, gave 5.4 g. (24%) of the product, b.p. 121° (0.35 mm.), n_D^{25} = 1.5960. The proton magnetic resonance (PMR) spectrum ($CDCl_3$) agreed well with that of the parent alkene (IV*c*) (6). The product formed an unstable *methiodide*, which formed a light-sensitive *hydrogen iodide*, m.p. 215–217° (methanol–ether), λ_{max} 282 nm. (ε 21,900).

Anal.—Calc. for $C_{12}H_{22}I_2N_2$: C, 32.04; H, 4.69; N, 6.28. Found: C, 32.30; H, 4.51; N, 6.28.

***p*-Aminophenylpropyltrimethylammonium Iodide (I*b*, n = 3)**—The aminoalkene (IV*b*) (1 g.) was dissolved in a mixture of ethanol and 10% palladium-on-carbon (0.4 g.) and hydrogenated overnight at room temperature and atmospheric pressure. The reaction mixture was filtered (kieselguhr), and the filtrate was evaporated to a small volume. After the addition of methyl iodide (2 ml.) and a few drops of ether, the product separated as gold needles (1.2 g.), m.p. 204–205°; PMR (D_2O): vinylic signals absent.

Anal.—Calc. for $C_{12}H_{21}IN_2$: C, 45.01; H, 6.61. Found: C, 44.79; H, 6.83.

Other Clemmensen Reductions—These were carried out in the manner described for IV*b*. Distillation of the crude products derived from II*c*, II*d*, and II*e* gave two fractions (Table I) with the following characteristics:

A mixture of III*c* and IV*c*, b.p. 62° (0.20 mm.), and the isomeric *dimer* V*c*, b.p. 168° (0.25 mm.), m.p. 148–150° (ethanol); M^+ at *m/e* 356 ($C_{22}H_{32}N_2O_2$) (both isomers).

Anal.—Calc. for $C_{22}H_{32}N_2O_2$: C, 74.12; H, 9.05. Found: C, 74.22; H, 8.89.

A mixture of III*d* and IV*d*, b.p. 66–68° (0.20 mm.), and the isomeric *dimer* V*d*, b.p. 168–169° (0.30 mm.), m.p. 170–172° (ethanol); M^+ at *m/e* 392 ($C_{22}H_{30}F_2N_2O_2$) (both isomers).

Anal.—Calc. for $C_{22}H_{30}F_2N_2O_2$: C, 67.32; H, 7.70. Found: C, 67.58; H, 7.48.

A mixture of III*e* and IV*e*, b.p. 80–82° (0.10 mm.), and the isomeric *dimer* V*e*, b.p. 230° (0.20 mm.), m.p. 198–200° (ethanol); M^+ at *m/e* 425/427 ($C_{22}H_{30}Cl_2N_2O_2$) (both isomers).

Anal.—Calc. for $C_{22}H_{30}Cl_2N_2O_2$: C, 62.11; H, 7.11. Found: C, 62.22; H, 7.09.

The aminoalkene–aminoalkane mixtures from the *m*-CF_3, *o*-CH_3, and *p*-CH_3 Mannich bases (II*f*, II*g*, and II*h*, respectively) were collected at ~70° (0.20 mm.) in various ratios (Table I).

In all the reductions specified, the PMR spectra ($CDCl_3$ and tetramethylsilane) of the low boiling products were compatible with mixtures of the aminoalkene (IV) and the aminoalkane (III). In most cases, direct comparison was possible with the PMR spectra of authentic aminoalkenes and aminoalkanes prepared by standard methods. The aminoalkanes showed $N(CH_3)_2$ singlets at higher field (~0.08 p.p.m.) than the corresponding signals for the aminoalkenes. The integral ratios of the $N(CH_3)_2$ peaks were used to assess the product ratios (Table I).

Lithium Aluminum Hydride–Aluminum Chloride Reductions—Treatment of 3-dimethylamino-1-phenylpropan-1-one (II*c*) with ethereal lithium aluminum hydride–aluminum chloride in the usual manner (15) gave 3-dimethylamino-1-phenylpropan-1-ol, identical to authentic material (6).

Similarly, lithium aluminum hydride–aluminum chloride reduction of 3-dimethylamino-1-*o*-tolylpropan-1-one (13) gave 3-dimethylamino-1-*o*-tolylpropan-1-ol, which formed a *methiodide*, m.p. 152–154° (ethanol–ether).

Anal.—Calc. for $C_{13}H_{22}INO$: I, 37.86. Found: I, 37.88.

Catalytic Reduction of 3-Dimethylamino-1-*p*-nitrophenylpropan-1-one (II*a*)—II*a* hydrochloride (17) (7.7 g.) was suspended in ethanol (100 ml.), and the mixture was saturated with hydrogen chloride gas. Most substrate went into solution and, after cooling, 10% palladium-on-carbon (0.5 g.) was added and the reaction mixture was hydrogenated at room temperature and atmospheric pressure until hydrogen absorption ceased (14 days). The filtered solution (kieselguhr) was evaporated to dryness, the residual solid was treated with ammonium hydroxide, and the liberated base was extracted into ether and dried (magnesium sulfate). Evaporation of the extracts gave an oil (5 g.), which was distilled to give 1-*p*-aminophenyl-3-dimethylaminopropane (III*b*), b.p. 120° (0.1 mm.), n_D^{20} = 1.5430, which formed the *methiodide* (I*b*, n = 3), m.p. 203–

Table I—Reaction Products from Clemmensen Reduction of Mannich Bases

[6] D. S. McQueen, Department of Pharmacology, University of Edinburgh, Edinburgh EH89JZ, U. K., personal communication.

[7] Melting points were recorded on a Mettler FP1 instrument connected to a pen recorder. The NMR spectra were recorded on Perkin-Elmer R10 and Varian HA-100 instruments. Mass spectrometry was carried out with an LKB-9000 (ev. 27.5).

204°, identical (PMR, mixed melting point) to the material prepared previously by the Clemmensen route.

CONCLUSIONS

Clemmensen reduction of Mannich bases leads to a variety of products, but the reaction can still be used to prepare members of the arylpropylamine series. Catalytic hydrogenation of the low boiling fraction distilled from the crude product ensures complete saturation of the side chain and the isolation of pure aminoalkane (III). These derivatives can then be converted to phenylpropyltrimethylammonium derivatives (I, n = 3), which have potential nicotinic properties (1).

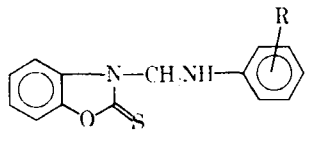
Potential Biologically Active Agents V: Synthesis and Pharmacological Screening of Substituted 3-Aminomethylbenzoxazolin-2-thiones

RAJENDRA S. VARMA

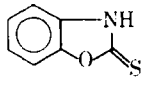
Abstract □ A series of substituted 3-aminomethylbenzoxazolin-2-thiones was synthesized and evaluated for antibacterial activity.

Keyphrases □ 3-Aminomethylbenzoxazolin-2-thiones—synthesized and screened as potential antibacterial agents □ Antibacterial agents, potential—synthesis and screening of 3-aminomethylbenzoxazolin-2-thiones □ Benzoxazolin-2-thiones, substituted—synthesized and screened as potential antibacterial agents

Benzazoles have been reported to exhibit diverse biological properties. The 2- and 3-substituted benzoxazolinone analogs have shown anticonvulsant (1) and antimicrobial (2, 3) activities. Antitubercular (4), antispasmodic (5), and antibacterial (6–9) activities have been observed for benzothiazolin-2-thione and 2-alkylmercaptobenzothiazoles. Substituted 3-aminomethylbenzothiazolin-2-thiones have displayed antimicrobial (10, 11) activity. Further antimicrobial (12, 13), diuretic (14), cancerostatic (15), antitubercular (15), hypoglycemic (16), parasympatholytic (17), and herbicidal (18) properties have been associated with benzoxazolin-2-thiones. In view of these reports, it was of interest to synthesize substituted 3-aminomethylbenzoxazolin-2-thiones (I) for biological screening. The synthesis of I was achieved by condensing benzoxazolin-2-thione (II), formaldehyde, and an amine.



I



II

BIOLOGICAL DATA

The compounds listed in Table I were screened for their inhibitory effect against *Escherichia coli* and *Staphylococcus aureus*[1] by the agar diffusion technique (19). Four compounds (I, VII, XII, and

[a] Recrystallized from ethanol. IR (μ): 2.95 (NH), 3.4 (OH, broad), and 5.92 (C=O). [b] Recrystallized from ethanol. [c] Recrystallized from ethanol. IR (μ): 2.95 (NH) and 5.92 (C=O). [d] Recrystallized from ethanol. IR (μ): 2.95 (NH), 3.4 (OH, broad), and 5.90 (C=O). [e] Recrystallized from ethanol. IR (μ): 2.95 (NH) and 5.85 (C=O). [f] Recrystallized from acetone. [g] Recrystallized from methanol. The compound is 3-(*N*-2-thiazolylaminomethyl)-benzoxazolin-2-thione. IR (μ): 3.12 (NH). [h] Recrystallized from methyl ethyl ketone. IR (μ): 2.97 (NH), 3.3 (OH, broad), and 5.97 (C=O). [i] Recrystallized from ethyl acetate.

XIII) showed inhibition against both organisms. Compounds III, V, VI, VIII, X, and XV were only effective against *E. coli*.

EXPERIMENTAL[2]

Benzoxazolin-2-thione was prepared by a published procedure (20). Esters of aminobenzoic acids were obtained by refluxing a mixture of appropriate alcohol, thionyl chloride, and the aminobenzoic acid for several hours.

The synthesis of the substituted 3-aminomethylbenzoxazolin-2-thiones (I) was conducted as follows. Compound II (1.51 g., 0.01 mole) and the amino compound (0.01 mole) were suspended in 20 ml. of boiling ethanol. To this suspension, 2 ml. of 37% formalin was added. The reaction mixture was warmed on a steam bath for 5 min. and then set aside at room temperature overnight. The solid product thus deposited was filtered, washed with petroleum ether (60–80°), and recrystallized from a suitable solvent.

The analyses, melting points, and other pertinent data are recorded in Table I.

New Compounds: Synthesis of 3,4,5-Trimethoxybenzenesulfonamides

GIORGIO PIFFERI▲ and RICCARDO MONGUZZI

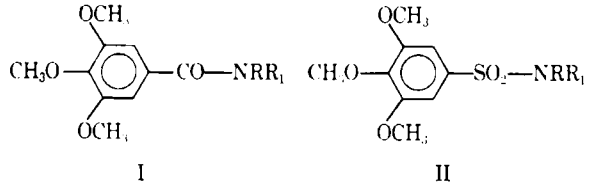
Abstract □ Some new 3,4,5-trimethoxybenzenesulfonamides were synthesized for biological screening. The intermediate 3,4,5-trimethoxybenzenesulfonic acid was unequivocally prepared from 3,4,5-trimethoxyaniline according to the procedure of Meerwein.

Keyphrases □ 3,4,5-Trimethoxybenzenesulfonamides—synthesized and tested for CNS and cardiovascular effects □ CNS activity—synthesis and screening of 3,4,5-trimethoxybenzenesulfonamides □ Cardiovascular effects—synthesis and screening of 3,4,5-trimethoxybenzenesulfonamides

In connection with pharmacological research on new heterocyclic analogs of 3,4,5-trimethoxybenzamide (I) (1), it was interesting to synthesize a series of 3,4,5-trimethoxybenzenesulfonamides (II) because of their steric and electronic similarity[1].

DISCUSSION

Although numerous derivatives of 3,4,5-trimethoxybenzoic acid are of biological interest (1, 3), the SO_2 analogs (II) are unknown in the literature. The present authors ascertained that the structure of the sulfonic acid derivative VII*b* was incorrectly assigned by Alimchandani (4); in fact, pyrogallol trimethyl ether (III) reacts with sulfuric acid in the experimental conditions reported (4) to give the vicinal isomer IV*b*. The same product was also prepared (Scheme I) by treating III with chlorosulfonic acid at room temperature and subsequent hydrolysis of the intermediate IV*a* to 2,3,4-trimethoxybenzenesulfonic acid (IV*b*). For the unequivocal synthesis of the isomer VII*b*, 3,4,5-trimethoxybenzoic acid (V) was converted *via* VI*a* into the aniline derivative VI*b* (5); the latter was diazotized and the diazonium salt was decomposed with sulfur dioxide according to the method of Meerwein *et al.* (6) to afford the sulfonyl chloride VII*a*. Subsequent hydrolysis gave 3,4,5-trimethoxybenzenesulfonic acid (VII*b*), which was easily distinguished from its isomer IV*b* by comparison of the NMR coupling constants of the two aromatic protons in the *meta*- and *ortho*-positions, respectively (7).



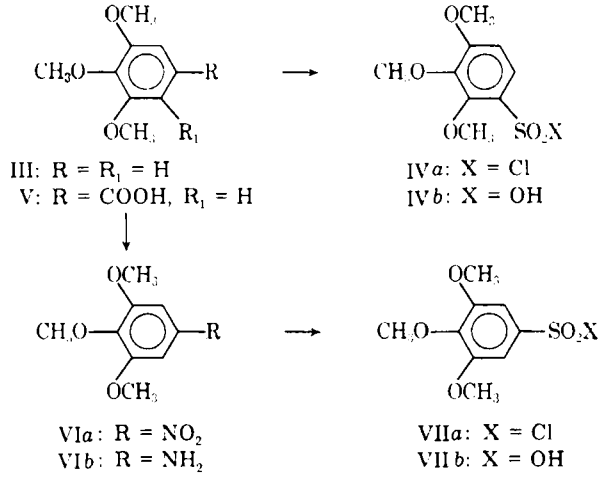
I II

To prepare the 3,4,5-trimethoxybenzenesulfonamides II*a*–II*e* (Table I), the sulfonyl chloride VII*a* was condensed with the appropriate amine according to experimental Procedures A and B. Isoxazolidine (1), morpholine (8), and heptamethyleneimine (9) were chosen as active moieties of new CNS drugs; isopropylguanidine (10) and ε-aminocaproic acid (11) were chosen as active moieties of new cardiovascular drugs.

Preliminary biological testing of II*a*–II*e* in the Irwin (12) neuropharmacological mouse profile did not show significant signs of depression at doses up to 300 mg./kg. i.p. The complete results will be published later.

EXPERIMENTAL[2]

2,3,4-Trimethoxybenzenesulfonyl Chloride (IV*a*)—A solution of 5 g. (29.7 mmoles) of pyrogallol trimethyl ether (III) in 80 ml. of dry



Scheme I

[1] Actually, carbonyl and sulfonyl groups may be considered as "nonclassical isosteres" (2).

[2] All melting points are uncorrected. IR spectra were recorded as mineral oil mulls with a Perkin-Elmer IR 157. A Varian Associates model A-60 NMR spectrometer was used to determine the proton magnetic resonance spectra. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate was used as a standard reference, and D_2O was used as the solvent.

[a] From ethanol.

chloroform was treated dropwise at 0° with 11.5 g. (98 mmoles) of chlorosulfonic acid. The reaction mixture was stirred for 30 min. at room temperature and poured into 150 g. of crushed ice. The organic layer was separated and the mother liquor was extracted two times with 30 ml. of chloroform. The combined extracts were washed with water and dried over sodium sulfate, the solvent was removed, and the oily residue was distilled through a Claisen head to yield 1.32 g. of IV*a*, b.p. 165° (1.5 mm.), which crystallized from hexane to a solid, m.p. 38–39°; IR: 1350 and 1170 (SO_2 asym. and sym.) and 815 (two adjacent aromatic hydrogens) $cm.^{-1}$.

Anal.—Calc. for $C_9H_{11}ClO_5S$: Cl, 13.30; S, 12.02. Found: Cl, 13.86; S, 11.95.

2,3,4-Trimethoxybenzenesulfonic Acid (IV*b*)—A solution of 10 g. (59.5 mmoles) of pyrogallol trimethyl ether (III) in 25 ml. of 96% sulfuric acid was stirred at 25–30° for 3 hr. After cooling, water (25 ml.) was added dropwise and the solution was kept overnight in a refrigerator. The white hygroscopic precipitate was filtered and crystallized from ethyl acetate to yield 8.45 g. (57%) of IV*b*, m.p. 96° [lit. (4) m.p. 95–97°; IR: 3600–2150 (OH), 1190 and 1145 (SO_3 group), and 815–805 (two adjacent aromatic hydrogens) $cm.^{-1}$; NMR: δ(p.p.m.) 3.90 s and 4.00 s (methyl protons of methoxy groups) and 6.88 d and 7.59 d (two *ortho* aromatic protons: J = 9.0 Hz.).

2,3,4-Trimethoxybenzenesulfonic Acid (IV*b*) from IV*a*—A stirred suspension of 0.3 g. (1.13 mmoles) of 2,3,4-trimethoxybenzenesulfonyl chloride (IV*a*) in 9 ml. of water was refluxed until a solution was formed. After concentration *in vacuo*, the residue was crystallized from ethyl acetate to yield 100 mg. (36%) of IV*b*, identical (by mixed melting point and IR comparison) with the sample described above.

3,4,5-Trimethoxynitrobenzene (VI*a*)—Compound VI*a* was prepared from 3,4,5-trimethoxybenzoic acid (V) and 70% nitric acid according to the method of Hughes *et al.* (5), m.p. 96–98° (from ethanol).

3,4,5-Trimethoxyaniline (VI*b*)—Compound VI*b* was obtained by catalytic reduction at room temperature of 3,4,5-trimethoxynitrobenzene (VI*a*) in the presence of 5% palladium-on-charcoal, m.p. 111–112° [lit. (5) m.p. 113–114°].

3,4,5-Trimethoxybenzenesulfonyl Chloride (VII*a*)—To 320 ml. of concentrated hydrochloric acid was added, at 70° with stirring, 40 g. (0.218 mole) of 3,4,5-trimethoxyaniline (VI*b*). The mixture was stirred at the same temperature for 10 min. and, after cooling to 0°, a solution of 15.2 g. (0.22 mole) of sodium nitrite in 30 ml. of water was added dropwise. The solution was then stirred at 0° for 15 min. and added dropwise with caution to a saturated solution of sulfur dioxide in 480 ml. of glacial acetic acid containing 4.8 g. of cuprous chloride. At the end of addition, the mixture was stirred at room temperature for 3 hr., poured into cold water, and extracted four times with 1 l. of dichloromethane. The combined organic extracts were washed with cold water and dried over calcium chloride, and the solvent was evaporated. The solid residue was recrystallized twice from hexane to yield 11.84 g. (20.5%) of VII*a*, m.p. 82–85°; IR: 1370 and 1175 (SO_2 asym. and sym.), and 835 (two *meta* aromatic hydrogens) $cm.^{-1}$.

Anal.—Calc. for $C_9H_{11}ClO_5S$: C, 40.55; H, 4.16; Cl, 13.30; S, 12.02. Found: C, 40.59; H, 4.29; Cl, 13.46; S, 12.22.

3,4,5-Trimethoxybenzenesulfonic Acid (VII*b*)—A stirred suspension of 0.9 g. (3.37 mmoles) of 3,4,5-trimethoxybenzenesulfonyl chloride (VII*a*) in 30 ml. of water was refluxed until solution. After evaporation *in vacuo*, the solid residue was crystallized from nitroethane to yield 0.5 g. (60%) of VII*b* as a very hygroscopic material, m.p. 147–149°. The mixed melting point with IV*b* was depressed. IR: 3700–2100 (OH), 1160 and 1130 (SO_3 group), and 835 (two *meta* aromatic hydrogens) $cm.^{-1}$; NMR: δ(p.p.m.) 3.83 s and 3.95 s (methyl proton of methoxy groups) and 7.20 s (two *meta* aromatic protons).

Anal.—Calc. for $C_9H_{12}O_6S$: C, 43.54; H, 4.87; S, 12.91. Found: C, 42.80; H, 5.21; S, 13.50.

3,4,5-Trimethoxybenzenesulfonamides (II)—*Procedure A*—A solution of 12 mmoles of 3,4,5-trimethoxybenzenesulfonyl chloride (VII*a*) in 15 ml. of dichloromethane was added at room temperature to a stirred solution of 27 mmoles of the appropriate base in 80 ml. of the same solvent. The mixture was refluxed for 3 hr., cooled at room temperature, and washed successively with diluted hydrochloric acid, a saturated sodium bicarbonate solution, and water. The organic extracts were dried over sodium sulfate and evaporated *in vacuo*, and the solid residue crystallized (Table I).

Procedure B—A solution of 15 mmoles of 3,4,5-trimethoxybenzenesulfonyl chloride (VII*a*) in 15 ml. of dichloromethane was added at room temperature to a stirred solution of 15 mmoles of the appropriate base hydrochloride and 34 mmoles of triethylamine in 80 ml. of the same solvent. The mixture was stirred for 1 hr. at room temperature and refluxed for 3 hr. After cooling, it was washed with diluted hydrochloric acid and water and dried over sodium sulfate. The solvent was evaporated and the residue was crystallized (Table I).

Sulfamate Sweeteners: A Reappraisal

Keyphrases □ Sulfamates, alicyclic—hydrolysis rate constants determined from polar and steric parameters, equation □ Cyclamates, alicyclic—hydrolysis rate constants determined from polar and steric parameters, equation □ Sweeteners, alicyclic sulfamates—hydrolysis rate constants determined from polar and steric parameters, equation

Sir:

There is evidence from feeding experiments that *in vivo* conversion of the nonnutritive sweeteners, the cyclamates [sodium cyclohexylsulfamate (I) and calcium cyclohexylsulfamate (II)] gives cyclohexylamine (1–4), which is considered to be responsible for the induction of tumors (4). These and other experiments (5–7) resulted in a ban since 1970 on the use of cyclamates in foodstuffs, beverages, and pharmaceuticals. No work appears to have been published on the nature of the metabolic conversion of cyclamate to cyclohexylamine. However, it is possible that the ease of metabolism to primary amine may be correlative with the hydrolytic stability of the sulfamate.

We derived a Taft–Pavelich-type equation (Eq. 1) which correlates the hydrolytic rate constants (measured under identical conditions) for cleavage of the nitrogen–sulfur bond with polar (σ^*) and steric (E_s) parameters for a large number of aromatic, aliphatic, and alicyclic sulfamates (8) and is of the form:

$$\log k = 2.35\Sigma\sigma^* - 1.0037\Sigma E_s + 0.6971 \qquad \text{(Eq. 1)}$$

Further tests on Eq. 1 indicate that it reproduces log k values to within an average of 12%. The k values are reproduced to within 26% on average. For Compound I, the k value was reproduced with an accuracy of 5%.

By using Eq. 1, it is possible to predict the hydrolytic stability of unsynthesized sulfamates (whose σ^* and E_s values are known). Equation 1 could thus act as a guide to the choice of sulfamates that might be more resistant to *in vivo* conversion to primary amines than are I and II. Such sulfamates may lack carcinogenic or cocarcinogenic activity because of the possibility of a lower conversion to amine. A second criterion in choosing sulfamates is that they have a comparable degree of sweetness to I and II. Audrieth and Sveda (9) showed that the retention of the sulfamate function, $-NHSO_3^-$, and the presence of a reduced ring (*e.g.*, cyclohexyl) appear to be essential for sweetness in sulfamates. Later results substantiated these findings and extended them to exclude ring substitution in the reduced ring since such compounds tend to be tasteless or to leave a bitter aftertaste (10–12). These criteria for sweetness should be met by Compounds III. In fact, sodium cyclopentylsulfamate (III, $n = 3$) (10), sodium cycloheptylsulfamate (III, $n = 5$), and sodium cyclooctylsulfamate (III, $n = 6$) (11) are extremely sweet.

Equation 1 predicts that the cycloheptyl compound (estimated $\sigma^* = -0.10$, $E_s = -1.10$)[1] will hydrolyze almost 3 times more rapidly than I or II, the cyclopentylsulfamate ($\sigma^* = -0.20$, $E_s = -0.51$) will hydrolyze 2.5 times more slowly, and the unprepared cyclobutyl (III, $n = 2$) compound (estimated $\sigma^* = -0.28$, $E_s = -0.06$) will hydrolyze 11 times more slowly. Compound IV, *N*-(α-cyclohexylmethyl)sulfamate ($\sigma^* = -0.06$, $E_s = -0.98$) is predicted to hydrolyze 2.5 times more rapidly than I or II. Cyclopropylsulfamate (III, $n = 1$) was prepared (10), but its sweetness was not assessed. Polar and steric parameters are not available for this compound or for cyclooctylsulfamate.

These observations suggest that an examination of the percent metabolism to primary amine and the

Sulfamate Sweeteners: A Reappraisal

Keyphrases □ Sulfamates, alicyclic—hydrolysis rate constants determined from polar and steric parameters, equation □ Cyclamates, alicyclic—hydrolysis rate constants determined from polar and steric parameters, equation □ Sweeteners, alicyclic sulfamates—hydrolysis rate constants determined from polar and steric parameters, equation

Sir:

There is evidence from feeding experiments that *in vivo* conversion of the nonnutritive sweeteners, the cyclamates [sodium cyclohexylsulfamate (I) and calcium cyclohexylsulfamate (II)] gives cyclohexylamine (1–4), which is considered to be responsible for the induction of tumors (4). These and other experiments (5–7) resulted in a ban since 1970 on the use of cyclamates in foodstuffs, beverages, and pharmaceuticals. No work appears to have been published on the nature of the metabolic conversion of cyclamate to cyclohexylamine. However, it is possible that the ease of metabolism to primary amine may be correlative with the hydrolytic stability of the sulfamate.

We derived a Taft–Pavelich-type equation (Eq. 1) which correlates the hydrolytic rate constants (measured under identical conditions) for cleavage of the nitrogen–sulfur bond with polar (σ^*) and steric (E_s) parameters for a large number of aromatic, aliphatic, and alicyclic sulfamates (8) and is of the form:

$$\log k = 2.35\Sigma\sigma^* - 1.0037\Sigma E_s + 0.6971 \qquad \text{(Eq. 1)}$$

Further tests on Eq. 1 indicate that it reproduces log k values to within an average of 12%. The k values are reproduced to within 26% on average. For Compound I, the k value was reproduced with an accuracy of 5%.

By using Eq. 1, it is possible to predict the hydrolytic stability of unsynthesized sulfamates (whose σ^* and E_s values are known). Equation 1 could thus act as a guide to the choice of sulfamates that might be more resistant to *in vivo* conversion to primary amines than are I and II. Such sulfamates may lack carcinogenic or cocarcinogenic activity because of the possibility of a lower conversion to amine. A second criterion in choosing sulfamates is that they have a comparable degree of sweetness to I and II. Audrieth and Sveda (9) showed that the retention of the sulfamate function, $-NHSO_3^-$, and the presence of a reduced ring (*e.g.*, cyclohexyl) appear to be essential for sweetness in sulfamates. Later results substantiated these findings and extended them to exclude ring substitution in the reduced ring since such compounds tend to be tasteless or to leave a bitter aftertaste (10–12). These criteria for sweetness should be met by Compounds III. In fact, sodium cyclopentylsulfamate (III, $n = 3$) (10), sodium cycloheptylsulfamate (III, $n = 5$), and sodium cyclooctylsulfamate (III, $n = 6$) (11) are extremely sweet.

Equation 1 predicts that the cycloheptyl compound (estimated $\sigma^* = -0.10$, $E_s = -1.10$)[1] will hydrolyze almost 3 times more rapidly than I or II, the cyclopentylsulfamate ($\sigma^* = -0.20$, $E_s = -0.51$) will hydrolyze 2.5 times more slowly, and the unprepared cyclobutyl (III, $n = 2$) compound (estimated $\sigma^* = -0.28$, $E_s = -0.06$) will hydrolyze 11 times more slowly. Compound IV, *N*-(α-cyclohexylmethyl)sulfamate ($\sigma^* = -0.06$, $E_s = -0.98$) is predicted to hydrolyze 2.5 times more rapidly than I or II. Cyclopropylsulfamate (III, $n = 1$) was prepared (10), but its sweetness was not assessed. Polar and steric parameters are not available for this compound or for cyclooctylsulfamate.

These observations suggest that an examination of the percent metabolism to primary amine and the

Determination of Trimethoprim and Its *N*-Oxide Metabolites in Urine of Man, Dog, and Rat by Differential Pulse Polarography

Keyphrases ☐ Trimethoprim and *N*-oxide metabolites—analysis in urine of man, dog, and rat, differential pulse polarography ☐ Polarography, differential pulse—analysis, trimethoprim in urine of man, dog, and rat

Sir:

An analytical method was recently reported for the determination of trimethoprim [2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine] in blood and urine of man and dog by differential pulse polarography (1). It was qualitatively noted that a portion of the dose was excreted as the unconjugated N_1-oxide, N_3-oxide, and hydroxy-methyl metabolites of trimethoprim, all of which are resolved by TLC. However, due to low recoveries, the measurement of these metabolites was not previously reported. The purposes of this work were to quantitate the *N*-oxide metabolites and to determine if a species difference existed regarding the formation of the *N*-oxides. Since recovery of the hydroxy-methyl metabolite remained low with this modified assay; its measurement is not reported.

A modification of the above-mentioned assay is reported, which includes a "salting-out" procedure to facilitate the extraction of the *N*-oxides into chloroform. In the modified procedure, 1 ml. urine and 4 ml. distilled water are added to a 50-ml. centrifuge tube to which 6 g. anhydrous potassium carbonate is then added. The method from this point onward is identical to the previously reported one (1), with the exception that polarography is performed in 1 *M* pH 3.0 phosphate buffer rather than in 0.1 *N* H_2SO_4. Five and ten micrograms of trimethoprim and the *N*-oxides added to urine as internal standards should be processed with the unknowns. The choice of pH 3.0 phosphate buffer for the urinary assay is dictated by the need for maximal separation in potential of the two *N*-oxide peaks for qualitative identification. This supporting electrolyte was completely free of background interferences in the region of the polarographic reduction of the *N*-oxides.

Polarography is a useful means of identifying and quantitating the *N*-oxides (Fig. 1). The *N*-oxides of trimethoprim possess two distinct polarographic peaks at −1.095 and −0.950 v. *versus* a saturated calomel electrode (SCE) in 1 *M* pH 3 phosphate buffer due to the reduction of the N_1- and N_3-oxide functional groups, respectively. These peaks are easily distinguished from the reduction peak of the azomethine bond in the pyrimidine ring of all three compounds, which occurs at −1.190 v. *versus* SCE in the pH 3.0 phosphate buffer. Although each *N*-oxide possesses a distinct functional group, the *N*-oxide compounds cannot be determined without prior separation because large quantities of trimethoprim in the urine result in a large analytical peak that masks the *N*-oxide peaks. Thus, TLC separation, in which the compounds are identified by comparison with the R_f values of the authentic compounds

Table I—Urine Levels of Trimethoprim and Trimethoprim *N*-Oxides in Man following Oral Administration[a]

	Trimethoprim			Trimethoprim N_1-Oxide			Trimethoprim N_3-Oxide			
	0–24 hr.	24–48 hr.	48–72 hr.	0–24 hr.	24–48 hr.	48–72 hr.	0–24 hr.	24–48 hr.	48–72 hr.	Total
Subject 1:										
Total milligrams equivalent to trimethoprim	118.4	122.0	16.9	3.6	6.0	n.m.[b]	9.1	n.m.	n.m.	276.0
Percent dose	29.6	30.5	4.2	0.9	1.5	—	2.3	—	—	69.0
Subject 2:										
Total milligrams equivalent to trimethoprim	178.9	34.9	s.n.t.[c]	6.6	n.m.	s.n.t.	4.1	n.m.	s.n.t.	224.5
Percent dose	44.7	8.7	—	1.6	—	—	1.0	—	—	56.0

[a] Total dose was 400 mg. trimethoprim (5.7 mg./kg.). Five tablets were given orally (each tablet contained 400 mg. sulfamethoxazole and 80 mg. trimethoprim). [b] n.m. = nonmeasurable. [c] s.n.t. = sample not taken.

Table II—Urine Levels of Trimethoprim and Trimethoprim *N*-Oxides in the Dog following Oral Administration[a]

	Trimethoprim		Trimethoprim N_1-Oxide		Trimethoprim N_3-Oxide		
	0–24 hr.	24–48 hr.	0–24 hr.	24–48 hr.	0–24 hr.	24–48 hr.	Total
Dog 1:							
Total milligrams equivalent to trimethoprim	32.7	5.6	0.8	n.m.[b]	6.5	1.1	46.7
Percent dose	16.3	2.7	0.4	—	3.2	0.6	23.2
Dog 2:							
Total milligrams equivalent to trimethoprim	48.8	9.5	0.6	n.m.	10.0	1.8	70.7
Percent dose	24.4	4.7	0.3	—	5.0	0.9	35.3

[a] Total dose was 200 mg. trimethoprim (16 mg./kg.). Two and one-half tablets were given orally (each tablet contained 400 mg. sulfamethoxazole and 80 mg. trimethoprim). [b] n.m. = nonmeasurable.

run alongside, is required before quantitative determination by polarography.

The modified method gives recoveries of the N_1- and N_3-oxide of 36.3 ± 8.4 and 59.1 ± 7.5 (*SD*), respectively, in the concentration range of 5.0–30.0 mcg. However, due to the salting out, large amounts of biological interferences are coextracted with the compound of interest. Since the biological interferences tend to make recognition of the zones on the TLC plate difficult, zones are chosen by R_f, *i.e.*, 0.16, 0.25, and 0.45 for N_1-oxide, N_3-oxide, and trimethoprim, respectively. To ensure that no overlap of the *N*-oxide zones occurs, the plates may be redeveloped using the same solvent system. Thus, this modified method is recommended only when metabolite information is required. For the determination of trimethoprim, the previous method (1) is preferred.

Trimethoprim was administered to man, dog, and rat, and the amounts of intact drug and *N*-oxides were measured as already outlined. The urines from two human subjects receiving tablets containing a total of 2000 mg. sulfamethoxazole and 400 mg. trimethoprim (5.7 mg. trimethoprim/kg. body weight) were analyzed for trimethoprim and its *N*-oxide metabolites (Table I).

Table III—Urine Levels of Trimethoprim and Trimethoprim *N*-Oxides in the Rat following Intraperitoneal Administration[a]

	Trimethoprim		Trimethoprim N_1-Oxide		Trimethoprim N_3-Oxide		
	0–24 hr.	24–48 hr.	0–24 hr.	24–48 hr.	0–24 hr.	24–48 hr.	Total
Rat 1:							
Total milligrams equivalent to trimethoprim	2.4	0.07	0.7	n.m.[b]	n.m.	n.m.	3.2
Percent dose	8.5	0.3	2.7	—	—	—	11.4
Rat 2:							
Total milligrams equivalent to trimethoprim	1.4	0.08	0.3	n.m.	n.m.	n.m.	1.8
Percent dose	5.0	0.3	1.0	—	—	—	6.3
Rat 3:							
Total milligrams equivalent to trimethoprim	0.55	0.04	0.10	n.m.	n.m.	n.m.	0.69
Percent dose	5.5	0.4	1.0	—	—	—	6.9
Rat 4:							
Total milligrams equivalent to trimethoprim	1.09	0.08	0.06	n.m.	n.m.	n.m.	1.23
Percent dose	10.9	0.7	0.6	—	—	—	12.3

[a] Total dose for Rats 1 and 2 was 28 mg. trimethoprim (140 mg./kg.). For Rats 3 and 4, it was 10 mg. trimethoprim (50 mg./kg.). The dosage form was 2 ml. of a suspension in 5% gum arabic. [b] n.m. = nonmeasurable.

In the two subjects, more than 50% of the administered dose was excreted mainly as intact drug in the 0–48-hr. period. Both the N_1- and N_3-oxides were found in the urine of man in approximately equal quantities, totaling 4.7 and 2.6% of the dose administered in Subjects 1 and 2, respectively. The urines from two dogs receiving tablets containing a total of 1000 mg. sulfamethoxazole and 200 mg. trimethoprim (16 mg. trimethoprim/kg. body weight) were analyzed for trimethoprim and its *N*-oxide metabolites (Table II). In the two dogs, 19.0 and 29.1% of the dose were excreted as intact drug. A significant amount of the N_3-oxide was excreted by both dogs in the 0–48-hr. period, while only a trace amount of the N_1-oxide was excreted. The urines of four rats receiving 28 mg. (140 mg./kg. body weight) and 10 mg. (50 mg./kg. body weight) trimethoprim i.p. in 5% gum arabic were analyzed for trimethoprim and its *N*-oxide metabolites. Between 5 and 12% of the dose was excreted as intact drug at both dose levels. Only the N_1-oxide metabolite was found in the 0–48-hr. rat urine, totaling between 0.6 and 2.7% of the administered dose (Table III).

Schwartz *et al.* (2) studied the metabolism of trimethoprim in man, dog, and rat and found that each species excreted the N_1-oxide as a urinary metabolite; this finding was confirmed in the present study. Meshi and Sato (3) detailed the metabolism of trimethoprim in the rat and reported levels of an *N*-oxide, but they were unable to determine the point of attachment of the oxygen to either nitrogen of the pyrimidine ring. Additional information on the *N*-oxidation of trimethoprim is presented in this study. Although limited numbers of subjects and animals of each species were studied, the results suggest that the human converts trimethoprim to the N_1-oxide and N_3-oxide with equal facility, whereas N_3-oxide formation is favored by the dog and N_1-oxide formation is favored by the rat.

BOOKS

REVIEWS

Basic and Clinical Pharmacology of Digitalis. (Proceedings of a Symposium sponsored by the Ohio State University College of Medicine, the American Heart Association, and the Central Ohio Heart Chapter). Edited by B. H. Marks and A. M. Weissler. Charles C Thomas, Springfield, IL 62703, 1972. 328 pp. 14.5 × 23 cm. Price $21.00.

The editors successfully present the work of distinguished scientists and clinicians who bring together the most recent advances in basic and clinical aspects of digitalis. In most instances, each of the 16 chapters presents a clear, readable, and succinct picture of the most important facets of digitalis glycosides. The materials throughout the book are well documented with adequate and current references (through 1971).

The application of basic pharmacological concepts to the clinical use of digitalis is the major theme of this book. The last five chapters of Part Two are particularly good and very useful for clinicians. In some instances, different views have been expressed by the authors on the same topic, but this is understandable, since all of these topics can be approached from a different point of view. Inclusion of chemical structures of various digitalis glycosides would have been helpful in following the discussions on the absorption and metabolic transformations of digitalis presented in chapters 2 and 12. However, this is a minor inconvenience since structural information is readily accessible from several reference books.

These authoritative presentations on basic and clinical aspects of digitalis glycosides deserve the careful scrutiny of pharmaceutical and medicinal chemists, practicing cardiologists, and internists, as well as academic and research specialists in cardiovascular physiology and pharmacology and all others who may be obliquely interested with digitalis.

Amino-Acids, Peptides, and Proteins, Volume 4. Senior Reporter, G. T. Young. The Chemical Society, Burlington House, London, W1V OBN, England, 1973. 498 pp. 13 × 21.5 cm. Price £9.00.

This volume is the fourth in the series of the literature review in the field of amino acids, peptides, and proteins. The selection of the reviewers by the Chemical Society is highly commendable. Under the able leadership of Dr. Young, these specialists have done a wonderful job and have provided an indispensible service by critically reviewing the wealth of the literature during the year 1971. The present volume is divided into five chapters. The first four chapters are devoted to the detailed survey of the literature on Amino-Acids, Structural Investigations of Peptides and Proteins, and Peptide Synthesis and Peptides with structural features not typical of proteins. The fifth chapter, a short one, concerns the revision of the I.U.P.A.C.-I.U.B. recommendations for the nomenclature of amino acids, peptides, and proteins. The second chapter is, by far, the most comprehensive and provides detailed survey of the litera-

In the two subjects, more than 50% of the administered dose was excreted mainly as intact drug in the 0–48-hr. period. Both the N_1- and N_3-oxides were found in the urine of man in approximately equal quantities, totaling 4.7 and 2.6% of the dose administered in Subjects 1 and 2, respectively. The urines from two dogs receiving tablets containing a total of 1000 mg. sulfamethoxazole and 200 mg. trimethoprim (16 mg. trimethoprim/kg. body weight) were analyzed for trimethoprim and its *N*-oxide metabolites (Table II). In the two dogs, 19.0 and 29.1% of the dose were excreted as intact drug. A significant amount of the N_3-oxide was excreted by both dogs in the 0–48-hr. period, while only a trace amount of the N_1-oxide was excreted. The urines of four rats receiving 28 mg. (140 mg./kg. body weight) and 10 mg. (50 mg./kg. body weight) trimethoprim i.p. in 5% gum arabic were analyzed for trimethoprim and its *N*-oxide metabolites. Between 5 and 12% of the dose was excreted as intact drug at both dose levels. Only the N_1-oxide metabolite was found in the 0–48-hr. rat urine, totaling between 0.6 and 2.7% of the administered dose (Table III).

Schwartz *et al.* (2) studied the metabolism of trimethoprim in man, dog, and rat and found that each species excreted the N_1-oxide as a urinary metabolite; this finding was confirmed in the present study. Meshi and Sato (3) detailed the metabolism of trimethoprim in the rat and reported levels of an *N*-oxide, but they were unable to determine the point of attachment of the oxygen to either nitrogen of the pyrimidine ring. Additional information on the *N*-oxidation of trimethoprim is presented in this study. Although limited numbers of subjects and animals of each species were studied, the results suggest that the human converts trimethoprim to the N_1-oxide and N_3-oxide with equal facility, whereas N_3-oxide formation is favored by the dog and N_1-oxide formation is favored by the rat.

BOOKS

REVIEWS

Basic and Clinical Pharmacology of Digitalis. (Proceedings of a Symposium sponsored by the Ohio State University College of Medicine, the American Heart Association, and the Central Ohio Heart Chapter). Edited by B. H. Marks and A. M. Weissler. Charles C Thomas, Springfield, IL 62703, 1972. 328 pp. 14.5 × 23 cm. Price $21.00.

The editors successfully present the work of distinguished scientists and clinicians who bring together the most recent advances in basic and clinical aspects of digitalis. In most instances, each of the 16 chapters presents a clear, readable, and succinct picture of the most important facets of digitalis glycosides. The materials throughout the book are well documented with adequate and current references (through 1971).

The application of basic pharmacological concepts to the clinical use of digitalis is the major theme of this book. The last five chapters of Part Two are particularly good and very useful for clinicians. In some instances, different views have been expressed by the authors on the same topic, but this is understandable, since all of these topics can be approached from a different point of view. Inclusion of chemical structures of various digitalis glycosides would have been helpful in following the discussions on the absorption and metabolic transformations of digitalis presented in chapters 2 and 12. However, this is a minor inconvenience since structural information is readily accessible from several reference books.

These authoritative presentations on basic and clinical aspects of digitalis glycosides deserve the careful scrutiny of pharmaceutical and medicinal chemists, practicing cardiologists, and internists, as well as academic and research specialists in cardiovascular physiology and pharmacology and all others who may be obliquely interested with digitalis.

Amino-Acids, Peptides, and Proteins, Volume 4. Senior Reporter, G. T. Young. The Chemical Society, Burlington House, London, W1V OBN, England, 1973. 498 pp. 13 × 21.5 cm. Price £9.00.

This volume is the fourth in the series of the literature review in the field of amino acids, peptides, and proteins. The selection of the reviewers by the Chemical Society is highly commendable. Under the able leadership of Dr. Young, these specialists have done a wonderful job and have provided an indispensible service by critically reviewing the wealth of the literature during the year 1971. The present volume is divided into five chapters. The first four chapters are devoted to the detailed survey of the literature on Amino-Acids, Structural Investigations of Peptides and Proteins, and Peptide Synthesis and Peptides with structural features not typical of proteins. The fifth chapter, a short one, concerns the revision of the I.U.P.A.C.-I.U.B. recommendations for the nomenclature of amino acids, peptides, and proteins. The second chapter is, by far, the most comprehensive and provides detailed survey of the litera-

In the two subjects, more than 50% of the administered dose was excreted mainly as intact drug in the 0–48-hr. period. Both the N_1- and N_3-oxides were found in the urine of man in approximately equal quantities, totaling 4.7 and 2.6% of the dose administered in Subjects 1 and 2, respectively. The urines from two dogs receiving tablets containing a total of 1000 mg. sulfamethoxazole and 200 mg. trimethoprim (16 mg. trimethoprim/kg. body weight) were analyzed for trimethoprim and its *N*-oxide metabolites (Table II). In the two dogs, 19.0 and 29.1% of the dose were excreted as intact drug. A significant amount of the N_3-oxide was excreted by both dogs in the 0–48-hr. period, while only a trace amount of the N_1-oxide was excreted. The urines of four rats receiving 28 mg. (140 mg./kg. body weight) and 10 mg. (50 mg./kg. body weight) trimethoprim i.p. in 5% gum arabic were analyzed for trimethoprim and its *N*-oxide metabolites. Between 5 and 12% of the dose was excreted as intact drug at both dose levels. Only the N_1-oxide metabolite was found in the 0–48-hr. rat urine, totaling between 0.6 and 2.7% of the administered dose (Table III).

Amino-Acids, Peptides, and Proteins, Volume 4. Senior Reporter, G. T. Young. The Chemical Society, Burlington House, London, W1V OBN, England, 1973. 498 pp. 13 × 21.5 cm. Price £9.00.

This volume is the fourth in the series of the literature review in the field of amino acids, peptides, and proteins. The selection of the reviewers by the Chemical Society is highly commendable. Under the able leadership of Dr. Young, these specialists have done a wonderful job and have provided an indispensible service by critically reviewing the wealth of the literature during the year 1971. The present volume is divided into five chapters. The first four chapters are devoted to the detailed survey of the literature on Amino-Acids, Structural Investigations of Peptides and Proteins, and Peptide Synthesis and Peptides with structural features not typical of proteins. The fifth chapter, a short one, concerns the revision of the I.U.P.A.C.-I.U.B. recommendations for the nomenclature of amino acids, peptides, and proteins. The second chapter is, by far, the most comprehensive and provides detailed survey of the litera-

ture concerning the primary structure and chemical modification of proteins and enzymes. The literature related to the use of X-rays for the studies of protein structure and the analytical tools employed in the elucidation of conformation and interaction of peptides and proteins is extremely well documented. The other chapters, likewise, have received the proper treatment.

The subject index has been abolished in this volume. However, this hardly reflects on the ease with which the proper subject reference can be located. This has been achieved by providing a detailed table of contents. This volume is a must for the desk of the scientist working in the areas of amino acids, peptides, and proteins.

Chemical and Biological Aspects of Drug Dependence. Edited by S. J. MULE and Henry BRILL, M.D. CRC Press, 18901 Cranwood Pkwy., Cleveland, OH 44128, 1972. 561 pp. 18 × 26.5 cm.

The purpose of this publication is to provide, in one reference source, the basic knowledge and background information that currently define the chemical and biological basis of drug dependence. To obtain a better understanding of drug dependence and drug abuse, the characteristics of drug dependence of various pharmacological classes of drugs are described. Theories related to tolerance development and physical dependence are then discussed. Finally, the biochemical mechanisms associated with biological strata, *e.g.*, enzymes, proteins, and hormones, are explained in relationship to drug dependence. Twenty-five separately authored discussions are divided into five sections covering significance and characteristics of drug dependence, criteria for their evaluation, chemical aspects, physiological and pharmacological aspects, and biochemical aspects.

Modern Analytical Methods. By D. BETTERIDGE and H. E. HALLAM. The Chemical Society, Burlington House, London W1V OBN, England, 1972. 220 pp. 14 × 21.5 cm. Price £2.00.

The objective of this publication is to acquaint teachers with the most important methods of modern analysis. To aid in understanding the analytical methods, modern methods of testing complex equilibria are also included. Although the discussion of individual techniques is condensed, an attempt has been made to include the fundamental theory necessary to understand the method or technique being discussed.

Handbook of Commercial Scientific Instruments, Volume 1: Atomic Absorption. By CLAUDE VEILLON. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1972. 174 pp. 15 × 23 cm. Price $11.75.

Commercially available instruments, by type, will be detailed in this new multivolume series. In volume 1, the instrumentation available for atomic absorption spectroscopy is covered. Specifications, descriptions, schematic drawings, photographs, approximate prices, and accessories are given in separate discussions for each manufacturer, and in summary tables given at the end of the book for quick comparisons.

The information is essentially that provided by the manufacturer. The volume authors are engaged in research in the area covered by their respective books and are familiar with the available instrumentation. The authors do not represent any instrument manufacturer.

This volume begins with a general discussion of atomic absorption spectroscopy requirements and instruments, followed by sections on each manufacturer and his instruments. A summary section focusing on cost considerations and tables comparing the discussed instruments complete the book.

This book and, presumably the rest of the series, bring together information available but from many diverse sources. The book should be useful in preliminary considerations of equipment acquisitions.

Chemical and Biological Aspects of Drug Dependence. Edited by S. J. MULE and Henry BRILL, M.D. CRC Press, 18901 Cranwood Pkwy., Cleveland, OH 44128, 1972. 561 pp. 18 × 26.5 cm.

The purpose of this publication is to provide, in one reference source, the basic knowledge and background information that currently define the chemical and biological basis of drug dependence. To obtain a better understanding of drug dependence and drug abuse, the characteristics of drug dependence of various pharmacological classes of drugs are described. Theories related to tolerance development and physical dependence are then discussed. Finally, the biochemical mechanisms associated with biological strata, *e.g.*, enzymes, proteins, and hormones, are explained in relationship to drug dependence. Twenty-five separately authored discussions are divided into five sections covering significance and characteristics of drug dependence, criteria for their evaluation, chemical aspects, physiological and pharmacological aspects, and biochemical aspects.

Modern Analytical Methods. By D. BETTERIDGE and H. E. HALLAM. The Chemical Society, Burlington House, London W1V OBN, England, 1972. 220 pp. 14 × 21.5 cm. Price £2.00.

The objective of this publication is to acquaint teachers with the most important methods of modern analysis. To aid in understanding the analytical methods, modern methods of testing complex equilibria are also included. Although the discussion of individual techniques is condensed, an attempt has been made to include the fundamental theory necessary to understand the method or technique being discussed.

Handbook of Commercial Scientific Instruments, Volume 1: Atomic Absorption. By CLAUDE VEILLON. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1972. 174 pp. 15 × 23 cm. Price $11.75.

Commercially available instruments, by type, will be detailed in this new multivolume series. In volume 1, the instrumentation available for atomic absorption spectroscopy is covered. Specifications, descriptions, schematic drawings, photographs, approximate prices, and accessories are given in separate discussions for each manufacturer, and in summary tables given at the end of the book for quick comparisons.

The information is essentially that provided by the manufacturer. The volume authors are engaged in research in the area covered by their respective books and are familiar with the available instrumentation. The authors do not represent any instrument manufacturer.

This volume begins with a general discussion of atomic absorption spectroscopy requirements and instruments, followed by sections on each manufacturer and his instruments. A summary section focusing on cost considerations and tables comparing the discussed instruments complete the book.

This book and, presumably the rest of the series, bring together information available but from many diverse sources. The book should be useful in preliminary considerations of equipment acquisitions.

High Pressure Liquid Chromatography

A. F. MICHAELIS▲, D. W. CORNISH, and R. VIVILECCHIA

Keyphrases □ High pressure liquid chromatography—review of theory, column design, instrumentation, methods, performance measurements, pharmaceutical applications □ Drug analysis—use of high pressure liquid chromatography, review □ Chromatography, high pressure liquid—review, use in drug analysis □ Column chromatography—review of high pressure liquid chromatography, theory, design, instrumentation, methods, performance, pharmaceutical applications

Prior to 1967, liquid column chromatography (LCC) separations were not normally carried out in an optimum manner; for this reason, the technique was viewed as slow and inefficient (1–3). Consequently, other techniques such as thin-layer chromatography (TLC) and gas chromatography (GC) found favor. Within the last 5 years, LCC has undergone dramatic changes and now rivals GC in speed of analysis and column efficiency. The modernized technique is commonly known as high pressure liquid chromatography (HPLC).

Table I roughly compares HPLC with other commonly used chromatographic techniques in terms of support particle size and speed of analysis, N_{eff}/t (see *Measurement of Column Performance*). A maximum N_{eff}/t means the shortest analysis time. Classical LCC and TLC are seen to be slow, although a new form of high speed TLC, thin-film chromatography, was recently described (4). GC and HPLC are seen to be comparable in speed and efficiency. A common misconception in comparing these two techniques is that HPLC is less efficient. Rather, with GC, longer columns and, hence, many more theoretical plates can be used. Because of the much lower permeability of HPLC columns, the apparatus places a limitation on the column length. The lower permeability results from the smaller particle sizes and the higher viscosities of liquids. However, even with relatively short columns, very difficult separations can be accomplished with HPLC due to its greater selectivity. Greater selectivity is achieved through choice of the mobile phase, solvent programming, and variation of the separation mechanism, *i.e.*, adsorption, ion exchange, or partition.

Much early work in HPLC involved the development of high efficiency and high speed systems according to theoretical guidelines. With a knowledge of modern chromatographic theory (5, 6), a better understanding of the basic principles underlying HPLC and the deficiencies of classical LCC techniques is achieved.

THEORY

General Considerations—Improvement in LCC has been achieved primarily through the use of more efficient columns and of higher mobile phase velocities. Column efficiency, or band broadening, is described by the height equivalent to a theoretical plate, H, concept, which is a measure of solute band broadening per unit length of the column. The height H is defined as:

$$H = \frac{\sigma_l^2}{L} = \frac{L}{N} \qquad \text{(Eq. 1)}$$

where σ_l is the standard deviation of the Gaussian function (the solute band profile) in length units, L is the column length, and N is the number of theoretical plates. The latter is given by:

$$N = 16(L/W)^2 \qquad \text{(Eq. 2)}$$

Table I—Comparison of Chromatographic Performance

Technique	Particle Diameter (d_p), μ	N_{eff}/t^a	Reference
TLC	2–20	<0.08	3
Classical LCC	150	<0.05	3
HPLC			
Silica gel	20	2	3
Porous layer beads			
Zipax	30	8	114
Corasil	28–37	2	114
Silica microspheres	5	23	51
GC			
Classical packed	130	10	150
Porous layer beads	90	50	150

[a] Effective plates per second, where $N_{eff} = N[k'/(1 + k')]^2$, N = number of theoretical plates, and k' = capacity factor.

where W is the peak width determined by tangents to the Gaussian profile. In the construction and operation of columns, it is desirable that H be as small as possible.

Until recently, the Van Deemter equation:

$$H = A + B/V + CV \qquad \text{(Eq. 3)}$$

had been used to represent the chromatographic band broadening mechanism. In Eq. 3, the A term arises from complex flow processes (eddy diffusion), the B term describes solute dispersion by longitudinal molecular diffusion, and the C term relates to nonequilibrium resulting from resistance to mass transfer in the stationary and mobile phases. There is now considerable evidence to show that Eq. 3 is generally inadequate (3, 5–7).

Huber and Hulsman (8) and Huber (9) developed an equation, in which H is the sum of four terms, which takes into account four independent processes: mixing by longitudinal molecular diffusion, H_{MD}; mixing by convection, H_{MC}; resistance to mass transfer in the stationary phase, H_{ES}; and resistance to mass transfer in the moving phase, H_{EM}. Hence:

$$H = H_{MD} + H_{MC} + H_{ES} + H_{EM} \qquad \text{(Eq. 4)}$$

The longitudinal molecular diffusion, H_{MD}, is given by:

$$H_{MD} = 2D_m/T_mV \qquad \text{(Eq. 5)}$$

Since H_{MD} is inversely proportional to mobile phase velocity, V, and since the diffusion coefficients, D_m, in liquids are 10^4–10^5 smaller than those in gases, this term contributes significantly only at very low velocities in LCC. Figure 1 illustrates this point and compares *H versus V* curves of LCC and GC. Consequently, at the velocities employed in HPLC, this term is negligible (5, 6).

The most complex dispersion mechanism is convective mixing in the mobile phase. This term is related to point-to-point velocity inequalities within the packed bed (eddy diffusion) and the compensating effects of transverse molecular diffusion and stream splitting (5, 6). Giddings (5, 10) stressed the fact that these terms are not independent but are coupled. An expression similar to the theoretically derived equation (5, 10) was developed (8, 9). The mobile phase mixing term, H_{MC}, is given by:

$$H_{MC} = \frac{2\lambda_1 d_p}{1 + \lambda_2(D_m/Vd_p)^{1/2}} \qquad \text{(Eq. 6)}$$

At high velocities, H_{MC} approaches a value equal to $2\lambda_1 d_p$ (classical eddy diffusion term). Thus, at the higher velocities, lateral diffusion has a smaller effect in decreasing the magnitude of this term. In addition, this term is independent of the capacity factor, k'.

The magnitude of the H_{MC} term is dependent upon the bed structure, the column-to-particle diameter ratio (d_c/d_p), the particle shape, and the packing technique (11, 12). Columns of uniform, dense packing structure give the best column efficiencies (6, 13, 14*a*). Such columns are most readily prepared from dense, spherical particles (13). In addition, Eq. 6 predicts that decreasing the particle diameter should increase efficiency. This effect is experimentally found to be true for particles less than 100 μ only if the correct packing technique is employed (4, 9, 14*a*). Furthermore, theory predicts that increasing the column-to-particle diameter ratio will increase band spreading due to the increasing importance of transcolumn flow inhomogeneities (5). However, the optimum column diameter was found to be between 2 and 4 mm. i.d. for regular packed columns ($d_c/d_p > 10$) (13, 14*b*). Below 2 mm., efficiencies are significantly poorer (13, 15). Apparently, this discrepancy is associated with the difficulty of packing small particles homogeneously into narrow bore tubes. With columns greater than 4 mm., distorted and doublet peaks have been noted (15). This distortion is probably associated with the different packing structure in the vicinity of the column wall (wall effects) (5), where the velocity is greater than the average. Since solute diffusion is slow in liquids, the solute in the vicinity of the walls does not have enough time to diffuse back to the center before elution; hence, bands elute unsymmetrically. However, Knox and Parcher (16) proposed a theory where slow diffusion leads to improved chromatographic performance. These authors calculated that, with a 5-mm. i.d. column of length <0.33 m. containing particles with a diameter of 30 μ, the solute never reaches the wall area before elution. Consequently, the band is not distorted by wall effects. This type of column is known as the "infinite diameter" column and was successfully demonstrated with columns of 7.94 and 10.9 mm. i.d. (15). A column is judged to be of infinite diameter if the column diameter, d_c, is greater than $(2.4Ld_p)^{1/2}$.

At velocities above the minimum in *H versus V* curves (Fig. 1) for GC or LCC, H_{ES} and H_{EM} terms become increasingly important as the velocity increases. These terms relate to nonequilibrium resulting from resistance to mass transfer in the stationary phase, H_{ES}, and the mobile phase, H_{EM} (5, 6). The extent of broadening from nonequilibrium is a function of the rate of flow of the mobile phase relative to the rate of mass transfer of the solute between the mobile and stationary phases. Rate-limiting processes that contribute to this type of broadening in LCC include desorption kinetics and diffusion in the mobile phase which is stagnant in pores of the support[1]. General

[1] For a detailed discussion of these terms, see *Reference 5*.

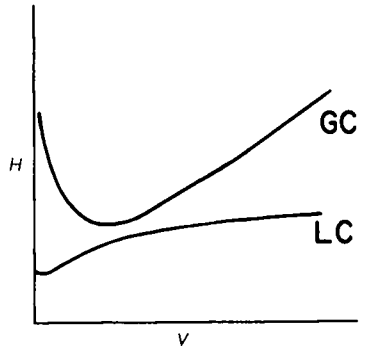

Figure 1—*Typical shapes of* H (*height*) versus V (*velocity*) *curves for GC and LC.*

equations (8, 9) that describe these processes are:

$$H_{EM} = \frac{1}{5.7} \frac{\epsilon_\alpha - \epsilon_m + K\epsilon_\beta}{\epsilon_\alpha + K\epsilon_\beta} \frac{\epsilon_m^{1/2} d_p^{1/2} \eta^{1/6} V^{1/2}}{(1 - \epsilon_m) D_m^{1/2}} \quad \text{(Eq. 7)}$$

and:

$$H_{ES} = \frac{1}{30} \frac{\epsilon_\alpha - \epsilon_m + K\epsilon_\beta}{(\epsilon_\alpha + K\epsilon_\beta)^2} \frac{\epsilon_m(1 - \epsilon_m)}{\epsilon_s} \frac{T_s d_p V}{D_{ts}} \quad \text{(Eq. 8)}$$

H_{ES} is more strongly dependent than H_{EM} upon the mobile phase velocity, V, and the particle diameter, d_p. However, both terms are minimized by decreasing d_p. Many workers have noted, however, that for $d_p < 100\ \mu$, H increases (4, 17, 18). This discrepancy from theory is associated with the difficulty of packing homogeneously small particles, especially those of a low density, nonspherical type (15, 18). However, with special packing techniques, the use of small diameter particles was impressively demonstrated by Hamilton (19), Scott *et al.* (20), and Burtis (21) using roughly 10–20-μ particle diameter ion-exchange resins. Piel (22) successfully used a variety of supports in the submicron region, and Huber and Hulsman (8) and Huber (9) packed efficient columns with 20–30-μ diatomaceous earth. The successful use of small diameter particles to reduce mass transfer effects requires dense uniform packing, *i.e.*, minimal contribution from H_{MC}. Recently, Kirkland (23) demonstrated the superiority of small particles with 5-μ porous silica microspheres (Table I).

Equations 7 and 8 indicate that the mass transfer term can also be reduced by maximizing solute diffusion coefficients, D_m and D_{ts}, in the mobile and stationary phases, respectively. Since the liquid diffusion coefficient is inversely proportional to liquid viscosity, the stationary and mobile phases with the lowest possible viscosities should be chosen (2, 24, 25).

Resistance to mass transfer from diffusional processes in the stationary phase can also be reduced by minimizing the diffusion path length (*i.e.*, minimizing stationary film thickness) (5, 11). In addition, a stagnant mobile phase in the pores of the support further contributes to slow mass transfer (5, 6, 11). These effects have been decreased by the reduction in particle size, since specific pore volume decreases with decreasing particle size (8, 9), and by the development of porous layer beads, which will be described.

Equation 8 can be simplified if it is assumed that the pores of the support are completely filled with β (stationary phase). In such a case:

$$H_{ES} = \frac{1}{30} \frac{k'}{(1 + k')^2} \frac{T_s d_p^2 V}{D_s} \quad \text{(Eq. 9)}$$

where k' is the capacity factor equal to $K(\epsilon_\beta/\epsilon_\alpha)$.

The capacity factor function reaches a maximum at $k' = 1$ and then decreases strongly with increasing k'. If mobile phase effects predominate over stationary phase effects, H is essentially independent of k' (6). However, since the magnitude of k' is related also to sample resolution and since low k' values are desirable for fast analysis, there is an optimum k' value (6). Snyder (3) calculated the optimum value of k' to be 5 for a given column length and any desired column pressure and 2.9 for a given column pressure and any column length.

Speed and Optimization in Liquid Chromatography—A number of recent papers dealt with the theoretical treatment of the optimization of chromatographic parameters for fast separations (1, 8, 17, 22, 26–28). Since the time of separation is a function of a number of parameters, mathematical optimization with respect to all relevant parameters is virtually impossible (28). The problem is simplified by holding a number of parameters fixed (26, 28). However, all treatments of the resolution of a two-component system start with the following equation:

$$t_r = (1 + k') \frac{L}{V} = N(1 + K') \frac{H}{V} \quad \text{(Eq. 10)}$$

Resolution is related to N, the number of theoretical plates necessary to achieve the separation. The difficulty of the optimization problem arises from the complexity of the H function, which is in itself a function of the other parameters in Eq. 10. Equation 10 does, however, show that the retention time, t_r, can be reduced by minimizing the H/V ratio. It follows that the optimum conditions for fast analysis correspond to the minimization of the H/V factor. However, the H/V factor initially decreases sharply with increasing V but then decreases slowly at higher velocities (6, 9, 26). The point at which the slope of the H/V *versus* V plot stops changing significantly can be considered as the optimum velocity, especially where pressure drop is a limitation. The optimum velocity for 2–3-mm. i.d. columns is about 2–3 cm./sec. (6). Beyond the optimum velocity, a decrease in analysis time is afforded only by a large increase in pressure drop, ΔP, in the column. Pressure drop is related to velocity through the column permeability, K^0:

$$K^0 = \frac{V\eta L f}{\Delta P} \quad \text{(Eq. 11)}$$

The importance of pressure drop and permeability in regard to analysis time can be seen by substituting the expression for V from Eq. 11 into Eq. 10:

$$t_r = \frac{(1 + k')\eta L^2 f}{K^0 \Delta P} \quad \text{(Eq. 12)}$$

For constant values of k', η, L, f, and ΔP, the more permeable the column the faster is the analysis time. Equation 12 also indicates that the analysis time can be

decreased by lowering the solvent viscosity, η, and the column length, L.

Equation 10 indicates that t_r can be reduced by optimizing factors that minimize H. These factors were discussed previously, but, in the main, a decrease in particle size (8, 9, 26) and the development of support materials that give flat H *versus* V curves will give the fastest analysis time.

The equations used previously to describe analysis time neglected the effects of extracolumn band broadening. The shorter the column length, the smaller must be the contributions from injection and detection (26, 28). Smuts and Pretorius (28) showed that, for simple separations, the minimum separation time is limited by extracolumn effects.

COLUMN DESIGN

Column Packings—The use of the relevant theories has led to the development of two methods to achieve high speed analysis by LCC: the development of porous layer beads of 30–50-μ diameter and the use of supports with particle diameters less than 10 μ. Because both supports have shallow pore depths, slow mass transfer in the stagnant mobile phase held within the pores is reduced.

A porous layer bead has a hard, nonporous core surrounded by a thin, porous shell. Golay (29) and Bohemen and Purnell (30) first suggested, from a theoretical standpoint, the advantages of porous layer beads for fast analysis. Other authors (31, 32) suggested the use of such supports for LCC. Rapid mass transfer is possible, since diffusion occurs only in a thin, porous layer. As a result, flat H *versus* V curves are produced; consequently, high carrier velocities can be used with small loss in efficiency. The various types of porous layer beads were described (6, 33, 34). Two commercially available supports, Zipax[2] (26, 35) and Corasil I and II[3] (36), have siliceous, porous layers of roughly 1-μ thickness. Zipax is a relatively inert support (35) and is used primarily in liquid–liquid chromatography (LLC). The Corasils are much more active and, therefore, can be used for both LLC and liquid–solid chromatography (LSC) (36). Supports with a porous layer of alumina have also been prepared (11, 37). A new type of support, the surface-textured bead having 30–40-μ diameter and surface-etched pores with 2–4-μ depths, has potential in high speed LLC (24). However, surface-textured beads have even a lower sample capacity than the porous layer beads. Porous layer adsorbents also have been developed for ion-exchange chromatography. A pellicular ion-exchange bead[4] in which the ion-exchange resin is polymerized on the surface of a spherical, solid glass bead has been introduced (11, 38*a*). Kirkland (39, 40) developed similar materials.

In addition to the fast mass transfer properties of porous layer beads, their spherical shape, high density, and rigid structure yield dense, regular packed beads which are stable at high pressures. However, because of their low surface areas, small sample sizes and very sensitive detectors must be used.

A possible solution to the capacity problem is to use porous supports of small particle diameters (<10 μ). As already noted, the use of supports with such small particle sizes has been successfully demonstrated. Supports that have been used are diatomaceous earth (8, 9, 41), silica gel (4, 22), alumina (22), carbon black (22), silica microspheres (23), and ion-exchange resins (20, 42). Huber and Hulsman (8), Huber (9), and Deelder *et al.* (41) used diatomaceous earth of 28–32 and 9 μ. The efficiency of these columns for retained or unretained solutes was comparable to efficiencies of porous layer beads. However, with the exception of ion-exchange resins, for which special packing techniques have been developed (43, 44), practical difficulties arise in preparing homogeneous beds of these small particles (4). Very narrow size fractions are a definite must in preparing satisfactory columns (8). Batch separation into narrow size fractions by elutrification was described for diatomaceous earth (41) and ion-exchange resins (42). With the development of reproducible packing techniques, 2–5-μ porous particles will become commonplace in the future. Some supports available for HPLC are shown in Table II.

Column Tubing and Shape—Kirkland (39) found significantly poorer efficiencies for solutes chromatographed in columns of seamless stainless steel relative to precision glass[5] and precision bore stainless steel. Karger *et al.* (24) also found precision glass tubing to give better efficiency than seamless stainless steel; however, the difference between the two column tubings was not as great as was found by Kirkland (39). Karger *et al.* (24) recommended that the seamless stainless steel be washed as follows: chloroform, acetone, water, 50% phosphoric acid, 10% nitric acid, water (until washings are neutral), acetone, and chloroform. Kirkland (45) recommended scrubbing the interior with laboratory detergent solution.

Columns filled with packings and then bent have shown a significant decrease in efficiency in comparison to straight columns (39, 46). Straight columns 50 or 100 cm. in length are generally used. To obtain more theoretical plates, columns can be connected in series with low dead volume connectors. Kirkland (33) obtained a 5–6% loss in efficiency for two connected columns and a 10% loss for three connected columns.

Column Packing Techniques—Column packing is one of the most difficult and most important experimental operations in high efficiency LCC. The various packing techniques were reviewed (4, 47). Columns are packed by either dry-fill (14, 45, 48) or wet-fill (14, 44, 49) techniques.

The standard dry-fill technique involves small incremental additions of dry packing, with horizontal tapping of the column at the level of the packing and with simultaneous vertical tapping of the column on the floor or benchtop. Sie and van den Hood (14*a*) found H to decrease by a factor of 5 or more for relatively large column diameters (d_c = 1.0 cm.) when a special dis-

tributor head for feeding the adsorbent evenly into the column, plus rapid rotation and tapping of the column, is used. These workers also found that smooth particles gave consistently better columns by the dry-fill technique. They found H to decrease in the following order: silica beads > silica gel > alumina > sil-o-cel. In addition to vibration, Stewart *et al.* (50) recommended gentle tamping (weight of rod on top of the packed adsorbent) for the dry fill of silica gel. The efficiencies of tamped columns improved with decreasing particle size down to about d_p equal to 50 μ. The loss in efficiency for smaller particle sizes is probably due to the difficulty of obtaining dense, regular bed structure with irregularly shaped particles of alumina or silica gel (4). Conversely, the dense, spherical porous layer beads can be efficiently packed with the standard dry-fill techniques for particle sizes down to 20–30 μ (33). Kirkland (45) described an optimum procedure for packing Zipax. Column efficiency was found to improve with a decrease in particle size down to at least 37 μ. For 1% β,β'-oxydipropionitrile on Zipax (<37 μ), plate heights of 0.23 mm. ($k' = 2$) were found at 1 cm./sec. mobile phase velocity. Although other porous layer packings were not included in this study, similar results are expected.

Other workers (8, 9, 41) were able to pack good liquid partition columns with diatomaceous earth with d_p down to 10 μ. Columns were packed by small incremental additions of the support, with tamping between increments using a closely fitting rod. However, such packings have the disadvantages of bed compression and lower permeability at pressures exceeding 1 atm./cm. (41).

For supports of particle sizes less than about 20 μ, the slurry packing technique is often used (14, 44, 49). The balanced slurry technique (49), where the support particles are suspended in a solvent of equal density, is probably the best method. Sie and van den Hood (14*a*) recommended the use of calcium sulfate hemihydrate as a binder in the slurry. Silica[6] with a mean particle size of 10 μ, when packed by the balanced slurry technique, gave columns of high efficiency (51). On the other hand, Stahl *et al.* (52) found poorer efficiencies by the slurry technique (probably not balanced slurry) than by a dry-fill technique for silica gel particles of less than 15 μ. More recently, Kirkland (23) introduced silica microspheres (5-6-μ particle diameter) and generated 23 effective plates/sec. (see *Measurement of Column Performance*) with these particles packed by a slurry technique in a column 35 × 0.32 cm. at 600 p.s.i. pressure drop.

INSTRUMENTATION

Many papers have been written on the overall design of LCC systems (53–61). Scheme I shows a block diagram of a simplified liquid chromatograph. Although many manufacturers supply complete systems, a liquid chromatograph can be built easily from individual components which are readily available. In general, all components should be constructed of corrosion-resistant materials such as stainless steel, glass, or Teflon.

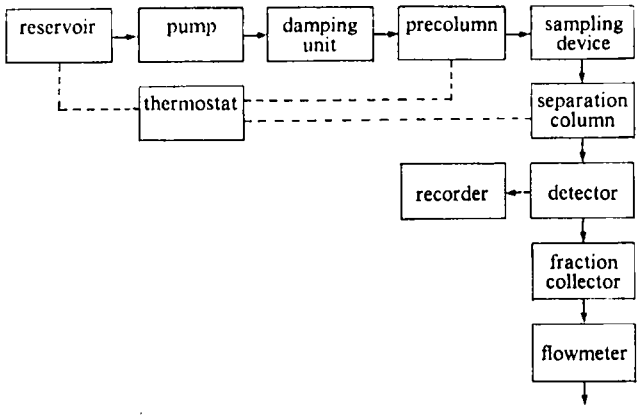
Flow System

Pumps can be classified into two major types: mechanical and gas displacement. Mechanical pumps are constant flow rate devices such as the screw-driven syringe pump and the reciprocating piston or diaphragm pumps. The former are pulse free, whereas the latter type requires pulsation dampening for detector stability. Several methods for pulsation dampening have been described (57, 60, 61). Karger and Berry (62) constructed a simple device for producing pulseless flow with inexpensive reciprocating piston pumps. Mechanical pumps can be purchased which operate to pressures of about 5000 p.s.i.

Of the gas-displacement pumps, the gas pressurized reservoir (2, 54) is the least expensive and is capable of pulseless flow. The reservoir can be a stainless steel container or a coil of stainless steel tubing, pressurized by nitrogen from a gas cylinder. A second type of gas-displacement pump is the gas-driven piston pump (55), which amplifies the gas pressure by utilizing a large area gas piston pushing against a smaller area liquid piston. The prime disadvantage of gas-displacement pumps is that the flow rate changes with varying back pressure.

The design of the injection port[7] is critical to minimize band spreading, especially for solutes of low k'. Inlet bandwidths must be restricted to submillimeter values. The major factors that describe band spreading in the injection port are: (*a*) distance between syringe needle and the column inlet, (*b*) mobile phase linear velocity, (*c*) sample volume, and (*d*) rapidity of radial mass transfer (63). Direct on-column injection gives minimum band spreading (63). Mobile phase swept injection ports (including sampling valves) are satisfactory for solutes with $k' > 1$ (53). Smuts *et al.* (63) designed

[6] Li Chrosorb, E. M. Laboratories, Inc., Elmsford, NY 10523
[7] For design of injection ports, see *References 53–61.*



Scheme I—Diagram of a liquid chromatograph

a unique solvent swept inlet system giving bandwidths as small as 0.3 mm.

Detectors

A number of excellent papers have been published on the various detectors available for LCC (64–66). Munk (67) and Huber (68) compared the most commonly used detectors. LCC detectors can be categorized as solute sensitive or bulk sensitive.

Solute-Sensitive Detectors—*UV and Visible Absorption*—The UV photometer is most commonly used since it is relatively insensitive to variations in flow rate or temperature and is adaptable to solvent programming. A number of workers (69–71) described the construction of low dead volume UV detectors. These detectors and the commercially available detectors are single wavelength units (254 or 280 nm.). Such detectors are capable of sensing less than 10^{-9} g./ml. (55). Commercial spectrophotometers have also been used successfully as high performance detectors (68, 72–74). The obvious advantage is wavelength selectivity. In addition, in some cases the number of solvents to choose from is increased. In cases where solutes have little or no UV absorption, the use of color-forming reactions can be of great value for increasing sensitivity and selectivity. Stahl *et al.* (52) described the construction of a high performance system for the analysis of carboxylic acids in the nano-equivalent scale, using the sodium salt of *o*-nitrophenol as the indicator. The authors suggested the use of umbelliferone, whose protonated form is highly fluorescent, as an alternative indicator. Such a technique can be of extreme value in trace analysis and metabolism studies.

Fluorescence—Although no work has been published using a fluorescence detector in HPLC, a high performance, dual-beam fluoro monitor[8] is on the market. In addition, filter fluorometers[9] can be converted with suitable flowthrough cells (75). The technique has the advantages of specificity and high sensitivity (about 10^{-9} g./ml.). In addition, fluorescent derivatives can be prepared from many compounds lacking fluorescent capabilities.

Flame Ionization—To obtain a suitable response in a flame-ionization detector, the solvent must be removed. This is done by coating part of the column effluent on a moving wire which then passes through a heated chamber. Currently, two general methods of getting the sample into the flame are used: direct combustion in the flame (76–81) and pyrolysis of the residue on the wire prior to detection in the flame (82–85). The former technique is noisier due to the movement of the wire through the flame and the intermittent misalignment of the wire in the flame. Scott and Lawrence (83) modified the pyrolysis detector in such a way as to reduce significantly the noise level. Instead of pyrolyzing the solute, combustion of the solute in an oxygen atmosphere to carbon dioxide is used. The carbon dioxide is then hydrogenated catalytically over nickel to methane which is then passed into the flame-ionization detector. This detector's response is directly proportional to the carbon content, and the sensitivity is about 2 mcg./ml. of mobile phase. The moving wire detector can be used with all modes of column chromatography including gradient elution. However, it has the disadvantages of: (*a*) poor sensitivity since only part of the effluent is detected, (*b*) markedly reduced sensitivity as solute volatility increases, and (*c*) imprecise quantitation if the sample is not homogeneously dispersed over the column cross section (68).

Polarographic—The polarographic detector is specific and highly sensitive. The detector is sensitive to solutes that can be oxidized or reduced at the mercury electrode. Additional specificity results from varying the half-wave potential. The only other requirement is that the mobile phase must have sufficient conductivity.

A detector based upon the dropping mercury electrode (DME) suitable for high speed LCC was described by Koen *et al.* (86). The cell volume was only a few cubic millimeters. The detector was successfully applied to the chromatographic analysis of methyl parathion and parathion at concentrations down to 10^{-8} mole/l., with a standard deviation less than 2%. The major problem of this design is dissolved oxygen in the mobile phase and the sample solution, and damping is required to reduce the noise associated with the DME. The sensitivity of the detector depends upon the electrochemical valency, the solute diffusion coefficient, the flow rate and drop time of the mercury, and the flow rate of the eluant.

Joynes and Maggs (87) described a simpler system based upon a carbon-impregnated silicone membrane as the electrode. The advantages over the DME are low residual currents, decreased proneness to mercury oxide films, simple construction, low noise level (no damping required), no atmospheric exposure of mercury, and 100 times lower interference from oxygen in the mobile phase. The linear dynamic range is of the order 1×10^5, with a detection limit of about 2×10^{-9} mole/l. (organics), and the reproducibility is about 0.25%.

Radioactivity—This detector is extremely useful for metabolic studies because of its specificity and high sensitivity. The utilization of β-radiation using suspended scintillators in continuous-flow systems was described (88). A detector suitable for high speed LCC

[8] Laboratory Data Control.
[9] American Instrument Co., G. K. Turner Associates.

was also described (89). The detector cell consists of a Teflon tube, 36 mm. in length × 0.38 mm. i.d., in a continuous-flow Geiger-Muller counter.

The following expression for detector sensitivity was derived:

$$\text{peak area} = \frac{S_A V_D}{\mu} A \qquad \text{(Eq. 13)}$$

where S_A is the sensitivity of the detector, V_D is the volume of the detector cell, μ is the volume flow rate, and A is the total activity of the sample component. The sensitivity is seen to be inversely proportional to the flow rate but directly proportional to the cell volume. A compromise must be made between the cell volume size and the tolerable band spreading.

Davies and Mercer (90) described an automated system for the analysis of labeled, unsaponifiable lipids. The scintillator flowthrough cell was packed with europium-activated calcium fluoride crystals.

Bulk-Sensitive Detectors—*Refractive Index*—The refractive index detector monitors the difference in refractive index between the reference and analytical column effluents, and sensitivity is determined by this difference. This detector is close to being a universal detector, the exception being when the solute and solvent have the same refractive index. Two types are commercially available: the deflection type[3] and the reflection type[10] (91). The sensitivity is about 10^{-7} refractive index unit full scale. However, to achieve such sensitivity, the temperature and flow rate must be controlled precisely (64, 67). The temperature coefficient is about 10^{-4} refractive index unit/°C. Heat exchanger tubing is commonly used. To minimize band spreading and to improve temperature stability in the heat exchanger, Deininger and Halasz (61) recommended that the free cross section of the heat exchanger be squeezed alternately at 90° angles. Thus, high radial mass transport in the heat exchanger tube is achieved through turbulent flow. The peak broadening is minimized to that of the high efficiency UV detectors, and the noise levels are reduced to less than 3×10^{-8} refractive index unit.

Solvent programming is not feasible unless solvents of the same refractive index are used (92). A new detector (93) based upon continuous evaporation of the eluate and redissolution of the residue in a fixed solvent gives the maximum response in a refractive index detector.

Heat of Adsorption—The heat of adsorption detector or microadsorption detector (94–100) is a universal detector which measures minute temperature changes accompanying the sorption of the eluent and the solute on an active solid surface, usually the support held in the chromatographic column. The detector can be used with all modes of chromatography. However, this detector is extremely flow and temperature sensitive. In addition, it requires frequent calibration, and the peak shape (97, 100) is unusual in that a positive component and negative component result. The real value of this detector is in qualitatively visualizing the elution pattern (64).

[10] Laboratory Data Control.

Other Detectors—The conductivity detector is sold by a number of manufacturers and is commonly used in amino acid analyzers and in gel permeation techniques (65). Other techniques that have been applied to HPLC are the gas density balance (101), the mass (102), the electron-capture (103), the interferometer (104), and the capacitance (105–107) detectors.

LIQUID CHROMATOGRAPHY METHODS

Selectivity—The ability of any chromatographic technique to perform separations depends upon the efficiency and selectivity of the chromatographic system. The former was discussed previously while the latter is expressed in terms of the relative retention, α, that is equal to the ratio of retention volumes of two solutes. Selectivity is determined by solute–solvent or solute–adsorbate interactions and, to a lesser extent, by their molecular size and shape (108).

Although chromatographic systems are primarily chosen by trial and error, some theoretical and empirical treatments have been developed which can be of aid. Snyder (109) discussed the role of the mobile phase in LCC. Solvent polarities are measured in terms of the Hildebrand solubility parameter, δ, and the solvent strength parameter, ϵ^0. In addition, Keller and Snyder (110) discussed the relationship between δ and ϵ^0.

Martire and Locke (111) considered the thermodynamic basis for selectivity in terms of both the athermal (size) and the thermal (energy) factors in LLC. Locke (112) measured the infinite dilution activity coefficients of hydrocarbons in the acetonitrile–squalene system.

Huber (113) reviewed the methods for prediction of partition coefficients in liquid–liquid systems. Recently, Huber *et al.* (114) developed a new method of predicting partition coefficients. The partition coefficient (K_i) is described as a function of P parameters, each having a solute factor (A_{ip}) and a liquid–liquid system factor (X_{kp}). The equation has the form:

$$\log K_i = \sum_P A_{ip} X_{kp} \qquad \text{(Eq. 14)}$$

The method was tested for 28 steroids in six ternary liquid–liquid systems composed of water, ethanol, and isooctane. For $P = 3$, a precision of about 4% was obtained.

Liquid–Liquid Partition—*Liquid–Liquid Systems*—The types of supports available for partition chromatography are shown in Table II. The various porous layer beads were evaluated by Karger *et al.* (115), and a similar comparison was made by Kirkland (33) and Majors (116). On the basis of the data given, Zipax appears to be the best porous layer support for liquid–liquid chromatography. The Corasils are much more active than Zipax since Corasil I, when packed dry, adsorbs 1.1% (w/w) β,β'-oxydipropionitrile from eluent saturated with β,β'-oxydipropionitrile. On the other hand, Zipax adsorbs only 0.25% (115). Majors (116) recommended that Corasil be deactivated by heating to 350° for LLC. Tailing was partially eliminated upon deactivation. Huber *et al.* (117, 118) successfully used small particles of ground Porasil (2–5 μ) and diatomaceous earth (5–10 μ, 20–30 μ) as LLC supports.

To produce columns of high capacity, Halasz *et al.* (119) proposed the use of heavily loaded columns. Columns packed with Porasil A (38–53 μ) coated with 50% (w/w) β,β'-oxydipropionitrile exhibited high capacity factors which were independent of carrier linear velocity. Such columns have low bleed rate and large sample capacity (at least 1 mg. in 2-mm. i.d. column). Heavily loaded columns should perform well in preparative applications, providing the stationary phase can be separated easily from the solutes. Kirkland (23) recently introduced the use of 5 6-μ silica microspheres. This packing is not yet commercially available.

A fluorocarbon support[11] coated with 23% Amberlite LA-1 gave excellent separation of steroids by reverse phase chromatography (120). Zipax and diatomaceous earth supports were also used in this study.

Karger *et al.* (24) introduced surface-textured beads, small particle diameter fractions of GLC-100 support[12]. Although very efficient columns (5500 plates/m., 1 cm./sec.) were produced, the capacity of the columns was poor.

Kirkland (33, 48) reviewed the various packed columns and the experimental techniques of LLC.

The choice of stationary phase in LLC is, at this stage, largely trial and error. Commonly, binary two-phase systems are used. For polar solutes, polar mobile phases such as β,β'-oxydipropionitrile, 1,3-propanediol, ethylene glycol, and Carbowax are used with nonpolar carriers saturated with stationary phase. To decrease retention times, polar modifiers such as chloroform, tetrahydrofuran, or alcohol can be added to the carrier up to about 10% (v/v). Binary, ternary, or quaternary two-phase systems are also useful.

Huber *et al.* (114, 118) described six ternary two-phase systems of water, ethanol, and isooctane for the analysis of steroids. With such systems, the relative polarities of the two phases can be varied to achieve optimum k' and α values. Other possible ternary systems are chloroform cyclohexane nitromethane, benzene–water–alcohol, and water ethyl acetate–*n*-butanol. Commonly, the polar phase is used as the stationary phase; however, for reverse phase applications, the less polar phase can be coated onto surface-deactivated supports. Commonly used nonpolar, stationary phases are squalene (112), hydrocarbon, or cyano ethyl silicone polymers (121). A series of liquid–liquid partition systems which may find use in LLC was described by Metzsch (122).

Experimental techniques necessary to obtain precise quantitative analysis with high speed LLC were described by Leitch (123).

Permanently Bonded Stationary Phases—LLC has such disadvantages as the tendency of the stationary phase to bleed and the inability to solvent program. To overcome these disadvantages, column packings with chemically bonded, organic, stationary phases have been developed. Two different types of chemically bonded phases are commercially available.

1. Esterified Siliceous Supports (Brushes)—Esterification of surface-active silanol groups (Si—O—H) of silica with alcohols creates the Si—O—C bond at the silica surface. Halasz and Sebestian (124) bonded 3-hydroxypropionitrile to the surface of Porasil C and demonstrated the usefulness of "brushes" for fast gas and liquid chromatographic separations. Durapaks[3] are commercially available silicate ester packings. A more efficient packing is made by the esterification of Corasil. The disadvantage of these packings is that the Si—O—C bond is not hydrolytically stable. In addition, extreme caution is necessary if the eluant contains proton donor liquids such as isopropanol (125). With such solvents, a good proportion of the bonded material elutes (126).

A more promising brush-type bonded phase is based upon the much more hydrolytically and thermally stable Si—C bond. Locke *et al.* (127) produced naphthyl-Porasil C by chlorinating the surface of Porasil with silicon tetrachloride or titanium tetrachloride followed by coupling with naphthylmagnesium bromide. Organic contents of 4.0 ± 0.5% were found. The reactive, bonded naphthalene ring can undergo such reactions as bromination or sulfonation. Repeated bromination of naphthyl-Porasil C and combination with naphthylmagnesium bromide provided a polynaphthyl-Porasil containing as much as 24% by weight of organic material. Both cation and anion exchangers were prepared from these substituted Porasils.

2. Chemically Bonded Silicone Polymers—Bonded silicone polymers are prepared by the reaction of organochlorosilanes with the active surface hydroxyls to form silicone polymers of the type Si—O—(R_2 Si—O—)$_n$, where R is an organic radical bonded by carbon to the siloxane chain. Aue and Hastings (128) described the means of preparation and chromatographic applications of surface-bonded silicones to diatomaceous earths, silica gels, silica beads, and glass beads. These materials were thermally and hydrolytically stable.

Similarly, Kirkland (49) and Kirkland and De Stefano (129) introduced two permanently bonded silicone polymer phases, where R = $C_6H_{12}O_2$, R′ = O—(ether bonded phase) and R = C_2H_4CN, R″ = CH_3 or —O— (nitrile bonded phase), for HPLC. Schmit *et al.* (130) introduced a bonded phase where R = $C_{18}H_{37}$ (octadecyl silicone) for reverse phase chromatography. Both the ether and nitrile bonded phases show selectivity toward proton donors (129). The octadecyl phase is selective for samples that are sparingly soluble in water and fairly soluble in alcohols and/or alkanes (130). The retention mechanism on these columns is not clearly understood; however, there is evidence that the mechanism is a combination of both partition and adsorption (33, 49, 130). Unlike conventional liquid–liquid systems, the temperature, the modifier, or the percent modifier can be varied at will without any column deterioration. Undoubtedly, many future developments in LCC will involve synthesis of many new bonded phases of varied polarities.

Liquid–Solid Chromatography For reviews and for detailed discussion of the experimental technique and selectivity in liquid–solid chromatography (LSC), consult the works of Snyder (1–3, 109, 110, 131–133).

[11] Plaskon CTFE-2300, Allied Chemical.
[12] Corning Glass.

LSC is best suited to samples of intermediate molecular weight (<1000), particularly those that are oil soluble (131). Any sample type that has been successfully chromatographed by TLC can be separated by LSC. Separations are usually carried out on polar adsorbents such as silica, alumina, or other inorganic solids[13].

Both porous layer materials and porous supports are used in high performance LSC. The porous layer materials (alumina and silica) produce faster and more efficient separations than porous support materials. Little *et al.* (36) found pellicular silica (Corasil I and II) to give substantially less peak broadening than conventional porous silica beads (Porasil) of the same particle diameter (37–50 μ). However, the disadvantage of porous layer beads is their low sample capacity. Recently, Majors (134) showed that columns packed with 10-μ diameter silica gel[14], when packed by the balanced slurry technique, can give 10^4 theoretical plates/m. Sample sizes of 1 mg./g. of adsorbent can be injected on such columns.

Snyder (2, 3) reviewed the factors affecting column efficiency in LSC.

Stewart *et al.* (50) compared high pressure LSC with TLC and found comparable separations; however, LSC produced better resolution and shorter analysis times.

Lebedeva *et al.* (135) studied the effect of the geometrical structure and the surface chemistry of silica gels on separations in LSC. They concluded that, for analytical purposes, it is preferable to use macroporous silica gels with specific surface areas of 80–300 $m.^2/g.$ and an average pore radius greater than 80 Å.

The need to control carefully the water content of the adsorbent and the mobile phase has been emphasized (131, 132). The addition of water to the adsorbent increases linear sample capacity and efficiency. For porous silica or alumina, 0.02–0.04 g. of water should be added for each 100 $m.^2$ of surface area (131).

The use of adsorbents impregnated with complexing agents can greatly improve separations of isomers and compounds within a homologous series. On the other hand, classical LSC is most selective for compound classes. Snyder (132) reviewed the use of complexing agents in LSC. For example, adsorbents impregnated with silver nitrate are selective for olefins. Recently, Vivilecchia *et al.* (136) used Zipax impregnated with silver oxide as a specific adsorbent for the rapid separation of polynuclear aza aromatic hydrocarbons. Selectivity is based upon complexation between the aromatic nitrogen atom and the silver ions.

Ion-Exchange Chromatography– The speed of ion-exchange chromatography was significantly improved by the development of pellicular ion exchangers by Horvath and coworkers (38). Pellicular ion exchangers consist of a nonporous, central core and a thin, porous outer shell of the ion-exchange resin. Similar materials were introduced by Kirkland (39, 40). Both anion and cation exchangers are available commercially[15]. These materials have small ion-exchange capacities in the order of 8–10 μeq./g. Dupont's cation exchanger exhibits an exchange capacity of 3.5 μeq./g. (40). Although sample capacity is low, these exchangers exhibit high efficiency.

Spherical, porous ion-exchange resins of small particle sizes in the range of 10 μ can be used as a high efficiency, high capacity packing (20, 43). A tabulation of the various ion exchangers for HPLC was compiled (134).

The performance of ion exchange is a complex function of many variables, including temperature, pH, buffer type, and ionic strength. Increasing temperature generally reduces retention volumes and improves column efficiency (38*a*, 40). Column performance improves with increasing temperature due to increased solute diffusivity in both phases. At present, no good guide exists for the optimization of the mobile phase. However, resolution is primarily affected by the pH and ionic strength. Temperature is of less importance in this respect.

To achieve optimum resolution of adenine and its metabolites, Gere *et al.* (137) reported that it is best to keep the temperature as high as possible while varying the pH and ionic strength. Since columns packed with pellicular ion-exchange resins are characterized by a large ratio of mobile phase to stationary phase, eluent strengths of the mobile phase can be much lower than in conventional ion-exchange columns.

Gel Chromatography– Steric-exclusion chromatography is most commonly used for the analysis of biological macromolecules and synthetic polymers. The large number of publications describing the principles and applications of gel chromatography are far beyond the limits of this paper. General reviews (138–140) and a monograph (141) were published on this subject.

Programming—The broad variance in band migration rates of a multicomponent sample under fixed experimental conditions (normal elution) often leads to poor separation of the first eluted components and/or excessive separation times with concomitantly poor detectability. This "general elution problem" can be handled by several techniques: flow or pressure programming, solvent programming, temperature programming, or coupled column operation (stationary phase programming).

Flow programming (142, 143) involves the continuous increase of mobile phase velocity to increase band migration rates of the later eluting peaks. In addition, slow mobile phase velocity at the beginning of elution can lead to increased resolution for the weakly retained components due to an increase in column efficiency at lower flow rates. However, resolution at the back end of the chromatogram is sacrificed (higher mobile phase velocity) as compared to normal elution (143).

The other techniques involve changes in capacity factors (k' programming). Of these techniques, solvent programming (gradient elution) is the most common. Snyder (144) reviewed gradient elution, and Henry (53) described several commercial gradient devices. Other gradient devices were recently described (92, 145, 146). Snyder and Saunders (147) theoretically derived optimum conditions for solvent programming

[13] See *Reference 134* for a complete compilation of LSC adsorbents.
[14] Available from E. M. Laboratories and Varian.
[15] Northgate Laboratories and Dupont Instruments.

with LSC. Under optimum conditions, gradient elution can provide marked improvement in resolution at all points in the chromatogram, particularly at the front end (143).

Temperature programming in LCC has not found much use. Two types of temperature programming have been used: "normal" programming where the temperature is raised during the separation (135) and "inverse" programming where the temperature is lowered (142, 148). Inverse programming is restricted to LSC with mobile phases containing a "moderator," a very strongly adsorbing compound at low concentration (*e.g.*, 0.15% isopropanol in *n*-heptane). As the temperature is lowered, the moderator covers more of the adsorbent active sites, thereby reducing the k' values of the solutes. The major problem with this technique is the long times required to reequilibrate the column to the starting condition (142).

Coupled-column operation involves the use of two or more columns, each with a different stationary phase or with the same stationary phase but different column lengths (143). The latter does not involve change in k' values. Snyder (143) described an LSC system where adsorbent strength is varied by water deactivation. Recently, Scott *et al.* (20) coupled anion- and cation-exchange columns for the analysis of urine constituents. With parallel gradient elution of the columns after injection, 16 new peaks (total >100) were resolved and analysis time was reduced from 24 to 14 hr.

Snyder (143) compared normal elution, coupled columns, solvent programming, flow programming, and temperature programming under time normalization. He found that resolution decreased in the order solvent programming > coupled columns > temperature programming > flow programming > normal elution. Solvent programming is especially useful for unknown samples but of less value for routine or repetitive samples since reequilibration time is long. Temperature programming has the same disadvantage. Coupled columns and flow programming are more amenable to repetitive analysis.

MEASUREMENT OF COLUMN PERFORMANCE

Since capacity factors (k') in HPLC are generally small, the use of the number of theoretical plates (N) as a measure of the separating power of a column is unsatisfactory since resolution is also a function of k'. A more suitable parameter is the number of effective plates, N_{eff} (6, 149), where:

$$N_{eff} = \left(\frac{k'}{1 + k'}\right)^2 N = 16\left(\frac{t_r - t_0}{w}\right)^2 \qquad \text{(Eq. 15)}$$

Effective plates is related to resolution by:

$$R_S = {}^1/_4\left(\frac{\alpha - 1}{\alpha}\right)N_{eff}^{1/2} \qquad \text{(Eq. 16)}$$

The number of effective plates per unit time, N_{eff}/t, can tell directly how long a separation must take; N_{eff}/t is related to k' by the following expression:

$$N_{eff}/t = \frac{V}{H}\frac{k'^2}{(1 + k')^3} \qquad \text{(Eq. 17)}$$

If H is assumed to be independent of k' (which is often true in HPLC), the optimum k' for fast separations is about 2 (6).

Some workers prefer the reduced parameters (5) for comparing column efficiency of different chromatographic systems as a function of mobile phase velocity. Reduced plate height (h), equal to H/d_p, and the reduced velocity (v), equal to Vd_p, D_m, are used instead of H and V. The reduced plate height normalizes H for particle diameter, and the reduced velocity normalizes for diffusion over a particle diameter distance. Halasz (125) and Snyder (3) pointed out the dangers of using reduced parameters for comparing different HPLC columns.

A semiquantitative method for comparing *H versus V* curves of different columns was described (3, 143); *H versus V* curves were found to obey the empirical relationship:

$$H = DV^n \qquad \text{(Eq. 18)}$$

where D is a constant for a given column and set of experimental conditions (*e.g.*, type of column packing, particle size, and packing technique), and n is 0.4 for LSC columns. This equation affords a simple basis for comparing column efficiencies obtained by different workers, using any set of experimental conditions.

The value of D for silica is found to decrease with decreasing d_p (4). Kirkland (45) found D to decrease with decreasing d_p down to at least 37 μ with Zipax coated with 1% stationary liquid.

The importance of extracolumn band broadening from the injector and detector should not be neglected in the determination of column performance since the variance of the peak measured by the detector is a summation of all the variances in the chromatographic system. Deininger and Halasz (150) considered the effect of the equipment on measured column efficiency and resolution.

PHARMACEUTICAL APPLICATIONS

To date, a relatively limited number of practical applications of HPLC has been reported in the literature. This paucity of publications can be expected to change very rapidly with the ever increasing availability of commercial instrumentation, with improved column technology, and with the realization that many separations, which had heretofore been both tedious and complicated, may now be effected quite readily by means of this powerful analytical technique. Many applications that have been developed are illustrative of this method's immense value for pharmacological studies of drug substances and their metabolites and for clinical investigations of metabolic disorders.

Schmit *et al.* (130) described the use of high speed reverse phase liquid chromatography for the separation of natural products and also biochemicals. The biologically active constituents of hashish were isolated and chromatographed by gradient elution (water to methanol) on an octadecylsilane permaphase column. Both water-soluble and oil-soluble vitamins have been separated on an octadecylsilane permaphase column, using a water to methanol gradient.

General—In a brief survey of the applicability of high speed liquid chromatography (HSLC) to pharmaceutical analysis, Williams *et al.* (151) described procedures for the rapid determination of different classes of drugs.

Using a Zipax controlled-surface porosity support coated with a 1% polyamide stationary phase, the separation of such antibiotics as penicillin and its derivatives, myosins, and rifampin was achieved. A suitable mobile phase was hexane–ethanol (75:25), which was also capable of separating impurities from these antibiotics.

Steroids and a variety of their derivatives have been successfully chromatographed from a number of matrixes using reverse phase chromatography on a hydrocarbon column, with a water–methanol solution as the eluant. Efficient separations of some steroids have also been obtained by normal phase chromatography on an ethylene glycol column, using hexane–chloroform as the eluting solvent.

A single-tablet analysis of thiabutazine was presented as an example of a rapid separation for a diuretic. The analysis was performed on an oxypropionitrile column, using *n*-hexane for the elution. The total time for elution was 4 min., with the minimum detectable limit being 10 ng. of the diuretic.

The antihistamine chlorpheniramine maleate was chromatographed in 2 min. on a trimethylene glycol column using 10% chloroform–*n*-hexane. Analyses were carried out on single-component and multicomponent tablets with no interferences from excipients or the other actives.

Barbiturates and Alkaloids—The applicability of high speed chromatography for the analysis of barbiturates, diphenylhydantoin, and their hydroxylated metabolites was reported (152). Separations were performed without the necessity of any derivatization, using a pellicular anion-exchange column and eluting with either a nongradient or gradient mode of operation. Column inlet pressures ranged from 700 to 1600 psig., and flow rates ranged from 26 to 36 ml./hr. The eluting peaks were detected at the microgram level with the aid of a fixed wavelength (254 nm.) UV detector.

Optimal conditions for the separation of diphenylhydantoin and its phenolic metabolite were established to be analogous to those conditions necessary for the separation of phenobarbital and the hydroxy derivative of phenobarbital. A nongradient mode of elution, performed at 80° using a 20.0 m*M* phosphate solution, buffered at pH 3.5, produced the most rapid and satisfactory resolution for these compounds. These conditions were unsatisfactory for other barbiturates, however. Successful separation of these parent compounds and their metabolites required the use of a linear sodium chloride gradient at 80°. The sensitivity of the method could be increased by working with neutral solutions due to the increased absorptivity of the barbiturates in more alkaline media.

Alkaloids in plant extracts have been separated on oxypropionitrile and cyanoethyl silicone columns, using either *n*-heptane or *n*-heptane with a polar modifier as the eluant (121). The choice of eluant depended upon how strongly the alkaloids were retained on the columns.

Urine and Blood Analysis—Burtis *et al.* (153) reported a high pressure anion-exchange chromatographic technique for the separation and identification of two metabolites of phenacetin in urine. These metabolites were ultimately shown to be 4-hydroxyacetanilide and 3-methoxy-4-hydroxyacetanilide. The system employed was a UV analyzer[16]; this system consisted of a 200-cm. small bore column filled with Dowex 1-X8 resin and a spectrophotometer, which was used to monitor the column effluents at various wavelengths. The mobile phase was an ammonium acetate–acetic acid buffer.

The UV analyzer (154–158) was able to separate 140 UV-absorbing compounds in urine and should prove to be invaluable in many pharmacological studies. In the present example, the two metabolites of phenacetin were separated on the anion-exchange column and subsequently identified by their UV, mass spectrometric, and IR spectra.

Recently, Scott *et al.* (20) described modifications of their original system to increase resolution and also to decrease analysis time. By using coupled anion- and cation-exchange chromatography and gradient elution (in which the concentration of the acetate ion in an ammonium acetate–acetic acid solution buffered at pH 4.4 was gradually increased from 0.015 to 6 *M*), 16 additional peaks were separated from urine samples. The anion-exchange resin used was Aminex A-27, with quaternary ammonium active sites, while the cation-exchange resin employed was Aminex A-6, with sulfonic acid active sites. The eluant was pumped at a flow rate of about 10.5 ml./hr. through the 150-cm. long column at pressures up to 3500 p.s.i., and the eluting peaks were detected at two wavelengths in the UV (254 and 280 nm.). With this system, the time of analysis was decreased from 24 to 14 hr.

Although the UV analyzer is capable of resolving a large number of components in complex biological mixtures, the qualitative identification of the eluting peaks, for the most part, has been extremely difficult. By using the chromatographic technique proposed by Scott *et al.* (154), Burtis (21) reported that reproducible chromatograms of urinary samples could be accomplished on a liquid chromatograph[17] by high pressure anion-exchange chromatography. Detection of nanogram amounts of substances was possible using an efficient microvolume UV photometer. It was proposed that the resultant chromatograms or "urinary profiles" could be used to great advantage in the diagnosis of certain abnormal metabolic or pathological conditions.

At present, only 50 of the molecular constituents that have been reported have been identified by a combination of analytical techniques (159).

Scott *et al.* (157) also reported the development of a companion carbohydrate analyzer, which has successfully separated and detected 48 different carbohydrates in urine and blood serum. This system also utilizes a high pressure anion-exchange column. Qualitative and

[16] Developed at the Oak Ridge National Laboratory.
[17] Varian Aerograph model LCS-1010.

quantitative detection of peaks was accomplished by use of a colorimeter, the color being produced through reaction of the eluting carbohydrates with a phenol–sulfuric acid reagent. Sodium borate–boric acid buffer concentration gradient solutions served as the eluant. The most effective anion-exchange resin was reported to be a Type 1 resin of small particle size, with a final cross-linkage of 7–10%.

The use of the carbohydrate analyzer in the clinical laboratory in the investigation of various carbohydrate metabolism disorders was proposed (160). The detection of excreted sugars and some of their derivatives was possible without interferences from other eluting substances such as vitamins, aliphatic and aromatic hydroxy and keto acids, and polysaccharides.

The automation of a system was described for rapid separations of saccharides by high pressure ion-exchange chromatography, using a neutral pH boric acid–2,3-butanediol buffer solution to minimize alkaline rearrangement reactions (161).

An improved automated system with more rapid analysis times was developed by Floridi (162). This system utilizes from one to three different borate buffers adjusted to pH 8.40 or 8.80. The analysis of the eluting mono-, di-, and trisaccharides was accomplished by the orcinol colorimetric method[18]. The one-buffer elution system allowed rapid and effective separations of monosaccharides, the two-buffer elution system produced high resolution of di- and trisaccharides, while the three-buffer solution effected a separation of 17 different saccharides in 10 hr. In all cases, the analyses were carried out on Dowex ion-exchange resin at a column temperature of 55°. Flow rates were varied according to the particular system employed.

A high speed ion-exchange chromatographic method was devised for the direct analysis of glucuronide and sulfate conjugates of drug substances in biological samples (163, 164). The analyses were carried out at 80° in narrow bore stainless steel columns, 250 cm. in length, containing a pellicular anion-exchange resin. Column inlet pressures were maintained between 800 and 1000 psig., giving rise to a flow rate of 0.5 ml./min. A fixed-wavelength (254 nm.) UV detector was employed to monitor the column effluent.

Both nongradient and gradient elution methods were required. The use of pH 3.0 formic acid solutions of high ionic strength (1.0 *M* potassium chloride) and a linear gradient solution of potassium chloride permitted the successful separation and quantitative determination of sulfate and glucuronide conjugates in urine in less than 40 min.

Benzodiazepines—To avoid the undesirable task of acid hydrolysis or derivatization, which is necessary for the GC determination of benzodiazepines, Scott and Bommer (126) utilized HSLC for the separation of these pharmacologically important compounds. The stationary phase was Durapak "OPN"—the oxypropionitrile group chemically bonded to porous glass beads—which was dry packed in a narrow bore stainless steel column 1 m. in length. Elution of the column was effected at a solvent flow rate of 1 ml./min. using either: (*a*) a constant composition hexane–isopropanol mixture or (*b*) an initial elution with 100% hexane followed by a stepwise change to a 70:30 mixture of hexane–isopropanol. The latter solvent system served to sharpen the elution pattern of the slowest eluting component without sacrificing the resolution of the more rapidly eluting substances. A fixed-wavelength (254 nm.) UV microvolume photometric cell detected the eluting substances at the microgram level.

This procedure not only effectively separated mixtures of benzodiazepines but also was useful for the separation and quantitative determination of the parent compounds and their metabolites in a pharmacological study of urine samples.

Steroids—High resolution liquid chromatography (HRLC) at moderate pressures, using small bore borosilicate glass columns, 50 cm. in length, was shown to be effective for the rapid analysis of steroid hormones (120). A representative number of polar and moderately polar steroids was separated by reverse phase chromatography, and separation conditions for the various classes of steroid hormones were described.

Three types of solid supports were investigated: (*a*) Anakrom AB diatomaceous earth, (*b*) Plaskon CTFE-2330 terpolymer, and (*c*) Zipax controlled-surface porosity silica beads. In all cases, Amberlite LA-1, a water-insoluble amine, was used as the stationary phase; each support was coated at a level giving optimal results for that material. Water or a water–methanol mixture was used as the eluant.

The separation patterns observed for the four classes of steroids studied (adrenal corticosteroids, androgens, progestins, and estrogens) indicated that the main factor governing the chromatography of these compounds was actually a competition between liquid–liquid partitioning with the stationary liquid phase and liquid–solid adsorption with the solid support. It was further demonstrated that the relative effect of each separation mechanism was dependent upon the percentage of liquid loading used. Therefore, optimal resolutions for various pairs of compounds could be obtained by merely varying the level of liquid loading.

Henry *et al.* (165) surveyed numerous applications of HSLC to the analysis of steroids and steroid conjugates. The column effluent was continually monitored with both a fixed-wavelength (254 nm.) UV photometer and a refractive index detector. The advantages and disadvantages of each detector were noted. For UV-absorbing steroids, the UV detector had a lower detection limit of about 10 ng., while the refractive index detector had a 1-ng. lower detection limit whether or not the steroid absorbed in the UV. The formation of a strongly absorbing 2,4-dinitrophenylhydrazine derivative of the nonabsorbing carbonyl-containing steroids was proposed as a useful and attractive technique for increasing sensitivities for these compounds.

Examples of separations of all major types of steroids (including estrogens, androgens, progestogens, and adrenocortical hormones) by conventional liquid–liquid partition chromatography, reverse phase chromatography, and ion-exchange chromatography were presented, and useful column packing materials, stationary phases and mobile phases were described.

[18] Performed with a Technicon Auto-Analyzer.

Mollica *et al.* (166) described a suitable stability-indicating assay for the steroid flumethasone pivalate. A quantitative determination could be effected by using a controlled-surface porosity support coated with β,β′-oxydipropionitrile as the stationary phase and eluting with a solvent system of 5% ethyl acetate and 0.2% acetonitrile in hexane. Other chromatographic studies were reported for the steroids dexamethasone, prednisolone, and hydrocortisone.

A rapid and precise method for the quantitative determination of estrogens in urine was developed and applied to the determination of estriol in pregnancy urine (118). Detection of the estrogens was accomplished with a UV spectrophotometer operated at a fixed wavelength of 281 nm., corresponding to the absorption maximum of this class of compounds. Separation was effected with the use of two coexistent phases of a water–ethanol–2,2,4-trimethylpentane system (molar ratios 0.229:0.680:0.09 and 0.019:0.177:0.804) as the stationary and mobile phases, respectively. The water-rich phase was coated on diatomaceous earth (28–32 μ in diameter), which was then packed into a 2.7-mm. i.d. borosilicate glass column (50 cm. in length) through which the water-poor phase eluant was pumped. All analyses were performed at a constant temperature of 22°.

Analgesics—Henry and Schmit (167) described the analyses of the active ingredients in analgesics. The analyses were performed on Zipax controlled-surface porosity supports coated with an anion-exchange resin, using small bore stainless steel columns 1 m. in length. The mobile phase was distilled water buffered at pH 9.2. To lower the retention times of the more highly retained components, the ionic strength of the mobile phase was increased by the addition of ammonium nitrate. Detection of the eluting peaks at the nanogram level was accomplished by means of a fixed-wavelength (254 nm.) UV photometer. By using benzoic acid as the internal standard, both single- and multicomponent tablets were determined quantitatively without any interference from excipients. A routine time of analysis was 10 min., using a flow rate of 1.5 ml./min. at a column inlet pressure of 1200 psig. Since all separations were performed at ambient temperature, no problems of thermal degradation occurred, as had been encountered in GC. In addition, by merely increasing the ionic strength of the mobile phase, the determination of the decomposition product, free salicylic acid, could be performed quantitatively, with pyromellitic acid employed as the internal standard.

In a similar study, the successful quantitative determination of the active ingredients in 12 commercial analgesic tablets was reported, using an anion-exchange column 300 cm. in length (168). The eluant was a 1.0 *M* aqueous solution of tromethamine buffered at pH 9.0. The flow rate was 8.6 ml./hr. at 925–1000-p.s.i. pressure and a temperature of 60°. The eluting peaks were detected with a fixed-wavelength UV detector. This chromatographic system permitted baseline separation of acetaminophen and phenacetin, which had previously eluted at the same time (1); therefore, a qualitative identification of the components in a single tablet could be made by comparison of retention times.

In an extension of this study, Wolford *et al.* (169) reported the separation of oxypurines and the determination of caffeine in pharmaceutical separations. By using 3 *M* NH_4OH as the eluant at a flow rate of 3 ml./min., caffeine was eluted as a sharp peak from a 1 × 20-cm. column in less than 10 min.; qualitative results were obtained. Phenacetin, which is strongly basic, appeared between 15 and 30 min. while such compounds as aspirin, salicylamide, tetracycline, and barbiturates were effectively retained.

Amino Acids, Nucleotides, and Nucleic Acid Bases—High speed ion-exchange chromatography on small bore columns has been shown to be amenable to the analysis of amino acids using a modified sequential multisample amino acid analyzer[19] (170).

By eluting the column with citrate buffers at varying pH's, a flow rate of 0.5 ml./min., and a pressure of 600 p.s.i., satisfactory resolutions were obtained for the acid, neutral, and basic amino acids in approximately 60 min. A photometer equipped with a high efficiency flow cell detected the eluting peaks, the areas of which were found to be directly proportional to the amount of amino acid present in the sample.

Numerous authors have used HSLC to great advantage for the separation and identification of nucleotides, nucleosides, and nucleic acid bases.

The ribonucleoside mono-, di-, and triphosphates of cytidylic, uridylic, adenylic, and guanylic acids were separated on anion-active and cation-active resins coated on glass beads, producing pellicular ion exchangers (38*a*). Rapid separations of nanomole quantities of the substances were achieved by using a linear gradient elution with a phosphate or an ammonium formate buffer solution. The eluting peaks were detected by means of a spectrophotometer at a wavelength of 260 nm. using a microvolume flow cell. Analyses could be accomplished in all cases in less than 90 min.

The four major bases (uracil, guanine, adenine, and cytosine) and nucleosides (uridine, guanosine, adenosine, and cytidine) formed by the hydrolysis of RNA were successfully separated and detected at subnanomole levels using a pellicular cation-exchange resin in small bore stainless steel columns (38*b*). Acidic potassium or ammonium phosphate solutions served as the mobile phase, and detection at these levels was afforded by a micro-UV detector operating at a fixed wavelength of 254 nm. The elapsed time for an analysis was 6 min. The optimal conditions for these separations were investigated and described. It was found that the pH of the sample and of the eluant had the most pronounced effect on the resolution.

A similar separation of the nucleotides and nucleic acid bases and other less commonly encountered purines and pyrimidines was successfully performed on controlled-surface porosity supports coated with strong cation- and/or anion-exchange resins (40). A 0.01 *N* nitric acid solution was utilized for the elution. The total time of analysis for the major hydrolysates of RNA was 5 min. By employing an ammonium formate solution first at 3000 p.s.i. with a flow rate of 50 ml./hr.

[19] Technicon.

and then at 4600 p.s.i. with a flow rate of 80 ml./hr., the elution times for these alkaline hydrolysis products were reduced to 4 and 2 min., respectively, by Burtis (171), who also suggested the obvious applicability of the method for the determination of the base composition of DNA following an enzymatic, rather than alkaline, hydrolysis reaction. The elution times and the conditions for many "unusual bases" and common ribo- and deoxynucleosides were also reported. Quantitation and detection at the nanomole to picomole level were possible. These high speed separations, with no derivative formation required, rival those observed for GC separations.

The use of citrate and acetate buffers as effective eluants for the chromatography of these compounds on a cation-exchange resin also was noted (172).

To eliminate the interferences and anomalous peaks caused by UV-absorbing substances present as contaminants in buffer solutions described by Horvath and Lipsky (38*b*), Shmukler (173) devised a purification system for potassium dihydrogen phosphate. Due to the relatively low solubility of potassium dihydrogen phosphate in water, the non-UV-absorbing salt, potassium chloride, was added to increase the total salt content of the eluant. With this buffer system, the chromatography of adenine nucleotides and ^{32}P-labeled compounds in a deproteinized mitochondrial reaction mixture was studied (174).

Sample preparation methods and elution conditions for the separation of mononucleotides, ribomononucleotides, deoxyribomononucleotides, nucleoside diphosphates, and dinucleotides were reported and their *R* values were tabulated (175). The chromatographic separation was carried out on an anion-exchange column, maintained at 70°, using a linear or exponential gradient elution technique and "purified" potassium phosphate solutions.

The qualitative and quantitative determination of nucleotide profiles of cell extracts was characterized (176), and optimal conditions for the rapid separation of the mono-, di-, and triphosphates of the naturally occurring ribosides, as well as for the sulfur analogs of some of these compounds, were noted. The method was developed with the aid of a high pressure chromatograph[20] equipped with an anion-exchange column and a double-beam UV detector operated at 254 nm. A potassium phosphate–potassium chloride gradient served as the eluant, and the eluting peaks were identified by one or more of the following methods: (*a*) spectrophotometric or chemical means, (*b*) injection of known standards, (*c*) comparison with chromatograms of known substances, and (*d*) use of known enzymatic reactions. "Enzymatic peak shifts" not only served to identify peaks but also aided in unmasking a chromatogram and allowing the detection of other smaller peaks to be made. A further use of this system combined with isotopic labeling to measure the radiospecific activities of nucleotides was proposed.

The four common 5′-deoxyribonucleotides were successfully analyzed on a Zipax strong anion-exchange column eluted with 0.008 *M* phosphate buffer at pH 4.40 (177).

Nucleotides, nucleosides, and nucleic acid bases were also successfully separated by ligand-exchange chromatography using a cation-exchange resin, Chelex 100, impregnated with copper (II) ion (178). The flow rate of the eluting agent (water and/or ammonium hydroxide, depending upon the substances being separated) was maintained at 0.75 ml./min., and the effluent was continually monitored with a UV spectrophotometer. The nucleotides were not retained on the column; the weakly basic nucleosides were separated by elution with water, the more basic nucleosides were resolved with 1 *N* ammonium hydroxide, and the nucleic acid bases required 2.5 *N* ammonium hydroxide to be displaced from the column.

The quantitative determination of enzymatically formed adenyl cyclase at the microgram level was reported (179), using high pressure anion-exchange chromatography following an initial zinc–barium precipitation step which removed interfering substances. The elution was effected by a nongradient mode of operation with a pH 2.20 hydrochloric acid solution as the eluant. A flow rate of 12 ml./hr. with an inlet pressure of 450 550 p.s.i. was employed, while the column temperature was controlled at 80°. Detection of the peaks was accomplished with a sensitive microvolume UV flow cell. The total time for an analysis was about 10 min.

Qualitative identification and quantitative detection of adenine and its metabolites in body fluids were described, and an empirical means of optimizing the separation conditions was discussed, presenting a systematic and logical approach to a HSLC problem (137).

Aza Aromatic Hydrocarbons—Snyder (133) developed a rapid liquid–solid chromatographic method for the analysis of hydrogenated quinoline mixtures, using alumina as the adsorbent and a 60% water-saturated 35% dichloromethane–pentane mixture as the eluting solvent. Qualitative and quantitative analyses could be performed over a long period with no changes in the efficiency of the column being observed, provided that the water level of the alumina was maintained at a constant level and the column was regenerated occasionally to remove strongly adsorbed components. Routine analyses of quinoline mixtures could be performed in less than 30 min., with the detection of the eluting substances being realized with a UV spectrophotometer equipped with a microvolume flow cell. Problems inherent in such procedures and methods of solving them were also presented.

A high speed liquid–solid column chromatographic procedure for the separation of polynuclear aza heterocyclic compounds was reported (136). The adsorbent was Zipax, a high efficiency chromatographic support, the surface of which was impregnated with silver ions. Separation was achieved by means of formation of donor–acceptor complexes between the silver ion and the heterocyclic nitrogen. The order of elution was found to be dependent upon both the basicity of the nitrogen and the steric accessibility of the lone pair of electrons.

A 1% (v/v) acetonitrile in *n*-hexane solution produced

[20] Picker Nuclear.

highly efficient separations. Unlike many liquid–solid chromatographic methods, no water deactivation of the column nor careful control of the solvent water content was required for this method to give consistently good results.

A high speed liquid chromatographic method has been developed for the separation and quantitative determination of isomeric mixtures of the cyano-, carboxamido-, and carboxy-substituted pyridines. A 1-m. × 2.1-mm. i.d. column filled with a strong cation-exchange resin (1% sulfonated fluorocarbon) coated on Zipax was employed. Elution was effected with an aqueous solution of 0.1 *N* sodium nitrate and 0.1 *N* phosphoric acid at a flow rate of 1.70 ml./min. at an inlet pressure of 1500 p.s.i. Detection of the eluting substances was accomplished with a fixed-wavelength (254 nm.) UV detector.

The analysis of trisulfapyrimidines by cation-exchange liquid chromatography was accomplished using a phosphate buffer solution for the mobile phase; an application for the quantitative determination of sulfadiazine, sulfamerazine, and sulfamethazine was presented (180).

Miscellaneous—A liquid–solid adsorption chromatographic technique, using microbore glass columns packed with dry silica gel, was developed by Gordon and Peters (181) to separate 4,4′-diaminodiphenylsulfone from its monosubstituted and disubstituted acetylated derivatives. 4,4′-Diaminodiphenylsulfone has had a great amount of pharmacological interest since it has been shown to be a highly effective antileprotic agent as well as an antimalarial drug.

The procedure was adapted from a TLC separation, with anhydrous ethyl acetate as the eluting solvent. A satisfactory separation of all three compounds was obtained in less than 30 min. by pumping the mobile phase through a 30-cm. column at a pressure of 100 p.s.i. and a flow rate of 0.25 ml./min. Detection of the compounds at the microgram level was accomplished by measuring the UV absorption at 280 nm. A linear relationship existed between the peak areas obtained and the amount of substance, thereby providing a rapid quantitative estimation of each compound.

N,*N*-Dimethyl-*p*-aminobenzeneazobenzoyl chloride reacts with a wide range of organic compounds to form colored products with differing polarities. This reaction was used in conjunction with HPLC, using small bore glass columns, and the effects of the various parameters were discussed (182). Either high speed cation-exchange chromatography using a strongly acidic sulfonated styrene–divinylbenzene resin or high speed liquid–solid adsorption chromatography on silica columns permitted satisfactory separations. A microvolume flow-through photometric detector continuously monitored the column effluent stream. The effect of the hydrochloric acid concentration in aqueous methanolic or aqueous ethanolic solutions and also the effect of the alcohol concentration in the eluting solutions were determined.

The acidic and neutral catabolites from catecholamines were quantitatively and rapidly separated on a cation-exchange resin, PA-28 (183). A scheme for the elution of the catabolites formed *in vivo* from dopamine, noradrenaline, and adrenaline was outlined: the column was successively eluted with sodium citrate buffers, pH 3.28 for 15 min., followed by a sodium citrate–boric acid buffer, pH 4.53, for 100–235 min., and, finally, with 0.2 *N* sodium hydroxide for 60 min. The flow rate was maintained at 50 ml./hr. with a back-pressure of 140–200 p.s.i. in the 60-cm. × 9 mm. column. All analyses were performed at a constant temperature of 55°. The eluting peaks were detected with a spectrophotometer[21] at 280 nm.

In a similar manner, Lange and Hempel (184) demonstrated that a wide range of aromatic acids, aldehydes, and alcohols could be separated. The eluting substances were determined by: (*a*) measuring the absorbance of the eluate at 280 nm. or (*b*) determining the fluorescence at 315 nm. of the effluent fractions by means of a spectrofluorometer[22]. The elution times for 50 aromatic compounds were tabulated, with the order of elution generally being dependent upon the polarities of the substances.

Efficient separations of aromatic monosulfonates and disulfonates and of isomeric and homologous aromatic sulfonates were achieved (185) by use of high speed anion-exchange chromatography, using narrow bore columns packed with a cross-linked polyalkylene amine resin. Elution of the sorbed substances was accomplished with an aqueous organic solution of water–acetonitrile–methanol (a 1:1:1 mixture provided the best performance) and a linear salt gradient of lithium chloride. A monochromator was utilized for the absorbance measurements over the UV range from 220 to 400 nm., which permitted the maximizing of general or selective sensitivities for the sulfonates being determined.

Linear gradient elution chromatography has provided an efficient means of separation of aromatic hydrocarbons having widely different boiling points (186). Analyses were carried out on small bore glass columns packed with alumina, using a pentane–ether gradient at a flow rate of 45 ml./hr. The eluting peaks were detected with the aid of a fixed-wavelength photometer at 260 nm., and identification was made either by comparison of retention times or by addition of pure standards to the mixture being analyzed.

Beyer (187) developed a quantitative HPLC analytical method for sulfonylurea antidiabetic agents. A column of 1% hydrocarbon polymer on Zipax eluted with citrate or borate buffers separated glyburide, chlorpropamide, tolazamide, tolbutamide, and acetohexamide.

HPLC was used for the analysis of *N*,*N*-dimethyl-2,2-diphenylacetamide and its metabolites in soybean plants (188). The analysis was obtained on a 1-m. hydrocarbon polymer column eluted with a water–methanol (4:1) mixture.

APPENDIX: LIST OF SYMBOLS

A = eddy diffusion term in the Van Deemter equation

B = longitudinal molecular diffusion in the Van Deemter equation

[21] Beckman DB.
[22] Aminco-Bowman.

C = mass transfer term in the Van Deemter equation
D_m = diffusion coefficient of solute in the mobile phase
D_{is} = diffusion coefficient of solute in the stationary phase
d_c = internal diameter of the column
d_p = particle diameter of the packing
f = total porosity in the column
h = reduced plate height (H/d_p)
H = height equivalent to a theoretical plate
K = distribution coefficient
K^0 = specific permeability of a column
k' = capacity factor = $K(V_s/V_m)$
L = column length
N = number of theoretical plates
N_{eff} = number of effective plates
N_{eff}/t = effective plates per second
ΔP = column pressure drop
R_s = resolution
T_m = interparticle tortuosity factor
T_s = intraparticle tortuosity factor
t = time of analysis
t_r = retention time of peak measured from start
t_0 = retention time of a nonsorbed species
V = mobile phase velocity
V_m = column mobile phase volume (dead volume)
V_s = column stationary phase volume
W = peak width
ϵ_α = fraction of column volume occupied by phase α
ϵ_m = fraction of column volume occupied by the moving phase
ϵ_s = fraction of column volume occupied by the static phase
ϵ = fraction of the column volume occupied by the two phases
$1 - \epsilon$ = fraction of column volume occupied by the support material
η = mobile phase viscosity
$\lambda, \lambda 2$ = dimensionless constants
σ_l = length-based standard deviation of the Gaussian band
μ = micron (micrometer)

Absorption and Distribution of Naloxone in Rats after Oral and Intravenous Administration

S. H. WEINSTEIN▲, M. PFEFFER, J. M. SCHOR, L. FRANKLIN, M. MINTZ, and E. R. TUTKO

Abstract □ The effect of route of administration on the absorption and distribution of naloxone, a narcotic antagonist, was investigated in rats. Plasma levels were determined by GLC. Five minutes after intravenous administration of 1 mg./kg., the plasma concentration was 258 ng./ml. Plasma levels after low oral doses were undetectable; but after 100 mg./kg. orally, the peak level of unchanged drug was almost 5000 ng./ml. In terms of percent of administered dose, the maximum amount of naloxone in the calculated plasma volume is 1.04% of the intravenous dose *versus* 0.19% of the oral dose. Pharmacokinetic parameters were generated with a computer program; the models constructed are of a rapidly absorbed and rapidly excreted and/or metabolized drug. These results, together with results from absorption studies with ligated intestinal loops, indicate that poor absorption of naloxone is not the cause of its relatively low oral potency. *In vitro* metabolic studies with rat liver slices confirmed rapid naloxone metabolism, suggesting that the lower potency of oral naloxone compared to parenteral naloxone is due to rapid first-pass liver metabolism.

Keyphrases □ Naloxone hydrochloride—absorption and distribution after oral and intravenous administration, rats □ Absorption and distribution, naloxone hydrochloride—after oral and intravenous administration, plasma levels, liver metabolism, rats

Naloxone [(−)-*N*-allyl-14-hydroxynordihydromorphinone] is a potent narcotic antagonist upon parenteral administration to laboratory animals (1, 2) or man (3), but it is approximately one-fiftieth as po-

Absorption and Distribution of Naloxone in Rats after Oral and Intravenous Administration

S. H. WEINSTEIN▲, M. PFEFFER, J. M. SCHOR, L. FRANKLIN, M. MINTZ, and E. R. TUTKO

Abstract □ The effect of route of administration on the absorption and distribution of naloxone, a narcotic antagonist, was investigated in rats. Plasma levels were determined by GLC. Five minutes after intravenous administration of 1 mg./kg., the plasma concentration was 258 ng./ml. Plasma levels after low oral doses were undetectable; but after 100 mg./kg. orally, the peak level of unchanged drug was almost 5000 ng./ml. In terms of percent of administered dose, the maximum amount of naloxone in the calculated plasma volume is 1.04% of the intravenous dose *versus* 0.19% of the oral dose. Pharmacokinetic parameters were generated with a computer program; the models constructed are of a rapidly absorbed and rapidly excreted and/or metabolized drug. These results, together with results from absorption studies with ligated intestinal loops, indicate that poor absorption of naloxone is not the cause of its relatively low oral potency. *In vitro* metabolic studies with rat liver slices confirmed rapid naloxone metabolism, suggesting that the lower potency of oral naloxone compared to parenteral naloxone is due to rapid first-pass liver metabolism.

Keyphrases □ Naloxone hydrochloride—absorption and distribution after oral and intravenous administration, rats □ Absorption and distribution, naloxone hydrochloride—after oral and intravenous administration, plasma levels, liver metabolism, rats

Naloxone [(−)-*N*-allyl-14-hydroxynordihydromorphinone] is a potent narcotic antagonist upon parenteral administration to laboratory animals (1, 2) or man (3), but it is approximately one-fiftieth as po-

tent when administered orally in human subjects (3). A similar relationship was reported for rats and mice (4).

The reduced oral effectiveness of a drug may be due to poor or incomplete absorption from the GI tract or to rapid first-pass metabolism in the liver since orally administered drugs enter the systemic circulation *via* the hepatic portal system. To determine the extent of absorption of naloxone from the intestine, *in vivo* intestinal loop experiments were performed in rats. This technique has been used to study the absorption of many compounds including quaternary ammonium compounds (5) and digitalis glycosides (6).

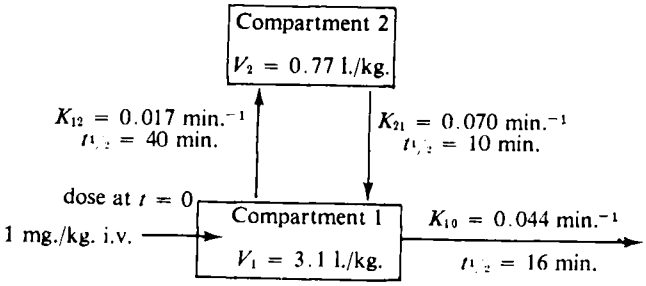
In vitro rat liver slice experiments were performed to determine the extent of naloxone metabolism in the liver. This method was previously applied to the study of morphine metabolism (7). Naloxone has been reported to undergo glucuronidation, *N*-dealkylation, and reduction of the 6-oxo group (8, 9).

Plasma levels of naloxone in rats were determined following oral and intravenous administration. Absorption and elimination rate constants, as well as other pharmacokinetic parameters, were calculated to gain insight into the fate of naloxone following administration by the two routes.

EXPERIMENTAL

Analytical Methods—Extraction of naloxone from rat plasma was performed as described by Mulé (10), except that chloroform containing 1% isopropanol was used as the solvent and was back-extracted with 1.3 ml. of 0.1 *N* HCl. A 1-ml. portion of the final hydrochloric acid extract was evaporated to dryness[1]. An internal standard, 500 ng. of tetraphenylethylene (25 μl. of a 20 mcg./ml. methanol solution), was then added. The samples were again evaporated to dryness, and 25 μl. of bis(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane[2] was added. Wilkinson and Way (11) demonstrated the efficacy of bis(trimethylsilyl)trifluoroacetamide as a silylating agent for morphine, and it was equally useful for naloxone. The tubes were flushed with dry nitrogen and closed with ground-glass stoppers, and the silylation reaction was carried out for 30 min. at 60–65° in a dry heating block[3]. One-microliter aliquots of the silylated samples were injected into a gas chromatograph[4], with carbon tetrachloride as a solvent flush. Naloxone was measured by comparing the peak height ratio of naloxone-tetraphenylethylene in the experimental samples to the peak height ratio obtained from standards extracted from plasma.

Naloxone was extracted from the liver and intestine by homogenizing the tissue in a total of 4 ml. of water (including the volume of water used to rinse the homogenizer), and the protein was precipitated by addition of 0.5 ml. of 10% $ZnSO_4$ and 0.5 ml. of 0.5 *N* NaOH. This was centrifuged 15 min. at 3000×*g*, and 3 ml. of the protein-free supernate was diluted to 15 ml. with 0.5 *M* phosphate buffer, pH 7.4. The diluted supernate was then sequentially extracted with three 15-ml. portions of chloroform. The pooled chloroform extracts were evaporated to dryness in a rotary evaporator[5], and the residue was quantitatively washed out of the evaporating flask with 5 ml. of chloroform into a conical centrifuge tube. This chloroform was removed by evaporation to dryness[1]. The residue was redissolved in 0.1 ml. chloroform containing 300 ng. of *N*-cyclobutylmethyl-7,8-dihydro-14-hydroxynormorphine (nalbuphine, 3 mcg./ml.) as the internal standard. A portion of this chloroform solution was injected into the gas chromatograph, and the naloxone was measured by comparing the peak height ratio of naloxone–nalbuphine to the peak height ratio obtained for standards also extracted from intestinal loops or rat liver slices. Metabolites such as noroxymorphone and naloxone glucuronide are not extracted under these conditions.



Scheme I—*Two-compartment open pharmacokinetic model for intravenous naloxone*

The gas chromatograph was equipped with a flame-ionization detector. The column was 3.8% UC-W98 on high performance Chromosorb W, 80–100 mesh. Conditions used were: oven, 245°; detector, 310°; flash heater, 300°; hydrogen flow rate, 37 ml./min.; helium, 75 ml./min.; and air, 350 ml./min.

Animal Studies—Three to five fasted, male, CFN rats (average weight 397 g.) were used for each time interval of the intravenous study. Naloxone hydrochloride (1 mg./ml., aqueous solution) was administered *via* the tail vein at a dose of 1 mg./kg. while the rats were under light ether anesthesia. At 5, 10, 15, 22, 30, 38, 45, 50, and 60 min. after dosing, blood was obtained by cardiac puncture with heparinized syringes. The plasma was separated by centrifugation at 3000×*g* for 20 min.

For the oral studies, naloxone hydrochloride was administered to fasted rats (average weight 375 g.) in aqueous solution (100 mg./ml.) *via* stomach tube at a dose of 100 mg./kg. At 2, 3.5, 5, 15, 22, 30, 35, 45, 50, and 60 min. after dosing, blood was obtained as already described. Four to 11 rats were used for each time interval.

Intestinal loops were prepared, while fasted rats were under ether anesthesia, by exposing the intestine and locating a section supplied by three blood vessels, approximately 20–22 cm. from the pyloric sphincter. One end of a segment approximately 2.54 cm. (1 in.) in length was securely ligated with thread. The other end of the segment was ligated with a 22-gauge needle entering the end through the center of the tightened loop of thread. Five hundred micrograms of the drug in 0.5 ml. of saline solution was injected and, as the needle was removed, the ligature was completed. The midline incision made to expose the intestine was then closed. At 30, 60, or 90 min. after treatment, the animals were again anesthetized and the previously tied section of gut was removed for analysis as already described. Controls for these intestinal loop experiments consisted of the incubation of 500 mcg. of naloxone in gut sections *in vitro* at 37° in normal saline for a time interval equal to that of the *in vivo* incubation. Loss of drug by absorption was determined by comparing the naloxone recovered from *in vivo* intestinal loops to the naloxone recovered from *in vitro* loops. Loss of drug due to metabolism by intestinal tissue itself was determined by comparing the naloxone recovered after incubation *in vitro* in intestinal loops to the naloxone recovered from *in vitro* loops that were not incubated but were homogenized and extracted immediately after the drug was placed within the loop.

For liver slice experiments, ether-anesthetized rats were killed and the livers were immediately removed. The livers were washed with ice-cold normal saline solution and sliced with a hand microtome[6]. Three hundred milligrams of liver slices was placed in 25-ml. conical flasks containing 1.5 ml. of Krebs–Henseleit solution. Then 0.5 mg. of naloxone hydrochloride in 0.5 ml. of Krebs–Henseleit solution was added, giving a total incubation volume of 2.0 ml. Prior to use, the Krebs solution was saturated with 95% O_2–5% CO_2 (7).

The incubations were carried out in duplicate on a shaking incubator[7] at 37° under a 95% O_2–5% CO_2 atmosphere delivered at a rate of 5 ft.^{3}/hr.

After 30, 60, and 120 min., duplicate incubation mixtures were homogenized. Extraction of naloxone from the homogenized in-

cubation mixture was carried out as previously described. The extracts were analyzed for unmetabolized naloxone by GLC. The peak height ratio (naloxone–nalbuphine) of naloxone obtained from extracts of incubation mixtures was compared with peak height ratios obtained from extracts of unincubated liver–naloxone mixtures. Duplicate determinations were performed for each sample.

As controls, to determine whether loss of naloxone was an assay artifact or due to liver metabolism, incubations were also carried out with boiled liver slices.

Pharmacokinetic Calculations—A computer program (COMPT) for optimizing the solution of integral nonlinear compartmental models of drug distribution, written in extended BASIC for use in time-sharing computer systems, was used to generate pharmacokinetic parameters (12).

The mathematical formulations for compartmental models (Schemes I and II) reduce, in their most general form, to sums of exponential terms:

$$f(T) = \sum_{i=1}^{M} N_i \exp(-a_i T) \qquad \text{(Eq. 1)}$$

The formulations for the one- and two-compartment models are, respectively:

$$C = \left(\frac{D}{V}\right)\left(\frac{K_{abs}}{K_{abs} - K_{el}}\right)[\exp(-K_{el}T) - \exp(-K_{abs}T)] \qquad \text{(Eq. 2)}$$

$$C_1 = \frac{D}{V_1(a_1 - a_2)}[(K_{21} - a_2)\exp(-a_2T) - (K_{21} - a_1)\exp(-a_1T)] \qquad \text{(Eq. 3)}$$

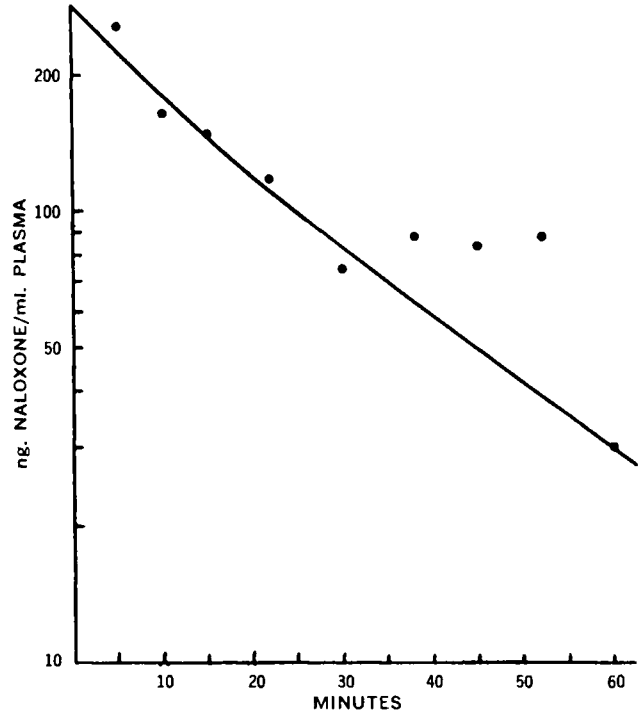

Figure 1—*Semilog plot of naloxone plasma concentrations in rats following 1 mg./kg. i.v.*

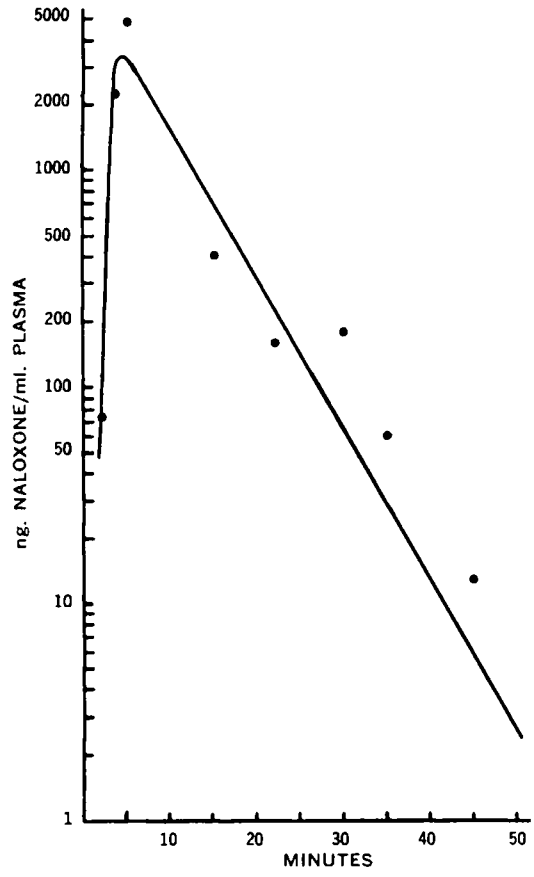

Figure 2—*Semilog plot of naloxone plasma concentrations in rats following 100 mg./kg. p.o.*

N_i and a_i are obtained from the line projected from the terminal portion of the log C *versus* T curve. Calculation of pharmacokinetic parameters for these models was extensively discussed by Wagner (13).

RESULTS

Gas Chromatography and Extractions—Under the described chromatographic conditions, tetraphenylethylene had a retention time of 2.2 min. and the trimethylsilyl derivative of naloxone had a retention time of 4.5 min. Underivatized naloxone and nalbuphine had retention times of 3.6 and 7.8 min., respectively.

The use of parallel extraction standards as controls was necessary because the recovery of naloxone from plasma was 50–60%. There was a linear, reproducible relationship between GLC response and plasma concentration of naloxone.

Preliminary experiments showed that naloxone was recovered from intestinal loops and liver slices in quantities sufficient for GLC analysis without silylation and that there was a linear relationship between naloxone concentration and GLC response.

Experiments in which naloxone was incubated *in vitro* in sections of gut showed that the gut itself did not metabolize naloxone. Therefore, disappearance from *in vivo* loops cannot be attributed to destruction within the loop but must be ascribed to absorption from the loop. When naloxone was incubated with boiled liver slices, the naloxone was recovered intact, indicating that the disappearance found with unboiled slices was due to metabolism. Metabolites such as naloxone glucuronide or noroxymorphone are not extracted under the conditions used.

Plasma Levels of Naloxone—Figure 1 is a plot of log of rat plasma levels of naloxone *versus* time after intravenous administration. The increases in drug levels between 38 and 52 min. may be due to biliary recycling. The curve shown is the best fit computed with the COMPT program, neglecting those points attributable to biliary recycling.

Initially, an oral dose of 10 mg./kg. was administered, but naloxone was not detectable in plasma at this level. At a dose of

Table I—Absorption of Naloxone from *In Vivo* Intestinal Loop in Rat[a]

Minutes	Number of Animals	Naloxone Remaining in Loop, % ± *SD*
30	5	55.5 ± 17.9
60	8	18.8 ± 12.5
90	4	4.73 ± 3.6

[a] Five hundred micrograms injected into ligated intestinal loop *in vivo* and assayed by GLC after indicated time. See text for details.

Table II—Percent Naloxone Remaining after Incubation with Rat Liver Slices

Minutes	Naloxone Remaining, %	
	Experiment 1[a]	Experiment 2
30	48.5	73.5
60	23.6	42.2
120	13.5	13.4

[a] Experiments 1 and 2 represent two separate experiments, each performed in duplicate.

100 mg./kg., detectable levels were obtained. Figure 2 is a plot of log of rat plasma levels of naloxone *versus* time after oral administration. The curve shown is the best fit computed with the COMPT program.

Absorption from Ligated Intestinal Loop—The percent of administered naloxone absorbed from *in situ* ligated intestinal loops at various time intervals is presented in Table I. Naloxone is well absorbed; 95.3% was absorbed at 90 min.

Metabolism by Rat Liver Slices—Table II presents the results of the incubation of naloxone with rat liver slices. After 2 hr., almost 90% of the added naloxone was metabolized. Earlier time intervals showed some variations; but in 30 min., 25–50% of the naloxone was metabolized.

Pharmacokinetics—The plasma level data obtained for intravenously administered naloxone (Fig. 1) fit a two-compartment open model (Scheme I). The data for orally administered naloxone (Fig. 2) fit a one-compartment model with first-order absorption (Scheme II).

DISCUSSION

The pharmacokinetic model (Scheme I) for intravenous naloxone yields a very rapid elimination rate ($t_{1/2}$ = 16 min.). The relatively large volume of distribution in Compartment 1 could indicate either extensive tissue binding or rapid metabolism, because the model is simply attempting to account for the absence of a large fraction of the administered dose as unchanged drug in the plasma. The small values of K_{12} and V_2 and the larger K_{21} value indicate slow entry into, little binding in, and rapid removal from a peripheral compartment, respectively.

The one-compartment model for naloxone plasma levels after oral administration (Scheme II) satisfies the available data. If a more sensitive analytical method were available, a leveling off of plasma concentrations probably would have been observed after 45 min., and the use of a two-compartment model would be indicated. The observed terminal straight-line portion of the curve in Fig. 2 is probably really the distributive phase. The computer-fitted curve does, however, show a very rapid absorption rate ($t_{1/2}$ = 0.72 min.) for naloxone. The large volume of distribution may indicate either extensive tissue binding or rapid metabolism. The pharmacokinetic models of naloxone are, therefore, those of a rapidly absorbed and rapidly excreted and/or metabolized drug.

Figures 1 and 2 show the plasma concentrations of naloxone after intravenous and oral administration. The peak concentration after oral administration, 4856 ng./ml., occurs at 5 min. In terms of percent of the administered dose, calculated from the average plasma volume of rats (40.4 ml./kg.) and the average weight of the rats used, the maximum amount of naloxone found in plasma is 0.19% of the oral dose. Five minutes after intravenous administration, the plasma concentration is 258 ng./ml. or 1.04% of the dose. This could indicate that a large portion of the oral dose is either not absorbed or is metabolized before reaching the systemic circulation.

The rapid absorption rate observed for orally administered naloxone is in agreement with the results of the ligated intestinal loop experiments. At 30 min., 45% of the drug is absorbed and after 90 min. absorption is virtually complete (Table I). In these experiments the entire intestinal loop was analyzed for naloxone, eliminating the possibility of naloxone loss through binding to some component of intestinal tissue, as reported by Levine *et al.* (5) for quaternary ammonium compounds.

These results lead to the conclusion that the lower therapeutic effectiveness of orally administered naloxone is not the result of poor absorption from the intestine. The remaining factor, rapid first-pass liver metabolism, therefore, appears to be the mechanism by which efficacy of orally administered naloxone is diminished. This conclusion is strongly supported by the rapid metabolism of naloxone by rat liver slices (Table II). To be sure, plasma concentrations of naloxone in rats are erratic after oral administration (coefficient of variation 1.10 compared to 0.25 for intravenous administration), but this may be due to the well-known biological variation in drug-metabolizing enzymes rather than to erratic absorption from the GI tract.

The data presented show that low oral effectiveness of naloxone cannot be attributed to poor absorption. Pentazocine's low oral effectiveness (compared to parenteral dosing) has been attributed to poor absorption (14), but this is now questionable since Berkowitz *et al.* (15) reported finding an additional metabolite in plasma following oral administration which has not been found after intramuscular administration. This indicates route-dependent metabolism of pentazocine.

Statistical Approach to Evaluating Effect of Physical and Chemical Factors on Fecal Excretion of Chlorophenothane

RAFIK H. BISHARA*▲, GORDON S. BORN*, VIRGIL L. ANDERSON†, and JOHN E. CHRISTIAN*

Abstract □ A study using ^{14}C-labeled chlorophenothane was statistically designed to evaluate the effect of five treatments (cold, fasting, levarterenol bitartrate, prediphenylhydantoin, and postdiphenylhydantoin) upon the fecal elimination of the pesticide from rats. To 24-hr.-fasted rats, 7 μc. of ^{14}C-chlorophenothane was administered intraperitoneally. The pesticide was allowed to distribute into the tissues of the animals for 5 days prior to initiation of the treatments which were continued for 3 days. The cold group was kept at 2–4°. The fasted rats were deprived of food but had water *ad libitum*. Levarterenol bitartrate and diphenylhydantoin were administered twice a day at 1.0 and 75.0 mg./kg. body weight, respectively. Diphenylhydantoin was administered before chlorophenothane (prediphenylhydantoin) to one group of rats and after administration of the pesticide (postdiphenylhydantoin) to a second group. The ^{14}C-activity in the feces was measured by liquid scintillation. Thirty-six rats were assigned in a randomized complete block design of three replicates with two rats per treatment, five treatments, and a control per replicate. Homogeneity of variance tests indicated that the variances between rats were homogeneous. Two-way analysis of variance tests showed that replicates could be pooled and the data reanalyzed as if a completely randomized design were run. Hence, a one-way analysis of variance and the Newman-Keuls sequential range tests were performed. The latter tested for significant differences between all pairs of treatments. The statistical design allowed for minimum expenditure of animals and radioisotope and provided reliable data. Cold treatment was the only treatment that increased the fecal elimination of chlorophenothane. Preadministration of diphenylhydantoin may have stimulated hepatic enzymes to alter deposition and increase apparent elimination of chlorophenothane.

Keyphrases □ ^{14}C-Chlorophenothane fecal excretion—effects of cold, fasting, and levarterenol bitartrate and diphenylhydantoin administration, statistical analysis, rats □ Pesticide removal from tissues—effects of cold, fasting, and levarterenol bitartrate and diphenylhydantoin administration on ^{14}C-chlorophenothane fecal excretion, rats □ Excretion, fecal, ^{14}C-chlorophenothane—effects of cold, fasting, and levarterenol bitartrate and diphenylhydantoin administration, rats

Although some countries and several states in the United States have banned the use of chlorophenothane[1] (1), the fact remains that the pesticide has been with us for more than 30 years and is still with us today. For most persons, residues in food represent the greatest source (90%) of exposure to persistent pesticides (2–5). Therefore, recent research activity on the accelerated removal of pesticides from animal and poultry products has increased (6). Many workers demonstrated the extensive accumulation of chlorophenothane in the fat depots of the body (7–20). The chlorophenothane concentrations found in adipose tissue were approximately 10 times those of liver and 100 times the concentration found in the kidney, gonads, and brain (21). The storage of chlorophenothane in body lipids was suggested as an effective detoxifying mechanism for such a lipophilic insecticide (22). However, this adipose tissue storage was nonpermanent, especially during accelerated lipid mobilization induced by starvation or increased energy expenditure due to exposure to cold (17, 22–26). Mobilization of fat eliminated some lipid-soluble pesticide from animals, and the remaining residues were further diluted as depot fat was replaced. Induction of drug-metabolizing enzymes of the liver microsomes involved in the metabolic degradation of many lipoid-soluble chemicals was another approach recommended for increasing the rate of removal of persistent pesticides from animals (6). The anticonvulsant drugs, specifically diphenylhydantoin and phenobarbital, are potent inducers of drug-metabolizing enzymes in the rat as well as man (1, 27–32).

The objectives of this work were to: (*a*) study the effect of some physical (cold and fasting) and chemical (levarterenol bitartrate and diphenylhydantoin) treatments on the fecal excretion of ^{14}C-chlorophenothane, and (*b*) find a treatment that would quickly deplete the residues from rats following a measured exposure to the pesticide. Cold, fasting, and endogenous norepinephrine (and the comparable drug entity, levarterenol bitartrate) stimulate the mobilization of fatty tissues (17, 19, 23, 25, 26), the main storage site of chlorophenothane. On the other hand, diphenylhydantoin stimulates certain hepatic microsomal enzymes that are involved in the breakdown of chlorophenothane (1, 27). A simple and efficient statistical design was used to minimize expenditure of animals, radioisotopes, and human efforts and to evaluate the treatment effects, replicability, and the interaction between replicates and treatment factors. For these purposes, randomized complete block and completely randomized designs (33) were applied.

Previous results (34) regarding the respiratory excretion of ^{14}C-chlorophenothane by rats indicated negligible (0.007% of the administered activity) $^{14}CO_2$ in the exhaled air after 24 hr. The cumulative ^{14}C urinary and fecal excretion of the same animals after 5 days were 1.8 and 12.4%, respectively, of the administered dose. Therefore, it was decided to study the fecal radioactivity as a reflector of the influence of the defined treatments on the elimination of chlorophenothane.

EXPERIMENTAL

^{14}C-Chlorophenothane Dosing Solution—The radiochemical purity of ^{14}C-chlorophenothane (*p,p'*-DDT), ring uniformly labeled[2] (specific activity 3.85 mc./mmole), was greater than 98.7%, as shown by TLC, autoradiography, and liquid scintillation counting techniques. The radiolabeled pesticide was dissolved in peanut oil.

[1] 1,1,1-Trichloro-2,2-bis(*p*-chlorophenyl)ethane (*p,p'*-DDT).

[2] Mallinckrodt-Nuclear, St. Louis, Mo.

Each milliliter of this solution contained 12.9 μc. of ^{14}C and 20 mg. of chlorophenothane. The administered radioactivity ranged from 6.78 to 7.32 μc./rat.

Treatments—The physical treatments investigated were cold and fasting. The cold was provided by a walk-in environmental room[3] maintained at 2–4°. Animals exposed to this treatment are referred to as the "cold group." The fasted rats were deprived of food, but water was allowed *ad libitum*. This group is referred to as the "fasted group." The chemical treatments evaluated were diphenylhydantoin[4] and levarterenol bitartrate[5]. The rats were treated with diphenylhydantoin either prior to administration of chlorophenothane (prediphenylhydantoin group) or after receiving the pesticide (postdiphenylhydantoin group). The dosage (30, 31) of diphenylhydantoin was 75 mg./kg. body weight i.p. twice a day. The animals receiving levarterenol bitartrate are referred to as the levarterenol group. The dosage (23) of levarterenol bitartrate was 1 mg./kg. body weight s.c. twice a day. The doses of diphenylhydantoin and levarterenol bitartrate were calculated as the base of the drug, and the necessary corrections were made to account for the difference due to the salts (sodium diphenylhydantoin and levarterenol bitartrate hydrate). The amount of diphenylhydantoin or levarterenol bitartrate administered to the animals was calculated individually, depending upon the rat body weight. The radioactivity in the feces was measured as a reflector of chlorophenothane excretion.

Thirty-six male Sprague–Dawley strain descendent rats[6], weighing 180–210 g. at the beginning of the experiment, were acclimated to laboratory conditions for 2 days. Each animal was kept in a 20 × 11.5-cm. stainless steel metabolism cage[7]. The rats were assigned to the six treatments in a randomized complete block design (33) of three replicates with two rats per treatment. The six treatments included control animals receiving only ^{14}C-chlorophenothane and the cold, fasted, prediphenylhydantoin, postdiphenylhydantoin and levarterenol bitartrate treatments previously defined. All groups of the first replicate, except prediphenylhydantoin, were fasted for 24 hr. prior to intraperitoneal dosing (on Day 1) with ^{14}C-chlorophenothane. The pesticide was allowed to distribute into the tissues of the animals for 5 days prior to initiation of treatments. On Day 6 following administration of the ^{14}C-chlorophenothane, each group was subjected to the assigned treatment, which was continued for 3 days. On Day 9 after dosing with the pesticide, the animals were sacrificed by decapitation using a small guillotine[8]. The prediphenylhydantoin group received diphenylhydantoin treatment for 3 days prior to the ^{14}C-chlorophenothane administration and then followed the same scheme as the other groups. The rats of the prediphenylhydantoin group were also fasted 24 hr. prior to dosing with the pesticide. The other two replicates were started on different days to allow subsequent replicate evaluation. The feces were collected daily, weighed, and stored frozen until the day of analysis.

Radioanalysis—The ^{14}C-radioactivity in all fecal samples was measured with an internal liquid scintillation spectrometer[9] equipped with bialkali phototubes. The scintillation solution consisted of 0.4% 2,5-diphenyloxazole in an equal volume of toluene and 2-ethoxyethanol. The percent counting efficiency of each sample was determined by adding ^{14}C-toluene internal standard and recounting. Whenever practical, the samples were counted with less than 5% counting error at the 95% confidence level. The feces pellets were homogenized by grinding in a glass mortar, and aliquots were digested as described by Bishara *et al.* (34). To about 20 mg. of the homogenized feces in a counting vial, 0.2 ml. of perchloric acid (70%) was added and mixed well to ensure thorough wetting. Two-tenths milliliter of hydrogen peroxide (30%) was then added and the contents were mixed. The vials were put in the oven for 15 min. at 70–75° and then cooled to room temperature. Another 0.5 ml. of hydrogen peroxide solution was added and the samples were bleached for 30 min. in the oven. The vials were allowed to cool to room temperature, and 15 ml. of the scintillation solution was added, mixed, and counted. Most fecal samples (72%) were assayed in quintet and the rest were assayed in triplicate. The results were averaged to get a mean value per sample of feces. The weights of the rats were recorded at the beginning and end of the experiment.

Table I—Daily Fecal ^{14}C-Activity (Chlorophenothane and/or Metabolites)

Treatment	Excreted Percentage of Administered Dose[a] Day 1	Day 2	Day 3	Day 4
Control	1.22	2.04	2.60	3.19
Postdiphenylhydantoin[b]	—	—	—	—
Prediphenylhydantoin	2.38	3.44	4.21	4.64

[a] Data expressed as mean ± *SE* for six rats. [b] Fecal samples were not analyzed for Days 1–5.

Statistical Analysis of Data[10]—Homogeneity of variance was tested for the 18 cells (six treatments × three replicates) using the Bartlett (35) and/or Burr–Foster (36) tests for all days. A two-way analysis of variance (33) was conducted to investigate the effects of treatments, replicates, and the interaction between replicates and treatment for each day. Since almost all of the analyses showed no significant effect at the 0.25 level (37) between replicates (no significance at the 0.17 level the 1st day) or interaction between replicates and treatments, the data were then pooled and analyzed as if the experiment were a completely randomized design (33). For the analysis of the completely randomized design, the pooled data were then subjected to a one-way analysis of variance (33), and the resultant *F*-ratio for testing the differences between the means of groups was compared with the corresponding critical *F*-value at the 0.05 probability level. Whenever a significant *F*-ratio was obtained, the data were tested by a Newman–Keuls sequential range test (38) to locate the treatment means that were significantly different by pairs.

RESULTS AND DISCUSSION

During the first 5 days of the experiment, analysis of daily fecal samples for ^{14}C-activity was conducted on the control, prediphenylhydantoin, and fasted groups. Analysis of the feces of the fasted and the control groups was to test the hypothesis that all animals could be considered as controls in the Day 1–5 period except the prediphenylhydantoin group. Analysis of the feces of the latter group allowed comparison of the effect of diphenylhydantoin on the excretion of chlorophenothane in relation to the control group since diphenylhydantoin has been reported as a hepatic enzyme activator (1, 27, 32, 39).

All daily fecal samples collected during Days 6 through 8 were analyzed to monitor the effect of exposing the animals to the five treatments.

Daily Excretion—The daily fecal raw data from the randomized complete block design of the groups and days defined previously were accepted to have homogeneous variances. Interpretation of the two-way analysis of variances showed that there was no effect

[a] Data expressed as mean ± *SE* for six rats.

of replicates nor treatment by replicate interaction. This indicated that repeating the experiment at different time intervals had no effect on the observed results; *i.e.*, the time interaction did not have any effect. Therefore, the data of each treatment were pooled and analyzed as if the experiment were a completely randomized design.

The pooled data were again statistically analyzed as described in the *Statistical Analysis of Data* section. Table I shows the mean daily excretion results of the pooled data for all groups from Days 6 to 8 and from Days 1 to 5 for the control, prediphenylhydantoin, and fasted groups.

Analysis of variance (ANOVA) was performed on the daily means to evaluate the differences due to the treatment effects. Significant *F*-ratios at the 0.05 level were obtained for Days 1, 2, 3, 6, and 7, indicating that the treatments affected the rats differently.

To locate the specific treatment effect, the data were then subjected to the Newman-Keuls sequential range test. The results are reported in Table II with the corresponding level of significance.

No significant differences were observed between the control and the fasted groups, indicating that for Days 1–3 the two groups could be considered as controls. Further elaboration on the fasted and control groups will be made later. The rats of the prediphenylhydantoin group excreted more ^{14}C-activity (chlorophenothane and/or metabolites) than the control groups for Days 1–3. The high excretion of ^{14}C-activity in the feces by the prediphenylhydantoin group may be the result of inducing the liver microsomal enzymes that metabolized chlorophenothane (39).

On Day 6, the cold treatment was significantly different from all other treatments. This indicated that the cold treatment has the strongest stimulating effect on the fecal excretion of chlorophenothane from the rats. There were also differences between the cold treatment and the fasted, levarterenol bitartrate, and postdiphenylhydantoin groups on Day 7. Since cold has been reported to mobilize fat (23, 25, 26), the high ^{14}C fecal activity, which was significantly different from other treatments, may be due to the availability of more chlorophenothane to be metabolized and excreted. However, the effect of the cold treatment seemed to wear off with time, since less differences were noticed on Day 7 and none was noticed on Day 8 between the cold group and the other groups. This may be due to the adaptability of the rats to the cold environment. Dirksen (40) reported that a cold environment affected rats most (detected by low adrenal ascorbic acid) at 6 and 18 hr. of exposure and that the animals adapted to the cold stress after this period.

The fasted group differed from the control group at the 0.05 and 0.01 levels of significance for Days 6 and 7, respectively. Although the fasted group was expected to mobilize its fat and the associated chlorophenothane, the low fecal excretion (due to no food ingestion) may explain the low activity excreted by the fasted group. There was a significant difference between the prediphenylhydantoin and the fasted groups at Days 6 and 7, which again reflected the low fecal excretion of the fasted group.

Cumulative Excretion—The daily means reported in Table I were then expressed as cumulative activity and were subjected to the same statistical tests. These were performed on data of Days 1–8 for the control, prediphenylhydantoin, and fasted groups. The mean cumulative fecal ^{14}C-activity for these three groups are reported in Table III. The statistical evaluation of the cumulative data clearly showed a significant difference (Table IV) between the fecal excretion of the prediphenylhydantoin group and each of the control and fasted groups for the Days 1–6 period. These results favorably backed the assumption that all rats were controls until the treatments started on Day 6. Further differences were observed between the fasted and prediphenylhydantoin groups for Days 7 and 8, thus indicating low fecal excretion of chlorophenothane and/or its metabolites by the fasted group.

When comparing the control and fasted groups based upon the cumulative data (Table III), no significant differences between them were noticed (Table IV). During the first 5 days of the experiment, these results were expected since it has been previously shown that both groups could be considered as controls. Due to the effect of the treatment starting on Day 6, a difference of chlorophenothane fecal excretion between the fasted and control groups was anticipated. However, the expected increased elimination was not observed. This may be due to the masking effect of the first 5 days of cumulative excretion.

The cumulative means starting from Days 6 to 8 for all six groups are reported in Table V. The data of prediphenylhydantoin are included in the table for completeness. It has already been shown (Table IV) that by Day 6 the prediphenylhydantoin group could be considered as a control group since the effect of the drug has been

[a] Data expressed as mean ± *SE* for six rats.

dissipated. The cumulative data clearly reflect that there is no statistical difference between the prediphenylhydantoin and control groups on Days 6–8 (Table VI).

The cumulative chlorophenothane fecal excretion starting from Day 6 (Table V) of the cold group was always the highest and was followed by the control, prediphenylhydantoin, postdiphenylhydantoin, levarterenol bitartrate and fasted groups in descending order. The cold group was statistically different from all other groups on Day 6. Also, significant effects (Table VI) of the cold treatment existed between this group and each of the fasted and levarterenol bitartrate groups for Days 7 and 8. On Day 7, the cold group differed from the postdiphenylhydantoin group. This difference was previously explained in the discussion of daily excretion data.

The fasted group differed from the control group on Days 6–8 while the levarterenol bitartrate group differed from the control only on Day 7. The latter case may be explained by the observation that the rats of the levarterenol group reduced their food consumption after administration of the compound, which resulted in less fecal excretion as was the case with the fasted group. Another explanation of the significant difference between the control and levarterenol bitartrate groups may be due to the fact that this drug inhibited some metabolizing enzymes (28, 41, 42). This may have resulted in low excretion of chlorophenothane and/or its metabolites.

The mean initial and final body weights of the rats used in this experiment are reported in Table VII. The final body weight means were all higher than the initial weights, except for the fasted group which was the same. The Newman–Keuls sequential range test (Table VIII) for these data showed a significant difference of the body weights between the fasted and all the other treatments at the 0.01 level. Postdiphenylhydantoin and cold groups differed from the control group at a significance level of 0.01 and 0.05, respectively. In the case of the postdiphenylhydantoin group, the animals did not consume as much food after dosing. On the other hand, the animals exposed to cold may have lost some of their fat that had been mobilized for energy during cold exposure.

In conclusion, the cold treatment was the most effective of all studied treatments in stimulating fecal excretion of ^{14}C-chlorophenothane and/or metabolites. However, the efficiency of this treatment diminished after the first 24 hr. due to adaptation.

The prediphenylhydantoin treatment may have stimulated the hepatic microsomal enzymes that metabolize chlorophenothane. This was clearly shown in the cumulative data starting from Day 1 (Table III) and is in agreement with previously published data (1, 27, 32, 39).

Standard error	3.8	5.9

[a] Data expressed as mean ± *SE* for six rats. [b] Body weight at 1st day of adaptation. [c] Body weight at day of sacrifice.

The postdiphenylhydantoin treatment was not effective in enhancing the fecal excretion of chlorophenothane and/or its metabolites. Similar results have been reported in the case of humans taking daily doses of diphenylhydantoin to determine the effect on chlorophenothane residue reduction. No reduction was detectable at 3 weeks, and the study was to be continued for 3 months (43). Recently, Davies *et al.* (44) reported that oral sodium diphenylhydantoin (300 mg. daily for up to 9 months) reduced the chlorophenothane and 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene (*p,p'*-DDE) residues in human volunteers by 75 and 61% of pretreatment levels, respectively.

Although several authors used diet restriction and fasting to mobilize fat (17, 19, 25) together with its pesticide content, the redistribution of the pesticide in other tissues was always the end result (19, 22, 24, 25, 45). In this study, fasting, which is a form of diet restriction, had the least effect on the excretion of chlorophenothane from rats.

The statistical designs (randomized complete block and completely randomized) used in this work complied with the basic principles of experimental design, namely replication, randomization, and local control (33). The designs also supplied statistically reliable data which lead to valid inferences with respect to the results obtained using minimum effort and expense.

Cardiovascular Effects of Isoxsuprine and Sotalol

GERALD J. KELLIHER▲ and SYDNEY P. SHANOR

Abstract □ Isoxsuprine, a vasodilating agent, and sotalol, a β-adrenergic receptor blocking agent, were administered separately and in combination to normotensive rats and hypertensive dogs. In rats, sotalol produced a hypotensive response only in low doses whereas isoxsuprine produced a significant hypotension at all doses used. Administration of either agent was followed by a significant decrease in heart rate. The combination of isoxsuprine with sotalol decreased the heart rate more than either drug alone, but the hypotensive response did not follow this pattern. In hypertensive dogs, isoxsuprine and sotalol significantly decreased blood pressure. In contrast to the rat, the hypotensive response to isoxsuprine in the dog was accompanied by an increase in heart rate. The combination of isoxsuprine with sotalol produced a greater hypotensive response than either drug alone in medium and high doses but not in low doses. Sotalol prevented the increase in heart rate that accompanied the hypotensive response to isoxsuprine. The data suggest that the combination of isoxsuprine and sotalol may be useful in the treatment of hypertension.

Keyphrases □ Isoxsuprine and sotalol—cardiovascular effects after separate and concurrent administration in rats and dogs, potential antihypertensive therapy □ Sotalol and isoxsuprine—cardiovascular effects after separate and concurrent administration in rats and dogs, potential antihypertensive therapy □ Antihypertensive activity—concurrent administration of isoxsuprine and sotalol evaluated, rats, dogs □ Cardiovascular effects—isoxsuprine and sotalol, separate and concurrent administration, rats, dogs

The treatment of essential hypertension has centered in recent years on the use of various agents that interfere with adrenergic neuronal transmission. Although this approach has been generally successful in reducing blood pressure, it is not without problems. Hypotensive agents that interfere with sympathetic nervous function commonly cause postural hypotension, weakness, lethargy, and sexual dysfunction (1–6).

Since an elevation of peripheral vascular resistance appears to be the major hemodynamic abnormality present in essential hypertension (7), a new treatment based on the concurrent administration of vasodilating and β-receptor blocking drugs was recently introduced (8, 9). In previous investigations, drugs such as hydralazine were used to produce vasodilation (9). Hydralazine was reported to decrease peripheral resistance by a direct relaxing action on arteriolar smooth muscle (10–12). Its antihypertensive effectiveness is limited, however, by a reflex action that increases heart rate and cardiac output (12, 13). Even though the reflex cardiac augmentation produced by hydralazine can be prevented by propranolol (9), other side effects, such as immunologic disturbances occurring during chronic therapy (14), make the use of different vasodilating drugs more desirable.

Isoxsuprine[1], an agent that produces vasodilation through a direct relaxing action on vascular smooth muscle (15–17) as well as by activation of β-adrenergic receptors (18, 19), appears to be more suitable for this purpose since it has been reported to be free of undesired effects (20). The hypotensive effect produced by isoxsuprine may be useful in the treatment of hypertension if the positive chronotropic and inotropic effects accompanying the hypotensive response can be prevented. In the present investigation, sotalol[2], a β-receptor blocking agent, was utilized in an attempt to block selectively the cardiac augmentation produced by isoxsuprine while retaining the peripheral vasodilating and hypotensive effects.

EXPERIMENTAL

Measurement of Blood Pressure and Heart Rate in Anesthetized Rats—Wistar albino rats of both sexes, weighing approximately 200–250 g., were anesthetized with 1.25 g./kg. of urethan administered intraperitoneally. The animals were secured ventral side up on an animal board. A midline incision was made over the tracheal region; the trachea was exposed and cannulated with polyethylene tubing[3] to ensure freedom of respiration. A common carotid artery was isolated and cannulated with polyethylene tubing[4], which was connected to a pressure transducer[5]; all recordings were made on a polygraph[6]. One femoral vein was isolated for injection purposes, and the blood pressure was allowed to stabilize before administration of any drug. In each case the experimental compounds, dissolved in saline, were administered in volumes of 0.2 ml. or less. Groups of three male and three female rats were administered intravenously either 2, 3, or 4 mg./kg. of isoxsuprine, sotalol, or equal combinations of both. The heart rate and systolic blood pressure were monitored for 90 min. following drug administration. The changes obtained after drug administration were compared to the control values obtained before drug administration and analyzed by the Student t test. Values of $p \leq 0.05$ were considered significant.

Measurement of Blood Pressure and Heart Rate in Unanesthetized Hypertensive Dogs—Two male and two female mongrel dogs were made hypertensive by the method of Grollman (21). In this study the method was modified in that both kidneys were ligated, thus increasing the amount of residual, normally functioning renal tissue and minimizing the possibility of uremia developing. Two mongrel dogs who were received from the supplier and found to be hypertensive were used as well. Systolic blood pressure was determined before surgery and at weekly intervals thereafter until a stable pressure of 180 mm. Hg or higher was attained. All dogs were given normal saline for drinking water *ad libitum*. The dogs were trained to lie quietly in a hammock, which allowed all four limbs to be freely suspended. The blood pressure and heart rate were recorded from the brachial artery by means of an infant sphygmomanometer cuff which contained a sensitive microphone[7]. The cuff was connected to an electrosphygmomanometer, and recordings were made on a physiograph[8]. Ten clear readings of the systolic blood pressure were recorded at each time interval, and an average value was obtained. Heart rate was determined from the pulse wave by partially occluding the artery for 15 sec.

Systolic blood pressure and heart rate were determined 5–10 min. before administration and at 30, 90, 180, and 360 min. after administration. Each dog served as its own control. All drugs were administrated orally as a powder in gelatin capsules. Each dog received nine drug dosages, and the schedule of administration and

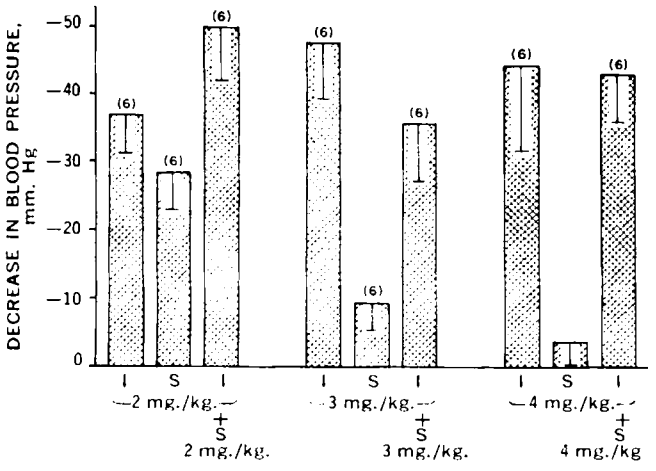

Figure 1—*Effect of isoxsuprine (I) and sotalol (S) on blood pressure in rats. Isoxsuprine and sotalol were administered intravenously alone and in combination (I + S). The number of observations is indicated in parentheses. The hypotensive response produced by I is not significantly different from I + S at any dose. The response to I + S is significantly greater than that to S at the 3- and 4-mg./kg. doses* ($p < 0.05$).

dosage was as follows: isoxsuprine at 6, 12, and 18 mg./kg.; sotalol at 10, 20, and 30 mg./kg.; and a simultaneously administered combination of 6, 12, and 18 mg./kg. of isoxsuprine with 10, 20, and 30 mg./kg. of sotalol, respectively. These doses of sotalol were reported by Lish *et al.* (22) to produce β-receptor blockade in dogs as measured by blockade of isoproterenol-induced tachycardia. A control series was performed in which lactose was administered in place of the active drugs, and the heart rate and blood pressure were followed over a time course identical to that of the drug studies. Each dog was given at least a 3-day rest between drug administrations. The effects of the drugs administered separately and in combination were analyzed by the Student *t* test. Values of $p \leq 0.05$ are considered significant.

RESULTS

Effect of Isoxsuprine and Sotalol on Blood Pressure and Heart Rate in Anesthetized Rats—The intravenous administration of isoxsuprine in rats produced a significant decrease in blood pressure ($p < 0.001$; Fig. 1). There was no significant difference in the magnitude of the hypotensive response between the three doses of isoxsuprine ($p > 0.05$). The decrease in blood pressure produced by isoxsuprine was not accompanied by a reflex increase in heart rate (Fig. 2). In fact, in all but two instances (2/18), the rats responded with a bradycardia, the magnitude of which was not significantly different between the three doses of isoxsuprine ($p > 0.05$).

The administration of the low dose (2 mg./kg.) of sotalol resulted in a significant decrease in blood pressure ($p < 0.05$), while the medium (3 mg./kg.) and high (4 mg./kg.) doses did not produce a significant depressor effect ($p > 0.05$; Fig. 1). The administration of sotalol produced a significant decrease in heart rate at all three doses employed ($p < 0.05$; Fig. 2). There was no significant difference in the magnitude of the effect at the different doses.

The combination of isoxsuprine and sotalol produced a significant hypotensive effect at all three dose levels ($p < 0.05$; Fig. 1). Although the hypotensive response produced by the combination was significantly greater than that produced by sotalol alone at the same dose ($p < 0.05$), it did not differ from that produced by isoxsuprine alone at the same dose ($p > 0.05$). Thus, there was no evidence to suggest that sotalol potentiated the hypotensive response produced by isoxsuprine. The combination of isoxsuprine with sotalol produced a greater negative chronotropic effect than the administration of either compound alone in the low and medium doses ($p < 0.05$) but not at the high dose ($p > 0.05$).

Effect of Isoxsuprine and Sotalol on Blood Pressure and Heart Rate in Unanesthetized Hypertensive Dogs—The oral administration of lactose to six unanesthetized hypertensive dogs did not produce any significant change in blood pressure or heart rate. The oral administration of isoxsuprine alone at low (6 mg./kg.), medium (12 mg./kg.), and high (18 mg./kg.) doses to hypertensive dogs produced a significant reduction in blood pressure of approximately 18–23 mm. Hg ($p < 0.05$; Fig. 3). There was no significant difference in the magnitude of the hypotensive effect between the three doses of isoxsuprine ($p > 0.05$). At each dose, a significant increase in heart rate accompanied the hypotensive response, the pattern being such that the high dose of isoxsuprine produced the greatest increase in heart rate (Fig. 4). The progressive elevation in heart rate produced by increasing the dose of isoxsuprine may explain the lack of a greater hypotensive response when the higher doses of isoxsuprine were administered.

The administration of sotalol produced a significant reduction in blood pressure, the magnitude of which was not different between the doses or from that produced by isoxsuprine at any dose (Fig. 3). However, the hypotensive response to sotalol, in contrast to isoxsuprine, was not accompanied by an increased heart rate but by a significant reduction in rate at each dose (Fig. 4). The magnitude of the effect was not different between doses of sotalol ($p > 0.05$). Diminution of sympathetic influences to the heart probably explains the hypotensive response to sotalol and the lack of any reflex adjustments.

The simultaneous adminstration of isoxsuprine and sotalol produced a consistent drop in blood pressure (Fig. 3). The maximum hypotensive response was achieved with the combination of 12 mg./kg. isoxsuprine and 20 mg./kg. sotalol (medium dose); increasing the dose of either drug did not result in a greater hypotensive response. Since the medium and high doses of the combination produced a decrease in blood pressure that was the same as the total of both drugs alone, the hypotensive effects of isoxsuprine and sotalol seem to be additive. It is possible that isoxsuprine in low doses (6 mg./kg.) produces vasodilation primarily through stimulation of β-receptors whereas higher doses produce a direct vasodilation which is independent of β-receptor activation. The β-receptor-mediated hypotensive response produced by low doses can be prevented by sotalol, but the direct vasodilation produced by high doses is not affected by sotalol.

The simultaneous administration of sotalol with isoxsuprine prevented the increase in heart rate produced when isoxsuprine was administered alone (Fig. 4). In the low and medium doses of the combination, sotalol converted the increase in heart rate to a decrease of approximately 16 beats/min. With the high dose of the combination, however, although there was an overall decrease in heart rate for the group, three of the six animals responded to the combination with an increase in heart rate which was, on the average, approximately 12 beats/min. It is possible, therefore, that the increase in heart rate in these animals may explain the lack of an increased hypotensive response with the high dose of the combination compared to the medium dose in which all dogs responded with a decrease in heart rate.

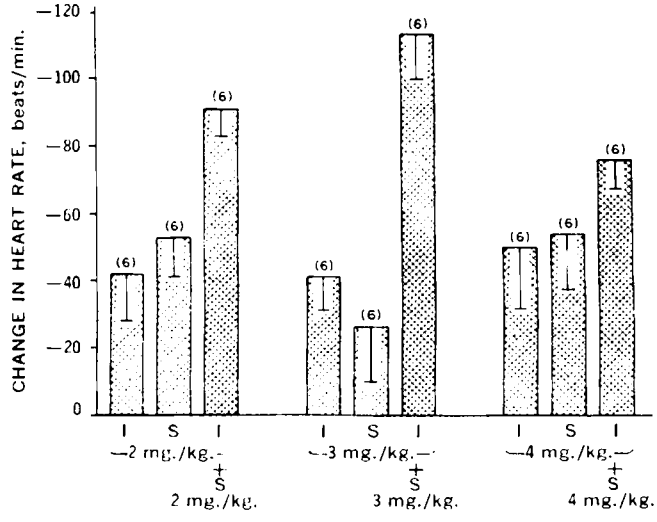

Figure 2—*Effect of isoxsuprine (I) and sotalol (S) on heart rate in rats. The response to I + S is significantly greater than the response to I or S alone at the 2- and 3-mg./kg. doses* ($p < 0.05$) *but not at 4 mg./kg. See Fig. 1 for details to legend.*

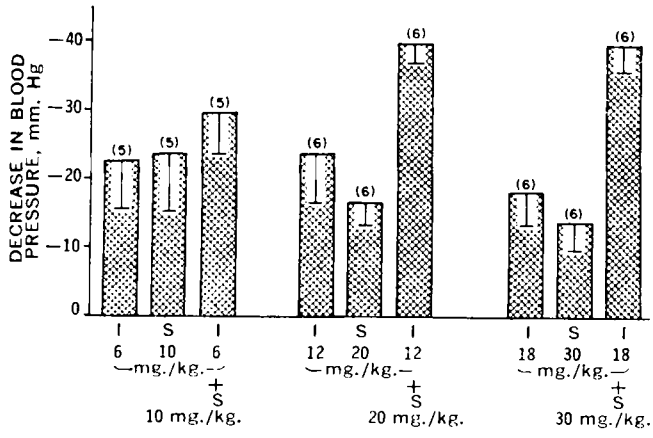

Figure 3—*Effect of isoxsuprine (I) and sotalol (S) on blood pressure in hypertensive dogs. Isoxsuprine and sotalol were administered orally alone and in combination (I + S). The number of observations is indicated in parentheses. The response to I + S is significantly greater than the response to I or S alone at the medium and high doses ($p < 0.01$). The response to I + S is the same as that to I or S at the low dose.*

DISCUSSION

The results of this study demonstrated that isoxsuprine is an effective hypotensive agent. Furthermore, the increase in heart rate produced by either a direct or reflex action of isoxsuprine could be prevented by the concurrent administration of sotalol whereas the hypotensive response was unaffected.

Marked differences were found in the heart rate effects of isoxsuprine in the conscious dogs and anesthetized rats. In the conscious dogs, the fall in arterial blood pressure produced by isoxsuprine was accompanied by an increase in heart rate, whereas in the rats the fall in blood pressure was always associated with bradycardia. Similar results were reported by Brunner *et al.* (23) using hydralazine as the vasodilating agent. These authors reported that the depressor response to hydralazine was accompanied by an increase in heart rate in conscious rats but a decrease in heart rate in anesthetized rats. It is concluded from the results of the present study that anesthetized rats must be used with caution in the evaluation of antihypertensive compounds where reflex cardiovascular changes may result since the anesthetized rat may obscure these changes. The present results in the unanesthetized dogs are not in agreement with Brunner *et al.* (23, 24), who reported that the administration of pronethalol prevented the direct vasodilating response to hydralazine in unanesthetized dogs. However, these results are in agreement with the findings of Gilmore *et al.* (25), Sonnerstedt *et al.* (26), Gottlieb *et al.* (8), and Zacest *et al.* (9), who found that the administration of β-blocking agents along with direct acting peripheral vasodilating agents prevents the reflex cardiac effects in response to a decrease in blood pressure but maintains or potentiates the hypotensive response. This study represents the first report of the use of isoxsuprine and sotalol for this purpose.

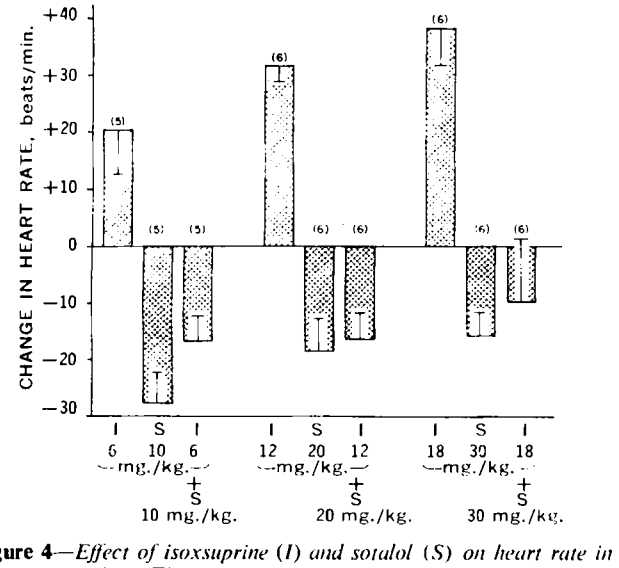

Figure 4—*Effect of isoxsuprine (I) and sotalol (S) on heart rate in hypertensive dogs. The response to sotalol alone is not significantly different from the response to I + S at any dose. See Fig. 3 for details to legend.*

Hydralazine is the only direct acting vasodilating agent currently used in the treatment of hypertension. Despite the capacity of this agent to lower blood pressure, its antihypertensive effectiveness is limited by the reflex increase in sympathetic discharge that produces an undesirable increase in both heart rate and cardiac output. Glick and Braunwald (27) showed that the reflex cardiovascular adjustment initiated by a fall in blood pressure consists of increased sympathetic discharge rather than a decrease in vagal activity. The cardiac augmentation produced by this means may often compromise the depressor response to this agent (12, 13). Several investigators showed that the cardiac augmentation resulting from the hypotensive action of hydralazine can be prevented by the concurrent administration of β-blocking agents (9, 26), but other side effects associated with this agent, *e.g.*, lupus-like reaction, suggest that vasodilating agents such as isoxsuprine and nylidrin would be more valuable adjuncts to β-blockade therapy.

Propranolol is the only β-blocking agent currently available in clinical practice in the United States that can be used in combination with vasodilating drugs. In some respects, sotalol is more desirable than propranolol for this purpose. The use of propranolol with a vasodilating agent may not result in as great a hypotensive response as would result with the use of other β-blockers since it has been reported that propranolol causes an increase in peripheral resistance (16, 28, 29). It is possible, therefore, that the increase in vascular resistance produced by propranolol may directly counteract the decrease in arteriolar resistance produced by the vasodilating drug. There have been no reports to date that sotalol produces such an increase in peripheral vascular resistance. In addition, propranolol has been reported to possess a direct myocardial depressant action (30, 31), which may limit its usefulness in patients with hypertensive heart disease. Sotalol, on the other hand, has been reported to be a "safer" β-blocking agent (32) since it does not directly reduce myocardial function at doses that produce β-blockade (30, 33).

Since at least part of the vasodilation produced by isoxsuprine is the result of stimulation of β-receptors (22) and since propranolol and sotalol block both cardiac and vascular β-receptors, these agents may reduce to some extent the hypotensive effect elicited by isoxsuprine. In this regard, β-blockers, such as practolol, that exert a specificity for blockade of the cardiac β-receptors more so than vascular β-receptors (34) should prove to be even more useful hypotensive drugs when combined with vasodilating agents such as isoxsuprine and nylidrin.

Detection of Prostaglandin $F_{2\alpha}$ as Pentafluorobenzyl Ester by Electron-Capture GLC

J. A. F. WICKRAMASINGHE▲, W. MOROZOWICH, W. E. HAMLIN, and S. R. SHAW

Abstract □ The pentafluorobenzyl ester of prostaglandin $F_{2\alpha}$ was synthesized on a preparative scale and was gas chromatographed as the tris(trimethylsilyl) ether. The latter was found to be stable during GLC and highly sensitive to electron-capture detection. The lower limit of detection was 12.5 pg. of the ester, injected on-column as the silylated product. The nanogram scale conversion of prostaglandin $F_{2\alpha}$ to the ester, under conditions amenable to electron-capture GLC detection, was developed. The electron-capture GLC response was linear over the 0.03–0.84-ng. range of the ester, injected as the tris(trimethylsilyl) ether.

Keyphrases □ Prostaglandin $F_{2\alpha}$—electron-capture GLC analysis as pentafluorobenzyl ester □ GLC, electron-capture detection—analysis, prostaglandin $F_{2\alpha}$ as pentafluorobenzyl ester

Prostaglandins are biologically important compounds that are active at very low concentrations, usually in the nanogram range. To study the physiological role and the mechanisms of action, as well as the absorption, metabolism, and excretion of these prostaglandins, simplified analytical methodology of high sensitivity and specificity is required. Among the many methods considered for the quantitation of prostaglandins are those based on biological responses (1, 2), enzymatic assay (3), fluorescence and UV spectroscopy (4–6), radioimmunoassay (7–11), and chromatography. The last includes: (*a*) high-pressure liquid chromatography for the detection of low levels of prostaglandins after conversion to the C-1-*p*-nitrobenzyl esters (12), and (*b*) GLC utilizing flame-ionization detection (13–15), mass spectrometric detection (16–22), or electron-capture detection (23–26). GLC methods utilizing flame ionization usually lack adequate sensitivity for the detection of low levels of prostaglandins incident in biological fluids. The GLC–mass spectrometric methods and the electron-capture GLC methods, which afford high sensitivity, also offer a high degree of specificity when combined with a preliminary TLC separation. In terms of general utility, the widely used and elegant GLC–mass spectrometric method has the disadvantage of requiring expensive and usually inaccessible instrumentation, as well as the synthesis of the isotopically labeled (deuterated) prostaglandins for internal standards and carriers.

Reported electron-capture GLC methods based on the inherent electron-capturing properties of prostaglandin B (PGB) compounds (23, 24) have drawn considerable attention. This approach, however, is limited to the PGB compounds or to prostaglandins that can be readily and quantitatively converted to the PGB's. The most common derivatives of the prostaglandins examined for electron-capture detection involve derivatization of the hydroxy groups as, for example, conversion to a heptafluorobutyrate ester (25, 26) or bromomethyl–dimethylsilyl ether (24). The thermal instability of the heptafluorobutyrate derivative, resulting in the formation of multiple GLC peaks, renders it unsuitable for electron-capture GLC analysis (26).

Since all naturally occurring prostaglandins contain a C-1 carboxyl group that has been shown to undergo facile reaction with benzylic halides, the C_1-penta-

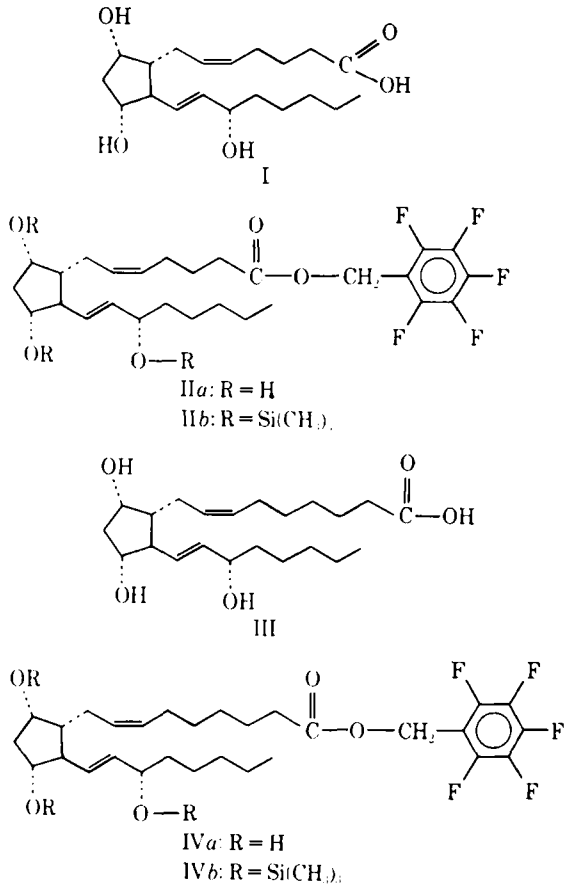
The electron-capture GLC response was linear over the 0.03–0.84-ng. range of the ester, injected as the tris(trimethylsilyl) ether.

Keyphrases □ Prostaglandin $F_{2\alpha}$—electron-capture GLC analysis as pentafluorobenzyl ester □ GLC, electron-capture detection—analysis, prostaglandin $F_{2\alpha}$ as pentafluorobenzyl ester

Prostaglandins are biologically important compounds that are active at very low concentrations, usually in the nanogram range. To study the physiological role and the mechanisms of action, as well as the absorption, metabolism, and excretion of these prostaglandins, simplified analytical methodology of high sensitivity and specificity is required. Among the many methods considered for the quantitation of prostaglandins are those based on biological responses (1, 2), enzymatic assay (3), fluorescence and UV spectroscopy (4–6), radioimmunoassay (7–11), and chromatography. The last includes: (*a*) high-pressure liquid chromatography for the detection of low levels of prostaglandins after conversion to the C-1-*p*-nitrobenzyl esters (12), and (*b*) GLC utilizing flame-ionization detection (13–15), mass spectrometric detection (16–22), or electron-capture detection (23–26). GLC methods utilizing flame ionization usually lack adequate sensitivity for the detection of low levels of prostaglandins incident in biological fluids. The GLC–mass spectrometric methods and the electron-capture GLC methods, which afford high sensitivity, also offer a high degree of specificity when combined with a preliminary TLC separation. In terms of general utility, the widely used and elegant GLC–mass spectrometric method has the disadvantage of requiring expensive and usually inaccessible instrumentation, as well as the synthesis of the isotopically labeled (deuterated) prostaglandins for internal standards and carriers.

Reported electron-capture GLC methods based on the inherent electron-capturing properties of prostaglandin B (PGB) compounds (23, 24) have drawn considerable attention. This approach, however, is limited to the PGB compounds or to prostaglandins that can be readily and quantitatively converted to the PGB's. The most common derivatives of the prostaglandins examined for electron-capture detection involve derivatization of the hydroxy groups as, for example, conversion to a heptafluorobutyrate ester (25, 26) or bromomethyl–dimethylsilyl ether (24). The thermal instability of the heptafluorobutyrate derivative, resulting in the formation of multiple GLC peaks, renders it unsuitable for electron-capture GLC analysis (26).

Since all naturally occurring prostaglandins contain a C-1 carboxyl group that has been shown to undergo facile reaction with benzylic halides, the C_1-penta-



fluorobenzyl ester of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) was prepared to examine its electron-capture detection properties.

EXPERIMENTAL

Preparative Scale Synthesis of $PGF_{2\alpha}$ Pentafluorobenzyl Ester (IIa)—A solution of $PGF_{2\alpha}$ (I) (40 mg.) in acetonitrile (2 ml.) was treated with pentafluorobenzyl bromide (0.2 ml.) and diisopropylethylamine (0.2 ml.). TLC examination [on silica gel in ethyl acetate–acetic acid (97:3)] indicated quantitative formation of the derivative (II*a*) (R_f 0.4) in 1 hr. with little evidence of side-products. The reaction mixture was diluted with 0.1 *M* citric acid (50 ml.) and extracted with ethyl acetate (50 ml.). The organic phase was washed with water (50 ml.) and dried with anhydrous sodium sulfate. The crude product was chromatographed[1], and the ester was eluted with ethyl acetate-acetone (6:4). Removal of the solvent gave a colorless oil (42 mg.) which showed a single spot with TLC and a single peak with GLC (flame-ionization detection) as the trimethylsilyl derivative (II*b*).

Submicrogram Scale Conversion of $PGF_{2\alpha}$ to IIa—$PGF_{2\alpha}$ (I) was treated with a solution of pentafluorobenzyl bromide in acetonitrile [10 μl. containing 5.8 mg. (0.022 mmole) of pentafluorobenzyl bromide] and a solution of diisopropylethylamine in acetonitrile [10 μl. containing 0.886 mg. (0.007 mmole) of diisopropylethylamine]. The reaction mixture was heated at 40° for 5 min. and then evaporated to dryness under nitrogen. The recovered sample was treated with the reagents again in a manner identical to that indicated previously and was evaporated to dryness under nitrogen.

Tris(trimethylsilyl) $PGF_{2\alpha}$ Pentafluorobenzyl Ester (IIb)—Electron-capture GLC analysis was carried out on the tris(trimethylsilyl) ether of the $PGF_{2\alpha}$ pentafluorobenzyl ester (II*a*).

On a preparative scale, II*a* (10 mg.) was dissolved in *N,O*-bis-(trimethylsilyl)acetamide–pyridine (1:1) (1 ml.), and the solution was heated at 60° for 15 min. Excess reagent was removed with a stream of nitrogen, and the residue was dissolved in tetrahydrofuran for GLC analysis. Appropriate dilutions of this stock solution were made with the same solvent. The gas chromatograms did not show any additional peaks or significant decrease in concentration on standing for 24 hr. at room temperature.

In a submicrogram scale analysis, II*a* residues from the esterification were treated with *N,O*-bis-(trimethylsilyl)acetamide (10 μl.) at room temperature (~23°) for 5 min. Aliquots (1 μl.) of the solution were directly analyzed by electron-capture GLC.

Internal Standard for GLC—The tris(trimethylsilyl) pentafluorobenzyl ester of 9-{3α,5α-dihydroxy-2β-[(3*S*)-3-hydroxy-*trans*-1-octenyl]-1α-cyclopentyl}-*cis*-7-nonenoic acid or 2*a*,2*b*-dihomo-$PGF_{2\alpha}$ (III) was used as an internal standard for GLC.

*Pentafluorobenzyl Ester of 9-{3α,5α-dihydroxy-2β-[(3S)-3-hydroxy-*trans*-1-octenyl]-1α-cyclopentyl}-cis-7-nonenoic Acid (III)*—A solution of III (31.91 mg.) in acetonitrile (2 ml.) was treated with pentafluorobenzyl bromide (0.2 ml.) and diisopropylethylamine (0.2 ml.) at room temperature. After stirring for 1 hr., the reaction mixture was concentrated (to about 0.5 ml.) by evaporation under nitrogen, diluted with 0.1 *M* citric acid (10 ml.), and extracted with ethyl acetate (2 × 10 ml.). The combined organic phase was washed with water (10 ml.), dried with anhydrous sodium sulfate, filtered, and evaporated. The crude product was purified by sequential preparative TLC on silica gel in solvent systems of: (*a*) ethyl acetate–acetic acid (97:3), and (*b*) ethyl acetate–acetic acid (95:5). The pentafluorobenzyl ester (IV*a*) zone was located by exposure of the reference spots on discrete lanes to iodine vapor in the manner indicated previously. Then IV*a* was extracted from the silica gel using ether (2 × 5 ml.). The purified ester (IV*a*) (9.48 mg.) was observed to be homogeneous by TLC on silica gel in ethyl acetate–acetic acid (95:5).

Tris(trimethylsilyl) Ether of Pentafluorobenzyl Ester (IVa)—An aliquot of IV*a* (2.04 mcg.) was converted to the tris(trimethylsilyl) derivative (IV*b*) by treatment with *N,O*-bis-(trimethylsilyl)acetamide (1 ml.) and examined by electron-capture GLC. A GLC peak corresponding to a minor impurity (retention time ~12 min.) was observed in addition to the peak due to the major product tris-(trimethylsilyl) pentafluorobenzyl ester (IV*b*). The identity of the latter was confirmed by GLC–mass spectrometry.

A solution of IV*b* in the silylating agent (65.174 mcg./ml.) was employed as the internal standard for GLC analysis. Aliquots (10 μl.) of this solution were added to submicrogram quantities of II*a* and mixed well[2]. Samples (1 μl.) of this solution were utilized for electron-capture GLC analysis.

Electron-Capture GLC—*Method A*—A chromatograph[3], equipped with a ^{63}Ni electron-capture detector, was operated with a constant (d.c.) polarizing voltage. Spiral glass columns [0.61 m. (2 ft.) × 0.28 cm. (0.125 in.) i.d.] packed with 3% OV-1 on 80–100-mesh Gas Chrom Q were utilized. High purity nitrogen was used as the carrier gas at a flow rate of 40 ml./min. The column oven was operated isothermally at 255°, the flash heater at 275°, and the detector at 290°. Samples of 1 μl. were chromatographed. Under these conditions, II*b* and the internal standard (IV*b*) had retention times of 8.9 and 16 min., respectively.

Method B—A second chromatograph[4] was equipped with a ^{63}Ni electron-capture detector (pulse interval of 5 μsec.). A glass column [0.77 m. (2.5 ft.) × 0.28 cm. (0.125 in.) i.d.] packed with 1% OV-1 on 100–120-mesh Gas Chrom Q was arranged for on-column injection. Argon (95%)–methane (5%) was used as the carrier gas at a flow rate of 60 ml./min. The column oven was operated isothermally at 250°, the flash heater at 250°, and the detector at 280°. Samples of 1 μl. were chromatographed. Under these conditions, the tris(trimethylsilyl) $PGF_{2\alpha}$ pentafluorobenzyl ester (II*b*) had a retention time of 4 min.

GLC–Mass Spectrometry—GLC–mass spectra were recorded on a gas chromatograph–mass spectrometer[5], utilizing a column [0.77 m. (2 ft.)] packed with 3% OV-1 on Diatoport S (60–80 mesh). The column was maintained at a temperature of 225° and the flash heater at 270°.

Tris(trimethylsilyl) $PGF_{2\alpha}$ Pentafluorobenzyl Ester (IIb)—A sample of $PGF_{2\alpha}$ (I) was converted to the pentafluorobenzyl ester (II*a*) on a microscale. The product was treated with *N,O*-bis-(trimethylsilyl)-acetamide, and an aliquot was analyzed.

[1] On Silicar CC-4, 50 g., prepacked in ethyl acetate.

[2] Using a Vortex mixer.
[3] Varian Aerograph model 1740.
[4] Hewlett-Packard model 5750.
[5] LKB-9000.

A GLC peak with a retention time of ~2.2 min. was observed. A mass spectrum of this material showed an M^+ ion at *m/e* 750 and prominent peaks at: 735 ($M^+ - 15$) due to loss of CH_3, 679 ($M^+ - 71$) due to loss of C_5H_{11}, 660 ($M^+ - 90$) due to loss of $(CH_3)_3$—Si—OH, 645 ($M^+ - 105$) due to loss of $(CH_3)_3$—Si—OH + CH_3, 589 ($M^+ - 161$) due to loss of C_5H_{11} + $(CH_3)_3$—Si—OH, 570 ($M^+ - 180$) due to loss of 2× [$(CH_3)_3$—Si—OH], 237 ($M^+ - 513$), and 181 ($M^+ - 569$) due to CH_3—C_6F_5.

Tris(trimethylsilyl) Pentafluorobenzyl Ester (IVb)—A sample of the pentafluorobenzyl ester (IV*a*) prepared was treated with *N,O*-bis-(trimethylsilyl)acetamide, and an aliquot was analyzed.

A GLC peak with a retention time of ~16.5 min. was observed. A mass spectrum of the material showed an M^+ ion at *m/e* 778 and prominent peaks at: 763 ($M^+ - 15$) due to loss of CH_3, 707 ($M^+ - 71$) due to loss of C_5H_{11}, 688 ($M^+ - 90$) due to loss of $(CH_3)_3$—Si—OH, 673 ($M^+ - 105$) due to loss of $(CH_3)_3$—Si—OH + CH_3, 617 ($M^+ - 161$) due to loss of C_5H_{11} + $(CH_3)_3$—Si—OH, 598 ($M^+ - 180$) due to loss of 2× [$(CH_3)_3$—Si—OH], 237 ($M^+ - 541$), and 181 ($M^+ - 597$) due to CH_3—C_6F_5.

RESULTS AND DISCUSSION

The preparative scale synthesis of $PGF_{2\alpha}$ C_1-pentafluorobenzyl ester (II*a*) was conducted in acetonitrile using excess pentafluorobenzyl bromide (0.2 ml.), diisopropylethylamine (0.2 ml.), and $PGF_{2\alpha}$ (40 mg.). Under these conditions, the reaction was virtually quantitative in less than 1 hr. at room temperature on the basis of TLC examination. The ester was purified by silica gel column chromatography[6], and GLC-mass spectroscopy of the tris(trimethylsilyl) derivative confirmed the structure.

Only two reports appear in the literature for the preparation of pentafluorobenzyl esters of carboxylic acids, and the reported methods are slower than the method employed herein. Kawahara (27) refluxed carboxylic acids in acetone with potassium carbonate and excess pentafluorobenzyl bromide for 3 hr. to effect ester formation. Ehrsson (28) developed an ion-pair extraction process employing methylene chloride and an aqueous alkaline solution of tetrabutylammonium sulfate. However, only long-chain esters gave quantitative reaction in less than 20 min. Formation of the *n*-butyrate and *n*-valerate esters was incomplete after 2 hr. The use of diisopropylethylamine in the present study allowed homogeneous reaction conditions, and the high steric requirement of the amine served to minimize quaternary ammonium salt formation with pentafluorobenzyl bromide.

The $PGF_{2\alpha}$ C_1-pentafluorobenzyl ester (II*a*) was converted to the tris(trimethylsilyl) derivative (II*b*) prior to GLC.

Electron-capture GLC was conducted on one of two chromatographs[3,4]. Under the GLC conditions employed (see *Experimental* section), the lower limit of detection was 12.5 pg. of II*a* injected on-column in one instrument[3]. The lower limit of detection on the second instrument[4] was not determined. Typical chromatograms at the 1- and 10-ng. levels of II*a* are shown in Fig. 1. The GLC peak height response due to II*b* was linear for the 0.5–10-ng. range of II*a* injected on-column on the first instrument[3] (Fig. 2) and for the 0.03–0.84-ng. range of II*a* on the second[4].

The reaction conditions for the submicrogram scale conversion of $PGF_{2\alpha}$ (I) to the pentafluorobenzyl ester (II*a*) were explored. Since poor yields of the pentafluorobenzyl ester were obtained on attempting to derivatize nanogram quantities of $PGF_{2\alpha}$ adopting the conditions described earlier, the influence of reagent concentrations, temperature, and reaction time on the submicrogram pentafluorobenzyl esterification of $PGF_{2\alpha}$ was studied. The formation of the $PGF_{2\alpha}$ pentafluorobenzyl ester (II*a*) was monitored by electron-capture GLC analysis of the trimethylsilyl ether of the isolated product. Maximum conversion with minimum background interference was achieved when a picogram or nanogram quantity of $PGF_{2\alpha}$ (or the tromethamine salt of $PGF_{2\alpha}$) was treated with pentafluorobenzyl bromide (0.022 mmole) in acetonitrile (10 μl.) and diisopropylethylamine (0.007 mmole) in acetonitrile (10 μl.) and heated at 40° for 5 min. Maximum consistency of reaction was realized when the product was treated with the reagents again under identical conditions.

Initial attempts to isolate the pentafluorobenzyl ester product from the acidified reaction mixture by solvent extraction presented difficulties. Traces of citric acid used for the acidification caused high backgrounds on electron-capture analysis, probably as a result of pentafluorobenzyl esterification. Furthermore, under these extraction conditions, recoveries of the submicrogram quantities of the ester II*a* were erratic. Isolation of the product by direct evaporation of the solvent and excess reagents under nitrogen at room temperature was found to be ideal. Electron-capture detection background interference was minimal, and no sample loss was involved. Avoiding a conventional "workup" has the obvious advantages of saving time and effort. The $PGF_{2\alpha}$ pentafluorobenzyl ester product (II*a*) was converted to the tris(trimethylsilyl) ether (II*b*) by treatment with *N,O*-bis-(trimethylsilyl)acetamide. Hydrolysis of the trimethylsilyl groups of the submicrogram quantity of the derivative by traces of moisture was prevented, and maximum consistency of sample response was achieved by injection of the samples directly in the silylating agent. Typical gas chromatograms of the reagent blank and of II*b* formed by the reaction of a nanogram quantity of $PGF_{2\alpha}$ (I) are illustrated in Fig. 3. Although conversion of the $PGF_{2\alpha}$ ester (II*a*) to a bromomethyldimethylsilyl ether of enhanced electron-capture response is feasible, the excess halogen-containing silylating reagent would have to be completely eliminated, since even traces may cause "swamping" of the electron-capture detector (or high backgrounds). Attempts to remove rigorously all traces of the excess halogen-containing reagent prior to dissolving in a dry solvent (*e.g.*, ether) invariably result in partial hydrolysis of the timethylsilyl groups of the submicrogram sample and a consequent loss in sample response. To select a suitable "internal standard" for GLC, several prostaglandin analogs were converted to their pentafluorobenzyl esters on a microscale, and the GLC properties of the tris(trimethylsilyl) ethers of these esters were examined. Among those investigated, the tris(trimethylsilyl) pentafluorobenzyl ester of 9-{3α,5α-dihydroxy-2β-[(3*S*)-3-hydroxy-*trans*-1-octenyl]-1α-cyclopentyl}-*cis*-7-nonenoic

acid (III) proved to be the most suitable. This compound (IV*b*) had a retention time of 16.0 min. Compound II*b* had a retention time of 8.9 min. under the same GLC conditions on the first instrument[3]. The pentafluorobenzyl ester (IV*a*) was synthesized on a preparative scale by reaction of III (31.9 mg.) in acetonitrile with pentafluorobenzyl bromide and diisopropylethylamine (see *Experimental* section). The product was isolated from the acidified reaction mixture using ethyl acetate and was purified by sequential preparative GLC. Compound IV*b* was characterized by GLC–mass spectrometry (see *Experimental* section). Microgram and submicrogram scale syntheses of IV*a* were carried out by treatment with pentafluorobenzyl bromide and diisopropylethylamine in acetonitrile in the manner described for the derivatization of $PGF_{2\alpha}$ (I). Excess reagents were removed by evaporation under nitrogen at room temperature. The pentafluorobenzyl ester product (IV*a*) was dissolved in the silylating agent *N,O*-bis-(trimethylsilyl)-acetamide and added to the $PGF_{2\alpha}$ pentafluorobenzyl ester (II*a*) prior to electron-capture GLC analysis. The electron-capture GLC response due to II*b* resulting from the submicrogram scale reaction of $PGF_{2\alpha}$ (I) was found to be linear over the concentration range of 0.2–5.6 ng. $PGF_{2\alpha}$ (Fig. 4) (determined on the first chromatograph[3]).

Thus, the pentafluorobenzyl ester of $PGF_{2\alpha}$ (II*a*) is easily formed, and the corresponding trimethylsilyl derivative (II*b*) allows quantitation of $PGF_{2\alpha}$ (I) in the picogram and nanogram range using electron-capture detection. The application of this methodology to the quantitation of $PGF_{2\alpha}$ in biological fluids is currently being developed.

Carbocyclic Analogs of Guanosine and 8-Azaguanosine

Y. FULMER SHEALY▲ and JOE D. CLAYTON

Abstract □ (±)-9-[*trans*-2,*trans*-3-Dihydroxy-*cis*-4-(hydroxymethyl)-cyclopentyl]guanine, the carbocyclic analog of guanosine, was synthesized by a five-step route beginning with (±)-*trans*-3-amino-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol and 2-amino-4,6-dichloropyrimidine. Preparation and reduction of a 5-(*p*-chlorophenylazo)pyrimidine derivative introduced the prerequisite 5-amino substituent. Formation of the imidazole ring from this 5-amino derivative with triethyl orthoformate and acidic hydrolysis of the resulting mixture of 2-amino-6-chloropurine derivatives furnished the guanosine analog. The same 5-aminopyrimidine intermediate was diazotized to the 2-amino-6-chloro-8-azapurine, and the latter derivative was hydrolyzed to the carbocyclic analog of 8-azaguanosine. Neither of these analogs was cytotoxic to human epidermoid carcinoma cells *in vitro*. In tests using leukemia L-1210, the guanosine analog was quite toxic but was inactive at nontoxic doses; the 8-azaguanosine analog was not active in initial (single-dose) tests.

Keyphrases □ Guanosine, cyclopentyl analog—synthesis, cytotoxicity □ 8-Azaguanosine, cyclopentyl analog—synthesis, cytotoxicity □ Carbocyclic analogs of purine nucleosides—synthesis and cytotoxicity of cyclopentyl derivatives of guanine and 8-azaguanine □ Cyclopentyl derivatives of guanine and 8-azaguanine—synthesis, cytotoxicity □ Purine nucleosides, carbocyclic analogs—synthesis, cytotoxicity

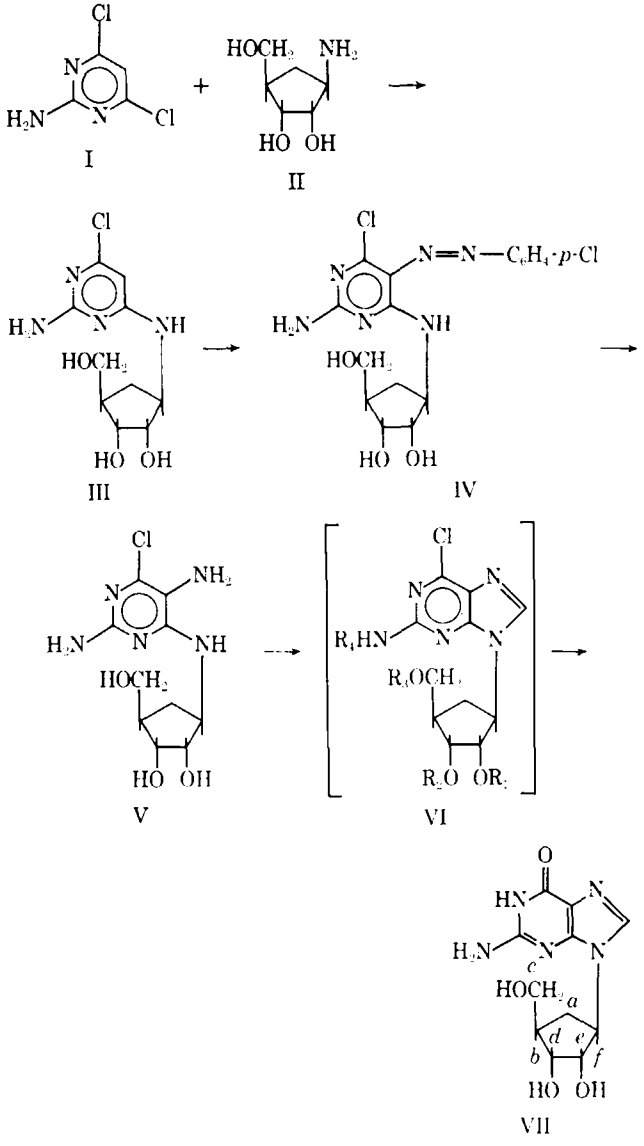
Syntheses of racemic, carbocyclic (cyclopentane) analogs of adenosine, 2′- and 3′-deoxyadenosine, adenylic acid, adenosine cyclic 3′,5′-monophosphate, and other 6-substituted purine nucleosides were described previously (1–4). Some of these nucleoside analogs, which have a stable carbon nitrogen bond at position 9 of the purine ring in place of the glycosidic bond, are cytotoxic to cells in culture (4–6), function as substrates for or inhibitors of purine-metabolizing enzymes (5–7), or display antimicrobial activity[1] (8). In the previously described analogs, the only substituent on the purine ring, other than the 9-cyclopentyl group, is at position 6. This report deals with the carbocyclic analogs of guanosine and 8-azaguanosine, which are 2-amino-6-substituted purines.

DISCUSSION

The synthesis of the racemic guanosine analog is outlined in Scheme I. Prolonged treatment of 2-amino-4,6-dichloropyrimidine (I) with *trans*-3-amino-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (II) (2) gave the pyrimidinylaminocyclopentane derivative (III). Triethylamine was employed as a proton acceptor, rather than an excess of II, because of the difficulty in obtaining large amounts of II. Coupling of III with *p*-chlorobenzenediazonium chloride in aqueous acetic acid buffered with sodium acetate gave good yields of the 5-(*p*-chlorophenylazo)pyrimidine (IV). The required 5-amino group was introduced by reducing the *p*-chlorophenylazo group with zinc in acetic acid, a method previously found (9) to effect this type of reduction of simpler derivatives without significantly affecting the chloro substituent on the pyrimidine ring.

The purine ring was formed by an acid-catalyzed reaction of triethyl orthoformate with the tetrasubstituted pyrimidine (V). Reactions of the hydroxyl groups and the 2-amino group with the reagent should produce derivatives (formyl, orthoester, cyclic orthoester, or polymeric) of the expected 2-amino-6-chloropurine (VI, $R_1 = R_2 = R_3 = R_4 = H$). The isolation of pure derivatives (VI) was not attempted; instead, the material obtained from V and triethyl orthoformate was subjected to acidic hydrolysis to hydrolyze the 6-chloro substituent and to liberate the functional groups simultaneously. That purine ring formation had proceeded satisfactorily was shown by the 78% overall yield of the guanosine analog (VII) from V. The proton magnetic resonance (PMR) and the UV absorption spectra were in accord with Structure VII.

Treatment of pyrimidine V (Scheme II) with sodium nitrite and aqueous acetic acid produced a high yield of the 5-amino-7-chloro-3*H*-*v*-triazolo[4,5-*d*]pyrimidine (VIII). Either acidic or basic hydrolysis of VIII gave the 8-azaguanosine analog (IX).



Scheme I—Letters a–f *identify protons with proton magnetic resonance chemical shifts* (*see* Experimental)

[1] R. F. Pittillo, Southern Research Institute, Birmingham, Ala., personal communication.

The guanosine analog (VII) was tested against leukemia L-1210 in mice on three treatment schedules[2]. When administered on Day 1 at doses of 400, 300, 150, and 75 mg./kg., VII displayed acute toxicity at the two higher doses. The difference (ΔW) between the average weight changes of the treated (T) and the untreated (C) mice indicated that the two lower doses were also toxic (ΔW = −5.6 and −3.9 g., respectively). Administered on Days 1, 5, and 9, doses of 38 and 19 mg./kg. were nontoxic and inactive; a shortened survival time (T/C = 70%) of treated animals indicated that a dose of 75 mg./kg. on this schedule is toxic. Doses of 38 and 19 mg./kg./day given *q.d.* 1–9 were toxic, as evidenced by shortened survival times (T/C = 71 and 83%, respectively) relative to untreated animals and by weight differences (ΔW = −5.1 and −2.3 g., respectively), whereas doses of 9.5 and 5 mg./kg./day were nontoxic and inactive. These data, especially the results of daily treatment, indicate that the toxicity of VII *in vivo* is approximately the same as that of the adenosine analog (4). In contrast to the similarity of the toxicity of the two analogs *in vivo*, the guanosine analog (VII) is not cytotoxic (ED_{50} >100 mcg./ml.) to human epidermoid carcinoma cells (H.Ep.-2) in culture, whereas the adenosine analog is highly cytotoxic[3] (ED_{50} = 0.7 mcg./ml.) (4).

The 8-azaguanosine analog (IX) was not cytotoxic (ED_{50} >100 mcg./ml.) to H.Ep.-2 cells in culture and was not active against L-1210 leukemia at doses of 100, 200, or 400 mg./kg. administered on the Day 1 schedule. The observed ΔW (−2.3 g.) at the highest dose was indicative of chronic toxicity.

EXPERIMENTAL[4]

(±)-*trans*-3-[(2-Amino-6-chloro-4-pyrimidinyl)amino]-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (III)—A mixture of 3.68 g. (22.4 mmoles) of 2-amino-4,6-dichloropyrimidine (I), 3.3 g. (22.4 mmoles) of *trans*-3-amino-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (II) (2), 2.26 g. (22.4 mmoles) of triethylamine, and 200 ml. of absolute ethanol was heated under reflux for 140 hr. The white, crystalline product was separated by filtration from the cooled reaction mixture, yielding 3.9 g. (63%), m.p. 234–238° dec. A specimen was recrystallized from water, m.p. 236–239° dec.; UV: λ_{max} 302 (sh), 287 (infl), 274 (ε 9600), 240 (ε 12,600), and 214 (ε 19,800) at pH 1; 286 (ε 10,200) and 237 (ε 11,400) at pH 7; and 287 (ε 10,200) and 238 (ε 11,200) at pH 13.

Anal.—Calc. for $C_{10}H_{15}ClN_4O_3$: C, 43.72; H, 5.51; N, 20.40; Cl, 12.90. Found: C, 43.53; H, 5.49; N, 20.20; Cl, 12.9.

(±)-*trans*-3-{[2-Amino-6-chloro-5-[(*p*-chlorophenyl)azo]-4-pyrimidinyl]amino}-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (IV)—A cold (0–5°) solution of *p*-chlorobenzenediazonium chloride, prepared from 5.90 g. (46.3 mmoles) of *p*-chloroaniline, 12.8 g. of 12 *N* HCl, 52 ml. of water, and 3.5 g. (50.5 mmoles) of sodium nitrite in 42 ml. of water, was added dropwise during 1 hr. to a well-stirred mixture of 11.53 g. (42 mmoles) of III, 84 g. of sodium acetate trihydrate, 200 ml. of acetic acid, and 200 ml. of water. The diazonium salt solution was maintained at 0–5° by adding it from a jacketed addition funnel kept cold with circulating ice water; the pyrimidine (III) solution was at room temperature. The mixture was stirred for 18 hr. at room temperature, cooled in an ice bath, and filtered to remove the yellow precipitate, which was washed with cold water and dried *in vacuo* over phosphorus pentoxide, yielding 14.1 g. (81%), m.p. 249–250° dec. (inserted at 230°); homogeneous by TLC [10 mcg., chloroform–methanol (5:1)]. After several days at room temperature, the filtrate deposited a second crop, weighing 1.25 g., m.p. 245–246° dec. A specimen of IV for analysis was recrystallized from dimethylformamide–water, m.p. 258–259° dec. (inserted at 240°, 2°/min.) and m.p. 262–263° dec. (inserted at 250°, 2°/min.); UV: λ_{max} 372 (ε 26,600), 280 (ε 8800), and 240 (ε 18,300) at pH 1; and 385 (ε 28,600), 280 (ε 10,700), and 227 (ε 16,300) at pH 7 and 13.

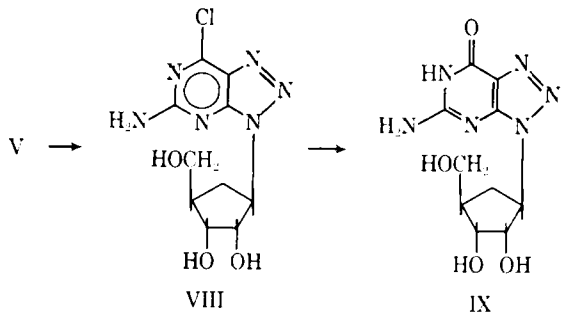
Anal.—Calc. for $C_{16}H_{15}Cl_2N_6O_3$: C, 46.50; H, 4.39; Cl, 17.16; N, 20.34. Found: C, 46.33; H, 4.29; Cl, 17.3; N, 20.32.

(±)-*trans*-3-[(6-Chloro-2,5-diamino-4-pyrimidinyl)amino]-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (V)—A mixture of 7.2 g. of the *p*-chlorophenylazopyrimidine (IV), 140 ml. of ethanol, 172 ml. of water, and 14 ml. of acetic acid was heated to 70° with vigorous mechanical stirring under a nitrogen atmosphere. Zinc dust (11.2 g.) was added in small portions during 45 min., and the mixture was heated at 70° with vigorous stirring for an additional 1.25 hr. Excess zinc was filtered from the hot mixture and washed with three portions of ethanol; the filtrate, combined with the ethanol washings, was concentrated *in vacuo* to about 50 ml.; and the resulting mixture was diluted with ethanol (50 ml.) and stored at 5° overnight. The tan crystalline precipitate was separated by filtration, washed with ethanol–water (3:1), and dried *in vacuo* at 78°, yielding 2.46 g. (49%), m.p. 245–247° dec. (inserted at 230°); UV: λ_{max} 298 (ε 8000), 237 (ε 15,500), and 210 (ε 16,200) at pH 1; 303 (ε 9000), 240 (sh), 225 (sh), and 204 (ε 19,200) at pH 7; and 303 (ε 9000), 240 (sh), and 225 (sh) at pH 13.

Anal.—Calc. for $C_{10}H_{16}ClN_5O_3$: C, 41.45; H, 5.57; Cl, 12.24; N, 24.18. Found: C, 41.22; H, 5.70; Cl, 12.4; N, 24.00.

The filtrate was concentrated *in vacuo*. A water (100 ml.) solution of the residual oil was washed with ether (3 × 75 ml.), concentrated *in vacuo* to about 30 ml., and kept at 5° overnight. Recrystallization of the brown crystalline precipitate from water gave 320 mg. of V (total yield 55%), m.p. 235–243° dec.

(±)-9-[*trans*-2,*trans*-3-Dihydroxy-*cis*-4-(hydroxymethyl)cyclopentyl]guanine (VII)—A solution consisting of 1.45 g. of V, 20 ml. of dimethylformamide, 40 ml. of triethyl orthoformate, and 1 ml. of 12 *N* HCl was kept at room temperature for 1.5 hr., at 5° for 16 hr., and at room temperature for 8 hr. The reaction solution was concentrated *in vacuo* at 30°. A mixture of the residual syrup and 200 ml. of 2 *N* HCl was heated under reflux for 5 hr. and then concentrated *in vacuo* at 50°. Several portions of water were evaporated *in vacuo* from the residue before it was dissolved in water (10 ml.). The pH of the aqueous solution was adjusted to 5 with 6 *N* NaOH, the mixture was chilled (5°) for 2 hr., and the solid precipitate (1.285 g.) was separated by filtration and washed with water. The precipitate was recrystallized from water (15 ml.) and dried *in vacuo* over phosphorus pentoxide at 78° for 18 hr., yielding 1.154 g. (78% as a 0.75 hydrate), m.p. 279–282° dec. (softened and resolidified in 250–260° range); purity 96–97% by UV (calculated as a 0.75 hydrate). A sample for analysis [white needles (150 mg.) obtained by recrystallizing 225 mg. of crude VII from 10 ml. of water] was dried at 100° over phosphorus pentoxide for 20 hr., m.p. 278–284° dec. (inserted at 230°, softened and darkened at 250–255°, resolidified);



Scheme II

[2] In the standard L-1210 leukemia test, mice are innoculated intraperitoneally on Day 0 with 10^5 L-1210 cells. Administration of a compound is also by intraperitoneal injection. Weight changes are determined 4 days after the first (or only) injection. Weight differences in excess of 4 g. or values of $T/C \lesssim 85\%$ are accepted criteria of chronic toxicity. Since the carbocyclic analogs have generally shown a good correlation between dose and weight difference (ΔW), a weight difference of 2–3 g. also appears to indicate chronic toxicity.

[3] ED_{50} = concentration of a compound that inhibits growth, measured by protein determinations, to 50% of the growth of untreated cells.

[4] Melting temperatures were determined in capillary tubes heated in a Mel-Temp apparatus and are not corrected. UV spectra were recorded with a Cary model 17 or 14 spectrophotometer. UV maxima are in nanometers; sh = shoulder, and infl = inflection. Solutions for UV determinations were prepared by diluting a 5-ml. aliquot of a water or ethanol solution (0.1 *N* HCl for III) to 50 ml. with 0.1 *N* HCl, phosphate buffer (pH 7), or 0.1 *N* NaOH; absorption maxima are reported at pH 1, 7, or 13. IR spectra were recorded with a Perkin-Elmer model 621 or 521 spectrometer from samples in KBr disks. PMR spectra were determined with a Varian model XL-100-15 spectrometer for observing proton resonance at 100 MHz. Chemical shift data (δ) are in parts per million downfield from tetramethylsilane, the internal reference; s = singlet, d = doublet, and m = multiplet. Unless otherwise indicated, TLC was performed on plates of silica gel, and spots were detected by: (*a*) UV light (254 nm.) after spraying the chromatogram with an optical whitening agent (Ultraphor WT, BASF Colors and Chemicals, Inc., Charlotte, N. C.) and (*b*) spraying with a basic solution of potassium permanganate. The quantity applied and the developing solvent are shown parenthetically at the appropriate places in the procedures.

IR: 1725, 1675, 1625, 1605 (sh), 1565, 1545, 1480, 1170, 770 (sharp), and 680 cm.$^{-1}$ and other bands (broad or weak); PMR[5] (dimethyl sulfoxide-d_6): δ about 1.3–1.7 (m, H*a*), about 1.8–2.4 (m, H*a*H*b*), 3.28–3.6 (m, H*c*H*c*), 3.37 (s, water), 3.72–3.9 (m, H*d*), 4.08–4.34 (m, H*e*), 4.36–4.78 (m, H*f* + 2OH), 4.82–4.98 (d, OH), 6.39 (s, NH_2), 7.79 (s, H_8 of purine ring), and 10.58 (s, NH of purine ring); UV: λ_{max} (ϵ calculated for 0.75 hydrate) at 278 (ϵ 8000) and 255 (ϵ 11,900) at pH 1; 268 (sh) and 253 (ϵ 13,000) at pH 7; and 268 (ϵ 11,100) and 257 (sh) (ϵ 10,500) at pH 13.

Anal.—Calc. for $C_{11}H_{12}N_5O_4 \cdot {}^3/_4H_2O$: C, 44.81; H, 5.64; N, 23.76. Found: C, 44.75; H, 5.87; N, 23.44.

Specimens of VII dried at 100° for about 20 hr. apparently rehydrated readily since they were observed to increase in weight during weighing for analysis. The melting point was evidently influenced by the degree of hydration as well as the heating rate. A specimen recrystallized from dimethylformamide ethanol melted at 298–300° dec. without prior softening (inserted at 100°, 2°/min. at 260°). Recrystallization of this specimen from water (including treatment with activated carbon) changed the melting point to 284–286° dec. (softened and darkened at 260°, resolidified; inserted at 230°, 2°/min. at 260°); homogeneous by TLC [silica gel or cellulose, 10 mcg., propanol–water (3:1); detection by UV, UV and spraying[6], and potassium permanganate spray]. The exact values of ϵ are also determined by the degree of hydration at the time the sample is weighed for UV determination.

(±)-*trans*-3-(5-Amino-7-chloro-3*H*-*v*-triazolo[4,5-*d*]pyrimidin-3-yl)-*trans*-5-(hydroxymethyl)-*cis*-1,2-cyclopentanediol (VIII) A solution of 240 mg. (3.48 mmoles) of sodium nitrite in 6 ml. of water was added dropwise to a cold (0°) mixture of 870 mg. (3.0 mmoles) of V, 9 ml. of water, and 3 ml. of acetic acid. The mixture was stirred at 0° for 1 hr., and the product was separated by filtration and washed with 5 ml. of cold water, yielding 828 mg. Recrystallization of the crude VIII from ethanol–hexane gave a white solid, which was dried *in vacuo* over phosphorus pentoxide at room temperature for 18 hr. and then at 78° for 0.5 hr., yielding 766 mg. (85%), m.p. 172–174° dec.; TLC: 1 spot [20 mcg., chloroform–methanol (4:1)]; UV: λ_{max} 226 (ϵ 21,600), 245–260 (infl), and 316 (ϵ 7500) at pH 1; 226 (ϵ 21,900), 245–260 (infl), and 316 (ϵ 7500) at pH 7; and 246 (ϵ 4700) and 286 (ϵ 9900) at pH 13.

Anal.—Calc. for $C_{10}H_{13}ClN_6O_3$: C, 39.94; H, 4.36; N, 27.95. Found: C, 39.75; H, 4.55; N, 27.71.

(±)-5-Amino-3,6-dihydro-3-[*trans*-2,*trans*-3-dihydroxy-*cis*-4-(hydroxymethyl)cyclopentyl]-7*H*-*v*-triazolo[4,5-*d*]pyrimidin-7-one (IX)— A mixture of 250 mg. of VIII and 20 ml. of 1 *N* HCl was heated under reflux for 4 hr. and concentrated *in vacuo* at 40° to a syrup. Water (2 × 20 ml.) was added to the residue and evaporated *in vacuo*, and ethanol (10 ml.) was then added. A gelatinous solid was separated by filtration, washed with acetone, and dried *in vacuo* over phosphorus pentoxide at 78°, yielding 75 mg. The filtrate and the acetone washings were combined and evaporated *in vacuo*, the residue was triturated with ethanol–hexane (1:1, 10 ml.), and a gelatinous solid was filtered away and dried *in vacuo* over phosphorus pentoxide at 78°, yielding 99 mg. (total yield 74%). Both portions were homogeneous according to TLC [20 mcg., ethanol–15 *N* aqueous ammonia (4:1)]. A 6 *N* HCl solution of the two portions was diluted with ethanol, and the gelatinous precipitate was dried as before, yielding 88 mg. (38%), m.p. 252–254° dec. (inserted at 240°, 2°/min.); IR: 1700, 1635, 1595 (sh), 1580, 1525, 780, and 680 cm.$^{-1}$; UV: λ_{max} 253 (ϵ 11,800) and 270 (sh) at pH 1, 253 (ϵ 11,700) and 270 (ϵ 8600) at pH 7, and 279 (ϵ 11,000) and 260 (sh) at pH 13.

Anal.—Calc. for $C_{10}H_{14}N_6O_4 \cdot {}^2/_3H_2O$: C, 40.81; H, 5.25; N, 28.56. Found: C, 40.99; H, 5.22; N, 28.60.

Hydrolysis of VIII with refluxing 1 *N* NaOH also yields IX.

Effects of Polyelectrolytes on Drug Transport I: Diffusion

K. F. FARNG and K. G. NELSON▲

Abstract □ The capillary method was used to determine the diffusive transport properties of radioactive salicylate ion in the presence of a commonly used polyelectrolyte, sodium carboxymethylcellulose. In a solution of this polymer, the self-diffusion coefficient of salicylate was found to decrease only moderately, even though the bulk macroscopic viscosity increased about two to three orders of magnitude. These data were evaluated with two theories from the literature. The tracer drug release rate out of the polymer solutions was also studied and was more rapid than if the polymer were not present. Increases of up to 40% were observed.

Keyphrases □ Diffusion properties, radiolabeled salicylate as co-ion in sodium carboxymethylcellulose—determined using capillary method □ Carboxymethylcellulose, sodium—effect on co-ion diffusion of radiolabeled salicylate, capillary method □ Salicylate, radiolabeled, diffusion coefficient and tracer release rate in sodium carboxymethylcellulose—determined using capillary method, co-ion effect □ Polyelectrolytes—effect of carboxymethylcellulose on salicylate co-ion diffusion □ Drug transport—effect of carboxymethylcellulose on salicylate co-ion diffusion

Hydrophilic polymers that are commonly added to pharmaceutical preparations can influence the transport properties of the system and, hence, the rate of drug absorption. Levy and Jusko (1) demonstrated that the increase in viscosity due to methylcellulose decreased the absorption rate of ethanol and salicylic acid in rats. Other investigators (2, 3) also reported similar viscosity–absorption effects.

The most widely known relationship between diffusive transport and viscosity is the Stokes–Einstein equation. This equation is based partly on the movement of a spherical solute through a continuous medium. With high molecular weight polymer solutions, however, the physical conditions are somewhat different. The relatively low concentration of polymer imparts a substantial increase in the bulk or "macroscopic" viscosity. The microscopic environment of a diffusion species, however, is largely solvent, and only infrequently does the diffusant encounter a polymer segment along its diffusion path. Thus, the Stokes–Einstein equation would not be expected to hold for diffusion in dilute polymer solutions.

Reports have appeared involving studies of diffusion in dilute polymer solutions. Florence *et al.* (4) measured the diffusion coefficients of sodium chloride and potassium chloride in aqueous solutions of polyethylene oxide (polyethylene glycol) and polyvinylpyrrolidone. Using these diffusion coefficients and the Stokes–Einstein equation, they calculated the "effective" or "microscopic" viscosities. These values were smaller than the corresponding relative bulk viscosities. Block and Lamy (5) also observed a difference between the bulk viscosity and that apparently experienced by a diffusant. Li and Gainer (6), working with organic solvents, developed equations relating the diffusivity in these systems to such parameters as heat of mixing, viscosity, and diffusivity (in the pure solvent). Taking another approach, Wang (7) developed an equation for the self-diffusion of water in protein solutions based on the physical obstruction by the protein and the hydration effect.

The self-diffusion of the counterion in dilute polyelectrolyte solutions was studied by Huizenga *et al.* (8) and Pefferkorn and Varoqui (9). They found that diffusion coefficients decrease as the degree of neutralization increases. Rinando *et al.* (10) also found that diffusivity decreases as the degree of substitution on carboxymethylcellulose increases. These results were explained in terms of electrostatic effects of the polyelectrolyte on the counterion.

The use of polyelectrolytes to enhance the absorption of drugs that are co-ions of the polymer was suggested by Higuchi *et al.* (11). The experimentally observed increased transport rate was attributed to the Donnan membrane effect. Diffusion properties in the solution were not considered.

The present studies were undertaken to determine the diffusional properties of drugs that are present as co-ions in polyelectrolyte solutions and the characteristics of their transport out of these solutions across a cellophane membrane. This article reports the results of the diffusion studies.

EXPERIMENTAL

The capillary method (12) was employed to determine the diffusion coefficient of salicylate in a solution of sodium carboxymethylcellulose. Briefly, this method is based on the diffusion of a radioactive tracer out of a capillary tube into a tracer sink, which has the

[a] Self-diffusion coefficient (see Case A in text). [b] Apparent diffusion coefficient (see Case B in text).

same chemical composition as the solution inside the capillary. The solution to Fick's second law corresponding to these boundary conditions is:

$$\frac{C}{C_0} = \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp\left[-(2n+1)^2 \pi^2 \frac{Dt}{4l^2}\right] \quad \text{(Eq. 1)}$$

where C_0 and C are the tracer activities in the capillary initially and at time t (seconds), l is the length of the capillary in centimeters, and D is the self-diffusion coefficient in square centimeters per second. Four capillaries were used for each run; they had an inside diameter of 0.5 mm. and nominal lengths of 2.4, 2.7, 3.1, and 3.5 cm. The accurate length of each capillary was determined with a projection device[1], and the volume was calculated from the weight of mercury required to fill the capillary at a known temperature. The capillary holder was so constructed that each opening of the set of four capillaries was at about the same level below the surface in a 250-ml. tall beaker, which held the sink solution (Fig. 1). The effect of stirring at 100 r.p.m. on the diffusion path length was negligible (13, 14).

Sodium salicylate[2] solutions (8 m*M*) were prepared containing the appropriate amount of sodium carboxymethylcellulose[3]. An appropriate amount of neutralized ^{14}C-salicylic acid[4] was added to about 0.3 ml. of the solution to yield an initial activity of about 5000 counts/min./μl. The tracer solution was degassed and then put into the capillary with a 33-gauge needle. The precaution about temperature equilibrium and immersing effects was followed as suggested by Wang (13). After 96–120 hr. of diffusion, the remaining activity in each capillary was washed into a counting vial with water (0.2 0.3 ml.) from a syringe. Most of the water in the vial was evaporated by heating in an oven to increase the counting efficiency. The radioactivity was obtained using the standard preset ^{14}C window opening[5]. The external standard ratio-efficiency curve was constructed to correct the quenching effect; background was also corrected. The range of C/C_0 was about 0.1–0.4. The diffusion coefficients were calculated from Eq. 1, and the average values and standard deviations are listed in Table I.

RESULTS AND DISCUSSION

The effect of sodium carboxymethylcellulose on salicylate diffusion was studied in two cases: Case A, polymer was both inside and outside of the capillary; and Case B, polymer was inside the capillary only. In both cases, the initial sodium salicylate concentration of 8 m*M* was the same inside and outside the capillary; *i.e.*, there was no salicylate concentration difference. The diffusion coefficient D obtained in Case A is the true self-diffusion coefficient since there is no chemical potential gradient at the capillary opening. The diffusion coefficient obtained in Case B is not the true self-diffusion coefficient, even though it was evaluated through Eq. 1, because there is a polyelectrolyte concentration gradient at the boundary.

Case A: Self-Diffusion—The relative viscosity of bulk solution deduced from the manufacturer's data booklet (15) is listed in Table II. It is apparent that the Stokes–Einstein equation does not hold since the relative viscosity increases over 1000-fold while the diffusion coefficient decreases less than 10% (Table I).

Mackie and Meares (16) proposed the following equation to calculate the mobility of an ion, U, in a polymer matrix:

$$U = U_0 \left(\frac{1 - V_p}{1 + V_p}\right)^2 \quad \text{(Eq. 2)}$$

where U_0 is the mobility of the ion in water, and V_p is the volume fraction of polymer. Since the diffusion coefficient, D, is proportional to U, one can write (4):

$$D = D_0 \left(\frac{1 - V_p}{1 + V_p}\right)^2 \quad \text{(Eq. 3)}$$

Since the density of a 2% carboxymethylcellulose solution at 25° is 1.0068 g./cm.³ (15), assuming weight to volume concentration equal to volume to volume concentration, the diffusivity in the polymer solutions can be calculated with Eq. 3 if D_0 is known. The experimental value of the diffusion coefficient for salicylate (8 m*M*) in water at 37° was found to be 1.11 × 10^{-5} cm.²/sec. Others have reported values of 1.00 × 10^{-5} (17), 1.33 × 10^{-5} (18), and 0.925 × 10^{-5} cm.²/sec. (19), all determined under somewhat different experimental conditions. The experimentally determined diffusivities, shown as the ratio D/D_0, are given in Fig. 2 (Case A). The line generated from Eq. 3 is included and it can be seen that the agreement is rather good.

Taking a somewhat different approach, Wang (7) developed an equation for self-diffusion of water in a protein solution. Neglecting the hydration effect, *i.e.*, the association between polymer and diffusant, the proposed equation is:

$$D = D_0(1 - \alpha V_p) \quad \text{(Eq. 4)}$$

where α is the shape factor of protein. This equation predicts a linear dependence of D on the volume fraction. At low values of volume fraction, *i.e.*, in the range of the present study, it can be shown that Eq. 3 reduces to:

$$D = D_0(1 - 4V_p) \quad \text{(Eq. 5)}$$

Thus, at low concentrations of polymer, Eqs. 3 and 4 have the same functional relationship. The current data thus appear to obey either equation because of the low polymer concentration.

Data from the literature are available to evaluate these two equations further. By using two sets of diffusion coefficients reported by Florence *et al.* (4), one set given by Wang (7), and the set deter-

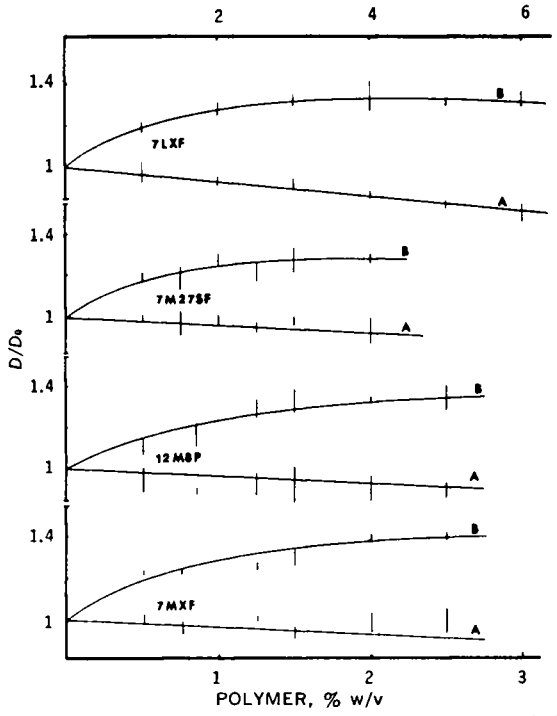

Figure 2—D/D_0 *of sodium salicylate* versus *concentration (w/v %) of sodium carboxymethylcellulose of various types: 7MXF, 12M8P, 7M27SF, and 7LXF. Upper scale is for 7LXF only. Case A = self-diffusion in polymer solution; Case B = diffusion* out of *polymer solution.*

mined for sodium carboxymethylcellulose (7LXF) in this work, the equations can be tested for higher concentrations of polymer. With these diffusion coefficients, V_p was calculated from Eq. 3 and plotted against polymer concentration (Fig. 3). By assuming the actual volume fraction of polymer to be directly proportional to the polymer concentration, if Eq. 3 is the correct equation, Fig. 3 should display linear relationships. It can be seen, however, that all data display positive curvature.

A similar test can be made for Eq. 4. Because of the constant factor α, the quantity αV_p calculated from Eq. 4 is plotted against polymer concentration (Fig. 4). Again, if the equation truly describes the phenomenon, this plot should be linear. It can be seen that Fig. 4 displays much better linear relationships than Fig. 3.

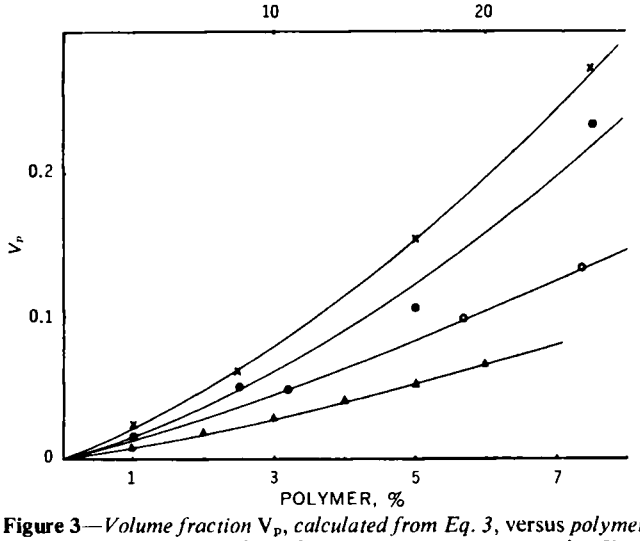

Figure 3—*Volume fraction* V_p, *calculated from Eq. 3,* versus *polymer concentration. Upper scale is for water-protein system only. Therefore, Eq. 4 appears to be a better representation for the experimental data at higher polymer concentrations.

A practical consideration based on this information is that the diffusive transport of a drug in a dilute polymer solution is dependent on αV_p. One can define $\overline{\alpha V_p}$ as the value of αV_p per unit concentration, so $\overline{\alpha V_p}$ can be evaluated experimentally. The slopes of the lines in Fig. 4 were $\overline{\alpha V_p}$ in units of volume fraction per percent. Their values are listed along with the standard errors in Table III, and these factors are different for different polymers. A polymer having a relatively large $\overline{\alpha V_p}$ decreases diffusive transport more than one having a small $\overline{\alpha V_p}$. This factor $\overline{\alpha V_p}$ may be a more useful term than viscosity to characterize a polymer relative to its effect on the diffusive properties of small molecules in dilute solutions of the polymer.

Case B—To study further the effect of the polyelectrolyte on the diffusive transport of a drug as co-ion of the polymer, release rates *out of* the polyelectrolyte solutions were determined. Experiments similar to those of Case A were performed, except that the polyelectrolyte was present only inside the capillary and not in the sink. Thus, the diffusion coefficient calculated from the data by Eq. 1 is not the true self-diffusion coefficient because of the existence of a polyelectrolyte gradient at the boundary. However, the calculated apparent diffusion coefficient, D', does give an indication of the polyelectrolyte effect on the co-ion transport. The D' values are reported in Table I and, for comparison with Case A, the results are presented in Fig. 2 (Case B) as a ratio of D' to D_0. It can be seen that the radioactive salicylate ion is released faster than in Case A.

The polymer contains a net ionic charge, although it does not correspond exactly to the degree of substitution. These concentrated charges create a rather strong electric field which influences the distribution of ions around the polymer. Since the polyelectrolyte is present inside the capillary only, the electrochemical potential of the co-ion is changed relative to that outside the capillary. In addition to the Brownian diffusive transport, this electric field gradient gives another driving force for the salicylate transport. This additional driving force increases the apparent diffusion coefficient.

The increase in D' may also arise from other sources. The polymer diffusion out of the capillary may carry with it some salicylate ion. However, this probably would be small because the diffusion coefficient of a high molecular weight polymer is relatively small. Also, the osmotic pressure arising from the polyelectrolyte may induce water to flow into the capillary, forcing out the salicylate ion. Experiments were performed using the strong electrolyte sodium fluoride in place of the polyelectrolyte to establish an osmotic pressure difference. Using sodium fluoride up to a concentration of 0.4 M inside the capillary did not change D' significantly from D,

Table II—Relative Viscosity of Various Types of Sodium Carboxymethylcellulose Solutions (15)

Type of Polymer	Degree of Substitution	Concentration (% by Weight) 1.0	1.5	2.0	2.5	3.0	4.0	5.0	6.0
7MXF, 12M8P	0.7, 1.2	50	1.8×10^2	4.5×10^2	1.2×10^3	—	—	—	—
7M27SF	0.7	1.6×10^2	6×10^2	1.5×10^3	3×10^3	—	—	—	—
7LXF	0.7	11	—	20	—	1×10^2	3×10^2	8×10^2	2×10^3

Table III—Factor $\overline{\alpha V_p}$ for Various Polymer Systems

Polymer System	$(\overline{\alpha V_p} \pm SE) \times 10^2$, Volume Fraction/%	Reference
Sodium chloride–polyethylene glycol 6000	8.31 ± 0.73	4
Potassium chloride–polyethylene glycol 6000	9.08 ± 0.20	4
Sodium chloride–polyvinylpyrrolidone	48.1 ± 0.42	4
Water–protein	1.73 ± 0.03	7
Sodium salicylate–sodium carboxymethylcellulose (7LXF)	3.80 ± 0.12	This work

which was determined with sodium fluoride present both inside the capillary and the sink (Table I). Therefore, it can be inferred that the osmotic effect of the polymer is negligible.

From a practical point of view, the release rate of a medication from a preparation is an important factor to be considered by the formulator. The present work shows that high molecular weight polymers commonly used to increase the viscosity in liquid preparations decrease the diffusion of drugs *within* the solution only slightly (Eq. 4). Also, if the drug is present as a co-ion of the polyelectrolyte, it will be transported *out of* the polymer solution faster than if the polymer were not present. Increases of up to 40% were observed (Fig. 2).

The use of polyelectrolytes to enhance drug absorption was suggested by Higuchi *et al.* (11) nearly 2 decades ago. The present work substantiates this proposal by means of a different experimental approach and sheds light on the diffusive transport properties of small molecules in these dilute polymer solutions.

For sodium carboxymethylcellulose (degree of substitution 0.7), the release of co-ion increases as the concentration of polyelectrolyte increases initially and then levels off at about 2–3% (w/v), regardless of the molecular weight of sodium carboxymethylcellulose. Thus, when using this polyelectrolyte, the viscosity needed determines the molecular weight of the polymer, whereas the optimum polymer concentration for the drug release is in the range of 2–3%.

Influence of Temperature and Nature of Hydrophobic Groups on Thermodynamic Parameters of Hydrophobic Bonding in a Model Polymeric System and Their Implications in Drug-Biopolymer Interactions

JANARDAN B. NAGWEKAR▲ and NUALTA MUANGNOICHAROEN

Abstract □ By using a model polymeric system, the thermodynamic parameters of hydrophobic bonding between the alkyl groups as well as between two methylene groups were determined. This was accomplished by studying the binding of the anions of fatty acids, propionate through caproate, by the hexyl copolymer from 28 to 45°. The hexyl copolymer was synthesized by quaternizing with hexyl bromide the vinylpyridine units of a copolymer of an overall composition of 1 unit of vinylpyridine to 22 units of vinylpyrrolidone. The hexyl vinylpyridinium units of the copolymer are shown to constitute the definite sites for hydrophobic bonding. The results of the present study, together with those of a previous study, revealed the influence of temperature and the nature of hydrophobic groups on the thermodynamic parameters of hydrophobic bonding. The significance of these characteristic properties of hydrophobic bonding in drug-biopolymer interactions is discussed. A GLC method, developed for quantitative determination of the fatty acids, is described.

Keyphrases □ Hydrophobic bonding between alkyl and between methylene groups—temperature effect, implications in drug-biopolymer interactions □ Drug-biopolymer interactions—temperature and group effects on hydrophobic bonding □ Thermodynamic parameters, hydrophobic bonding—effects of temperature and length of alkyl group □ Temperature effect—thermodynamic parameters of hydrophobic bonding, alkyl fatty acids and vinylpyridine–vinylpyrrolidone polymer □ Vinylpyridine–vinylpyrrolidone copolymer—used to study hydrophobic bonding between alkyl and between methylene groups

In addition to the noncovalent forces such as ionic attraction and hydrogen bonding, the importance of hydrophobic bonding is well recognized in drug-receptor interactions (1). Hydrophobic bonding is the interaction between hydrophobic groups in an aqueous medium, and such an interaction is characteristically accompanied by positive enthalpy and entropy effects (2). In view of the biopharmaceutical significance of hydrophobic bonding phenomena, a model water-soluble polymeric system was devised and studied (3); it served to demonstrate certain properties of hydrophobic bonding between the phenyl and alkyl groups. An interesting feature noted in this study, carried out at 15, 22, 30, 37, and 45°, was that the binding between the hydrophobic groups increased up to 37° but decreased at 45°. Furthermore, when the corresponding binding constant was plotted against the alkyl copolymer of the homologous series, an ascending zigzag curve was obtained.

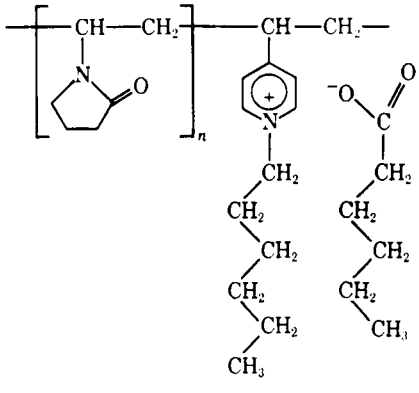
Based on a physical model, Nemethy and Scheraga (4) theorized that hydrophobic bond formation becomes stronger up to 42° between the aromatic hydrocarbons but that it becomes stronger up to 58° between the aliphatic groups. Therefore, the purposes of the present study were: (*a*) to determine the thermodynamic parameters of hydrophobic bonding (28–45°) between the alkyl groups, as well as between two methylene groups, using a model water-soluble alkyl copolymer containing known sites of hydrophobic bonding; and (*b*) to determine if the hydrophobic bonding between the alkyl groups in the model system continues to be stronger up to 45°, as well as with the increase in chain length at a given temperature.

MODEL SYSTEM

The present model system consists of the study of the binding of the fatty acid anions, propionate through caproate, by the hexyl copolymer. The procedures for synthesis and overall composition determination of the hexyl copolymer were previously reported (3). The overall composition of the copolymer was 1:23 (1 unit of quaternized vinylpyridine to 23 units of vinylpyrrolidone). The fatty acids (pKa 4.81–4.87) were expected to remain in solution in the ionized form since the interactions were carried out at pH 7.4. The binding energy involved in these interactions is due to both electrostatic binding and hydrophobic bonding. Scheme I depicts how the electrostatic binding facilitates the approach of the fatty acid anions sufficiently close to the quaternized units so that hydrophobic bonding can occur between the alkyl group of the carboxylate ion and the hexyl group of the hexyl copolymer. Evidence has been obtained (as explained later) to indicate that the sites on the alkyl copolymers for binding of fatty acid anions are indeed the vinylpyridinium units. The suitability of such a model system in determining the thermodynamic parameters of hydrophobic bonding between the interacting hydrophobic groups was explained previously (3).

EXPERIMENTAL

Materials—Hexyl copolymers (1:23, 1:27, and 1:42) were synthesized according to the method previously described (3). Sodium propionate[1] and sodium butyrate[1] were recrystallized from



Scheme I—Representation of the interaction of a caproate ion with a hexyl copolymer unit. The iceberg structures around the methylene and methyl groups are not shown. In the diagram, n represents the average 23 units of vinylpyrrolidone to 1 unit of quaternized vinylpyridine.

Table I—Retention Times Observed for the Fatty Acids[a]

Compound	Column Temperature	Retention Time, min.
Propionic acid	120°	6.0
Butyric acid	140°	4.5
Valeric acid	150°	5.0
Caproic acid	160°	5.0

[a] The conditions used were: sensitivity, range 10, attenuation 8–32×; injection port temperature, 210°; detector temperature, 210°; and helium flow rate, 30 ml./min.

an acetone–water (5:1) mixture according to Childers and Struthers (5). Sodium valerate and sodium caproate were prepared from *n*-valeric acid[2] and *n*-caproic acid[1], respectively, according to the methods described by Childers and Struthers (5). Other chemicals used were reagent grade.

Apparatus—The fatty acids were quantitatively analyzed with the aid of a gas chromatograph[3] equipped with a flame-ionization detector. The column employed was a 1.21-m. long and 0.63-cm. o.d. copper tube packed with 80–100-mesh diatomite[4] coated with 15% diethylene glycol adipate. Helium was used as the carrier gas. A 10-μl. standard syringe[5] was used for injecting the sample. A recording spectrophotometer[6] was used for the copolymer analysis. An expandomatic pH meter[7] was used for the potentiometric determination of bromide content of the hexyl copolymer and for pH determinations of the solutions. Plexiglas dialysis cells[8] of 2-ml. capacity were used in the equilibrium dialysis studies.

Solution of Hexyl Copolymer—A 4% (w/v) solution of hexyl copolymer (1:23) was prepared in a pH 7.4 phosphate buffer of 0.1 ionic strength. Similar solutions of hexyl copolymers (1:27 and 1:42) were also prepared. The ionic strength of all solutions was adjusted to 0.114 with sodium chloride.

Solution of Sodium Salt of Fatty Acid—The solutions of each acid (0.004–0.014 *M*) were prepared in pH 7.4 phosphate buffer. The ionic strength of each solution was adjusted to 0.114 with sodium chloride.

Dialysis Procedure—Each dialysis cell consisted of two Plexiglas halves, 5 × 5 × 2 cm., each with a cavity having 1-ml. capacity. The dialysis cells were set up in the same manner as previously described (3). The solutions were transferred into each cavity of the dialysis cell by means of 1-ml. tuberculin syringes. The cells were allowed to shake in a water bath maintained at 28, 32, 37, or 45 ± 0.3°. Although the system attained equilibrium in 60 hr., the cells were allowed to shake in the bath for 84 hr. To ensure accuracy of the results, the standard dialysis cells were set up along with the sample cells. The standard cells were set up in the same manner as the sample cells, except that 1 ml. solution of pH 7.4 phosphate buffer of appropriate ionic strength was used in place of 1 ml. solution of the hexyl copolymer.

After 84 hr., the cells were removed from the bath and promptly the contents from the nonpolymer side and polymer side of each cell were quantitatively transferred to 2.5-ml. graduated tubes by means of Pasteur pipets. The graduated tubes were stoppered and allowed to stand until the contents of the tubes attained room temperature. The volume of solution obtained from the nonpolymer side of each cell generally measured 0.9 ml. and that obtained from the polymer side of each cell generally measured 1.1 ml. Therefore, the appropriate correction was made for the concentration of hexyl copolymer in the polymer solution in each dialysis set-up. All studies were carried out in duplicate at each concentration of the fatty acid.

Quantitative Determination of Fatty Acids by GLC—The quantitative determinations of the fatty acids in the solutions obtained from the nonpolymer side of each cell were carried out by GLC, using 15% diethylene glycol adipate liquid phase coated on diatomite[4]. Immediately prior to GLC analysis, 0.01 ml. concentrated hydrochloric acid was added to each solution to convert the salt of the fatty acid to the free fatty acid. The pH of such solutions was found to be about 1. Four microliters of the acidified solution was then injected into the GLC column. The conditions for analysis are given in Table I. A typical chromatogram of fatty acids is shown in Fig. 1. The area under the curve of each chromatogram was calculated by the trapezoidal rule. The calibration curves relating the area under the curve to the concentration were prepared for each fatty acid by analyzing gas chromatographically the acid solutions of known concentration. A typical calibration curve obtained for valeric acid is shown in Fig. 2.

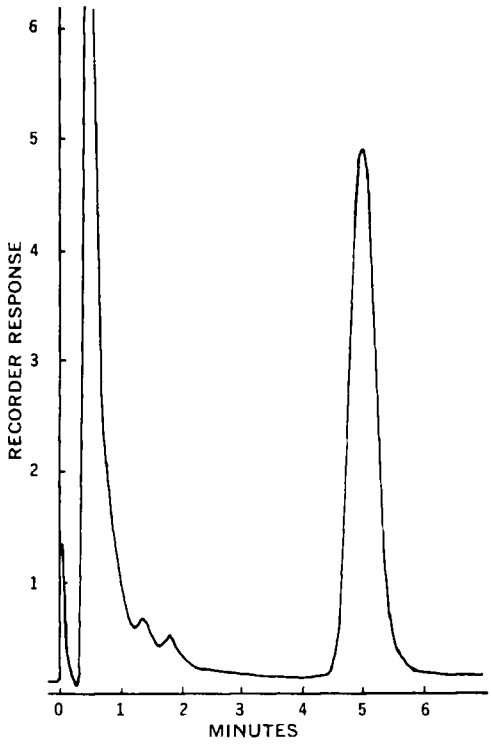

Figure 1—*A typical gas chromatogram obtained for valeric acid.*

Binding of Anions of Valeric Acid by 1:27 and 1:42 Hexyl Copolymers—To determine if binding of the fatty acid anions by the hexyl copolymer was solely due to the quaternized vinylpyridine units of the latter, the binding of the anions of valeric acid (0.006 *M*) by the hexyl copolymers (1:27 and 1:42) was studied at 37° and 0.114 ionic strength in the usual manner.

RESULTS AND DISCUSSION

Quantitative Determination of Fatty Acids by GLC—The use of 15% diethylene glycol adipate as the liquid phase in the quantitative GLC analysis of the fatty acids was found to be satisfactory (Fig. 2). With reference to such a standard plot as in Fig. 2, the amounts of the fatty acid contained in the solutions from the nonpolymer side of the sample cells were calculated. To ascertain the accuracy of such quantitative analyses, the standard plots were constructed for the fatty acid contained in the standard cells of each run. The amount of fatty acid bound by hexyl copolymer in each dialysis cell was calculated in the usual manner. It was generally observed that the difference between the quantity of fatty acid calculated from each duplicate sample was about 1–2%. None of the fatty acids was bound to the cellophane membrane or the dialysis cells.

Identification of Binding Sites in Hexyl Copolymer—As noted in Fig. 3, the extent of binding of valerate ions was directly proportional to the molar concentration of the hexyl vinylpyridinium bromide content of the hexyl copolymer, indicating that the hexyl vinylpyridinium groups constituted the binding sites for the fatty acid anions. Further support to this conclusion was obtained by demonstrating that a negligible amount of valerate ions is bound by nonquaternized 1:42 copolymer (4% w/v) at 37° and 0.114 ionic strength.

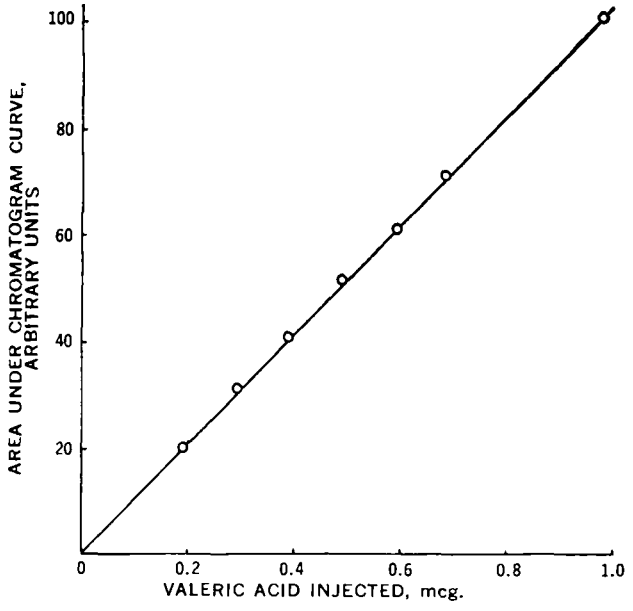

Figure 2—*Calibration curve for valeric acid.*

each fatty acid were treated according to the Klotz equation (6):

$$1/r = 1/n + 1/nKa \qquad \text{(Eq. 1)}$$

where r is the number of moles of fatty acid anion bound per mole of hexyl copolymer, n is the average number of binding sites per mole of the hexyl copolymer, a is the molar concentration of free fatty acid anion at equilibrium, and K is the binding constant (liters per mole). As shown in Fig. 4, typical Langmuir plots of $1/r$ *versus* $1/a$ were constructed for the binding data of the anion of each fatty acid, and the values of n and K were determined from the intercept ($1/n$) and the slope ($1/nK$) of the straight line obtained by the least-squares method. The binding constants are listed in Table II. The straight-line plots in Fig. 4 indicate that the fatty acid anions bind to identical sites present in the hexyl copolymer. Also, out of every 10 binding sites, the number of sites available on the hexyl copolymer for the binding of the fatty acid anion was about 7–9.7. This may be due to some coiling of the hexyl copolymer molecules, making a few sites unavailable for binding (3).

As seen in Table II, not only the extent of binding of the fatty acid anion increased with the increase in the chain length at each temperature but also the extent of binding of the anion of each fatty acid increased with the increase in temperature from 28 to 45°.

Thermodynamic Parameters for Binding of Fatty Acid Anion—The free energy of binding (ΔF_b) of the fatty acid anion was calculated from the following equation:

$$\Delta F_b = -RT \ln K \qquad \text{(Eq. 2)}$$

where R and T have the usual meanings. Since the plots of log K *versus* $1/T$ (Fig. 5) were reasonably straight lines (least squares), the enthalpy of binding is considered to be constant over the 28–45° range. The enthalpy of binding (ΔH_b) was calculated from the slope of the straight line obtained according to the van't Hoff equation:

$$\log K = \frac{-\Delta H}{2.33RT} + \text{constant} \qquad \text{(Eq. 3)}$$

The values of entropy of binding (ΔS_b) were calculated from the following relationship:

$$\Delta S_b = \frac{\Delta H_b - \Delta F_b}{T} \qquad \text{(Eq. 4)}$$

The thermodynamic constants thus determined are listed in Table III.

Since the binding of the fatty acid anion by the hexyl copolymer was found to be associated with the positive enthalpy and entropy effects (Table III), it is concluded that the polymeric system used in the present study exhibits the properties of hydrophobic bond formation. Despite the fact that the positive enthalpy observed in the study is unfavorable for the binding process, the ΔF_b becomes increasingly negative (and, therefore, favorable) with the increase in temperature because of the gain in entropy. The gain in entropy occurs due to hydrophobic interactions in the aqueous medium between the alkyl groups of the hexyl copolymer and those of the fatty acid resulting in the release of water molecules from the "icebergs" around the alkyl groups and, consequently, in the release of configurational entropy of the alkyl groups (3).

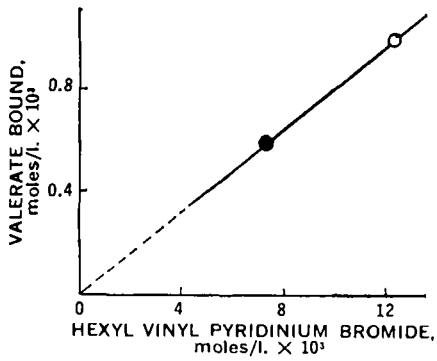

Figure 3—*Binding of valeric acid anion (6 μmoles/dialysis cell) by 1:42 (●) and 1:27 (○) hexyl copolymers at 37° and 0.114 ionic strength.*

The fact that the ΔF_b in the present system increased with the increase in chain length of the fatty acid further substantiates that the present polymeric system displays the characteristics of hydrophobic bonding.

Determination of Thermodynamic Parameters of Hydrophobic Bonding—Since the hexyl vinylpyridinium units of the hexyl copolymer constitute the sites for binding of fatty acid anions, it is apparent that the observed ΔF_b is mainly a combination of the free energy of binding due to electrostatic forces (ΔF_e) and the free energy of binding due to hydrophobic bonding between the side chains ($\Delta F_{H\phi}{}^S$):

$$\Delta F_b = \Delta F_e + \Delta F_{H\phi}{}^S \qquad \text{(Eq. 5)}$$

Furthermore, the ΔF_e of the anions of all fatty acids can be considered to be the same. Therefore, from the data in Table III, the $\Delta F_{H\phi}{}^S$ due to the alkyl groups of the copolymer and the corresponding fatty acid anions can be calculated by subtracting the ΔF_b of the appropriate fatty acid anion from those of the higher homologs at each temperature. It is recognized that there is a possibility

	32°	58.97
	37°	75.61
	45°	170.73

that the alkyl groups attached to the charged groups (such as the quaternary nitrogen in the hexyl copolymer and the carboxylate group of the fatty acid anion) may influence the structure of water around them differently than when they exist in water as aliphatic hydrocarbons. Therefore, in this context, the appropriate fatty acid anion in the homologous series refers to that anion of sufficient chain length whose end methyl group is just beyond the sphere of electrostatic effect of its charged group. This would then make it possible to determine the thermodynamic parameters of hydrophobic bonding between two methylene groups if, indeed, the iceberg structure around the methylene groups of the alkyl groups is uniform beyond the sphere of the electrostatic influence of the charged group. However, it is recognized that in a homologous series such uniformity in the iceberg structure around the methylene groups can be expected only up to a limited chain length of the alkyl group, since the alkyl groups beyond a certain chain length are subject to curling to reduce their surface exposure to water.

In view of the enthalpy of solution data in water reported by Snell and Greyson (7) for sodium formate (−0.269 kcal./mole), sodium acetate (−3.973 kcal./mole), sodium propionate (−3.015 kcal./mole), and sodium butyrate (−3.385 kcal./mole) at 25°, it

Caproate	−2336	−2471	−2665	−3247	13,817	53.40

becomes apparent that there exists a nonuniformity in the iceberg structure around the alkyl groups of short-chain fatty acid anions. Unfortunately, such thermodynamic data are not available for sodium salts of valeric and caproic acids to suggest that the nonconformity is minimized in the iceberg structure around the tail-end methylene groups of the alkyl chains of these salts. However, Everett (8) observed that the singly charged ions such as the quaternary nitrogen and carboxylate group exert a significant influence on the solvent (water) structure only over a distance of 5 Å. Since the C—C bond length is about 1.54 Å (8), this would then suggest that the influence of the singly charged groups of the copolymer and fatty acid anions on the structure of water around the methylene groups, which are separated from them by at least three methylene groups, should be minimal. Therefore, it is considered appropriate to obtain the data for free energy of hydrophobic bonding between the alkyl groups by subtracting the ΔF_b of butyrate ions from those of the higher homologs at corresponding temperatures. In this manner the free energy of hydrophobic bonding between the CH_2 group of valerate ion and the CH_2 group of the hexyl chain of the copolymer and between the CH_2—CH_2 group of caproate ion and the CH_2—CH_2 group of the hexyl chain of the hexyl copolymer can be estimated. The values of free energy of hydrophobic bonding thus obtained for the portions of the alkyl groups of the reactants are designated as $\Delta F_{H\phi}{}^{PA}$ (Table IV).

As shown for ΔF_b in Eq. 5, the two types of forces that contribute to the enthalpy of binding as well as to the entropy of binding of the fatty acid anions by the hexyl copolymer can be described as follows:

$$\Delta H_b = \Delta H_e + \Delta H_{H\phi}{}^{S} \qquad \text{(Eq. 6)}$$

$$\Delta S_b = \Delta S_e + \Delta S_{H\phi}{}^{S} \qquad \text{(Eq. 7)}$$

The contribution of ΔH_e and ΔS_e due to electrostatic interaction can be considered to be the same for all of the fatty acid anions. Therefore, the enthalpy ($\Delta H_{H\phi}{}^{PA}$) and the entropy ($\Delta S_{H\phi}{}^{PA}$) due to hydrophobic bonding between the portions of the alkyl groups of the reactants involved are calculated by subtracting the ΔH_b and ΔS_b of the butyrate ions from those of the higher homologs. The values thus calculated are presented in Table V.

It is interesting to note that the values of $\Delta H_{H\phi}{}^{PA}$ and $\Delta S_{H\phi}{}^{PA}$ (Table V) obtained for the interaction between CH_2—CH_2 (copolymer) and CH_2—CH_2 (caproate) are almost twice those obtained for the interaction between CH_2 (copolymer) and CH_2 (valerate). Although these data are limited, it appears that the enthalpy and

Table IV—Free Energy ($\Delta F_{H\phi}^{PA}$) Determined by Hydrophobic Bond Formation between the Corresponding Portions of the Alkyl Groups of the Hexyl Copolymer and the Fatty Acid Anions at 0.114 Ionic Strength

Temperature	Interacting Portions of Alkyl Groups of Hexyl Copolymer	Fatty Acid Anion	$\Delta F_{H\phi}^{PA}$, cal./mole
28°	CH_2	CH_2 (valerate)	−193
	CH_2—CH_2	CH_2—CH_2 (caproate)	−478
37°	CH_2	CH_2 (valerate)	−136
	CH_2—CH_2	CH_2—CH_2 (caproate)	−440
45°	CH_2	CH_2 (valerate)	−339
	CH_2—CH_2	CH_2—CH_2(caproate)	−687

Table V—Enthalpy ($\Delta H_{H\phi}^{PA}$) and Entropy ($\Delta S_{H\phi}^{PA}$) Determined for Hydrophobic Bonding between the Corresponding Portions of the Alkyl Groups of the Hexyl Copolymer and the Fatty Acid Anions at 0.114 Ionic Strength

Interacting Portions of Alkyl Group of Hexyl Copolymer	Fatty Acid Anion	$\Delta H_{H\phi}^{PA}$, kcal./mole	$\Delta S_{H\phi}^{PA}$, e.u.
CH_2	CH_2 (valerate)	1.69	6.15
CH_2—CH_2	CH_2—CH_2 (caproate)	3.26	12.15

entropy of hydrophobic bonding between two methylene groups can be expected to be uniform as long as these groups of the alkyl chain are not influenced by the charged groups and are fully exposed to water. This finding also corroborates the observation made by Everett (8) that the singly charged ions significantly influence the structure of water only over a distance of 5 Å. This may also explain why the $\Delta H_{H\phi}^{PA}$ and $\Delta S_{H\phi}^{PA}$ values calculated by subtracting the ΔH_b and ΔS_b values of propionate ions from those of the higher homologs do not appear to be as uniform as those obtained by subtracting the ΔH_b and ΔS_b values of butyrate ions. This becomes evident by considering, for instance, the $\Delta H_{H\phi}^{PA}$ values of 2.34, 4.04, and 5.61 kcal./mole obtainable from the data in Table III (upon subtracting ΔH_b of propionate ions) for hydrophobic bonding between CH_2 (copolymer) and CH_2 (butyrate), CH_2—CH_2 (copolymer) and CH_2—CH_2 (valerate), and CH_2—CH_2—CH_2 (copolymer) and CH_2—CH_2—CH_2 (caproate), respectively. However, the extrathermodynamic analysis (Fig. 6) of the $\Delta H_{H\phi}^{PA}$ and $\Delta S_{H\phi}^{PA}$ data obtainable from Table III by subtracting the ΔH_b and ΔS_b values of propionate ion, or those data presented in Table V, reveals that a single interaction mechanism (in this case the hydrophobic bonding) is operative in the binding of the various alkyl groups of the anions of fatty acids with the alkyl group of the hexyl copolymer. This conclusion is drawn not only from the linear relationship observed between $\Delta H_{H\phi}^{PA}$ and $\Delta S_{H\phi}^{PA}$ according to the theory advocated by Leffler and Grunwald (9) but also from the compensation temperature (T_c) of 270° (10) noted from the slope of the straight line passing practically through the origin.

Comparison of Nature of Binding Constant Data Obtained for Hydrophobic Bonding between Phenyl and Alkyl Groups and between Alkyl Groups—It was observed in the present study that the binding constant of the fatty acid anions increased with the increase in the chain length. In the previous study (3), however, an ascending zigzag pattern in the binding constant was observed. The zigzag pattern was explained in terms of probable closer orientation of the terminal methyl group of the propyl and pentyl chain of the alkyl copolymers to the phenyl group of the target sulfonate ion than the terminal methyl group of the butyl and hexyl chain of the alkyl copolymers. In the present model system, both interacting groups involved in hydrophobic bonding are alkyl groups. Therefore, having brought these alkyl groups closer to each other through electrostatic forces, it does not seem unreasonable to expect the alkyl groups to align against each other in such a way that each methylene group and methyl group of the fatty acid would approach the methylene groups of the hexyl chain of the hexyl copolymer within the same van der Waals radius. Such alignment of the alkyl groups would result in the release of water molecules from the icebergs around the methylene groups in increasing numbers, thereby increasing the binding constants, with the increase in the chain length of the fatty acid anion.

Comparison of Temperature Effects of Hydrophobic Bonding between Phenyl and Alkyl Groups and between Alkyl Groups—In the previous study (3), it was observed that the binding of *p*-toluenesulfonate ions by the alkyl copolymers, ethyl through hexyl, increased with an increase in temperature up to 37° but decreased at 45°. However, it is noted in the present study that binding of fatty acid anions by the hexyl copolymer increased with an increase in temperature up to 45°. The decrease in binding of the sulfonate ions by the alkyl copolymers was attributed to the breakdown of the icebergs around these ions at 45°. Therefore, a gain in entropy due to hydrophobic interaction between the alkyl groups of the alkyl copolymer and the phenyl group of the sulfonate ions at 45° was substantially lower than that at 37°. The finding of the present study then suggests that the icebergs around the alkyl groups are not disrupted at 45°. Consequently, a gain in entropy due to hydrophobic interaction between the alkyl groups of the hexyl copolymer and those of the fatty acid anions would be expected to continue at 45°. These findings are in agreement with the theoretical expectation by Nemethy and Scheraga (4). It is, therefore, reasonable to conclude further that the polymeric system employed in the present study is successful in revealing experimentally the additional characteristic of hydrophobic bonding with regard to its temperature dependency.

SIGNIFICANCE

The interesting feature of the polymeric system employed in this study is that the hexyl copolymer contained the binding sites (to interact with fatty acid anions) whose chemical nature was known, thereby making it possible to determine the apparent thermodynamic parameters of hydrophobic bonding between two methylene groups.

The previous (3) and present studies, both of which involved essentially the same polymeric system, demonstrated that the strengths of hydrophobic bonds depend on the nature (aliphatic or aromatic) of the interacting hydrophobic groups. For instance, on comparison, it becomes clear that the hydrophobic bonding noted in the previous study between the toluyl group and the hexyl group is much weaker than that between the pentyl group and the hexyl group noted in the present study. It was also observed that the strength of the hydrophobic bond formed between the toluyl group and each of the alkyl groups (ethyl through hexyl) did not increase with the increase in chain length of the alkyl groups but varied in a zigzag manner, reflecting the importance of the odd or even number of carbon atoms contained in the alkyl groups. In the present study, however, the strength of hydrophobic bonding of the hexyl group of the hexyl copolymer with the alkyl groups (propyl through hexyl) of the fatty acid anions increased with the increase in chain length of the alkyl groups. Therefore, it is conceivable that these features of hydrophobic bonding can provide a useful basis for revealing the presence of polar or nonpolar (aliphatic or aromatic) groups in the vicinity of a binding site (or a receptor) of an enzyme or a similar biopolymer responsible for the action of a drug, by appropriately evaluating the thermodynamic parameters of the binding of a drug and its suitable homologs with the biopolymer. Such an approach has been the basis of the macromolecular perturbation theory of drug action developed by Belleau (11).

A similar approach can also be useful in detecting the hydrophobic groups present in the vicinity of the charged binding site(s) of the plasma proteins for a variety of drugs that remain in the charged form in the plasma. Such approaches will by no means provide instant knowledge of the chemical nature of the binding or receptor sites on the macromolecules, but they will serve to focus attention on the more likely chemical entities or residues of macromolecules that possess positive or negative charges in the plasma. For instance, one would consider evaluating the amino acid residues such as lysine and arginine as the possible binding sites if the binding of anionic drugs to proteins is being investigated, or one would evaluate the amino acid residues such as aspartic acid and glutamic acid as the possible binding sites if the binding of cationic drugs to proteins is concerned.

The effect of temperature on the icebergs around the phenyl group as noted in the previous study (3), in contrast to those around the alkyl groups in the present study, is noteworthy. This phenomenon, in case of hydrophobic bonding between a drug molecule and a biopolymer, should offer additional means of revealing if the hydrophobic bonding is due to the interaction between the phenyl

groups, between the alkyl groups, or between the alkyl and phenyl groups of the interacting species. Also, in this context, the degree of effect of higher body temperature (fever) on the tertiary structure of vital biopolymers (enzymes), and consequently on their physiological activities, could be expected to depend on the nature of hydrophobic groups involved in hydrophobic bonding responsible for maintaining the tertiary structure of the biopolymers.

Preparation and *In Vitro* Evaluation of Cellulose Acetate Phthalate Coacervate Microcapsules

H. P. MERKLE and P. SPEISER▲

Abstract □ Microcapsules of phenacetin were prepared by coacervation of aqueous cellulose acetate phthalate solutions. Appropriate solutions were made by dissolving cellulose acetate phthalate in an equivalent concentration of disodium hydrogen phosphate. A triangular phase diagram of the coacervation system was elaborated by using sodium sulfate as the coacervating agent, and the coacervation and encapsulation conditions were optimized. The amount of drug encapsulated has no significant effect on the particle-size distribution of the capsules; however, it influences the release rates of the drug, indicating that drug diffusion through the shells is the controlling step. When the shells are plasticized by imbibition with glycerol, the release rate is no longer controlled by drug diffusion through the shells but by the dissolution of phenacetin in the microcapsules.

Keyphrases □ Cellulose acetate phthalate coacervate microcapsules—formulation, *in vitro* drug (phenacetin) release rates, effect of glycerol plasticizer □ Encapsulation—formulation and *in vitro* testing of cellulose acetate phthalate coacervate microcapsules of phenacetin □ Coacervation of cellulose acetate phthalate—formulation of microcapsules, *in vitro* phenacetin release rates, plasticizer effect □ Microcapsules, phenacetin- formation from cellulose acetate phthalate coacervate system, release rates, plasticizer effect

The preparation of microcapsules by coacervation can be applied to various products (1). Different coating materials, suitable for coacervate encapsulation, were reported by Ranney (2). In pharmacy, however, the most common preparation technique is either simple coacervation of gelatin with ethanol or sodium sulfate as dehydrating agents (3–9) or complex coacervation of gelatin-acacia mixtures (10–12). Coacervation methods with pure gelatin and mixtures are rather complicated and difficult to keep under control, particularly with regard to the hardening of shells and the recovery technique of the microcapsules. The suitability of other coacervation systems for pharmaceutical purposes has not yet been studied.

Cellulose acetate phthalate was used by Jensen and Wagner (13) as a film-forming agent for encapsulation of a herbicide by simple coacervation. However, the encapsulation procedure presented in this patent is not practicable, owing to the insolubility of the cellulose ester in pure water and its total hydrolysis at pH 9.7, which is proposed as the encapsulation pH. Due to acidic groups, the cellulose ester is insoluble in strong acids but soluble in weak acids (>pH 5.5), neutral electrolytes, and bases. It is a suitable encapsulation material for timed-release dosage forms. Due to its very low acute and chronic toxicity, cellulose acetate phthalate was chosen as the encapsulating material in this study.

The present article reports a relatively uncomplicated process for the encapsulation of solid drugs by the simple coacervation of the cellulose ester, which is dissolved in appropriate disodium hydrogen phosphate solutions. The coacervation is induced by the dehydrating effect of the added sodium sulfate solution. Furthermore, the optimal coacervation and encapsulation conditions and the properties of the resulting microcapsules are examined with regard to drug content, size distribution, and release and release mechanisms of drugs.

EXPERIMENTAL

Materials and Methods—The cellulose acetate phthalate used was of Ph. Helv. VI quality, containing 34.1% phthalic acid and 2.7% free acid, calculated as phthalic acid.

Phenacetin (*N*-acetyl-*p*-aminophenetidin), of Ph. Helv. VI quality (m.p. 134–135°), was chosen as the drug model for the encapsula-

groups, between the alkyl groups, or between the alkyl and phenyl groups of the interacting species. Also, in this context, the degree of effect of higher body temperature (fever) on the tertiary structure of vital biopolymers (enzymes), and consequently on their physiological activities, could be expected to depend on the nature of hydrophobic groups involved in hydrophobic bonding responsible for maintaining the tertiary structure of the biopolymers.

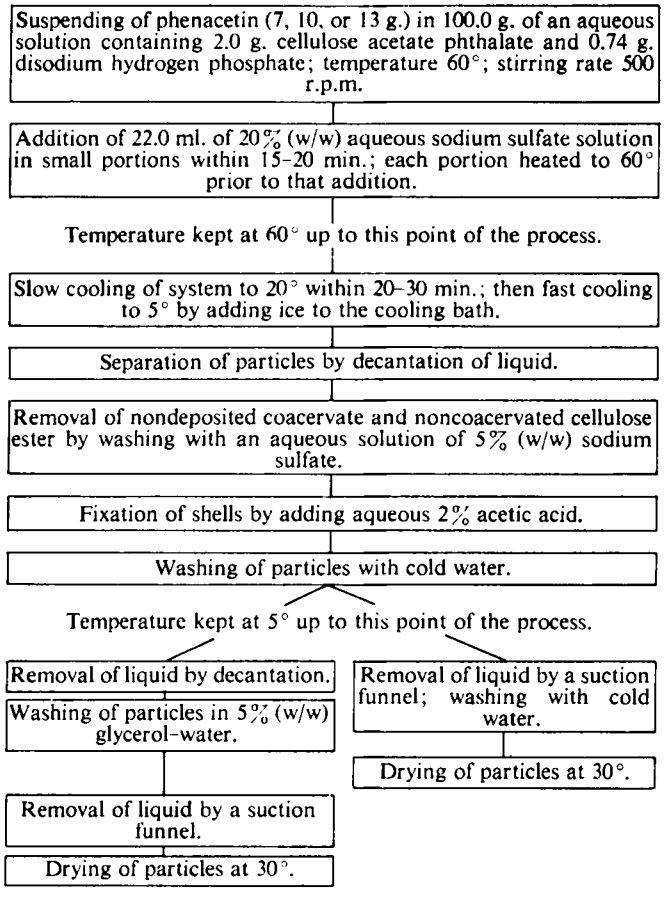
Furthermore, the optimal coacervation and encapsulation conditions and the properties of the resulting microcapsules are examined with regard to drug content, size distribution, and release and release mechanisms of drugs.

EXPERIMENTAL

Materials and Methods—The cellulose acetate phthalate used was of Ph. Helv. VI quality, containing 34.1% phthalic acid and 2.7% free acid, calculated as phthalic acid.

Phenacetin (*N*-acetyl-*p*-aminophenetidin), of Ph. Helv. VI quality (m.p. 134–135°), was chosen as the drug model for the encapsula-



Scheme I—Preparation of cellulose acetate phthalate microcapsules

tion, primarily because of its sufficient stability and insolubility in aqueous cellulose ester solutions. These properties are the fundamental requirements for good core materials. Sieve fractions of 0.10–0.50-mm. diameter were used.

Sodium sulfate (reagent grade) in a 20% (w/w) aqueous solution was used as a coacervating agent. All other compounds used were reagent grade.

Preparation of Cellulose Acetate Phthalate Solutions—A certain amount of cellulose ester was agitated in an aqueous solution of stoichiometrically equivalent quantities of disodium hydrogen phosphate (Na_2HPO_4) (calculated on the basis of the acidity of cellulose ester amounts, including free and bound acid, with 1.0 g. of cellulose ester being equivalent to 0.37 g. Na_2HPO_4) by means of a high speed stirrer (Polytron type) at 60°. After 1 min., most of the cellulose ester suspended was dissolved. The remaining solid cellulose ester was dissolved by low speed stirring using a magnetic stirrer at 60°. The dissolution was completed in about 15–20 min. The resulting solutions were filtered and stored at room temperature. The solutions proved to be stable for at least 1 week and showed no variation in coacervation behavior during that time.

Preparation of Microcapsules—As a preliminary proceeding, a triangular diagram was elaborated for the three phases participating in the cellulose ester coacervating system, *i.e.*, water, the cellulose ester, and salt. The latter consisted of disodium hydrogen phosphate (solvating agent) and sodium sulfate (dehydrating and coacervating agent). Portions of 100.0 g. of the cellulose ester solution were placed in a flask, which was maintained at 60° in a thermostated water bath and equipped with a reflux condenser. The solutions were stirred by a two-blade propeller at 500 r.p.m. For the coacervation of the cellulose ester, a 20% (w/w) aqueous sodium sulfate solution was added in parts. The supply of the sodium sulfate solution was constantly maintained at 60° with the help of a thermostated heating mantle. The start of coacervation was optically observed under the microscope. Solutions with 0.5 and 1.0–10.0% (1.0% interval) of cellulose ester were tested.

For microencapsulation, the same procedure was repeated by adding 10.0 g. of phenacetin to each concentration of the cellulose ester tested. The encapsulating and coacervating behavior of the slurries was observed microscopically. An optimum of coacervation and encapsulation was reached at a minimum agglomeration of the particles, a maximum deposition of coacervate on particles, and a minimum deformation of the liquid shells during encapsulation.

Following this procedure, all batches of microcapsules were produced within the field of optimum coacervation and encapsulation conditions. The method of preparation is shown in Scheme I. The encapsulations were made in a three-necked, 250-ml. beaker, equipped with a reflux condenser and a thermostated water bath for heating and cooling. The mixtures were agitated by a two-blade propeller-stirrer at a constant stirring rate of 500 r.p.m. The position of the stirrer was kept constant in all experiments. Special attention was given to the position of the stirrer, which must produce efficient mixing without nonconvected regions, an important requirement for preventing agglomeration of the particles. As may be seen from Scheme I, gelling of liquid shells was caused by cooling to 5°. The cellulose ester, which was not coacervated or deposited on the particles, was removed by washing and decanting with a 5% (w/w) aqueous sodium sulfate solution at 5°. Thereafter, the shells were fixed by addition of 2% acetic acid to the final pH 3.5. This process converted the solvatized cellulose ester gel to the nondissociated insoluble cellulose ester acid. If desired, the shells of washed particles can be treated with water-soluble plasticizers by washing the particles, for example, with a 5% (w/w) aqueous glycerol solution for 15 min. at 5°. The plasticizer treatment of the microcapsules should prevent rupture of the shells during drying.

Assay of Phenacetin Content—Microcapsules, 100.0 mg., were thoroughly triturated in a mortar. The resulting powder was transferred to a 600-ml. beaker. After a thorough rinsing of mortar and pestle with water, the powder was suspended in approximately 250 ml. of water (including the water used for rinsing). For complete rupture of the shells, the suspension was treated with ultrasonics for 2 min.[1]. The completeness of rupture by this treatment was observed previously. Heating to 40° and stirring with a magnetic stirrer for about 30 min. provide a complete dissolution of the phenacetin crystals. The resulting solution was filtered through a glass suction funnel (G3) to separate the shell fragments. After thorough rinsing of all equipment, the solution was transferred into a 500.0-ml. volumetric flask. More water was used for rinsing and to reach the total volume of 500.0 ml. Samples of this solution were diluted at a ratio of 1 to 20 with aqueous pH 1.2 buffer (0.1 *M* hydrochloric acid, 0.1 *M* sodium chloride) and assayed spectrophotometrically[2] at 245 nm.

Particle-Size Analysis—Before analyzing the particle-size distributions, the microencapsulated phenacetin was put through a 0.63-mm. analytical sieve to separate coarse, agglomerated particles exceeding this size. The following method for the determination of particle size and particle-size distribution was developed. Microphotos of pure and microencapsulated drug were enlarged on photographic paper. The reproduced particles were counted and measured with a semiautomatic particle-size analyzer[3]. For each analysis, a minimum of 500–600 particles was evaluated from several microphotos. The particle-size distributions were calculated by means of a computer program (ALGOL).

Release—The release of drug from microcapsules was followed by a flow cell column method, similar to that described by Langenbucher (14) and Tingstad and Riegelman (15). Column height was 3.0 cm. and cross-sectional area was 3.14 cm.^{2}. The solvent used was 0.1 *M* hydrochloric acid, which was brought to an ionic strength of 0.2 by addition of sodium chloride. Solvent was pumped with a two-roller silicone tube pump through the flow cell. The quantity of the solvent and the flow rate were kept constant for all experiments (500.0 ml. of solvent; flow rate of 50 ml./min.). Before passing through the flow cell, the solvent was thermostated at 37 ± 0.5° by a heat exchanger. An amount of microcapsules, equivalent to a mass load of 65.0 mg. of total drug, was taken for all experiments. To analyze the phenacetin content of the solution, samples of 2.0 ml. were taken out of the solution reservoir after appropriate intervals. After diluting with the same solvent, the samples were analyzed spectrophotometrically at 245 nm. The maximum drug concentration in the solution did not exceed 10% of the saturation

concentration of the drug, which guaranteed sufficiently good sink conditions.

RESULTS AND DISCUSSION

Triangular Phase Diagram of the Coacervate System—The isothermal triangular diagram of phase boundaries of the coacervate system of cellulose acetate phthalate, water, and salt is shown in Fig. 1. The salt phase consists of two components: disodium hydrogen phosphate and sodium sulfate as solvating agent and coacervating agent, respectively. The values on the total salt axis in Fig. 1 are the additive percentages of the individual salt species in the system. A procedure to calculate these individual concentrations from this graph is given. The combination of both salt species to one phase was necessary to reduce the actual four-component system to a three-component system which can be visualized graphically by a usual triangular phase diagram.

The phase diagram presented is divided into three fields: A, B, and C. In field A, the cellulose ester is only partially dissolved. At the boundary between fields A and B, the ratio between the amounts of disodium hydrogen phosphate and the cellulose ester is constant. At this ratio, *i.e.*, 0.37, the cellulose ester is completely dissolved. Within field A, the salt phase consists only of disodium hydrogen phosphate. The salt species additionally added to the system in fields B and C is sodium sulfate. The coacervation starts at the boundary separating fields B and C. Field C indicates the region of coacervate and equilibrium phases. The explanations demonstrate the recalculation procedure of the individual salt species in the system for any given point. Within field A, the salt consists of the phosphate only. Within fields B, C, and D, the point of intersection of the boundary A B and the line of a given constant concentration of the cellulose ester mark the phosphate concentration for that given cellulose ester concentration. For example, a coacervate mixture containing 6% cellulose ester and 86% water obviously contains 8% total salt. The line of 6% cellulose ester has an intersection point with the boundary A–B. This point indicates about 2% disodium hydrogen phosphate. Two percent phosphate subtracted from 8% total salt gives a 6% concentration of sodium sulfate for the mixture discussed.

Table I—Effect of Drug Amount Encapsulated on Drug Content of Microcapsules[a]

Amount of Drug, g.[b]	Drug Content of Microcapsules, %[c] Without Plasticizer	With Plasticizer (Glycerol)
7 I	88.5	82.0

Mean of glycerol deposited	0.78	

[a] Encapsulation conditions: 60°, 100.0 g. 2% cellulose ester solution, 22.0 ml. 20% (w/w) sodium sulfate solution, and 500 r.p.m. [b] Each batch made twice (I and II). [c] Data calculated from corresponding data in Table I.

Microencapsulation—After addition of the sodium sulfate solution, part of the total cellulose ester available is coacervated, separating in the form of viscous liquid drops. These drops tend to deposit on the surface of phenacetin particles suspended in the solution. The subsequent cooling of the system causes a continually passing coacervation of further cellulose ester. During the cooling

[Encapsulation and coacervation conditions were constant; amounts of drug to encapsulate varied (7, 10, and 13 g.); batches made with and without glycerol treatment; batches made twice; points are means of all formulations; bars indicate range of values.]*

Table III—Effect of Drug Amount and Plasticizer Treatment on the Mean Cumulative Percentage Undersize Diameter of Microcapsules[a]

Amount of Drug, g.[b]	Mean Diameter of Microcapsules at 50% Cumulative Undersize, μm.[c] With Plasticizer (Glycerol)	Without Plasticizer
7 I	300	320
7 II	300	285
10 I	280	245
10 II	270	240
13 I	265	280
13 II	295	275

[a] Encapsulation conditions: 60°, 100.0 g. 2% cellulose ester solution, 22.0 ml. 20% (w/w) sodium sulfate solution, and 500 r.p.m. [b] Each batch made twice (I and II). [c] Data graphically determined from their individual logarithmic probability plots of the percent cumulative undersize distributions of all the different formulations.

process, the coacervate phase is gradually deposited on already formed walls of the cellulose ester coacervate.

Optimum encapsulation conditions were found at about 1–3% cellulose ester and 5% total salt concentration (D in Fig. 1). Higher concentrations of the cellulose ester (5–6%) produced filiform bulks of coacervate surrounding the core particles. A higher total salt concentration than 6% caused agglomeration of particles and deformation of the coacervate films still in the liquid state. The deposition of coacervate onto the particles (examined microscopically) was nearly complete at the optimum encapsulation conditions. The encapsulation technique was simple in the region of optimum coacervation and encapsulation. The agglomeration of particles and the deformation of the liquid coacervate films by the shearing forces of the stirring occurred only to a small extent.

For better utilization of the cellulose ester available in solution, it is desirable to work at higher sodium sulfate concentrations, which produce higher portions of coacervate. But this is not possible by simply increasing the sodium sulfate concentration owing to the increased agglomeration and deformation tendency at high salt concentrations. Therefore, a technique was developed for the continuous addition of sodium sulfate during the cooling of the system. Suitable cooling with addition of sodium sulfate produced thicker coacervate films than the coventional method. These films were found to be laminated, and the inner layers were heavily vacuolized. However, after washing and drying, no significant increase of the cellulose ester content of the microcapsules would be noticed.

Drug Content of Microcapsules—Table I shows the drug content of several formulations of microcapsules. The amounts of the cellulose ester available in solution and the coacervation conditions were kept constant, whereas the amount of drug to encapsulate and the use of glycerol as shell plasticizer were varied. The data show good reproducibility of the encapsulation process with regard to the drug content. When glycerol was used to plasticize the shells, it was incorporated in the shell structure and so decreased the drug percentage of the microcapsules as compared with the corresponding nonplasticized formulations. Table II shows the amounts of shell material deposited on the drug particles in the encapsulation process. The figures in this table were deduced from Table I using the following formula:

$$\text{shell material deposited} = \frac{\text{amount of drug encapsulated}\left(100\% - \text{percent drug content}\right)}{\text{percent drug content}} \quad \text{(Eq. 1)}$$

The mean amount of glycerol deposited was calculated from the difference of the arithmetic means of the shell material deposited in both procedures. Table II indicates that the amounts of the cellulose ester deposited on the phenacetin crystals and the glycerol uptake by the cellulose ester shells are almost constant. The data clearly show that the described encapsulation process is able to produce microcapsules of varying drug-to-shell ratios in a reproducible way. This is a fundamental requirement for controlling release rates by shell thickness. Other information about the encapsulation process is provided by the calculation of the utilization

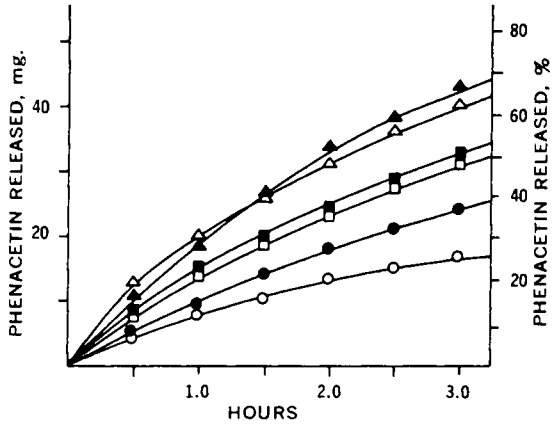

Figure 3—*Release plots of microencapsulated phenacetin, nonplasticized formulations. Key: ●, 7 g. I; ○, 7 g. II; □, 10 g. I; ■, 10 g. II; ▲, 13 g. I; and △, 13 g. II. [Temperature 60°; 100.0 g. 2% cellulose ester solution; 22.0 ml. 20% (w/w) sodium sulfate solution; 500 r.p.m.; each batch made twice (I and II); points on plot indicate mean of two determinations; amounts of drug varied.]*

factor of the cellulose acetate phthalate in the system used to prepare the microcapsules. Out of the 2.0 g. cellulose ester available in the system, about 0.9 g. was deposited on the drug crystals; therefore, the utilization factor of the ester was about 0.45.

Particle Size of Microcapsules—The amounts of coarse and agglomerated particles larger than 0.63 mm. in diameter, as determined by sieve analysis, never exceeded 3% of the total mass of the final encapsulated product. The mean geometric diameters of different formulations, which were graphically determined from the individually obtained logarithmic probability plots of the percent cumulative undersize curves, are shown in Table III. The data show small variations between the different formulations, which are, however, within the confidence limit of the determination method. It is, therefore, assumed that the amount of drug to encapsulate, as well as the treatment with glycerol as plasticizer, has no significant influence on the particle size. The mean logarithmic probability plot of percent cumulative undersize is shown in Fig. 2. The mean plot of all encapsulated formulations is transformed to a greater diameter than compared with the nonencapsulated phenacetin.

Drug Release—The formulations of microcapsules previously assayed for drug content were examined for drug release. The re-

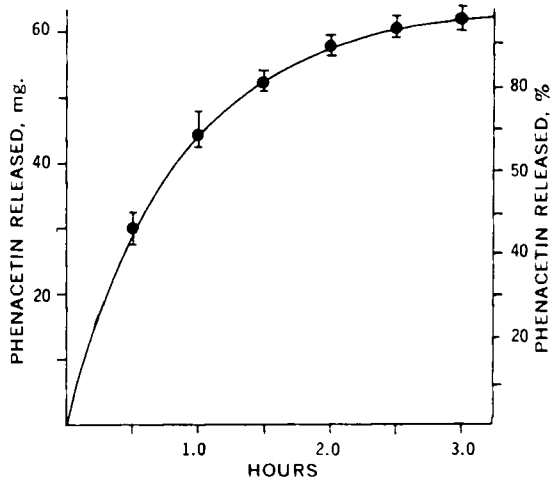

Figure 4—*Release plots of microencapsulated phenacetin, plasticized formulations. [Temperature 60°; 100.0 g. 2% cellulose ester solution; 22.0 ml. 20% (w/w) sodium sulfate solution; 500 r.p.m.; each batch made twice (I and II); amounts of drug varied (7, 10, and 13 g.); two determinations were run on I and II at each drug amount; points on plot are means of all determinations, batches, and drug amounts; bars indicate range of values obtained.]*

lease plots for nonplasticized formulations shown in Fig. 3 demonstrate a good correlation between the drug content of microcapsules and the release rate, *i.e.*, between the shell thickness and the release rate. The release of parallel batches with the same drug content can be considered as reproducible, because the noticeable differences between two parallel batches are inevitable due to individual technological variations. In contrast, all batches of plasticized capsules showed identical release curves in spite of different drug contents (Fig. 4).

To explain this obvious difference in the release mechanisms of plasticized and nonplasticized formulations, the individual steps of drug release from microcapsules are illustrated. In the first step, the film of cellulose ester takes up solvent by imbibition. In the second step, the solvent diffuses into the free space within the capsules. In the third step, the dissolution of drug takes place; and in the fourth, the dissolved drug is released by diffusion through the coacervate film, whereas further drug is continually dissolved. In the case of plasticized films, the porosity of these films is supposed to be so high that the dissolved drug can easily diffuse through the pores, which are formed by washing out glycerol, without any hindrance. Under this assumption, drug release depends only on the dissolution rate of the encapsulated phenacetin. In the case of pure, nonplasticized films of cellulose ester, the data show that the film thickness influences the release rates of a drug, indicating that diffusion of a drug through the shells is the controlling factor of release. Along with analogous results for ethylcellulose-coated microcapsules (16), it is indeed reasonable to assume that this is the only way release might occur for the capsules tested; leaching of the drug out of the microcapsules is, therefore, regarded to be negligible.

In contrast to the typical release curves of Nixon *et al.* (5) and Nixon and Walker (9), which show an extremely rapid initial release from gelatin coacervate microcapsules, the release of drug in the present studies was more regular and the release curves are smoother. This may be due to the more complete encapsulation of the core material. Furthermore, in contrast to the findings of these authors, the release of drug from microcapsules can be controlled significantly by the ratio of the amounts of drug to shell substance, *i.e.*, the technological formulation.

CONCLUSIONS

The results of this investigation show that cellulose acetate phthalate coacervate encapsulation is a more suitable encapsulation technique, less complicated and less difficult to control than other methods of coacervate encapsulation. The data demonstrate clearly that simple variations of the encapsulation process can significantly affect drug release rates. The importance of these accurately defined release rates on the therapeutic application of drugs is well known and has often been described. Owing to the broad variety of film-forming materials, which are not yet tested for this purpose, more research is needed in the field of preparation and evaluation of coacervate microcapsules.

Adenosine Analogs: Structure–Activity Relationships in Vascular and Intestinal Smooth Muscle

S. W. LESLIE▲, J. L. BOROWITZ, and T. S. MIYA

Abstract □ The relaxant effects of a series of adenosine analogs were compared on isolated intestinal and aortic smooth muscle of the guinea pig. Blood pressure-lowering effects of these compounds were also compared in the guinea pig and dog. Analogs with a modified purine ring system (1-methyladenosine and toyocamycin) were more effective in relaxing intestinal than vascular smooth muscle. Substituents that decreased the basicity of the N_1-position or interfered with hydrogen bonding in the 6-position decreased activity in both vascular and intestinal smooth muscle. Deoxyadenosine, which lacks an oxygen in the 2′-position of the ribose portion of the molecule, was ineffective in intestinal but still relaxed vascular smooth muscle. It was concluded that intestinal smooth muscle interacts significantly with the 2′-position of the ribose portion of the adenosine molecule whereas vascular smooth muscle requires an intact purine ring system in the molecule for maximal activity.

Keyphrases □ Adenosine analogs, structure–activity relationships—relaxant effects on isolated ileal and aortic smooth muscle, blood pressure depression compared in guinea pig and dog □ Smooth muscle relaxation, isolated ileal and aortic muscle—effects of adenosine analogs, structure–activity relationships □ Relaxation of isolated ileal and aortic smooth muscle—effects of adenosine analogs, structure–activity relationships □ Blood pressure depression—adenosine analogs, guinea pig and dog □ Structure–activity relationships—adenosine analogs, smooth muscle relaxation and blood pressure depression

Adenosine is thought to be a breakdown product of the purinergic transmitter (1) and is found circulating in the blood in a concentration of 4×10^{-8} *M* (2). It is known to be released from intestinal (3), cardiac (4, 5), and adrenal (6) tissue. Adenosine relaxes bronchiolar (7), intestinal (8), and certain vascular (9) smooth muscle.

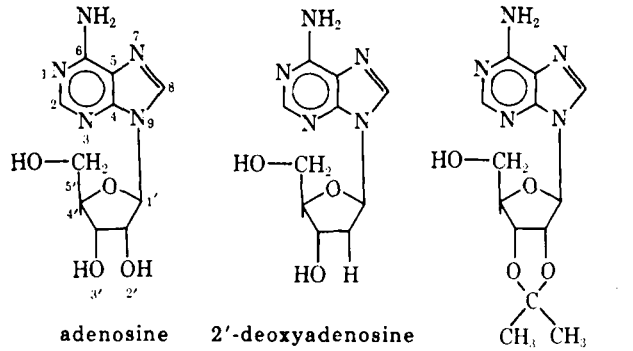
The interaction between adenosine and adenosine deaminase was studied at the molecular level (10), but the structure–activity relationships for adenosine's relaxant effects on intestinal and vascular smooth muscle are not fully known (11–14). Therefore, structural characteristics of a series of adenosine analogs important for relaxation of these smooth muscles were determined.

METHODS

A series of purine ribosides was tested *in vitro* on longitudinal smooth muscle of the guinea pig ileum and on circular smooth muscle of guinea pig descending thoracic aorta. *In vivo* blood pressure studies were also performed in guinea pigs and dogs to determine whether analogs that were inactive *in vitro* in the descending thoracic aorta were also inactive within the vascular bed as a whole.

Fasted (18–24 hr.) male guinea pigs (300–600 g.) were sacrificed by cervical dislocation, and a segment of ileum 20 cm. from the ileocecal junction was excised. Ileal strips 2–4 cm. in length were suspended in an oxygenated bath with Tyrode's solution maintained at 37°.

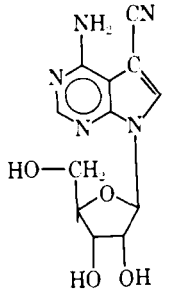
The descending thoracic aorta was also excised and prepared as described by Furchgott and Bhadrakom (15). The spirally cut segments were suspended in an oxygenated bath with the Krebs-Henseleit solution maintained at 37°.



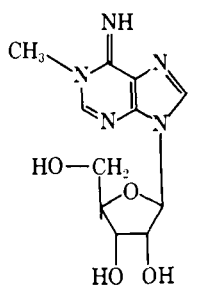
adenosine

2′-deoxyadenosine

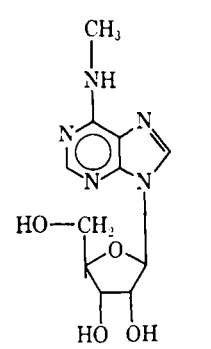
2′,3′-isopropylidene adenosine



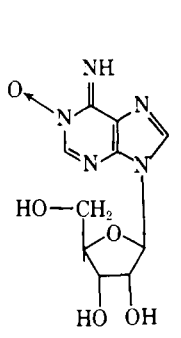
toyocamycin



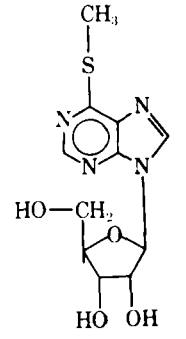
1-methyladenosine



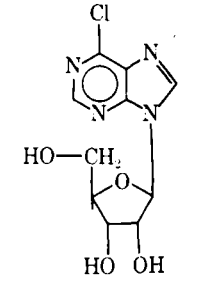
N-6-methyladenosine



adenosine *N*-oxide



6-methylmercapto-purine riboside



6-chloropurine riboside

One gram of tension was placed on both the longitudinal muscles of the ileum and the circular muscles of the aorta, and contraction was recorded[1]. The aortic strips were allowed to equilibrate in the bath for 2 hr. and the ileal strips for 1 hr.

Nicotine was used as the agonist in the ileum, and epinephrine was used as the agonist in the aorta. The concentrations of nicotine or epinephrine were the same for all experiments (ranging from 10^{-9} *M* to 3×10^{-6} *M* or from 10^{-7} *M* to 3×10^{-5} *M*, respectively). Drugs were pipeted directly into the baths and did not dilute the baths by more than 1%.

The purine ribosides used in this study were adenosine[2], 2′-deoxyadenosine, 6-methylmercaptopurine riboside, 2′,3′-isopro-

Table I—Inhibitory Effects of Adenosine and Its Analogs on Isolated Guinea Pig Ileum and Thoracic Aorta

Compound	Concentration, *M*	Tissue	Inhibition[a] of Contraction, %	*N*
Adenosine	10^{-5}	Ileum	49	6
Adenosine	10^{-5}	Aorta	30	6
N-6-Methyladenosine	10^{-5}	Ileum	35	5
N-6-Methyladenosine	10^{-5}	Aorta	39	5
Isopropylidene adenosine	5×10^{-5}	Ileum	43	6
Isopropylidene adenosine	5×10^{-5}	Aorta	0	5
Isopropylidene adenosine	10^{-4}	Aorta	53	5
Deoxyadenosine	10^{-4}	Ileum	0	5
Deoxyadenosine	10^{-4}	Aorta	59	7
1-Methyladenosine	10^{-4}	Ileum	43	8
1-Methyladenosine	10^{-4}	Aorta	0	4
Toyocamycin	10^{-5}	Ileum	34	6
Toyocamycin	10^{-6}	Aorta	0	6

[a] Percent inhibition produced by adenosine and adenosine analogs was calculated for concentrations of 1×10^{-6}, 3×10^{-6}, and 5×10^{-6} *M* nicotine in ileal tissue and for concentrations of 4×10^{-9}, 1.4×10^{-8}, 4.4×10^{-8}, and 1.4×10^{-7} *M* epinephrine in the aorta. The values obtained were then added and a mean percent depression was calculated.

pylidene adenosine, adenosine *N*-oxide[3], 1-methyladenosine, *N*-6-methyladenosine[4], and toyocamycin (a pyrrolo [2,3-*d*]pyrimidine nucleoside antibiotic)[5].

Male guinea pigs (300–600 g.) or healthy mongrel dogs (8–13 kg.) were anesthetized with pentobarbital (35 or 50 mg./kg., respectively) and carotid blood pressures were recorded. Drugs were injected *via* the external jugular vein in the guinea pig and *via* the femoral vein in the dog. A control series of five doses (25–400 mcg./kg.) of adenosine was first injected into each animal, followed by a series of doses of the adenosine analogs (25 mcg./kg.–5 mg./kg.). A test dose of adenosine (25 mcg./kg.) was injected after each series of doses of each analog to ensure that no potentiation or desensitization of the blood pressure response had occurred.

RESULTS

Effects of Adenosine Analogs on Isolated Ileum and Thoracic Aorta—A summary of the inhibitory effects of adenosine and adenosine analogs on isolated intestinal and arterial smooth muscle is presented in Table I. Adenosine and *N*-6-methyladenosine had inhibitory effects in both tissues (Table I). These compounds were previously reported to inhibit vascular smooth muscle contractions (14), and adenosine was reported to relax intestinal smooth muscle (8).

At a concentration of 1×10^{-4} *M*, isopropylidene adenosine significantly depressed contractions of the aorta in response to 1.4×10^{-7} *M* ($p < 0.001$) and 4.4×10^{-7} *M* ($p < 0.025$) epinephrine. At a lower concentration, 5×10^{-5} *M* isopropylidene adenosine depressed ($p < 0.05$) nicotine- (3×10^{-6} *M*) induced contractions in the ileum.

Deoxyadenosine depressed contractions in arterial tissue (Fig. 1) but not in the ileum at a concentration of 10^{-4} *M*. By contrast, 1-methyladenosine and toyocamycin (Figs. 2 and 3, respectively) depressed contractions in the ileum but not in isolated aorta at the concentrations used. 6-Chloropurine riboside, 6-methylmercaptopurine riboside, and adenosine *N*-oxide were each tested (10^{-4} *M*) in at least three ileal and three aortic preparations and were found to be ineffective in inhibiting the contractile responses.

Since toyocamycin and 1-methyladenosine appear to produce a rather selective relaxation of ileal contractions induced by an indirect-acting agonist (nicotine), further experiments were performed with these two analogs ($N = 6$ in each case) against acetylcholine, a direct-acting agonist. Results were similar to those with nicotine, although these analogs were somewhat less potent in depressing acetylcholine-induced contractions. Toyocamycin (1×10^{-4} *M*) produced a mean depression of 44%, while 1-methyladenosine (1×10^{-4} *M*) resulted in a 16% mean depression of acetylcholine-induced contractions (mean percent depression was calculated by averaging percent depressions produced by 1×10^{-7}, 3×10^{-7}, 1×10^{-6}, and 3×10^{-6} *M* acetylcholine).

Concentration–response curves of the guinea pig ileum to nicotine were consistently reproducible. However, a decrease in sensitivity of the aorta to epinephrine was seen, as previously reported (15). No further desensitization was noted after the first concentration–response curve (four experiments). Therefore, in the guinea pig ileum, the responses obtained in the presence of the inhibitors were compared statistically with the mean value of the control and recovery responses, while in the aorta the responses obtained in the presence of the inhibitors were compared statistically only with the recovery responses.

Effects of Adenosine Analogs on Guinea Pig and Dog Blood Pressure—Adenosine (Fig. 4) was found to produce a transient blood pressure depression in the guinea pig, resulting in a 27-mm. Hg decrease after the highest dose of 400 mcg./kg. Depressor responses were generally short lived, and pressure returned to control levels in about 30 sec. The effect was more prolonged (about 3 min.) when doses of 1 mg. or more of the analogs were given. *N*-6-Methyladenosine (Fig. 4) also depressed guinea pig blood pressure but was only one-fourth to one-half as potent as adenosine.

Although 1-methyladenosine was approximately 10 times less

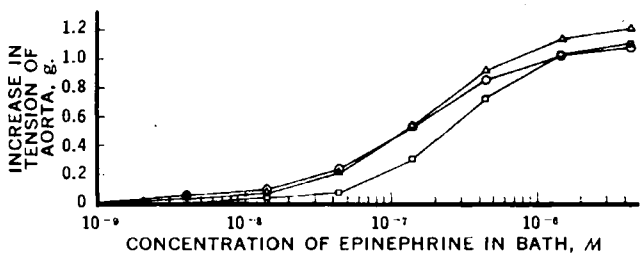

Figure 1—*Effect of deoxyadenosine (1×10^{-4} M) on epinephrine-induced contractions in the guinea pig descending thoracic aorta. Each point represents the mean response of seven aortic strips. Deoxyadenosine significantly depressed the contractile response to 1.4×10^{-7} M ($p < 0.01$) and 4.4×10^{-7} M ($p < 0.01$) epinephrine. The paired difference form of the Student t test was used to compare the recovery response with the responses obtained in the presence of the adenosine analog in all experiments involving the aorta. Toyocamycin significantly depressed the contractile response to 1×10^{-6} M ($p < 0.01$) and 3×10^{-6} M ($p < 0.005$) nicotine. Key: ○, control; □ toyocamycin, 1×10^{-5} M; and △, recovery.*

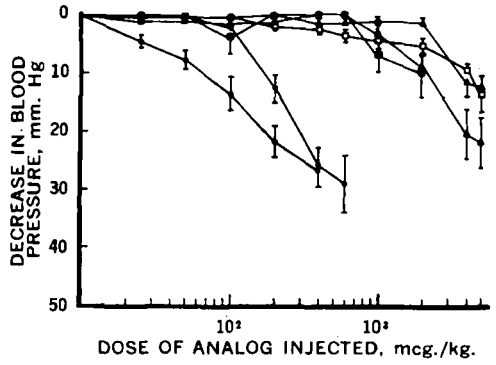

Figure 4—*Effect of adenosine and adenosine analogs on the diastolic blood pressure in the guinea pig. Each point represents the mean response ± SE in from five to seven male guinea pigs. Mean control blood pressure was 42.3 mm. Hg, which is comparable to reported values for the guinea pig (16). Key: ●, adenosine; ○, N-6-methyladenosine; □, deoxyadenosine; △, isopropylidene adenosine; ■, toyocamycin; and ▲, 1-methyladenosine.*

potent than adenosine in relaxing ileal smooth muscle, it was 25–50 times less potent in depressing blood pressure. Thus, 1-methyladenosine was about four times more potent in ileal smooth muscle than in vascular smooth muscle.

Toyocamycin, at a dose of 1×10^{-5} *M*, was shown to be approximately equal to adenosine in inhibiting contractions of smooth muscle of the guinea pig ileum but was not effective in relaxing the descending thoracic aorta nor in depressing guinea pig blood pressure unless a large dose (1 mg./kg.) was used. The effect of toyocamycin in ileal smooth muscle was about 50 times that in vascular smooth muscle. This analog was peculiar in that, at doses of 500 mcg./kg. or greater, it markedly potentiated the vasodepressor effects of adenosine in the guinea pig. No other analog produced this effect.

Adenosine and each adenosine analog were also tested on the blood pressure of two to five mongrel dogs. The vasodepressor action of these compounds was similar relative to one another in this species compared to the activity in the guinea pig. However, toyocamycin did not potentiate the vasodepressor response to adenosine in the dog.

DISCUSSION

Molecular changes that increase the electron density and thus the basicity of the N_1-position of adenosine are known to increase its affinity for adenosine deaminase (10). This study shows that a certain degree of basicity of the N_1-position is also important for adenosine's interaction with smooth muscle. Addition of an oxygen to the N_1-position of adenosine to form the *N*-oxide decreases the basicity of this area and results in loss of activity in both vascular and ileal smooth muscle.

The aromaticity of the purine ring system appears to influence the selectivity of action of adenosine analogs on smooth muscle. Replacing the nitrogen in the 7-position of the purine riboside with a cyano-carbon group, as in toyocamycin, alters electronic and steric factors which affect the electron distribution of the whole purine ring. Toyocamycin is approximately 50 times more active in intestinal muscle relative to arterial smooth muscle. Addition of a methyl group to the N_1-position of adenosine also tends to disrupt the aromaticity of the ring system and again results in a more selective activity on intestinal musculature. This methyl group also increases the basicity of the N_1-position, which may explain the increased activity remaining in vascular smooth muscle as compared to toyocamycin and reinforces the assumption that basicity of this area of the purine ring is important for activity in both tissues. Apparently, the usual purine ring system is not rigidly required for relaxation of intestinal smooth muscle by adenosine analogs, but basicity of the N_1-position is required in both tissues.

It was suggested (10) that hydrogen bonding occurs between adenosine and adenosine deaminase before removal of the amino group in the 6-position is completed. If a similar hydrogen bonding is required at the adenosine receptor to produce smooth muscle relaxation, replacement of the 6-amino group with moieties that modify hydrogen bonding should reduce or eliminate activity. Addition of a methyl group to the 6-amino group decreases the hydrogen-bonding capabilities and/or increases steric hindrance and, as shown in this study, results in a general reduction of activity. Replacement of the 6-amino group with a methylmercapto or chloride group results in elimination of hydrogen-bonding capabilities and, as shown in this study, also eliminates the effect on smooth muscle. Thus, hydrogen bonding through the *N*-6-position of adenosine may be important for the adenosine effect.

This study also showed that an intact ribose moiety is essential for complete activity of adenosine. The 2′-hydroxyl group seems to play an important role in the activity of the compound. The 2′-hydroxyl and 3′-hydroxyl groups contain electrons which are available for hydrogen bonding. If hydrogen bonding from the 2′-hydroxyl group to a site on the receptor is required for activity, it would be expected that removal of the 2′-hydroxyl group would result in loss of effectiveness. Studies with deoxyadenosine showed that a decrease in activity did in fact occur. It appears, however, that this hydrogen bonding may be more necessary in ileal smooth muscle than in vascular smooth muscle since some activity remained in the latter tissue after removal of the 2′-hydroxyl group.

Attachment of the 2′,3′-isopropylidene radical would be expected to decrease the proton-accepting power of the oxygen atoms involved. Thus, hydrogen bonding with the ribose part of the molecule is reduced but not eliminated in the isopropylidene derivative of adenosine. In this case, a relative reduction of the relaxant effect was obtained in both tissues, which suggests that some hydrogen-bonding capability of the 2′,3′-positions of the ribose moiety of adenosine is required for activity.

This study showed that the basicity of the N_1-position and hydrogen-bonding capabilities of the N_6-position of adenosine are important for activity in both intestinal and vascular smooth muscle. An intact purine ring system favors activity in vascular smooth muscle but is not required for maximal activity in intestinal smooth muscle. Hydrogen-bonding capabilities of the 2′-hydroxyl group are more important for relaxation of vascular than intestinal smooth muscle.

Nalidixic Acid and Hydroxynalidixic Acid Analysis in Human Plasma and Urine by Liquid Chromatography

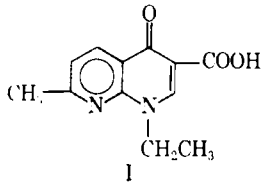
L. SHARGEL▲, R. F. KOSS, A. V. R. CRAIN, and V. J. BOYLE

Abstract □ A high pressure liquid chromatographic method was developed for the assay of nalidixic acid and hydroxynalidixic acid in human plasma and urine. This procedure measures both compounds in the same sample. The lower limits of detection for nalidixic acid and hydroxynalidixic acid were 0.25 mcg./ml. of each in plasma and 2.5 mcg./ml. of each in urine. Correlation coefficients for the analysis of nalidixic and hydroxynalidixic acids in urine of humans medicated with two different tablet formulations were 0.83 and 0.94 in comparison with a microbiological assay.

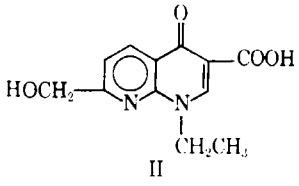
Keyphrases □ Nalidixic and hydroxynalidixic acids—analysis in human plasma and urine, high pressure liquid chromatography □ Hydroxynalidixic and nalidixic acids—analysis in human plasma and urine, high pressure liquid chromatography □ High pressure liquid chromatography—analysis, nalidixic and hydroxynalidixic acids in human plasma and urine

Nalidixic acid[1] (I) is currently used as an antibacterial agent in urinary tract infections (1–3). A major metabolite is hydroxynalidixic acid (II). This metabolite has an *in vitro* antibacterial spectrum similar to that of nalidixic acid (4). Both compounds have similar chemical structures and fluorescent spectra.

The original fluorescent method for the assay of nalidixic acid and hydroxynalidixic acid (4) involved differential extraction, which provided only partial separation of nalidixic acid and hydroxynalidixic acid. Thus, simultaneous equations were employed for the determination of the two drugs. Furthermore, blank values were occasionally high and erratic, giving unsatisfactory values for nalidixic acid.



I



II

The use of liquid chromatography for the separation and quantitation of many compounds has increased in recent years. The availability of a modern, high speed, liquid chromatograph allows the measurement of both nalidixic acid and hydroxynalidixic acid simultaneously. This report describes a new liquid chromatographic assay procedure for nalidixic acid and hydroxynalidixic acid which is more rapid and precise than previously published methods.

EXPERIMENTAL

Materials—Nalidixic acid[2] and hydroxynalidixic acid[2] were routinely prepared in the same standard solution of 0.03 *N* NaOH. Chloroform, analytical reagent grade[3], was used for all extractions. All other reagents were purchased from commercial sources.

Plasma Assay—To a 15-ml. glass-stoppered centrifuge tube were added 1.0 ml. of plasma[4] and 1.0 ml. of a standard solution containing both nalidixic acid and hydroxynalidixic acid in concentrations ranging from 0 to 40 mcg./ml. For unknown plasma samples, 1.0 ml. of sample was added to 1.0 ml. of 0.03 *N* NaOH. To this mixture was added 0.5 ml. of 0.6 *N* HCl (final pH approximately 1.0) and 5 ml. of chloroform. The tubes were stoppered, shaken 5 min., and centrifuged. The upper aqueous phase was then aspirated. A 4.0-ml. aliquot of the chloroform phase was transferred to a clean 15-ml. glass-stoppered centrifuge tube, and 1.0 ml. of 0.03 *N* NaOH was added. The tubes were shaken for 5 min. and centrifuged. The aqueous phase containing nalidixic acid and hydroxynalidixic acid was then subjected to high pressure liquid chromatography.

Urine Assay—To a 50-ml. glass-stoppered extraction tube were added 1 ml. of urine and 1 ml. of a standard solution containing 0–250 mcg./ml. each of nalidixic acid and hydroxynalidixic acid. For unknown urine samples, a 1.0-ml. aliquot was added to 1.0 ml. of 0.03 *N* NaOH. The glucuronides of nalidixic acid and hydrox-

[4] Since fresh human plasma caused less emulsion formation during extraction than outdated Red Cross plasma, the former was more desirable to use for processed standards.

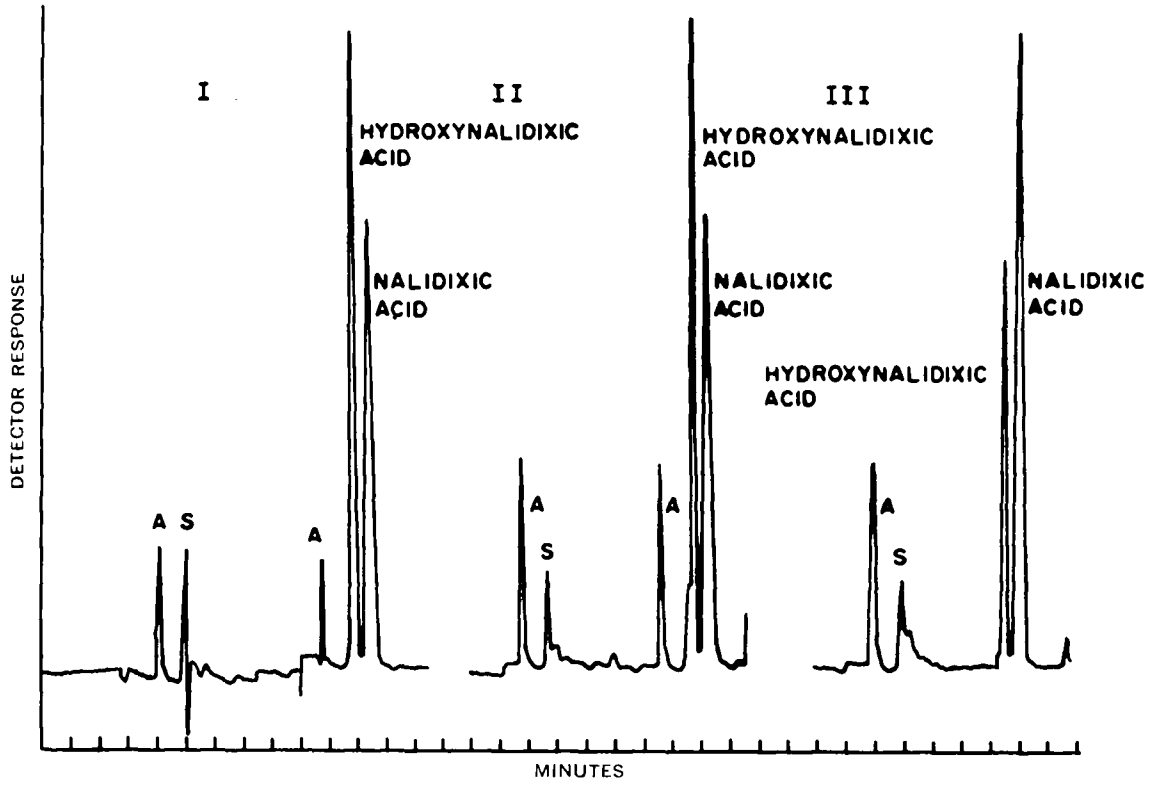

Figure 1—*Liquid chromatograms of processed standards of nalidixic acid and hydroxynalidixic acid in plasma and urine. Key: I, plasma blank (attenuation 0.02), and plasma containing 10 mcg./ml. each of nalidixic acid and hydroxynalidixic acid (attenuation 0.02); II, nonhydrolyzed urine blank (attenuation 0.02), and nonhydrolyzed urine containing 25 mcg./ml. each of nalidixic acid and hydroxynalidixic acid; III, hydrolyzed urine blank (attenuation 0.02), and hydrolyzed urine (attenuation 0.16) containing 280 mcg./ml. nalidixic acid and 125 mcg./ml. hydroxynalidixic acid; A, sample injection; and S, solvent front. Liquid chromatographic conditions are described in the* Experimental *section.*

ynalidixic acid were hydrolyzed by adding 0.5 ml. of 0.6 *N* HCl (final pH approximately 1.0) and heating the extraction tube on a steam bath for 30 min. The mixture was then neutralized with 0.5 ml. of 0.6 *N* NaOH. To the extraction tubes containing nonhydrolyzed urine samples was added 0.5 ml. of 0.6 *N* NaOH to keep the ionic strength and pH constant.

To both the hydrolyzed and nonhydrolyzed urine mixtures were added 1 ml. of a 0.2 *N* sodium phosphate buffer, pH 6.0, and 1.0 ml. of water. Nalidixic acid and hydroxynalidixic acid were extracted into 25 ml. of chloroform. The tubes were shaken for 5 min., followed by centrifugation. The aqueous upper phase was aspirated, and a 4.0-ml. aliquot of the lower chloroform phase was placed into a clean 15-ml. glass-stoppered centrifuge tube containing 1.0 ml. of 0.03 *N* NaOH. The tube was shaken for 5 min. and centrifuged. Then the aqueous phase containing nalidixic acid and hydroxynalidixic acid was subjected to high pressure liquid chromatography.

Liquid Chromatography[5]—Solutions were chromatographed at room temperature on a 0.5-m. stainless steel column (2.1 mm. i.d.) packed with Zipax SAX[6] strong anion-exchange resin. The eluting mobile phase was a solution containing 0.05 *M* sodium sulfate and 0.02 *M* boric acid (pH 9). Column pressure was maintained at 600 p.s.i. by compressed nitrogen gas. The flow rate of the eluate was 0.8 ml./min.

A 10-μl. aliquot of the extracted urine or plasma sample was chromatographed by a modified stop-flow procedure[7]. Direct standards of nalidixic acid and hydroxynalidixic acid were made in 0.03 *N* NaOH and chromatographed similarly. Recovery of nalidixic acid and hydroxynalidixic acid was calculated by comparing the peak heights of the processed standards to standards made directly in base. Concentrations of the unknown urine or plasma samples were calculated by comparing the peak heights of the extracted samples to processed standards.

Correlation with Microbiological Assay—Two tablet formulations containing 1000 mg. of nalidixic acid[8], but differing in tablet excipients, were administered orally to 16 adults of both sexes. The drug was administered with water after an 8-hr. fast. A premedication urine sample and a 0–24-hr. postmedication urine sample were obtained. After measurement of the volume and pH, the urine samples were frozen until analyzed for free and conjugated nalidixic and hydroxynalidixic acids by the liquid chromatographic assay. Only nonconjugated, biologically active nalidixic acid and hydroxynalidixic acid were analyzed by the microbiological assay.

Microbiological Assay—Urinary levels of nalidixic and hydroxynalidixic acids were determined by a modified, four-point, agar-diffusion method (5). Nalidixic acid standards were prepared in pooled, normal human urine to give final concentrations of 10 and 20 mcg./ml. Urine samples from medicated subjects were diluted appropriately to give estimated concentrations corresponding to those of the standards. By means of forceps, 1.3-cm. (0.5-in.) filter paper disks were saturated by immersion into the standard or sample solutions and excess fluid was removed. Saturated disks from the standard and sample solutions were placed on the surface of each agar plate seeded with the test organism, *Klebsiella pneumoniae* (ATCC 10872). Five plates containing standard and sample disks at constant dilution intervals were employed for each assay.

Following a prediffusion period of 2 hr. at 4°, all plates were incubated at 37° for 16–18 hr. and the zones of inhibition (diameters in millimeters) were recorded. The levels of biologically active drug (nalidixic acid and hydroxynalidixic acid) in the samples were calculated by extrapolation from the standard dose responses (6).

[5] Performed on a duPont model 840 liquid chromatograph equipped with a UV (254 nm.) photometric detector and a Hewlett-Packard model 7128A strip-chart recorder.

[6] Instrument Product Division, E. I. duPont de Nemours & Co., Wilmington, Del.

[7] The modified stop-flow procedure is as follows. The liquid chromatograph is maintained at 600 p.s.i. The valve is turned to the "Flow Off" position. After 30 sec., 10 μl. of the sample is injected on the column. The valve is then placed on the "Flow On" position and the sample is chromatographed. This method provided sharper peaks, possibly due to less diffusion of the drug prior to being chromatographed through the column and less "blowback" of sample from the syringe.

[8] NegGram Caplet, Winthrop Laboratories, New York, N. Y.

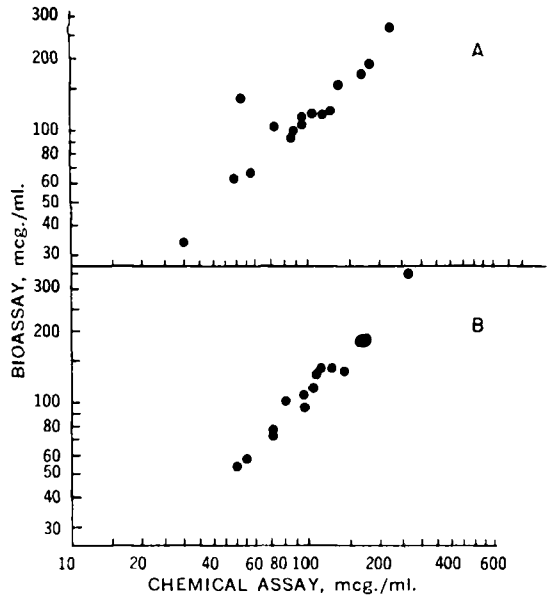

Figure 2—*Correlation of the liquid chromatographic and microbiological assays for nalidixic acid and hydroxynalidixic acid in urine. Human volunteers were administered 1000 mg. of nalidixic acid contained in tablet Formulation A or Formulation B. Nalidixic acid and hydroxynalidixic acid in the 24-hr. urine samples were assayed by both methods. Correlation coefficients for Formulations A and B were 0.83 and 0.94, respectively.*

RESULTS

Nalidixic acid and hydroxynalidixic acid were measured simultaneously by liquid chromatography. The retention times for hydroxynalidixic acid and nalidixic acid were 1.2 and 1.6 min., respectively. Chromatograms from control plasma and control urine yielded a small blank which did not interfere with the chromatograms from processed standards (Fig. 1). Plasma extracts demonstrated an "on-column" lower detection limit of 2 ng. each of nalidixic acid and hydroxynalidixic acid, corresponding to a plasma concentration of 0.25 mcg./ml. for each drug. Urine extracts demonstrated an on-column lower detection limit of 4 ng. each of nalidixic acid and hydroxynalidixic acid, corresponding to a urine concentration of 2.5 mcg./ml. for each drug. The sensitivity of this assay was comparable to that of the fluorescent method (4). Processed standards in plasma and urine were linear in concentrations up to 250 mcg./ml. One advantage of this method is that high urine levels need not be reprocessed; the sensitivity of the instrument is attenuated upward and the sample is reinjected.

Recoveries of processed standards of nalidixic acid from plasma and urine were 99.2 and 101%, respectively; the recoveries of processed standards of hydroxynalidixic acid were 91.0 and 88.8%, respectively (Table I). The lower recovery of hydroxynalidixic acid is possibly due to partitioning between the aqueous and chloroform phases. The small standard errors shown for the recovery data in Table I demonstrate that these compounds can be measured with high precision.

Urine from patients medicated with two different oral tablet formulations of nalidixic acid were subjected to both the microbiological and liquid chromatographic assays (Fig. 2). The mean ($\pm SE$) urine levels of nalidixic acid and hydroxynalidixic acid after administration of Formulation A were 121 ± 55.1 mcg./ml. (biological) and 109 ± 53.2 mcg./ml. (liquid chromatographic). The mean ratio of biological to liquid chromatographic values was 1.20. Only one major discrepancy was noted between the two assays (ratio 2.50). The mean ($\pm SE$) urine levels of nalidixic acid and hydroxynalidixic acid after administration of Formulation B were 129 ± 71.9 mcg./ml. (biological) and 110 ± 55.6 mcg./ml. (liquid chromatographic). The mean ratio of biological to chemical values was 1.04. Correlation coefficients for Formulations A and B were 0.83 and 0.94, respectively.

Table I—Recovery of Nalidixic Acid and Hydroxynalidixic Acid from Plasma and Urine[a]

Concentration, mcg./ml.	Percent Recovery	
	Nalidixic Acid	Hydroxynalidixic Acid
	Plasma	
1.0	98.9	76.9
2.5	95.0	91.1
5.0	101	94.4
10	102	93.8
20	98.9	94.2
30	99.4	94.5
Mean ± *SE*	99.2 ± 1.0	91.0 ± 3.1
	Urine	
12.3	101	89.8
25	101	89.7
50	100	87.7
100	99.7	87.2
150	104	89.5
Mean ± *SE*	101 ± 0.6	88.8 ± 0.5

[a] Standards were made in 0.03 *N* NaOH. Dilutions were added to human urine or plasma and processed according to the procedure described in the *Experimental* section.

DISCUSSION

The advantages of the liquid chromatographic assay of nalidixic acid and hydroxynalidixic acid include: (*a*) simple, rapid, and reproducible analyses of a multicomponent system without the need for an involved separation and purification method; and (*b*) more precision and specificity than the fluorescent method used previously. Moreover, 30–40 samples/day (8 hr.) can be determined by a single technician compared to 6–8 samples/day by the fluorescent method.

Microbiological assays of antibacterial agents such as nalidixic acid and hydroxynalidixic acid have been used frequently in the clinic. Although the bioassay is not specific (both nalidixic acid and hydroxynalidixic acid have similar antibacterial activity), the high degree of correlation between these methods demonstrates that either assay can be used routinely in the clinical laboratory.

Quantitative Effect of Topically Applied Anti-Inflammatory Agents on External Ocular Inflammation in Rats

ITALO MAISTRELLO▲, GIUSEPPINA RIGAMONTI, CARLO FROVA, and PIETRO de RUGGIERI

Abstract □ A new quantitative approach to investigate the effect of topically applied anti-inflammatory agents is proposed. An external ocular inflammation was produced in the rat by topical instillation of ocular irritants. The method requires a short time and is based upon quantitatively determining the degree of edema by weighing the eyelid. This end-point can be evaluated objectively, in contrast to the subjective results obtained by many widely used methods. Hydrocortisone, triamcinolone acetonide, triamcinolone, fluocinolone acetonide, and dexamethasone were tested. Dose-response relationships were obtained, and relative potencies were determined by parallel-line assay, using hydrocortisone as a reference standard. Fluocinolone acetonide, the most potent steroid studied, had a topical relative potency of 2745; triamcinolone, the least potent, had a topical relative potency of 4.9. The systemic relative potency was also investigated. The results obtained show that the experimental model of external ocular inflammation appears to be a reliable method for quantitative assay of topical anti-inflammatory agents.

Keyphrases □ Anti-inflammatory steroids, topical—quantitation of relative effects using external ocular inflammation technique in rats □ Ocular inflammation technique—used to quantitate effects of topical anti-inflammatory steroids, rats □ Steroids, anti-inflammatory—quantitation of relative effects using external ocular inflammation technique in rats

Several methods have been reported for provoking ocular inflammation to study the effect of anti-inflammatory substances. The most frequently used procedures are the lamellar graft technique, consisting of the insertion of a pig corneal button intralamellarly into the rabbit cornea (1); the immuno uveitis model (2–4); and methods based upon the topical instillation (5, 6) or injection (7) of ocular irritants. Opacity and vascularization of the cornea, edema, and hyperemia of the conjunctiva and iris and exudation in the anterior chamber are the parameters used for determining the degree of ocular inflammation produced. However, scoring is subjective and arbitrary due to the lack of criteria that can be evaluated objectively. Furthermore, some methods are too time consuming for routine screening.

Therefore, the development of a method to produce temporary ocular inflammation in the rat having an end-point that could be evaluated objectively was desirable. In these experiments, the quantitative determination of the weight of the inflamed eyelid was the end-point. By using this method, dose-response rela-

tionships and the relative potency of several anti-inflammatory substances were determined after topical and systemic administration.

MATERIALS AND METHODS

Experimental Animals—Female Sprague Dawley rats, weighing 60–70 g., were randomly divided into groups of nine or 10 animals. The animals were fed standard rat chow and water *ad libitum* up to sacrifice.

Induction of Palpebral Edema—A combination of two irritants, 2-(2-ethoxyethoxy)ethanol[1] (I) and croton oil, was selected to produce a satisfactory external ocular inflammation. Both substances were instilled in the conjunctival sac of the right eye of the rat. 2-(2-Ethoxyethoxy)ethanol was administered as such, while croton oil was administered as a 4% solution in 2-(2-ethoxyethoxy)-ethanol.

Figure 1 illustrates the handling of the animal for drug instillation. Particular care was taken to prevent mechanical damage to the ocular tissue by the needle; a 25-μl. syringe[2] was fixed in a clamp at about 45° to the horizontal plane to prevent spontaneous leakage of the drop of solution. The eyelids were spread apart with curved forceps which were prevented from opening more than 5 mm. at the tips. The rat was then delicately moved toward the syringe until a drop was applied to the center of the cornea, from where it spread onto the entire conjunctival sac. The lids were kept apart for 2–4 sec. to assure adequate diffusion of the substance in the conjunctival sac. The volume of instillation was 2.5 μl.

External ocular inflammation was obtained by instilling two doses of I followed by two doses of croton oil (Fig. 2A). The steroids used for the study of anti-inflammatory activity were administered both systemically and topically. For systemic administration, the drugs were given orally by stomach tube in 1 ml./100 g. body weight of an aqueous vehicle containing 0.9% sodium chloride, 0.5% sodium carboxymethylcellulose, 0.4% polysorbate 80, and 0.9% benzyl alcohol. The treatment schedule is shown in Fig. 2B. For topical administration, the compounds were dissolved in I, which is an optimal solvent for steroidal substances (8), and administered by instillation into the conjunctival sac in two doses of 2.5 μl. each. The treatment schedule is shown in Fig. 2C.

The effect of the irritants and the anti-inflammatory activity of the products tested were evaluated by isolating and weighing the inflamed upper eyelid. Two hours after the last administration (Fig. 2), the animal was killed by cervical fracture and the upper eyelid was isolated, using straight and sharply honed scissors (Fig. 3). After making an incision in the skin of the cranium, the skin was peeled away toward the eyelids (Fig. 3A). When arriving at the palpebra, the skin was cut along the palpebral edge (Fig. 3B). The

skin-free palpebra was then removed by cutting along the orbital arc (Fig. 3C). No bleeding was evident during the isolation procedure. The excised eyelid tissue was then immediately weighed on a torsion balance[3] to the nearest 0.2 mg. without blotting. The whole procedure can be carried out in 40–45 sec. after some practice.

Drugs—The anti-inflammatory activity of the following substances was tested: hydrocortisone, triamcinolone (alcohol), triamcinolone acetonide, dexamethasone, and fluocinolone acetonide.

Statistical Analysis—Relative potencies were determined by the parallel-line assay (9). The precision index of the test (λ) was obtained according to Bliss (10).

RESULTS

Time Course of Palpebral Edema Formation—For this experiment, 150 rats were subdivided into 15 groups of 10 animals each. The animals were killed at various times after beginning treatment with the irritants. Increase in eyelid weight began immediately after the first instillation of irritant and reached a peak 2 hr. after the last instillation (Fig. 4). At the peak, the eyelids weighed 50.6 ± 1.5 mg. (mean value ± standard error) compared to the controls weighing 15.5 ± 0.46 mg.—an increase of 226%. The edema remained elevated for 2 hr. more and then began to decline slowly, reaching normal values 10 hr. after the last instillation of irritant.

Anti-Inflammatory Bioassay—The anti-inflammatory effect of various compounds was investigated in eight different experiments. The substances were administered topically in four of these experiments (A, B, C, and D of Table I) and systemically in the other experiments (E, F, G, and H of Table II). In each experiment, the rats were subdivided into various groups of nine animals each,

[3] Sauter.

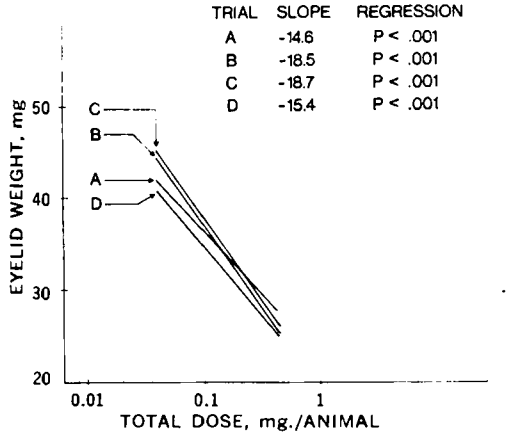

Figure 5—*Regression lines of hydrocortisone, administered topically, obtained in several experiments.*

arranged as indicated in Tables I and II. The animal treatment schedule employed was that shown in Fig. 2; 2 hr. after the last instillation of croton oil in I, the animals were killed and the eyelids were excised and immediately weighed.

Hydrocortisone was used as a reference standard in each test, and at least three doses of the test compounds were used. All compounds significantly reduced palpebral edema, and good linear log dose–response regressions were obtained.

To demonstrate the reproducibility of the method, the regression lines for the topically applied hydrocortisone standard of Table I are shown in Fig. 5. The slopes of the lines were only slightly varied, and the regressions were highly significant by statistical analysis.

The dose–response data for the various assays are plotted in Figs. 6–9. Each figure gives the results of a single steroid applied

Table III—Relative Potencies of Corticoids after Topical and Systemic Administration

Compound	Topical Activity Potency	Topical Activity λ[a]	Systemic Activity Potency	Systemic Activity λ[a]
Hydrocortisone	1		1	
Dexamethasone	103 (67–160)	0.35	238 (185–310)	0.21
Triamcinolone	4.9 (3.6–7.0)	0.25	7.7 (5.6–10.3)	0.23
Fluocinolone acetonide	2745 (1813–4512)	0.38	267 (203–338)	0.19
Triamcinolone acetonide	180[b]	—	157 (122–197)	0.22

[a] Precision index. [b] Graphical estimation (40% inhibition).

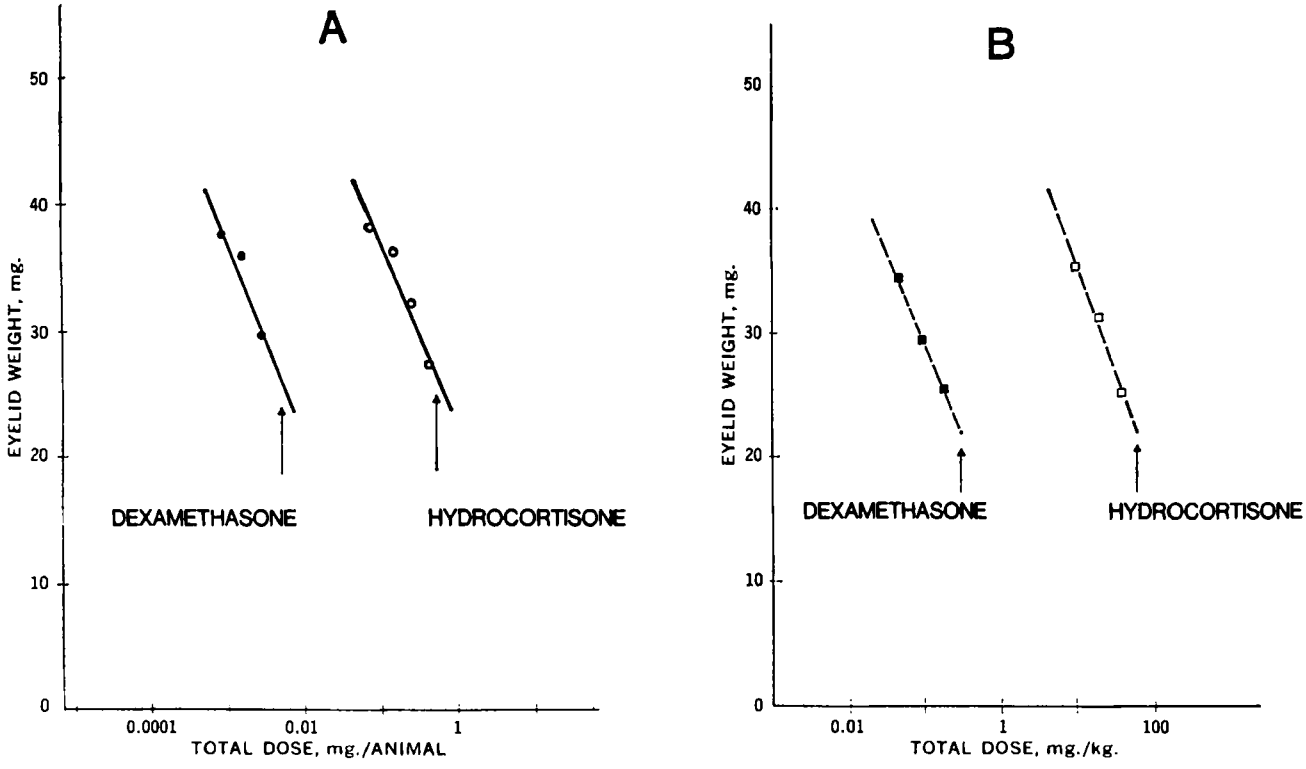

Figure 6—*Anti-inflammatory activity of dexamethasone* versus *hydrocortisone after topical (A) and systemic (B) administration.*

topically and systemically. The regression lines for each test compound, applied either topically or systemically, showed no significant dèparture from linearity. With the exception of triamcinolone acetonide applied topically, the regression line for each compound was parallel to the hydrocortisone standard administered by the same route. Thus, in each case, the relative potency could be determined by the parallel-line assay method. Table III reports the relative potencies of these compounds, with their 95% confidence limits and the precision index (λ).

Triamcinolone acetonide, applied topically, presented a significantly different and less steep regression than hydrocortisone. Thus, a precise relative potency estimate could not be made. However, a graphical estimate was made by comparing the doses producing a 40% inhibition in palpebral edema. Fluocinolone acetonide, applied topically, was the most active compound, already producing a significant reduction in edema at a total dose of 0.034 mcg./animal. The relative potency was 2745. The activity of fluocinolone acetonide was lower after oral administration, having a relative

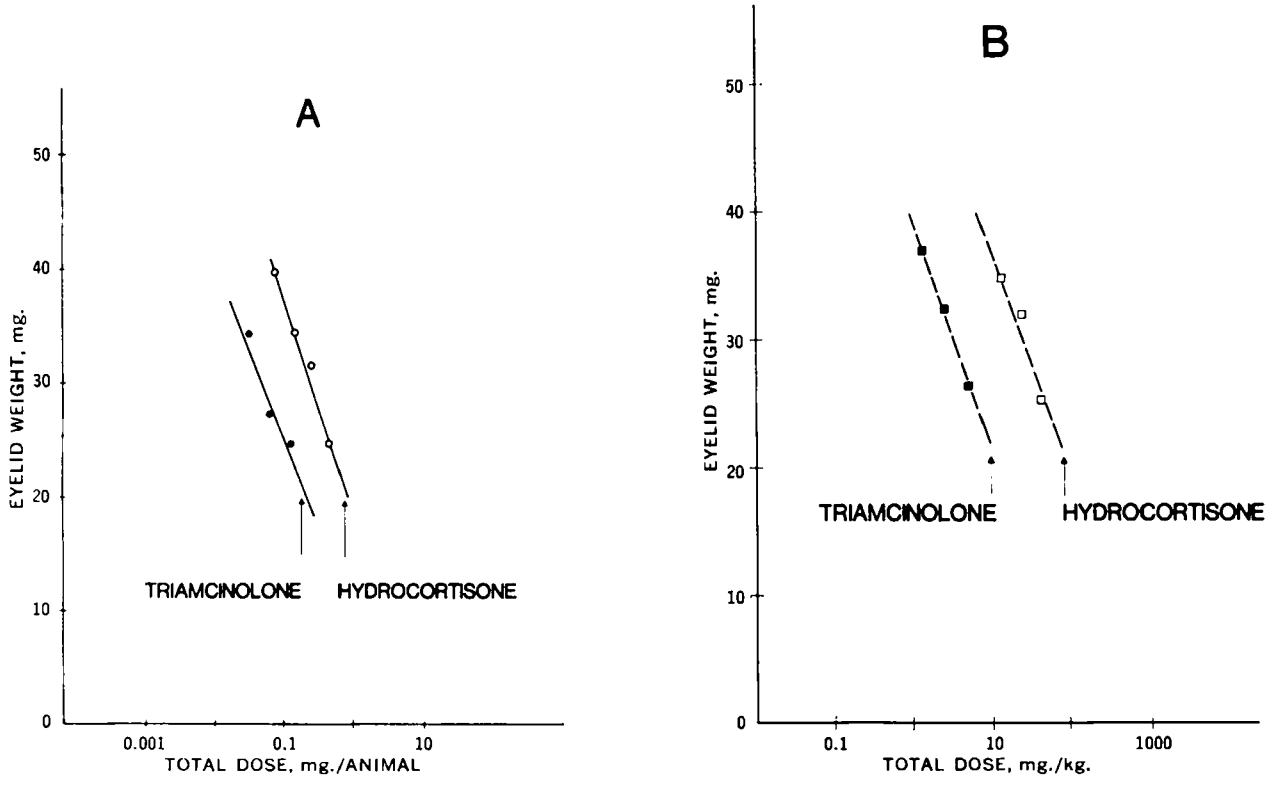

Figure 7—*Anti-inflammatory activity of triamcinolone* versus *hydrocortisone after topical (A) and systemic (B) administration.*

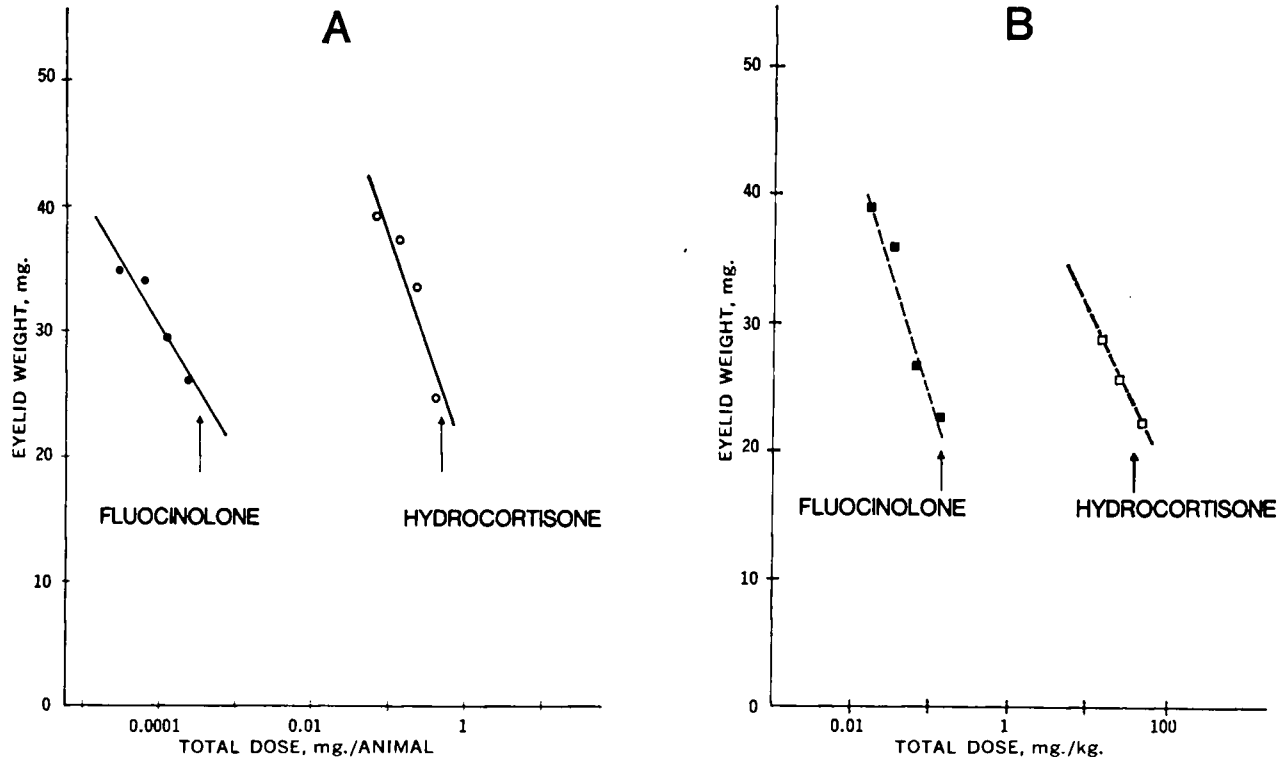

Figure 8—*Anti-inflammatory activity of fluocinolone acetonide* versus *hydrocortisone after topical (A) and systemic (B) administration.*

potency of 267. The least active product was triamcinolone, having relative potencies after topical and systemic administrations of 4.9 and 7.7, respectively. The relative potencies of dexamethasone were 103 (topical) and 238 (systemic).

The graphical estimate of topical relative potency (TRP) for triamcinolone acetonide was 180, while the systemic relative potency (SRP) for this compound was 157. A smaller quantity of the given substance was required to produce an anti-inflammatory effect when applied topically rather than systemically.

DISCUSSION

Preliminary experiments indicated that it is relatively simple to produce inflammation by instilling various types of irritants into

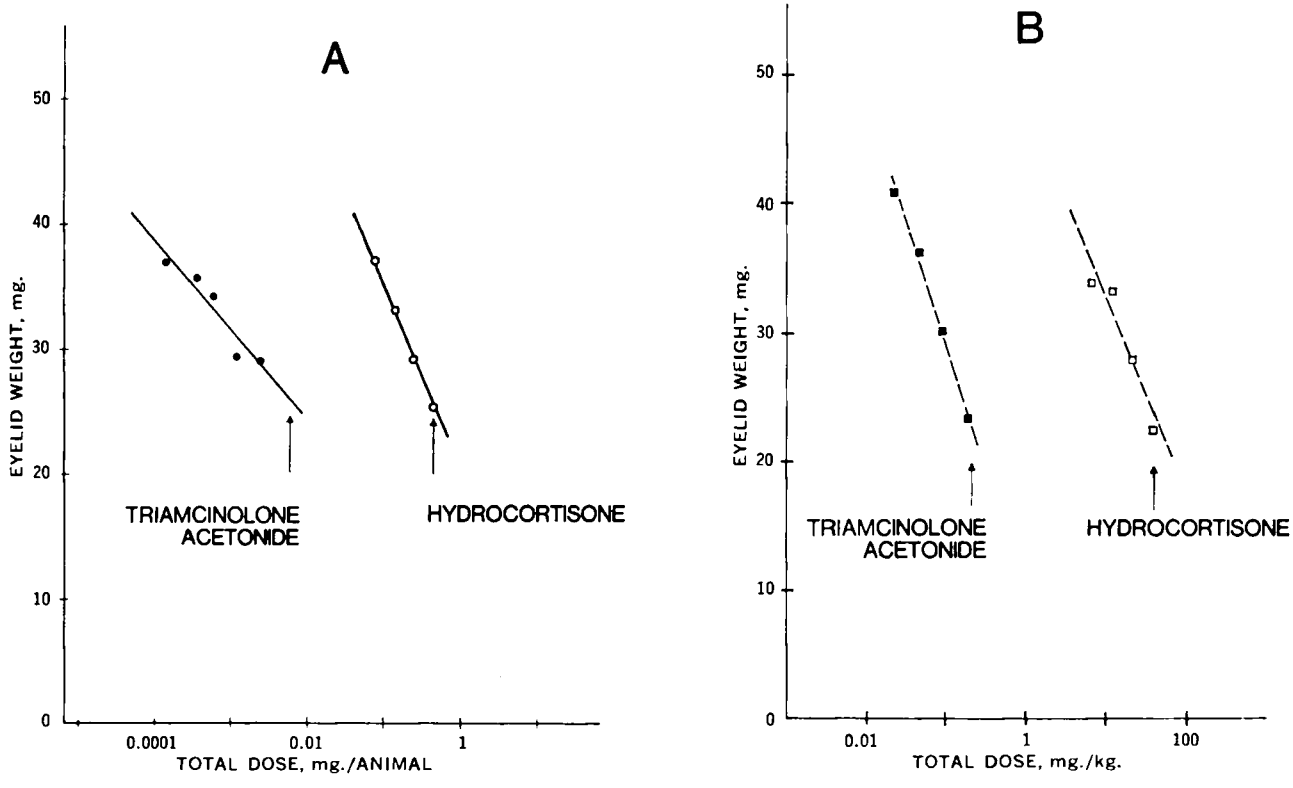

Figure 9—*Anti-inflammatory activity of triamcinolone acetonide* versus *hydrocortisone after topical (A) and systemic (B) administration.*

the conjunctival sac; the inflammation is also reduced significantly by treatment with anti-inflammatory steroids (11). The difficulty is increased considerably, however, when statistically valid and reproducible dose–response relationships are desired. The described scheme for producing irritation was adopted after considerable trial and error and is the only one that permitted quantitative determinations of relative potency within statistically acceptable limits.

Previously described methods on various types of ocular inflammation have permitted only an approximate ranking of the products or have yielded relative potency values with high confidence limits due to great biological variations (4). Moreover, it appears arbitrary to transfer results obtained from topical cutaneous tests or other general tests such as the carrageenin edema assay and the pellet granuloma inhibition assay to the eye.

The differences observed between the topical relative potency and systemic relative potency values demonstrate that it is not possible to ignore the importance of the conjunctiva as a biological membrane on the activity of anti-inflammatory substances. With triamcinolone acetonide, the dose–response relationship of the topically administered compound tended to be flatter than the dose–response curve of the same product given orally.

Regarding the characteristics of inflammation produced in these experiments, it was observed that they pertain to the anterior segment of the eye. The most evident symptoms were exudation, conjunctival hyperemia, and edema. The edemal component of inflammation was used as the sole parameter, since it is an anatomical part easily isolatable and measurable by objective criteria. This model of inflammation, although limited to the anterior segment of the eye, is of interest since the most frequent ocular diseases and the use and abuse of the glucocorticoids involve the lid edge and conjunctiva (12).

The method requires a short time, similar in this respect to methods producing inflammation in the rat paw by injection of irritating substances such as carrageenin and egg white.

The results of the method are highly reproducible. The reproducibility is more notable when compared with the method most frequently used, carrageenin-induced paw edema, which shows great variability from experiment to experiment and from day to day (13, 14).

The method is sensitive, particularly to substances administered topically. Therefore, only small quantities of substances are required for testing.

The use of rats rather than rabbits, which are generally used in ocular inflammation methods, is advantageous in bioassay experiments where large groups of animals are required.

Tetracycline Degradation Products in Commercially Available Tetracycline-7-^{3}H

ROBERT C. LANMAN▲, THOMAS M. LUDDEN, and LEWIS S. SCHANKER

Abstract □ The radiochemical purity of three commercially available tritium-labeled tetracycline products was investigated using TLC and spectrophotometry. All three products contained, in addition to tetracycline, substantial amounts of radioactively labeled 4-epitetracycline and anhydrotetracycline. Two products also contained an unidentified component which remained at the origin.

Keyphrases □ Tetracycline-7-^{3}H—radiochemical purity and identification of degradation products in three commercial samples □ Radiolabeled tetracycline—radiochemical purity and identification of degradation products in three commercial samples □ 4-Epitetracycline, radiolabeled—identified as degradation product in commercial tetracycline-7-^{3}H □ Anhydrotetracycline, radiolabeled—identified as degradation product in commercial tetracycline-7-^{3}H □ TLC—analysis, radiochemical purity of tetracycline-7-^{3}H

The chemical purity of commercially available tetracycline products was the subject of several recent investigations (1–5). In these studies, various analytical techniques revealed that virtually all products investigated contained, in addition to tetracycline (I), varying small amounts of tetracycline degradation products such as 4-epitetracycline (II), anhydrotetracycline (III), and 4-epianhydrotetracycline (IV). In view of these findings, the question arose whether commercially available, radioactively labeled I might also contain tetracycline-like impurities. The presence of such radiolabeled contaminants could result in serious errors in biological studies in which the antibiotic is assayed by nonspecific radioisotopic methods.

The purity of tetracycline-7-^{3}H obtained from two commercial suppliers was investigated using TLC and radiochromatographic scanning of TLC plates. These methods allowed estimation of the relative amounts of I, II, and III.

EXPERIMENTAL

Reagents—Analytical grade reagents used were disodium ethylenediaminetetraacetate, methanol, glycerin, polyethylene glycol 400, succinic acid, citric acid, *n*-butanol, and methyl ethyl ketone.

Solvent Systems—Two solvent systems were used: A, methyl ethyl ketone saturated with McIlvaine's buffer (pH 4.7)(6); and B, *n*-butanol–methanol–10% citric acid (4:1:2). It was previously reported (6) that I does not undergo degradation during TLC with Solvent System A.

Thin-Layer Plates—Kieselguhr G[1] and kieselguhr N[2] TLC plates were prepared as described by Gyanchandani *et al.* (6). Acid-washed silica gel[3] and silica gel[4] plates were pretreated by soaking for 1 hr. in a 0.1 *M* solution of disodium ethylenediaminetetraacetate and then were air dried for at least 16 hr. before use.

Table I—TLC Analysis of Nonlabeled Reference Compounds[a]

Compounds	R_f Values—Acid-Washed Silica Gel—Solvent System A[b]	R_f Values—Acid-Washed Silica Gel—Solvent System B[c]	R_f Values—Silica Gel—Solvent System B
I	0.51	0.52	0.87
II	0.30	—	—
III	0.95	0.85	0.99

[a] Compounds dissolved in Gomori's succinate buffer, pH 4.65. [b] Methyl ethyl ketone saturated with McIlvaine's buffer, pH 4.7. [c] *n*-Butanol–methanol–10% citric acid (4:1:2).

Nonlabeled Reference Compounds—I-Hydrochloride (I-HCl)[5] was used as the tetracycline reference standard. Compound II, the carbon-4 isomer of I, was prepared according to McCormick *et al.* (7). The III-base was prepared by the method of Simmons *et al.* (8).

Radioactive Materials—Two samples of I-HCl, labeled with tritium at C_7 (V and VI)[6], and a single lot of I-base, similarly labeled (VII)[7], were studied.

Detection—Nonlabeled reference compounds (I, II, and III) were visualized on TLC plates by their fluorescence in longwave UV light[8]. Tritium-labeled V, VI, and VII, along with radiolabeled degradation products, were detected using a radiochromatogram scanner[9]. All radiochromatogram scans were quantitated by tracing onto graph paper, cutting out the tracing, and expressing the weight of individual peaks as a percentage of the weight of the entire tracing.

RESULTS

Nonlabeled Reference Compounds—Twenty-five-microliter aliquots of 0.06% solutions of I, II, and III, dissolved in pH 4.65 Gomori's succinate buffer, were manually streaked in a band 2 cm. from the bottom and 1 cm. from each edge of 5 × 20-cm. acid-washed silica gel[3] or silica gel[4] plates, using one compound per plate. Immediately after drying, the plates were allowed to develop 14–15 cm. (45–50 min.) in Solvent Systems A and B at room temperature. The R_f values obtained are given in Table I. It can be seen that I, II, and III applied to the acid-washed silica gel plates[3] were well separated by Solvent System A. Solvent System B provided good separation of I and III but failed to distinguish these compounds from the C_4-epimer, II. Good separation of I and III was also obtained using the silica gel plates[4] and Solvent System B, but again II was not resolved.

Product V—One millicurie (1.2 mg.) of this product was received in the dry state. The material was dissolved in 1 ml. of methanol, appropriate volumes (50–100 μl.) of solution were transferred to siliconized[10] 1-dram vials, and the vial contents were taken to dryness *in vacuo* at room temperature. Vials were then sealed, protected from light, and stored at room temperature.

For TLC, a vial containing 50–100 μc. of Product V was dissolved in Gomori's succinate buffer (pH 4.65), distilled water, or methanol containing sufficient I-HCl to give a final concentration of 48 mcg./ml. Twenty-five-microliter amounts of these solutions were ap-

Kieselguhr N	Buffer	0	7.0	0.41	19.7	0.75	53.8	1.00	10.4	90.9

[a] Components identified by reference to nonlabeled reference compounds (Table I) and quantitated as described under *Experimental*. [b] Solvent System A (see Table I). [c] Total area of peaks on basis of weight and exclusive of background. [d] Gomori's succinate buffer, pH 4.65.

plied to 5 × 20-cm. acid-washed silica gel[3], kieselguhr G, and kieselguhr N plates by streaking, and the plates were developed to 14–15 cm. in Solvent System A. As shown in Table II, Product V was resolved by Solvent System A and acid-washed silica gel[3] plates into four areas of radioactivity. Whether Gomori's succinate buffer, water, or methanol was used as the initial solvent, the resulting chromatograms were qualitatively similar. Three radioactive peaks were identified as I, II, and III by reference to chromatograms of nonlabeled reference compounds. The results suggest that Product V is composed of 57–61% I, 16–20% II, 10–18% III, and 4–7% unknown material with zero R_f.

Results obtained with kieselguhr plates and Solvent System A compared favorably with those given above, except that there was a higher percentage of unknown material at the origin with kieselguhr G.

Since the tetracyclines have the property of forming chelates with certain metal ions, the material at the origin might be a complex of this nature. However, despite the presence of disodium ethylenediaminetetraacetate, a peak at the origin was consistently observed, even with kieselguhr N, which lacks a binding agent. If the radioactivity localized at the origin were a bound form of Product V, under- or overstreaking with nonlabeled I should reduce or eliminate this peak. However, spotting 0.3 mcg. of V in methanol on acid-washed silica gel, alone and before or after applying 100 mcg. of nonlabeled I, resulted in virtually identical chromatograms when developed in Solvent System A. The resulting chromatograms all contained four areas of radioactivity representative of 51–54% I (R_f 0.49–0.52), 17–21% II (R_f 0.25–0.28), 14–18% III (R_f 0.93–0.95), and 3–5% unknown material which failed to migrate.

The nature of this material at the origin has not been determined, but it is either firmly bound or very polar since it could not be eluted with methanol. Although elution was accomplished using Solvent System B, rechromatography of the eluted material on acid-washed silica gel with Solvent System A produced a single radioactive peak which remained at the origin.

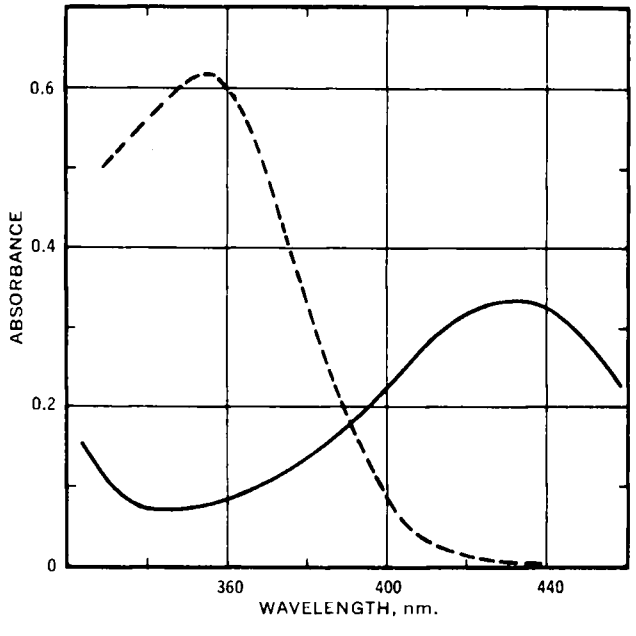

Figure 1—*Spectrophotometric curves for I-HCl (- - -) and Product VI (——). Each solution contained 20 mg. of compound/l. of 0.1 N hydrochloric acid.*

Product VI—One millicurie (1 mg.) of VI, as received in the dry state, was dissolved in 1 ml. of methanol, and 50 μl. of a 1:200 dilution in methanol was streaked on acid-washed silica gel and chromatographed in Solvent System A. One-tenth-milliliter aliquots of the remaining initial methanol solution were pipeted into 1-dram vials and treated as described previously for Product V. The vial contents were reconstituted by adding 1 ml. of methanol, and chromatography was accomplished by spotting 5 μl. (0.5 μc.) of this solution on acid-washed silica gel and silica gel and developing in Solvent Systems A and B, respectively. Methanol solutions of I-HCl and III (1 mg./ml.) were spotted in 5-μl. aliquots on the same plates.

Chromatograms of the initial solution of Product VI (before it was divided and taken to dryness) produced three areas of radioactivity (Table III). Two radioactive peaks were identified as I (R_f 0.50) and III (R_f 0.90) by reference to results obtained simultaneously with nonlabeled reference compounds. The third peak of radioactivity remained at the origin. The major radioactive component had the most rapid migration rate and was localized at an R_f value corresponding to that obtained with III.

Chromatograms of Product VI taken to dryness and reconstituted with methanol also produced three areas of radioactivity (Table III). As with the initial solution, a minor peak was present at the origin; the remaining peaks were identified as I (R_f 0.51) and III (R_f 0.94). Once again, the major radioactive component was localized at an R_f value corresponding to that obtained with III.

When reconstituted Product VI was chromatographed on silica gel with Solvent System B (Table III), a single radioactive peak was obtained with an R_f value equal to 0.98, the value expected with III in this system. Thus, TLC of both initial and reconstituted methanol solutions of Product VI on acid-washed silica gel and silica gel with Solvent Systems A and B suggested that this product is mainly III rather than I.

To confirm the chromatographic results, Product VI was assayed spectrophotometrically[11] using the absorbance ratio method described by Pernarowski *et al.* (9). Seven and one-half milliliters of 0.1 *N* hydrochloric acid was added to a vial of Product VI containing 150 mcg. of material. The spectral characteristics of this solution were determined by scanning from 320 to 460 nm., using 0.1 *N* hydrochloric acid as a blank. The spectral characteristics of I-HCl (20 mg./l. of 0.1 *N* hydrochloric acid) were determined in the same manner (Fig. 1). All scans were completed within 3 hr. after solution preparation.

The spectrophotometric curve obtained with I-HCl indicated an absorption maximum at 357 nm., in agreement with results of Pernarowski *et al.* (9). In contrast, the absorption maximum obtained with Product VI was at 434 nm., the wavelength of maximal absorption for III and IV (9). Furthermore, the absorbance of solutions of I-HCl and Product VI were equal (A_s = 0.178) at 391 nm., the wavelength at which I, III, and IV have identical absorptivity values (a_s) (9).

The absorbance of the solution of Product VI at 357 and 391 nm. was used with the following equation (9) to calculate the percentage of I present in the solution:

$$\%\ \mathrm{I} = \frac{Q{:}357{:}391 - 0.23}{0.0367} \qquad \text{(Eq. 1)}$$

in which Q:357:391 represents the absorbance ratio value, while

II	—	0.29	—	—	—	—
III	—	—	—	0.91	—	0.99

[a] As described in Table I. [b] Product VI, as received in the dry state, dissolved in methanol. [c] Major radioactive component. [d] 1:10 methanol dilution of initial solution of Product VI. [e] Methanol solutions, 1 mg./ml.

0.0367 and 0.23 are the slope and y-intercept, respectively, of the equation for the linear relationship between Q values and percent I in various synthetic mixtures. By using Eq. 1, the relative concentration of I in the solution of Product VI was calculated to be only 6.1%, while application of Eq. 1 to the absorbance values obtained with a solution of nonlabeled I-HCl indicated the presence of 88% I.

Product VII—This product was received as a solution containing 1 mc. (53 mcg.) in 2 ml. of ethanol. The solution was stored in a sealed vial at 0° and samples were taken as needed.

For chromatography, 50 μl. of Product VII was diluted to 1 ml. with methanol or Gomori's succinate buffer containing nonlabeled I. Twenty-five-microliter quantities of these solutions were applied to acid-washed silica gel plates and developed in Solvent System A (Table IV). Product VII was resolved into three areas of radioactivity. The R_f of the major peak was the same as that of I, and the R_f values of the two minor peaks were the same as those of II and III (Table I). Unlike Products V and VI, Product VII did not show a radioactive peak at the origin when chromatographed in an identical manner.

DISCUSSION

All three samples of commercially available tritiated tetracycline were found to contain substantial amounts of radioactive degradation products. In fact, chromatographic and spectrophotometric studies suggested that Product VI is almost entirely a mixture of III and IV. Products V and VII contained 50–60% I together with smaller amounts of II and III. In addition, Products V and VI contained labeled material that remained at the origin after TLC. The amount of this material was not significantly altered by understreaking or overstreaking the site of application with a solution of nonlabeled I, as might be expected if the material were a bound form of I. It is possible that this material is chemically different from bound I or is a decomposition product of I other than those resulting from epimerization.

Gyanchandani *et al.* (6) reported that when I and its degradation products were chromatographed on kieselguhr G using Solvent System A, I and IV migrated at nearly the same rates with R_f values of 0.53 and 0.47, respectively. In the present study with acid-washed silica gel plates and Solvent System A, I and IV were not resolved into separate radioactive peaks. Therefore, the radioactive peaks identified in this study as I probably represent a summation of the percentages of I and IV, in which case the percentages of I listed in the tables would be maximal values. Since epimerization results in an equilibrium mixture (7), the presence of relatively small proportions of III means that a correspondingly small fraction of IV will be present also. Conversely, when larger proportions of III are present, the proportion of IV should be correspondingly greater. The latter situation appears to exist in the case of Product VI.

Table IV—R_f Values and Percent Composition[a] of Product VII as Determined by TLC[b]

Diluent	II		I		III		Total[c], %
	R_f	%	R_f	%	R_f	%	
Methanol	0.27	17.5	0.51	51.4	0.94	23.7	92.6
Buffer	0.31	15.9	0.53	52.5	0.95	24.9	93.3

[a] Components identified by reference to TLC of nonlabeled reference compounds and quantitated as described under *Experimental.* [b] Original ethanol solution diluted with methanol or Gomori's succinate buffer, pH 4.65, and chromatographed on acid-washed silica gel with Solvent System A (see Table I). [c] Total area of peaks on basis of weight and exclusive of background.

Whereas chromatographic analysis of reconstituted Product VI indicated the presence of about 25% I, the calculated amount of I present as determined spectrophotometrically was 6.1%. Apparently about 19% of the material in Product VI that has an R_f value corresponding to I is actually IV. With only 6.1% of I present, it is unlikely that detectable amounts of II would be formed by epimerization; this could account for the apparent absence of II from Product VI.

Biological tracer studies with labeled compounds that contain radioactive degradation products may be misinterpreted if the investigator is unaware of the presence of such contaminants. For example, the labeled isomeric forms of I present in Products V, VI, and VII cannot be assumed to be handled by the body in a manner identical with I. Therefore, the use of such a product in a pharmacodynamic study would necessitate using a method of assay that could quantitatively distinguish among the various components of the radioactive product. Such a requirement greatly reduces the advantages of using labeled I over nonlabeled I.

Results of this study underline the importance of verifying the radiochemical purity of commercially available labeled compounds using analytical systems that have been demonstrated to resolve isomers and degradation products adequately.

Isolate from the Annelid, *Reteterebella queenslandia* (Australia), Active against Ehrlich Ascites Tumor

TED R. NORTON[A], MIDORI KASHIWAGI, and RONALD J. QUINN

Abstract □ A fraction, isolated by dialysis and gel permeation chromatography from an aqueous ethanolic extract of the tentacles of *Reteterebella queenslandia*, controlled and cured Ehrlich ascites tumor in mice in microgram doses. It is effective by either intraperitoneal or subcutaneous injection.

Keyphrases □ *Reteterebella queenslandia*—isolation, antitumor activity against Ehrlich ascites tumor in mice □ Annelids, extract of *Reteterebella queenslandia*—isolation, antitumor activity against Ehrlich ascites tumor in mice □ Antitumor activity—fraction isolated from annelid *Reteterebella queenslandia* □ Gel permeation chromatography—isolation of extract from *Reteterebella queenslandia*

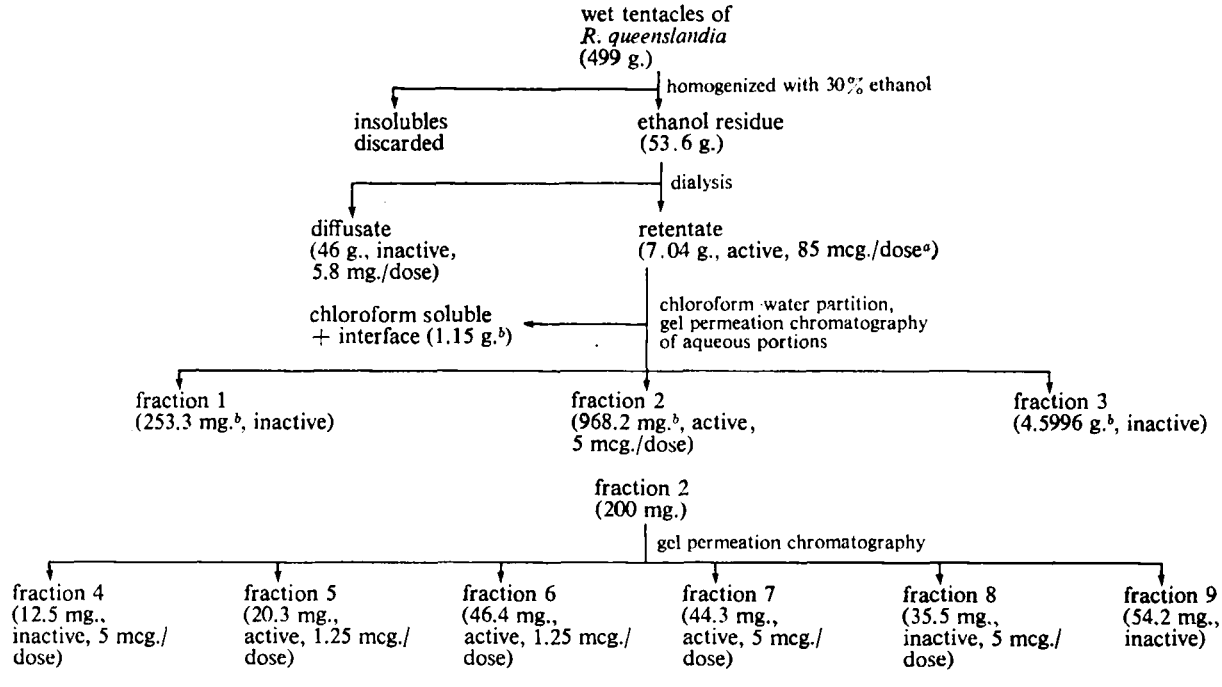
During the pharmacological evaluation of ancient Polynesian medicines, the polychaetous annelids *Lanice conchilega* and *Reteterebella queenslandia* were studied. The Kaunaoa (*L. conchilega*) was reported by Tabrah *et al.* (1) to have been used by the Hawaiians for cancer control in humans. Aqueous ethanolic extracts of both related annelids showed significant antitumor activity against Ehrlich ascites tumor in mice.

Although *L. conchilega* is found widely in the Hawaiian Islands coastal waters and tidepools, it is not found in large numbers. Because of the great difficulty in collecting, and the possible danger of depleting, *L. conchilega*, the more plentiful and closely related *R. queenslandia* from the Great Barrier Reef was chosen for purification and administration method studies.

RESULTS AND DISCUSSION

The purification of the antitumor agent is summarized in Scheme I. The indications of activity are based on >50% survivors at 30 days using 20 doses over 10 days. Controls had a mean survival time of about 17 days and never survived for 30 days, based on more than 2000 diseased control mice used during the past 4 years. Intraperitoneal drug inoculation was started 20 hr. after intraperitoneal inoculation of 5×10^6 Ehrlich ascites tumor cells. The details of the Ehrlich ascites tumor testing were described previously (1).

The fresh tentacles of the *R. queenslandia* were preserved in ethanol and shipped by air from Heron Island[1] to Honolulu where they were kept at −18° until processed. The tentacles were homogenized with 30% ethanol, and the mixture was centrifuged. The crude extract was dialyzed and the active retentate was defatted with chloroform before gel permeation chromatography[2]. The active fraction was eluted[3] at void volume, indicating a molecular weight above 30,000 (if globular protein), so that G-75 was used. All of the antitumor activity was found in fraction 2 (V_e/V_0 = 1.34-2.34). A small sample of fraction 2 was chromatographed on both anionic and cationic cellulose at pH 7.0 with 0.02 *M* phosphate buffer. The active material was not retarded by either ion-exchange column. Fraction 2 was rechromatographed[2] with peak antitumor activity being found



Scheme I—Procedure for purification of the antitumor agent in R. queenslandia. (*[a] Since 25-g. mice were used, 1 mcg./dose was equivalent to 40 mcg./kg./dose. Doses were 0.1 ml. in volume. [b] These weights are extrapolated (1.637 factor) from the somewhat smaller scale run described in the* Experimental *section.*)

in fractions 5 and 6 (V_e/V_0 = 1.44–1.87), which did not coincide with the UV absorption peak at 280 nm. (V_e/V_0 = 1.87). Figure 1 illustrates the UV absorption curve, and Table I lists the bioassay data.

In an attempt to correlate the antitumor activity of the gel permeation fractions with some physical or chemical parameter, 17 15-ml. fractions from V_e/V_0 = 0.90–2.47 were assayed for UV absorption at 254 nm., chromate oxidizables, foam stability (height at 48 hr.), dry weight, and anti-Ehrlich ascites tumor activity. The data are plotted in Fig. 2 and described in the *Experimental* section. The activity parameter peak did not correlate with any of these properties.

A sample of fraction 2 run through both cationic and anionic cellulose gave a 37% recovery of nonretarded material, showing a 75% cure rate using Ehrlich ascites at 0.36-mg./kg. doses. A sample of the latter, hydrolyzed for 90 hr. at 110° in 12 *N* HCl, showed an array of amino acids by a ninhydrin test[4] and showed negative tests for sugars. Since the fraction was still impure, this is only an indication that the active substance may be a protein.

Gel electrophoresis of fractions 5 and 6 at pH 4.3 with 15% cross-linked polyacrylamide (5 ma./tube, 200 v., 105 min.) showed two major bands when stained with naphthol blue black at R_f 0.16 and 0.73 (basic fuchsin at R_f 1.00) and six minor bands at R_f 0.41, 0.45, 0.52, 0.57, 0.61, and 0.66. Fraction 5 had a somewhat intensified R_f 0.73 band and a considerably diminished R_f 0.16 band. Fractions 7 and 8 had a considerably diminished R_f 0.73 band and an intense R_f 0.16 band. Based on the bioassays of these fractions, the band at R_f

			Drug	10.0	20 (10 days)	10	5	37 (0–98)	

[a] Mice used weighed 25 g., so 1 mcg./ dose was equivalent to 40 mcg./kg./dose. [b] EA = Ehrlich ascites tumor. [c] Mean survival time 17 days. [d] Drug administered 20 hr. after Ehrlich ascites tumor cells inoculated. [e] All nonascitic. The eight nonascitic survivors were kept for 3 months with no signs of abdominal distension.

Table III –Gel Permeation Chromatographic Fractions from the Retentate

Fraction	V_e/V_0	V_e/V_0 Peak Absorbance, UV at 280 nm.	Weight, g.
1	0.85–1.35	1.03	0.1574
2	1.35–2.30	1.95	0.5914
3	2.30–3.70	3.09	2.8094

Table IV –Gel Permeation Chromatographic Fractions from Fraction 2

Fraction	V_e/V_0	UV Absorbance at 280 nm.	Weight, mg.
4	0.83–1.44	0.04–0.08	12.5
5	1.44–1.67	0.08–0.18	20.3
6	1.67–1.87	0.18–0.41 (max.)	46.4
7	1.87–2.06	0.41–0.18	44.3
8	2.06–2.31	0.18–0.10	35.5
9	2.31–4.05	0.10–0.05	34.2

0.73 (high positive charge to mass ratio) appears to be the active basic protein.

Fraction 5 was used to study the effectiveness of various modes of administration of the drug. It was found to be 100% effective with 20 doses over 10 days at 100 mcg./kg. and 62.5% effective with only one dose of 1.0 mg./kg. The drug given 36 hr. prior to inoculation with Ehrlich ascites tumor cells showed 20% control. Systemic activity was indicated by some control of intraperitoneally induced tumor by subcutaneous injection of drug and by good control of subcutaneously induced solid tumors by intraperitoneally administered drug, with 50% of the mice developing *no* solid tumors (Table II). Antitumor evaluations were carried out using the method described previously (1), with exceptions as noted in Table II.

The drug (fraction 2) showed no activity against P-388 mouse leukemia[5]. Tests on other systems are still in progress.

EXPERIMENTAL

Extraction and Purification—A 499-g. wet drained weight sample of the tentacles of *R. queenslandia*, preserved in 95% ethanol for air shipment, was kept on arrival at −18° until use. One liter of 30% ethanol was used to homogenize the sample at top speed in a blender[6] for 5 min. The solids were removed by centrifugation at 30,000-$\times g$ for 1 min. and then triturated with 200 ml. of 30% ethanol and recentrifuged; the combined supernates were evaporated at ≦50° to 400 ml. volume. Some solid that separated was removed by filtration using a büchner funnel and a small amount of diatomaceous earth[7] filter aid. The solid was washed with 50 ml. of water, and the filtrate was adjusted to 500 ml. (dry weight 53.6 g.).

The 500 ml. of crude aqueous extract was dialyzed using a 1.0-m.[2] hollow-fiber artificial kidney[8]. The extract was passed through the fibers at 10 ml./min. concurrently with 1 l./min. of tap water flowing outside the fibers through the jacket (total of 50 l. of water). After flushing the kidney, the retentate was lyophilized to give 7.0385 g. of solids.

A 4.30-g. sample of this retentate was dissolved in 150 ml. water and thoroughly shaken with 150 ml. chloroform. The emulsion formed was centrifuged for 5 min. at 20,000$\times g$, and the aqueous layer was removed using a pipet. The chloroform and interface were dried and weighed 0.70 g. The clear aqueous layer was evaporated at ≦50° to 50 ml. and chromatographed in four 12.5-ml. batches (total dry weight 3.60 g., 900 mg./batch).

[5] These tests were carried out at the Southern Research Institute with the cooperation of Dr. Jonathan Hartwell, National Cancer Institute.

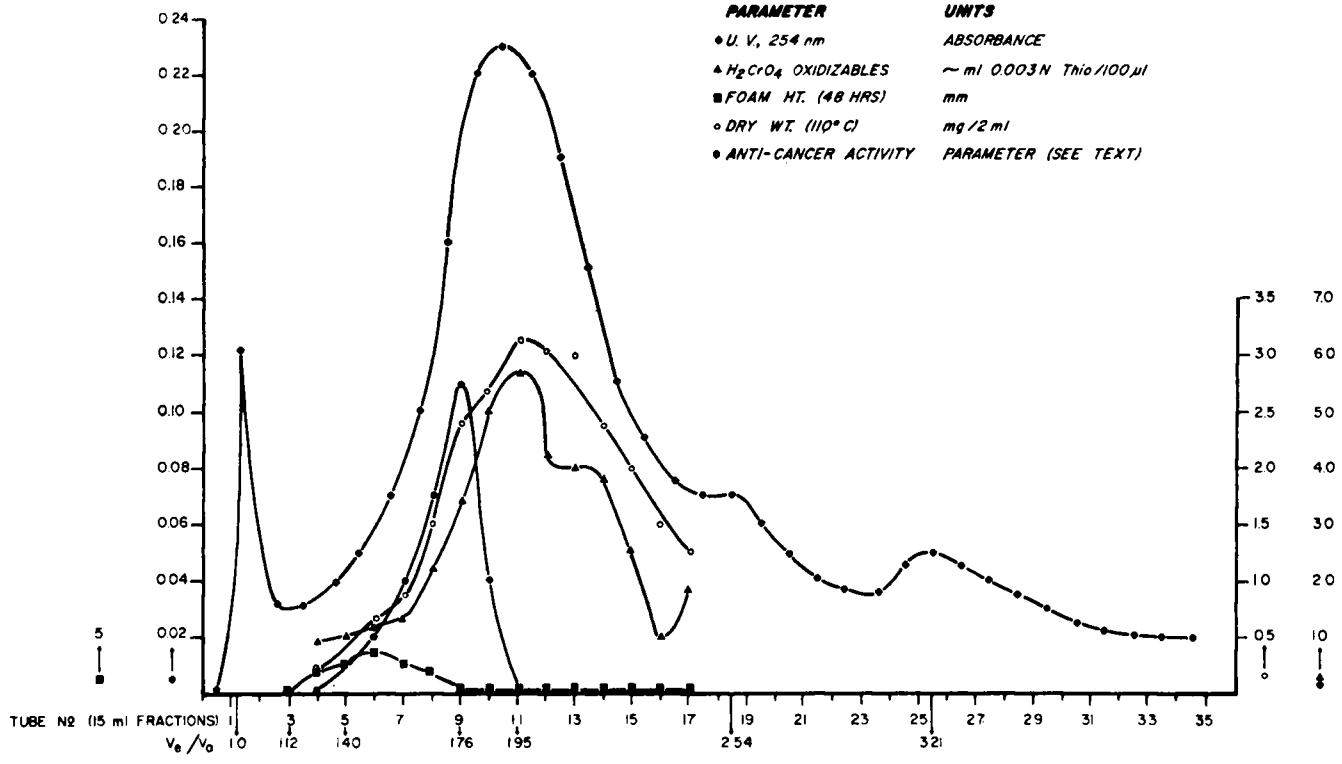

Figure 2—*Gel permeation chromatography of fraction 2, parameter correlations.*

Table V—Antitumor Assay of Tubes 4–11 from Gel Permeation Chromatography of Fraction 2

Tube Number	Number of Survivors at 30 Days		Parameter
	Nonascitic	Ascitic	
4	0	0	0
5	0	1	0.5
6	1	0	1.0
7	2	0	2.0
8	3	1	3.5
9	5	1	5.5
10	2	0	2.0
11	0	0	0

The 12.5-ml. batches were each chromatographed on 550 ml. (wet) resin[9] in a column (44 × 4 cm.) using distilled water for elution at about 3 ml./min. The void volume (V_0) was determined to be 170 ml. using 12.5 ml. of a 0.15% solution of blue dextran of mol. wt. 200,000. The fractions were collected as shown in Table III. Each fraction was lyophilized, weighed, and stored under refrigeration.

A 200-mg. sample of fraction 2 dissolved in 5 ml. water was chromatographed on 585 ml. (wet) resin[9] in a column (47 × 4 cm.) equilibrated with 0.030 *N* NaCl saturated with chloroform and eluted with the same solvent. The void volume was 174 ml. The fractions collected were desalted using a 0.1-m.[2] hollow-fiber beaker dialyzer[8], passing distilled water through the fibers at 80 ml./min. for 31 min. (2.5-l. total), and then lyophilized to give the dried fractions (Table IV).

Behavior on Ion Exchange—A 50-mg. sample of fraction 2 was dissolved in 1.0 ml. water and put on a 25 × 1-cm. column of previously conditioned cation-exchange packing[9] (5.0 g. dry and 0.73-meq./g. capacity), which had been equilibrated with 0.02 *M* phosphate at pH 7.0, and was eluted with the same solvent. The peak 280-nm. UV absorption was at V_0 (0.94 absorbance). The fraction from 13–31 ml. effluent (18 ml.) was desalted[10] (sample at V_0, phosphate retarded to V_e/V_0 = 1.8–2.2) and lyophilized to give 51.8 mg. (104% recovery, probably contains a trace of phosphate).

The same procedure was used on this 51.8-mg. sample with the anion-exchange packing[11] (capacity 0.93 meq./g.), providing 18.4 mg. (fraction 10) in the void volume fraction at pH 7 and 0.02 *M* phosphate. Under these conditions the active substance was not retarded by either the anionic or cationic cellulose.

Hydrolysis of Fraction 10—A 1.0-mg. sample of fraction 10 and 1.0 ml. of 12 *N* HCl was sealed in a Pyrex tube under nitrogen and heated at 110° for 90 hr. The acid was removed from the colorless hydrolysate by evacuation over sodium hydroxide pellets in a desiccator. The dry residue was dissolved in 0.5 ml. water, and 1 µl. was spotted[12]; using an *n*-butanol–water–acetic acid (3:1:1) solvent, strong ninhydrin positive spots were observed at R_f values of 0.054, 0.127, 0.17, 0.27, 0.34, and 0.38 with the solvent front 15.75 cm. from the origin.

A test of the hydrolysate for reducing sugars with Fehling's solution was negative.

Correlation of Physical and Chemical Properties with Antitumor Activity—A 241-mg. sample of fraction 2 equivalent (prepared in a different run from above) was dissolved in 10 ml. water and spun at 20,000 × *g* for 5 min. to remove a trace of insolubles. The supernate was put on 550 ml. of resin[9] in a column (44 × 4 cm.) and eluted with water. The void volume (V_0) was 165 ml. A total of 32 fractions of approximately 15 ml. each was collected. The exact total volume eluted (V_0) was noted at the end of each fraction, and the UV absorption at 254 nm. was recorded continuously. Dry weights were determined using 2 ml. of the cut heated at 130° to constant weight. The foam height was determined by giving each tube 30 sharp raps by hand, allowing the samples to stand for 48 hr., and measuring the height of the foam.

To determine chromate oxidizables, a modification of the method of Märki and Witkop (2) was used. The procedure involved carefully adding exactly 2.00 ml. of the chromic acid solution (0.02013 *N* $Na_2Cr_2O_7 \cdot 2H_2O$ in 98% H_2SO_4) to 100 µl. of the fractions and to control blanks and heating for 20 min. in a steam bath. The solution was then diluted to 100 ml., 1 ml. of 5% KI was added, and the solution was allowed to stand no less than 10 nor more than 20 min. (less time gave incomplete I^- to I_2 conversion and more than 20 min. gave a gradual drop in titer). The liberated iodine (I_2) was titrated with the 0.00303 *N* thiosulfate using a starch indicator; the end-point was taken when the starch–iodine color was first completely extin-

[9] Cellex CM, Bio-Rad Labs., Richmond, Calif.
[10] Using Sephadex G-25.
[11] Cellex D, Bio-Rad Labs., Richmond, Calif.
[12] Celplate F-25.

guished (on standing the color reappeared). The blanks required 13.40 ml. thiosulfate (theory = 13.29 ml.).

The activity parameter was determined as follows. A 5-ml. portion of the fraction was diluted to 60 ml., and a 0.1-ml. dose was given intraperitoneally twice daily for 10 days to eight mice starting 20 hr. after inoculation of 5×10^6 Ehrlich ascites tumor cells. At 30 days, the number of ascitic (abdominal distension) and nonascitic survivors was counted. The activity parameter is the sum of the nonascitic survivors and one-half the ascitic survivors out of the group of eight mice used for each bioassay. Only tubes 5–10 had any survivors at 30 days. The bioassays gave the results shown in Table V. The data on all of the parameters obtained are plotted in Fig. 2.

Nonsink Dissolution Rate Equation

PAKDEE POTHISIRI and J. THURØ CARSTENSEN▲

Abstract □ An equation was developed which describes the dissolution of monodisperse particles beyond the point where concentrations are small compared to solubility. If it is assumed that a stagnant layer model applies, the thickness of these layers is of the same order of magnitude as calculated *via* the Hixson–Crowell treatment but dissolution rate constants are 1.5–2 times as large. The application of the equation to dissolution of hydrocortisone, levodopa, and *p*-hydroxybenzoic acid is shown.

Keyphrases □ Dissolution rates, monodisperse particles—equation developed for nonsink conditions, applied to hydrocortisone, levodopa, and *p*-hydroxybenzoic acid □ Particles, monodisperse—nonsink dissolution rate equation developed, applied to hydrocortisone, levodopa, and *p*-hydroxybenzoic acid

The equation by Hixson and Crowell (1) has been employed for many years [*e.g.*, Wurster and Taylor (2)] for the purpose of describing the dissolution rates of monodisperse powders. Higuchi and Hiestand (3), Carstensen and Musa (4), and Brooke (5) extended its use to describe the dissolution kinetics of polydisperse powders. The treatment relies on an assumption of sink conditions, a condition that frequently—but not always (particularly for sparingly soluble compounds)—applies. Therefore, it was considered appropriate to seek a solution not relying on sink conditions.

THEORY

When Fick's law (6) is applied to dissolution of a spherical particle under laminar flow conditions, allowing for an adsorbed surface film, it takes the form:

$$dm/dt = (L)\,dC/dt = \frac{DO}{h}[S - C] = LkO[S - C] \quad \text{(Eq. 1)}$$

where m is the mass dissolved, L is the volume of the dissolution medium, C is the concentration in the dissolution medium, t is time, ρ is the density of the solid, D is the diffusion coefficient, O is the surface area, h is the thickness of the adsorbed liquid film, S is solubility, k is the dissolution rate constant[1], n is the number of particles, r is the diameter of each particle, and subscript zero denotes initial magnitudes.

The Hixson–Crowell treatment emanates from the Noyes–Whitney equation, where it is assumed that $C \ll S$; this leads to the well-known cube root equation:

$$m_0^{1/3} - m^{1/3} = Kt \quad \text{(Eq. 2)}$$

where:

$$K = 1.61LkS(n^{1/3})/(\rho^{2/3}) \quad \text{(Eq. 3)}$$

If sphericity is assumed as above, S is assumed to be independent of r, and sink conditions are not invoked, one has the following expression for the concentration in the medium at time t:

$$C = \frac{n\rho}{L}\frac{4\pi}{3}[r_0^3 - r^3] = \alpha[r_0^3 - r^3] \quad \text{(Eq. 4)}$$

where:

$$\alpha = \frac{n\rho}{L}\frac{4\pi}{3} \quad \text{(Eq. 5)}$$

Equations 1 and 4 may be combined in the form:

$$dC = -\frac{n\rho}{L}\frac{4\pi}{3}3r^2\,dr = k(n^{1/3}\pi r^2)[S - \alpha(r_0^3 - r^3)]\,dt \quad \text{(Eq. 6)}$$

or:

$$-\frac{\rho}{L}dr = k[\beta + \alpha r^3]\,dt \quad \text{(Eq. 7)}$$

where:

$$\beta = S - (m_0/L) \quad \text{(Eq. 8)}$$

is positive when:

$$m_0 < SL \quad \text{(Eq. 9)}$$

The assumption is made in the following that the amount of

[1] The dimension of k is cm.$^{-2}$ sec.$^{-1}$. Some authors denote kL (cm./sec.) as the dissolution rate constant.

guished (on standing the color reappeared). The blanks required 13.40 ml. thiosulfate (theory = 13.29 ml.).

The activity parameter was determined as follows. A 5-ml. portion of the fraction was diluted to 60 ml., and a 0.1-ml. dose was given intraperitoneally twice daily for 10 days to eight mice starting 20 hr. after inoculation of 5×10^6 Ehrlich ascites tumor cells. At 30 days, the number of ascitic (abdominal distension) and nonascitic survivors was counted. The activity parameter is the sum of the nonascitic survivors and one-half the ascitic survivors out of the group of eight mice used for each bioassay. Only tubes 5–10 had any survivors at 30 days. The bioassays gave the results shown in Table V. The data on all of the parameters obtained are plotted in Fig. 2.

Nonsink Dissolution Rate Equation

PAKDEE POTHISIRI and J. THURØ CARSTENSEN▲

Abstract □ An equation was developed which describes the dissolution of monodisperse particles beyond the point where concentrations are small compared to solubility. If it is assumed that a stagnant layer model applies, the thickness of these layers is of the same order of magnitude as calculated *via* the Hixson–Crowell treatment but dissolution rate constants are 1.5–2 times as large. The application of the equation to dissolution of hydrocortisone, levodopa, and *p*-hydroxybenzoic acid is shown.

Keyphrases □ Dissolution rates, monodisperse particles—equation developed for nonsink conditions, applied to hydrocortisone, levodopa, and *p*-hydroxybenzoic acid □ Particles, monodisperse—nonsink dissolution rate equation developed, applied to hydrocortisone, levodopa, and *p*-hydroxybenzoic acid

The equation by Hixson and Crowell (1) has been employed for many years [*e.g.*, Wurster and Taylor (2)] for the purpose of describing the dissolution rates of monodisperse powders. Higuchi and Hiestand (3), Carstensen and Musa (4), and Brooke (5) extended its use to describe the dissolution kinetics of polydisperse powders. The treatment relies on an assumption of sink conditions, a condition that frequently—but not always (particularly for sparingly soluble compounds)—applies. Therefore, it was considered appropriate to seek a solution not relying on sink conditions.

THEORY

When Fick's law (6) is applied to dissolution of a spherical particle under laminar flow conditions, allowing for an adsorbed surface film, it takes the form:

$$dm/dt = (L)\,dC/dt = \frac{DO}{h}[S - C] = LkO[S - C] \quad \text{(Eq. 1)}$$

where m is the mass dissolved, L is the volume of the dissolution medium, C is the concentration in the dissolution medium, t is time, ρ is the density of the solid, D is the diffusion coefficient, O is the surface area, h is the thickness of the adsorbed liquid film, S is solubility, k is the dissolution rate constant[1], n is the number of particles, r is the diameter of each particle, and subscript zero denotes initial magnitudes.

The Hixson–Crowell treatment emanates from the Noyes–Whitney equation, where it is assumed that $C \ll S$; this leads to the well-known cube root equation:

$$m_0^{1/3} - m^{1/3} = Kt \quad \text{(Eq. 2)}$$

where:

$$K = 1.61LkS(n^{1/3})/(\rho^{2/3}) \quad \text{(Eq. 3)}$$

If sphericity is assumed as above, S is assumed to be independent of r, and sink conditions are not invoked, one has the following expression for the concentration in the medium at time t:

$$C = \frac{n\rho}{L}\frac{4\pi}{3}[r_0^3 - r^3] = \alpha[r_0^3 - r^3] \quad \text{(Eq. 4)}$$

where:

$$\alpha = \frac{n\rho}{L}\frac{4\pi}{3} \quad \text{(Eq. 5)}$$

Equations 1 and 4 may be combined in the form:

$$dC = -\frac{n\rho}{L}\frac{4\pi}{3}3r^2\,dr = k(n^{1/3}\pi r^2)[S - \alpha(r_0^3 - r^3)]\,dt \quad \text{(Eq. 6)}$$

or:

$$-\frac{\rho}{L}dr = k[\beta + \alpha r^3]\,dt \quad \text{(Eq. 7)}$$

where:

$$\beta = S - (m_0/L) \quad \text{(Eq. 8)}$$

is positive when:

$$m_0 < SL \quad \text{(Eq. 9)}$$

The assumption is made in the following that the amount of

[1] The dimension of k is cm.$^{-2}$ sec.$^{-1}$. Some authors denote kL (cm./sec.) as the dissolution rate constant.

120	6.782	6.562	0.049	6.551	0.1×10^{-3}
			$\frac{\Sigma\Delta^2}{9-1} = 0.328$		$\frac{\Sigma\Delta^2}{10-2} = 4.29 \times 10^{-3}$

[a] Calculated *via* cube root equation corresponding to $\sqrt[3]{m_0} - \sqrt[3]{m} = 0.0049t$. [b] Calculated *via* Eq. 13 corresponding to $\psi(r) = 3.136 - (5.714 \times 10^{-3}) \times t$ (where $q = 0.00683$ cm. and $\beta = 2.2173$ mg./ml.).

powder used is insufficient to saturate completely the dissolution medium or just suffices to do so. Since the term $(\beta + \alpha r^3)$ is positive, Eq. 7 may be rewritten:

$$\frac{dr}{\beta + \alpha r^3} = -\frac{kL}{\rho}\,dt \qquad \text{(Eq. 10)}$$

The integral of the left-hand side is:

$$\psi(r) = \frac{q}{6\beta} \ln\left[\frac{(r+q)^2}{r^2 - qr + q^2}\right] + \frac{q}{\beta\sqrt{3}} \operatorname{arctg} \frac{r\sqrt{3}}{2q - r} \qquad \text{(Eq. 11)}$$

where:

$$q = (\beta/\alpha)^{1/3} \qquad \text{(Eq. 12)}$$

Equation 10, when integrated and subjected to initial conditions, therefore becomes:

$$\psi(r) = \psi(r_0) - \frac{kL}{\rho}t \qquad \text{(Eq. 13)}$$

$\psi(r)$, when plotted *versus* t, should then give a straight line with intercept $\psi(r_0)$ and slope $-kL/\rho = -(DL)/(h\rho)$.

RESULTS AND DISCUSSION

To test whether Eq. 13 gives results significantly different from Eq. 2 (and Eq. 3), the data reported by Hussain were plotted (7), primarily because the dissolution rates reported were carried into nonsink concentration ranges (30% saturation) and because Hussain rigorously reported all values of parameters necessary for computations of the cited nature.

Furthermore, the range of dissolution was extended in the following manner, using *p*-hydroxybenzoic acid as a test substance. *p*-Hydroxybenzoic acid was recrystallized from water, dried *in vacuo*, and screened. Material finer than 60 mesh but coarser than 80 mesh (USP) was used; this material had an average "diameter" of 212 μm., *i.e.*, $r = 106$ μm. The density of the material was determined pycnometrically to be 1.2626 g./ml. at 25 ± 0.1°. Three hundred milliliters of 0.1 *N* HCl was placed in a 1000-ml. conical flask and agitated by a magnetic stirrer at 58 r.p.m. The temperature was maintained at 25 ± 0.5°, and 2.485 g. of the *p*-hydroxybenzoic acid was added at zero time. Samples were withdrawn by pipet through glass wool at various time intervals and assayed at the UV absorption peak at 255 nm.

Results are listed in Tables I and II and shown graphically in Figs. 1–3. The calculated parameters in the tables are least squares fitted. It is noted from Figs. 1 and 2 that Eqs. 2 and 13 are adhered to well. How well can be estimated by the variances of the fits in

linear form, *i.e.*, $C = f(t)$. The variance is $\Sigma \Delta^2/\nu$, where $\Delta = \hat{C} - C$, ν denotes degrees of freedom, and $\hat{C}$ is the concentration calculated from the least-squares fit. For example, at time $t = 40$ in hydrocortisone dissolution (Table I), $\sqrt[3]{0.022} - \sqrt[3]{m} = 0.00105 \cdot 40$, so $m = 0.0135$ or $\hat{C} = 0.0135/500 = 27 \times 10^{-3}$ mg./ml. as compared to $C = 23 \times 10^{-3}$ mg./ml. found experimentally. The calculation of $\hat{C}$ corresponding to Eq. 13 is more cumbersome but can be done either graphically or by aid of a computer. It is noted from Table II (Fig. 3) that for p-hydroxybenzoic acid under nonsink conditions, Eq. 13 affords a significantly better fit than Eq. 2 [$F = 76$ as compared to $F_{0.01}$ (critical) = 5.5]. In the case of hydrocortisone and levodopa (where nonsink conditions were not so prevalent), both equations afford comparable fits.

Although statistical comparisons are worthwhile, the main point is that Eq. 13 gives a theoretically more correct solution than Eq. 2 under nonsink conditions and the data support this by exhibiting reasonable fits.

From the slope of the data plotted *via* Eq. 13, k can be found through knowledge of L and ρ. Similarly, knowledge of L, S, n, and ρ allows calculation of k from the slopes of data plotted *via* Eq. 2. These k values are listed in Table III. It is noted, as a general trend, that k values calculated from Eq. 2 are about half as large as those calculated from Eq. 13. Diffusion constants can be estimated *via* the Stokes-Einstein equation either *via* radius estimates from crystallographical parameters or *via* Wilke's method (8). The data by Haner and Norton (9) were used to obtain a diffusion coefficient for hydrocortisone of 2.47×10^{-6} cm.^{2}/sec.; by Wilke's method a value of 6×10^{-6} cm.^{2}/sec. results. By employing the relation $k = D/(hL)$, the value of h (the thickness of the adsorbed layer of liquid) can be estimated and is found to be 0.6×10^{-3} cm. = 60 μm. when using $D = 2.47 \times 10^{-6}$ cm.^{2}/sec. and 140 μm. when using $D = 6 \times 10^{-6}$ cm.^{2}/sec. Other values of this type are listed in Table III. The values are of the same order as those estimated by Hussain (7), Levy (10), and Cressman *et al.* (11).

The dimension of q is obtained from Eqs. 9 and 5 and was found to be $\{(\text{g./ml.})/[\text{g./(ml.)}^2]\}^{1/2}$ = cm. The polynomial $r^2 - qr + q^2$ has no rational roots. The term in the denominator of the arctg function in Eq. 11 must be larger than zero; *i.e.*, cubing the inequality $2q > r$ (which is allowable since $\beta/\alpha > 0$), one gets: $(\beta/\alpha) = \{[S - (m_0/L)]/(n\pi 4\rho/3L)\} > (r^3/8)$ or $(LS - m_0) > (m/8)$, so that there is the added requirement that $LS > (9m_0/8)$ (since m can be at most m_0). This requirement is slightly more stringent than the one expressed in Eq. 9 and was adhered to in the experiment dealing with p-hydroxybenzoic acid (the initial amount being 80% of solubility). Not all of the p-hydroxybenzoic acid was dissolved at the end of the experiment, and the particle-size range was sufficiently narrow so that the number of particles had not decreased (4).

The arctg function is not single valued; $x = r\sqrt{3}/(2q - r)$ is here expressed in radians between 0 and $\pi/2$. Equation 11 could equally well have been expressed with values of x between 2π and $5\pi/2$, but this would simply increase both $\psi(r)$ and $\psi(r_0)$ by $2\pi q/(\beta\sqrt{3})$ and Eq. 13 would still apply. Hence, using $0 < x < \pi/2$ does not cause a loss in generality.

Bridged D-Ring Steroid Analogs XII: Effect of D-Ring Substituents on Chemical Shift of Angular Methyl Protons

A. J. SOLO▲, S. ENG, and BALDEV SINGH*

Abstract □ The chemical shifts of the C_{18}- and C_{19}-hydrogens of 30 14α,17α-bridged 20-ketopregnanes and of four 14α,17α-bridged 17-cyanoandrostanes were correlated by means of additive substituent constants. Because the bridged D-ring of these steroids is a substituted bicyclo[2.2.1]heptane system, attempts were made to explain the magnitude of some of these substituent constants by analogy to empirical effects in other such systems as well as by reference to more general theory. The data indicate that the acetyl side chain of the bridged 20-ketopregnanes exists in one rotomer form if the D-ring bears no extra substituents or a 16α-substituent and that it exists in a second form if a 16β-substituent or a 16-substituent on a double bond is present. In the latter case, the carbonyl group deshields the C_{18}-hydrogens by an extra 0.11 p.p.m.

Keyphrases □ Steroids, bridged D-ring -effect of D-ring substituents on chemical shifts of angular methyl protons, NMR spectroscopy □ Pregnanes, 14α,17α-bridged—effect of D-ring substituents on chemical shifts of angular methyl protons, NMR spectroscopy □ 5-Androstenes, 3β-acetoxy-14α,17α-ethano—effect of D-ring substituents on chemical shifts of angular methyl protons, NMR spectroscopy □ Bridged D-ring steroids—effect of D-ring substituents on chemical shifts of angular methyl protons □ NMR spectroscopy—substituent effect on chemical shifts of angular methyl protons in bridged D-ring steroids

During initial investigations of the 14α,17α-etheno-20-ketopregnane system, the use of NMR for the determination of the stereochemistry of the bridged D-system was attempted. A comparison of the NMR spectra of some of the first compounds prepared in that series (*e.g.*, X and XI in Table I), if considered according to the theory of that time (1), would have resulted in assignment of wrong stereochemistry for these compounds. Fortunately, internal inconsistencies in the NMR data, together with the fact that other evidence (2) tended to favor the correct structures, recommended the use of other methods. Since a large group of compounds of rigorously proved structure (3–5) is now available for this series, it seemed appropriate to reconsider the spectra of these compounds in the hope of correlating the chemical shifts of their C_{18}- and C_{19}-hydrogens and of explaining the origin of the shifts in terms of current theory.

DISCUSSION

Table I lists a variety of 14α,17α-ethanopregnane derivatives and the positions of their angular methyl groups in the NMR. Six pairs of these compounds (I–II, V–VI, VII–VIII, IX–X, XII–XIII, and XIV–XV) differ only in the presence or absence of a double bond in the 14α,17α-bridge. These compounds show that such a double bond has essentially no effect on the C_{18}-hydrogens, even though it causes a shielding of the more distant C_{19}-hydrogens by 0.04 ± 0.005 p.p.m. In contrast, conversion of the saturated bridged D-ring to the doubly unsaturated system (compound pairs XI–XVI, XVIII–XIX, XXII–XXIII, XXIV–XXV, and XXVI–XXVII) results in a deshielding of the C_{18}-hydrogens by 0.30 ± 0.042 p.p.m. while shielding the C_{19}-hydrogens by 0.03 ± 0.008 p.p.m.

Recently, by synthesizing and determining the NMR of 3β-acetoxy-14α,17α-ethano-5,15-pregnadien-20-one (Compound XXX in Table I) the introduction of a 15,16-double bond was demonstrated to have almost no effect on the chemical shift of either the C_{18}- or C_{19}-hydrogens[1] (6).

Since introduction of a single double bond into either bridge of these D-rings has almost no effect on the chemical shift of the C_{18}-hydrogens, the shift of 0.30 p.p.m. which occurs on introducing double bonds into both bridges was considered to be anomalously large. This paper attempts to assess a variety of factors for their possible contributions to this effect.

Orientation of 17-Acetyl Side Chain—Examination of the pairs of compounds that were compared to determine the effect of introducing a single double bond into the bridged D-ring system reveals that, within each pair, the configuration of all substituents on the molecule (hydrogens excepted) remains constant. In contrast, in each pair in which two double bonds were introduced into the bridged D-ring system, a C_{16}-substituent or C_{15},C_{16}-disubstituents

were oriented beta in the saturated member of the pair but shifted to the nodal plane of the 15,16-double bond in the unsaturated member of the pair.

Cross and coworkers (14, 15) demonstrated that interaction between substituents in 16,17-disubstituted steroids can lead to conformational changes in the D-ring and to changes in the preferred rotomer form of substituents, especially of a C_{17}-acetyl group. These changes have been shown to result in appreciable changes in the chemical shift of the C_{18}-hydrogens and numerous warnings have been given against too ready use of additive substituent constants for calculation of chemical shifts in cases where the substituents may interact sterically, by hydrogen bonding, or by dipole-dipole effects (15, 16).

In the present case, the rigidity of the bridged D-ring prevents any major conformational change in the C- or D-ring of the steroid. However, the possibility does remain that substituents, particularly those at C_{16}, may cause a change in the preferred orientation of the 17-acetyl group and thereby cause an additional change in the chemical shift of the C_{18}-hydrogens.

Previously, an X-ray structure determination on 3β-acetoxy-14α,17α-ethano-16α-iodo-5-pregnen-20-one (XXVIII) was reported (3). It showed that, in the crystalline state, the acetyl group of XXVIII is oriented with the oxygen beta and at an angle of 38° with respect to the plane containing atoms C_{14}, C_{15}, C_{16}, and C_{17}.

In an attempt to find a structural abnormality that could explain the deshielding of the C_{18}-hydrogens of the 15-dehydro-14α,17α-etheno compounds, an X-ray structure determination of XXVII was made. That study (5) disclosed no structural anomalies, but it did show that the vicinal angle defined by the acetyl group and the plane containing atoms C_{14}, C_{15}, C_{16}, and C_{17} is 11° larger in XXVII than in XXVIII.

This change in orientation of the acetyl group is similar to the change postulated (15) to occur in 20-ketopregnanes when a 16β-substituent is introduced. Cross and Beard (15) assigned a ψ-equatorial conformation to the 16β-substituent; in that form, the relative orientation of the 13β-methyl, the acetyl group, and the 16-substituent is very similar to that of the corresponding groups in XXVII. If this analogy is valid, one could argue that the deshielding observed going from a 16α-substituted 14α,17α-ethenopregnan-20-one to the 15-dehydro analog (from X to XI) is, at least in part, the expected result of reorientation of the acetyl side chain. To the extent that this is true, it changes the task to that of explaining the relative lack of deshielding by the 16β-substituents.

Cross and Beard's estimate (15) of the long-range shielding effect of different acetyl rotomers was qualitative and was based on Jackman's (1) early view regarding the shape of the carbonyl shielding cones. Since that time, more refined views of the long-range shielding effect of the carbonyl group have emerged (17–19) and the importance of also considering the shielding effects of carbon-carbon single bonds and of carbon-hydrogen bonds has been emphasized (8, 19). Accordingly, equations of ApSimon *et al.* (8, 18) were used to estimate the shielding effect exerted by the acetyl group, in its various rotomer forms, on the C_{18}-hydrogens. These calculations showed a larger shielding for the 16α-substituted compound, XXVIII (−0.09 p.p.m.), than for the unsaturated compound, XXVII (−0.16 p.p.m.)[2]. As shown in Fig. 1, the rotomer that points the acetyl oxygen toward the center of rotation of the C_{18}-hydrogens would be maximally deshielded while the rotomer in which the carboxyl bond axis has been rotated by 180° would be maximally shielded. These results demonstrate that reorientation of the acetyl group may account for at least a small portion of the anomalous deshielding observed for the C_{18}-hydrogens of the 14α,17α-etheno-15-pregnen-20-ones.

17-Cyano Compounds—Because the calculation of the shielding of the C_{18}-hydrogens by the acetyl group involves many assumptions, it was necessary to determine experimentally the magnitude of this effect. This was done by studying compounds in which the acetyl group was replaced by the axially symmetrical cyano group. Accordingly, 3β-acetoxy-17-cyano-5,14,16-androstatriene (2) was reacted with dimethyl acetylenedicarboxylate to afford 3β-acetoxy-17-cyano-15,16-dicarbomethoxy-14α,17α-etheno-5,15-androstadiene (XXXI)[3]. Hydrogenation of XXXI over palladium-on-charcoal afforded 3β-acetoxy-17-cyano-15β,16β-dicarbomethoxy-14α,17α-ethano-5-androstene, XXXII.

[2] These calculations do not pertain to the compounds studied by Cross and Beard (15) since those compounds could undergo conformational changes in the D-ring as well as rotation of the acetyl group. Moreover, the torsional angle formed by the C_{13}–C_{18} and C_{17}–C_{20} bonds is greater in the present case than in the compounds of Cross and Beard (15).

[3] Stereochemistry was assigned by analogy to that which was demonstrated in the corresponding 20-ketopregnane system (3, 4).

In Table II, the chemical shifts of the angular methyl hydrogens of four 17-cyano-14α,17α-bridged steroids are compared to those of the corresponding 17-acetyl compounds. The C_{18}-hydrogens of the 16α-substituted 17-acetyl compounds, XXXV and X, are shielded by 0.14 ± 0.01 p.p.m. relative to those of the cyano steroids, XXXIII and XXXIV. By contrast, both in the case of 16β-substituted steroids and in the case of 16-substituted 15,15′-didehydrosteroids, the acetyl compounds are shielded by only 0.03 ± 0.01 p.p.m. relative to the cyano compounds. These data can be rationalized by postulating a change in orientation of the acetyl group on going from the 16α-substituted compounds, XXXV and X, to the 15,15′-didehydro-16-substituted or 16β-substituted compounds, XIX and XVIII. This change in rotomer form would be accompanied by a decrease in shielding of 0.11 ± 0.01 p.p.m. Such a change in shielding is in reasonable agreement with that calculated (0.07 p.p.m.) to occur going from the 16α-substituted compound, XXVIII, to the unsaturated compound, XXVII. The unique geometry of the 16β-substituted series would be expected to lead to a new shielding curve similar to those in Fig. 1. However, the similarity of the curves in Fig. 1, for the range of interest, leads to the expectation that the similar shielding effect of the acetyl group in the 16β-substituted series and in the doubly unsaturated bridged series reflects a similar orientation of the group in the two series.

While, as discussed previously, the data in Table II do confirm[4] that a change in acetyl rotomer form is responsible for a small part of the increased deshielding of the C_{18}-hydrogens of 16-substituted 15,15′-didehydropregnan-20-ones as compared to those of the corresponding 16α-steroids, they also clearly show that some additional factor must contribute to the deshielding of the C_{18}-hydrogens of the didehydrosteroids as compared to those of either the 16α- or the 16β-substituted steroids. Alternatively, the data could be explained by assuming that some factor causes the C_{18}-hydrogens of the 16α- and/or the 16β-steroids to be excessively shielded.

Substituent Constants—As a further test for unusual factors affecting the shielding of the angular methyl groups of these bridged steroids, an attempt was made to correlate their chemical shifts by the use of additive substituent constants after the manner of Zurcher (20). By using the values shown in Table III together with Zurcher's values (20) for substituents in the A- or B-ring, one can obtain the values shown as "calculated" in Tables I and II.

Shielding by Substituents at C_{15} and C_{16}—The constants in Table III clearly illustrate that 16β-trifluoromethyl and 16β-carbomethoxy groups cause little deshielding of the C_{18}-hydrogens, and correlations with the cyano steroids show that this effect is not caused by changes in orientation of the 17-acetyl group. Initially, these results were surprising because it was known that, in accord with theory (21), substituents such as halogen and hydroxyl, located 1–3 to a methyl on a cyclopentane ring, generally cause a greater deshielding of the methyl group when they are *cis* to it than when they are *trans* to it (20, 22–24). Of particular pertinence, because the bridged D-ring of these steroids constitutes a 7-methylbicyclo-[2.2.1]heptane system (where the 7-methyl is C_{18} of the steroid), is the fact that this effect has been confirmed in a variety of 7-methylbicyclo[2.2.1]heptanes (25). In the latter series, *exo*-substituents deshield the 7-*syn*-methyl group by 0.16–0.31 p.p.m., which is 2–6 times more than that caused by the corresponding *endo*-substituents. Calculations show that such substituents, when located at the 2-position of a 7-*syn*-methylbicyclo[2.2.1]heptane, should deshield the methyl hydrogens least when the substituent is *endo*, slightly more in the 2-dehydro compound, and most when the substituent is *exo* (21).

In view of this dicussion, the 16β-substituted compounds listed in Table I appear to show surprisingly little deshielding of the C_{18}-hydrogens by the 16β-substituents. For example, in Compounds IX, X, XII, XIII, XIV, and XV the *endo*-carbomethoxy group causes a deshielding of the C_{18}-hydrogens, which averages 0.06 p.p.m., but the *exo*-carbomethoxy group of Compound XVI has no apparent effect on them. Also, an alternative estimate of the effect of such a carbomethoxy group can be made by assuming that the effect of a 2-substituent on the 7-*syn*-methyl in the bornane system is a linear function of Taft's σI value (26) for such a substituent; such a relationship has been shown to hold for hydrogens on the carbon beta (27) or alpha (28) to the substituted one. Extrapolation

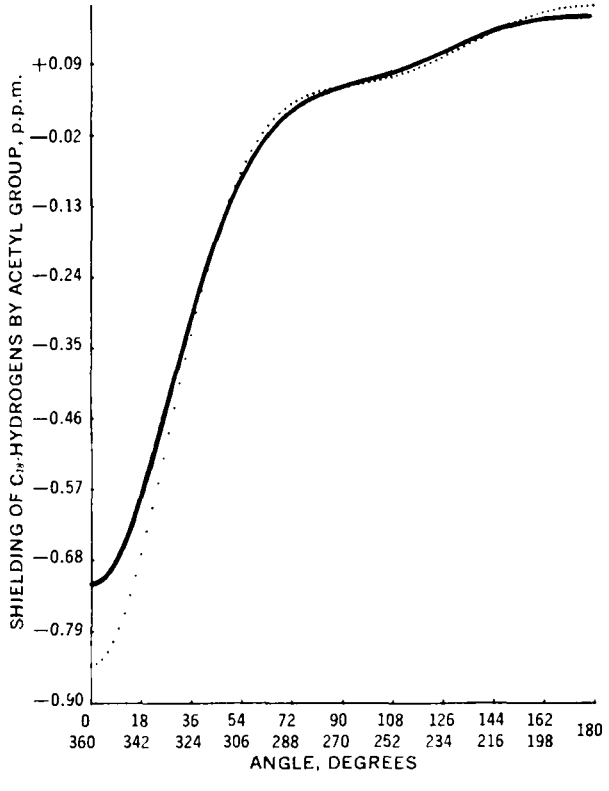

Figure 1—*Shielding of C_{18}-hydrogens by acetyl group* versus *the angle defined by the C_{20}-oxygen bond axis and the vector that is perpendicular to the C_{17}–C_{20}-bond axis and that passes through the center of rotation of the C_{18}-hydrogens. The solid line was calculated for XXVII, and the dotted line was calculated for XXVIII.*

[4] In response to a referee's suggestion that the restricted conformational freedom, postulated for the 17-acetyl compounds, should be partly cancelled by an increase in temperature, the effect of temperature on the chemical shift of the C_{18}-hydrogens of progesterone and of Compounds III, XIV, and XXII was studied. The C_{18}-hydrogens of all of these compounds appear to be less shielded at higher temperatures. While this could be interpreted as supporting the present position, it was decided not to attribute any significance to these data because: (*a*) in carbon tetrachloride or deuteriochloroform, the shifts are so small as to be only slightly greater than the probable error of the measurements; (*b*) the shifts are solvent dependent (larger in dioxane and much larger in dimethyl sulfoxide than in carbon tetrachloride or deuteriochloroform; and (*c*) other peaks such as that of the C_{18}-hydrogens also shift with temperature. Effects (*b*) and (*c*) could result from temperature-dependent solvent–solute interactions of sufficient magnitude as to obscure the observation of the rotational isomerism.

from the known effect of 2-substituents in the bornane system (25) leads to the prediction that a 16α-carbomethoxy group, in the bridged steroids, should cause a deshielding of the C_{18}-hydrogens of 0.06 p.p.m., as observed, and that a 16β-carbomethoxy group should cause a deshielding of 0.20 ± 0.05 p.p.m. By a similar process, one can estimate that the effect of a 16β-trifluoromethyl group on the C_{18}-hydrogens should be to deshield them by 0.24 ± 0.05 p.p.m.

In the discussion of the effects on the shielding of the C_{18}-protons resulting from changes in configuration of 16-substituents, calculations were based on the geometry that would be obtained if the substituent were a halide or hydroxyl group. However, the results of those calculations might not be valid for the trifluoromethyl or carboxy ester groups. To avoid the problems introduced by possible hindered rotation of the carbomethoxy group, calculations were based on the trifluoromethyl group and were further simplified by considering only the effects caused by the net dipole of the trifluoromethyl group. These calculations (21) indicate that, to the extent that deshielding of the C_{18}-protons by the trifluoromethyl group is caused by a direct electrostatic effect rather than by a classical inductive effect, the deshielding should be greatest when the trifluoromethyl group is *endo* (alpha). The change in geometry caused by introduction of a 15,16-double bond should cause the deshielding to decrease by 50%, and a change to an *exo*- (beta) orientation of the trifluoromethyl group should result in a *shielding* twice as great as the *deshielding* caused by the field effect of the *endo*-isomer. While these results are based on crude approximations[5], they do correlate exactly with the chemical shifts found for the 16α- and 16β-carboxy ester substituted compounds. The possibility of undefined vicinal interactions in the 15,16-disubstituted compounds makes them a less reliable test of the validity of this approach. While the deshielding caused by the 15-dehydro-16-carbomethoxy moiety is clearly excessive in terms of the predictions, a number of factors, including resonance interactions which put a partial positive charge at C_{13}, could easily account for the discrepancy. This is unfortunate in the sense that the plurality of possible explanations could mask a small but anomalous deshielding peculiar to the 7-methylbicyclo-[2.2.1]heptadiene system[6].

EXPERIMENTAL[7]

3β-Acetoxy-14α,17α-ethano-5α-pregnan-20-one (III)—A solution of 291 mg. of II in 100 ml. of ethanol and 4 ml. of water was reduced over 52 mg. of 10% palladium-on-charcoal, at an initial pressure of 3.71 kg./cm.², for 18 hr. at room temperature. Standard workup of the reaction mixture afforded 235 mg. of III as white flakes from methanol, m.p. 177–179°.

Anal.—Calc. for $C_{23}H_{38}O_3$: C, 77.68; H, 9.91. Found: C, 77.76; H, 9.85.

3β-Acetoxy-14α,17α-ethano-15β,16β-dicarbomethoxy-5-pregnen-20-one (XVIII)—A solution of 1.0 g. of XIX in 200 ml. of methanol was hydrogenated over 150 mg. of 10% palladium-on-charcoal at an initial pressure of 3.71 kg./cm.² for 13 hr. at room temperature. Standard workup afforded XVIII, in a yield of 698 mg., as white rods from ethanol, m.p. 176–177°; ν (mineral oil): 1735 (sh), 1730, 1690, and 1625 cm.⁻¹. The NMR spectrum has singlets at δ 2.06 [OC(=O)CH_3], 2.22 (C_{21} H's), 3.75, and 2.85 [C(=O)OCH_3].

Anal.—Calc. for $C_{29}H_{40}O_7$: C, 69.58; H, 8.05. Found: C, 69.53; H, 7.85.

3β-Acetoxy-17-cyano-15,16-dicarbomethoxy-14α,17α-etheno-5,15-androstadiene (XXXI)—A mixture of 314 mg. of 3β-acetoxy-17-cyano-5,14,16-androstatriene (2), 5 mg. of hydroquinone, and 1.0 ml. of dimethyl acetylenedicarboxylate was heated at 128–130°, in a sealed tube, for 148 hr. The crude product was chromatographed over 12 g. of acid-washed alumina[8]. Elution with benzene afforded XXXI as a foam (from ether) in a yield of 285 mg. (68%); ν (mineral oil): 2242 and 1730 cm.⁻¹. The NMR spectrum had singlets at δ 2.02 [OC(=O)CH_3] and 3.82 (OCH_3), a multiplet at δ 5.35 (C_6 H), and doublets at δ 6.83 and 6.88 (bridge vinyl hydrogens).

Anal.—Calc. for $C_{28}H_{33}NO_6$: C, 70.13; H, 6.94; N, 2.92. Found: C, 70.36; H, 7.26; N, 2.76.

3β-Acetoxy-17-cyano-15β,16β-dicarbomethoxy-14α,17α-ethano-5-androstene (XXXII)—A solution of 151 mg. of XXXI in 200 ml. of methanol and 5 ml. of water was reduced over 22 mg. of 10% palladium-on-charcoal for 18 hr. at room temperature under an initial pressure of 3.65 kg./cm.². The product was chromatographed over 15 g. of neutral activity III alumina[9]. Elution with mixtures of ethyl acetate and benzene afforded XXXII as a glass, in a yield of 96 mg.; ν ($CHCl_3$): 2335 and 1722 cm.⁻¹. The NMR spectrum had singlets at δ 2.04 [OC(=O)CH_3] and 3.84 [C(=O)-OCH_3] and a multiplet at δ 5.35 (C_6 H).

Anal.—Calc. for $C_{28}H_{37}NO_6$: C, 69.54; H, 7.71; N, 2.90. Found: C, 69.49; H, 7.64; N, 2.80.

3β-Acetoxy-14α,17α-etheno-15α,16α-dicarboxyanhydride-5-pregnen-20-one (XXXV)—A mixture of 0.35 mg. of 3β-acetoxy-5,14,16-pregnatrien-20-one, 0.45 g. of maleic anhydride, and 15 mg. of hydroquinone was heated at 95–100° for 25 hr. in a sealed glass tube under nitrogen. The unreacted maleic anhydride was removed by distillation under reduced pressure at 100°. The residue was chromatographed over 15 g. of silica gel. Benzene containing up to 10% ethyl acetate eluted XXXV as a foam in a yield of 0.32 mg.; ν (mineral oil): 1830, 1765, 1720, and 1685 cm.⁻¹. The NMR spectrum has singlets at δ 2.04 [OC(=O)CH_3] and 2.31 (C_{21} H's), doublets at δ 3.50, 4.45 [J = 8 Hz., CC(=O)H], 6.39 and 6.49 (J = 6.5, CH=CH), and a multiplet at 5.46 (C_6 H).

Anal.—Calc. for $C_{27}H_{32}O_6$: C, 71.66; H, 7.13. Found: C, 71.57; H, 7.20.

SUMMARY

Correlation of the chemical shifts of 30 14α,17α-bridged 20-ketopregnanes and of four similarly bridged 17-cyanoandrostanes, by means of additive substituent constants, requires the assumption that, depending upon the substitution pattern at C_{16}, the acetyl group of the pregnanes exists in one of two possible rotomer forms. Thus, introduction into these bridged pregnanes of a 16β-substituent or of a 16-substituent on a 15,16-double bond presumably causes the β-oriented carbonyl group to rotate toward C_{18}, which results in a 0.11 p.p.m. deshielding of the C_{18}-hydrogens. Support for this assumption is provided by X-ray crystal structures which were determined for 3β-acetoxy-14α,17α-ethano-16α-iodo-5-pregnen-20-one and for 14α,17α-etheno-15,16-di(trifluoromethyl)-4,15-pregnadiene-3,20-dione. Calculation, by the method of ApSimon *et al.* (8, 18), of the shielding effect of the acetyl group for each of the above structures indicates that the C_{18}-hydrogens of the latter compound should be deshielded by 0.07 p.p.m. relative to those of the former.

The finding that carboxy ester and trifluoromethyl groups substituted at the 15β- and/or 16β-positions of these bridged steroids cause little deshielding of the C_{18}-hydrogens contrasts sharply with the known tendency of 2-*exo*-halide functions to deshield 7-*syn*-methyl groups strongly in bicyclo[2.2.1]heptane systems. However, the dipoles of the former substituents bear a different geometrical relationship to the methyl than do those of the latter. Calculation of the expected field effects for these compounds shows that the observed chemical shifts are normal. Calculations also reveal that

[5] Approximations because: (*a*) the calculated values show large changes for relatively small variations in molecular geometry, (*b*) the geometry shown in the Dreiding models for the β-isomer is not correct in that it does not compensate for the crowding between the trifluoromethyl and methyl groups, (*c*) the authors did not correct for any partial charge transfer from the trifluoromethyl group to C_{16} or for the interaction of the 16-substituent with the double bond in the 15-dehydro compound, and (*d*) the method of calculation may be invalid for the β-isomer because of th proximity of the trifluoromethyl and methyl groups.

[6] Introduction of double bonds into norbornanes has been found to cause the chemical shifts of the C_7-hydrogens to change anomalously (7, 29, 31). While a partial explanation for this phenomenon has been advanced (28, 30, 31), recent data raise doubts as to its adequacy (32), and no satisfactory explanation has yet been put forward for the unusual deshielding of the corresponding hydrogens of norbornadiene (29). A similar effect of reduced magnitude seems to be shown by the methyl hydrogens of 7-methylbicyclo[2.2.1]heptadiene (33) which are more deshielded than the corresponding hydrogens of either of the 7-methylbicyclo[2.2.1]heptenes (7). In contrast, the *tert*-butyl hydrogens of the corresponding 7-*tert*-butyl compounds appear to have normal chemical shifts (34).

[7] Melting points were determined in capillary tubes on a Mel-Temp apparatus and are uncorrected. Elemental analyses were performed by Galbraith Microanalytical Laboratories, Knoxville, Tenn. NMR spectra were determined in $CDCl_3$ on a Varian A-60 spectrometer and are reported in parts per million downfield from a tetramethylsilane internal standard.

15-Dehydro-15,16-di(trifluoromethyl)	0.27	0.03

[a] For solution in deuteriochloroform. A positive shift indicates a shift downfield from tetramethylsilane.

the strong deshielding associated with a substituted 15,16-double bond could be a normal consequence of a field effect arising from the dipole created by electron donation from the double bond to the substituent.

While it appears possible to explain the NMR observations on these compounds, many discussed effects could not have been anticipated. Because of this situation and because of continuing reports of anomalies in related small bridged ring compounds (35, 36), caution should be used in interpreting the NMR spectra of such substances.

Biopharmaceutics of Drugs Administered in Lipid-Containing Dosage Forms I: GI Absorption of Griseofulvin from an Oil-in-Water Emulsion in the Rat

PHILIP J. CARRIGAN and THEODORE R. BATES▲

Abstract □ The GI absorption characteristics of micronized griseofulvin from an oil-in-water emulsion dosage form, an oil suspension, and an aqueous suspension were assessed in the rat. Although there was a slight delay in the time of occurrence of the peak plasma concentration of griseofulvin following its oral administration in the emulsion, this dosage form produced a mean peak plasma antibiotic level 1.5 and 2.3 times higher than the oil and aqueous suspensions, respectively. In addition, the emulsion dosage form significantly increased the time over which plasma concentrations of drug were maintained above 1 mcg./ml. All six rats dosed with the emulsion attained this 1-mcg./ml. plasma level or greater (mean duration of 7.5 hr.), while only two out of six rats dosed with the aqueous suspension (duration of 3.7 and 4.0 hr., respectively) and four out of six rats dosed with the oil suspension (mean duration of four rats of 3.9 hr.) ever achieved this plasma concentration. Based on area under the plasma concentration *versus* time curve measurements, it was established that the bioavailability of micronized griseofulvin can be increased 2.5-fold, as compared to an aqueous suspension, by orally administering this relatively water-insoluble antibiotic in an oil-in-water emulsion dosage form.

Keyphrases □ Griseofulvin (micronized) GI absorption profiles—oil-in-water emulsion compared to oil suspension and aqueous suspension, rats □ Absorption, GI, micronized griseofulvin—plasma concentration *versus* time curves, oil-in-water emulsion compared to oil and aqueous suspensions □ Lipid-containing dosage forms—GI absorption of micronized griseofulvin from oil-in-water emulsion, oil suspension, and aqueous suspension

Griseofulvin is a relatively water-insoluble, systemic, antifungal antibiotic, whose oral absorption has been shown to be dissolution rate limited (1). As a result, its absorption from the GI tract of lower animals (2, 3) and man (4–6) has been characterized as being erratic and incomplete. The rate and extent of absorption of this drug in man have also been shown to be dependent on particle size (7, 8), dosage form (1, 9, 10), and formulation factors (11, 12).

Several investigators demonstrated that the absorption of both regular and micronized griseofulvin in rats (13), guinea pigs (14), and man (5, 7, 15) could be markedly enhanced if coadministered with meals high in fat or triglyceride content. The application of these findings to the clinical treatment of fungal infections offers obvious advantages. However, to date, there are no commercially available dosage forms containing the drug and lipid. Since poor palatability and patient acceptance of an oil suspension dosage form is anticipated, it appears that an oil-in-water emulsion would be the best delivery system for this drug.

The GI absorption of drugs orally administered to intact animals in two- or three-phase, lipid-in-water emulsion dosage forms has received limited attention in the literature (16–21), and no studies have explored the various factors affecting drug release and absorption from such dosage forms. The emulsion dosage form is unique in that it represents the only conventional dosage form containing appreciable quantities of triglycerides or other lipids. The potential influence of the presence of lipid in the GI tract on the absorption of drugs (22) prompted the present preliminary investigation, which was designed to assess the absorption profiles of micronized griseofulvin following its oral administration to rats in the form of an aqueous suspension, a corn oil suspension, and a three-phase corn oil-in-water emulsion dosage form.

EXPERIMENTAL

Materials—The griseofulvin[1] employed in this study was the micronized form (specific surface area 1.32 $m.^2/g.$). Polysorbate[2] 60, mono- and diglycerides of edible fats[3] (I), and corn oil USP[4] were used as received. Anhydrous, reagent grade ether was distilled, immediately prior to use, from an all-glass still having a 47-cm. vigreaux column. Reagent grade anhydrous methanol was treated with activated charcoal[5] to remove fluorescent impurities; water was double distilled.

Dosage Forms—Three dosage forms were subjected to *in vivo* bioavailability testing. The first was an aqueous suspension containing 10 mg. of micronized griseofulvin and 10 mg. of polysorbate 60/ml. The second preparation was a corn oil suspension containing 25 mg. of micronized griseofulvin and 25 mg. of polysorbate 60/ml. The third dosage form was a three-phase oil-in-water emulsion containing 10 mg. of micronized griseofulvin, 10 mg. of polysorbate 60, 10 mg. of I, 0.4 ml. of corn oil, and a sufficient quantity of distilled water to make 1 ml. The emulsion was refined in a blender[6] and finally passed twice through a hand homogenizer[7]. The mean globule size of the internal (oil) phase of the resultant emulsion, as determined by a modification of the photomicrographic method of Singiser (23), was 5.2 μ in diameter (3.8 μ < 90% of globules < 9.7 μ).

Each test dosage form was assayed in duplicate for drug content by dissolving an aliquot of the preparation in ethanol and subsequently measuring its absorbance at 292 nm. in a recording spectrophotometer[8]. The resultant absorbance values were converted to concentration units with the aid of a Beer's law plot constructed over the 0–10-mcg./ml. range. The constituents of the three dosage forms, in the quantities present in the assay samples, were found not to interfere with the determination of griseofulvin.

***In Vivo* Absorption Studies**—Adult, male, Sprague–Dawley rats[9], weighing 250–300 g., were fasted for 20 hr. prior to, and for a 12-hr. period subsequent to, the initiation of the absorption experiments. However, they were allowed free access to water throughout the experiment. Each freshly prepared dosage form was administered by oral intubation to six rats at a constant griseofulvin dosage level of 50 mg./kg. body weight. The dosing volume employed for

the aqueous suspension and emulsion dosage forms was 5.0 ml./kg. body weight. To maintain the volume of oil administered in the form of the corn oil suspension consistent with that of the emulsion dosage form, a dosing volume of 2.0 ml./kg. body weight was used. The animals were subsequently placed in restraining cages, and approximately 0.5-ml. blood samples were collected from the tail vein into heparinized tubes at 1, 2, 4, 6, 8, and 12 hr. postadministration. Twenty-four-hour samples were obtained *via* decapitation. The blood samples were then centrifuged, and a 0.2–0.3-ml. aliquot of the plasma obtained was accurately measured directly into glass-stoppered extraction vessels. A 2.0-ml. plasma sample was obtained at the 24-hr. time period. All plasma samples were immediately frozen solid and assayed for intact drug content within 48 hr. of collection.

Assay Procedure for Griseofulvin in Plasma—The specific spectrofluorometric procedure of Shah *et al.* (24) for plasma griseofulvin was appropriately modified for handling small plasma samples. The method essentially involves extracting griseofulvin from the plasma samples under neutral pH conditions into 7 ml. of freshly distilled ether and subsequently evaporating to dryness an aliquot (3–5 ml.) of the organic phase. The residue is then reconstituted with 2 ml. of a 1:1 (v/v) mixture of water and methanol and washed with 2 ml. of reagent grade hexane; the fluorescence of the hydroalcoholic phase was measured on a spectrofluorometer[10] using activation and emission wavelengths of 303 and 428 nm. (uncorrected), respectively. Subsequently, 4 drops of concentrated sulfuric acid was added to the sample and the fluorescence was redetermined.

On each assay day, a linear calibration curve of net fluorescence intensity (sample minus quench reading) *versus* concentration, over the range of 0.0071–0.143 mcg./ml. of hydroalcoholic solution, was constructed by carrying standard solutions of griseofulvin through the entire extraction procedure. The net fluorescence values of the extracted plasma samples were first corrected for the small positive intercept value of the calibration plot and then converted to concentration units by dividing the corrected net values by the least-squares slope value of the calibration plot.

Recovery studies performed with plasma samples containing 0.040–0.800 mcg. of griseofulvin indicated that the extraction procedure employed was capable of quantitatively removing the drug from plasma [mean recovery $\pm SD$ ($n = 6$) was $105 \pm 2.4\%$].

RESULTS AND DISCUSSION

To provide a basis for valid comparisons, control dosage forms employed in this *in vivo* absorption study (*i.e.*, aqueous and oil suspensions) were designed to incorporate certain components present in the emulsion dosage form. For example, both control dosage forms contained the same amount of nonionic surfactant (polysorbate 60) and the same particle-size fraction of drug. In addition, animals dosed with either the oil suspension or emulsion dosage form received an equivalent amount of triglyceride (corn oil).

Based on the results of equilibrium solubility studies performed at 25°, it was established that at the time of dosing a maximum of only 0.5, 2.4, and 2.7% of the orally administered dose of drug was

in solution in the aqueous suspension, oil suspension, and emulsion dosage forms, respectively. Hence, differences encountered among the absorption characteristics of the drug from the three dosage forms cannot be attributed to this potential variable.

The results of *in vivo* absorption studies are summarized in Table I. Figure 1 depicts representative plasma griseofulvin concentration *versus* time plots obtained following the oral administration of a single 50-mg./kg. dose of micronized griseofulvin to individual rats in the aqueous suspension, oil suspension, and oil-in-water emulsion dosage forms. Examination of this figure, together with the mean data for the six animals dosed with each test preparation (Table II), reveals that a delay existed in the attainment of peak plasma drug levels following oral administration of both the oil suspension and emulsion as compared to the aqueous suspension (*i.e.*, 5–6 hr. *versus* 3 hr.). However, the magnitude of the mean peak plasma level of griseofulvin from the emulsion was approximately 1.5 and 2.3 times higher than from the oil and aqueous suspensions, respectively (Table II). These differences are highly significant as determined by Student's t tests performed on the mean data.

Griseofulvin blood levels greater than 1 mcg./ml. are required to effect a cure in human *Tinea capitis* infections (25). The same minimum effective blood level was also reported for dogs (26). If it is assumed that a similar value exists for the rat, an indication of differences among the dosage forms as to the duration of therapeutic levels may be realized. An interesting finding was that all six rats receiving the emulsion maintained a plasma level of 1 mcg./ml. or greater for approximately 6–11 hr. (mean duration of 7.5 hr.), while only two out of six rats dosed with the aqueous suspension (duration of 3.7 and 4.0 hr., respectively) and four out of six rats dosed with the oil suspension (mean duration of four rats of 3.9 hr.) ever achieved this proposed plasma level.

By using the trapezoidal rule, the area under the plasma griseofulvin level *versus* time curve from time zero to 24 hr. was determined for each animal and test preparation. The results of these area calculations, which reflect the amount of griseofulvin absorbed in 24 hr., are summarized in Table III. A one-way analysis of variance performed on the area under the plasma level–time curve for the three dosage forms yielded an F value of 10.4 (df 2,15) with $p < 0.005$. Individual differences between two treatments were tested statistically using Student's t test (Table III). As can be seen from an examination of the mean area under plasma level-time curve values, there is no statistical difference between the fraction of the oral dose of griseofulvin absorbed from the aqueous and oil suspensions. However, there is a highly significant 1.6- and 2.5-fold increase in the amount of drug absorbed from the emulsion dosage form as compared to the oil and aqueous suspensions, respectively. As reflected by the magnitudes of the coefficients of variation listed in Table II, the uniformity of absorption of micronized griseofulvin decreased in the following order: emulsion > oil suspension > aqueous suspension.

Table III—Bioavailability of Micronized Griseofulvin following Its Oral Administration as a Single 50-mg./kg. Dose in Three Test Dosage Forms

	Area under Plasma Level–Time Curve from Time Zero to Twenty-Four Hours (mcg.-hr./ml.)

The physicochemical and/or physiological mechanism(s) by which the presence of triglyceride in the emulsion dosage form markedly enhances the absorption characteristics of griseofulvin, and possibly other poorly absorbed drugs, is currently under intensive investigation in these laboratories. Several possible physiological mechanisms being explored involve the influence of unemulsified and emulsified triglyceride (corn oil) on the rate of gastric emptying, GI motility, and bile flow. The results of these studies will be subsequently reported.

Photolytic Decomposition of *N*-(2,6-Dichloro-*m*-tolyl)anthranilic Acid (Meclofenamic Acid)

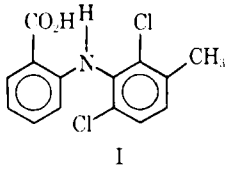
JOSE PHILIP▲ and DALE H. SZULCZEWSKI

Abstract □ Exposure of dilute solutions of *N*-(2,6-dichloro-*m*-tolyl)anthranilic acid to visible or UV light results in fairly rapid decomposition with concurrent formation of approximately equimolar amounts of 8-chloro-7-methylcarbazole-1-carboxylic and 8-chloro-5-methylcarbazole-1-carboxylic acids.

Keyphrases □ *N*-(2,6-Dichloro-*m*-tolyl)anthranilic acid (meclofenamic acid)—isolation, identification of photolytic decomposition products □ Meclofenamic acid [*N*-(2,6-dichloro-*m*-tolyl)anthranilic acid]—isolation, identification of photolytic decomposition products □ Photolysis, *N*-(2,6-dichloro-*m*-tolyl)anthranilic acid (meclofenamic acid)—isolation, identification of decomposition products

N-(2,6-Dichloro-*m*-tolyl)anthranilic acid (meclofenamic acid)[1], I, is an investigational new drug being evaluated for use as an anti-inflammatory agent. Results from previous studies in these laboratories indicated that one possible route of decomposition involved decarboxylation to the corresponding substituted diphenylamine in accord with the general chemistry of anthranilic acids. This reaction, however, proceeds at an appreciable rate only at elevated temperatures (100° for strongly acidic solutions or above the melting point, 258.5–259.5° in the case of the solid state) and would have little relevancy to dosage form shelflife at near ambient temperatures.

As part of continuing preformulation studies, the



I

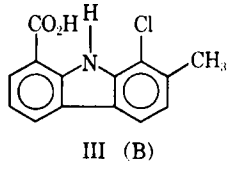
II (A)



III (B)

influence of light, as another condition of stress, was studied.

DISCUSSION

Sequential UV spectra obtained during exposure of a dilute solution of I (c 0.00426%, methanol) to visible light[2] are shown in Fig. 1. There was a fairly rapid spectral change during the initial period of exposure, after which the spectra become essentially constant. Spectra obtained from aqueous alkaline solutions exposed in the same manner were qualitatively similar, whereas like solutions stored in the dark gave spectra invarient with time.

A thin-layer chromatogram obtained on a methanolic solution of I (R_f 0.7) exposed to the point of spectral redundancy showed the formation of at least two reaction products (1, R_f 0.4; and 2, R_f 0.31), one of which predominated. Available data indicate that I undergoes a facile reaction in the presence of light, but the nature of this reaction is unknown. Relevant information from the literature is rather scarce; however, the work of Bowen and Eland (1) indicated that diphenylamine is converted to carbazole in the presence of light.

To determine the nature of this reaction, reaction products were isolated for identification. A large volume of a more concentrated methanolic solution of I was exposed to UV light[3] (c 0.1%), and the solvent was removed under vacuum. The residue was recrystallized to remove residual I and the minor decomposition product. During the recrystallization, fractions were obtained whose R_f values were the same as the major decomposition product but whose

influence of light, as another condition of stress, was studied.

DISCUSSION

Sequential UV spectra obtained during exposure of a dilute solution of I (c 0.00426%, methanol) to visible light[2] are shown in Fig. 1. There was a fairly rapid spectral change during the initial period of exposure, after which the spectra become essentially constant. Spectra obtained from aqueous alkaline solutions exposed in the same manner were qualitatively similar, whereas like solutions stored in the dark gave spectra invarient with time.

A thin-layer chromatogram obtained on a methanolic solution of I (R_f 0.7) exposed to the point of spectral redundancy showed the formation of at least two reaction products (1, R_f 0.4; and 2, R_f 0.31), one of which predominated. Available data indicate that I undergoes a facile reaction in the presence of light, but the nature of this reaction is unknown. Relevant information from the literature is rather scarce; however, the work of Bowen and Eland (1) indicated that diphenylamine is converted to carbazole in the presence of light.

To determine the nature of this reaction, reaction products were isolated for identification. A large volume of a more concentrated methanolic solution of I was exposed to UV light[3] (c 0.1%), and the solvent was removed under vacuum. The residue was recrystallized to remove residual I and the minor decomposition product. During the recrystallization, fractions were obtained whose R_f values were the same as the major decomposition product but whose

Table I—IR Spectral Data for Fractions A and B (KBr Dispersion)

Group	Wave Number, $cm.^{-1}$ A		B	
—NH	3450	(sharp)	3460	(sharp)
—CO_2H	3300–2400	(broad)	3300–2400	(broad)
	1665	(strong)	1680	(strong)
CO_2H dimer	928		920	

UV spectra differed. In particular, absorption near 300 nm. varied, taking the form of a shoulder in some and a distinct maximum in others (Figs. 2 and 3). The crystalline materials (A and B) giving these two spectra were investigated to determine structure.

The empirical formula, $C_{14}H_{10}ClNO_2$, as determined by elemental analysis and the molecular weight, 259, determined by mass spectroscopy for both A and B indicated that they were isomeric compounds, each differing from I by the elements of HCl. The presence of amino and carboxylic acid moieties in both was established from corresponding IR spectra (Table I). NMR spectra (Figs. 4 and 5 and Table II) were definitive and, together with preceding data and information, established the dominant photolytic products to be 8-chloro-5-methylcarbazole-1-carboxylic acid (II) and 8-chloro-7-methylcarbazole-1-carboxylic acid (III).

The relative amounts of II and III formed during photolysis were determined from the terminal UV spectrum of the spent reaction mixture. The observed absorbance ratio ($R_{obs} = A_{\lambda 302}/A_{\lambda 351}$) was 1.18, which indicated that the product distribution was 1 : 1.

EXPERIMENTAL[4]

Initial Photolysis Studies—Solutions of I, approximately 0.004%, were prepared in methanol and pH 9.0 phosphate buffer. Volumetric flasks containing 100-ml. aliquots of these solutions were placed in the light cabinet and sampled periodically for UV determination.

Preparation and Isolation of Major Photolysis Products—Two liters of a 0.1% methanolic solution of I was placed in a flat tray

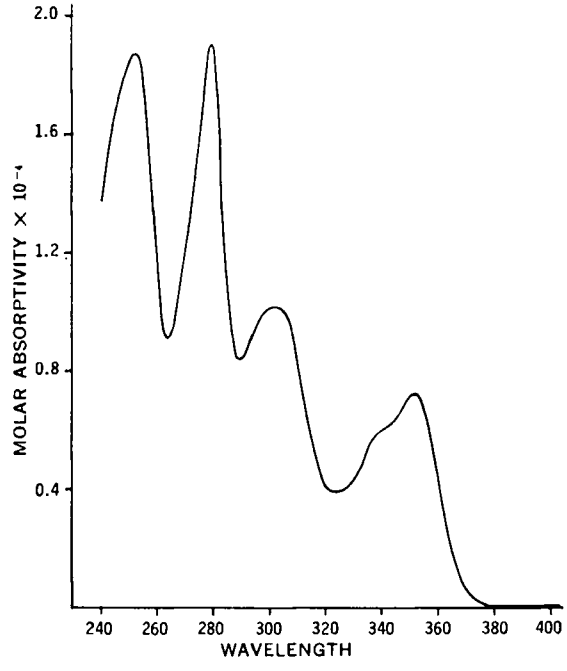

Figure 3—*UV spectrum of III in 95% methanol–0.01* N *hydrochloric acid.*

[4] UV spectra were determined using a Cary 14 spectrophotometer. NMR spectra were recorded on a Varian A-60 spectrophotometer. IR spectra were taken in potassium bromide disks using a Perkin-Elmer 457 grating IR spectrophotometer. Thin-layer chromatograms were run using silica gel plates (Quantum Industries, QIF, 250 μ).

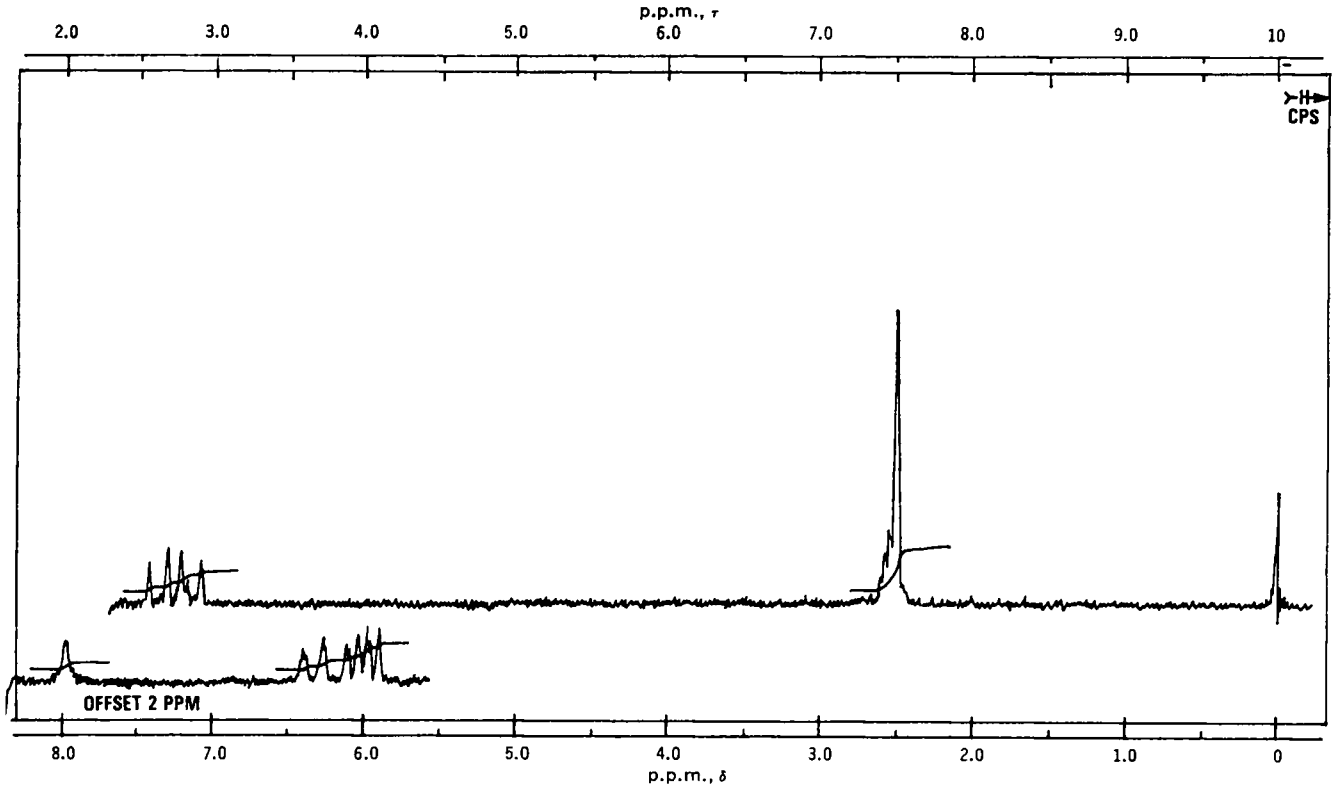

Figure 4—*NMR spectrum of III in dimethyl sulfoxide-*d_6. *For carbazole (acetone as solvent):*

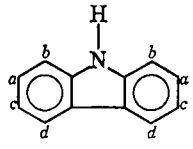

the following assignments are made (2) (p.p.m.): a, *7.17;* b, *about 7.45;* c, *7.49; and* d, *8.12.*

and irradiated with three germicidal lamps[3] resting on the rims of the tray. After the reaction was essentially complete (monitored by TLC and UV spectroscopy), the solvent was removed and the residue was recrystallized from ethyl acetate–isooctane to free it of residual I and other minor products (TLC).

A second recrystallization from ethyl acetate yielded a crystalline precipitate (A) whose UV spectrum (Fig. 2) differed from the terminal spectrum (Fig. 1) obtained during the reaction in that there was no maximum in the 302-nm. region. Material obtained from the mother liquor of this recrystallization (B) showed a distinct maximum in this region. Furthermore, A showed an absorption in its NMR spectrum at 2.70 p.p.m., whereas B showed two peaks in this region (2.70 and 2.50 p.p.m.). Fraction B was then repeatedly recrystallized until the compound contained in A was removed to yield crystalline material whose NMR spectrum showed only a single peak at 2.50 p.p.m. Both compounds had identical behavior with regard to TLC [silica, chloroform–ethyl acetate–acetic acid (75:25:1)]; *i.e.*, they both had the same R_f (0.40) and matched the major decomposition product seen in the TLC of the spent reaction mixture. Neither A nor B melts below 290°.

Table II—NMR Data[a] Obtained for Fractions A and B

Group or Proton	Chemical Shifts, p.p.m.[b] 5-Methyl Isomer, II	7-Methyl Isomer, III
CH_3	2.70	2.50
H-2[c]	8.27 (d)	8.33 (d)
H-3[c]	7.30 (t)	7.30 (t)
H-4[c]	8.05 (d)	8.05 (d)
H-5[c]	—	7.97 (d)
H-6[c]	6.96 (d)	7.15 (d)
H-7[c]	7.37 (d)	—

[a] Chemical shifts are in parts per million from external tetramethylsilane; d = doublet, t = triplet. [b] Dimethyl sulfoxide as solvent. [c] Center of multiplet.

Anal.—Calc. for $C_{14}H_{10}ClNO_2$: C, 64.80; H, 3.86; Cl, 13.70; N, 5.41. Found (A): C, 64.74; H, 3.93; Cl, 13.61; N, 5.44; (B): C, 64.71; H, 4.03; Cl, 13.89; N, 5.35.

As seen in Figs. 4 and 5, whereas protons *a*, *b*, and *c* show only small shift differences, a large difference exists between the *d* protons and the remaining protons. In this case, the isomer having protons in the 5,6-positions, *i.e.*, III, would be expected to exhibit a larger shift difference than the isomer having protons in the 6,7-positions, *i.e.*, II. Protons in the 2-, 3-, and 4-positions are common to both structures. Furthermore, the anisotropic effect (3) of this aromatic system would likewise cause the signal arising from the methyl protons in the 5-methyl isomer to be shifted downfield to a greater extent than would the chlorine atom (position 8), which is adjacent to the methyl group in the 7-methyl isomer.

Absorptions characteristic of —NH— and —CO_2H were observed in the IR spectra (KBr dispersion) of both A and B (Table I).

UV spectra were determined in solvents as noted (Figs. 1–3). The UV properties for II, λ_{max} ($\epsilon \times 10^{-3}$), were 355 (7.98), 280 (18.4), and 253 (22.0) nm. For III, λ_{max} ($\epsilon \times 10^{-3}$), they were 351 (7.21), 302 (10.09), 278 (18.90), and 252 (18.65) nm.

The relative amounts of II and III as produced by photolysis were determined from the UV spectrum of the spent reaction mixture, with the assumption that the observed spectrum was the result of significant absorption contribution from only II and III.

Compounds II and III have equal molar absorptivities at 351 nm. whereas at 302 nm. absorptivity differs. The absorbance ratio, $R = A_{\lambda 302}/A_{\lambda 351}$, then reflects relative composition and is independent of concentration. The R values for pure II and III are 0.94 and 1.435, respectively. The fraction of the total carbazole photolysis

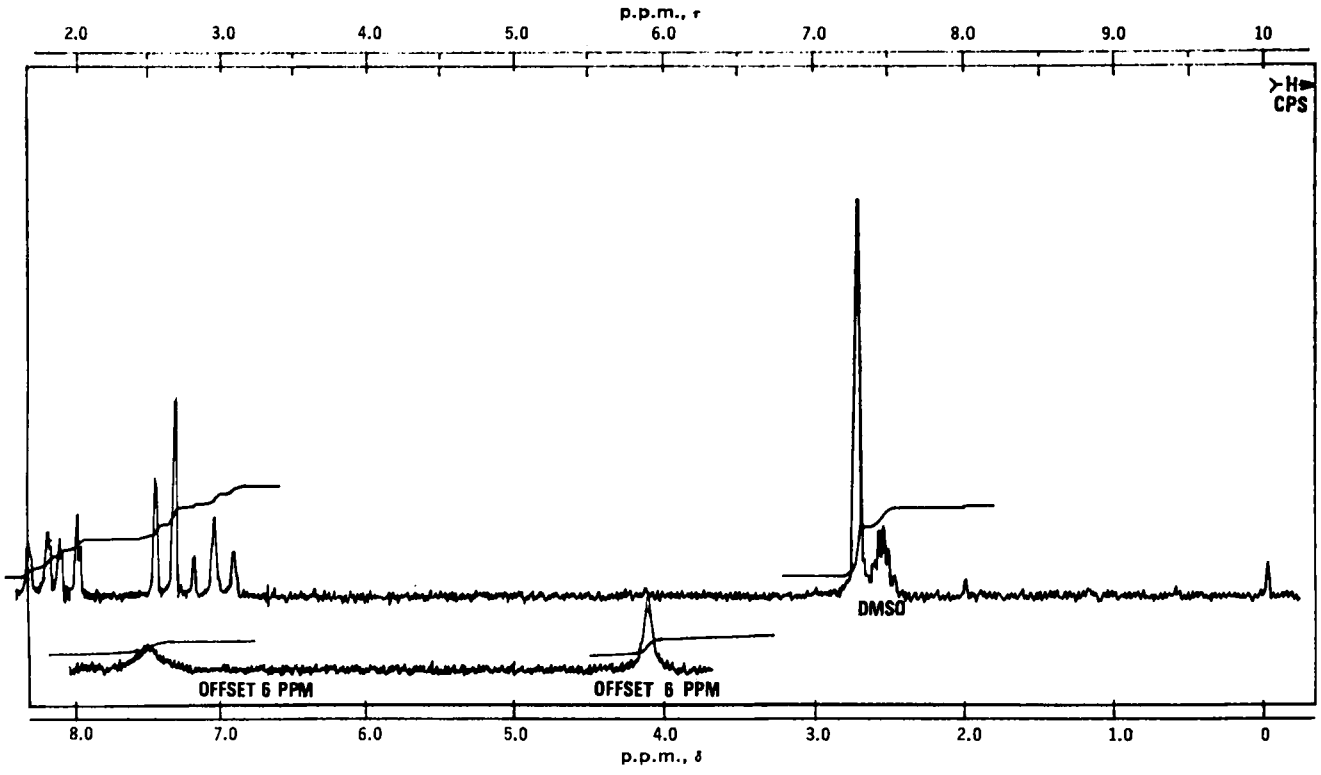

Figure 5—*NMR spectrum of II in dimethyl sulfoxide-*d_6. *For carbazole (acetone as solvent):*

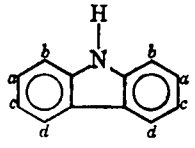

the following assignments are made (2) (p.p.m.): a, *7.17;* b, *about 7.45;* c, *7.49; and* d, *8.12.*

products present as III is calculable from the following equation:

$$f_{III} = \frac{R_{obs} - R_{II}}{R_{III} - R_{II}} \qquad \text{(Eq. 1)}$$

The value of R_{obs} was 1.175, which then leads to an f_{III} value of 0.475 and an f_{II} value of 0.525. An equimolar mixture would have $f_{II} = f_{III} = 0.50$.

CONCLUSIONS

Irradiation of solutions of *N*-(2,6-dichloro-*m*-tolyl)anthranilic acid results in decomposition to 8-chloro-5-methylcarbazole-1-carboxylic acid and 8-chloro-7-methylcarbazole-1-carboxylic acid (and HCl). The photolysis products are formed in approximately equimolar amounts.

Renal Contribution to Overall Metabolism of Drugs IV: Biotransformation of Salicylic Acid to Salicyluric Acid in Man

B. VON LEHMANN*, S. H. WAN†, S. RIEGELMAN▲, and C. BECKER

Abstract □ Salicylic acid was infused at three different steady-state levels to study its possible metabolism to salicyluric acid within the kidney in man. Concomitant with the salicylic acid infusion, radiolabeled salicyluric acid was infused at a constant rate to define its intrinsic renal clearance characteristics. Thereby, the rate of formation of salicyluric acid from salicylic acid, within the kidney, was calculated to be approximately 60–70% of the total amount formed.

Keyphrases □ Salicylic acid—renal metabolism to salicyluric acid in man □ Salicyluric acid—biotransformation after salicylic acid administration in man, renal clearance characteristics determined using salicyluric acid-^{14}C □ Renal metabolism—biotransformation of salicylic acid to salicyluric acid, man

The liver is usually considered the primary organ involved in the metabolism of drugs. Nevertheless, conjugation of aromatic acids with glycine in the kidney has been shown to take place both *in vitro* (1–7) and *in vivo* (8–10). Wan and coworkers (11–13) showed extensive *in vivo* conjugation in animals and reviewed the earlier studies in this field. In some species studied, the specific enzyme activity in the kidney has been found to be higher than that of the liver (1, 5–7, 10). However, Schachter and Manis (14) found no evidence for the renal synthesis of salicyluric acid from salicylic acid in man. Their statement is based on the observation that the clearance of salicyluric acid did not exceed the approximate renal plasma flow. The latter was calculated from the endogenous creatinine clearance. This conclusion is not in agreement with the results reported here.

Previous studies from these laboratories on the conversion of benzoic acid to hippuric acid in the rabbit (11), aminobenzoic acid to *p*-acetamidobenzoic acid and *p*-aminohippuric acid in the rabbit (12), and salicylic acid to salicyluric acid in the monkey (13) showed clearly that the kidney plays a major role as a metabolizing organ for these compounds. A summary of these findings is shown in Table I. These results encouraged the investigation of the renal rate of formation of salicyluric acid in man. A survey of the literature revealed that the apparent half-lives for the plasma disappearance of salicylic acid in man increased with dose (15–17), with values ranging from 2.4 to 19 hr. in adults. Similar results are evident from studies of the urinary excretion of salicylates as a function of dose (18), which show that the percentage of the dose excreted at a given time decreases with increasing dose. Practically all of an administered dose can be recovered in the urine as free, unaltered salicylic acid and as four major metabolites. At low doses, the main metabolite is salicyluric acid. The percent of salicyluric acid excreted in the urine has been observed to range from 0 to 91% of the dose of salicylic acid administered (14, 18, 19), decreasing as the total dose of salicylic acid increases. The remainder of the dose is excreted as salicyl phenolic glucuronide (12–30%), salicyl acyl glucuronide (0–10%), and gentisic acid (1%) (19) and its conjugates. The dose-dependent kinetics of salicylic acid have been attributed to the saturation of the metabolic process, which leads to the formation of salicyluric acid. This has been shown to be the reason for the observed wide variation in the plasma half-lives (18, 20–23). Since the rhesus monkey has been shown (12) to metabolize salicylic acid to salicyluric acid in similar amounts as man, it became increasingly interesting to examine if the human kidney functions similarly.

Table I—Renal Contribution to Metabolism of Benzoic Acid Derivatives and Salicylic Acid in Animals

Compound	Animal	Percent of Metabolite Formed in— Kidney	Liver[a]
Benzoic acid–hippuric acid	Rabbit	79	21
	Rabbit	28	72
	Rabbit	55	45
Aminobenzoic acid–*p*-acetamidobenzoic acid	Rabbit	52	48
Aminobenzoic acid–*p*-aminohippuric acid	Rabbit	70	30
Salicylic acid–salicyluric acid	Monkey	100	0

[a] Metabolism within the body as a whole, other than that which takes place in the kidney, is referred to in this table as "liver" metabolism.

EXPERIMENTAL

Subject One healthy male adult with no history of liver or kidney dysfunction or salicylate idiosyncrasy was studied.

Materials—Salicyluric acid-carboxy-^{14}C was synthesized, m.p. 170°, from salicylic acid-carboxy-^{14}C[1], following the method of Froemming and Vollenberg (24). The specific activity, as determined by liquid scintillation counting, was 34.9 μc./mmole. The efficiency was calculated using the internal standard method. A purity of >99% was established by radioscan of the TLC silica gel plate. The solvent system was butanol–acetic acid–water (4:1:1). Salicylic acid and salicyluric acid have R_f values of 0.49 and 0.62, respectively. No trace of radioactive starting material was observed in the radioscan. The absence of glycine was confirmed by NMR, which is capable of detecting low concentrations of glycine (2% or more).

The salicylic acid infusion solution was prepared by dissolving varying amounts of sodium salicylate in normal saline, whereas salicyluric acid was only soluble in a 5% sterile solution of sodium bicarbonate. All intravenously administered solutions were prepared under aseptic techniques and were bacteriologically filtered shortly before use.

[1] Tracerlab.

Infusion Procedures—A 10-μc. sample of salicyluric acid-carboxy-^{14}C, isotopically diluted in 300 mg. total salicyluric acid and dissolved in 5% sodium bicarbonate solution, was infused at a rate of 27.4 mg./hr. throughout the experiment. An intravenous priming dose of 200 mg. (8 μc.) salicyluric acid-carboxy-^{14}C was administered 20 min. prior to the start of the infusion. This initial infusion was done to define the renal clearance characteristics of salicyluric acid in man. The salicyluric acid infusion was continued through the experiment to ascertain the constancy of the salicyluric acid renal clearance. Two hours later, an intravenous priming dose of 250 mg. salicylic acid was given, followed by infusion of salicylic acid at a dose level of 14.2 mg./hr. (level 1). This procedure was repeated with an intravenous priming dose of 50 mg. salicylic acid and an infusion rate of 28.4 mg./hr. (level 2) and another intravenous priming dose of 100 mg. salicylic acid and an infusion rate of 56.8 mg./hr. (level 3). The infusion was maintained at each level for 2 hr. At these doses, the calculated plasma levels of salicylic acid were 5–20 mcg./ml. All infusions were made into a fast flowing intravenous drip of normal saline–5% dextrose.

Sampling Time—Five-milliliter blood samples were obtained at each sampling period. Blood and urine blanks were taken before the start of the experiment. Four blood samples were taken at 15-min. intervals during the 2nd hr. of the infusion at each level. (A total of 16 blood samples was taken.) Urine was voided in 15-min. intervals and collected between the blood sampling times for a total of 20 urine samples. Due to the amount of fluids infused into the test subject, the amount of urine voided in 15 min. averaged 111 ml.

ANALYTICAL METHODS

Plasma and urine samples were assayed for salicylic acid and salicyluric acid spectrophotometrically after elution from a column[2] according to the method described by Wan and Riegelman (12). Amounts of salicylic acid and salicyluric acid greater than 0.5 mcg./ml. of plasma or urine could be detected. The calibration curve showed linearity to at least 20 mcg./ml. and allowed accurate analysis even if one substance was in a 20-fold excess. None of the other metabolites of salicylic acid interfered with the assay. For the detection of the lowest levels of salicyluric acid, 0.5 ml. plasma was treated with 0.5 ml. isopropyl alcohol to precipitate the protein. A 0.6-ml. sample of the supernate was placed on the column and the salicyluric acid and salicylic acid fractions were collected as described previously (12). The effluents were directly measured in a spectrophotofluorometer[3]. A 50–100-μl. sample of urine was placed on the column and eluted with buffer (0.7 *M* phosphate buffer, pH 7.0). The fractions were measured at an activation wavelength and emission wavelength of 305 and 400 nm., respectively. The slit width was 6 mm.

The radioactivity in the urine samples was determined in a liquid scintillation counter[4]. A 0.5-ml. sample of urine was mixed in a polyethylene vial with 10 ml. modified Bray's cocktail having a composition of 8 g. 2,5-diphenyloxazole, 0.6 g. 1,4-bis-2-(4-methyl-5-phenyloxazolyl)benzene (or 6 g. of an alternate cocktail[5]), and 150 g. reagent grade naphthalene, dissolved in 100 ml. ethoxyethanol and 20 ml. ethylene glycol, and was made up to 1 l. with scintillation grade dioxane. The window was set on 50–1000 and the gain was set on 50 ± 1%. The efficiency was determined by the internal standard method (25) using a toluene-^{14}C standard with an activity of 3.48×10^6 d.p.m./ml. The efficiency ranged between 94 and 97% with a maximum standard deviation of 0.7%.

RESULTS AND DISCUSSION

Studies by Rowland and Riegelman (26) elucidated some pharmacokinetic parameters. When a 250-mg. i.v. dose of salicylic acid was administered, the half-life for the slow disposition phase was found to range from 120 to 170 min. and the volume of distribution at steady state ($V_{d_{ss}}$) was 9.6 ± 0.8 l. From these parameters, the priming dose as well as the rate of infusion was calculated for each level. During the first infusion period (level 1), the concentration of salicylic acid did not reach steady state. The rate of excretion of ^{14}C-labeled salicyluric acid stayed constant throughout the experiment except for the first level (Fig. 1). This indicates that no changes in the clearance took place for levels 2 and 3, in spite of the increasing doses of salicylic acid.

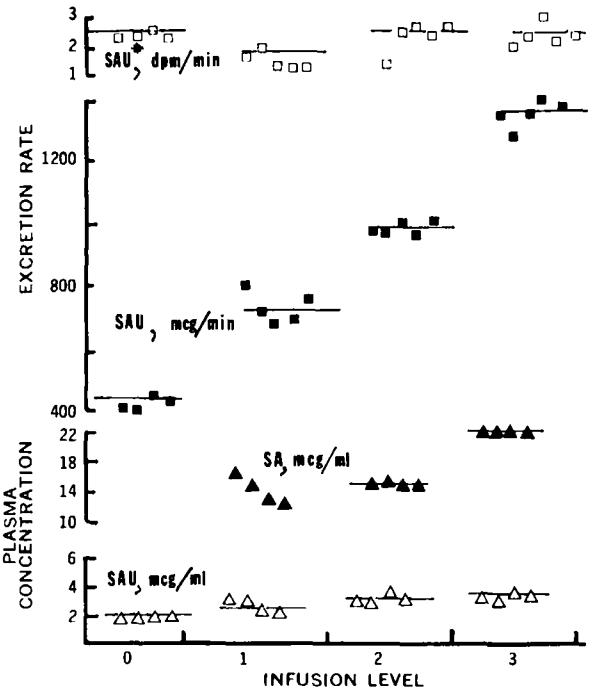

Figure 1—*Plasma concentration and urinary excretion rates during salicyluric and salicylic acid infusion in man. Each horizontal line represents 1-hr. infusion interval. (SAU = salicyluric acid, and SA = salicylic acid.)*

The renal clearance of salicyluric acid remained essentially constant at 227 ml./min., uncorrected for protein binding and body surface. Since the assessment of this value is critical to the remaining calculation of renal metabolism, comparison of this value with literature values is warranted. Corrected renal clearance values of salicyluric acid were reported by Schachter *et al.* (14) to be 444 ± 112 ml./min./1.73 m.[2] body surface. Unfortunately, the data of Schachter *et al.* (14) did not permit an estimate of the free fraction of salicyluric acid. Knoefel *et al.* (27), in 1962, reported data for salicyluric acid binding; the data indicate a rather large change in binding of the drug with changes in total plasma concentration[6]. Schachter *et al.* (14) used a complex assay procedure[7]. Although there are potential errors in the procedure due to the number of steps, the assay is essentially based on the separation of salicylic acid from the insoluble salicyluric acid when carbon tetrachloride is used. In our studies of this system, salicyluric acid was found to be slightly, but significantly, soluble in carbon tetrachloride. For example, 2- and 4-mcg./ml. solutions of salicyluric acid in 0.1 *N* hydrochloric acid were extracted with 15 volumes of carbon tetrachloride. The organic phase was reextracted with 1 *N* sodium hydroxide and as-

[2] Sephadex G-10.
[3] Hitachi MPF-2A fluorescence spectrophotometer.
[4] Packard model 3375.
[5] Omnifluor, New England Nuclear.

[6] When using the Freundlich absorption isotherm, log-log plots result in the following data. They include two data points of Knoefel *et al.* (27) and two data points obtained by extrapolation to lower total plasma concentration of salicyluric acid.

Total Plasma Concentration, mcg./ml.	Free Concentration, mcg./ml.	Bound Concentration, mcg./ml.	Percent Free
82.4 [experimental (27)]	71	11.4	86
5.0 [experimental (27)]	32	18	64
1.9 (extrapolated)	10	9	53
0.92 (extrapolated)	4	5.2	44

[7] The assay included a formation of salicylic hydroxamate from the acylglucuronide, precipitation of plasma protein, extraction of salicylic acid and salicyluric acid with ether, and evaporation to dryness. The residue, equivalent to 1.6 ml. plasma, was then extracted with 18 ml. carbon tetrachloride to remove salicylic acid, presumably leaving the salicyluric acid for the final fluorometric assay.

Table II—Steady-State Plasma Concentrations and Excretion Rates of Salicylic Acid and Salicyluric Acid at Different Infusion Levels

Level of Infusion	Cp, mcg./ml.		dA/dt, mcg./min.[a]	
	Salicylic Acid	Salicyluric Acid	Salicylic Acid	Salicyluric Acid
0	0	1.9 ± 0.15	0	431 ± 44
1	14.4 ± 1.8[b]	2.3 ± 0.1	0	717 ± 56
2	13.4 ± 0.9	2.8 ± 0.4	0	981 ± 32
3	21.7 ± 0.2	3.1 ± 0.3	54	1352 ± 108

[a] This refers to the urinary excretion of salicylic acid or salicyluric acid in micrograms per minute. [b] This plasma salicylic acid level was still declining from a high of 16.2 to a low of 12.6 mcg./ml. during the experimental period of infusion.

sayed on a spectrophotofluorometer (excitation 320 nm., emission 420 nm.). The results indicate that 25% of the salicyluric acid was extracted into carbon tetrachloride. Additional studies of salicylic acid in the presence of salicyluric acid indicate incomplete extraction of the salicylic acid by the carbon tetrachloride, leading to further potential error.

Smith *et al.* (28), in 1945, estimated the corrected clearance of salicyluric acid in two subjects. Their results for the two subjects were 269 and 487 ml./min./1.73 m.^{2} body surface. They infused salicylic acid and estimated the values using a reaction of the phenolic group of salicyluric acid with *N*-2,6-trichlorobenzoquinonimine. Our studies indicated that the Smith *et al.* reaction leads to high and variable plasma blank values, and once again there may be some question as to the method of correction for protein binding since the results are not specified.

Levy and coworkers (29, 30) also utilized the carbon tetrachloride method for the separation of salicylic acid and salicyluric acid. The exact method is not clearly identified in the reference; however, it undoubtedly included a solvent extraction and fluorometric analysis. They (29) reported the partitioning characteristics of salicyluric acid at 250 mcg./ml. in the presence of 500 or 1000 mcg./ml. of salicylic acid. These concentrations in the extraction procedure are probably appropriate for urine, so, their data are probably valid for urine studies. However, they do not verify separation of the two compounds at plasma levels, which usually are 1–3 mcg./ml. of salicyluric acid in the presence of 1–40 mcg./ml. of salicylic acid.

One can attempt to estimate the renal clearance of salicyluric acid from the data of Levy *et al.* (30) by estimating the excretion rate of salicyluric acid at the appropriate equivalent plasma concentrations. The resultant (corrected) value appeared to possibly exceed the renal plasma flow rate.

It is suggested, therefore, that the available literature data on renal clearance of salicyluric acid are ambiguous. The data of the present study were derived with concomitant infusions of the salicyluric acid-^{14}C. The renal excretion of this compound remained fairly constant throughout the study, which indicated that the excretion remained virtually constant. The excretion rate determined from the amount of salicyluric acid-^{14}C in the urine was found to be 426 mcg./min. This value agrees well with the value of 431 mcg./min. found from the cold assay. At an infusion rate of 456 mcg./min., the value of 431 mcg./min. represents a 94.5% urinary recovery of salicyluric acid. Unfortunately, the plasma radioactivity levels were in the range of background and, therefore, could not be used to estimate clearance. The plasma concentrations and rates of excretion found for salicylic acid and salicyluric acid at each infusion level are included in Table II and Fig. 1. At level 1, the plasma concentration of salicylic acid did not reach steady state. The same problem was observed with the plasma level of salicyluric acid, where only the last two data points of the first level could be considered to be at steady state. In the urine, salicylic acid could only be detected in the terminal infusion level, indicating that only negligible amounts of salicylic acid were excreted unchanged over this range of infusion.

The true and apparent clearance values for salicyluric acid (Table III) were calculated from the observed plasma levels and excretion rates of salicyluric acid. In spite of the declining plasma concentration of salicylic acid during the first infusion period, one can calculate an apparent clearance of salicyluric acid since the salicyluric acid plasma data do not reflect the magnitude of difference seen in the salicylic acid data. However, the apparent clearance for the first infusion period (Table III) was calculated only from the last two data point times (Fig. 1). With increasing amount of salicylic acid being infused, the percent of the dose excreted as salicyluric acid decreased (column 2 of Table IV). The mass balance for the initial infusion of salicyluric acid (level 0) shows that 94.5% of the input was recovered in the urine. This value agrees well with the value reported by Levy *et al.* (30). The method of calculating the contribution of kidney metabolism to overall metabolism was recently published (1). Equation 1 describes the rate of formation of salicyluric acid by the kidney:

$$\left(\frac{dM}{dt}\right)_{\text{kidney}} = \left(\frac{dM}{dt}\right)_{\text{total}} - \left(\frac{dM}{dt}\right)_{\text{liver}} \qquad \text{(Eq. 1)}$$

At steady state, (dM/dt) liver[a] is given by the equation:

$$\left(\frac{dM}{dt}\right)_{\text{liver}} = (\dot{V}_{cl})_{ex} \times Cp(\text{SAU}) \qquad \text{(Eq. 2)}$$

where $(\dot{V}_{cl})_{ex}$ is the renal clearance of salicyluric acid (SAU) as calculated from the level 0 data (Table III). By multiplying this value by the plasma concentration of salicyluric acid at each infusion level, one obtains the rate of formation of metabolite at any time. At steady state, the total rate of metabolism, (dM/dt) total, equals the rate of excretion. This definition is valid only if no portion of metabolite synthesized by the kidney is reabsorbed back into the blood.

Table IV includes an estimate of the rate of formation of salicyluric acid by the kidney and extrarenal processes (liver) and also as a percent of the total rate of metabolism. The resultant data indicate that an average of 67 ± 4% of salicyluric acid was formed in the kidney. To our knowledge, no similar study of the contribution of renal metabolism has been reported for man. While this study was done in only one subject, the results indicate clearly the importance of the kidney as a site of salicylate metabolism in man.

Table III—True and Apparent Renal Clearances of Salicyluric Acid in Man

Compound $(\dot{V}_{cl})_{ex}$	$(\dot{V}_{cl})_{app}$ at Levels		
	1	2	3
Salicyluric acid 227	312	350	436

Table IV—Contribution of Renal Metabolism to Overall Metabolism of Salicylic Acid in Man

Level of Infusion	Percent of Dose Excreted as Salicyluric Acid[a]	Excretion Rate (dM/dt), mcg./min.		Percent Salicyluric Acid Formed	
		Kidney	Liver	Kidney	Liver
1	85	195	91	70	30
2	81.5	346	204	63	37
3	68.3	649	272	71	29

[a] The values were estimated by calculating the excretion rate of salicyluric acid resulting from salicylic acid metabolism (by correcting for the steady-state excretion rate for salicyluric acid of 431 mcg./min.), multiplying by the time interval, and correcting for the molecular weight.

Animal Models for Investigating Intestinal Drug Absorption: Various Antibiotics

DONALD PERRIER▲ and MILO GIBALDI

Abstract □ Among the most commonly used methods for studying intestinal drug absorption are the *in vitro* everted rat gut and the *in situ* rat intestinal loop. The methods were compared employing various penicillins, cephalosporins, and tetracyclines. Steady-state and, particularly, initial drug clearances across the everted rat gut and the *in situ* absorption data were not always in agreement. A comparison of these results with antibiotic absorption data in man demonstrated rank-order agreement between absorption from the *in situ* intestinal loop and human GI absorption. Based on present observations, the *in situ* intestinal loop of the rat appears suitable as an animal model for predicting human drug absorption.

Keyphrases [ ] Absorption, intestinal- *in vitro* everted rat gut and *in situ* rat intestinal loop drug permeability data, compared to antibiotic absorption data in man □ Antibiotic (penicillins, cephalosporins, and tetracyclines) intestinal absorption *in vitro* everted rat gut and *in situ* rat intestinal loop data compared to absorption data in man □ Drug permeability across intestinal membrane data from *in vitro* everted rat gut and *in situ* rat intestinal loop techniques compared to antibiotic absorption in man

A variety of *in vitro* and *in situ* animal techniques have been employed to study drug permeability across the intestinal membrane. Many of these techniques were recently discussed by Bates and Gibaldi (1). The present investigation was undertaken to compare the data obtained from two such techniques, the *in vitro* everted gut and the *in situ* intestinal loop, and to evaluate these techniques as possible models for human drug absorption. Several groups of antibiotics were studied, since this class of compounds offers a wide range in the degree to which absorption occurs in man.

METHODS

Male, Sprague–Dawley strain rats[1], weighing approximately 250 g., were fasted 14–20 hr. prior to the experiment. Water was allowed *ad libitum*.

Drug Transfer across Isolated Everted Rat Intestine—Intestinal transfer rates were determined using a modification of the method of Crane and Wilson (2). The method for preparing the everted intestine preparation was described previously (3). After severing the intestine at the pyloric junction, the first 15 cm. of intestine was discarded, the gut was everted, and the proximal portion was divided into two 10-cm. segments. The initial, proximal segment was designated Segment 1 and the distal portion was designated Segment 2.

Both segments were placed into test tubes containing approximately 100 ml. of mucosal drug solution, previously equilibrated at 37° and continually gassed with oxygen–carbon dioxide (95:5 v/v). Two milliliters of a modified physiological Krebs bicarbonate

Keyphrases [ ] Absorption, intestinal- *in vitro* everted rat gut and *in situ* rat intestinal loop drug permeability data, compared to antibiotic absorption data in man □ Antibiotic (penicillins, cephalosporins, and tetracyclines) intestinal absorption *in vitro* everted rat gut and *in situ* rat intestinal loop data compared to absorption data in man □ Drug permeability across intestinal membrane data from *in vitro* everted rat gut and *in situ* rat intestinal loop techniques compared to antibiotic absorption in man

A variety of *in vitro* and *in situ* animal techniques have been employed to study drug permeability across the intestinal membrane. Many of these techniques were recently discussed by Bates and Gibaldi (1). The present investigation was undertaken to compare the data obtained from two such techniques, the *in vitro* everted gut and the *in situ* intestinal loop, and to evaluate these techniques as possible models for human drug absorption. Several groups of antibiotics were studied, since this class of compounds offers a wide range in the degree to which absorption occurs in man.

METHODS

Male, Sprague–Dawley strain rats[1], weighing approximately 250 g., were fasted 14–20 hr. prior to the experiment. Water was allowed *ad libitum*.

Drug Transfer across Isolated Everted Rat Intestine—Intestinal transfer rates were determined using a modification of the method of Crane and Wilson (2). The method for preparing the everted intestine preparation was described previously (3). After severing the intestine at the pyloric junction, the first 15 cm. of intestine was discarded, the gut was everted, and the proximal portion was divided into two 10-cm. segments. The initial, proximal segment was designated Segment 1 and the distal portion was designated Segment 2.

Both segments were placed into test tubes containing approximately 100 ml. of mucosal drug solution, previously equilibrated at 37° and continually gassed with oxygen–carbon dioxide (95:5 v/v). Two milliliters of a modified physiological Krebs bicarbonate

[1] Blue Spruce Farms, Altamont, N. Y.

buffer[2] (pH 7.4) was placed inside each sac (serosal solution). In any given experiment, the initial mucosal and serosal solutions were identical except for the presence of drug in the mucosal solution; the mucosal concentration of drug remained essentially constant throughout each experiment due to its large volume. Sink conditions were maintained at all times, and the maximum serosal concentration obtained in any one experiment was less than 20% of the mucosal drug concentration. The serosal compartment was sampled every 30 min. for 2 hr. At each sampling time, the entire serosal volume was removed and then 2 ml. of buffer solution was introduced into the serosal compartment as a rinse, immediately removed, and added to the previous sample. Finally, another 2 ml. of buffer was placed into the serosal compartment for withdrawal at the next sampling interval.

A loss of functional and structural integrity of the everted gut preparation with time was reported previously (4, 5). To account for these changes, experiments were conducted where the everted intestinal preparation was incubated in drug-free buffer solution for up to 90 min. During incubation, sham samples of serosal solution were taken at 30-min. intervals and discarded. After incubation, the preparation was immediately transferred to a mucosal drug solution. The serosal compartment was sampled in the usual manner for 30 min.

In another experiment, the everted intestinal sac was incubated for 30 min. in drug-free buffer solution, at which time sham samples of serosal solution were taken and discarded. The mucosal surface was then scraped with forceps to remove the epithelial layer from the muscularis. The resulting preparation was transferred to the mucosal solution containing drug and sampled in the usual manner after 30 min.

Drug transfer rates across the everted rat intestine were expressed as mucosal-to-serosal clearances (milliliters per minute) and calculated from Eq. 1:

$$\text{clearance} = \frac{\text{amount transferred in 30 min.}}{\text{mucosal drug concentration} \times 30} \quad \text{(Eq. 1)}$$

Clearances corrected for loss of functional integrity of the everted gut preparation were calculated for sampling periods ending at 60, 90, and 120 min., denoted as Periods II, III, and IV, respectively. The clearance for the first 30 min., Period I, was used as the standard. Employment of Period I as a standard assumes that essentially no change in the functional integrity of the everted gut occurs within the first 30 min. This assumption appears valid, since Levine *et al.* (4) observed that everted gut preparations from ether-anesthetized rats show only a 10–15% loss in structural integrity in the first 60 min.

The clearance values obtained from the studies involving incubations in buffer for 30, 60, and 90 min., followed by 30 min. in drug solution, are represented by II_i, III_i, and IV_i, respectively. The increase in clearances II_i, III_i, and IV_i over Period I is attributed to a loss of functional integrity of the everted gut; when this increase is subtracted from the respective clearances for Periods II, III, and IV, the corrected clearances result. For example, to calculate the corrected clearance for Period III, III_c, Eq. 2 could be employed:

$$III_c = III - (III_i - I) \quad \text{(Eq. 2)}$$

Similarly for Periods II and IV:

$$II_c = II - (II_i - I) \quad \text{(Eq. 3)}$$

and:

$$IV_c = IV - (IV_i - I) \quad \text{(Eq. 4)}$$

When the corrected clearances for two consecutive periods were within 10% of each other, the achievement of steady-state clearance was assumed. The average of these two clearances will be referred to as the steady-state clearance.

Absorption from *In Situ* and *In Vitro* Intestinal Loops—The method of Levine *et al.* (6) was utilized to study *in situ* absorption from the rat small intestine. The animals were anesthetized with urethan, 1.3 g./kg. i.p., for the duration of the experiment. A midline incision was made, the small intestine was located, and two loops, approximately 5 cm. long, were formed. The first loop was approximately 15 cm. from the pylorus, with 1 cm. of intestine separating the two consecutive loops. One milliliter of a modified Krebs buffer solution containing drug was injected into a loop, through a ligature, by means of a syringe and blunt needle. After 30 min., the loops were excised and rinsed with normal saline. The sac was cut open at both ends, and the drug solution remaining inside the sac was permitted to run out. Approximately 25 ml. of buffer was then used to rinse out the inside of each sac.

In vitro experiments were conducted where two consecutive loops were prepared as before but, immediately prior to injection of drug solution, the loops were excised from the animal. Each loop containing drug solution was then suspended in 40 ml. of buffer solution, which was stirred at a constant rate and maintained at 37° in a jacketed beaker. At the end of 30 min., these loops were treated in the same manner as the *in situ* loops.

Before assaying the solutions obtained from the intestinal loops, each solution was passed through a 0.45-μ filter[3] to remove all solid material. Control experiments indicated that no drug was removed by this filtration step.

Drugs—The drugs examined were sodium dicloxacillin[4], sodium ampicillin[5], sodium benzylpenicillin[6], tetracycline hydrochloride[7], doxycycline hyclate[8], cephaloridine[9], and cephalexin monohydrate[10].

Assay—Cephaloridine and cephalexin were assayed polarographically using a dropping mercury electrode polarograph[11], based on the procedure reported by Benner (7). Five milliliters of 1.5 *N* sulfuric acid or 1.5 *N* sodium hydroxide was added to an equal volume of drug solution containing cephaloridine or cephalexin, respectively. The cephalexin–sodium hydroxide solution was heated at 50° for 1 hr. To both solutions, 5 drops of a nonionic detergent[12] was added as a maximum suppressor. The solutions were then deoxygenated by bubbling nitrogen through them for 5 min. Cephaloridine samples were then scanned from −0.7 to −1.2 v., while cephalexin samples were scanned from −0.5 to −1.1 v. The concentration of cephaloridine and cephalexin was related to the wave intensity, in microamperes, at −1.05 and −0.9 v., respectively.

The tetracyclines, doxycycline and tetracycline, were assayed spectrophotometrically with a spectrophotometer[13] by the method of Chatten and Krause (8). Equal volumes of 5% thorium nitrate in 0.012 *N* hydrochloric acid and tetracycline solution were combined, producing a pH 6.05 solution. The absorbance of the complex formed was measured at 395 nm.

Spectrophotometric assays were also employed for dicloxacillin, ampicillin, and benzylpenicillin. Benzylpenicillin was assayed by the method of Brandriss *et al.* (9) under the conditions outlined by Tutt and Schwartz (10). Equal volumes of a pH 2.5 glycine–hydrochloric acid buffer (0.4 *M*) containing mercuric chloride (1.6×10^{-2} *M*) and drug–buffer solution were combined, producing a final pH of 2.7. This solution was assayed at 325 nm., after standing at 25° for 100 min.

The method of Smith *et al.* (11) was employed for assaying ampicillin. A pH 4.9 citric acid (0.2 *M*)–dibasic sodium phosphate (0.4 *M*) buffer containing copper (30 mcg./ml.) was prepared. Five milliliters of pH 4.9 buffer and an equal volume of drug solution were combined, yielding a final pH of 5.2, and heated at 75° for 30 min. Absorbance was measured at 320 nm. A modified ampicillin assay was used to quantitate dicloxacillin. When equal volumes of drug solution and pH 2.2 citric acid–phosphate were mixed, a pH 2.45 solution resulted. This solution was heated at 75° for 40 min. and then assayed at 340 nm.

Microbiological assays were employed for ampicillin and dicloxacillin in the *in situ* loop experiments due to the presence of unidentified material which interfered with the chemical method. It was also decided to employ a microbiological method to check

Table I—Mucosal-to-Serosal Clearance of Various Antibiotics across the Everted Isolated Rat Jejunum

Antibiotic	Clearance, ml./min. × 10^6, ± SE^a Period I	Steady State
Benzylpenicillin (250)[b]	229 ± 36	219 ± 47
Ampicillin (500)	395 ± 54	373 ± 45
Dicloxacillin (1000)	445 ± 45	791 ± 72
Tetracycline (500)	184 ± 39	615 ± 78
Doxycycline (5000)	199 ± 32	912 ± 38
Cephaloridine (2000)	454 ± 44	749 ± 50
Cephalexin (2000)	454 ± 43	719 ± 57

[a] Mean ± standard error, five determinations. [b] Parenthetic values denote mucosal concentration in micrograms per milliliter.

Table II—Absorption of Various Antibiotics from the *In Situ* Loop of the Rat

Antibiotic	Percent Absorbed ± SE^a
Benzylpenicillin (250)[b]	15.8 ± 1.9 (6)[c]
Ampicillin (500)	22.3 ± 2.9 (5)
Dicloxacillin (1000)	30.3 ± 2.1 (6)
Tetracycline (500)	41.7 ± 0.3 (5)
Doxycycline (5000)	66.1 ± 1.6 (6)
Cephaloridine (7500)	19.4 ± 1.8 (4)
Cephalexin (7500)	53.4 ± 1.2 (3)

[a] Percent absorbed = 100 × (amount injected into loop − amount remaining in loop after 30 min.)/amount injected into loop. Mean ± standard error. [b] Parenthetic values denote initial concentration of drug in the *in situ* loop in micrograms per milliliter. [c] Parenthetic values denote number of determinations.

the *in situ* cephaloridine results obtained with the polarographic method. This procedure was followed because, following oral administration of cephaloridine to rats, virtually all of the absorbed dose was eliminated as degradation products which were believed to have been formed in the GI tract (12). It is conceivable that the polarographic method may not differentiate between cephaloridine and such degradation products. Excellent agreement was obtained between these two methods. An additional assay was not felt to be necessary for cephalexin because, following oral administration to rats, cephalexin was shown to be totally eliminated unchanged (13). For all three antibiotics, the agar well method of Bennett *et al.* (14) was used with *Bacillus subtilis* as the organism. Assays were performed in triplicate.

RESULTS

For all of the antibiotics studied, Period I clearances for the second segment of the everted gut were consistently less than the corresponding clearances for the first segment. The same general trend was observed with steady-state clearance values. This variation in clearance can probably be related to surface area differences between the two segments. However, little qualitative difference in the overall behavior of the two segments was observed. Accordingly, only data from the second segment are presented.

Mucosal-to-serosal clearances across the isolated everted gut during Period I indicate that dicloxacillin is the most permeable of the three penicillins studied, followed by ampicillin and then by benzylpenicillin (Table I). However, the differences in clearance are not very substantial. Penicillin clearances at steady state were of the same rank order as was observed for Period I, although the steady-state dicloxacillin clearance was significantly greater than Period I dicloxacillin clearance. The relative extent of penicillin absorption from the *in situ* loop (Table II) was in the same rank order as steady-state and Period I clearances.

Very little difference was seen between the Period I clearance values for doxycycline and tetracycline (Table I). However, there was approximately a 50% difference in their steady-state clearances, with doxycycline being cleared across the everted gut at a more rapid rate. The same rank order was observed in the *in situ* absorption studies (Table II) as was seen in steady-state clearance across the everted gut. In initial clearance studies with doxycycline, a steady-state clearance was not reached when a mucosal doxycycline concentration equal to the tetracycline concentration (0.5 mg./ml.) was employed. This inability to reach steady state was possibly due to continual uptake and accumulation of doxycycline in the everted gut. As a result, a doxycycline mucosal concentration significantly greater than the concentration used for tetracycline was employed to reach a steady-state doxycycline clearance.

Period I clearance values for cephaloridine and cephalexin were identical (Table I). At steady state, cephaloridine had a slightly higher clearance than did cephalexin. The everted gut clearance data for these two cephalosporins are not in agreement with *in situ* absorption results (Table II). In the latter case, cephalexin was absorbed much more extensively than cephaloridine.

In an attempt to explain the discrepancy in cephalosporin results obtained with the everted gut and *in situ* loop techniques, further studies were undertaken; the results are presented in Tables III and IV. Cephalexin traversed the intestinal membrane much more readily than did cephaloridine *in situ* (Table III). However, little difference existed between these two antibiotics in the extent to which they permeated the intestine *in vitro*, as measured by employing isolated intestinal loops. Also, there was no significant difference in the mucosal-to-serosal clearance of cephalexin and cephaloridine across the everted gut in either the presence or absence of the epithelial layer (Table IV).

DISCUSSION

Results of the present investigation demonstrated rank-order agreement between Period I and steady-state clearances across the everted gut and the *in situ* absorption data for the penicillins. Dicloxacillin was cleared at a faster rate and was absorbed more extensively than ampicillin. Of the penicillins studied, benzylpenicillin was the most slowly cleared and poorly absorbed. Period I clearance values did not differentiate either the cephalosporins or tetracyclines. However, *in situ* loop absorption results did show significant differences between doxycycline and tetracycline and between cephalexin and cephaloridine, with doxycycline and cephalexin being more extensively absorbed in their respective groups. The steady-state rank-order clearances between the two tetracyclines agreed with *in situ* absorption data. However, no difference in steady-state clearance was observed between the cephalosporins, which is contrary to the *in situ* cephalosporin results. As can be seen, *in vitro* and *in situ* methods do not agree with respect to the relative intestinal permeabilities of the various antibiotics studied.

To evaluate these two animal techniques, the *in vitro* everted gut and the *in situ* intestinal loop, with respect to their ability to serve as possible models for human drug absorption, the results obtained were compared to human absorption data from the literature. The extent to which the various antibiotics studied are absorbed from the human GI tract was calculated, employing literature urinary excretion data, using an intravenous dose as the standard.

A number of factors are involved in determining the extent to which an orally administered drug is absorbed from the GI lumen. Since the vast majority of orally administered drugs are supplied as solid dosage forms, the extent to which the drug is released from its supporting matrix becomes of prime importance. Once released, the drug's solubility and stability in solution must be considered. Resistance to degradation and lack of interaction with components present in the GI tract are desirable. The drug must also possess suitable physical properties that enable it to permeate the GI membrane. One or more of these factors appears responsible for rendering the majority of the antibiotics studied in the present investigation incompletely absorbed from the GI lumen.

In most literature reports surveyed, human GI absorption was studied employing solid dosage forms. This raises the problem of potential dissolution rate-limited absorption rather than permeability rate-limited absorption. However, in our view, the antibiotics studied would be expected to be permeability rather than dissolution rate limited in their absorption since they are freely soluble in water.

Benzylpenicillin is very susceptible to acid hydrolysis and attack by penicillinase in the GI tract (15, 16). Both processes compete for drug at the absorption site. Ampicillin, which is relatively stable in acid and neutral solutions (15, 17), would on a stability basis be expected to be and, in fact, is more extensively absorbed than benzylpenicillin (Table V) even though it does not appear to be

Table III—Transfer of Cephalosporins out of Rat Jejunum Loops

Cephalosporin	Percent Transferred ± SE[a]	
	In Situ	*In Vitro*
Cephaloridine (7500)[b]	19.4 ± 1.8 (4)[c]	18.2 ± 2.3 (4)
Cephalexin (7500)	53.4 ± 1.2 (3)	24.1 ± 1.6 (3)

[a] Percent transferred = 100 × (amount injected into loop − amount remaining in loop after 30 min.)/amount injected into loop. Mean ± standard error. [b] Parenthetic values denote initial concentration of drug in loop in micrograms per milliliter. [c] Parenthetic values denote number of determinations.

Table IV—Effect of Epithelial Layer Removal on Clearance of Cephalosporins across the Everted Isolated Rat Jejunum

Cephalosporin	Clearance, ml./min. × 10^6, ± SE[a]	
	Control	Epithelial Layer Removal
Cephaloridine (2000)[b]	712 ± 23	832 ± 24
Cephalexin (2000)	748 ± 22	761 ± 47

[a] Mean ± standard error, five determinations. [b] Parenthetic values denote mucosal concentration in micrograms per milliliter.

resistant to penicillinase (18). However, it should not be implied that if a particular penicillin derivative is not subject to GI degradation it will be 100% absorbed. For example, dicloxacillin appears resistant to both acid-catalyzed hydrolysis and degradation by penicillinase (19), but considerably less than 100% of this drug appears to be absorbed (Table V).

The rank order obtained with respect to the steady-state penicillin clearance across the everted gut and absorption from the *in situ* intestinal loops is in agreement with the relative extent of penicillin absorption in humans (Tables I, II, and V). Benzylpenicillin had the lowest clearance and percent absorbed of the three penicillins studied, followed by ampicillin and then dicloxacillin. The everted gut studies (notably steady-state studies) as well as *in situ* studies suggest that the penicillins do indeed have different membrane permeability characteristics. At normal intestinal pH as well as the pH of the everted gut studies, the carboxyl group of the penicillins would be essentially totally dissociated, which may partly explain the generally poor permeability of the penicillins. With ampicillin, the negative charge associated with the carboxyl group would be partially balanced by the positive charge associated with the amino group, which has a pKa of 7.25 (20), resulting in an ampicillin molecule with a net partial negative charge rather than a total negative charge. This difference in overall polarity of these two penicillins may aid in explaining why ampicillin is more permeable than benzylpenicillin. Dicloxacillin, even though totally dissociated, appears to have a substantially more lipophilic substituent than the α-aminophenyl and phenyl substituents of ampicillin and benzylpenicillin, respectively. Such an increase in lipophilicity may account for the increased permeability of dicloxacillin over the other two penicillins.

The cephalosporins are structurally very similar to the penicillins but are much more stable than the penicillins (17). Cephalexin and ampicillin are identical in structure except for the basic differences in the cephalosporin and penicillin nuclei, but cephalexin is essentially totally absorbed on oral administration (21). Higher steady-state clearance values and increased absorption from the *in situ* intestinal loops were observed for cephalexin as compared to ampicillin (Tables I and II). These permeability differences can be attributed to the variation in the basic nuclei of the penicillin and cephalosporin molecules.

Although cephalexin is extensively absorbed, cephaloridine is very poorly absorbed (1–2%) in human subjects (22). This lack of absorption has been attributed to the presence of the pyridinium group (23). *In vitro* clearance values suggest that there is no significant difference in the permeability characteristics of cephalexin and cephaloridine (Table I). This is totally inconsistent with *in situ*[14] rat and human absorption results (Tables II and V), and an attempt was made to explain this anomaly. Initially, the extent to which the cephalosporins were transported across *in vitro* intestinal loops was studied. Cephalexin and cephaloridine permeated the *in vitro* loop to comparable degrees, even though substantial differences were observed *in situ* (Table III).

In vivo and *in situ* the epithelial cell of the intestinal villus constitutes the only anatomical barrier of significance controlling the movement of drug from the lumen of the gut into the body. Once past this barrier, the transferred drug gains ready access to either blood or lymph capillaries. Therefore, *in vivo* and *in situ* the process of intestinal absorption is governed by properties of the epithelial barrier and the rates of blood and lymph flow. However, *in vitro* a drug must traverse the epithelium plus the underlying connective and muscle tissue. As a result, the rate-limiting barrier for *in vitro* transport might be the intestinal musculature, a barrier that would not be encountered in *in vivo* and *in situ* transfer. The *in situ* and *in vitro* intestinal loop results in the present investigation suggest that the muscle and connective tissue serve as significant barriers to cephalexin transfer resulting in both cephalosporins being cleared or absorbed to similar extents *in vitro*. Further support for this postulate are the results of a study where clearance measurements were made across the everted gut from which the epithelial layer had been removed, leaving only the underlying muscle layer and connective tissue. There is relatively little change in the mucosal-to-serosal clearance after removal of the epithelial layer, and no significant difference was observed in the clearance values either before or after the everted gut was stripped of the epithelial layer (Table IV). These results suggest that the epithelial layer is probably not the primary barrier to cephalosporin transport *in vitro* and that the muscle layer serves as an equal barrier to both cephalexin and cephaloridine *in vitro*. Based on these results, the everted gut technique appears unsuitable as a model for human drug absorption in the case of the cephalosporins.

The initial clearance values (Period I) of doxycycline and tetracycline are essentially identical. However, steady-state clearances suggest that doxycycline is considerably more permeable than tetracycline (Table I). Furthermore, this increase in permeability of doxycycline over tetracycline is in agreement with absorption data from the *in situ* loop studies (Table II). The difference in permeability of these two tetracyclines is consistent with observed differences in their chloroform–water partition coefficients. Doxycycline was shown to have a significantly higher partition coefficient than tetracycline over the 2–8 pH range (24). It is generally accepted that doxycycline is better absorbed than tetracycline in man (25), and studies in the literature support such claims. An analysis of oral and intravenous plasma level data, presented recently by Leibowitz *et al.* (26), suggests that 85% of an oral dose of doxycycline is absorbed. This study supports the data of Fabre *et al.* (27), where 93% of an oral doxycycline dose was reported to be absorbed. These findings can be compared to 77% for tetracycline (Table V). Differences in absorption are further supported by studies where doxycycline and tetracycline have been administered with food. Food appears to have little influence on doxycycline absorption (28–30) while significantly depressing the oral absorption of tetracycline (31). Furthermore, dissolution studies[15] conducted in this laboratory indicate that doxycycline hyclate has approximately a 3.5 times greater dissolution rate than tetracycline hydrochloride. This finding may also contribute to better absorption of doxycycline.

CONCLUSIONS

Based on the results of the present investigation, *in vitro* methods, where the drug must traverse both the epithelial and underlying connective tissue and muscle layers rather than just the epithelial layer to permeate the intestinal membrane, should be employed as models for GI absorption only with extreme caution. Period I clearances across the everted gut yield very limited insight into human GI absorption. Although the rank order in Period I clear-

[14] Due to limitations in assay sensitivity, initial cephalosporin concentrations in the *in situ* loop were substantially greater than the initial mucosal concentrations employed in the everted gut studies, 7.5 *versus* 2 mg./ml. Based on one run at a mucosal concentration of 7.5 mg./ml., the clearances of both cephalosporins across the everted gut were the same as the clearances obtained when a mucosal concentration of 2 mg./ml. was employed.

[15] Rotating-disk method as described by Levy and Sahli (32) using a precision speed control apparatus (33), modified Krebs bicarbonate buffer, 37°, and a rotation speed of 60 r.p.m.

Table V—Absorption of Various Antibiotics following Oral Administration to Humans

Antibiotic	Percent Absorbed[a]	Reference[b]
Benzylpenicillin	18	31, 34
Ampicillin	35	35, 36
Dicloxacillin	64	34, 37
Tetracycline	77	38
Doxycycline	93	27, 30
Cephaloridine	2	22
Cephalexin	83	21, 39

[a] Amount eliminated in urine after oral administration as a percent of amount eliminated in urine after an equal intravenous dose. [b] Literature reference from which human data was obtained.

ances of the penicillins agrees with human absorption data, relatively small differences in clearances were observed as compared to human studies. Moreover, Period I clearance values did not differentiate either the cephalosporins or the tetracyclines. Steady-state clearance measurements did yield a reasonable rank-order estimate of the relative extent to which the penicillins and tetracyclines were absorbed in man. However, steady-state clearances seriously failed with the cephalosporins. Even where appropriate, steady-state clearance studies require much more time and are more difficult to run than are *in situ* loop studies.

The *in situ* loop technique proved to be a very suitable animal model for predicting antibiotic absorption in man. Within each group of antibiotics, the same rank order was obtained between the extent of absorption from the *in situ* loop and the human GI lumen. The *in situ* intestinal loop technique also serves as a reasonable model for absorption even when all of the antibiotics studied are considered as a single group. With the exception of cephaloridine, excellent rank-order agreement was obtained between *in situ* loop and human studies. The *in situ* loop studies indicate more extensive absorption of cephaloridine than would be expected. This may be due to an inherent error in the technique since the amount of drug leaving the loop lumen is measured and not the amount of drug that actually reaches the blood supply. Therefore, extensive accumulation of cephaloridine in the intestinal tissue may account for the apparent overestimate in the extent of cephaloridine absorption from the intestinal loop.

Application of Quantitative GC-Mass Spectrometry to Study of Pharmacokinetics of Amphetamine and Phentermine

ARTHUR K. CHO▲, BARBARA J. HODSHON, BJÖRN LINDEKE, and GERALD T. MIWA

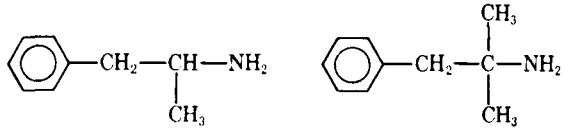
Abstract □ Quantitative GC–mass spectrometric assays were used to determine plasma and brain levels of amphetamine and phentermine. Deuterium-substituted variants of the two amines were used as internal standards in the procedures, which were sensitive to 10 pmoles/ml. The levels in rats given doses of 0.5 mg./kg. i.v. were examined in terms of a two-compartment open model. Levels of amphetamine were also examined after bilateral nephrectomy.

Keyphrases □ Amphetamine plasma and brain levels—GC-mass spectrometric analysis, rats □ Phentermine plasma and brain levels—GC-mass spectrometric analysis, rats □ GC-mass spectrometry—analysis, amphetamine and phentermine, plasma and brain, rats

The phenylisopropylamines are an interesting class of pharmacological agents because of their similar behavioral effects and their differing actions on the biogenic amines. For example, *p*-chloroamphetamine [1-(4-chlorophenyl)isopropylamine] and amphetamine (1-phenylisopropylamine, I) are qualitatively similar in their ability to cause central stimulation and anorexia. Various related compounds exhibit similar behavioral actions (1). The actions of these compounds on the biogenic amines are more diverse and, while amphetamine reduces steady-state levels of brain norepinephrine (2), *p*-chloroamphetamine reduces levels of 5-hydroxytryptamine (3).

An additional example of the differences observed within this class of compounds is the multiple pathways of metabolism, reflecting both chemical and species differences. In general, there are three initial sites of metabolism: the aromatic ring, the α-carbon, and the amino nitrogen. Metabolites resulting from oxidation at each position have been described, and the relative proportions of each metabolite differs with species (4). In the rat, the major metabolite of amphetamine *in vivo* is the *p*-hydroxy compound; in the rabbit, phenylacetone and benzoic acid resulting from deamination are the major metabolites. The role of divergent metabolic pathways in the pharmacology of these compounds has been studied by numerous investigators (2, 5–7).

Phentermine (2-methyl-1-phenylisopropylamine, II) is another structural variant of amphetamine which has similar anorexic action; but like *p*-chloroamphetamine, it has reduced central nervous system (CNS) stimulatory activity (1). The structural differences between phentermine and amphetamine are reflected in their chemical and biochemical differences. The base strength and partition coefficient of phentermine are higher than those for amphetamine, and the α-methyl group should prevent the α-oxidation–deamination pathway of metabolism (8). These differences could also result in differences in the distribution of the two drugs which, in turn, might account for some pharmacological differences. In the present study, the pharmacokinetics of these two compounds in rats were examined after intravenous administration.



I

II

The compounds were estimated by quantitative GC–mass spectrometry using procedures developed in these laboratories. The procedure for amphetamine was described elsewhere (9), and the procedure for phentermine was developed during these studies using analogous techniques. The assays involve extraction of the amines from the biological fluid, derivatization, and GC, using a mass spectrometer to monitor the effluant. The spectrometer is set to monitor mass fragments that are characteristic for the substance to be analyzed and for an isotopically enriched variant of the substance, which is the internal standard. Quantitation is based on the ratio of spectrometer response to unknown and to internal standard. The data collected were analyzed according to the two-compartment open kinetic model described for plasma decay curves (10).

EXPERIMENTAL

Extraction and Sample Preparation—The amines were extracted from the biological fluids and converted to their *N*-trifluoroacetyl derivatives for analysis by GC–mass spectrometry. Thus, a 2-ml. volume of plasma or a 4-ml. volume of brain extract was charged with 500 pmoles of deuterium-labeled amine as internal standard, alkalinized with 0.5 ml. of 5 *M* NaOH, and extracted with 6 ml. of benzene by shaking for 20 min. on a mechanical shaker. After centrifugation to separate layers, 5 ml. of the benzene layer was transferred to another extraction tube and shaken with 0.6 ml. of 1 *N* HCl. A 500-μl. aliquot of the aqueous phase was then transferred to another extraction tube containing 1.2 ml. of benzene and 0.2 ml. of 5 *M* NaOH. The resulting mixture was again shaken, 1 ml. of the benzene layer was transferred to a microcentrifuge tube, and 20 μl. of trifluoroacetic anhydride was added. The acetylation was allowed to proceed overnight at 4° and then the benzene was evaporated under a stream of nitrogen. The overnight acetylation time is not necessary but was carried out for convenience in scheduling the mass spectrometer. The residue from the evaporation step was dissolved in 20 μl. of acetonitrile for introduction into the GC–mass spectrometry system.

A standard curve was routinely prepared by adding 50–500 pmoles of amine to a series of extraction tubes containing 2 ml. of a 5% solution of plasma proteins[1] and 500 pmoles of internal standard. These tubes were then carried through the extraction and quantitation procedure.

Analysis—The GC–mass spectrometry system[2] utilized an ionizing energy set at 70 ev. with the emission current at 250 μamp. The GC column was a 2-m. × 2-mm. (i.d.) silynized glass column packed with 3% OV-17 on Gas Chrom Q (80–100 mesh), operated at 130°; the injection port and separator were operated at 180 and 185°,

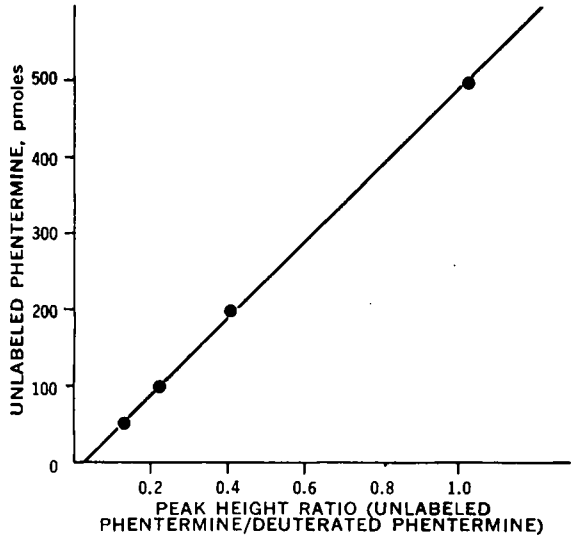

Figure 1—*Standard curve for phentermine determination.*

respectively. The mass spectrometer was operated in its specific ion detection mode (11) focused on masses 140 and 143 for amphetamine and 154 and 157 for phentermine. Quantitation was achieved by comparing the mass spectrometer responses at 140 and 143 (internal standard) for amphetamine and 154 and 157 (internal standard) for phentermine. The GC retention times for the trifluoroacetyl derivatives of amphetamine and phentermine were approximately 2.3 and 1.9 min., respectively. The internal standards used in the assays were 1-phenyl[3,3,3-$^2H_3$]isopropylamine (12) and 2-methyl-1-phenyl[3,3,3-$^2H_3$]isopropylamine (13) of 99.9 and 99.8% isotopic purity, respectively.

Animal Procedures—Male Sprague–Dawley rats, weighing 250–300 g., were given an intravenous injection of amine salt equivalent to 0.5 mg. free base/kg. at 0.25 ml./100 g. The animals were lightly anesthesized with ether, and blood was collected by cardiac puncture with a heparinized syringe. The brains were then removed and immediately frozen. The whole blood was centrifuged (3000 × *g*), and aliquots of plasma were taken for analysis. The brain was homogenized in four volumes of 0.1 *N* HCl, and the protein was precipitated by the addition of 0.2 ml. of 60% perchloric acid and centrifugation. A 4-ml. aliquot of the supernate was then extracted as described for plasma.

Bilateral nephrectomized animals were prepared by ligation of both renal arteries and veins, followed by excision of both kidneys under ether anesthesia. The animals were allowed to recover overnight before administration of the drug[3].

RESULTS AND DISCUSSION

A typical standard curve for phentermine is shown in Fig. 1. The standard deviation of the slopes from three curves was 1.3%. The standard deviation for the average slopes of five amphetamine curves was 0.3%. The 95% confidence limits calculated from these standard curves was 2–5 pmoles/ml. sample for amphetamine and 3–8 pmoles/ml. for phentermine.

The specificity of the extraction procedure was established for phentermine by focusing the specific ion detector on three major mass peaks of the spectrum of the compound. Thus, the GC peak at 1.9 min. in the extracts from phentermine-treated animals was examined for the relative intensities at *m/e* 154, 132, and 59, major peaks in the spectrum of phentermine. As shown in Table I, the relative abundances of these fragments were identical to those of authentic compounds. A similar experiment was reported previously for amphetamine (9).

In quantitative GC–mass spectrometry, the spectrometer is alternately focused on two mass numbers, one representing a major fragment in the spectrum of the compound to be analyzed and the other representing the corresponding fragment from the internal standard. For these quantitative analyses, the specific ion detector was focused on *m/e* values corresponding to the base peak for each compound. The mass spectra of the trifluoroacetyl derivatives of amphetamine and phentermine have base peaks at *m/e* 140 and 154, corresponding to the fragment (III) that results from cleavage between the α- and

amphetamine: R = H
phentermine: R = CH_3

β-carbons (14). The internal standard is labeled with three deuterium atoms at the side-chain methyl group and the corresponding fragments for the labeled variants occur at *m/e* 143 and 157. The use of the base peak is desirable for maximal sensitivity, but it is more important that the peak chosen for detection is relatively isolated in the spectrum (9).

The internal standard serves to quantitate the spectrometer response so that the unknown concentration can be obtained by the ratio of responses. In addition, by its presence at levels of 500 pmoles, it acts as a "carrier" to minimize losses of the compound to be analyzed by absorption into glass columns, *etc.*, during extraction and chromatography. These losses become significant when picogram levels of amines are being handled but are minimized with this technique, since the addition of internal standard is equivalent to operating at nanogram levels where the losses are not significant.

The changes in brain and plasma levels of amphetamine and phentermine with time are plotted in Figs. 2*a* and 2*b*. Brain levels are consistently higher than plasma for both drugs, with the ratio of brain to plasma level gradually decreasing with time. Early (<1 hr.) levels of the two amines were very close, but plasma phentermine declined more rapidly after 3 hr. Results (Table II) of an analysis of the data are based on a two-compartment open model (Scheme I), where V_{dist} is the volume of distribution; V_1 and V_2 are the volumes of the central and second compartments, respectively; and the *k*'s refer to the rate constants for movements indicated by the arrows. The $t_{1/2}$ values are derived from the β term in the two-exponential equation: $C_p = Ae^{-\alpha t} + Be^{-\beta t}$ (10). The data indicate that the transfers out of the different compartments were comparable but that the apparent volumes were different. The volume of distribution of phentermine was higher than that of amphetamine, suggesting that greater localization occurs with the more lipid-soluble amine.

The decay curves for plasma and brain were not single exponentials and were analyzed according to the two-compartment model discussed by Riegelman *et al.* (10), using a nonlinear regression analysis procedure (Table II). In the case of amphetamine, the differ-

The dotted lines in* 2a *represent the corresponding curves for data from nephrectomized animals.*

ing volumes (V_1 and V_2) calculated for the two compartments reflect the differences in tissue concentrations, with the plasma volume about 10-fold greater. The rate constants are comparable for the two tissues, indicating that they are both part of the central compartment. This would be expected from the high perfusion rate of the brain and the ease with which amphetamine would penetrate the blood–brain barrier.

Analysis of the phentermine data gives similar results, with the ratios of the plasma and brain volumes differing by a factor of 20. The values of the rate constants were somewhat different, perhaps reflecting the greater deviation of the 3- and 4-hr. brain levels from the calculated curve representing two-compartment kinetics (Fig. 2*b*).

The plasma volume of distribution calculated for phentermine was larger than that for amphetamine, reflecting the difference in the volume of V_1, the central compartment. The difference is consistent with the higher organic–aqueous partition coefficient (1) for phentermine, since highly lipid-soluble compounds tend to be localized and give larger volumes of distribution. Another example of this phenomenon is the larger volume of distribution of thiopental compared to its more polar analog, pentobarbital (10). However, in contrast to the amines, it is the volume of the second compartment that reflects the differing volumes of distribution of these weakly acidic compounds.

The role of excretion in controlling the volume of distribution and half-life of amphetamine was examined in nephrectomized rats. The changes in plasma level are shown in Table III and are compared to the levels from control animals.

Nephrectomy caused a small increase in the plasma half-life as calculated from β, the disposition rate constant (10). This increase, from 87 to 141 min., reflected differences in plasma levels at later time points (Fig. 2*a*). In contrast, inhibition of metabolism increased brain levels (2) and the brain half-life (15) of amphetamine by a factor of 5. A corresponding increase in the plasma half-life of the drug can be assumed since both brain and plasma belong to the central compartment. These data indicate that metabolism is considerably more important than renal excretion as the route of elimination of amphetamine.

[a] The plasma and brain levels were fitted to the two-exponential function describing the two-compartment model of Riegelman *et al.* (10). A Wang desk computer programmed for nonlinear regression analysis was used.

Little information is available on the *in vivo* metabolism of phentermine. Vree *et al.* (16) reported that phentermine is not metabolized in man but is excreted unchanged in the urine. In preliminary experiments with rat liver microsome preparations, we found little if any *p*-hydroxylation occurring but observed *N*-hydroxylation in the rabbit (17). However, it is difficult to demonstrate *p*-hydroxylation of amphetamine *in vitro* (18) and a similar situation may exist

Novel Method for Bioavailability Assessment

K. C. KWAN▲ and ALICE E. TILL

Abstract □ An alternative strategy is proposed for the assessment of bioavailability. It is based on estimates of renal clearance, plasma clearance, and urinary excretion of unchanged drug. The method is totally compatible with pharmacokinetic methods but lends itself to a more flexible sampling schedule and is model independent.

Keyphrases □ Bioavailability—determination with flexible, model-independent method based on estimates of renal clearance, plasma concentration, and urinary excretion of unchanged drug □ Plasma concentration and urinary excretion data—used in flexible, model-independent method for assessing bioavailability □ Urinary excretion and plasma concentration data—used in flexible, model-independent method for assessing bioavailability

There are many ways to estimate bioavailability; each one entails a set of assumptions, some of which can be experimentally verified. Oser *et al.* (1) assumed that the same fraction of the absorbed compound from different preparations is excreted unchanged in the urine. Hence, the ratio of the urinary recovery following a test preparation to that following the same dose administered as a solution is taken to be a measure of relative absorption, which they defined as "physiologic availability."

Pharmacokinetic methods of assessing bioavailability from blood plasma concentrations or urinary excretion data were summarized by Wagner (2). In essence, methods based on plasma concentration data are predicated on comparisons of the products of plasma clearance, $\dot{V}_{cl,p}$, and the total area under the plasma concentration curve, $(AUC)_\infty$. If one assumes $\dot{V}_{cl,p}$ to be constant for a given subject from one test dose to another, then the ratio of $(AUC)_\infty$ is a measure of relative absorption. But if there are intrasubject variations in elimination, the assumption of constant $\dot{V}_{cl,p}$ will not hold and an adjustment is indicated. The nature of such an adjustment depends on one's ability to estimate the terminal plasma $t_{1/2}$ in a region free from the influence of continued absorption and on one's conception of the pharmacokinetic model (3, 4). In any event, a proper

Novel Method for Bioavailability Assessment

K. C. KWAN▲ and ALICE E. TILL

Abstract □ An alternative strategy is proposed for the assessment of bioavailability. It is based on estimates of renal clearance, plasma clearance, and urinary excretion of unchanged drug. The method is totally compatible with pharmacokinetic methods but lends itself to a more flexible sampling schedule and is model independent.

Keyphrases □ Bioavailability—determination with flexible, model-independent method based on estimates of renal clearance, plasma concentration, and urinary excretion of unchanged drug □ Plasma concentration and urinary excretion data—used in flexible, model-independent method for assessing bioavailability □ Urinary excretion and plasma concentration data—used in flexible, model-independent method for assessing bioavailability

There are many ways to estimate bioavailability; each one entails a set of assumptions, some of which can be experimentally verified. Oser *et al.* (1) assumed that the same fraction of the absorbed compound from different preparations is excreted unchanged in the urine. Hence, the ratio of the urinary recovery following a test preparation to that following the same dose administered as a solution is taken to be a measure of relative absorption, which they defined as "physiologic availability."

Pharmacokinetic methods of assessing bioavailability from blood plasma concentrations or urinary excretion data were summarized by Wagner (2). In essence, methods based on plasma concentration data are predicated on comparisons of the products of plasma clearance, $\dot{V}_{cl,p}$, and the total area under the plasma concentration curve, $(AUC)_\infty$. If one assumes $\dot{V}_{cl,p}$ to be constant for a given subject from one test dose to another, then the ratio of $(AUC)_\infty$ is a measure of relative absorption. But if there are intrasubject variations in elimination, the assumption of constant $\dot{V}_{cl,p}$ will not hold and an adjustment is indicated. The nature of such an adjustment depends on one's ability to estimate the terminal plasma $t_{1/2}$ in a region free from the influence of continued absorption and on one's conception of the pharmacokinetic model (3, 4). In any event, a proper

Oral No. 2	0	50.81	48.08	(26.91)	(13.74)	10.12	3.10	0.20	(152.96)

estimate of the terminal plasma $t_{\frac{1}{2}}$ is usually required to calculate $(AUC)_\infty$ by extrapolation beyond the last data point; in some cases, this extrapolation process may also be model dependent (5).

Methods based on urinary excretion data for unchanged drug or metabolites embody the same assumptions as those of Oser *et al.* (1). In pharmacokinetic terms, the assumptions are that component rates of total elimination are individually constant or that the ratio of the rate of urinary excretion to the overall rate of elimination of that which is absorbed is constant. Intrasubject variations in the rate of urinary excretion are manifested as changes in the slopes of the amounts remaining to be excreted *versus* time plots. Compensations are subject to the same considerations as with plasma $t_{\frac{1}{2}}$ and are, therefore, also model dependent.

Depending on the biological disposition of the drug, bioavailability studies are designed to utilize one or more of these methods. Such studies should include means for testing some of the assumptions. Where it is safe and experimentally feasible, it is generally desirable to include at least one intravenous dose as a reference of maximum bioavailability. The purpose of this report is to describe a different experimental strategy which utilizes plasma concentration and urinary excretion data together so as to permit greater flexibility in the design of bioavailability protocols.

THEORETICAL

Plasma and renal clearances are physiological phenomena which should not be model dependent. Estimates of plasma and renal clearances become model dependent when their values are inferred from pharmacokinetic parameters. Observed plasma concentrations are manifestations of the net effect of absorption, distribution, metabolism, and excretion; hence, sets of plasma concentration data points by themselves are not model dependent. But mathematical reconstructions of plasma concentration data may be model dependent or uncertain when projections are made concerning AUC beyond the last data point. The proposed strategy for the assessment of bioavailability is based on determinations of renal clearance and assumptions about the constancy of plasma clearance or parts thereof following test doses of a drug.

Suppose the bioavailability of an oral dosage form is to be assessed by comparing it with an intravenous injection of the same drug. From the total urinary recovery of unchanged drug following the intravenous dose:

$$Ff = \frac{U_\infty}{D} \qquad \text{(Eq. 1)}$$

For an intravenous dose, $F = 1.0$; hence:

$$f^{iv} = \frac{U_\infty{}^{iv}}{D^{iv}} \qquad \text{(Eq. 2)}$$

where F is the fraction of the dose D that reaches the general circulation unchanged, f is the fraction of F that is excreted in the urine unchanged, U_∞ is the total amount of unchanged drug recovered in the urine, and the superscripts refer to the treatment. Renal clearance, $\dot{V}_{cl,r}$, of unchanged drug can be estimated from plasma samples taken over intervals coinciding with one or more fractional urine collection periods, *i.e.*:

$$\dot{V}^{iv}_{cl,r} = \frac{U_{t_2} - U_{t_1}}{\int_{t_1}^{t_2} Cp\, dt} \qquad \text{(Eq. 3)}$$

where U_{t_1} and U_{t_2} are the cumulative amounts of unchanged drug excreted in the urine at times t_1 and t_2, respectively; and $\int_{t_1}^{t_2} Cp\, dt$ is the area under the plasma curve from t_1 to t_2, which can be estimated by the trapezoidal rule or other suitable means. Plasma clearance is estimated by:

$$\dot{V}^{iv}_{cl,p} = \frac{\dot{V}^{iv}_{cl,r}}{f^{iv}} = \frac{D^{iv}\dot{V}^{iv}_{cl,r}}{U_\infty{}^{iv}} \qquad \text{(Eq. 4)}$$

Following oral administration, the observed fraction of the unchanged drug excreted in the urine is the product of the fraction absorbed and the fraction of the compound that is absorbed and excreted unchanged, *i.e.*:

$$F^{po}f^{po} = \frac{U_\infty{}^{po}}{D^{po}} \qquad \text{(Eq. 5)}$$

If plasma clearance is assumed to be constant between test doses, $\dot{V}^{iv}_{cl,p} = \dot{V}^{po}_{cl,p}$, then:

$$f^{po} = \frac{\dot{V}^{po}_{cl,r}}{\dot{V}^{po}_{cl,p}} = \frac{\dot{V}^{po}_{cl,r}}{\dot{V}^{iv}_{cl,p}} \qquad \text{(Eq. 6)}$$

and the fraction absorbed:

$$F^{po} = \frac{F^{po}f^{po}}{f^{po}} = \frac{U_\infty{}^{po}\dot{V}^{iv}_{cl,p}}{D^{po}\dot{V}^{po}_{cl,r}} \qquad \text{(Eq. 7)}$$

The assumption of constant plasma clearance may be reassessed by comparing observed values for $\dot{V}^{po}_{cl,r}$ and $\dot{V}^{iv}_{cl,r}$. If they are equal, it may be reasonable to accept the hypothesis of constant plasma clearance in the absence of contrary evidence. This is tantamount to saying that the ratio of fractional urinary recovery, Ff, is a measure of bioavailability when the ratio of $\dot{V}_{cl,r}$ to $\dot{V}_{cl,p}$ is constant between treatments. However, if they are not equal, several obvious alternatives can be considered. First, the observed differences may be ignored on the premise that the nonrenal components of plasma clearance would be compensating. Second, one may assume that only the renal components change but that the nonrenal components remain constant, in which event:

$$\dot{V}^{po'}_{cl,p} = \dot{V}^{po}_{cl,r} + \dot{V}^{iv}_{cl,p} - \dot{V}^{iv}_{cl,r} \qquad \text{(Eq. 8)}$$

and:

$$f^{po} = \frac{\dot{V}^{po}_{cl,r}}{\dot{V}^{po'}_{cl,p}} \qquad \text{(Eq. 9)}$$

Third, the nonrenal component of $\dot{V}_{cl,p}$ may be thought to vary in

Oral No. 1			223.1	646.3	0.265	0.768
Oral No. 2	186.6	609.8			0.306	

[a] By Eq. 3. [b] By Eq. 13. [c] By Eq. 17. [d] By Eq. 1. [e] By Eq. 16.

direct proportion to changes in the renal clearance, so that:

$$\dot{V}_{cl,p}^{po''} = \frac{\dot{V}_{cl,r}^{po}}{\dot{V}_{cl,r}^{iv}} \cdot \dot{V}_{cl,p}^{iv} \qquad \text{(Eq. 10)}$$

and:

$$^{po} = \frac{\dot{V}_{cl,r}^{po}}{\dot{V}_{cl,p}^{po''}} \qquad \text{(Eq. 11)}$$

Finally, one may take the view that none of the first three alternatives is reasonable; hence, no estimate of bioavailability is warranted. The choice of alternatives may be dictated by one's understanding of the physicochemical and pharmacological properties of the drug and prior knowledge of its disposition in animals and in man. For example, changes in cardiac output would influence $\dot{V}_{cl,p}$ and $\dot{V}_{cl,r}$ and the other excretory components of $\dot{V}_{cl,p}$ proportionately, whereas changes in urinary pH may affect only $\dot{V}_{cl,r}$ of some drugs.

The proposed strategy applies even when an intravenous dose is not included. In such cases, one treatment is usually designated as the standard (s) to which all other treatments (x) are compared. Accordingly:

$$\frac{U_\infty^s}{D^s} = F^s f^s \qquad \text{(Eq. 12)}$$

and:

$$[\dot{V}_{cl,p}^{s}]_{ex} = \frac{\dot{V}_{cl,r}^{s}}{F^s f^s} \qquad \text{(Eq. 13)}$$

The quantity $[\dot{V}_{cl,p}^{s}]_{ex}$ denotes an experimentally derivable value which is only proportional to the true plasma clearance, $\dot{V}_{cl,p}^{s}$, in that:

$$\dot{V}_{cl,p}^{s} = F^s[\dot{V}_{cl,p}^{s}]_{ex} \qquad \text{(Eq. 14)}$$

For $\dot{V}_{cl,r}^{s} = \dot{V}_{cl,r}^{x}$:

$$f^x = \frac{\dot{V}_{cl,r}^{x}}{\dot{V}_{cl,p}^{x}} = \frac{\dot{V}_{cl,r}^{s}}{\dot{V}_{cl,p}^{x}} = \frac{\dot{V}_{cl,r}^{x}}{F^s[\dot{V}_{cl,p}^{s}]_{ex}} \qquad \text{(Eq. 15)}$$

Relative absorption is given by:

$$\frac{F^x}{F^s} = \frac{F^x f^x}{F^s f^x} = \frac{U_\infty^x \cdot [\dot{V}_{cl,p}^{s}]_{ex}}{D^x \dot{V}_{cl,r}^{x}} \qquad \text{(Eq. 16)}$$

Corrective measures, when indicated, should be applied to $[\dot{V}_{cl,p}^{s}]_{ex}$. Thus, Eqs. 8 and 10 are revised to read as follows:

$$[\dot{V}_{cl,p}^{x}]_{ex}' = \dot{V}_{cl,r}^{x} + [\dot{V}_{cl,p}^{s}]_{ex} - \dot{V}_{cl,r}^{s} \qquad \text{(Eq. 17)}$$

and:

$$[\dot{V}_{cl,p}^{x}]_{ex}'' = \frac{\dot{V}_{cl,r}^{x}}{\dot{V}_{cl,r}^{s}} \cdot [\dot{V}_{cl,p}^{s}]_{ex} \qquad \text{(Eq. 18)}$$

DISCUSSION

Experimentally, the proposed method calls for the complete collection of urine in planned increments. Plasma sampling times should at least coincide with selected incremental urinary collection periods. Intermediate plasma samples may also be indicated to permit accurate determinations of the incremental areas under the plasma curve, which is essential to the calculations of renal clearance. Assays of plasma and urine specimens should be specific for unchanged drug. The number of plasma points may be minimized by choosing relatively short urine collection periods at times when plasma concentrations do not change rapidly. It is also prudent to include more than one estimate of $\dot{V}_{cl,r}$ per treatment. In this regard, it might be advantageous to make estimates of $\dot{V}_{cl,r}$ from contiguous urine collection periods. This is so in respect both to economy in the required number of plasma data points and to the modulation of experimental difficulties in voiding completely and on time. (See Appendix for sample calculations.)

The description of the proposed method is confined to the case where bioavailability is defined as the amount, or relative amount, of drug reaching the general circulation unchanged. In some cases, such as with prodrugs, it may be more appropriate to define bioavailability as that fraction, or relative fraction, of the dose reaching the general circulation as a specific metabolite. The proposed strategy accommodates these situations with the following provisions. Estimates of $\dot{V}_{cl,r}$ and $\dot{V}_{cl,p}$ are those of the metabolite. Equation 4 applies only if the intravenous dose is administered as the metabolite; otherwise, only estimates of relative absorption would be possible, and Eq. 13 should be used regardless of the route of administration. Because the method relies on estimates of $\dot{V}_{cl,p}$ or $[\dot{V}_{cl,p}]_{ex}$, it may be considered only when bioavailability can be appropriately defined in terms of drug or metabolite(s) reaching the general circulation. Thus, if metabolism is route dependent, then, by definition, drug metabolized on the first pass through the liver is nonavailable. For this reason, this method is generally inappropriate if estimates of bioavailability of a drug are attempted through measurements of metabolite(s).

In summary, the proposed method requires estimates of U_∞ and $\dot{V}_{cl,r}$, from which $\dot{V}_{cl,p}$ or $[\dot{V}_{cl,p}]_{ex}$, f, and F can be calculated. Some salient features are:

1. It is model independent. The only assumptions are those related to plasma clearance or components thereof. It should be recalled that the same assumptions concerning $\dot{V}_{cl,p}$ and/or $\dot{V}_{cl,r}$ are implicit in all pharmacokinetic methods; however, the proposed method does not entail further assumptions concerning individual

or hybrid model parameters. Since estimates of $\dot{V}_{cl,p}$ and $\dot{V}_{cl,r}$ are not influenced by the nature of the absorption process, this method should apply even when absorption is inordinately slow or defies mathematical description. At the same time, the techniques are not only compatible with but also may be applied advantageously in conjunction with pharmacokinetic techniques.

2. A complete definition of the time course of change in plasma concentrations is not needed; thus, the required number of plasma data points is flexible. It is, therefore, particularly well suited in situations where large volumes of plasma are required per sample, such as when the assay method lacks sensitivity or when the dosages are low. If necessary, several doses may be given repetitively so that plasma levels will be sufficiently high before estimates of $\dot{V}_{cl,r}$ are made. In this event, one would obtain an assessment of average bioavailability upon repetitive dosing, but one does not need to wait for the attainment of steady state before terminating the study.

3. Since $\dot{V}_{cl,p}$ is an estimate of the net result of physiological disposition, the method should yield valid assessments of bioavailability even when enterohepatic recirculation exists or is suspected.

4. Even though the present discussion on intrasubject variations, manifested as changes in $\dot{V}_{cl,r}$, considers only alternative assumptions, concomitant measurements of metabolic turnover rates and renal clearances of endogenous substances, particularly those with both renal and extrarenal components of elimination, are seen as interesting possibilities as independent indicators of change in $\dot{V}_{cl,r}$ and $\dot{V}_{cl,p}$. This would entail tracer doses of the indicator, which should be selected among candidates having elimination patterns resembling those of the drug being studied. Various applications of the proposed method will be discussed in future reports.

APPENDIX

Sample calculations using the proposed method are performed on a set of simulated data for a subject who received the same dose of a drug intravenously once and orally on two other occasions. Except for the renal clearance of unchanged drug, all other aspects of drug disposition remained constant for each of the three test doses. Absorption was arbitrarily fixed at 55.0 and 68.8% for the two oral doses. Typical plasma concentration and urinary excretion data for unchanged drug simulated according to the prescribed conditions are shown in Table I.

Application of the proposed method does not require all of the data in Table I. An assessment of bioavailability can be attempted from just a few selected points, such as those shown in parentheses. Sample calculations using the intravenous dose as the standard reference are shown in Table II. Renal clearances are calculated from incremental urinary recoveries at 2–3 and 3–4 hr. and trapezoid areas under the plasma curve for the corresponding times. Since they are different for each test dose, estimates of $\dot{V}_{cl,p}^{po\prime}$ are made with the aid of Eq. 8. The fractions absorbed, F^{po}, are then calculated from $\dot{V}_{cl,r}^{po}$, $\dot{V}_{cl,p}^{po\prime}$, and U_{∞}^{po} using Eq. 7. The difference between the calculated and the true fraction absorbed is due to the trapezoid approximation of areas under the plasma curve. Had the true areas been used, the answers would have been exact; these are shown in parentheses.

With the assumption that there were no data from an intravenous dose, calculations of relative absorption from the two oral doses are shown in Table III in which the second oral dose is designated as the standard. The answer, $F^2/F^1 = 0.767$, is slightly different from the ratio of $F^1/F^2 = 0.788$ obtained in Table II using the intravenous dose as the standard. This is because the appropriate expressions for estimating $\dot{V}_{cl,p}^{po\prime}$ (Eq. 8) and $[\dot{V}_{cl,p}^{2}]_{ex}{}'$ (Eq. 17) in this example are not linearly related to $\dot{V}_{cl,p}^{iv}$ and $[\dot{V}_{cl,p}^{1}]_{ex}$, respectively; hence, an exact proportionality is not expected when different standards are used. Conversely, when linear expressions, such as Eqs. 9 and 18, are appropriate, exact correspondence between ratios should result regardless of how the standards are chosen.

Effect of Concurrent Administration of Choline Salicylate and Acetaminophen on Their Mutual Biotransformation in the Rat

GOLLAMUDI RAMACHANDER[A], FLORENCE D. WILLIAMS, and JANE FRANCES EMELE

Abstract □ Rats were administered either choline salicylate (2 mg./kg.) or acetaminophen (10 mg./kg.) or a combination of both by gastric intubation. Plasma levels of salicylic acid and acetaminophen were measured at various time intervals by suitable modifications of reported analytical methods. Concurrent administration of the two drugs did not alter the plasma salicylic acid levels but resulted in a slight increase of the plasma acetaminophen values at 5 and 10 min. Differing degrees of glucuronidation of the two drugs may explain this interaction which, however, appears too low to be of clinical significance.

Keyphrases □ Choline salicylate and acetaminophen, concurrent administration—effect on individual plasma levels, rats □ Acetaminophen and choline salicylate, concurrent administration—effect on individual plasma levels, rats □ Analgesics, concurrent administration of choline salicylate and acetaminophen—effect on individual plasma levels, rats □ Plasma levels—choline salicylate and acetaminophen after concurrent administration, rats

Mutual inhibition of the metabolism of drugs sharing a common biotransformation pathway is well documented (1–3). Among the nonprescription analgesics, such interactions have been reported to occur between salicylamide and acetaminophen (4) and salicylic acid and salicylamide (5). In man, salicylic acid is metabolized to salicyluric acid, salicyl acylglucuronide, phenolic glucuronide, and gentisic acid (6). The main metabolic pathway of acetaminophen is conjugation to the glucuronide and sulfate (7). It is conceivable that salicylic acid and acetaminophen would compete for sites on the enzyme systems responsible for their biotransformation, this competition leading to decreased glucuronide formation which, in turn, might result in increased blood levels of the free drug(s). Levy and Regårdh (8) observed little interaction in the biotransformation of acetaminophen and salicylic acid in human volunteers. In their study, acetaminophen and sodium salicylate were given at different time intervals, and the urinary excretion rates of the metabolites were studied. Amsel and Davison (9) administered acetaminophen with single and multiple doses of aspirin and observed no effect on acetaminophen metabolism in man.

The present study was initiated to determine if the plasma levels of acetaminophen and salicylic acid are affected by concurrently administering the former with choline salicylate to rats. This experimental design was chosen because: (*a*) choline salicylate has been reported to be absorbed much faster, giving rise to higher blood levels of salicylic acid than an equivalent dose of aspirin in man (10, 11); and (*b*) in experimental animals like the rat, it is more convenient and amenable to measure quantitatively plasma drug levels at various intervals like 5, 10, and 15 min. than urinary excretion rates.

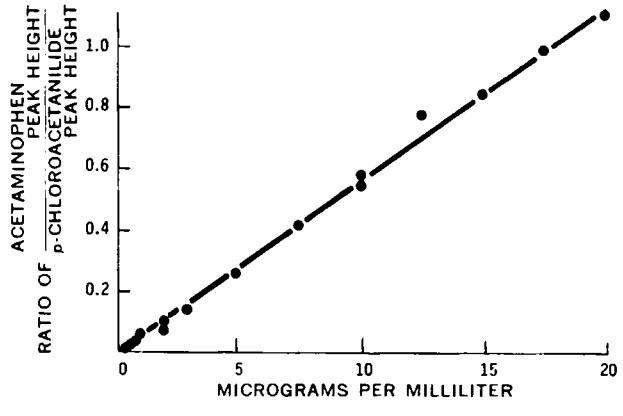

Figure 1—*Calibration curve of acetaminophen added to rat plasma.*

EXPERIMENTAL

Materials—The following were used: dichloroethane, spectroquality[1]; ethyl acetate, spectroquality[1]; phosphate buffers, 1.0 *M*, pH 8.0, and 0.1 *M*, pH 7.0; sodium sulfate, anhydrous, reagent grade[2]; *p*-chloroacetanilide[3]; nitrogen gas, high purity[4]; bis(trimethylsilyl)trifluoroacetamide[5]; pyridine[6]; choline salicylate, 51% (w/w) aqueous solution[6]; a column conditioner containing trimethylsilyl donors[7]; phenyl methyl silicone, 50% phenyl (OV-17)[8]; and Gas Chrom Q[8].

Methods—*Determination of Acetaminophen in Rat Plasma*—The method of Prescott (12) was modified and adopted as follows. Rat plasma (2.0 ml.) was adjusted to pH 8.0 by the addition of 1.0 ml. phosphate buffer, 1.0 *M*, pH 8.0, and then extracted by shaking for 10 min. with 6.0 ml. ethyl acetate. The mixture was centrifuged for 5 min. at 6000 r.p.m. The organic layer was separated and dried over 1.0 g. anhydrous sodium sulfate. A 4.0-ml. aliquot of the extract was transferred to a screw-capped conical tube containing 15 mcg. *p*-chloroacetanilide in ethyl acetate. The solvent was evaporated by heating at 60° under a stream of dry nitrogen. The sides of the tube were washed with 1.0 ml. ethyl acetate, and the solvent was again removed by evaporation. The residue was dissolved in 15 μl. pyridine, reacted with 15 μl. bis(trimethylsilyl)trifluoroacetamide at 60° for 30 min., and cooled; then 1.0 μl. was injected into a gas chromatograph[9] equipped with a flame-ionization detector.

The chromatographic conditions were: glass column, 0.63 cm. (0.25 in.) o.d., 1.82 m. (6 ft.), containing 10% phenyl methyl silicone (50% phenyl) on Gas Chrom Q (100–120 mesh); carrier gas (nitrogen) at a flow rate of 45 ml./min.; column temperature, 160°; injection block temperature, 210°; and detector temperature, 220°. The retention times of *p*-chloroacetanilide and acetaminophen were 4.0 and 7.8 min., respectively.

Determination of Salicylic Acid in Rat Plasma—The spectrofluorometric method of Rowland and Riegelman (13) was modified as follows. Plasma (2.0 ml.) was acidified to pH 2.0 with 3.0 *N* HCl and extracted with dichloroethane (25 ml.). Salicylic acid from

a 20-ml. aliquot of the organic layer was reextracted into 5.0 ml. of phosphate buffer, 0.1 *M*, pH 7.0, and the fluorescence was measured in a spectrophotofluorometer[10]. Activation and emission wavelengths were 302 and 406 nm., respectively, and both slit dials were set at 4.0 nm.

Separation and Estimation of Acetaminophen and Salicylic Acid from Rat Plasma in the Presence of Each Other—By employing the two procedures already outlined, a method was developed for the separation and estimation of acetaminophen and salicylic acid in plasma.

Two milliliters of plasma was extracted by shaking with ethyl acetate and analyzed for acetaminophen by the GLC procedure already described. The aqueous layer (2.5 ml.) was then reextracted with 6.0 ml. of ethyl acetate to remove residual acetaminophen in solution. The organic layer was discarded, and 2.0 ml. of the aqueous phase was acidified with 0.2 ml. of 6 *N* HCl and extracted with 25 ml. of dichloroethane. The salicylic acid was taken into phosphate buffer, 0.1 *M*, pH 7.0, and the fluorescence was measured as described earlier.

Plasma Levels of Acetaminophen and Salicylic Acid in Rats—Groups of 10 female Sprague–Dawley rats, 220–260 g., were fasted for 18 hr. They then received, by stomach tube, aqueous solutions of: (*a*) acetaminophen, 10 mg./kg.; (*b*) choline salicylate, 2 mg./kg.; or (*c*) a combination of acetaminophen, 10 mg./kg., and choline salicylate, 2 mg./kg. Blood samples were withdrawn into heparinized tubes by cardiac puncture immediately prior to and at 5, 10, 15, 30, 45, 60, 90, and 120 min. after treatment. Ten rats were used per time period. The plasma was separated by centrifugation and analyzed for acetaminophen and/or salicylic acid according to one of the three described procedures.

RESULTS

Determination of Acetaminophen in Rat Plasma—A linear relationship was observed between the concentration of acetaminophen (0.05–20 mcg./ml.) and the peak height ratio (peak height of acetaminophen/peak height of *p*-chloroacetanilide) when known amounts were added to normal rat plasma and assayed by the analytical procedure (Fig. 1). The recovery of added drug was 67%. It was found that the column efficiency could be maintained better by periodic injections of five 10-μl. portions of column conditioner[7] at 60° and programming the column to 200° at 2°/min. with its detector end disconnected after every 20–30 analyses.

Known amounts of salicylic acid (1.0–10 mcg./ml.) were added to rat plasma and assayed. A linear relationship was observed between the salicylic acid concentration and the fluorescence (Fig. 2). The recovery was 100%.

Varying concentrations of acetaminophen (1–20 mcg./ml.) were added to rat plasma in the presence of 20 mcg. of salicylic acid, as were known concentrations of salicylic acid (0.5–20 mcg./ml.) in the presence of 20 mcg. of acetaminophen. Then the samples were assayed differentially according to the procedure already outlined. There was no interference by either drug on the recovery or measurement of the other. Consequently, the calibration curves shown in Figs. 1 and 2 were employed to determine the concentrations of the two drugs in plasma samples containing the two in unknown proportions.

Plasma Levels of Acetaminophen and Salicylic Acid in Rats—The average plasma levels of salicylic acid and acetaminophen attained after administration of either drug alone or in combination to rats are shown in Tables I and II, respectively.

Oral administration of choline salicylate (2 mg./kg.) to rats resulted in peak salicylic acid plasma levels (6.9 mcg./ml.) within 5 min., which slowly decreased over 2 hr. to 4.4 mcg./ml. at 120 min. Concurrent administration with acetaminophen (10 mg./kg.) resulted in similar levels of salicylic acid, which were 6.7 mcg./ml. at 5 min., 6.8 mcg./ml. at 15 min., and 4.6 mcg./ml. at 120 min.

Acetaminophen (10 mg./kg.) administered orally to rats produced plasma levels that rose quickly to a peak (11.3 mcg./ml.) at 15 min. and then declined sharply to 0.1 mcg./ml. by 120 min. However, concurrent administration of acetaminophen (10 mg./kg.) with choline salicylate (2 mg./kg.) resulted in higher plasma acetaminophen levels at 5 and 10 min. ($0.05 < p < 0.1$ by a two-tail *t*-test).

DISCUSSION

Derivatizing acetaminophen by heating with bis(trimethylsilyl)-trifluoroacetamide under controlled conditions resulted in quantitative and more reproducible results. Employing dichloroethane in place of ether for extracting salicylic acid rendered the operation more facile and less hazardous. Therefore, the methodology appeared to be an improvement over existing ones (12, 13).

Levy and Regårdh (8) observed no interaction in man in the biotransformation of acetaminophen and salicylate on the basis of urinary excretion data. They did not rule out, however, the possibility of the inhibition of glucuronide and/or sulfate formation under forced or different conditions. Amsel and Davison (9) suggested that the two drugs might be metabolized by different systems in man.

The interaction between acetaminophen and salicylates in experimental animals has not been studied before. In the present study, concurrent administration of these two drugs to the rat resulted in slightly elevated plasma acetaminophen concentrations at 5 and 10 min. while the salicylate levels remained unaffected. The dose (per body weight) of acetaminophen given to rats compares favorably with that given to humans by earlier workers (8, 9). Salicylate was administered at a much lower dose because: (*a*) choline salicylate given orally resulted in peak plasma levels by 5 min. which slowly declined up to 120 min., and (*b*) too high plasma salicylate levels could so saturate the enzyme systems as to make it difficult to discern any alterations caused by acetaminophen. The interaction in rats, although it may be too low to be of any clinical significance, is possibly due to differing degrees of glucuronidation undergone by the two drugs in the rat. This is analogous to the inhibitory effect of benzoic acid on the formation of salicyluric acid from salicylate in man (14). Salicylic acid, on the other hand, was without an effect on hippuric acid formation from benzoic acid. The latter is almost completely biotransformed to hippuric acid, whereas only 50–70% of the former is conjugated with glycine in man. If it is assumed that a substrate or a drug with a greater affinity to the glucuronide-

DRUG STANDARDS

Individual Tablet Analysis for Codeine and Caffeine in Codeine-Aspirin-Phenacetin-Caffeine Tablets

THERON JAMES

Abstract □ A procedure is reported for determining the codeine and caffeine content of individual codeine-aspirin-phenacetin-caffeine tablets. Codeine is determined fluorometrically after extraction into dilute sulfuric acid; caffeine is extracted from a chloroform solution of the remaining ingredients with phosphoric acid and determined by UV spectroscopy. Average recoveries with a synthetic mixture were 99.7 and 98.9% for codeine and caffeine, respectively. Assay results are reported for codeine [1–65 mg. (1/65–1 grain)/tablet] and caffeine [32 mg. (1/2 grain)/tablet] in several different commercial samples. The proposed procedure is also compared with official methods.

The NF XIII monograph (1) for tablets containing codeine and aspirin-phenacetin-caffeine (1) requires content uniformity tests for codeine and caffeine. The methods involve a GC determination for codeine, while caffeine is determined by UV spectroscopy after column chromatographic separation. Utilization of these procedures for content uniformity necessitates two separate analyses. Consequently, a single tablet is not tested for *both* drugs (*i.e.*, codeine is determined in one group of tablets while caffeine is determined in

another). In addition, the assay procedures have several disadvantages when they are used for individual tablet analysis:

1. The original method for codeine (1) uses propoxyphene hydrochloride as an internal standard. Erratic results are often obtained because of the thermal decomposition of this compound.

2. The revised method for codeine (2) uses another internal standard but includes a lengthy *system suitability* procedure.

3. Assay results on tablets containing less than 30 mg. codeine are questionable because errors inherent in multiple extractions, transfers, and evaporations are greatly magnified when the active ingredient is at a low concentration.

4. Applying the assay procedure (1) for I to individual tablet analysis requires the acquisition and preparation of at least 10 chromatographic columns. With the accessory glassware needed as well, the method becomes both lengthy and cumbersome.

Obviously, a utilitarian method for determining both drugs in the same tablet would have more appeal. Heuermann and Levine's (3) method for determining I with other drugs has been used to determine codeine and caffeine. Codeine is trapped on a strong acid column and subsequently eluted with triethylamine in chloroform. Incomplete elution of codeine is common because of difficulty in completely basifying the strong acid column. Furthermore, the triethylamine must be completely removed prior to the determinative step and be of sufficient purity so as not to leave any UV-absorbing residues. Compound I passes through this acid column, and caffeine is determined as previously described by Levine (4). A procedure reported by Siegmund (5) is also capable of assaying both drugs. Its application to individual tablet analysis, however, is unwieldy because it requires *two* chromatographic columns per analysis. Parenthetically, Siegmund also reported incomplete separation of codeine and caffeine if the sample is not ground sufficiently.

The sensitivity and separation properties inherent in GLC offer another plausible alternative; however, reported procedures (6–9) are not apposite for individual tablet analysis. The methods of Hoffman and Mitchell (6) and Haefelfinger *et al.* (7) do not include codeine, and the method reported by Dechene *et al.* (8) involves a preliminary separation and temperature programming. Retention data reported by Rader and Aranda (9) indicate good separation between codeine and I. However, most parameters in their procedure (*e.g.*, sample extraction, instrument operating conditions, and retention times) need modification for individual tablet analysis.

The quest for a more practical approach generated this investigation. It was determined experimentally that caffeine can be quantitatively extracted from chloroform and effectively separated from phenacetin by using phosphoric acid. This discovery, coupled with the easy extractability of codeine by dilute acids, led to the development of a practical, facile method for individual tablet analysis for codeine and caffeine in common analgesic tablets. In the proposed method, a single tablet is dispersed in dilute sulfuric acid and extracted with chloroform. The acid layer retains codeine, which is determined fluorometrically after filtration and proper dilution. Caffeine is extracted from a portion of the chloroform solution with phosphoric acid and subsequently determined by UV spectroscopy.

EXPERIMENTAL

Apparatus—Fluorescence measurements were made using a recording spectrophotofluorometer[1] with 1-cm. cells. The following instrument parameters were employed: xenon lamp; meter multiplier, 0.03; sensitivity, 40–50; 1P21 photomultiplier; slit arrangement No. 4; excitation wavelength, about 285 nm.; and emission wavelength, about 355 nm.

UV spectra were obtained using a recording spectrophotometer[2] with 1-cm. cells.

Reagents—Reagent grade chloroform and ether and approximately 0.1 *N* ether-saturated sulfuric acid were used. A phosphoric acid solution was prepared by mixing equal volumes of distilled water and reagent grade phosphoric acid.

Standard Solutions—The following were used:

1*a*. Codeine phosphate stock solution, 0.13 mg./ml. in 0.1 *N* ether-saturated sulfuric acid.

1*b*. Codeine phosphate working solution, 13 mcg./ml. Dilute 10.0 ml. stock solution to 100 ml. with 0.1 *N* ether-saturated sulfuric acid.

2*a*. Caffeine stock solution, 1 mg./ml. in chloroform.

2*b*. Caffeine working solution, 0.01 mg./ml. Pipet 1.0 ml. stock solution into a 100-ml. volumetric flask and evaporate to dryness. Then add 30 ml. phosphoric acid solution to the residue, swirl to dissolve, and dilute to volume with distilled water.

Sample Preparation—Place one tablet in a separator containing about 30 ml. 0.1 *N* ether-saturated sulfuric acid and allow to disintegrate by swirling or standing. Extract with four 20-ml. portions of chloroform, collecting the extracts in a 100-ml. volumetric flask. Dilute to volume with chloroform and save for the caffeine determination.

Codeine Determination—Wash the acid solution in the separator with one 50-ml. portion of ether, and filter acid layer through a wetted filter into a 100-ml. volumetric flask. Rinse separator and filter with several portions of 0.1 *N* ether-saturated sulfuric acid, adding rinsings to flask. Finally, dilute to volume with 0.1 *N* ether-saturated sulfuric acid and mix. Using 0.1 *N* ether-saturated sulfuric acid, dilute an appropriate aliquot to a codeine phosphate concentration of 10–13 mcg./ml.

With the codeine phosphate working standard, at an excitation wavelength of 285 nm., adjust the spectrophotofluorometer to about 70% relative fluorescence intensity at 355 nm. Scan the sample and standard solutions from 285 to 375 nm., reading the maximum at about 355 nm. Use 0.1 *N* ether-saturated sulfuric acid as a blank.

Caffeine Determination—Pipet 3.0 ml. of the chloroform solution from the sample preparation into a separator containing 20 ml. chloroform. Add 30 ml. of the phosphoric acid solution and extract by shaking vigorously for 2 min. Allow the layers to separate and discard the chloroform. Backwash the acid layer with another 20 ml. of chloroform and discard wash. Rinse the stopper with distilled water and add about 25 ml. distilled water to the acid solution. Mix and filter through a wetted filter into a 100-ml. volumetric flask. Rinse separator and filter with several portions of distilled water, and finally dilute to volume with distilled water. Compare the absorbance of this solution to that of the caffeine working standard at 269 nm., using 30% phosphoric acid solution in distilled water as a blank.

RESULTS AND DISCUSSION

Caffeine is sparingly soluble in aqueous solutions, while phenacetin is only very slightly soluble. However, because phenacetin is present in relatively large amounts and because of its high absorptivity, an essentially complete separation is necessary for an ac-

curate caffeine determination. Previously, it was generally thought impossible to separate caffeine from phenacetin by liquid–liquid partitioning in a separator. The organic phase must be chloroform to prevent significant amounts of phenacetin from extracting into the aqueous phase, but sulfuric acid, the commonly used aqueous phase, will not quantitatively extract caffeine from chloroform. The switch to phosphoric acid proved eminently successful. Under the experimental conditions used, caffeine is completely recovered in a *single* phosphoric acid extraction. Traces of phenacetin in the acid extract are effectively removed with an additional chloroform wash, thereby permitting UV determination of caffeine.

Although the natural fluorescence of codeine was previously reported (10, 11), it was thought to be too nonspecific and insensitive for clinical or biological work and its application to pharmaceutical analysis has been largely overlooked. Fluorescence was chosen in this instance because the UV spectra for codeine in some commercial samples showed interferences and because the sensitivity of the fluorescence permitted easy assay of low level codeine preparations [1 and 8 mg. ($^1/_8$ grain)]. However, at the sensitivity used, it was determined empirically that ether-saturated aqueous solvents contribute to the fluorescence of the solute. Consequently, all codeine solutions were prepared in ether-saturated sulfuric acid.

A synthetic mixture was prepared to contain the usual combination of I [*i.e.*, 227 mg. ($3^1/_2$ grains), 162 mg. ($2^1/_2$ grains), and 32 mg. ($^1/_2$ grain), of aspirin, phenacetin, and caffeine, respectively] plus 16 mg. ($^1/_4$ grain) codeine, about 16% starch, and 2% magnesium stearate. Ten sample weights, each approximating one theoretical tablet, were assayed by the proposed procedure (Table I). The average recoveries were 99.7 and 98.9% for codeine and caffeine, respectively.

The proposed procedure was compared to official methods for codeine (12) and caffeine (1) by assaying composites of four different commercial preparations (Table II). The method shows excellent agreement with the existing methods.

Table III shows individual tablet data. The samples represent five different manufacturers. The time required for analysis of five tablets was about 1.5 hr.

With minor modification, the described procedure may be adaptable to the determination of aspirin and phenacetin also. The chloroform washes from the caffeine determination contain aspirin and phenacetin. A single extraction with 5% sodium bicarbonate will remove aspirin. The chloroform solution can then be evaporated, and the phenacetin residue can be determined by UV spectroscopy after dissolution in chloroform and isooctane. Aspirin can be reextracted into chloroform after acidifying the bicarbonate solution and also determined by UV spectroscopy. Cursory experiments indicate that this approach is quite feasible, but an extensive investigation was not undertaken.

Spectrophotometric Determination of Methenamine and Its Salts by 2-Hydrazinobenzothiazole

JAMES K. LIM▲ and CONNIE C. C. CHEN

Abstract □ A rapid and sensitive method is described for the assay of the pure powder form and the tablet dosage form of methenamine and its salts. The procedure is shown to be capable of measuring as little as 0.005 μmole of material and is highly reproducible. The proposed method is based on the color development of formaldehyde released from the acid hydrolysis of methenamine with a dye, 2-hydrazinobenzothiazole. Beer's law is obeyed in the concentration range of 1–8 μ*M* of methenamine at 510-nm. wavelength. This method offers greater versatility over the official assay methods, which have been designed primarily for determining specifically either methenamine or its mandelate salt. Data comparing the assays obtained by the official methods with this new technique are presented.

Keyphrases □ Methenamine and salts in powders and tablets—colorimetric analysis using 2-hydrazinobenzothiazole, compared to compendial methods □ 2-Hydrazinobenzothiazole—used as color-forming agent in spectrophotometric analysis of methenamine and its salts □ Colorimetry—analysis, methenamine and salts in powders and tablets

The NF XIII (1) assay for methenamine involves its acid hydrolysis by reflux until the "odor of formaldehyde is no longer perceptible," followed by back-titration with an alkali. The procedure proved to be not only tedious but also subject to inaccuracies arising from human error in obtaining the "perceptible end-point," *i.e.*, absence of formaldehyde odor. The USP XVIII (2) method for determining methenamine mandelate, on the other hand, represents an indirect method of analysis. It essentially involves nesslerization followed by an iodometric titration of the mandelic acid moiety; therefore, this method cannot be employed for determining other salts of methenamine.

Other methods also have been developed for the quantitation of this compound, including those based on chromotropic acid reactions (3–5), the Hantzsch reaction between acetylacetone, ammonia, and formaldehyde (6), and fluorometric techniques (7). This report presents a method for determining methenamine and its salts through the formation of xanthylinum dicationic dyes with formaldehyde and formaldehyde-releasing compounds. Measurements based on such a reaction are reported (8, 9) to be more sensitive than those by chromotropic acid.

EXPERIMENTAL

Apparatus—Absorbance measurements were made on a spectrophotometer[1].

Reagents and Chemicals—2-Hydrazinobenzothiazole[2] was the dye-forming reagent used. Powdered samples of methenamine[3–5], methenamine mandelate[6], and methenamine hippurate[7] were used as received. All other chemicals and reagents used were USP or the highest grade of commercial materials. Several commercial brands of either the plain or enteric-coated tablets of methenamine, methenamine mandelate, and methenamine hippurate were employed for the tests comparing the official assays with the proposed method. The dye reagent consists of a 0.5% solution of 2-hydrazinobenzothiazole in 10% hydrochloric acid. It is stable for 2 weeks.

Assay Procedure—Aqueous solutions of methenamine or the methenamine salt in the concentration range of 0.01–0.08 μmole/ml. were made up in 100-ml. volumetric flasks. A 0.5-ml. volume of each solution was placed in a test tube and mixed with 0.5 ml. of 10 *N* sulfuric acid. The samples were refluxed in a boiling water bath for 15 min. to obtain complete hydrolysis and were allowed to cool to room temperature before the addition of 0.5 ml. of the 2-hydrazinobenzothiazole reagent. After 5 min., 0.5 ml. of a 1% aqueous solution of potassium ferricyanide was added and this reaction was allowed to proceed another 20 min. before the final admixture of 3 ml. of dimethylformamide solvent. The color thus formed was allowed to stabilize for 20 min. before absorbance readings were made at a 510-nm. wavelength against a reagent blank.

Table I—Absorbance by Different Methenamine Concentrations

± *SD*	0.004	0.009	0.008	0.007

Table II—Assay of Commercial Methenamine Powder by the 2-Hydrazinobenzothiazole and NF Methods

Powder	Percent Found—2-Hydrazinobenzothiazole Method	NF Method
A	98.5[a] ± 1.08[b]	98.8
B	96.3 ± 2.07	93.5

[a] Average of three determinations. [b] Standard deviation.

RESULTS AND DISCUSSION

Absorbance of the color obtained of known standards in the concentration range of 0.005–0.04 μmole/5 ml. of methenamine was seen to obey Beer's law. The calculated linear correlation coefficients were: methenamine, 0.9996; and methenamine mandelate and methenamine hippurate, 0.9969 and 0.9975, respectively. Initial studies showed that the slopes might vary from time to time, probably due to aging of the reagents employed with the 2-hydrazinobenzothiazole reaction. However, the experimental values were reproducible within the normal analysis period (Table I). It is, therefore, recommended that a fresh standard curve be prepared with each analysis.

Table II compares the percentages of methenamine ($C_6H_{12}N_4$) found in two different commercial brands of methenamine powder as assayed by the 2-hydrazinobenzothiazole and the NF methods.

3	96.6	99.0	99.0	99.0	91.0
Average	96.6	99.0	100.6	99.0	92.4
± *SD*	0.0	2.0	2.3	2.0	2.0

Only 0.02 μmole of material was needed per determination in this proposed procedure compared to approximately 1 g. or 7.1 mmoles in the NF method. Table III presents the results of assays on methenamine mandelate and methenamine hippurate powders and those on their tablet dosage forms. Tablets were crushed, dissolved, and filtered, if necessary, before an aliquot representing approximately 0.02 μmole was withdrawn for the determination. There appeared to be no significant interference in absorbance where color was formulated in the tablets because of the high dilutions involved in obtaining the extremely small amount of material.

It is clear from these data that the proposed 2-hydrazinobenzothiazole procedure possesses several distinct advantages over the present official methods for the analysis of methenamine or methenamine mandelate. It offers the convenience of a single method for the analysis of either the free base or salts. It has been found to be simple, sensitive, and less time consuming. It does not require prior standardization of a number of titrants, as for nessleriza-tion with the official assay of methenamine mandelate. Furthermore, the proposed method can be used for the assay of other salts of methenamine, unlike the USP procedure. With respect to the NF method, the lengthy period needed for the acid hydrolysis of methenamine using 1 *N* sulfuric acid as well as the uncertain end-point of the hydrolysis can be eliminated with the 2-hydrazinobenzothiazole procedure.

Chromatographic Separation and Assay of Morphine in Injectables

I. J. HOLCOMB, R. B. LUERS, Jr., and S. A. FUSARI▲

Abstract □ A method specific for the determination of morphine sulfate in injectables was developed. Morphine is separated from preservatives, pseudomorphine, and other degradation products by a column chromatographic method. The eluate containing morphine is extracted into an acid solution and determined spectrophotometrically. Recovery from standard solutions is better than 99%. The method presented is more specific for the separation and determination of morphine in injectables than present official methods.

Keyphrases □ Morphine sulfate injection—separation from preservatives and degradation products, UV analysis □ Column chromatography—separation, morphine from preservatives and degradation products, morphine sulfate injection □ UV spectrophotometry—analysis, morphine sulfate injection

Morphine has been well established as an effective analgesic and sedative since its isolation in 1805 (1, 2). Due to the limited solubility of morphine base in aqueous media, the more soluble hydrochloride and sulfate salts have been used in pharmaceutical preparations. The dosage form commonly employed since 1941 has been morphine sulfate as an injectable aqueous solution, since it is the most stable of the morphine salts in solution (3). When stored for a long time or exposed to heat, morphine sulfate injections develop a light-brown color.

The discoloration is not desirable, since decomposition of the dosage form is suggested and is, in fact, taking place; however, the extent of the discoloration is not an indication of the extent of decomposition. The cause has been attributed to the decomposition of morphine sulfate to pseudomorphine and further oxidation products (4–8). Foster *et al.* (5) and later Lach and Yeh (9–11) demonstrated that morphine injections decomposed first to pseudomorphine and then to oxidation products of pseudomorphine. Foster *et al.* (5) also showed that rubber closures contributed to the discoloration of the morphine injection and possibly to the decomposition of morphine sulfate.

Numerous assay methods have been developed for

Spectrophotometric Determination of Methenamine and Its Salts by 2-Hydrazinobenzothiazole

JAMES K. LIM▲ and CONNIE C. C. CHEN

Abstract □ A rapid and sensitive method is described for the assay of the pure powder form and the tablet dosage form of methenamine and its salts. The procedure is shown to be capable of measuring as little as 0.005 μmole of material and is highly reproducible. The proposed method is based on the color development of formaldehyde released from the acid hydrolysis of methenamine with a dye, 2-hydrazinobenzothiazole. Beer's law is obeyed in the concentration range of 1–8 μ*M* of methenamine at 510-nm. wavelength. This method offers greater versatility over the official assay methods, which have been designed primarily for determining specifically either methenamine or its mandelate salt. Data comparing the assays obtained by the official methods with this new technique are presented.

Keyphrases □ Methenamine and salts in powders and tablets—colorimetric analysis using 2-hydrazinobenzothiazole, compared to compendial methods □ 2-Hydrazinobenzothiazole—used as color-forming agent in spectrophotometric analysis of methenamine and its salts □ Colorimetry—analysis, methenamine and salts in powders and tablets

The NF XIII (1) assay for methenamine involves its acid hydrolysis by reflux until the "odor of formaldehyde is no longer perceptible," followed by back-titration with an alkali. The procedure proved to be not only tedious but also subject to inaccuracies arising from human error in obtaining the "perceptible end-point," *i.e.*, absence of formaldehyde odor. The USP XVIII (2) method for determining methenamine mandelate, on the other hand, represents an indirect method of analysis. It essentially involves nesslerization followed by an iodometric titration of the mandelic acid moiety; therefore, this method cannot be employed for determining other salts of methenamine.

Other methods also have been developed for the quantitation of this compound, including those based on chromotropic acid reactions (3–5), the Hantzsch reaction between acetylacetone, ammonia, and formaldehyde (6), and fluorometric techniques (7). This report presents a method for determining methenamine and its salts through the formation of xanthylinum dicationic dyes with formaldehyde and formaldehyde-releasing compounds. Measurements based on such a reaction are reported (8, 9) to be more sensitive than those by chromotropic acid.

EXPERIMENTAL

Apparatus—Absorbance measurements were made on a spectrophotometer[1].

Reagents and Chemicals—2-Hydrazinobenzothiazole[2] was the dye-forming reagent used. Powdered samples of methenamine[3–5], methenamine mandelate[6], and methenamine hippurate[7] were used as received. All other chemicals and reagents used were USP or the highest grade of commercial materials. Several commercial brands of either the plain or enteric-coated tablets of methenamine, methenamine mandelate, and methenamine hippurate were employed for the tests comparing the official assays with the proposed method. The dye reagent consists of a 0.5% solution of 2-hydrazinobenzothiazole in 10% hydrochloric acid. It is stable for 2 weeks.

Assay Procedure—Aqueous solutions of methenamine or the methenamine salt in the concentration range of 0.01–0.08 μmole/ml. were made up in 100-ml. volumetric flasks. A 0.5-ml. volume of each solution was placed in a test tube and mixed with 0.5 ml. of 10 *N* sulfuric acid. The samples were refluxed in a boiling water bath for 15 min. to obtain complete hydrolysis and were allowed to cool to room temperature before the addition of 0.5 ml. of the 2-hydrazinobenzothiazole reagent. After 5 min., 0.5 ml. of a 1% aqueous solution of potassium ferricyanide was added and this reaction was allowed to proceed another 20 min. before the final admixture of 3 ml. of dimethylformamide solvent. The color thus formed was allowed to stabilize for 20 min. before absorbance readings were made at a 510-nm. wavelength against a reagent blank.

Table II—Assay of Commercial Methenamine Powder by the 2-Hydrazinobenzothiazole and NF Methods

Powder	Percent Found—2-Hydrazinobenzothiazole Method	NF Method
A	98.5[a] ± 1.08[b]	98.8
B	96.3 ± 2.07	93.5

[a] Average of three determinations. [b] Standard deviation.

RESULTS AND DISCUSSION

Absorbance of the color obtained of known standards in the concentration range of 0.005–0.04 μmole/5 ml. of methenamine was seen to obey Beer's law. The calculated linear correlation coefficients were: methenamine, 0.9996; and methenamine mandelate and methenamine hippurate, 0.9969 and 0.9975, respectively. Initial studies showed that the slopes might vary from time to time, probably due to aging of the reagents employed with the 2-hydrazinobenzothiazole reaction. However, the experimental values were reproducible within the normal analysis period (Table I). It is, therefore, recommended that a fresh standard curve be prepared with each analysis.

Table II compares the percentages of methenamine ($C_6H_{12}N_4$) found in two different commercial brands of methenamine powder as assayed by the 2-hydrazinobenzothiazole and the NF methods.

Chromatographic Separation and Assay of Morphine in Injectables

I. J. HOLCOMB, R. B. LUERS, Jr., and S. A. FUSARI▲

Abstract □ A method specific for the determination of morphine sulfate in injectables was developed. Morphine is separated from preservatives, pseudomorphine, and other degradation products by a column chromatographic method. The eluate containing morphine is extracted into an acid solution and determined spectrophotometrically. Recovery from standard solutions is better than 99%. The method presented is more specific for the separation and determination of morphine in injectables than present official methods.

Keyphrases □ Morphine sulfate injection—separation from preservatives and degradation products, UV analysis □ Column chromatography—separation, morphine from preservatives and degradation products, morphine sulfate injection □ UV spectrophotometry—analysis, morphine sulfate injection

Morphine has been well established as an effective analgesic and sedative since its isolation in 1805 (1, 2). Due to the limited solubility of morphine base in aqueous media, the more soluble hydrochloride and sulfate salts have been used in pharmaceutical preparations. The dosage form commonly employed since 1941 has been morphine sulfate as an injectable aqueous solution, since it is the most stable of the morphine salts in solution (3). When stored for a long time or exposed to heat, morphine sulfate injections develop a light-brown color.

The discoloration is not desirable, since decomposition of the dosage form is suggested and is, in fact, taking place; however, the extent of the discoloration is not an indication of the extent of decomposition. The cause has been attributed to the decomposition of morphine sulfate to pseudomorphine and further oxidation products (4–8). Foster *et al.* (5) and later Lach and Yeh (9–11) demonstrated that morphine injections decomposed first to pseudomorphine and then to oxidation products of pseudomorphine. Foster *et al.* (5) also showed that rubber closures contributed to the discoloration of the morphine injection and possibly to the decomposition of morphine sulfate.

Numerous assay methods have been developed for

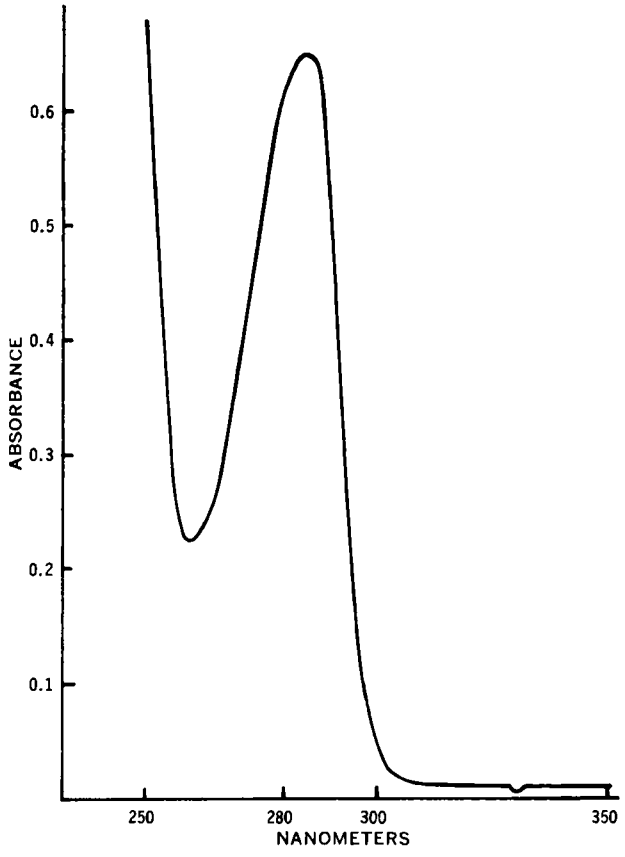

Figure 1—*UV spectrum of morphine sulfate, 0.1622 mg./ml., in 0.05* N *hydrochloric acid.*

the determination of morphine, using gravimetric (12, 13), colorimetric (14–19), fluorometric (20, 21), titrimetric (22, 23), and spectrophotometric (24) procedures. These methods are satisfactory for freshly prepared solutions of morphine sulfate but are not always specific for the determination of morphine in the presence of its degradation products. Ion-exchange (25–27) and partition chromatographic (9, 28–30) methods have been used to separate morphine in pharmaceutical preparations. Most of these procedures are time consuming and are not applicable to routine analysis. A partition chromatographic method was developed (9,

15.10	15.09	99.8

28) for the separation of intact morphine from degradation products; this method was employed in studies on the stability of morphine in aqueous solution (9–11). This procedure was also time consuming. The present USP extraction–titrimetric method (23) extracts small amounts of decomposition products as well as morphine from discolored solutions of morphine injection, giving false, high assay values. When the extracts from the USP procedure were examined by TLC, both morphine and pseudomorphine were found.

The purpose of the present investigation was to provide a simple, rapid chromatographic method specific for the separation of morphine from its degradation products. The same procedure may be employed to separate morphine from such alkaloids as atropine and codeine. The separation of morphine and

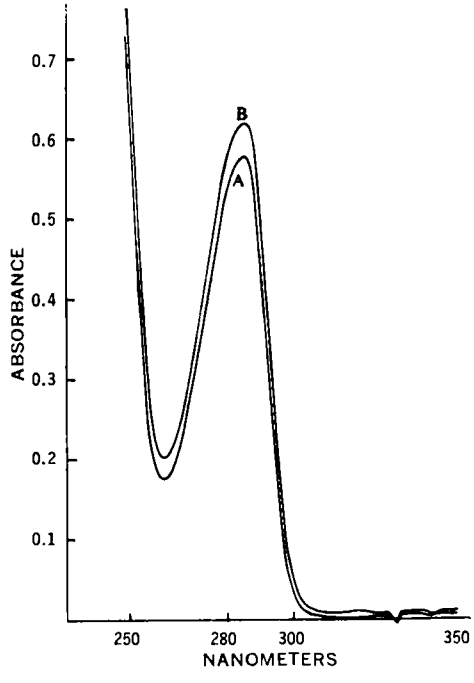

Figure 3—*UV spectra of: A, morphine sulfate, 0.1486 mg./ml., in 0.05* N *hydrochloric acid; and B, morphine sulfate, 0.1486 mg./ml., and pseudomorphine, 0.0075 mg./ml., in 0.05* N *hydrochloric acid.*

	14.32	95.5
B	15.35	102.3
	15.47	103.1

atropine is significant because of the use of these alkaloids in combination for preanesthetic injection.

The procedure involves a release of morphine as the base with the use of sodium bicarbonate. Chloroform elution through an acidic trap layer removes neutral substances such as the parabens and bases such as codeine and atropine. Morphine, which is partially eluted by chloroform, is retained by the acidic trap layer and is finally eluted from the column using isobutanol in chloroform. The decomposition products are retained on the column.

EXPERIMENTAL

Reagents and Apparatus—*USP Grade Chemicals*—The following were used: morphine sulfate, codeine phosphate, atropine sulfate, methylparaben, and propylparaben.

Reagent Grade Chemicals—Reagent grade acid-washed diatomaceous earth[1], sodium bisulfite, isobutanol, chloroform, and anhydrous ether were used. Pseudomorphine base was prepared by oxidation of morphine in a basic solution with potassium ferricyanide (31). The product was washed with methanol and dried. TLC showed only one zone, confirming the purity of the base.

Apparatus—The following were used: 25 mm. i.d. × 15 cm. long chromatographic column[2] with a coarse fritted disk in the base of the column, 1-cm. quartz cells, and a spectrophotometer[3] with a recorder[4].

Separation—In a 100-ml. beaker, 2.0 ml. of 1 *M* pH 6.5 potassium phosphate buffer solution was mixed with 3 g. of reagent grade, acid-washed diatomaceous earth. The mixture was transferred to the chromatographic column and packed firmly. To 1.0 ml. of the test solution in a 150-ml. beaker, 0.5 g. sodium bicarbonate was added and mixed well. Then 3 g. of reagent grade, acid-washed diatomaceous earth was added and mixed well. The mixture was transferred to the chromatographic column and packed firmly. The beaker was wiped with a pledget of glass wool, and the glass wool was placed on the top of the packed column. The column was eluted with 25 ml. of reagent grade chloroform, and the eluate was discarded. The column was then eluted with 55 ml. of 15% (v/v) isobutanol in chloroform, and the eluate was collected in a 250-ml. separator. Water-washed ether, 100 ml., was added to the eluate in the separator, and the contents were carefully mixed. The solvent mixture was extracted with three 25-ml. portions of 0.05 *N* hydrochloric acid. The acid phases were collected in a 100-ml. volumetric flask, and 0.05 *N* hydrochloric acid was added to volume and mixed. The spectrum of the acid solution was obtained from 350 to 250 nm. (Fig. 1). The absorbance maximum obtained at 285 nm. was used to calculate the quantity of morphine sulfate.

Table V—Separation of Morphine Sulfate from Degradation Products

Theoretical, mg./ml.	Conditions of Treatment	Recovery, mg./ml.	Recovery, %
17.00	Initial assay	16.95	99.7
	After 17 days at 105°	15.94	93.8

By employing this chromatographic procedure, aqueous solutions of morphine sulfate and of morphine sulfate in combination with other substances present were assayed.

Morphine Sulfate Solutions—Aqueous solutions of morphine sulfate USP, ranging in concentration from 13.76 to 17.95 mg./ml., were prepared and assayed (Table I).

Morphine Sulfate Standard Formulation—A morphine sulfate aqueous solution was prepared using methylparaben and propylparaben as preservatives and sodium bisulfite as an antioxidant. The standard formulation consisted of the following (mg./ml.): morphine sulfate USP, 15.10; methylparaben USP, 1.69; propylparaben USP, 0.21; and sodium bisulfite, reagent grade, 1.03.

Assay results for the standard formulation are given in Table II.

The standard formulation was modified by the addition of other substances (pseudomorphine and atropine sulfate) commonly associated with morphine sulfate in injectables and with the chemi-

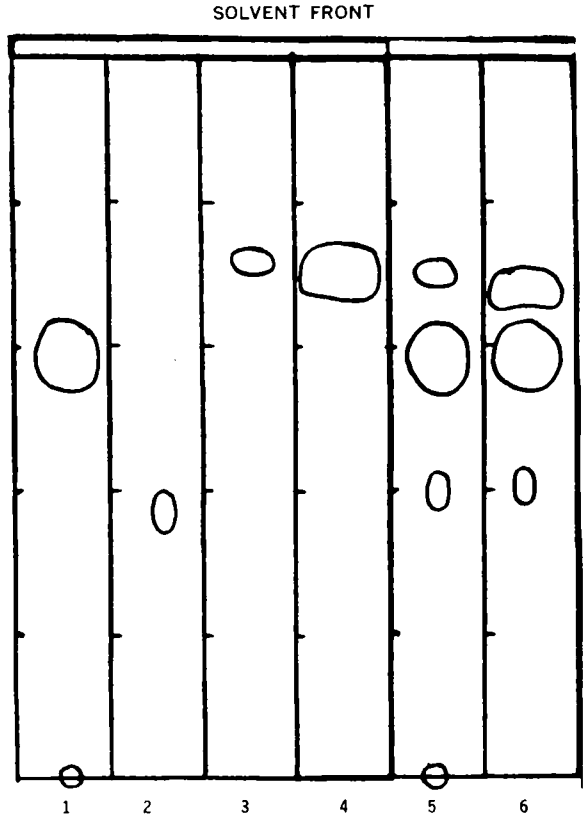

Figure 4—*Chromatogram of reference compounds used in the thin-layer examination study of morphine sulfate, standard formulation, and decomposition products. Key: 1, 150 mcg. of morphine sulfate; 2, 3 mcg. of pseudomorphine; 3, 3 mcg. of morphine* N*-oxide; 4, 18 mcg. of methylparaben and propylparaben mixture; 5, mixture of morphine sulfate, pseudomorphine, and morphine* N*-oxide; and 6, mixture of morphine sulfate, pseudomorphine, and parabens.*

cally related substance codeine. Morphine was successfully separated and quantitatively assayed in the presence of these substances (Table III). These separations were confirmed by TLC. To demonstrate the applicability of this assay method to formulations, samples of morphine injection USP [sulfate], 15 mg./ml., were obtained and assayed (Table IV).

UV Spectra: Morphine and Pseudomorphine—The UV curves of morphine sulfate (Fig. 1) and pseudomorphine (Fig. 2) in 0.05 *N* hydrochloric acid clearly show the spectral differences of the two compounds. The curves in Fig. 3 show the effect of pseudomorphine sulfate at the maximum at 285 nm. Application of the column chromatographic method separates morphine from pseudomorphine and other degradation products.

Separation from Degradation Products—To show the separation of morphine sulfate from degradation products, a solution of morphine sulfate was submitted to conditions to accelerate the decomposition. A solution of morphine sulfate was sealed in a glass ampul and placed in an oven at 105° for 17 days. The solution developed a distinct brown color. The ampul was opened and the contents were assayed. The morphine content definitely decreased, as indicated by the data in Table V. The brown color originally present was retained on the chromatographic column. The morphine eluate and subsequent acid extract were clear and colorless. Thus, the chromatographic system is capable of separating intact morphine from its colored degradation products.

Additional work on the aged product involved assay of room temperature samples which were 4–10 years old. These samples were assayed by both the column chromatographic procedure and GLC (Table VI).

TLC—Complete separation of morphine in the preceding standard mixtures was monitored by TLC. Following the chloroform and chloroform–isobutanol elutions, the chromatographic columns were eluted with 0.01 or 0.05 *N* hydrochloric acid in methanol to remove the remaining decomposition products.

Precoated silica gel GF plates[5] (10 × 20 cm.) were used as the stationary phase. The mobile phase consisted of chloroform–methanol–diethylamine (80:15:5).

Eluates from the chromatographic columns were concentrated to 1 ml. prior to application to the stationary phase. Twenty microliters of each concentrate was applied, and the plates were developed to a height of 15 cm. from the origin. Plates were air dried and examined under long and short wavelength UV light.

In every instance, complete and clean separation of intact morphine was obtained from the other substances present or added (Figs. 4–8).

Table VI—Assay Values on Sterile Morphine Injection in Rubber-Stoppered Amber Glass Vials

5	1968	14.84(91.6)	14.92(92.1)

[a] The GLC assays were performed by Mr. V. G. Davies.

RESULTS AND DISCUSSION

The recovery data in Table I indicate that quantitative recovery of morphine sulfate was obtained from the morphine sulfate solutions assayed. No morphine was detected in the initial chloroform eluate from the chromatographic column. Recovery of morphine sulfate from the morphine sulfate standard formulation was quantitative (Table II). The other ingredients in the formulation did not

Key: 1, 20 μl. of the standard formulation with atropine sulfate; 2, 20 μl. of the chloroform eluate; 3, 20 μl. of the chloroform–isobutanol (85:15) eluate; and 4, 20 μl. of the 0.05* N *hydrochloric acid eluate in methanol.*

interfere with the assay of morphine. The separation of morphine sulfate from the standard formulation with pseudomorphine added was complete and quantitative (Table III). The column chromatographic separation of morphine and pseudomorphine was confirmed by TLC (Fig. 5). Morphine sulfate was quantitatively recovered from the standard formulation with codeine phosphate added (Table III). The codeine was quantitatively recovered in the initial chloroform eluate from the chromatographic column; therefore, it did not interfere with the determination of morphine sulfate. Finally, morphine sulfate was completely and quantitatively separated from the standard formulation with atropine sulfate added (Table III). The atropine was found in the initial chloroform eluate from the chromatographic column. All of the preceding tabulated data indicated quantitative recovery of morphine sulfate from the solutions and mixtures.

CONCLUSIONS

By using this chromatographic procedure, morphine sulfate was separated quantitatively from its degradation products and from other substances present in an aqueous formulation of morphine sulfate for injection and from other alkaloidal salts which might be employed with morphine sulfate in injectables. The method is simple, rapid, and stability indicating for measuring actual morphine content in aged or discolored morphine injections.

Purity Profiles for Heroin, Morphine, and Morphine Hydrochloride

SUE E. HAYS*, LEE T. GRADY*▲, and ALICE V. KRUEGEL†

Abstract □ Purity profiles were established for samples of heroin (diacetylmorphine), morphine, and morphine hydrochloride in order to define the scope of utility of each as qualitative and/or quantitative analytical standards. Systems for solubility analysis and high-pressure liquid chromatography were investigated. A heroin synthesis affording a product of high purity is described.

Keyphrases □ Purity profiles—heroin, morphine, and morphine hydrochloride, phase solubility analysis, high-pressure liquid chromatography □ Heroin—synthesis, purity profile, phase solubility analysis, high-pressure liquid chromatography □ Morphine and hydrochloride salt—purity profiles, phase solubility analysis, high-pressure liquid chromatography □ Phase solubility analysis—purity profiles for heroin, morphine, and morphine hydrochloride □ High-pressure liquid chromatography—analysis, purity profiles, heroin, morphine, and morphine hydrochloride

Increased concern in recent years has given rise to demands for greater specificity and accuracy of analytical procedures for various abuse drugs, notably morphine and heroin. Along with this arises a need for standards for these drugs, having known scopes of utility for known qualitative and quantitative applications. The purposes of this report are to identify analytical procedures of value in determining the purity profiles (1) of these drugs and to define the analytical utility of given samples of the drugs. A synthesis of heroin is described which has yielded material suitable for use as an analytical standard.

METHODS AND MATERIALS

Morphine and its hydrochloride salt were obtained commercially. All reagents used were USP, NF, or ACS grade, except as noted.

Phase Solubility Analysis (2)—The method described in NF XIII (3) was followed. Nine 10-ml. tared glass ampuls were flushed with nitrogen, charged with an appropriate progression of sample weights and a fixed volume (3 ml. by pipet) of solvent, and flame sealed. All solvents were freshly distilled and degassed, starting with spectroquality or commercial distilled-in-glass grades. The bath temperature was 25°, the time allowed for equilibration varied with the drug, and rotation was 28 r.p.m. The residues obtained were dried to constant weight at 130°, except for heroin which was dried at 105°. All samples were kept in the dark when possible or in subdued light. The appropriate Student's t value, two-tailed, was used in calculating (2) the 95% confidence limits. In computing and graphing the system composition, the sample weights used were converted to the anhydrous basis.

Titrations—Commercial equipment[1] was used for all potentiometric titrations (n = 3, averages given in Table I) and the dead-stop end-point titration (duplicates).

Nonaqueous Titration (*4a*, *5*)—The sample was dissolved in 5 ml. of glacial acetic acid and titrated to the potentiometric end-point with 0.1 *N* acetous perchloric acid, using a glass indicating electrode and a calomel reference electrode filled with 0.02 *N* lithium chloride in glacial acetic acid. The titrant was standardized against dried potassium biphthalate. Five milliliters of glacial acetic acid served as a blank.

Chloride—The sample was dissolved in 5 ml. of 1.5 *N* sulfuric acid and was titrated to the potentiometric end-point with 0.1 *N* silver nitrate, using a silver indicating electrode and a mercurous sulfate reference electrode. The titrant was standardized with dried sodium chloride, and 5 ml. of 1.5 *N* sulfuric acid served as a blank.

Moisture (*4b*, *6*, *7*)—An aliquot of sample was dissolved in anhydrous methanol, injected into a vessel containing methanol titrated to the end-point, and titrated with Karl Fischer reagent[2], using the dead-stop end-point technique and a 20-sec. delay. An aliquot of methanol was titrated as a blank. The titrant was standardized by titrating known volumes of water, delivered by gravimetrically calibrated microsyringe. Loss on drying to constant weight was determined on 300-mg. samples at 130°, except for heroin which was dried at 105°.

Spectroscopy—Recording UV[3] and IR[4] spectrophotometers were used to obtain spectra of the samples, and rotation data were obtained using an automatic polarimeter[5]. Absorptivity data in Table I are the averages of triplicates and rotational data are the averages of duplicates.

GLC—The GLC system[6] was as follows: on-column injection; 1.2-m. × 4-mm. i.d. glass columns; methylsilicone gum on silanized, acid-washed, flux-calcined diatomite; cured, conditioned, and tested as described previously (8); helium carrier gas at 50 ml./min.; flame-ionization detector; and automatic digital integrator[7] for area normalization. Temperature programs were 150–250°, and isothermal purity determinations were at 210°. A nonlinear adsorption graph was prepared for 0.5–100-mcg. sample injections of morphine, codeine, heroin, acetylcodeine, and both acetylmor-

[a] Values reported on anhydrous basis. [b] Morphine was the monohydrate (theoretical = 5.9%) and the hydrochloride was the trihydrate (theoretical = 14.4%), with moisture values on the as is basis.

phines. Morphine exhibited a trailing factor of 1.5 at 5% of peak height and efficiency, n = 1500; greater efficiency, n = 2600, was observed for heroin which, in contrast, did not trail. At the 100-mcg. injection level, heroin showed overload effects.

High-Pressure Liquid Chromatography (HPLC)—The HPLC system[8] was as follows: low-pressure mercury, 254-nm., UV detector; electronic integrator[7] for area normalization; and 1.0-m. × 2.2-mm. i.d., prepacked, stainless steel columns. The conditions tried were: (*a*) 40% methanol in water–chemically bonded ether on porous silica, 45°, 600 p.s.i.; and (*b*) pH 8.6 phosphate buffer–octadecylsilane on porous silica, 50°, 850 p.s.i. Strong cation-exchange experiments used a chemically bonded sulfonated fluorocarbon polymer. All solvents were filtered through suitable membrane filters and degassed prior to use.

TLC—Each undried sample was dissolved in methanol and 200, 100, and 20 mcg. were applied with micropipets (Drummond) to glass plates precoated commercially[9] with: (*a*) a 0.25-mm. layer of silica gel containing a fluorescent indicator, or (*b*) a 0.10-mm. layer of microcrystalline cellulose containing a fluorescent indicator. Sample application was made in subdued light, and the spots were dried in a stream of nitrogen and developed to a height of 10 cm. in the dark in glass chromatographic tanks containing one of the seven mobile phases listed. Spots were visualized by one or more of the five agents. Due to the low abundances of organic impurities in these samples and the lack of a common visualization agent, high-low TLC as described elsewhere (1) was not applicable. Some systems (II, III, V, VIII, and IX) were obtained from general references (9, 10). Relative mobility, R_f, of the main spots only are given here.

Systems for Morphine and Its Salt—The systems used were:

I. Glacial acetic acid–ethanol–water (3:6:1), R_f 0.52
II. Methanol–25% ammonium hydroxide (200:3), R_f 0.32
III. Ethanol–pyridine–dioxane–water (10:4:5:1), R_f 0.22
IV. Methanol, R_f 0.30 (cellulose)
V. Benzene–dioxane–ethanol–25% ammonium hydroxide (10:8:1:1), R_f 0.10
VI. Dimethylformamide–ethyl acetate (1:3), R_f 0.25

Systems for Heroin—The systems used were:

VII. Glacial acetic acid–ethanol–water (3:6:1), R_f 0.44
VIII. Methanol–25% ammonium hydroxide (200:3), R_f 0.38
IX. Benzene–dioxane–ethanol–25% ammonium hydroxide (10:8:1:1), R_f 0.46
X. Methanol, R_f 0.38
XI. 2-Propanol–water–glacial acetic acid (8:1:1), R_f 0.72 (cellulose)

Visualization (All Samples)—The following were used: long wavelength UV light (366 nm.), short wavelength UV light (254 nm.), iodine in chloroform spray (0.5%), acidified iodoplatinate spray (0.25 g. of platinic chloride and 5 g. of potassium iodide dissolved in sufficient water to make 100 ml. with 2 ml. of hydrochloric acid added), and acidified iodoplatinate spray followed by exposure to ammonia vapor.

Differential Scanning Calorimetry—Thermograms were recorded[10] from 80° to beyond the melting or decomposition points using microsamples in nitrogen-flushed, open pans.

Heroin Synthesis—Morphine monohydrate (the lot analyzed herein, 350 g., 1.154 moles) and acetic anhydride (99+%; 1095 ml., 1185 g., 11.6 moles) were placed in a 2-l. conical flask, and the resulting suspension was placed on a steam bath and kept at a temperature of 90° for 3 hr. The dark red-brown solution obtained was allowed to stand at room temperature for 3 days. All liquid (acetic acid and acetic anhydride) was removed with a rotary evaporator over a boiling water bath. Sufficient water was added to the solid residue to give an aqueous suspension with a volume of about 2.4 l. The aqueous suspension was cooled in an ice bath and made basic by slow addition, with stirring, of 5% aqueous sodium carbonate.

The pinkish-tan solid which precipitated was collected by filtration, washed twice with water, air dried, and powdered to give 419.4 g. of crude heroin base. Two recrystallizations from acetone afforded 117.9 g. of heroin base as a white crystalline powder, m.p.[11] 173.8–174.7°; molecular ion[12] m/e 369.

Second and third crops of heroin base were isolated from the combined recrystallization filtrates. The second crop consisted of 197.8 g. of a cream-colored crystalline powder, m.p. 172.5–174.1°, and the third crop consisted of 35 g. of a pale-tan crystalline powder,

[8] DuPont model 820 fitted with gradient elution accessory. Column packings were of the same manufacture; an ethereal polymer (ETH), octadecylsilane (ODS), and SCX Permaphase on Zipax support.

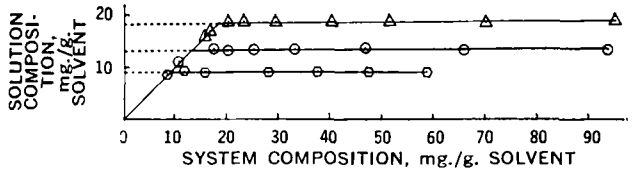

Figure 1—*Phase solubility diagrams of: △, morphine monohydrate in 2:1 methanol–ethanol, solubility (intercept) = 18.4 mg./g., slope (soluble impurity) = 0.38 ± 0.37%, undissolved phase was the monohydrate; ○, heroin in 3:1 hexane–dioxane, solubility = 13.3 mg./g., slope = 0.07 ± 0.71%; and ○, morphine hydrochloride (anhydrous) in ethanol, solubility = 9.2 mg./g., slope = −0.07 ± 0.85%, undissolved phase was the anhydrous.*

m.p. 171.6–173.5°. A total of 350.7 g. (82.3%) of heroin base was obtained.

RESULTS AND DISCUSSION

Heroin (Diacetylmorphine)—Heroin was prepared by acetylation of morphine with acetic anhydride in a manner similar to reported syntheses (11–16). Morphine and acetic anhydride were reacted in direct mixture to form the acetate salt of heroin. The heroin base was then isolated from aqueous sodium carbonate and purified by two recrystallizations from acetone. Product identification was verified by reference to published IR, UV, and rotation data (9, 17–19), in addition to the molecular ion and melting point. Literature melting points vary over a range of 169–173° (12–16).

Solubility analysis was achieved, after several attempts, with 3-day equilibration in a dry hexane–dioxane mixture (Fig. 1). GLC analysis of the undissolved crystals and the residue from the supernate showed that hydrolytic decomposition had not occurred. It is important that the dioxane used be freshly treated with iron dust (20) followed by activated charcoal to remove any peroxides and then distilled to give a dry, residue- and peroxide-free fraction. Solubility analysis in diluted ethanol, 55% in degassed water, failed due to hydrolytic decomposition: 8% after 1 day as determined by GLC. Insoluble impurities were not present in either solubility system. Analyses by GLC of the two phases of the latter system showed that the hydrolysis products did not form solid solutions.

Titrimetric and calorimetric purity data were consistent with the assay by solubility analysis. TLC did not reveal any impurities. Calculation of apparent eutectic impurities was done by the usual Van't Hoff relationship discussed elsewhere (1). Remelt of a sample showed, by the appearance of a probable eutectic endotherm at 4° less than the melting point, that some thermal decomposition had occurred on melting the sample, even under nitrogen.

UV-absorbing impurities were not detected (Fig. 2) by HPLC, using gradient elution in the adsorption–cation-exchange mode. Morphine, codeine, and both acetylmorphines are eluted more rapidly than heroin in this system, the most desirable situation for purity evaluations. These impurities (≤ 0.2%) were ruled out for this sample. The order of elution is that of decreasing polarity of substituents and, presumably, decreasing solubility in the aqueous salt solution. Heroin, 200 mcg., gave 0.065 absorbance unit peak height, with overload effects apparent. Calibration mixtures of O^6-acetylmorphine in heroin exhibited a rectilinear relationship in the peak height ratio (0.05 height ratio unit per 1% impurity). Because HPLC is in an early stage, it was deemed prudent to test the reliability of this system. Three other packed columns, from other laboratories, were tested in this laboratory with similar results. Figure 2 represents intermediate performance.

Acetylcodeine, an important heroin impurity, eluted just prior to heroin and can be estimated only when present in abundance, as is the case for the mixture of authentic drug substances in Fig. 2. Acetylcodeine was completely overlapped by the heroin peak when present to the extent of a few percent, so that GLC would be preferred for the measurement of this impurity in the usual illicit samples of heroin.

Cashman and Thornton (21) reported an adsorption–liquid chromatographic separation of heroin, O^6-acetylmorphine, and morphine, in that order of elution. Unfortunately, heroin eluted first and was poorly separated from acetylmorphine, rendering the system less useful for purity or stability work.

GLC revealed two unresolved peaks (total area 0.15%) at 0.65–0.70 relative retention, which were the two acetylmorphines. This system almost separated them[13] [resolution factor (8) ~0.7]. This level is too low for reasonable correction for nonlinear adsorptive losses. No acetylcodeine was evident in the sample, as would be expected for a sample prepared from morphine of defined purity.

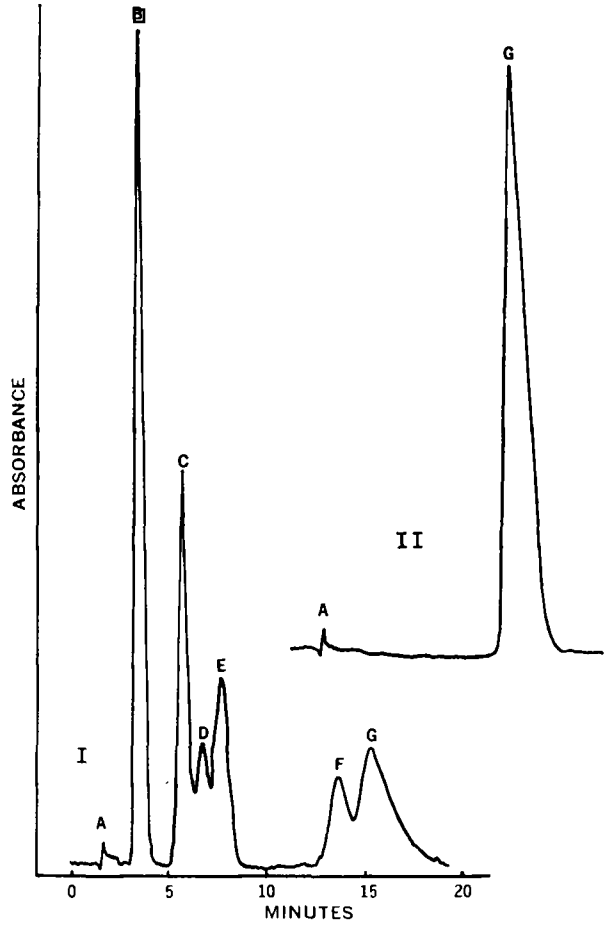

Figure 2—*High-pressure liquid chromatograms of: I, authentic mixture; and II, analytical sample. Key: A, solvent; B, morphine; C, O^6-acetylmorphine; D, O^3-acetylmorphine; E, codeine; F, acetylcodeine; and G, heroin. Gradient elution 0.4–1.4 M sodium perchlorate in 0.01 M pH 6.8 aqueous phosphate buffer containing 10% ethanol; 35°; SCX, 1000 p.s.i.*

The HPLC system is to be preferred over GLC for determining the morphine and acetylmorphine contents of heroin unless several percent of impurities is present so that reasonable correction for nonlinear adsorptive losses can be made. Such losses are characteristic of phenols and commonplace for compounds with several polar functional groups, *i.e.*, morphine and its polar derivatives. It is also characteristic that individual chromatographic systems vary widely in this regard. Because any derivatization step can be the occasion either of purification or decomposition, purity values by such methods (except where a separately defined standard is examined concomitantly) are not considered reliable, even though they may be the basis of entirely satisfactory assay procedures once a standard is otherwise established.

All these purity profile data showed this sample of heroin to be satisfactory for use as an analytical standard in qualitative and quantitative applications.

Morphine Monohydrate—Phase solubility analysis (Fig. 1), using 6-day equilibration, indicated that this sample of morphine was essentially single-component material. Nonaqueous titration results (Table I) were consistent with this indication. The base and hydrochloride were characterized by UV (17) and IR spectropho-

[13] O^3-Acetylmorphine at 0.66, acetylcodeine at 0.68, and O^6-acetylmorphine at 0.71. For comparison, on OV-17/Q these relative retentions (heroin = 1.0) are 0.58, 0.56, and 0.59, respectively, but higher temperatures make this even less desirable as a phase. Silylation (bistrimethylsilylacetamide) does not improve this situation.

tometry (9, 18) and optical rotation (19). The spectra were found to be similar to published spectra and identical to those of another dried sample of morphine.

TLC showed the material to be nearly homogeneous using six systems. One small but distinct impurity was detected which appeared as a yellow fluorescent spot having the approximate mobility of papaverine (orange fluorescence), indicating the possible presence of such a benzylisoquinoline. Semiquantitation (1) was not feasible due to the lack of a common visualization agent. Within the morphine spot was an area of blue fluorescence not separable from the main spot by any solvent system tried; this was interpreted to be pseudomorphine, an artifact (22) of on-plate oxidation, particularly in the presence of ammonia. Two-dimensional TLC did not reveal any additional artifacts.

Temperature-programmed GLC revealed no impurities of greatly different vapor pressures in the morphine sample. Isothermal purity determination showed the two impurities (Table 1) at relative retentions of 0.94 and 4.2, respectively. The retentions of the two impurities resembled those of papaverine and codeine. Spiked samples indicate that the larger impurity may be codeine and the same experiment tends to exclude papaverine. It is not possible at such low levels of impurities to exclude firmly or identify likely impurities without mass spectrograms of the eluted peaks; for example, reagent rather than spectroquality chloroform gives a peak at the same locus as codeine.

In the HPLC of morphine, three packings[14] were tried in both normal and reverse phase modes. Although these packings are among the most reliable available, none yields ideal peak shapes, and substantial adsorptive trailing precluded exact quantitation. Exchange resins also were investigated. Only the reverse phase systems yielded interpretable chromatographic purity data. Electronic area integration did not give useful data because of the contribution of trailing-in from earlier peaks. The single impurity peak had the same mobility as codeine and it is estimated that this is less than 0.5%.

Samples of both dried and undried material were examined by differential scanning calorimetry. Due to decomposition, however, no purity estimate can be made. The undried sample showed a substantial endotherm in the 110–140° region, which represents the removal of water, and a sharp endotherm at about 260° with severe decomposition. A sample dried at 50° *in vacuo* showed only traces of the lower endotherm, and a sample dried at 130° lacked this endotherm completely. No attempt was made to prepare or identify different polymorphs, although polymorphism has been observed for this drug[15].

Drying of morphine monohydrate at 130° was shown by differential scanning calorimetry and Karl Fischer titrimetry to remove all moisture from the sample, and TLC of the dried material indicated no decomposition. Drying of this material, in small amounts for quantitative use, at 130° for 2 hr. in static air is, therefore, recommended.

The purity profile afforded by these data allowed the recommendation of this sample of morphine monohydrate as an analytical standard for both qualitative and quantitative applications.

Morphine Hydrochloride Trihydrate—This sample was found to be nearly homogeneous by TLC with six solvent systems, and these results were essentially the same as those reported for morphine.

Prior to GLC, the hydrochloride salt was converted to the free base by extraction from pH 9.5 buffer into a 10% solution of 2-propanol in chloroform. This same solvent mixture also was used for morphine. Isothermal operation revealed one impurity with a relative retention of 0.94, and temperature programming revealed no additional impurities. Spiked samples suggested that this impurity was codeine, but at such low abundances that positive identification is difficult. HPLC located one minor impurity, similar to that in the morphine sample.

Nonaqueous titration (Table 1) of morphine hydrochloride required that mercuric acetate be added to the titration medium to convert all chloride salts to titratable bases; however, in this system any alkali metal or ammonium ions present also titrate as bases (5), contributing by a disproportionately large amount to the total titration value. Taken with the high chloride content, titrimetry clearly indicates lower molecular weight impurities. The moderate pH value (4.7 using a 2% aqueous solution) excluded excess hydrochloric acid as a significant factor. Chromatographic analyses showed a lack of substantial organic impurity. Inorganic chlorides were indicated, and some sodium was shown to be present by a classic flame test.

Samples of both dried and undried material were examined by differential scanning calorimetry. Due to decomposition, however, no purity estimate was possible. In the 60–110° range, two endothermic peaks were found. No evidence was found of a main melt in the 50–260° range by this technique. A scan of material dried at 50° *in vacuo* showed a slight trace of the two endotherms, whereas material dried at 130° lacked these peaks completely. When taken together with the titrimetric moisture and comparative TLC results, these results substantiate the complete removal of moisture and lack of significant degradation at 130°. The moisture content was found to be consistent with the expected trihydrate form, but the material should be dried prior to use as a semiquantitative standard.

An initial solubility analysis in alcohol (10-day equilibration) gave 2.2 ± 0.4% slope; however, anhydrous drug was isolated as the undissolved phase whereas the trihydrate was used as the sample, indicating that solvent composition was not constant. Coupled with common-ion effects of the inorganic chlorides, this rendered the slope uninterpretable[16] (23), and this slope value was ignored in constructing the purity profile of the sample. An 8-day equilibration of previously dried sample gave a −0.1% slope. Because titrimetry revealed lower equivalent weight chloride salts in the sample, this slope also cannot directly reflect sample composition because the excess chloride equivalent can exert a common-ion effect on the slope that is opposite to the mass impurity effect. Titrimetric values and this latter slope are consistent with the equivalent of 0.5–0.6% sodium and ammonium chlorides.

These data are interpreted as representing an organically pure sample of morphine as the trihydrated hydrochloride salt which contains inorganic material. This would not impair the qualitative utility of this standard. The morphine monohydrate, because of its single-component composition, would be required for *quantitative* use.

SUMMARY

Samples of heroin, morphine, and morphine hydrochloride were evaluated by phase solubility analysis, titrimetric moisture, loss on drying, nonaqueous titration, chloride titration, UV and IR absorption, differential scanning calorimetry, optical rotation, GLC, TLC, and HPLC.

Systems for solubility analysis and HPLC were developed in support of this work. A synthetic method yielding heroin of a high degree of purity is reported.

The purity profiles established for each sample allowed definition of the scope of utility of each as an analytical standard in either qualitative or quantitative applications.

PHARMACEUTICAL TECHNOLOGY

Shear Cell Measurements of Powders: Determination of Yield Loci

E. N. HIESTAND▲, S. C. VALVANI, C. B. PEOT, E. P. STRZELINSKI, and J. F. GLASSCOCK, Jr.

Abstract □ The usefulness of the Jenike-type shear cell and associated procedure for the characterization of some powder bed properties has been established by others. An attempt to use a simpler procedure and a different shear cell and thereby to reduce the quantity of powder required is described. The yield loci obtained are very nearly linear. Multiple-regression analysis is used to obtain characteristic constants from the data for the family of yield loci. Examples of the data obtained for various pharmaceutical powders are presented.

Keyphrases □ Shear cell measurements—simplified determination of yield loci for powders □ Powder bed properties—simplified procedure and shear cell for determination of yield loci

It is postulated that the flow of powder occurs when the forces acting on a powder bed cause the resultant shear force just to exceed the powder bed's shear strength in any given direction. Therefore, the flow characteristics of the powder can be described in terms of an orthogonal set of principal forces. Only two, the major and minor forces, have a significant effect on the location of the shear plane. The magnitude of these forces depends upon the state of consolidation of the powder bed. For many applications, it is adequate to describe the changes of unconfined powder bed properties with the change in the state of consolidation. This description is in the form of a failure function, a plot of the major stress necessary to cause failure of an unconfined bed *versus* the major stress that produced the given state of consolidation.

The failure function can be estimated from shear cell data (1) or a triaxial test method (2); both methods usually fail to provide completely accurate evaluations. The shear cell methods are the most popular. This article briefly discusses the theory relating to these concepts and reports results of studies with a simple shear cell. Also included is a limited comparison of the data obtained with one sample using two different shear cells.

CONCEPTS

Figure 1 shows the direction of forces acting in both the triaxial test and the shear cell. It also shows the Mohr semicircle used to describe the stress balance at failure. With the triaxial method, the major stress, σ_m, and the minor stress, σ_s, are the applied stresses and τ and σ_n are the resultant stresses. Moreover, the angle α is observed, so the corresponding Mohr semicircle can be constructed. With the shear cell, σ_m, σ_s, and α are not determined; only τ and σ_n are known. Therefore, a single measurement does not provide enough information to permit construction of the corresponding Mohr semicircle. When σ_m and σ_s are of the correct magnitude to produce failure, *i.e.*, shearing of the powder bed, then τ and σ_n appear on the circle. As can be seen from Fig. 2, the principal stress, σ_i, which is intermediate in magnitude, does not influence the failure. The resultant τ and σ_n values represented by the Mohr semicircles involving σ_i are always less than any τ, σ_n values on the semicircle between the major and minor principal stresses. There-

PHARMACEUTICAL TECHNOLOGY

Shear Cell Measurements of Powders: Determination of Yield Loci

E. N. HIESTAND▲, S. C. VALVANI, C. B. PEOT, E. P. STRZELINSKI, and J. F. GLASSCOCK, Jr.

Abstract □ The usefulness of the Jenike-type shear cell and associated procedure for the characterization of some powder bed properties has been established by others. An attempt to use a simpler procedure and a different shear cell and thereby to reduce the quantity of powder required is described. The yield loci obtained are very nearly linear. Multiple-regression analysis is used to obtain characteristic constants from the data for the family of yield loci. Examples of the data obtained for various pharmaceutical powders are presented.

Keyphrases □ Shear cell measurements—simplified determination of yield loci for powders □ Powder bed properties—simplified procedure and shear cell for determination of yield loci

It is postulated that the flow of powder occurs when the forces acting on a powder bed cause the resultant shear force just to exceed the powder bed's shear strength in any given direction. Therefore, the flow characteristics of the powder can be described in terms of an orthogonal set of principal forces. Only two, the major and minor forces, have a significant effect on the location of the shear plane. The magnitude of these forces depends upon the state of consolidation of the powder bed. For many applications, it is adequate to describe the changes of unconfined powder bed properties with the change in the state of consolidation. This description is in the form of a failure function, a plot of the major stress necessary to cause failure of an unconfined bed *versus* the major stress that produced the given state of consolidation.

The failure function can be estimated from shear cell data (1) or a triaxial test method (2); both methods usually fail to provide completely accurate evaluations. The shear cell methods are the most popular. This article briefly discusses the theory relating to these concepts and reports results of studies with a simple shear cell. Also included is a limited comparison of the data obtained with one sample using two different shear cells.

CONCEPTS

Figure 1 shows the direction of forces acting in both the triaxial test and the shear cell. It also shows the Mohr semicircle used to describe the stress balance at failure. With the triaxial method, the major stress, σ_m, and the minor stress, σ_s, are the applied stresses and τ and σ_n are the resultant stresses. Moreover, the angle α is observed, so the corresponding Mohr semicircle can be constructed. With the shear cell, σ_m, σ_s, and α are not determined; only τ and σ_n are known. Therefore, a single measurement does not provide enough information to permit construction of the corresponding Mohr semicircle. When σ_m and σ_s are of the correct magnitude to produce failure, *i.e.*, shearing of the powder bed, then τ and σ_n appear on the circle. As can be seen from Fig. 2, the principal stress, σ_i, which is intermediate in magnitude, does not influence the failure. The resultant τ and σ_n values represented by the Mohr semicircles involving σ_i are always less than any τ, σ_n values on the semicircle between the major and minor principal stresses. There-

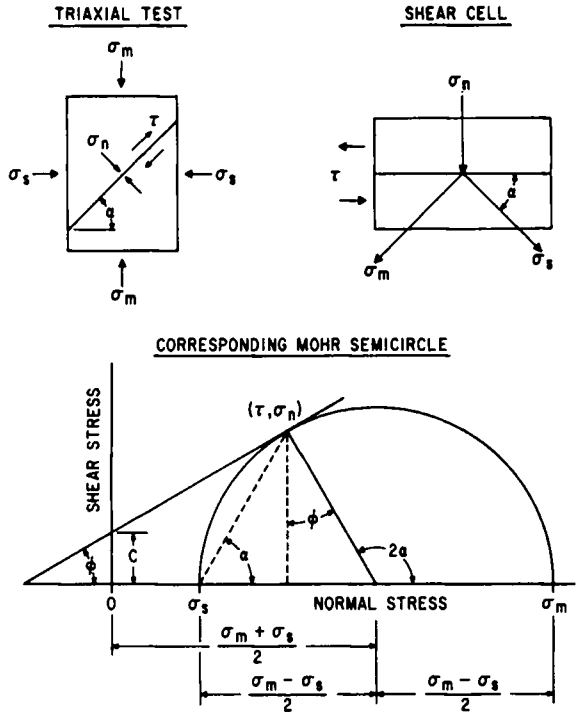

Figure 1—*Relationship of the triaxial test, the shear cell, and the Mohr semicircle. The stress equations are:*

$$\tau = \tfrac{1}{2}(\sigma_m - \sigma_s) \sin 2\alpha$$
$$\sigma_n = \tfrac{1}{2}(\sigma_m + \sigma_s) + \tfrac{1}{2}(\sigma_m - \sigma_s) \cos 2\alpha$$

Their relationship to the Mohr semicircle is obvious.

fore, the two-dimensional representation of the Mohr semicircle is adequate where the precision required is not outside the limits of the simple shear failure model.

Figure 3 is developed from the triaxial diagram, but it applies also to the shear cell. It shows the relationship between the angle α and the internal friction coefficient, which for this discussion is designated μ and is assumed to be a constant. By using any given combination of σ_m and σ_s that produces failure, the resultant magnitudes of the normal and shear stresses at any angle, α, may be calculated. These resultant stresses are σ_α and τ_α, respectively; τ_s is the shear strength of the powder bed. It is calculated from the friction coefficient, μ, the normal stress, σ_α, and an apparent cohesion, C. When τ_α is equal to τ_s, the angle of failure in shear is determined. At this point, $\mu = \tan \phi$.

A series of combinations of σ_m and σ_s can be found that produce shear failure with any given state of consolidation of a powder bed. When the corresponding τ and σ_n values are plotted, a yield locus may be drawn through the points. Each respective Mohr circle will be tangent to the yield locus, and it is this property that permits the shear cell to be used to determine α. A series of values obtained with

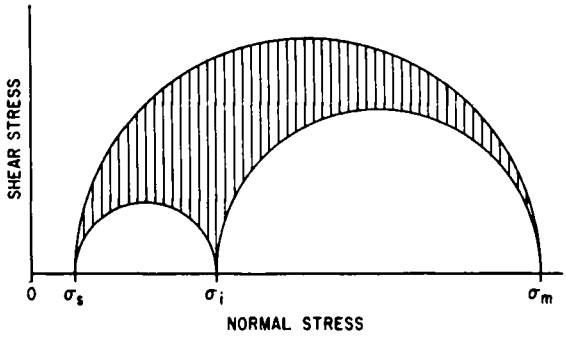

Figure 2—*The Mohr semicircles show that the largest shear stresses are produced as a resultant of the major and minor principal stresses, σ_m and σ_s, and not as a resultant of the intermediate principal stress, σ_i, with either σ_m or σ_s.*

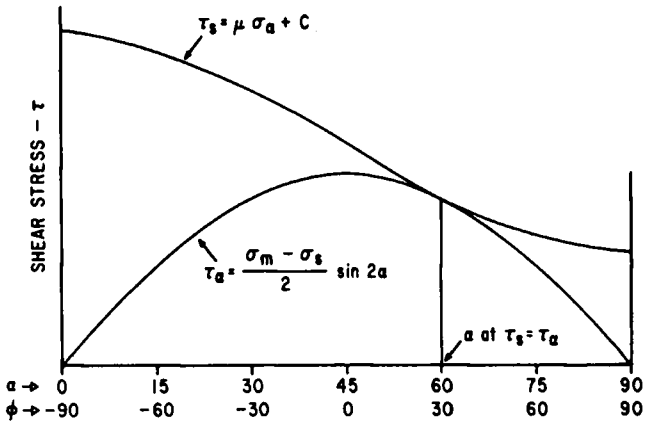

Figure 3—*Failure occurs at the angle where the resultant shear stress, τ_α, is equal to the shear strength, τ_s. Note that the shear strength results from the internal friction and cohesion. The change of both τ_s and τ_α with change in ϕ or α is shown; ϕ is the angle of friction and is equal to $2\alpha - 90°$.*

the shear cell determine a yield locus. Any corresponding combination of σ_m and σ_s can be obtained by drawing a Mohr circle tangent to the yield locus through the τ, σ_n point of interest.

SHEAR CELL DESIGN AND TREATMENT OF DATA

Probably the most popular shear cell design is that of Jenike (1). Schwedes (3) showed that the shear region in the cell has a lenticular shape. However, Williams *et al.* (2) claimed that the results are consistent with the triaxial test. Schwedes used a shear cell similar to that of Roscoe (4) and a very low, constant rate of shear. His choice of cells was, in part, based on the conclusion that the stress conditions in the Jenike cell cannot be determined.

In the authors' laboratory, the choice of cells was based on the need to work with small amounts of powders and to accumulate useful data rapidly. It was hoped that the stress distributions would be more uniform and easily defined in a thin layer of powder because the shear region would be restricted. A modification of a cell described by Nash *et al.* (5) was adopted, and a method of obtaining reproducibly a given state of consolidation was developed. The shear cell (Fig. 4) consists of a thin layer of powder between two sandpaper-covered surfaces (see *Appendix* for details). To determine a yield locus, the powder is brought to a reproducible state of consolidation by repeatedly initiating shear in the powder bed while keeping the normal load constant. The shear stress is returned to zero as soon as possible so that minimal movement occurs. After a series of shear initiations, the observed shear force becomes constant. This is called the plateau condition and is the reference state of consolidation for the powder under that specific applied load. The cell and procedures were described previously (6, 7). The plateau load is the maximum load in a given yield locus. Other points on the yield locus are obtained by reducing the load after a plateau condition has been reached; then shear is initiated just once after the load is reduced. The reduced load and resultant shear force provide one point on the yield locus, and this procedure is repeated to obtain additional points. Different yield loci are obtained by

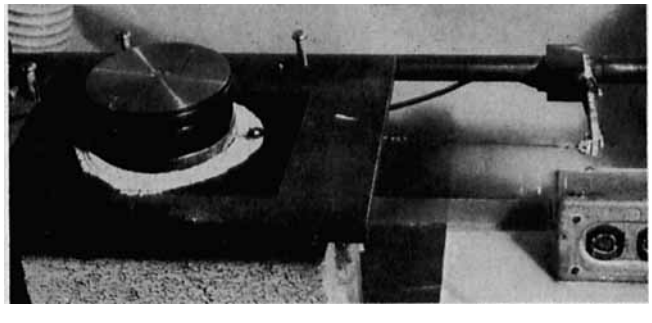

Figure 4—*Simple shear cell.*

Table I—Results of Shear Cell Studies of β-Sitosterol (40 Mesh)

	35-Point Data	Replicate 14-Point Data	14 Points from 35-Point Data
Estimate of tan ϕ	0.660	0.657	0.666
95% confidence interval for tan ϕ	0.635, 0.685	0.616, 0.698	0.626, 0.706
Estimate of tan β	0.167	0.166	0.162
95% confidence interval for tan β	0.146, 0.188	0.134, 0.198	0.131, 0.193

[a] Kilodynes/cm.^{2}.

using a different normal load to attain the plateau condition and then reducing the load from that state of consolidation.

Reducing the load after reaching a state of consolidation leads to partial elastic recovery of the powder bed. Thus, the yield locus is determined under conditions analogous to those used in evaluating other solids, *i.e.*, yield conditions under various elastic stresses; this differs from the dynamic steady-rate condition used with the other cells already discussed. This simple cell can be criticized in several ways. Obviously, it is difficult to demonstrate that the shear plane is in the powder and not at the sandpaper surface. Also, edges of the cell may not have powder under identical stress and consolidation conditions as the interior regions of the cell. However, the thin layer of powder helps to minimize these effects and, of course, requires less powder, an important consideration when working with expensive medicaments.

Powders are more complex than ordinary solids because powders have a broad range of consolidations. The shear strength changes with the state of consolidation. Thus, instead of one yield locus characterizing the powder, a family of yield loci is necessary, one for each state of consolidation. With the procedure used in this study, the plateau load is the principal factor in determining the state of consolidation. Empirically, it has been found that the family of yield loci corresponds to a simple relationship:

$$\tau_r = \sigma_r \tan \phi + \sigma_p \tan \beta + b \qquad \text{(Eq. 1)}$$

where subscript r denotes the reduced load values, subscript p denotes the plateau or consolidation condition, and tan ϕ is the internal friction coefficient; $\sigma_p \tan \beta + b$ describes the apparent cohesion (C in Fig. 1), and, therefore, tan β is the rate of change and b is the intercept of the apparent cohesion function.

These relationships and related equations were described previously (7). Equation 1 is the classical empirical law of friction, with additional terms to account for the different states of consolidation.

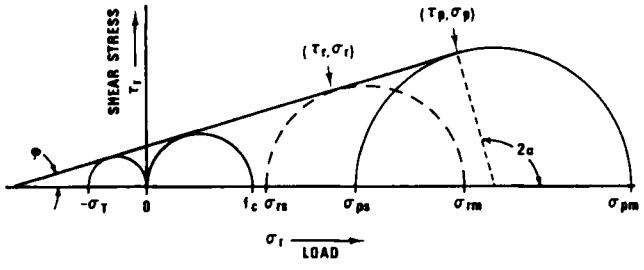

Figure 5—*Mohr semicircles, drawn tangent to a linear yield locus, that represent the plateau condition between* σ_{ps} *and* σ_{pm}, *a reduced load condition between* σ_{rs} *and* σ_{rm}, *the unconfined yield stress* f_c, *and the ultimate tensile strength* σ_T.

Table II—Loads Used on an 8.8-cm. (3.5-in.) Diameter Cell in Shear Cell Studies[a]

Plateau Load	Reduced Load				
3352	3109	2372	1392	902	412
(2862)	(2770)	(2170)	(1420)	(920)	(412)
(2372)	2274	1882	1392	902	(412)
(1980)	1882	(1587)	1196	804	412
(1588)	(1490)	1294	902	706	412
(1196)	1147	1000	(804)	608	412
(902)	(853)	(706)	(608)	(510)	(412)

[a] All values are in kilodynes. The 14-point data are indicated by parentheses.

The individual yield locus is associated with only one state of consolidation. Therefore, it is not surprising that it is linear[1] since the conditions become identical to those between two large pieces of solid, where the linear relationship is the accepted and expected result. Different equations have been used with data obtained with the Jenike shear cell. The Warren Springs equation[2] is said to provide adequate flexibility in describing nonlinear yield loci such as those obtained in the dynamic conditions used with the Jenike cell (8). However, it would have to be modified to incorporate the large tensile strength values observed here. The simplicity of a linear relationship permits other interesting relationships (*e.g.*, Eqs. 2 and 3) to be derived readily (7).

In the authors' laboratory, values of τ_r, σ_r, and σ_p are used in a multiple-regression analysis[3] to obtain estimates of tan ϕ, tan β, and b. These values may be used to determine the failure function and the ultimate tensile strength function. Equation 2 is the former and Eq. 3 is the latter:

$$f_c = \left[\frac{2 \cos \phi \tan \beta}{1 + \cos \phi \tan \beta}\right]\sigma_{pm} + \frac{2b(1 + \sin \phi)}{\cos \phi (1 + \cos \phi \tan \beta)} \qquad \text{(Eq. 2)}$$

$$\sigma_T = \left[\frac{1 - \sin \phi}{1 + \sin \phi}\right]f_c = \left[\frac{2(1 - \sin \phi)^2 \tan \beta}{\cos \phi(1 + \cos \phi \tan \beta)}\right]\sigma_{pm} + \frac{2b(1 - \sin \phi)}{\cos \phi(1 + \cos \phi \tan \beta)} \qquad \text{(Eq. 3)}$$

Equations 2 and 3 are derived from Eq. 1 and the geometric relationships shown in Fig. 5; σ_{pm} is the major consolidation stress, f_c is the unconfined yield stress (the major principal stress when the minor one is zero); and σ_T is the ultimate tensile strength. The ultimate tensile strength is the strength a powder bed would have in tensile failure if conditions comparable to those in the shear cell could be

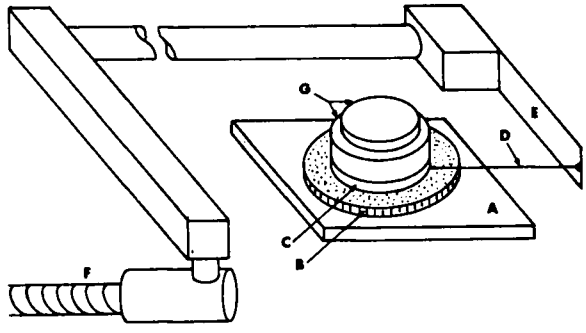

Figure 6—*Arrangement of apparatus. Key: A, bottom plate of shear cell; B, powder bed; C, top plate of shear cell; D, tow line; E, strain gauges; F, jack (motor driven); and G, weights.*

[1] Some deviation from linearity is observed. However, for many materials (*e.g.*, β-sitosterol) the tensile strength is too large to conform to the curvilinear model. Therefore, the linear model has been proposed.

[2] The Warren Springs equation is of the form $(\tau_r/C)^n = (\sigma_r/S) + 1$ where τ_r, σ_r, and C have the same meaning as already given, S is the tensile strength, and n is an empirical constant.

[3] The point (τ_p, σ_p) usually is below the corresponding yield locus. Therefore, it is not used in the multiple-regression analysis. A procedure analogous to that used by Jenike in a similar situation (1) is used here; *i.e.*, a $f(\tau_r, \sigma_r)$ point is determined where σ_r is approximately 95% of σ_p. This is the largest value used in evaluating an *individual* yield locus.

Table III—Tan ϕ Calculated by Least Squares for Each Individual Yield Locus[a]

realized in a tensile strength measurement. Of course, the value also is based on the assumption that the yield locus is linear into the tension region so that the extrapolation is valid; this is not easily demonstrated. However, comparison of the tensile strengths calculated from shear cell measurements with values obtained using the diametral compression method of evaluating compacts provides strong evidence that, at least in some cases, the extrapolation is not grossly in error (7).

RESULTS AND DISCUSSION

To illustrate the reproducibility of evaluations of powders with this cell, some experimental results are included in the tables. Table I shows the observed properties of a β-sitosterol sample, and Table II shows the normal load forces used in this study. Column 1 of Table I shows the results of using a 35-point determination. The middle column is for a duplicate determination in which only 14 points were collected. The normal loads for these 14 points are shown in parentheses in Table II. The last column of Table I shows the results when the corresponding 14 data points (those in parentheses) are selected from the 35-point data. The 35 points defined seven yield loci. Table III shows the values of these slopes, tan ϕ, for each individual yield locus. As illustrated by this example, tan ϕ often is less for small conditioning loads. Note that the multiple-regression analysis yields a value for tan ϕ characteristic of the yield loci for larger conditioning loads. The slope and intercept values for the corresponding failure functions, Eq. 2, are given at the bottom of Table I. These variations are larger than desired but they are believed to be respectable when one allows for the great difficulties experienced in evaluating powders.

Table IV illustrates the usefulness of the shear cell data. Two different, small production lots of a new drug were compared. Shear cell measurements were not necessary to reveal that the flow properties of the two lots were different. Lot A would not fall through a coarse screen without agitation, but Lot B fell through unless carefully placed on the screen. Obviously, both lots had poor—but not equally poor—flow properties. Both, the slope and intercept of the failure function, f_c *versus* σ_{pm}, indicate poorer flow characteristics for A than for B. Thus, the shear cell study measured quantitatively the differences. It also established that these differences were not due just to the equilibration with different atmospheres. Obviously, it is important to determine what causes variations such as those in Table IV, but the ability to measure meaningful flow properties must come first. Unfortunately, small differences in measured values are not always significant. The determinations are not accurate to the three significant figures shown in the tables, but the multiple-regression analysis yields the associated confidence limits to serve as guides to the significance of the values.

Table V shows the values obtained in two different equilibrium humidity environments for sucrose, starch, and a mixture of the two powders. It is obvious that the starch is a less cohesive powder than the sucrose, especially at the lower humidity. Furthermore, the starch is effective at the 25% level in imparting low cohesiveness to the mixture when the humidity is low. At higher humidity, the influence is less. Again, these data are included to illustrate the shear cell method of evaluation. No explanation of the observed effects are established at this time.

The only data available to the authors are inadequate for a thorough comparison of the results with the simple shear cell method described here and the Jenike method. However, the available data are included to provide a limited comparison and to illustrate some problems in evaluating powders. A powder mixture was submitted to a commercial laboratory, one that uses the Jenike cell and procedures. They made only a six-point determination, three points on each of two yield loci, and reported the failure function graphically. It was equivalent to $f_c = 0.186\ \sigma_{pm}$. The values of f_c and σ_{pm} were obtained by drawing Mohr semicircles tangent to the yield loci. For comparison, the multiple-regression analysis method was applied to their data (Table VI). In the authors' laboratory, the simple shear cell was used to obtain a 40-point determination on the same lot of material (Table VI). It is difficult to compare 40-point and 6-point data except through statistical values, such as in Table VI. It is obvious that improved precision would be desirable. The simple cell used in this study was only 5.1 cm. (2 in.) in diameter. Later, the diameter was increased to 8.8 cm. (3.5 in.) and significant improvement in precision resulted. The other data reported in this paper were obtained with the larger cell.

The graphs submitted by the commercial laboratory showed that one data point had been omitted in their analysis. The last column of Table VI shows the results of the multiple-regression analysis when the same point is omitted. Since only three points were available to determine a yield locus, rejection of one left only two. The criterion for such a selection is not obvious, but certainly it improves the multiple-correlation coefficient. Also, the calculated failure function corresponds much more closely to the one reported graphically.

CONCLUSION

The examples discussed demonstrate that the simple shear cell can be used to provide characterization of the unconfined yield strengths of powders. It is not anticipated that the results will be identical to those obtained by different procedures. However, the simplicity of the system and the use of small quantities of powder make this approach attractive. In time, definitive work may determine which procedure and cell yield the most accurate data.

APPENDIX: SHEAR CELL AND POWDER BED PREPARATION

A 12- by 16-cm. piece of 50-grit X-weight aluminum oxide emery cloth is bonded (using double-sided pressure sensitive tape) to a level, heavy piece of steel plate to form the bottom element of the shear cell. A 12.4-cm. diameter disk of the same material is bonded to the bottom of a 12.4-cm. diameter brass disk to form the upper element. A small steel hook is silver soldered to the bottom of the edge of the brass disk to provide a connection for pulling as near to the shear plane as possible.

A hole of 10.5-cm. diameter is made in a piece of aluminum plate to serve as a template for forming the powder bed. Plates of various thicknesses are available, permitting a choice in powder bed thickness. The initial thickness of the powder bed usually is 0.31 cm. (0.125 in.) with coarse materials and 0.15 cm. (0.06 in.) with fine materials. The template is placed over the bottom emery cloth, and powder is sifted into the hole of the template. A spatula is used to scrape across the plate to level the powder while avoiding packing of the bed. Excess powder is pushed out of the way and the template is removed. The top element of the shear cell is placed gently onto the powder bed, and the steel tow line from the strain gauge is placed over the hook. Care is exercised to assure that the pulling motion is parallel to the plane of the powder bed (Fig. 6).

A series of thin brass weights are made from brass cylinders to facilitate stacking and removal of selected weights. After placing the desired weights on the top element of the cell, shear is induced by moving a cantilever-type strain gauge. The elastic deflection of the gauge beam is 6.2 mm./kg. The magnitude of this deflection influences the movement of the top element of the shear cell each time shear is initiated. Excess movement affects the magnitude of stress on the next shear initiation.

Computer Optimization of Pharmaceutical Formulations II: Application in Troubleshooting

JOSEPH B. SCHWARTZ*▲, JOEL R. FLAMHOLZ†, and ROBERT H. PRESS*

Abstract □ The computer optimization technique presented in a previous paper was applied to a practical situation. The data generated by the set of statistically designed experiments and the subsequent computer analysis were used to indicate the directions necessary to improve various characteristics of a production tablet. Data from experimental size and production size batches are compared with computer predictions.

Keyphrases □ Computer optimization of pharmaceutical formulations—application in troubleshooting production tablet characteristics □ Formulation of pharmaceutical preparations—computer optimization, troubleshooting production tablet characteristics □ Pharmaceutical technology—application of computer optimization to troubleshooting characteristics of a production tablet

The previous paper in this series (1) described the general procedure used for computer optimization developed in these laboratories. The ability of the program to aid in the selection of a formulation with optimum properties was demonstrated.

The optimization technique can be useful in the development of a product by virtue of its capacity to generate a large amount of information and thus help the investigator understand his or her system. The present article reports on the practical application of such a program to another problem area in the pharmaceutical industry—troubleshooting.

The model system originally selected for the optimization study was a product formula. During the development of the optimization technique, it was learned that this product was experiencing some rejections in the production area for failure to meet a dissolution specification. Therefore, dissolution became the response of primary interest, but the objective was to increase the dissolution response without sacrificing other tablet properties.

For practical purposes, in this case a product that was already in production, the experimental range used to collect data for the optimization study was too large. That is, many possible solutions were located where the level of a given ingredient was outside the limits specified in the New Drug Application (NDA) for the product (2). Nevertheless, the results of the optimization procedure were useful because they pointed in the direction of an improved formulation.

Table I—Directions for Improvement from First Grid Search

Independent Variable		Qualitative Level
X_1	Diluent ratio	High
X_2	Compressional force	High[a]
X_3	Disintegrant level	High
X_4	Binder level	Low
X_5	Lubricant level	Low

Dissolution, % dissolved at 50 min.	37.13	84.33
Friability, %	0.29	2.44

EXPERIMENTAL

The data utilized here are the same data discussed previously (1). The results of the 27 optimization experiments were analyzed according to the procedures outlined, and the predictions in this paper are based on the second-order regression equations generated[1]. Any additional measurements were carried out by the methods previously reported (1).

RESULTS AND DISCUSSION

The "grid search" program discussed previously (1) resulted in eight choices for an optimum formulation. Although they all contained ingredient levels unacceptable to the present very constrained problem, a trend was noted (Table I).

To test these predictions, it was decided to prepare a formulation with each variable set at its NDA limit in the direction specified by Table I. The method of preparation was identical to that for the 27 optimization experiments, *i.e.*, different from the production method. The initial interest was primarily in trends or qualitative results so that differences in batch size, equipment, lot numbers of material, and test methods were not of immediate concern.

The responses of primary interest for this formula as well as for a sample from production are shown in Table II. The dissolution response had indeed been improved by the changes.

For obvious reasons, as few changes as possible should be made in a production formula. The disintegrant level and the lubricant level, since they are added in the dry state at the end of the process, would be changed most easily.

[1] The predicting ability of individual equations is discussed in *Reference 1*.

Table IV—Computer-Predicted and Experimental Values for Tablet Responses

Response	Production Formula —Prepared on Laboratory Scale— Predicted	Experimental	Recommended Change —Prepared on Laboratory Scale— Predicted	Experimental

[a] Samples not available for measurement.

Unlubricated granulation was obtained from the production area and lubricated with the dry "adds" at two levels: (*a*) at the production level and (*b*) with the disintegrant and lubricant levels changed to NDA limits. The responses for the two sets of tablets are shown in Table III. Since the production material responded in the same manner as the experimental material (*i.e.*, dissolution improved with the changes in lubricant and disintegrant), such changes were recommended, although of a lesser magnitude.

As a test, two formulations were prepared in the laboratory. One was prepared with the production formula and one with the recommended changes; the changes involved an increase in disintegrant of 0.4 mg./tablet and a decrease in lubricant level of 0.35 mg./tablet.

By using the appropriate coding in statistical units, the computer was asked to perform the same experiments. The results are shown in Table IV. It is important to note that the predicted change is *qualitatively* correct for each response listed. That is, the predicted change and the experimental change are always in the same direction. This in itself makes the optimization program useful. It *can* point in the direction of an improved formulation.

In addition, many computer predictions in the table are quantitatively matched by experimental results. This, of course, is the ultimate goal of the optimization technique and an ideal situation.

As a final test, since the recommended formula performed satisfactorily in the laboratory, a production sample was necessary. Table V represents predicted and experimental values for the responses for tablets prepared totally in production. These data were obtained using the testing procedures previously mentioned (1). For the improved formulation, the dissolution value obtained by the quality control procedure (increased rotation) is approximately 100%. The results were further substantiated by many subsequent production batches.

CONCLUSIONS

The optimization technique is useful in troubleshooting as well as in the development of a new formulation. Because the statistical design and the computerized calculations result in an understanding of variable interactions, more than one variable can be changed at a time with predictable results. Very small changes in ingredient levels result in significantly improved tablet properties, which are adequately reflected in the computer predictions.

It is unlikely that one would carry out an optimization study if faced with the specific problem presented here. An improved formulation would eventually have been found by trial and error; but, if the optimization information is available, its use allows the investigator to reduce the time necessary to accomplish this objective.

The point to be emphasized is that once the optimization data have been generated (usually during development), it can be of great utility in a troubleshooting situation.

Performance of Tablet Breaking Strength Testers I: Intralaboratory Comparison and Prediction

J. F. BAVITZ, N. R. BOHIDAR, J. I. KARR, and F. A. RESTAINO▲

Abstract □ Two motorized and two manually powered instruments were used to measure the breaking strength of tablets of three different shapes, each of two sizes and each at three different target breaking strength values. The experimental results were statistically analyzed. The uniformity among breaking strength testers was compared and these results are presented. A high correlation among devices was observed, allowing for the derivation of regression equations which could be used to predict precisely the breaking strengths from one instrument to another. Manually operated instruments tended to yield lower and more variable values than those of their electrically powered counterparts. Tablet shape and size were also found to affect the uniformity and consistency of tablet breaking strengths.

Keyphrases □ Tablet breaking strength—comparison among six different tablets and four hardness testers, effect of tablet tester, tablet size and shape, and target breaking strength □ Instruments for testing tablet breaking strength—characterization, comparison, effect of tablet shape and size, regression equations to predict breaking strength values □ Breaking strength testers for tablets—comparison among six different tablets and four hardness testers

Resistance to breaking, more commonly referred to as hardness, is one of the most important parameters measured as indexes of a pharmaceutical tablet quality. Available to the development pharmacist is a wide and ever increasing variety of instruments[1] designed for measuring this property.

Frequently during the development of a pharmaceutical tablet formulation, the researcher, either out of personal preference or because of availability limitations, uses one instrument for making breaking strength measurements on the formulation he or she is developing. In the interest of consistency, this instrument is usually used throughout the development program. The assignment of specifications for the final product is then based on the specific tablet tester used. It has been observed that the breaking strength of the same product can be different when a tablet tester other than the one specified is used for measurement. Such occurrences frequently arise in multinational organizations where more than one manufacturing site exists. Presently, there are no known procedures available to the pharmacist for converting specifications based on one device to those of another.

A resolution of this problem was, in part, the purpose of the work described here. More specifically, an attempt was made to: (*a*) characterize a selected number of tablet breaking strength testers with respect to their uniformity, consistency, and average values for a number of selected target breaking strengths; (*b*) compare the testers with respect to their averages and variances; (*c*) study the effect of tablet shape and size on tablet breaking strength values associated with each tester; (*d*) study the combined effect of the three factors (tablet testers, shape and size, and target breaking strength) on values; and (*e*) estimate the correlation between breaking strength values associated with the tablet testers and develop regression equations to predict breaking strength values of one instrument from those of another.

[1] A partial list would include the Stokes (formerly Monsanto) tester (Stokes Compacting Division, Pennwalt Corp., Warminster, Pa.), the Heberlein tester (Cherry-Burell, Park Ridge, Ill.), the Ahiba tester (Gubelin International Corp., Mount Kisco, N. Y.), the Pfizer tester (Chas. Pfizer & Co., Brooklyn, N. Y.), the Strong-Cobb tester (Strong-Cobb Inc., Cleveland, Ohio), and the Erweka tester (Chemical and Pharmaceutical Industry Co., New York, N. Y.).

HISTORICAL

In marked contrast to the past, a large number of instruments for measuring tablet breaking strength has been made available recently to the pharmaceutical industry. It was not until the early 1930's that the first instrument for measuring tablet breaking strength, the Monsanto (now Stokes) tester, became available. Since, then, elaborate studies on tablet breaking strength and related equipment have been completed and reported. Nutter Smith (1–5) for example, studied and discussed conditions that influence the resistance of tablets to normal "wear and tear"; two devices, one each for testing the breaking point of tablets and effects of abrasion; and two instruments for measuring the surface hardness of tablets. None of the equipment Nutter Smith studied, however, other than the Stokes tester has received wide acceptance in the industry.

In the decade of 1940–1950, the Strong-Cobb testing device became available and continues to enjoy wide appeal. Subsequently, Fairchild and Michel (6) described and evaluated the Pfizer tablet tester and compared it against the Stokes tester for ease of operation, accuracy, and reliability. In 1961, Endicott *et al.* (7) reported on an instrument they developed and evaluated which produced values of tablet breaking strength expressed in terms of fracture resistance. De Lonca *et al.* (8) reported on work with two devices (the Dynestat and Erweka) for measuring tablet breaking strength, and in 1968 Brook and Marshall (9) pointed out that variations observed on four devices involved in their studies were partly due to inaccuracies in equipment mechanisms and emphasized the need for calibration when comparing the results of one machine to another. In none of this work, however, was there an attempt to relate values obtained on one instrument to those of another.

EXPERIMENTAL

Tablets evaluated in this study contained the following: hydrous dibasic calcium phosphate NF, 32%; lactose USP, 32%; microcrystalline cellulose NF, 32%; starch USP, 3.5%; and magnesium stearate USP, 0.5%. The formulation was manufactured in one batch large enough to conduct all experiments.

All tablets were compressed on a single-punch press[2] operated at a rate of 90 tablets/min. Tablets of three different shapes, each in two sizes at target breaking strengths of 4, 8, and 12 kg., were prepared. The tablet sizes and shapes selected for the study were: Tablet I, round, standard concave, 7.14 mm. (0.28 in.) in diameter; Tablet II, round, standard concave, 10.3 mm. (0.40 in.) in diameter; Tablet III, capsule shaped, deep concave, 3.97 × 9.52 mm. (0.15 × 0.37 in.); Tablet IV, capsule shaped, deep concave, 4.76 × 11.9 mm.

[a] The values are the geometric average and its standard error, respectively, based on Cochran's approximation (12). [b] Two testers' averages are not statistically different (at $p = 0.05$) if they have at least one superscript in common. Two testers' averages are statistically different (at $p < 0.05$) if they have different superscripts. Note: These intercomparisons in this section are designated with superscript letters.

(0.18 × 0.46 in.); Tablet V, oval, deep concave, 5.56 × 10.3 mm. (0.21 × 0.40 in.); and Tablet VI, oval, deep concave, 7.14 × 12.7 mm. (0.28 × 0.50 in.).

The following four testers were evaluated: T-1, a manually powered, spring-loaded tester[3]; T-2, a motorized tester[4] whose function is derived from a counterweight principle; T-3, a manually operated tester[4] whose function is derived from a counterweight principle; and T-4, a motorized, spring-loaded tester[5].

To achieve the target breaking strengths desired, an arbitrary tablet weight for each size and shape was selected. This weight of powder mix was introduced into the corresponding die and pressure was exerted onto the mass. The resulting tablet was then measured for breaking strength on tester T-3. If the target value was not achieved, a new charge of powder mix of the same weight was introduced into the die and a different pressure was exerted. The resulting tablet was again measured for breaking strength. This procedure was repeated, if necessary, until the correct pressure to achieve the desired tablet breaking strength was reached. Once the correct set of machine adjustments was obtained, 500 tablets were compressed, keeping tablet weights ±4% of target and tablet thicknesses ±1% of target. When this operation was completed, a new size or shape was chosen and the same procedure was repeated until all of the different sizes, shapes, and target breaking strengths were manufactured.

The design protocol called for obtaining at random, for each shape and size, samples of four tablets each for testing on the four testers (involving random assignment of tablets to testers). The four breaking strength values for each occasion were determined concurrently. This procedure was repeated sequentially until 10 such samples of four were collected at each of the target values of 4, 8, and 12 kg. Only one operator was involved in the completion of all operations.

DISCUSSION

The discussion presented here is based upon the results of the statistical analysis of the 720 breaking strength values obtained from the randomized design of experiment described in the previous section. To compare the breaking strength values (Table I) generated by the testers in this study, both the ANOVA and Duncan's multiple range test (10) were used. The Levene (11) test of homogeneity of average absolute mean deviations (Table II) was employed for comparing the variability of instruments. The results of the regression analysis are presented in Table III; linear regressions were the best fit for the data and polynomial regressions were tried but did not contribute substantially to the fit.

[3] Stokes tester.
[4] Heberlein tester.
[5] Ahiba tester.

Using known breaking strength values experimentally obtained, one can now predict the breaking strength value from one tester to another using the following equation:

$$Y = A + BX_0 \qquad \text{(Eq. 1)}$$

where Y is the predicted breaking strength value, A and B are the numerical coefficients from Table III, and X_0 is the experimentally obtained breaking strength value associated with a given tester.

For instance, if one wishes to predict breaking strength values for T-4 from an experimentally obtained breaking strength value associated with T-3, Eq. 1 has the following form:

$$\text{(T-4)} = A + B\text{(T-3)} \qquad \text{(Eq. 2)}$$

The 95% confidence limits of the predicted breaking strength value can be computed by inserting the appropriate X_0 value into the formula given in the last column of Table III. The explicit expression of the confidence limits formula for the predicted values

[a] The values are the geometric averages based on 10 observations. [b] Two groups are not statistically different ($p = 0.05$) if they have at least one superscript in common. Two groups are statistically different ($p < 0.05$) if they have different superscripts. Note: These intercomparisons in this section are designated with superscript letters.

has the following form (10):

$$\hat{Y}_0 \pm t_{0.05} S_{yx} \sqrt{\frac{1}{n} + \frac{(X_0 - \bar{X})^2}{[X^2]}} \qquad \text{(Eq. 3)}$$

Comparisons of the averages and variabilities of breaking strengths among size-shape groups were also made and are presented in Tables IV and V, respectively.

The results given in Table I indicate that, in most cases, the two motorized testers yielded breaking strength values significantly higher than those of the manually operated instruments. T-4 generally gave higher readings than T-2, and these differences were significant for the five cases in the 12-kg. group. Breaking strength values generated with T-3 were significantly lower than those of the other three testers in 17 of the 18 possible cases. In the 12-kg. group, all devices were significantly different from one another in four out of six cases; that is, the two manually operated and the two motorized testers were significantly different from each other in this group.

With the data in Table IV, it is possible to make 15 comparisons derived from the combination of six categories taken two at a time within any given row. Such an exercise reveals that there are significant differences among many size-shape groups. The two sizes associated with the round shape (Tablets I and II) had significantly different breaking strength values in eight of the 12 possible cases. This result is somewhat surprising and unexplainable. Size made a difference in three out of 12 comparisons in each of the capsule-shaped (Tablets III and IV) and oval-shaped (Tablets V and VI) groups, but the effect of size was not pronounced in the capsule- and oval-shaped groups for the target values of 8 and 4 kg., respectively.

An analysis of the data presented in Table II shows that T-1 maintained a higher level of variability than the other testers in more than half of the possible cases. However, there was no significant difference in variability when all testers were compared in 10 out of 18 cases. Furthermore, there was no significant difference among T-3, T-4, and T-2 as far as their variabilities in 16 out of 18 cases.

Table V reveals that, except for the oval shape (Tablets V and VI) at the 8-kg. target, there were significant differences in variability related to a size-shape grouping in only two cases.

The use of the equation for predicting breaking strength values from one instrument to another is evident from Table III. The correlation between any two testers under consideration can be obtained by taking the square root of the RSQ value [RSQ(%)/100] noted in Table III. RSQ(%) is calculated as follows:

$$\text{RSQ}(\%) = \frac{B^2[X^2]100}{[Y^2]} \qquad \text{(Eq. 4)}$$

where B is the linear regression coefficient, $[X^2]$ is the corrected sum of squares for X's, and $[Y^2]$ is the corrected sum of squares for Y's.

The values of the correlation coefficients ranged from 0.90 to 0.99 in this study (the theoretical range here is from 0.0 to 1.0). One must be aware, however, that accurate predictions can be obtained only if: (*a*) the X_0 value is the average of exactly 10 breaking strength values experimentally derived, (*b*) the X_0 value lies between 3.0 and 15.75 kg., and (*c*) the experimental conditions are as close to those described in this paper as possible.

CONCLUSION

The characterization and comparison of tablet breaking strength

Table V—Variability[a] Comparison of Size-Shape Groups[b]

[a] The values are the average absolute mean deviations based on 10 observations. [b] Two groups are not statistically different ($p = 0.05$) if they have at least one superscript in common. Two groups are statistically different ($p < 0.05$) if they have different superscripts. Note: These intercomparisons in this section are designated with superscript letters.

testers offered considerable insight into the performance capability of the instruments studied. The characterization information is fundamental to any developmental work in this area. The study also revealed a sufficiently high correlation among the tablet testers to permit precise prediction of breaking strength values. It is possible now to expand the study to evaluate breaking strength testers of the same kind in interlaboratory crossover experiments.

Semiautomated UV Analysis of Caffeine in Aspirin–Phenacetin–Caffeine Tablets

MACK W. OVERTON▲, LARRY L. ALBER, and RAYMOND S. VALENTINE

Abstract □ A semiautomated individual tablet assay was developed for caffeine in aspirin–phenacetin–caffeine formulations. Caffeine and phenacetin are extracted from the bicarbonate tablet solution with chloroform. The caffeine and some phenacetin are extracted from the chloroform with acid, and an additional chloroform wash of the acid phase removes any phenacetin. The caffeine is determined by UV spectroscopy in the acid at 266 nm. at a rate of 20 tablets/hr. The coefficient of variation for 10 determinations of one sample solution was 1.72. The difference in results between the NF XIII method and the proposed method, expressed as percent of declared, did not exceed 2.6% when 10 different products were analyzed.

Keyphrases □ Aspirin–phenacetin–caffeine tablets—semiautomated UV analysis of caffeine □ Caffeine in aspirin–phenacetin–caffeine tablets—semiautomated UV analysis □ UV spectrophotometry—analysis, caffeine in aspirin–phenacetin–caffeine tablets

Aspirin, phenacetin, and caffeine in pharmaceutical preparations are determined quantitatively by the official NF procedure (1). Since the monograph employs a partition chromatographic separation on a diatomaceous earth[1] column (2), the content uniformity requirement for caffeine in the tablets is extremely time consuming.

An automated method for caffeine in blood converts the caffeine to an aromatic amine, with subsequent diazotization for color determination (3). This procedure could not be used in the presence of phenacetin.

Caffeine has been reported to fluoresce in chloroform, where the excitation at 280 nm. causes emission that can be measured at 310 nm.[2]. With filter fluorometer equipment normally applied to an automated analyzer[3], excitation energy from the source lamp is rather weak at 280 nm. In addition, the fluorescence is not strong and linearity may be difficult to achieve.

In the method reported here, the caffeine and phenacetin are extracted from the bicarbonate solution with chloroform. The caffeine is extracted from the chloroform with dilute sulfuric acid, which is washed with chloroform to remove any phenacetin from the acid phase. The caffeine is determined by measuring its UV absorbance at 266 nm.

EXPERIMENTAL

Apparatus—The following were used: Liquid sampler II[4] (20/hr.), proportioning pump[4] I, and a spectrophotometer[5] equipped with a 10-mm. flow cell[6].

Reagents—The following were used: 4 *N* sulfuric acid; 0.1 *M* $NaHCO_3$; and chloroform, reagent grade, free of UV-absorbing impurities.

Standard Preparation—Place 82 mg. of caffeine in a 250-ml. volumetric flask with 25 ml. of 0.1 *M* $NaHCO_3$, and heat on a steam bath 4–5 min. to dissolve. Cool and dilute to volume with 0.1 *M* $NaHCO_3$. The concentration of the standard solution is 0.328 mg./ml.

Sample Preparation—For tablets declared to contain 30 mg.

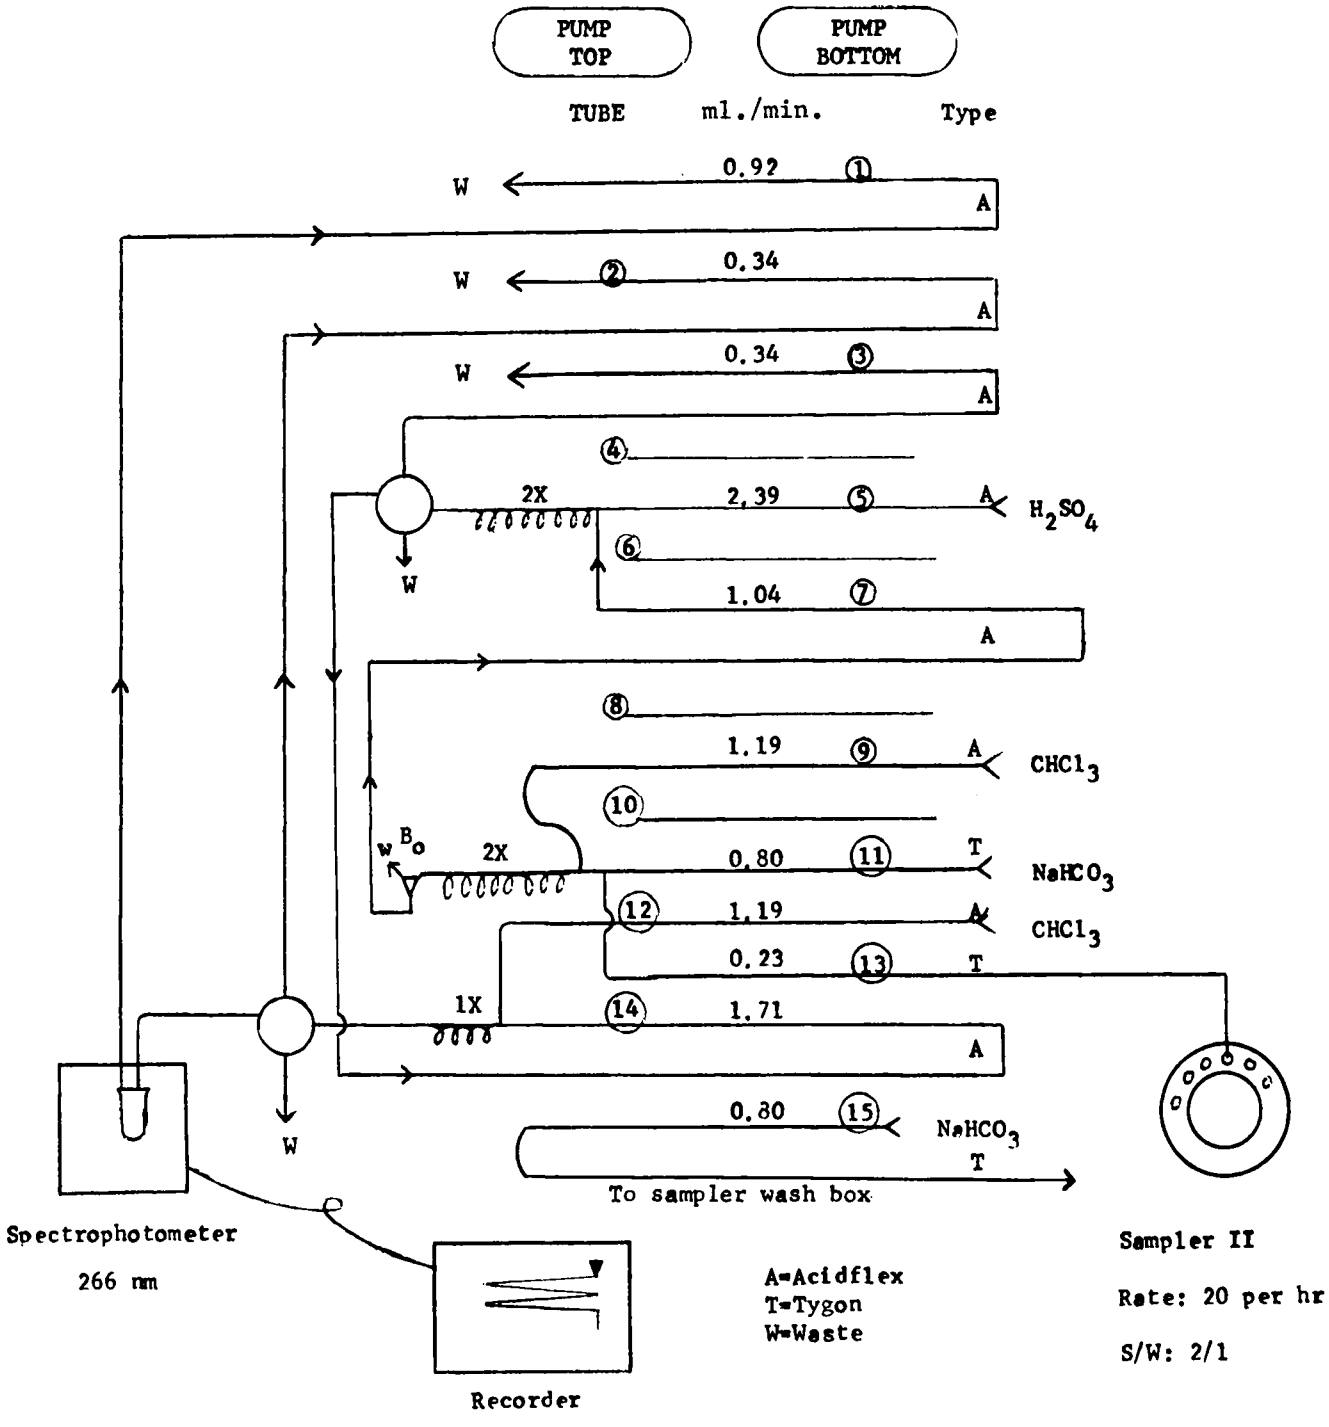

Figure 1—*Automated analyzer flow diagram for caffeine in aspirin–plenacetin–caffeine tablets.*

(1/2 gr.) caffeine, place them separately in a series of 100-ml. volumetric flasks. Add 25 ml. of 0.1 *M* $NaHCO_3$, heat on the steam bath 4–5 min., cool, dilute to volume with 0.1 *M* $NaHCO_3$, and mix (much of the phenacetin will not dissolve, even in warm 0.1 *M* $NaHCO_3$). For tablets declared to contain 15 mg. (1/4 gr.) caffeine, place them separately in a series of containers and add 25.0 ml. of 0.1 *M* $NaHCO_3$ from an automatic delivery pipet. Heat 4–5 min., cool, add another 25.0 ml. of 0.1 *M* $NaHCO_3$, and mix. Filter all tablet solutions through filter paper before placing in sample cups.

Automated Sample Assay—The flow system and the manifold settings are shown in Fig. 1. Coils labeled 1X are 14 turns, 2 mm. i.d.; those labeled 2X are 28 turns, 2 mm. i.d.

Special Connector for Automated System—To eliminate gas bubbles which formed at the interface of two immiscible liquids in the automated system, a special connector was developed (Fig. 2). The two immiscible liquids are pumped into the connector where the heavier liquid settles to the bottom (D) and is pushed to waste by the excess liquid being pumped in. Some less dense liquid is pumped out the top (B) through the pump to waste, along with any gas released from the interface. This eliminates air bubbles from the flow cell compartment. In addition, if any droplets of the denser liquid are attached to the gas bubble, it falls through D to waste. The liquid, free of gas bubbles, goes out the connector at C.

RESULTS AND DISCUSSION

A warm bicarbonate solution was selected for tablet preparation because caffeine dissolved completely, while much of the phenacetin

remained at the bottom of the flask. This greatly reduced the interference of phenacetin in the automated UV procedure. Heating on the steam bath seemed to effect solution more completely than did the sonic vibrator.

During this study, the tubing employed in the automated system seemed particularly subject to fatigue and failed after approximately

composite solution in 10 separate cups. The usual sequence used in this laboratory is as follows: three standards, five tablets, standard, five tablets, *etc.*, composite, and two standards. The composite is a weighed portion of 20 tablets ground to fine powder, equivalent to one tablet weight. The coefficient of variation for 10 determinations of one composite solution was 1.72 (Table I).

The accuracy of the procedure was studied by comparing the automated assay with the NF column method on 10 different product composites. Both analyses were made on the same mixed powdered composites. The results of the automated method were in general agreement with those by the NF procedure (Table II). The deviation, expressed as percent of declared, was less than ±2.6%.

Dissolution Rate Studies IV: Solvent Flow Patterns in a Column-Type Apparatus

J. TINGSTAD▲, J. DUDZINSKI, L. LACHMAN, and E. SHAMI

Abstract □ Solvent flow patterns in a column-type, continuous flow apparatus were determined using a flow visualization technique. A supporting bed of glass spheres in the dissolution chamber ensures laminar flow, and this is preferred over the complex, poorly defined flow found with static beaker methods.

Keyphrases □ Dissolution rate studies—solvent flow patterns and laminar flow conditions, column-type equipment □ Tablet dissolution—solvent flow patterns and laminar flow conditions, column-type equipment □ Solvent flow in column-type dissolution equipment—flow patterns, laminar flow conditions □ Column-type dissolution equipment—solvent flow patterns, laminar flow conditions

The advantages of the column-type, continuous flow method for determining the dissolution characteristics of solids have been repeatedly emphasized (1–4). One important advantage is that solvent flow is columnar as opposed to the complex, poorly defined flow found with static beaker methods (5). However, some problems have been encountered with columnar flow because of turbulence (4), problems that would be minimized under conditions of laminar flow. This report describes, for a column-type apparatus, (*a*) solvent flow patterns under various experimental conditions, and (*b*) the necessary conditions for laminar flow.

EXPERIMENTAL

Equipment—The dissolution apparatus was the column type described previously (3). The light sources were a common laboratory microscope light and an electronic tachometer and motion analyzer[1]. The latter was calibrated with respect to the powerline frequency according to the instruction manual. The reflecting spheres were polystyrene base beads[2] (diameter 90–125 μ; specific gravity 1.06).

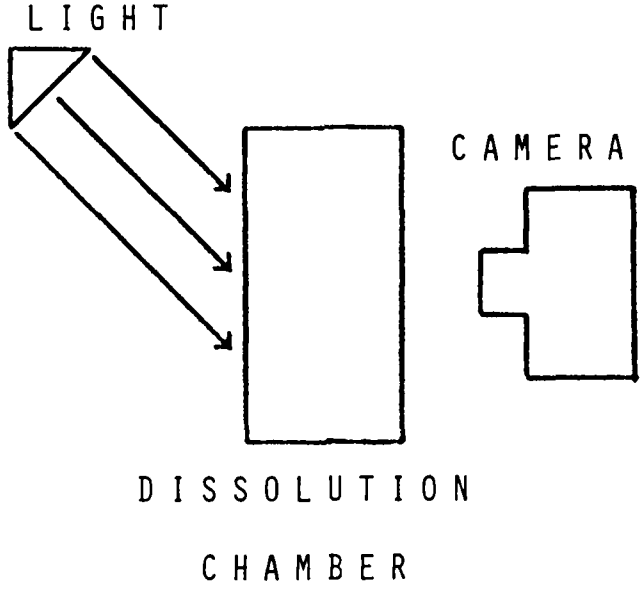

Figure 1—*Arrangement of equipment for photographic and television work.*

A lens hood was used to reduce flare with the still camera[3]. Depending on the tachometer flashing rate, apertures varied between f-11 and f-22 and exposure times between 0.5 and 0.25 sec. All photographs were taken at one-half life size image.

The television camera[4] had a 75-mm. f-1.9 lens and a video tape recorder[5].

Procedure—The experimental procedure was similar to that described by Withey and Bowker (5) but was appropriately modified for the column-type apparatus. The basic arrangement of the equip-

Dissolution Rate Studies IV: Solvent Flow Patterns in a Column-Type Apparatus

J. TINGSTAD▲, J. DUDZINSKI, L. LACHMAN, and E. SHAMI

Abstract □ Solvent flow patterns in a column-type, continuous flow apparatus were determined using a flow visualization technique. A supporting bed of glass spheres in the dissolution chamber ensures laminar flow, and this is preferred over the complex, poorly defined flow found with static beaker methods.

Keyphrases □ Dissolution rate studies—solvent flow patterns and laminar flow conditions, column-type equipment □ Tablet dissolution—solvent flow patterns and laminar flow conditions, column-type equipment □ Solvent flow in column-type dissolution equipment—flow patterns, laminar flow conditions □ Column-type dissolution equipment—solvent flow patterns, laminar flow conditions

The advantages of the column-type, continuous flow method for determining the dissolution characteristics of solids have been repeatedly emphasized (1–4). One important advantage is that solvent flow is columnar as opposed to the complex, poorly defined flow found with static beaker methods (5). However, some problems have been encountered with columnar flow because of turbulence (4), problems that would be minimized under conditions of laminar flow. This report describes, for a column-type apparatus, (*a*) solvent flow patterns under various experimental conditions, and (*b*) the necessary conditions for laminar flow.

EXPERIMENTAL

Equipment—The dissolution apparatus was the column type described previously (3). The light sources were a common laboratory microscope light and an electronic tachometer and motion analyzer[1]. The latter was calibrated with respect to the powerline frequency according to the instruction manual. The reflecting spheres were polystyrene base beads[2] (diameter 90–125 μ; specific gravity 1.06).

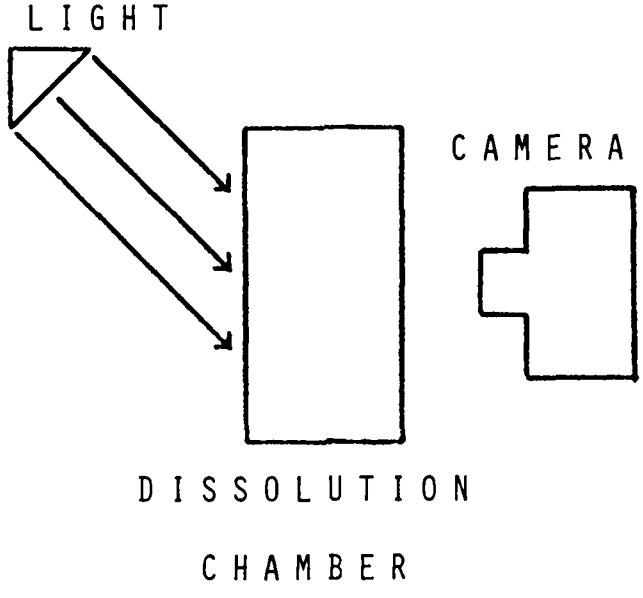

Figure 1—*Arrangement of equipment for photographic and television work.*

A lens hood was used to reduce flare with the still camera[3]. Depending on the tachometer flashing rate, apertures varied between f-11 and f-22 and exposure times between 0.5 and 0.25 sec. All photographs were taken at one-half life size image.

The television camera[4] had a 75-mm. f-1.9 lens and a video tape recorder[5].

Procedure—The experimental procedure was similar to that described by Withey and Bowker (5) but was appropriately modified for the column-type apparatus. The basic arrangement of the equip-

ment for the photography and television work is shown in Fig. 1. The angle between the tachometer and the camera was approximately 135°. The microscope light was used for making simple visual observations.

The polystyrene spheres reflect the light and, since their specific gravity is close to that of water, their flow patterns are essentially representative of the solvent molecules. The tachometer, properly pulsed for a given set of experimental conditions, reveals the paths of the particles as a series of images (usually streaks) on photographic film or video tape. However, the most accurate method for determining flow patterns is simple visual observation.

The solvent reservoir was a 150-ml. beaker containing 100 ml. of a 1-mg./ml. suspension of the polystyrene spheres in distilled water, with 0.05% polysorbate 80 added to reduce air entrapment. After determining that flow patterns were essentially identical with or without filters, all experiments were performed without filters (but with screens) at ambient temperature. The suspension could then

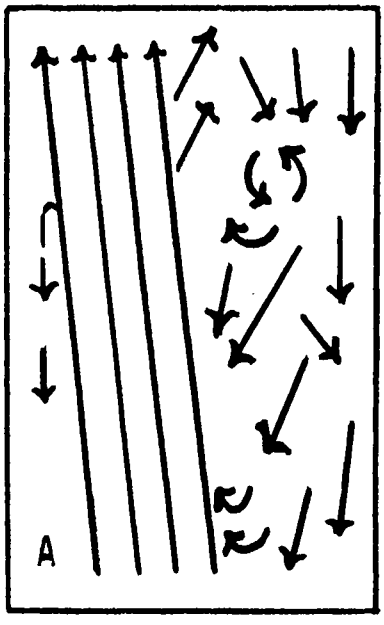

Figure 3—*Diagram of flow patterns with 25-mm. dissolution chamber at a flow rate of 55 ml./min. "A" is an area of low solvent velocity.*

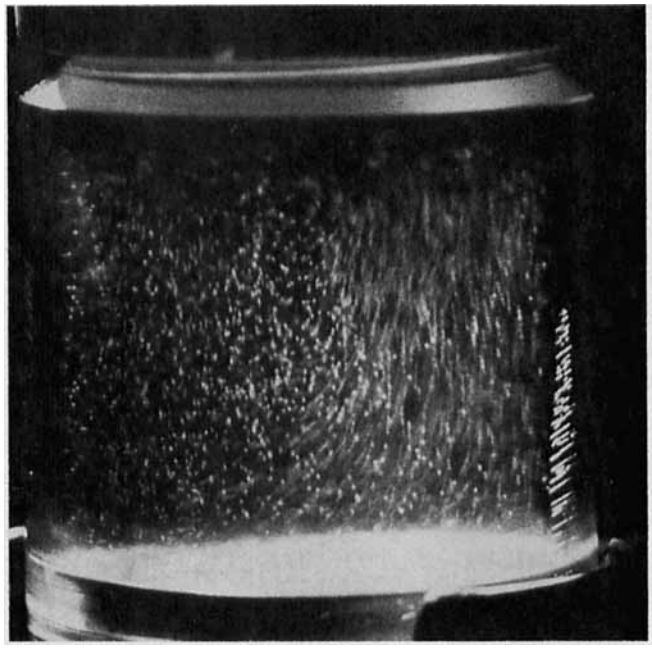

Figure 4—*Photograph of flow patterns with 25-mm. dissolution chamber at a flow rate of 48 ml./min. The tachometer flashing rate was 6000/min., the aperture was f-11, and the exposure time was 0.25 sec.*

be pumped through the dissolution chamber and recycled to the reservoir. The flow rate was varied, and the flow patterns in the 13- and 25-mm. chambers were observed and (when desirable) photographed or recorded on video tape.

RESULTS AND DISCUSSION

With the 25-mm. chamber at relatively low flow rates (5–9 ml./min.), the flow patterns shown in Fig. 2 was observed. While the solvent flow coming into the chamber (solid arrows) had essentially laminar characteristics, solvent was dispersed as it struck the upper screen and filter holder, and some returned to the bottom of the cell, still with the characteristics of laminar flow. This two-directional flow is, of course, undesirable. At intermediate flow rates (14–34 ml./min.), the same general pattern held except that turbulence increased and, in general, downward flow was much slower than upward flow. The degree of turbulence progressed with an increasing flow rate until (*e.g.*, at 48–55 ml./min.) a column of solvent moved rapidly upward and randomly dispersed after striking the upper screen and filter holder. Turbulence was much more wide-

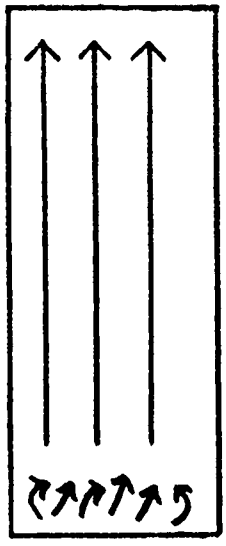

Figure 5—*Diagram of flow patterns with 13-mm. dissolution chamber at a flow rate of 13 ml./min.*

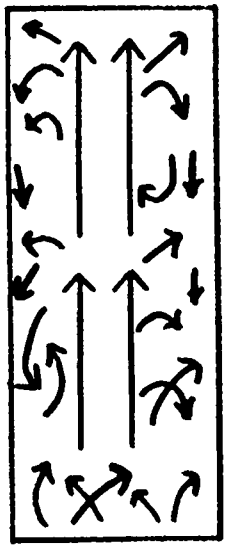

Figure 6—*Diagram of flow patterns with 13-mm. dissolution chamber at a flow rate of 36 ml./min.*

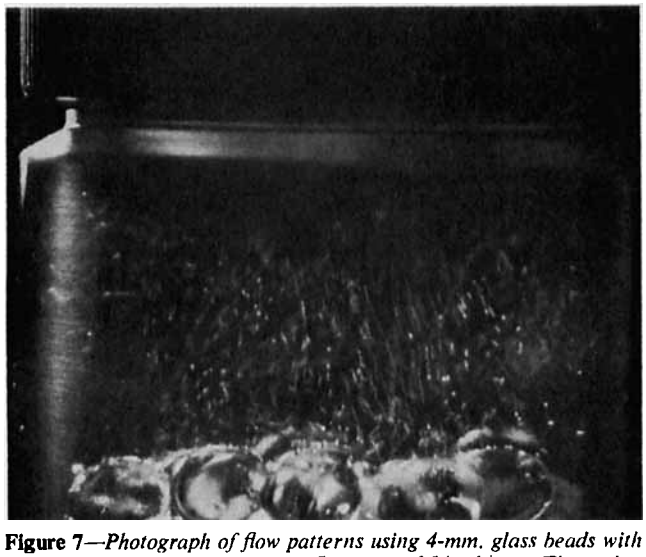

Figure 7—*Photograph of flow patterns using 4-mm. glass beads with 25-mm. dissolution chamber at a flow rate of 54 ml./min. The tachometer flashing rate was 6000/min., the aperture was f-16, and the exposure time was 0.5 sec.*

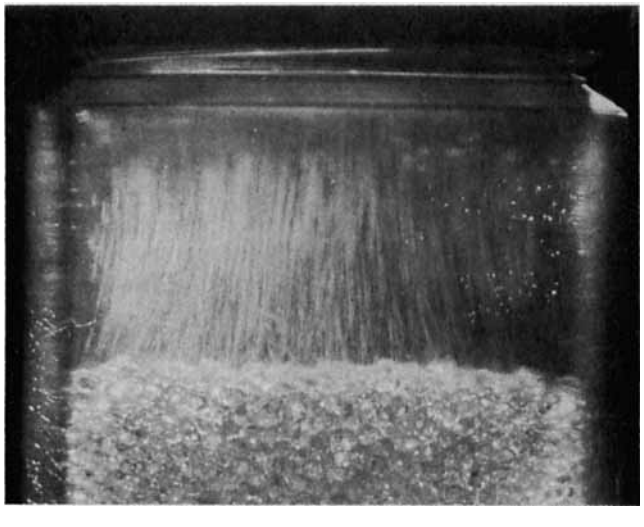

Figure 8—*Photograph of flow patterns using 1-mm. glass beads with 25-mm. dissolution chamber at a flow rate of 73 ml./min. The tachometer flashing rate was 12,000/min., the aperture was f-16, and the exposure time was 1 sec.*

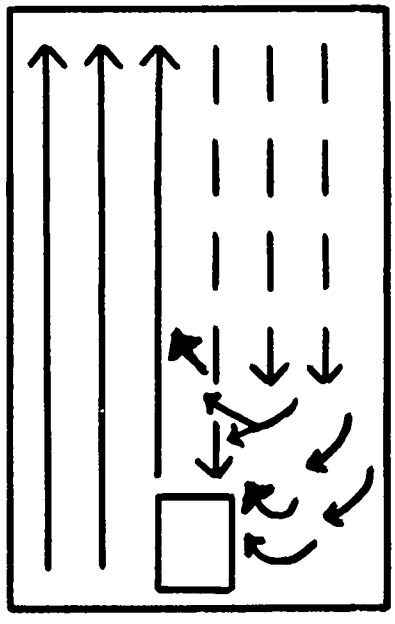

Figure 9—*Diagram of flow patterns with constant-surface pellet in the center of the lower screen of 25-mm. dissolution chamber. Flow rate was 34 ml./min.*

spread and dominant, and areas of low solvent flow developed (Figs. 3 and 4).

With the 13-mm. chamber at low flow rates (5–13 ml./min.), the flow was essentially laminar except for some turbulence in the first 0.5–1 cm. of the cell (Fig. 5). This is also undesirable because the area of turbulence would surround the tablet. At 36 ml./min., the flow was quite turbulent throughout the cell (Fig. 6). The spheres moved in relatively straight lines up the center of the chamber, but there was considerable turbulence on either side and at the bottom. It was not possible to obtain acceptable photographs with the 13-mm. cell because of excessive reflection and glare.

During these investigations, it was noted that flow patterns would vary considerably from one experiment to another (under the same set of conditions) if excessive air was trapped within the lower filter holder and beneath the lower screen. To minimize this variation and attain more laminar flow over a wider range of solvent velocities, a

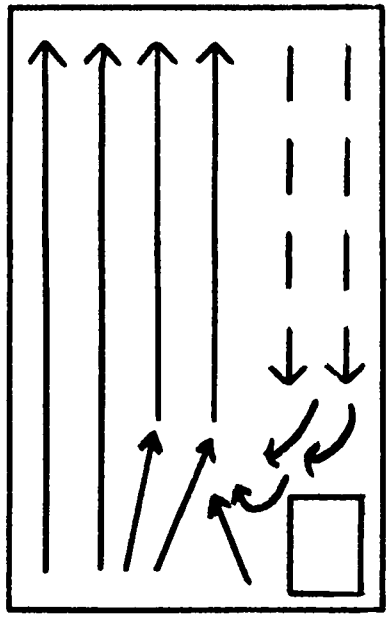

Figure 10—*Diagram of flow patterns with constant-surface pellet at the side of the lower screen of 25-mm. dissolution chamber. Flow rate was 34 ml./min.*

bed of glass beads was added to both cells, occupying about half of the chamber volume. The beads acted as dampers, and the 4-mm. size improved the flow characteristics considerably (Fig. 7 *versus* Fig. 4). However, it was necessary to use 1-mm. beads before proper laminar flow was attained (Fig. 8). Laminar characteristics were observed up to 80 ml./min., the highest flow rate used.

Because the photographs and drawings are two dimensional and static, they do not accurately represent the total, dynamic, three-dimensional situation. The video tapes from the television work provide a better record of solvent flow patterns because the actual motion is recorded. As mentioned earlier, visual observation is best.

In a previous investigation (4), constant-surface pellets of salicylic acid were used with the column apparatus. To gain more insight into the results of those experiments, flow patterns were observed in the 25-mm. chamber with the pellet in the center of the lower screen (Fig. 9) and at the side (Fig. 10). The results confirmed that, for a given flow rate, the lowering of the dissolution rate when the pellet was moved to the side of the chamber was due to the lower rate of solvent flow in that region.

SUMMARY

These results indicate that using a bed of 1-mm. glass beads with the column apparatus helps ensure laminar flow over a wide range of liquid velocities. This type of solvent flow is much preferred over the poorly defined, random-type flow characteristic of all beaker methods. Because surface tension slows solvent movement near the sides of the chambers, it is preferable to place the tablet well away from the sides of the cell.

Dustiness of Pharmaceutical Formulations I: Instrumentation

G. GOLD▲, R. N. DUVALL, B. T. PALERMO, and R. L. HURTLE

Abstract □ Instrumentation for evaluating the dustiness of tableting materials is reported. The sample is dropped into a dust chamber where a controlled flow of air carries the resulting dust particles through a beam of light. The scattered light is received by a photodetector which converts light pulses into electrical pulses. The instrumentation was precalibrated in particle-size ranges of 0.5–10, 11–50, and >50 μ, and the number of particles in each size range is displayed on a digital counter. The particle size refers to the equivalent diameter of the dust particle that generates the same electrical response in the photodetector as the reference particle used to calibrate the instrumentation. Eleven commonly used tableting aids were classified into three categories based on their relative dustiness. Data obtained with the dust counter were shown to correlate with the dustiness resulting from the bulk handling of larger quantities of materials.

Keyphrases □ Dustiness of tableting materials—determination using light-scattering method and equipment □ Pharmaceutical technology—method and equipment for determining dustiness of tableting materials □ Tableting materials—measurement of dustiness □ Light-scattering method and equipment—determination of dustiness of tableting materials

Dust of any kind in a pharmaceutical plant is a serious matter. Areas of particular concern are: (*a*) cross-contamination of other products, and (*b*) potential hazards to the health of workers. There is always a risk of cross-contamination occurring with potentially serious consequences in pharmaceutical plants that utilize the same manufacturing facility to produce a variety of pharmaceutical products. Cross-contamination of a product with penicillin, for example, is capable of causing a serious reaction or even death to a person sensitive to penicillin (1). It is essential, therefore, that dust always be kept under control.

In regard to the workers' health, dust may be classified as a lung-depositing dust, toxic dust, primary irritant dust, sensitizing dust, or nuisance dust. A lung-depositing dust is deposited and retained in the lungs, where it may be benign or cause lung pathology. Toxic dust is a systemic poison which enters the circulation by absorption from the respiratory tract or after being swallowed. A primary irritant is limited largely to the mucous membranes of the eyes, nose, and throat. Prolonged exposure to low-grade irritants is capable of producing disturbances in respiratory function and secondary infection (2). A sensitizing dust elicits the antigen–antibody response in susceptible individuals as a result of either inhalation, skin contact, or ingestion. A nuisance dust is primarily discomforting to the worker and is often associated with increased colds and bronchitis. In general, the inhalation of any kind of dust in sufficient amounts for long periods of time can lead to disturbances in pulmonary function (3).

Particle size, frequency of exposure, quantity of concentration, and chemical action on the body tissue and fluids are important factors that influence whether a

Keyphrases □ Dustiness of tableting materials—determination using light-scattering method and equipment □ Pharmaceutical technology—method and equipment for determining dustiness of tableting materials □ Tableting materials—measurement of dustiness □ Light-scattering method and equipment—determination of dustiness of tableting materials

Dust of any kind in a pharmaceutical plant is a serious matter. Areas of particular concern are: (*a*) cross-contamination of other products, and (*b*) potential hazards to the health of workers. There is always a risk of cross-contamination occurring with potentially serious consequences in pharmaceutical plants that utilize the same manufacturing facility to produce a variety of pharmaceutical products. Cross-contamination of a product with penicillin, for example, is capable of causing a serious reaction or even death to a person sensitive to penicillin (1). It is essential, therefore, that dust always be kept under control.

In regard to the workers' health, dust may be classified as a lung-depositing dust, toxic dust, primary irritant dust, sensitizing dust, or nuisance dust. A lung-depositing dust is deposited and retained in the lungs, where it may be benign or cause lung pathology. Toxic dust is a systemic poison which enters the circulation by absorption from the respiratory tract or after being swallowed. A primary irritant is limited largely to the mucous membranes of the eyes, nose, and throat. Prolonged exposure to low-grade irritants is capable of producing disturbances in respiratory function and secondary infection (2). A sensitizing dust elicits the antigen–antibody response in susceptible individuals as a result of either inhalation, skin contact, or ingestion. A nuisance dust is primarily discomforting to the worker and is often associated with increased colds and bronchitis. In general, the inhalation of any kind of dust in sufficient amounts for long periods of time can lead to disturbances in pulmonary function (3).

Particle size, frequency of exposure, quantity of concentration, and chemical action on the body tissue and fluids are important factors that influence whether a

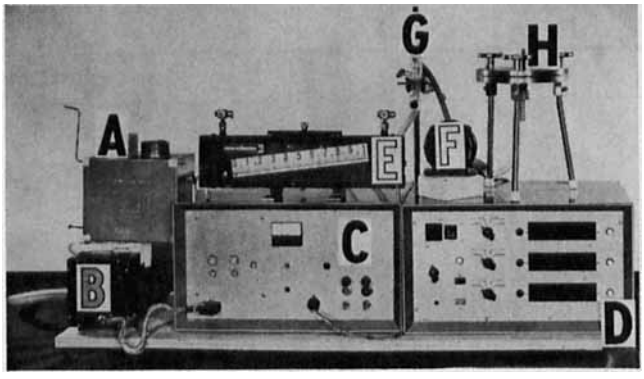

Figure 1—*Photograph of instrumentation showing sample chamber (A), detection chamber (B), pulse height discriminator (C), three-channel counter (D), inclined draft gauge (E), spiral exhauster (F), rotometer (G), and filter assembly (H).*

dust is an industrial health hazard (4). Particles between 1 and 2 μ have the greatest probability of being deposited in the pulmonary air spaces, and particles >10 μ are essentially removed in the nasal chamber and have little probability of penetrating to the lungs (5). Silica dust particles reaching and remaining in the alveoli are believed to be largely limited to the size ranging between 0.1 and 3 μ (6). The published threshold limit values (7) for several hundred materials refer to airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse effect. The threshold limit values for nuisance dusts are 5 mg./m.^{3} for the respirable fraction and 15 mg./m.^{3} for total dust.

With the enactment of the Williams–Steiger Occupational Safety and Health Act of 1970, there will be more stringent governmental control of the concentration of dust in manufacturing plants; the formulator now has the added responsibility of preparing products that generate minimal dust. Unfortunately, little information is available for selecting low dust-yielding ingredients. Often the formulator is not aware of a dust problem until a production scale-up run is made, at which time it is extremely costly and time consuming to reformulate the product or to design a manufacturing system to control the dust. Furthermore, the present method for evaluating dustiness by simply observing the workroom environment is empirical and may lead to erroneous conclusions. Since the harmful respirable particle size is below the normal limit of visibility, work atmospheres that appear to be only slightly dusty often contain extremely hazardous concentrations of dust (8), and several cases were reported (9) where visible dust was practically absent from the air but the workers still contracted pulmonary disease.

The purpose of the first phase of this study was to develop a practical, objective method for measuring the relative dustiness of pharmaceutical powders. To meet this objective, instrumentation was developed based on light-scattering principles for sizing and counting airborne particles in the harmful respirable range. This report describes the instrumentation and indicates how it may be used to evaluate the relative dustiness of raw materials.

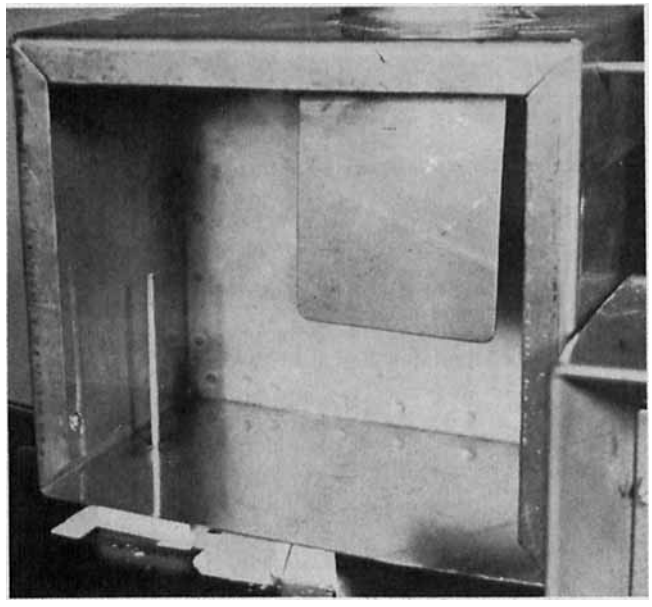

Figure 2—*Photograph of sample chamber (front removed) showing the inlet tube and platform (tripped position).*

EXPERIMENTAL

Instrumentation—The instrumentation (Fig. 1) consists of a sample chamber (A), a detection chamber (B), a pulse height discriminator (C), a three-channel counter (D), an air-flow system which includes a draft gauge[1] (E), a spiral exhauster[2] (F), a rotometer[3] (G), and a filter assembly[4] (H).

The sample is placed on the platform of the sample chamber (Fig. 2) and dropped by tripping the platform lever. The resulting dust particles enter the inlet tube of the sample chamber where they are carried by a controlled flow of air to the detection chamber. In the detection chamber, the dust particles are surrounded by filtered air entering from the filter and passed through a beam of light emanating from a light source[5] within the chamber. Scattered light is picked up by a photomultiplier[6] located within the chamber at a 40° angle from the light beam and converted to an electrical pulse. A preamplifier intensifies the electrical pulse from the photomultiplier, and a pulse height discriminator using stearing logic and pulse height detectors transfers the pulse to one of three channels of the counter. The counter is constructed with digital integrator circuits using wire-wrapped panels. Three separate scalers are used with a common time base generator and three 4.5-digit displays and overrange indicators. Three decades of prescaling are provided for each channel with a range selector switch. The timer can be adjusted in minute intervals up to 10 min. with an expired time indicator light.

Calibration—The instrument was calibrated using reference latex spheres[7] having particle diameters of 0.091, 0.481, 6–14, and 50–100 μ. The reference spheres were packaged as aerosols in which the particles were kept separated from the propellent and sprayed into one opening of a 1-l., three-necked distilling flask. Heat was blown into the second opening, and the third opening was connected to the inlet tube of the detection chamber. For each reference sphere size, the average pulse height was measured at the input of the pulse height discriminator. A linear relationship was found to exist between the size of the reference sphere and the pulse height. The three discriminator circuits were then adjusted so that one channel of the counter measured particle-diameter ranges of 0.5–10 μ, the second channel 11–50 μ, and the third channel >50 μ. The particle size refers to the

equivalent diameter of the particle that generates the same electrical response in the photodetector as the reference particle used to calibrate the instrument (10). Using the soap film method of calibration, the air flow through the inlet tube of the sample chamber was 870 ml./min. at a reading of 0.13[8]. For checking the counting and light circuitry, a secondary calibration system was incorporated in the instrumentation which consists of a d.c. μ ammeter to measure the dark current of the photomultiplier and a 60-Hz. line frequency check for the prescaling, scalers, time base, and display circuitry.

Measurements—A 15-g. sample was placed on a platform located 15 cm. above the floor of the sample chamber. The platform lever was then tripped and the timer was started. Particle counts for each size range were recorded in 1-min. intervals up to 5 min. Three measurements were made for each sample and were repeated on 2 different days for a total of nine measurements. Measurements were made in a temperature- and humidity-controlled room using conventional engineering equipment in which the temperature varied from 23 to 27° and the relative humidity did not exceed 20%.

Materials—The following commercially available USP, NF, or pharmaceutical grade tableting ingredients were evaluated for dustiness: direct compression dextrose[9], unmilled dicalcium phosphate dihydrate[10], spray-dried lactose[11], magnesium stearate, microcrystalline cellulose[12], starch, direct compression starch[13], direct compression sucrose[14], direct compression sucrose formulation[15], talc, and terra alba[16].

RESULTS AND DISCUSSION

One- and 5-min. dust counts in the 0.5–10-μ range (for several commonly used tableting aids) are tabulated in Table I. One-minute dust counts varied from a low mean of 25.8 for direct compression dextrose to a high of 10,362 for talc. Five-minute dust counts varied from 26.9 for direct compression dextrose to a high of 12,991 for

[a] A 15-g. sample, 0.5–10 μ, 1 min. [b] Unico sampler, Gelman type A filter, 30-kg. sample dropped from a 3-ft.^{3} twin-shell dry blender. [c] Mean of nine counts. [d] Mean of four counts. [e] Contains 0.1% FD&C Red No. 2 and 0.5% magnesium stearate.

talc. A paired comparison between the 1- and 5-min. data using the *t* statistic indicated that the 5-min. data were significantly higher than the 1-min. data. Dust particles in the 0.5–10-μ range have the highest probability of being deposited in the pulmonary air spaces and represent the greatest hazard to health.

Although particles in the 11–50-μ range have little probability of penetrating to the lungs, they may be swallowed to produce systemic activity. Dust counts in the 11–50-μ range are listed in Table II. The 1-min. dust counts varied from a low mean of 1.3 for direct compression dextrose to a high mean of 2287.4 for magnesium stearate. Five-minute dust counts varied from a low of 1.4 for direct compression dextrose to a high of 2312.2 for magnesium stearate. The lower dust counts in the 11–50-μ range and the absence of a significant difference between the 1- and 5-min. data are indicative of the faster settling-out rates of the larger size particles.

A classification of relative dustiness was devised based on placing the 1-min. mean counts of the 0.5–10-μ range particles into one of three groups. Group I was assigned a mean count range of 0–1000; Group II, 1001–6000; and Group III, >6000. The 95% confidence limits about the mean (Table I) were used in classifying the tableting aids into the various groups. The tableting aid was classified in the group whose range included the limits about the mean. As indicated in Table III, Group I consists of direct compression dextrose, direct compression sucrose formulation, spray-dried lactose, and terra alba. Group II contains direct compression sucrose, unmilled dicalcium phosphate, and starch. Direct compression starch is classified between Groups II and III. Group III contains microcrystalline cellulose, magnesium stearate, and talc.

An experiment was designed to determine if the data obtained with the dust counter correlated with dust generated during the bulk handling of larger quantities of the same materials. Direct compression dextrose, dicalcium phosphate, and microcrystalline cellulose were selected from the classification as representing various levels of dustiness. To each material, 0.1% FD&C Red No. 2 and 0.5% magnesium stearate were added. Dust counts for each of these three formulations were made using the dust counter as already described. Dustiness of the same three formulations was also measured using an air sampler[17] by dropping 30 kg. of each formulation from a 3-ft.^{3} twin-shell dry blender. The results (Table IV) indicate a high correlation coefficient (r = 0.998) between the dust counts obtained with the laboratory dust counter and the dustiness resulting from the bulk handling of larger quantities of the same material.

Formula Modifications in a Solvent-Free Tablet Film Coat

PAUL A. TUERCK and DUNCAN E. McVEAN▲

Abstract □ Solvent-free formulations suitable for use as film coatings are described. Coatings are applied by spraying molten mixtures onto tablets in a conventional coating pan. The effects of a series of 17 additives on two representative basic formulations are evaluated. Results are presented relative to appearance, disintegration, friability, and uniformity. Desirable characteristics imparted by the additives may be easily selected from tables and used in the formulation of subsequent coating compositions. The concentration of shellac in the basic formulations was found to govern the rapidity of disintegration of the coatings regardless of additives. Of the additives evaluated, only castor oil, cocoa butter, and isopropyl myristate improved the basic formulations.

Keyphrases □ Tablet coating—solvent-free shellac polyethylene glycol 4000 formulations, effects of 17 additives, molten mixture spraying □ Shellac-polyethylene glycol 4000 solvent-free tablet film coatings—formulation, effects of 17 additives, molten mixture spraying □ Film coatings—formulation of solvent-free shellac-polyethylene glycol 4000 films for molten mixture spraying of tablets, effect of 17 additives

The use of coatings on tablets and pills is well documented. For example, "Remington's Pharmaceutical Sciences" lists a bibliography of 322 references pertaining to the subject (1). Those familiar with the art of tablet coating are acquainted with the reasons for coating and advantages and disadvantages of the application methods.

Until recently, sugar coating was overwhelmingly preferred and it still provides tablets of exceptional esthetic qualities. But for reasons of economy, both with respect to labor and material costs, other methods have gained popularity. Film-type coatings, in particular, offer reduced labor and material costs, are thin enough that embossed emblems are retained, mask tastes and odors, offer improved stability over sugar coatings, provide increased resistance to abrasion, and provide increased luster when compared to compressed tablets (1).

Unfortunately, it is necessary that most newer film coatings be applied with the film-forming material dissolved or suspended in volatile solvents such as acetone, chloroform, and alcohol. While these solvents evaporate quickly and make it possible to complete the coating operation in a short period, they also have many disadvantages. These solvents evaporate quickly, necessitating the use of large quantities which are either lost completely during the drying cycle or are partially recovered with expensive recovery systems. Elaborate precautions are sometimes necessary to protect against their inherent toxicity. The associated hazards of explosion and fire from local concentrations of vapors also must not be ignored. Furthermore, it is sometimes necessary to alternate the coating applications with drying cycles, since the use of solvent tends to dissolve portions of the coating already applied, resulting in sticking and clumping of tablets in the coating pan.

Film coating may also be accomplished by other methods, such as the Wurster air-suspension technique. This unique method also involves volatile solvents as vehicles for the film-forming materials (2, 3).

Pan coating remains one of the most widely used methods for applying film coats. Numerous modifications of methods exist for applying the coating materials and include the time-honored method of pouring on solutions in frequent and divided portions with intermittent drying cycles; spraying, using air pressure for atomization; and airless spraying, using hydraulic pressure alone for atomization. All these methods have been automated in part or *in toto* (4).

A recently issued patent (5) is concerned with some basic, novel coating compositions of dry shellac with polyethylene glycol. It is possible to apply these combinations as molten solutions to tablets with the aid of steam-jacketed pneumatic spray heads.

The purpose of this experimental work was to conduct screening studies to determine the effect of various additives on two basic film coating compositions containing 10 and 20% shellac in polyethylene glycol 4000 (I). The method and formulas described obviate the use of volatile organic solvents and the attendant hazards of toxicity or explosion.

EXPERIMENTAL

Preliminary feasibility work indicated that satisfactory coatings could be expected from application of any one of several basic formulas described in the patent (5). Two basic formulations containing pharmaceutical grade shellac (10 and 20%) and I were selected. Since little is known concerning the solvent properties of the molten I–shellac mixtures, selection of materials for screening could not be made on this basis. Therefore, approximately 50 materials were selected with different properties, *i.e.*, hydrophobic, hydrophilic, or surface active. Each was also believed not to represent a toxicological hazard should it be considered for future use.

Each additive was first prepared as 1 and 10% (by weight) solutions or dispersions in the molten mixture to determine miscibility. Approximately 60% of the additives were miscible at both levels. This group, in general, included alcohols, acids, esters, and glycols. Saccharides as a group were insoluble. Only 17 additives are included in this report. The others were eliminated, since, during later trials, their inclusion made application of satisfactory film coats impossible.

Materials that appeared soluble in the basic coating mixture at 110–140° included cocoa butter, castor oil, stearic acid, oleic acid, abietic acid, I, polyethylene glycol 6000, glycerin, propylene glycol, glyceryl monostearate, acetylated monoglycerides[1], tristearin, benzyl benzoate, polyoxyethylene-polyoxypropylene block polymers of molecular weight 2500[2] (II) and 8350[3] (III), polyoxyethylene lauryl ether[4], and polysorbate 80. Carnauba wax, cetyl alcohol, and stearyl alcohol were soluble at 140° but insoluble at 110°. Materials insoluble at 100–140° included paraffin, mineral oil, corn oil, beeswax, solid petrolatum, mannitol, carboxypolymethylene,

[a] Median of the range of 12 tablets disintegrated as described in USP XVII. [b] Range encountered in disintegration of 12 tablets as described. [c] Average coating weight in milligrams based on an average of 30 tablets as compared to an average weight of 30 uncoated control tablets. [d] Standard deviation in milligrams based on 30 individual weights of coated tablets (or an uncoated control). [e] Standard deviation in milligrams of the coat; obtained from $SD = \sqrt{(SD)_c^2 - (SD)_u^2}$, where $(SD)_c$ = standard deviation of coated tablets, and $(SD)_u$ = standard deviation of uncoated tablets. [f] Percent loss—20 tablets rotated for 4 min. in a Roche friabilator. (1) signifies splitting. [g] Coefficient of variation (of coat) = $\sqrt{(SD)_c^2 - (SD)_u^2}/W_c \cdot 100$, where W_c = weight of coat. [h] A number indicating the delay in disintegration contributed by a unit weight of applied coating. Units of this number are seconds per milligram. The lower the number, the faster the coat will disintegrate. [i] Average point-score rating of six people familiar with tablet dosage forms (1 = excellent and 18 = very poor). Tablets were inspected for smoothness, mottling, shine, and general appearance.

lactose, sucrose, dextrose, corn syrup solids, sorbitol, ethylcellulose (50 cps.), microcrystalline cellulose, sodium alginate, sodium carboxymethylcellulose, sodium lauryl sulfate, hydroxypropyl methylcellulose, polyvinylpyrrolidone, cetylpyridinium chloride, urea, sorbitan tristearate[6], hydroxypropyl cellulose[6], and gelatin. Isopropyl myristate and acacia, while insoluble, were readily suspendable and sprayable. Glyceryl monostearate and tristearin, while soluble, were eliminated because they imparted poor spraying characteristics to the basic formulations.

EQUIPMENT, MATERIALS, AND METHODS

A rotary tablet machine[7] (16 station) equipped with 0.95-cm. (0.375-in.) deep cup punches was used to compress placebo tablets. Tablets were prepared by direct compression from anhydrous lactose USP, direct tableting grade[8], and lubricated with 1% magnesium stearate. Tablets were compressed at a weight of 250 mg. each.

Two basic coating mixtures were prepared. One consisted of a 10% solution, by weight, of pharmaceutical grade dry shellac[9] with 90% I. The second was a mixture of 20% shellac, by weight, with 80% I. Approximately half the required amount of I was melted, shellac was added with constant stirring, and heat was applied until solution was complete. Heat was then discontinued, and the remainder of I was added and mixed. The molten mass was cast into paper cups and allowed to harden. The resulting ingots were later remelted and mixed with other ingredients. At this time, 0.5% of D&C Yellow No. 10 was added to define more easily areas of application and to evaluate the uniformity of the coat during the spraying operation.

During the coating process, the tablets were rotated in a stainless steel coating pan having a diameter of approximately 16.51 cm. (6.5 in.) at a rate of 43 r.p.m.

The coating compositions were applied to the rotating tablets by spraying molten material at 110–140° through a steam-jacketed pneumatic spray head[10]. Low pressure (12 psig.) steam was introduced into the steam jacket to keep the spray head hot during the operation. In each instance, the spray coat was applied to batches of 175 g. of tablets for 5 min. Air pressure for atomization was regulated at 15 psig.

Within 10 days after they were coated, the tablets were evaluated initially for friability, appearance, disintegration, and tablet-to-tablet uniformity of coat. Since these were screening studies, factors such as the additives being capable of assuming more than one crystalline form on cooling were not considered. These factors could be defined later should an additive appear promising as a result of this preliminary evaluation. Weights of tablets were obtained using a balance[11], and friability was determined[12] (6). Disintegration times were determined using the Stoll–Gershberg apparatus, with disks, and 37° distilled water as described in the USP XVII (7). The appearance of the coats before and after storage for 9 months at ambient room temperature was checked visually. In addition, the tablets were inspected for sticking (clumping), fading, and general appearance.

Tables I and II record disintegration times (in seconds) presented as a median of the range of 12 tablets for each formula modification presented, the range of disintegration times (in seconds), the coating weight, friability, appearance, coefficient of variation of the coat, and a factor derived from the other physical parameters.

The range of disintegration times, in general, may reflect uniformity or nonuniformity of the coat, with the more uniform coat exhibiting the narrowest range.

The weight of the coat is an index of the sprayability of the coating material. Since the time of application is uniform, the increase in coating weight over that of the coated control indicates increasing sprayability and vice versa. Since the weight of the coat varied from additive to additive and with the coated control, a normalizing

[a–i] See footnotes to Table I.

factor, called a disintegration factor (D.F.), was developed to aid comparison among modified coatings as follows:

$$\text{D.F.} = \frac{t}{W_c} \qquad \text{(Eq. 1)}$$

where t = median of the disintegration time of 12 tablets (seconds), and W_c = average weight of the coat (milligrams). A comparison of the disintegration factor for a modified coating material with that of the coated control indicates the effect of the additive upon the apparent rate of solution of the basic coating formulation.

DISCUSSION

Throughout the experiment, attempts were made to keep variables at a minimum. The objective was to determine the effects of individual additives on the coating. Although certain additives such as carnauba wax, cetyl alcohol, and stearyl alcohol were miscible with the basic coating formulations, these materials raised the melting points of the formulations to such an extent that acceptable coats could not be achieved when these additives were used in 10% concentrations.

Other additives such as isopropyl myristate and acacia were not miscible with the coating compositions. However, they were suspendable to some degree and were included since they did not interfere with the sprayability of the coats. Isopropyl myristate formed a temporary emulsion and greatly improved the performance of the spraying operation as well as the appearance of the finished tablets.

It was generally observed that the series consisting of 10% shellac–90% I could be applied much more easily and resulted in tablets of a more elegant appearance than the series containing 20% shellac–80% I (last column, Tables I and II).

Examination of tablets stored 6 weeks at 45° revealed that all tablets had faded except those containing cocoa butter, castor oil, oleic acid, or glycerin. The mechanism of the stabilizing effect of these additives on the D&C Yellow No. 10 is not clear at this time. Tablets stored 9 months at room temperature did not exhibit the same degree of color instability.

Tablets stored 6 weeks at 45° containing benzyl benzoate, polyethylene glycol 400, propylene glycol, or II had softened to the point where they had clumped together. Here, again, tablets stored 9 months at room temperature presented a slightly different picture.

In general, the 9-month room temperature evaluation was more revealing than the high temperature study. The coated control

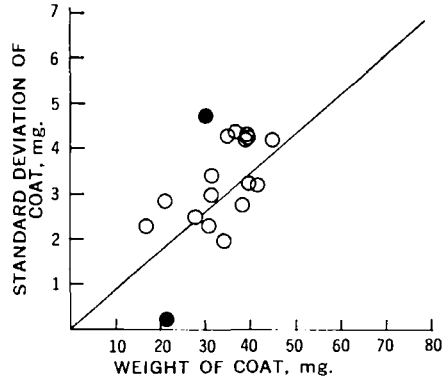

Figure 2—*Dependence of the standard deviation of the coat upon the weight of the coat illustrated for the 20% shellac–80% I system. Key: ●, parameters of additives that are statistically different from the parameters of the other additives;* i.e., *the process is out of control.*

Table III—Comparative Rank of Acceptable Additives According to Descriptive Factors

Additive	Disintegration Factor		Coefficient of Variation		Appearance		Row Total
	A[a]	B[b]	A[a]	B[b]	A[a]	B[b]	
Castor oil	1	3	1	3	4	2	14
Cocoa butter	3	2	4	2	3	3	17
Isopropyl myristate	2	1	1	3	1	1	9
Polyethylene glycol 6000	5	5	5	5	2	5	27
Coated control	4	3	3	1	5	4	20

[a] A = 10% shellac–90% I base. [b] B = 20% shellac–80% I base.

tablet exhibited a slight degree of clumping, and tablets could easily be separated with one or two gentle shakes of the container. This was also the case with all tablets found to exhibit clumping, with the exception of those containing benzyl benzoate, polyethylene glycol 400, polysorbate 80, propylene glycol, II, abietic acid, and acetylated monoglycerides, which required slightly more vigorous shaking.

Coatings composed of the 10% shellac–90% I base with cocoa butter, polyethylene glycol 6000, or isopropyl myristate additives exhibited no clumping or fading after 9 months of storage at room temperature.

Coatings composed of the 20% shellac–80% I base with castor oil, polyethylene glycol 6000, isopropyl myristate, or cocoa butter additives performed in a like manner. With respect to clumping and fading, these additives provide an improvement over the coated control.

As a result of the 9-month room temperature evaluation, only four of the 17 miscible additives were found to be useful as modifying agents to the basic formulations. These additives are castor oil, cocoa butter, isopropyl myristate, and polyethylene glycol 6000.

Regarding weight, the coefficients of variation (α) of the coats are listed in Tables I and II and were calculated by:

$$\alpha = 100 \cdot \frac{\sqrt{(SD)_c^2 - (SD)_u^2}}{W_c} \qquad \text{(Eq. 2)}$$

where $(SD)_c$ = standard deviation of coated tablets, $(SD)_u$ = standard deviation of uncoated tablets, and W_c = average weight of coating. An F test shows acacia and polyethylene glycol 6000 to be significantly different from the remainder when the data in Table I are considered; glycerin and II are likewise significantly different from the remainder when the data in Table II are considered. The coefficient of variation *for the process* can be obtained from a plot of standard deviation of coats, SD, *versus* W_c (with the constraint of zero intercept), and the coefficient of variation for the process emerges in the slope of the line (Figs. 1 and 2).

A least-squares fit yields $\alpha = \Sigma SD \cdot W_c / \Sigma W_c^2 = 0.0952$ or 9–10% for Fig. 1 and 0.0988 or 9–10% for Fig. 2. These values are, of course, close to the coefficient of variation for the coated control, showing that, within statistical limits, the substances tested (other than acacia and polyethylene glycol 6000 in Table I and glycerin and II in Table II) are not detrimental to the uniformity of the coat.

The disintegration factor, coefficient of variation of the coat, and appearance rating for each additive were ranked in relation to the others and to those of the coated control. The order of rank was assigned on the basis of the lowest number in each category being assigned first order in rank, *etc.* The results of this ranking are in Table III. Note that each additive is ranked for each criterion in each of the two basic formulations.

To select an order of preference for the use of these additives, the ranks which each additive held in each category and for each basic formulation were summed ("Row Total" column of Table III). Again, the lower the sum the more desirable is the effect of the additive upon the basic formulation. From Table III, it can be seen that isopropyl myristate, castor oil, and cocoa butter all improved the basic formulations while polyethylene glycol 6000 ranks lower than the coated control.

The disintegration factor for each additive to the 10% shellac–90% I basic formulation was divided by the corresponding factor in the 20% shellac–80% I basic formulation. The quotients were then summed and averaged, and their standard deviation was computed. When this average, 0.66 ($SD = \pm 0.15$), is compared to the quotient obtained from a like division of the disintegration factors for the coated controls, 0.76, the conclusion can be made that shellac is the controlling factor with regard to disintegration of this type of coating composition.

A similar treatment was applied to the coefficients of variation. The ratio for glycerin was aberrent to those obtained for the other additives. When the ratio for glycerin is eliminated, the average of the ratios for the remaining additives, 1.17 ($SD = \pm 0.58$), was, within statistical limits, consistent with that for the coated controls, 1.3. Examination of the quotients for individual additives reveals that glycerin, acacia, polyethylene glycol 6000, and propylene glycol effect a considerable increase in uniformity with increasing concentration of shellac. These agents probably act as plasticizers for the shellac and should be considered as such when used in combination with shellac. Since only one concentration of each additive was evaluated with each of two concentrations of shellac, a more comprehensive factorial analysis of the data was not attempted. However, the results of these screening studies did elucidate additives suitable for future work.

SUMMARY AND CONCLUSIONS

1. A novel method was described for application of tablet coatings. Tables citing the effect of various additives to the two basic coating compositions described were presented.

2. A disintegration factor was developed to aid comparison of basic coating formulations and the effect of additives upon them in conjunction with the use of the coefficient of variation. Use of these factors resulted in the selection of three additives that favorably modify the basic formulations described herein. Based on an overall appraisal, improvements in the basic coats were attained by addition of 10% (w/w) castor oil, cocoa butter, or isopropyl myristate to a shellac–polyethylene glycol 4000 mixture. These additives not only improved stability with respect to clumping and fading but also with respect to disintegration, friability, uniformity of coat, and appearance.

3. The concentration of shellac in the basic formulation appears to control disintegration regardless of additives.

Physical and Chemical Characteristics of Water-Soluble, Semisolid, Anhydrous Bases for Possible Ophthalmic Use

DAVID W. NEWTON*, CHARLES H. BECKER▲, and GEORGE TOROSIAN

Abstract □ Following a preliminary review of pertinent literature citations, a total of 84 semisolid, water-soluble, anhydrous bases for possible ophthalmic use was formulated. Of these 84 exploratory bases, five were designated evaluatory bases for further study on the basis of apparent pH and/or desirable physical spreadability characteristics over the temperature range of 0–50°. Four of the five bases were further characterized by rotational viscometer studies, and an organogel was selected on the basis of several of its listed attributes as the best attempt in this investigation to formulate the type of semisolid base desired for possible ophthalmic use.

Keyphrases □ Semisolid bases—formulated, evaluated for use as potential ophthalmic ointments, pH and viscosity considerations □ Ophthalmic ointments, potential—formulation, evaluation of semisolid, water-soluble, anhydrous bases, pH and viscosity considerations □ Organogels—formulated for use as possible ophthalmic ointments

In USP XVIII (1), four classes of ointment or semisolid bases are recognized on the basis of physical characteristics: hydrocarbon or grease-type bases, absorption bases, water-removable bases, and water-soluble bases. Although polyethylene glycol ointment USP is the only official nonaqueous, water-soluble base, the more recent organogel-type bases comprise a little investigated supplement to these classes.

In the past, a hydrocarbon-type base was the most frequent choice when an anhydrous base was required; however, the nonaqueous organogels may offer advantages over the hydrocarbons and other traditional bases because of some of the following undesirable attributes of the latter bases:

1. Spreadability or extrudability over only a narrow incidence of temperatures.
2. Irritation to eyes and mucous membranes.
3. Inability to release effectively active medicinal ingredients.
4. Incompatibility with body tissue at site of application.
5. Instability of active ingredient(s) in base, *e.g.*, physical separation and/or chemical decomposition upon storage, especially because of improper pH, oxidation-reduction reaction, hydrolysis, *etc.*
6. Lack of cosmetic or esthetic appeal, *e.g.*, greasiness or stickiness, which could result in improper application of the base by the patient.
7. Lack of a completely dependable sterilization method.
8. Difficulty in removal of contaminating particulate matter from the base because of inherent physical, chemical, and/or viscosity characteristics.

The purpose of this investigation was to formulate, by reproducible methods, semisolid, anhydrous, water-soluble bases spreadable and/or extrudable over the general temperature range of 0–50° and with an apparent acidic pH. Furthermore, the bases should be: (*a*) compatible with a variety of drugs for ophthalmic use, *e.g.*, antibiotics, alkaloids, dimercaprol, and corticosteroids; (*b*) clinically nonirritating to the eyes; and (*c*) able to release medicinal agents in a desirable therapeutic manner.

DISCUSSION

A gel (2) is a solid or semisolid system of two or more ingredients, including a matrix that encloses and is interpenetrated by a liquid vehicle. Gels that are formed by aggregates or floccules of small particles represent two-phase systems; upon standing, they may exist as semisolids but, upon stirring or agitation, they liquefy and thus are termed thixotropic or shear thinning. Gels may also consist of entangled and/or matted strands of long-chain polymeric macromolecules, which may be joined by van der Waals forces and may align in a parallel-type sequence to maintain a gel matrix within a vehicle. These gels of macromolecules are usually one-phase systems and may be termed organogels.

The main disadvantage of certain anhydrous organogel-type systems is a tendency toward syneresis, which was defined (3) as: "The spontaneous separation of an initially homogeneous colloid system into two phases, a coherent gel and a liquid. The liquid is actually a dilute solution whose composition depends on the original gel. When the liquid appears, the gel contracts, but there is no net change in volume."

USP XVIII (4) requires only that ophthalmic bases be free from contamination with viable microorganisms and palpable particulate matter, that they be nonirritating, that they permit effective release of medicinal agents, and that they maintain the activity of the agents for a reasonable time during storage.

Unfortunately, the ophthalmic applications and characteristics of water-soluble, anhydrous, organogel-type bases have not received much study. However, cosmetic applications are numerous and at least one topical base (5) containing the antifungal agent tolnaftate[1] exists. Moreover, some industrial pharmacists recently recommended use of the polyethylene glycol polymers in water-soluble ophthalmic bases and emphasized the importance of their cosmetic appeal with concomitant medicinal efficacy (6).

A variety of factors influence the ophthalmic use of drugs and/or semisolid bases. The primary site of drug action in the eye is the cornea. Although recent studies (7, 8) indicated precorneal tear film to be lipid in nature, most drugs probably penetrate to the cornea from semisolid bases with little influence from this thin precorneal tear film.

One study (9) involving rabbits indicated that particles greater than 50 μ in size are capable of causing significant mechanical eye irritation. Furthermore, application of excess amounts of hydrocarbon bases to postsurgical eyes resulted in the entry of visible globules of base into the anterior chamber, and in one case a globule of petrolatum persisted innocuously for 3 years (10, 11).

The pH values of normal human tears and of ophthalmic pharmaceuticals have received some attention; the pH of normal tears is about 7.4. Tears are reported to have a great buffer capacity and are able to alter almost immediately a drop of unbuffered solution between pH 3.5 and 10.5 to neutrality or slight alkalinity; for this reason, buffering of some ophthalmic products is not recommended by some authorities (12, 13). The importance of pH adjustment rather than buffering in some ophthalmic bases includes prevention of excess lacrimation (and subsequent drug loss from the eye) and maintenance of drug stability. As a general rule, most ophthalmic

[1] Tinactin Cream, Schering Corp., Bloomfield, N. J.

drugs are 100 times more stable at pH 5.0 than at pH 7.0, contingent upon dissociation characteristics of the compound and upon relative stability of the free base and cation (14).

Isotonicity is another factor of importance to ophthalmic products. Rosenberg (13) reported that tears directly in contact with the cornea are slightly hypertonic. A second source (15) indicated 0.93% rather than the classical 0.90% as the true NaCl equivalent of normal tears and suggested that irritation to the eyes occurred only when the NaCl equivalent extremes of less than 0.6% and more than 2.0% existed.

Nearly all eye irritation tests involve the use of animals, usually albino rabbits, and clinical observation of their eyes periodically following instillation of the test compound. The standard for these tests is the Draize eye irritation test (16). The Draize test, when compared with several other similar tests in a recent comprehensive study (17), indicated as high as 100% error for a given test compound between it and the test normally used by the participating laboratory. Thus, results such as these support the need to delineate between irritation such as definite physical damage (*e.g.*, lesions, tissue swelling, and excess erythema) to the eyes of animals and the transitory discomfort irritation experienced subjectively by humans.

Viscosity (18), *i.e.*, resistance to flow of a fluid under stress, has been directly related to both the diffusion rate of a drug from a semisolid base and the therapeutic efficacy of the drug in the base (19–21). However, one study (22) of some organogel-type bases made from carboxy vinyl polymers[2] and involving ocular absorption of several drugs from the bases showed no correlation between viscosity of the base and drug release. A second study (23) indicated no change in viscosity of some carboxy vinyl polymer gels after 4 weeks of exposure to sunlight or repeated autoclaving at 121° and 15 p.s.i. for 15 min.

NF XIII (24) suggested that medications including antibiotics may be more effective in water-soluble rather than in hydrocarbon-type bases. This contention was corroborated for some polyethylene glycol-type bases by some investigators (25, 26). One study (27) involving incorporation of sulfa drugs, coal tar, and ichthammol into semisolid carboxy vinyl polymer bases indicated good stability of the drugs in the bases. However, the disadvantage of complexation of certain drugs with polyethylene glycols was established in other studies (28, 29). Some researchers (23, 30) indicated contaminants within the polyethylene glycols and carboxy vinyl polymers as a source of drug and/or semisolid base degradation.

A final important factor in the ophthalmic use of semisolid bases is sterility. The cornea and anterior chamber of the eye offer an optimum environment for growth of many types of pathogenic microorganisms, since these tissues lack the immunological defenses ambient in the bloodstream (31). Therefore, there is a stringent requirement for sterility in the manufacture and product life of semisolid bases for ophthalmic use. Several different studies (22, 32–34) of the sterility of commercially prepared ophthalmic ointments each indicated that some portion of the sample population was contaminated with viable microorganisms.

EXPERIMENTAL[3]

Materials—Materials used in this investigation were selected on the basis of previous similar research[4] (35) and with consideration of water-solubility, official and unofficial reports of low incidence of eye irritation and/or acute toxicity, ability to form semisolid bases or organogels in selected combinations, and commercial availability. All materials were of USP grade unless otherwise specified.

Table I—Percent (Weight) of Materials and Methods of Preparation of Evaluatory Bases

Base	Matrix Solids	Percent	Vehicles	Percent	Method of Preparation
E-1	Micronized, fumed silica, M-5[a]	7.3	Glycerin	91.2	A
	Nonionic surfactant polyol, F68[b]	1.5

Formulation and Evaluation of Bases—Initial investigation in this study involved formulation of approximately 100 g. of each of 84 exploratory bases produced by one of the following methods:

Method A—The liquid vehicle was heated to 90° on a water bath with stirring at medium speed. Then the matrix polymer (solid) was added with continued heating and stirring until either a homogeneous dispersion or gelation resulted.

Method B—The matrix polymer was added to the liquid vehicle with stirring at medium speed at 22–25° for 48 hr. Then the dispersion was heated carefully to 125° with stirring and maintained at 125° for 1 hr., after which a homogeneous gel resulted.

Method C—The liquid vehicle and polymer solids were combined with stirring at medium speed at 65° until homogeneously mixed. Heat was then removed and the mixture was allowed to congeal or thicken with continuous stirring until its temperature reached 30°.

Method D—The matrix polymer was added to the liquid vehicle(s) with stirring at medium speed at 22–25°; stirring was continued for 1–2 hr. until a homogeneous dispersion resulted. This dispersion was then heated to 85–95° with stirring at medium speed and neutralized with an appropriate amine to yield a collapsed or viscous organogel.

Each of the 84 exploratory bases was developed incrementally by the addition of small portions of matrix solids to the balance of the liquid vehicle(s). After each addition, the physical characteristics of each base were observed at 0, 30, and 50°, and increments of matrix ingredients were added until a desirable base resulted or the amount

[2] Various Carbopols, B. F. Goodrich Chemical Co., Cleveland, Ohio.

[3] All liquids not measured in standard graduated cylinders were weighed on either an Ohaus "Dial-O-Gram" 1600 series balance (which reads to 0.1 g.) or a Mettler B-5 analytical balance. Bases were mixed in glass beakers of appropriate size using a model F "Lightnin' Mixer" equipped with a three-bladed marine-type impeller. Heat was provided by a Corning model PC-35 hot plate. Determinations of pH were conducted on a Corning model 10 pH meter with standard Corning electrodes; a Corning model PC-353 magnetic stirrer was used to mix all samples constantly for pH determinations. Samples of bases were placed into 90-ml. (3-oz.), general purpose (NP), amber glass ointment jars fitted with metal screw caps with waxed cardboard liners; they were stored in Thelco model 6M ovens adjusted to 30 and 50° and in a Herrick refrigerator adjusted to 0°. Viscosity studies were conducted on a Haake Rotovisko (model 67-369) rotational viscometer equipped with six-bladed star-shaped paddle (FL-10).

Table II—Physical Characteristics of Evaluatory Bases at Selected Temperatures[a]

Base	0°	30°	50°
E-1	tr, sp, ss	c, f, tk, sp, l	tr, f, tk, sp, l
E-2	tr, sp, ss	tr, sp, s	tr, sp, ss
E-3	tr, sp, ss	c, sp, ss	c, sp, ss
E-4	o, sp, ss	o, sp, ss	o, sp, ss
E-5	c, sp, ss	c, sp, ss	o, sp, ss

[a] Abbreviations are as follows: c, clear or transparent; f, flowing; tr, translucent; o, opaque; tk, thick; sp, spreadable; l, liquid (a base that flows to some extent at temperature specified); and ss, semisolid (a base that is spreadable and/or extrudable at temperature specified).

Table III—Apparent pH values for Diluted Evaluatory Bases

Base	pH of 10 g. Base Diluted to 50 ml. with Distilled Water[a]
E-1	5.4
E-2	3.3
E-3	4.4
E-5	4.2

[a] The pH of the distilled water used to dilute all samples was 7.0.

of solids approached 15% by weight (because of limited amounts of some ingredients) and a semisolid base did not result.

On the basis of physical characteristics at 0, 30, and 50° and of apparent pH, five of the 84 exploratory bases were designated evaluatory Bases E-1 through E-5. The formulas and physical characteristics of Bases E-1 through E-5 are listed in Tables I and II, respectively.

Determinations of apparent pH of the bases studied were conducted as follows. Exactly 10 g. of the base was diluted to 50 ml. with distilled water and thoroughly dispersed. The pH value of the dispersion was then observed. The pH values of E-1, E-2, E-3, and E-5 are listed in Table III. In an attempt to determine arbitrarily if these four bases were buffer-type systems, 10 g. of each was thoroughly dispersed in distilled water to make 100 ml. and this dispersion was titrated with 0.1 *N* NaOH solution until pH 7.0 was reached. The results of these titrations are listed in Table IV.

Viscosity studies[5] were conducted at 30° on 100-g. samples of E-1, E-2, E-3, and E-5 by immersing the star-shaped paddle to a standard depth in the sample, allowing it to remain in place for 1 min., and then engaging the clutch at a selected *U* value. Upon clutch engagement, the initial *S* value, S_0, was read; the viscometer was then allowed to operate for 2 min. until a second *S* value, S_2, was recorded. An undisturbed sample of each base was used for each separate determination at each given *U* value.

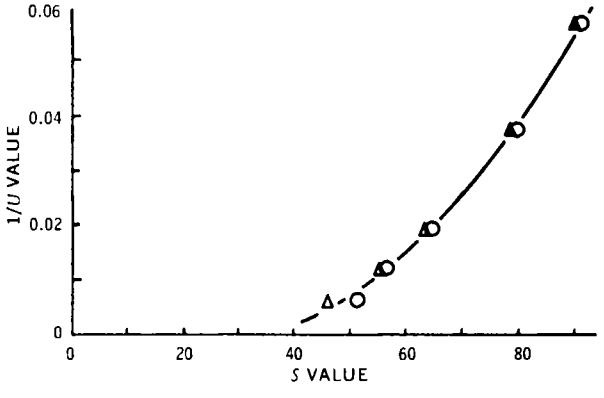

Figure 1—*Characteristic viscosity curve for Base E-5 at zero time and observed at 30°. Key:* ○, S_0; *and* △, S_2.

Table IV—Amount of 0.1 *N* NaOH Solution Required to Neutralize 10 g. of Base Diluted to 100 ml. with Distilled Water[a,b]

Base	pH of 10 g. Base Diluted to 100 ml.	Amount 0.1 *N* NaOH Required, ml.
E-1	6.1	0.1
E-2	3.5	11.9
E-3	4.0	—[c]
E-5	3.9	—[c]

[a] The pH of the distilled water used was 7.0. [b] All readings were taken at 30°. [c] Addition of approximately 2.5 ml. of 0.1 *N* NaOH solution yielded a thick, collapsed semisolid gel of pH 5.2, which thickened more with further addition of 0.1 *N* NaOH and prevented pH determination concurrent with titration by 0.1 *N* NaOH.

Following viscometer evaluations of each base at five different *U* values at zero time (0–96 hr. after formulation of the base), five tightly sealed samples of each base were stored in glass containers for 1 month in two ovens adjusted to 30 and 50°, respectively. Following this storage, viscometer studies on E-1, E-2, E-3, and E-5 were completed as previously described and at 30°.

RESULTS

The findings after storage of samples of Bases E-1, E-2, E-3, and E-5 at 30 and 50° for 1 month and subsequent viscosity studies and attempts to describe rheological[6] (36) characteristics of these bases are summarized as follows.

1. Storage of E-1 at 50° for 1 month resulted in syneresis of the normally thixotropic system; storage of E-1 at 30° for 1 month resulted in a viscous liquid-type system, which appeared nearly Newtonian in rheological behavior.

2. Storage of E-2 at 50° for 1 month resulted in a two-layered system (liquid upper phase and semisolid lower phase). Storage of E-2 at 30° for 1 month resulted in a homogeneous organogel system, which indicated development of some thixotropy.

3. Storage of E-3 at 50° for 1 month resulted in an apparent dilatent (shear-thickening) system, probably as a result of redispersion of microscopic transparent lumps of matrix polymer by the agitation of the viscometer paddle. Storage of E-3 at 30° for 1 month resulted in plots of S_0 and S_2 that were nearly coincidental and were very similar to plots for E-3 at zero time.

4. Storage of E-5 at 50° for 1 month resulted in an organogel containing some small dense lumps, whereas storage of this base at 30° for 1 month resulted in a thick homogeneous organogel. A comparison of plots of S_0 and S_2 in Fig. 1 with those in Figs. 2 and 3 indicates that storage of E-5 for 1 month at 30 and 50°, respectively, resulted in some thixotropy of the base. However, for given *U* values, plots of S_0 are in approximately the same position along the abscissas of all three figures; this suggests acceptable stability

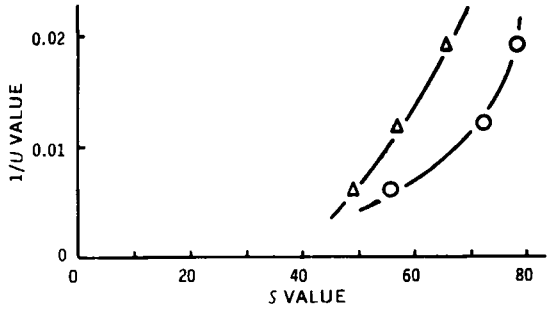

Figure 2—*Characteristic viscosity curve for Base E-5 after storage for 1 month at 30° and observed at 30°. Key:* ○, S_0; *and* △, S_2.

[5] The viscometer is fitted with an *S* scale of 0–100 arbitrary units, corresponding to shearing stress, and with a *U* scale of 10 arbitrary clutch values, corresponding to rates of shear. The viscometer is also equipped with a sensitivity switch adjustable for "fine" or "normal" and with a head setting switch with the settings 50 and 500 (the 500 setting is theoretically 10 times as sensitive as the 50 setting and is used for highly viscous samples).

[6] Rheology may be defined as the study of deformation of solids and flow of liquids.

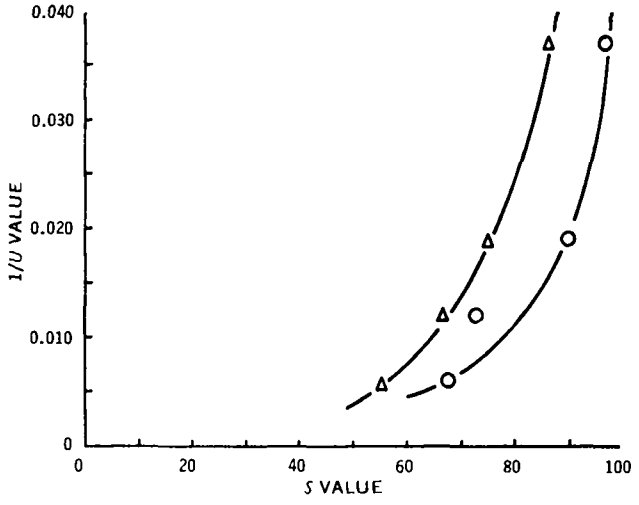

Figure 3—*Characteristic viscosity curve for Base E-5 after storage for 1 month at 50° and observed at 30°. Key: O, S_0; and Δ, S_2.*

of E-5 regarding resistance to changes in viscosity resulting from storage at 30 and 50° for at least 1 month.

Preliminary analyses[7] of E-5 (for dimercaprol content) containing approximately 6% dimercaprol and stored at selected temperatures in Type I glass containers are reported in Table V. Dimercaprol was selected as the initial test medicament for incorporation into Bases E-1 through E-5. It is employed ophthalmically as an antidote for heavy metal poisons and certain vesiccants, and its stability is a function of pH, temperature, and oxidation.

Formulation of E-2 (without dimercaprol) by Method B resulted in the appearance of a dark-pink color as the dispersion reached 125°. This is a probable result of a chemical reaction of poly(methyl vinyl ether-maleic anhydride) 139 with polyethylene glycol 200, since such reactions are known to occur (37); the reaction product (probably a chromophore compound) is possibly only an intermediate since the pink color disappeared after storage of the base for 1–2 weeks at 30°. This possible reaction could explain large variations in the physical consistency of E-2 at zero time as compared to that when the base is stored for 1 month at 30 and 50°.

The appearance of small, dense lumps in E-3 and E-5 after storage for 1 month at 30 and 50° may be the result of coalescence of microscopic particles of partially dissolved carboxy vinyl polymer 940; appearance of the lumps could also be suspected to be a function of prolonged storage at higher temperatures.

A serious disadvantage of the methods of preparation of the bases in this investigation is the entrainment of large amounts (in some cases) of small air bubbles, especially in organogels formulated from carboxy vinyl polymers. This entrainment of air could result in a nonhomogeneous rheological system, degradation of the base upon storage, and/or decomposition of potentially active medicinal ingredients. It is possible that these air bubbles could have been eliminated by preparing the bases under partial vacuum or that they could have been removed from the finished bases by partial evacuation of the system. Vacuum treatment, however, was not investigated. Furthermore, one investigator (38) studied the use of ultrasonic homogenizers in preparing organogels of carboxy vinyl polymers which were virtually free of entrained air.

CONCLUSIONS

In this investigation, Base E-5 represented the best attempt to formulate a semisolid, anhydrous, water-soluble base for ophthalmic use as determined by the following parameters:

[7] Analyses of E-5 containing approximately 6% dimercaprol were conducted as follows. Three 0.1–0.3-g. samples of E-5, weighed to the nearest 0.1 mg., were placed in nitrogen-flushed, 125-ml., rubber-stoppered conical flasks. Then 30–40 ml. distilled water and 3 ml. of 0.30 *M* phosphate buffer (pH 7) were added, the samples were thoroughly dispersed, and the dimercaprol was titrated with fresh iodide solution using freshly prepared starch solution as the end-point indicator.

Table V—Results of Preliminary Analyses of Approximately 6% (w/w) Dimercaprol in Base E-5 Stored in Type I Glass Vials[a,b]

Time Stored	Storage Temperature	Dimercaprol Remaining, %	Degradation of Dimercaprol, %
Zero time	30°	5.73	0.0
2 weeks	30°	5.76	0.0
1 month	30°	5.71	0.3
2 months	30°	5.75	0.0
3 months	30°	5.67	1.0
Zero time	50°	5.73	0.0
2 weeks	50°	5.63	1.7
1 month	50°	5.63	1.7
2 months	50°	5.57	2.8
3 months	50°	5.40	5.8

[a] Differences of 0.15 (or less) unit regarding percent dimercaprol remaining were considered insignificant and probably due to human variation in the precision of the analyses. [b] Results for bases other than E-5 and for other temperatures and containers other than Type I glass will be reported in subsequent studies.

1. Desirable physical spreadability characteristics over the temperature range of 0–50°.
2. An apparent pH value in the acidic range (which may be important to the stability of many ophthalmic drugs).
3. Desirable lubricity.
4. The cosmetic appeal of greaselessness and possible esthetic and technical attributes of transparency.
5. Least observed change in physical characteristics of all bases studied after storage at 30 and 50° for 1 month.
6. Apparent lack of strong buffer capacity and thickening due to viscosity of a 10% (w/v) aqueous dispersion with addition of small amounts of dilute alkali which, in the near neutral environment of the eye, could result in advantageous prolonged contact of a medicated base with the eye.
7. Content of the maximum amount[8] of the most desirable (in this investigation) vehicle, polyethylene glycol 400; polyethylene glycol 400 is the least hygroscopic (39) of the solvents used, its known eye irritation and acute toxicity are low, it is official in USP XVIII, and it has desirable lubricity and viscosity characteristics.
8. Known low eye irritation by the primary matrix polymer, carboxy vinyl polymer 940, as reported for a 1% aqueous solution (40), resistance of some gels of carboxy vinyl polymer 940 to support fungal and bacterial growth (41); and the possibility that some gels of carboxy vinyl polymer 940 may be sterilized by autoclaving without significant change in viscosity (23).
9. Optimistic preliminary reports of tolerable rates of degradation of dimercaprol incorporated in E-5 when stored in Type I glass vials at various temperatures for selected time (Table V).

Further research concerning ophthalmic bases such as those formulated for this investigation will attempt to elucidate eye irritation properties of the bases through animal testing, compatibility of the bases with several types of containers designed for unit dose-type application, compatibility and stability of various ophthalmic drugs in the bases, and therapeutic efficacy of the bases in antidoting the deleterious effects of selected compounds through a program of clinical diagnosis of the eyes of intentionally inoculated animals.

Differential Thermal Analysis as Screening Technique for Candidate Adjuvants in a Parenteral Formulation: Cephradine for Injection

HAROLD JACOBSON▲ and IRWIN GIBBS

Abstract □ Differential thermal analysis (DTA) was used to study parenteral formulations of cephradine. Such studies showed that cephradine interacted with *N*-methylglucamine, tromethamine, and trisodium phosphate dodecahydrate, but it did not react with anhydrous sodium carbonate. The presence of an interaction does not necessarily indicate incompatibility, but it is an early warning of such a possibility. Finally, because DTA showed no new characteristic peaks, the absence of eutectics or of other specific phase entities could be presumed. Chemical analyses of various test formulations that had been stored at 23 and 50° gave excellent correlations with the results obtained earlier by DTA and showed that the interactions had been ones of incompatibility.

Keyphrases □ Adjuvants, parenteral formulations—use of differential thermal analysis as a screening technique, cephradine □ Parenteral formulations—drug–adjuvant interactions screened using differential thermal analysis □ Cephradine—suitability of adjuvants for parenteral formulation screened using differential thermal analysis □ Differential thermal analysis—use in determining suitability of adjuvants for cephradine parenteral formulation

Jacobson and Reier (1) discussed the application of differential thermal analysis (DTA) to problems of compatibility and stability that occur with mixtures of solid-state drugs and excipients, notably combinations of penicillin and stearic acid. The method is here extended to a study of parenteral formulations of cephradine, a new antibiotic of the cephalosporin class, coincidentally emphasizing the general utility of this rapid screening method.

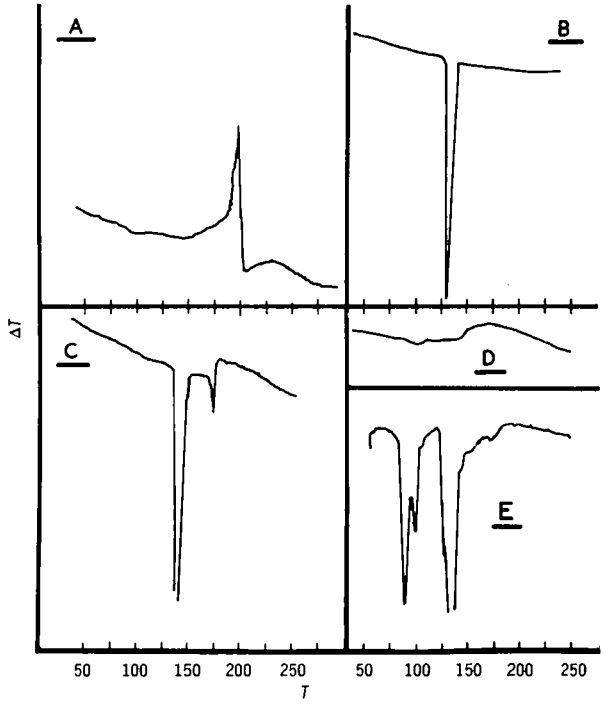

Figure 1—*Thermograms of pure materials. Key: A, cephradine; B, N-methylglucamine; C, tromethamine; D, anhydrous sodium carbonate; and E, trisodium phosphate dodecahydrate.*

In the formulation of a parenteral dosage form of cephradine, a stable, dry powder for reconstitution was sought which could be readily dissolved just prior to injection. Dürsch[1] suggested the use of a solubilizing adjuvant for the parenteral form of cephradine.

Several physiologically acceptable solubilizing adjuvants exist, and it became necessary to establish that the dry powder mixture of each adjuvant with cephradine exhibited stability under the usual storage conditions. Among the possible solubilizers, *N*-methylglucamine, tromethamine, trisodium phosphate dodecahydrate, and anhydrous sodium carbonate appeared useful.

EXPERIMENTAL

Blends of cephradine with the appropriate solubilizer were prepared, using the minimum amount of solubilizer that would give a complete solution in 1 min. or less when 250 mg. of cephradine was reconstituted with 1.2 ml. of water.

The tromethamine and trisodium phosphate dodecahydrate employed were reagent grade, the *N*-methylglucamine was USP grade (2), and the anhydrous sodium carbonate conformed to specifications in the British Pharmacopoeia (3).

The mole fractions of solubilizer in the respective blends were: *N*-methylglucamine, 0.445; trisodium phosphate dodecahydrate, 0.374; tromethamine, 0.564; and anhydrous sodium carbonate, 0.500.

Each solubilizer was passed through a 40-mesh screen before being blended with cephradine in a mortar and pestle. Containers for storage were 7.5-ml. siliconed, type III glass vials with butyl rubber stoppers. Samples were stored at 23 and 50°.

The thermograms of the freshly prepared mixtures were obtained on a thermal analyzer[2], using 2-mm. microsample tubes. A heating rate of 15°/min. was used, with a differential sensitivity of 1°/2.54 cm. The thermograms were obtained in the presence of static air.

The stability of cephradine in each blend was determined by an iodometric assay method (4).

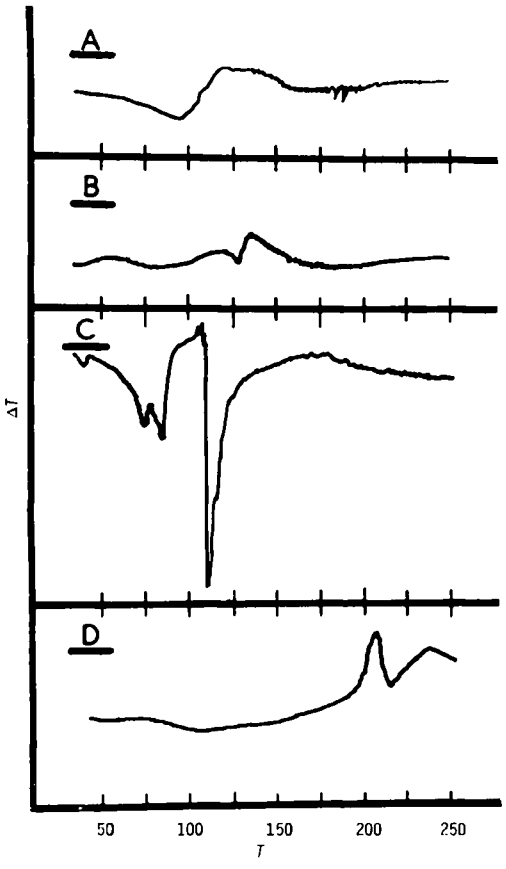

Figure 2—*Thermograms of mixtures of cephradine with: (A) N-methylglucamine, (B) tromethamine, (C) trisodium phosphate dodecahydrate, and (D) anhydrous sodium carbonate.*

RESULTS AND DISCUSSION

Thermograms of the pure materials are shown in Fig. 1. The exotherm observed with cephradine between 175 and 200° was due to an oxidative degradation. The endotherm exhibited by *N*-methylglucamine at about 129° was due to melting; those in tromethamine were due to a solid-solid phase transition (5) and to melting. Sodium carbonate had no characteristic features at temperatures of interest (up to about 350°). The first two endotherms of trisodium phosphate dodecahydrate (Fig. 1E) were due to desolvation, and the third was due to the boiling of released water.

Thermograms of the various mixtures are shown in Fig. 2. It was evident that interactions had taken place when cephradine was mixed with *N*-methylglucamine, tromethamine, or trisodium phosphate dodecahydrate. With the former two compounds, the features of both components of the mixture had been changed or obliterated. With trisodium phosphate dodecahydrate, only the features of cephradine were obliterated; those of the phosphate were largely intact and unchanged. In the thermogram of the mixture of cephradine and anhydrous sodium carbonate, the most significant feature is the retention of the cephradine exotherm at about 200°. It can be surmised that no interaction had taken place.

The presence of a physical or chemical interaction does not necessarily indicate incompatibility. It may indicate the formation of a eutectic mixture or the occurrence of a new phase with different thermal characteristics which are not necessarily deleterious to stability. However, the fact of an interaction is undeniable and gives an early warning for a more rational approach to the design of formulations.

In the examples examined in this work, DTA showed no new characteristic thermal peaks. Consequently, it could be presumed that eutectic mixtures or other specific phase entities, such as the formation of a new compound, were absent.

Figures 3 and 4 illustrate the potencies of the various blends as a function of time at 23 and 50°. The least stable blend (that with trisodium phosphate dodecahydrate) showed marked instability after storage at room temperature for 1 month. The other blends did not show a decline in potency by chemical assay when stored at room temperature for 6 months. At 50°, the mixture of cephradine with sodium phosphate dodecahydrate exhibited complete loss of potency as determined by chemical assay after 2 weeks of storage, while testing for at least 1 month was required to make a judgment of instability for the other mixtures. By use of DTA, the cephradine

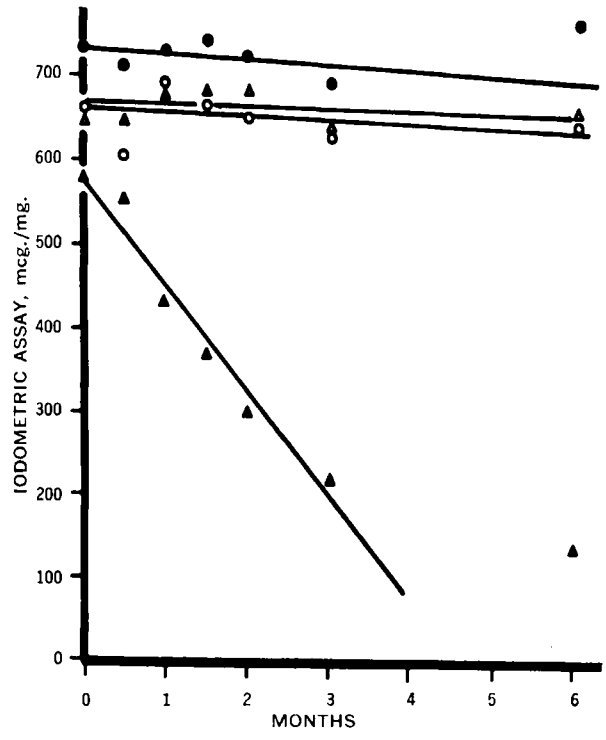

Figure 3—*Potencies of blends of cephradine as a function of time at 23°. Key for adjuvants: ▲, trisodium phosphate dodecahydrate; O, tromethamine; △, N-methylglucamine; and ●, anhydrous sodium carbonate.*

sodium carbonate mixture could be predicted to be the most stable blend after 1 day of testing. The prediction was clearly confirmed by results of a classical stability study requiring up to 6 months of storage at 50°.

Drug-Albumin Interactions Using Spin Labeling

J. BLANCHARD*, T. N. TOZER▲, D. L. SORBY, and L. DALLAS TUCK

Abstract □ Three spin labels were used to monitor possible drug-induced conformational changes in bovine serum albumin. The electron spin resonance spectra of labeled bovine serum albumin in all cases consisted of two subspectra corresponding to labels in a partially immobilized environment and a strongly immobilized environment. Only bovine serum albumin with the triazine spin label was suitable for quantitation of data. The strongly protein-bound acidic drug, phenylbutazone, caused a conversion of strongly immobilized sites to partially immobilized sites, an effect that was proportional to the amount of drug added. This probably was due to the initial drug binding inducing a conformational change in the bovine serum albumin, thereby exposing additional binding sites.

Keyphrases □ Drug–albumin interactions—use of three spin labels to monitor drug-induced protein conformational changes, electron spin resonance spectra □ Albumin–drug interactions—use of three spin labels to monitor drug-induced protein conformational changes, electron spin resonance spectra □ Spin labeling—monitoring drug-induced conformational changes in bovine serum albumin, three spin labels studied

The technique of spin labeling was recently applied to a number of macromolecular systems where conformational changes were suspected (1, 2). This report describes, for the first time, an attempt to monitor drug-induced changes in bovine serum albumin utilizing this method. Although various analogous systems have been studied similarly (3–5), the pharmacodynamically important drug–albumin system (6, 7) has not been investigated; preliminary data are reported here.

EXPERIMENTAL

Materials and Methods—The spin labels *N*-(1-oxyl-2,2,6,6-tetramethyl-4-piperidinyl)bromoacetamide and *N*-(1-oxyl-2,2,6,6-tetramethyl-4-piperidinyl)maleimide were purchased[1]. The spin label 2,2,6,6-tetramethyl-4-dichlorotriazineaminopiperidine-1-*N*-oxyl was synthesized according to a reported procedure (8). These spin labels are referred to here as bromoacetamide, maleimide, and triazine, respectively.

Prior to use, the crystalline bovine serum albumin[2] was dialyzed against several changes of glass-distilled water at 4° followed by lyophilization. Protein concentration was checked by the biuret assay (9) or by measurement of absorbance at 279 nm., using a = 0.667 (10). Spin-labeled derivatives of bovine serum albumin were prepared using techniques similar to those previously reported (8, 11). All solutions were prepared and labeled in phosphate buffer of pH 6.9 (μ = 0.0527). Electron spin resonance spectra were recorded on an *X*-band spectrometer, utilizing 100-kHz. field modulation and Fieldial control of the magnetic field. The titration of triazine spin-labeled bovine serum albumin with increasing amounts of phenylbutazone was performed at ambient temperature using a quartz flat cell and a syringe pump set up similarly to one described elsewhere (3). Each spectrum could be recorded under identical instrumental conditions, thereby facilitating direct comparison of successive spectra.

RESULTS AND DISCUSSION

The electron spin resonance spectra obtained with both maleimide and bromoacetamide spin-labeled bovine serum albumin did not change appreciably when interacted with phenylbutazone. This could be due to the fact that these two sulfhydryl group-directed labels were located at a site far removed from the binding locus for phenylbutazone. Another possibility is that these labels may have been present in too low a concentration to have their spectra detectably altered by the binding process. It is also possible that the sulfhydryl grouping may be in a region of the protein that results in the attached labels being too strongly immobilized for their spectra to be adequately perturbed by the binding process.

In contrast, the amino group-directed triazine spin label, which at pH 6.9 is linked solely to histidine residues (8), appears to contain a ratio of strongly immobilized sites amenable to quantitation. Figure 1A shows that the spectrum of triazine spin-labeled bovine serum albumin actually consists of two types of signals, a sharp three-line spectrum corresponding to a label at a partially immobilized site and a superimposed broadened spectrum characteristic of the label in a strongly immobilized environment. Figure 1B shows the effect of adding 24 moles of phenylbutazone/mole of labeled bovine serum albumin. This spectrum represents the endpoint in the titration, because this was the maximum amount of phenylbutazone added. Spectra of several intermediate ratios of phenylbutazone to labeled bovine serum albumin were also recorded. Figure 2 shows a plot of the relative intensities of the high field peak of the partially immobilized spectrum (peak 4) *versus*

All solutions were prepared and labeled in phosphate buffer of pH 6.9 (μ = 0.0527). Electron spin resonance spectra were recorded on an *X*-band spectrometer, utilizing 100-kHz. field modulation and Fieldial control of the magnetic field. The titration of triazine spin-labeled bovine serum albumin with increasing amounts of phenylbutazone was performed at ambient temperature using a quartz flat cell and a syringe pump set up similarly to one described elsewhere (3). Each spectrum could be recorded under identical instrumental conditions, thereby facilitating direct comparison of successive spectra.

RESULTS AND DISCUSSION

The electron spin resonance spectra obtained with both maleimide and bromoacetamide spin-labeled bovine serum albumin did not change appreciably when interacted with phenylbutazone. This could be due to the fact that these two sulfhydryl group-directed labels were located at a site far removed from the binding locus for phenylbutazone. Another possibility is that these labels may have been present in too low a concentration to have their spectra detectably altered by the binding process. It is also possible that the sulfhydryl grouping may be in a region of the protein that results in the attached labels being too strongly immobilized for their spectra to be adequately perturbed by the binding process.

In contrast, the amino group-directed triazine spin label, which at pH 6.9 is linked solely to histidine residues (8), appears to contain a ratio of strongly immobilized sites amenable to quantitation. Figure 1A shows that the spectrum of triazine spin-labeled bovine serum albumin actually consists of two types of signals, a sharp three-line spectrum corresponding to a label at a partially immobilized site and a superimposed broadened spectrum characteristic of the label in a strongly immobilized environment. Figure 1B shows the effect of adding 24 moles of phenylbutazone/mole of labeled bovine serum albumin. This spectrum represents the endpoint in the titration, because this was the maximum amount of phenylbutazone added. Spectra of several intermediate ratios of phenylbutazone to labeled bovine serum albumin were also recorded. Figure 2 shows a plot of the relative intensities of the high field peak of the partially immobilized spectrum (peak 4) *versus*

[1] Synvar Associates, Palo Alto, Calif.

[2] A grade, Calbiochem.

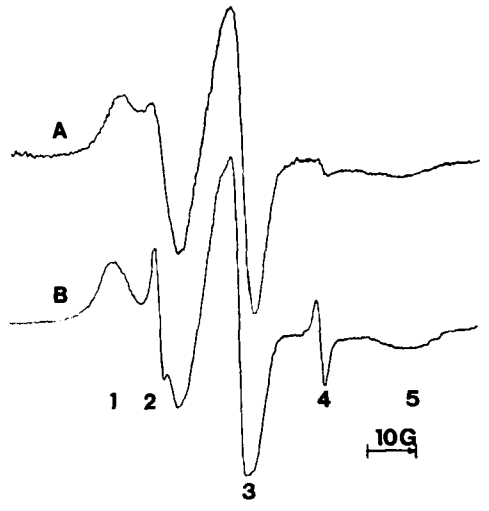

Figure 1 *Electron spin resonance spectrum of triazine spin-labeled bovine serum albumin before (A) and after (B) addition of 24 moles of phenylbutazone. Peaks 1, 3, and 5 correspond to strongly immobilized sites and peaks 2, 3, and 4 correspond to partially immobilized sites.*

increasing drug concentration. The increase in this peak was taken as a measure of the conversion of strongly immobilized sites to partially immobilized sites as a result of the interaction of the phenylbutazone with bovine serum albumin. This parameter was chosen since it appeared to be little affected by overlap of the strongly immobilized spectrum and, therefore, was a relatively accurate measure of the number of partially immobilized sites actually present.

The fact that this effect seems to increase monotonically up to molar ratios of 20:1 or more before leveling off seems to indicate that there is indeed more than one binding site for phenylbutazone on bovine serum albumin. This could possibly be due to the initial binding of the drug inducing a conformational change in the albumin (reflected by the triazine spin label as a conversion of strongly immobilized sites to partially immobilized sites), thereby enabling the macromolecule to accommodate successive drug molecules. The possibility of these secondary binding sites becoming available only after occupation of the primary binding site without a conformational alteration of the bovine serum albumin seems unlikely.

Chignell (12) and Chignell and Starkweather (13), using circular dichroism spectrometry, correlated the molar ellipticity of the complex between phenylbutazone and human serum albumin with the binding of phenylbutazone. The molar ellipticity increased up to a limit of 2.6 moles of drug bound/mole of albumin. This extrinsic Cotton effect is a result of a perturbation of the carbonyl chromophore of phenylbutazone when bound to the albumin. In the present studies, it is the effect of binding on the environment of the spin label attached to the albumin that is being observed. These two different approaches to the study of phenylbutazone-albumin interactions yield different kinds of information about the binding process. in these studies the environment of the spin label is apparently altered at drug to albumin concentration ratios above which the molar ellipticity seems to have a limiting value.

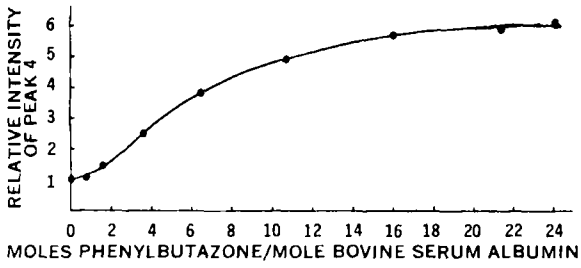

Figure 2—*Plot of the relative spectral intensity of peak 4 against the molar ratio of phenylbutazone–bovine serum albumin.*

It would be instructive to know the extent to which the observed spectral changes correspond to the actual degree of binding of the drug molecule. In addition, some data on the universality of this effect with other strongly binding drugs are desirable. These areas are being investigated further, and complete details of this work will appear shortly.

New Schistosomicidal and Carcinostatic Agents of the Thiaxanthone Type III

I. NABIH[▲] and A. ZAYED

Abstract □ Compounds structurally related to cyclohexenothiaxanthone were synthesized. In biological testing, a representative compound, 1-(β-diethylaminoethylamino)-3,4-cyclohexenothiaxanthone, showed pronounced schistosomicidal and antitumor activity.

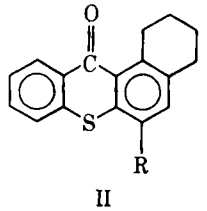
Keyphrases □ Thiaxanthone derivatives—synthesized and screened as potential schistosomicidal and carcinostatic agents □ 1-(β-Diethylaminoethylamino)-3,4-cyclohexenothiaxanthone—synthesized and screened as potential schistosomicidal and carcinostatic agent □ Schistosomicidal agents, potential—synthesis and screening of cyclohexenothiaxanthone analogs □ Carcinostatic agents, potential—synthesis and screening of cyclohexenothiaxanthone analogs

The thiaxanthone derivatives are considered to be the first nonmetallo-organic compounds of biological activity in the chemotherapy of schistosomiasis (1). They have received increasing interest since the discovery of their carcinostatic activity (2, 3). The most promising member in this group is 1-(β-diethylaminoethylamino)-4-methylthiaxanthone (I), but this agent is poorly tolerated by patients and usually induces severe unfavorable side effects during treatment (4). Because of these considerations, efforts were made to synthesize and develop new related structures suitable for application in both schistosomiasis and cancer.

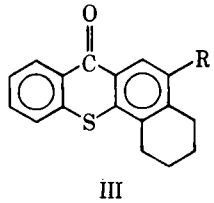
DISCUSSION

In a previous article[1] (5), the total syntheses and biological activity of two new agents related to cyclohexenothiaxanthone, namely, 1,2-cyclohexeno-4-(β-diethylaminoethylamino)thiaxanthone (II) and 2-(diethylaminoethylamino)-3,4-cyclohexenothiaxanthone (III), were described. The rationale for including the reduced tetralin system in these structures was also discussed.

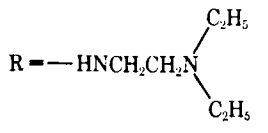
The approach to the synthesis of both II and III began with sulfuric acid condensation of thiosalicylic acid with the corresponding chlorotetralin compound. However, attempts to introduce the desired diamino side chain by replacing the chlorines in both condensation products failed. The chlorine atoms in both products, 2-chloro-3,4-cyclohexenothiaxanthone and its isomer 4-chloro-1,2-cyclohexenothiaxanthone, were resistant to any further substitution. This could be explained by the absence of the activating effect of the carbonyl groups on the lability of both these chlorine atoms. Such an effect suggested preferential condensation of the diamino side chain with 1-chloro-4-methylthiaxanthone, as with the synthesis of I (1).



II



III



Alternatively, both II and III were obtained through the condensation of the corresponding acetaminotetralin with thiosalicylic acid in the presence of sulfuric acid, followed by subsequent hydrolysis and condensation of the free amine with the desired side chain. Generally, in this type of condensation of thiosalicylic acid with aromatic components by sulfuric acid, the sulfide function forms first. The configuration of the condensation products depends upon the nature of these components (6). In the case of 5-chlorotetralin or 5-acetaminotetralin, the sulfide linkage initially formed at the 8-position, since this is activated due to the presence of the chlorine located *para* and the cyclic methylene group located *ortho*. In electrophilic substitution, *e.g.*, sulfonation, 5-chloro-8-sulfonic acid is the exclusive product (7). With 6-chlorotetralin and 6-acetaminotetralin, the 7-position is preferred for sulfide linkage formation.

In this work, the synthesis of another isomer of II and III, namely, 1-(β-diethylaminoethylamino)-3,4-cyclohexehothiaxanthone (IV), was of interest. This compound represents a direct structural analogy to I, where the cyclic methylene stands for the 4-methyl group located *para* to the diamino side chain. The synthesis of IV by any described approach using sulfuric acid condensation with chlorotetralin or acetaminotetralin was not successful, so other routes were tried. Diazotized 5-amino-7-nitrotetralin (8) reacted with thiosalicylic acid to give the intermediate, 2',3'-cyclohexeno-5'-nitrodiphenylsulfide-2-carboxylic acid (V). Reactions of the diazotized amines with thiophenols led to the formation of the sulfide linkage (9). Reduction of V gave the free amine VI which, upon cyclization with polyphosphoric acid, gave 1-amino-3,4-cyclohexenothiaxanthone (VII). Condensation of VII with β-chlorodiethylaminoethylamine gave the desired Compound IV.

The acidic intermediate V could also be obtained in better yield through the reaction of 5-iodo-7-nitrotetralin (10) with thiosalicylic acid in the presence of sodium carbonate. Furthermore, this route of synthesis was applied as an alternative for the preparation of II. For this purpose, diazotized 6-amino-7-nitrotetralin (11) reacted with thiosalicylic acid to build the acid intermediate, 2'-nitro-4',5'-cyclohexenodiphenylsulfide-2-carboxylic acid (VIII). Similarly, this was obtained through the reaction of 6-iodo-7-nitrotetralin (12) with thiosalicylic acid in the presence of sodium carbonate. Upon cyclization of VIII, 1,2-cyclohexeno-4-nitrothiaxanthone (IX) was obtained. This compound was reduced by hydrochloric acid and iron powder to give the free amine, 1,2-cyclohexeno-4-aminothiaxanthone (X). This product was identical to that obtained from the previously described synthesis of II (5).

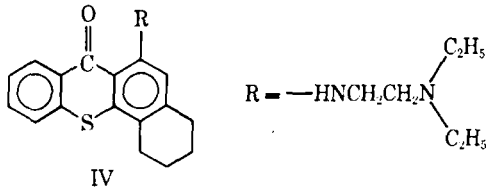
Compound III also was prepared by this route. Diazotized 5-amino-8-nitrotetralin (13) was reacted with thiosalicylic acid; the product, 2',3'-cyclohexeno-4'-nitrodiphenylsulfide-2-carboxylic acid (XI), was reduced to give 2',3'-cyclohexeno-4'-aminodiphenylsulfide-2-carboxylic acid (XII). Compound XII, upon cyclization with polyphosphoric acid, gave the amine, 2-amino-3,4-cyclohexenothiaxanthone (XIII). This product was identical to that obtained from the previously described synthesis of III (5).

BIOLOGICAL TESTING

The biological data for Compounds II and III in schistosomiasis and cancer were reported previously (5). In this work the isomer IV was submitted for testing as follows.

Schistosomiasis—Two groups of six mice, weighing 20–24 g. each, were infected with cercaria of *Schistosoma mansoni* obtained from a number of snails to ensure that both sexes were in the infecting cercaria. Ten weeks after infection, both groups showed viable eggs in their stools. The six members of one group were given

[1] Part I of this work. Part II will be published in *J. Chem. UAR.*



IV

daily oral doses (in water solution) of 80 mg./kg. body weight of IV as the hydrochloride, through a polyethylene feeding tube, for 12 consecutive days. The six mice in the other group were controls. After 1 week from the end of treatment, regular examination for ova excretion (every other day) was carried out for 3 weeks. In the treated group, a gradual decrease in the ova count was observed and ova excretion ceased by the end of the observation period (3 weeks). In the control group, ova excretion continued without remarkable change. Upon sacrificing the animals in both groups, living worms were found distributed in the liver and mesenteric venules. In the treated group, dead worms were present in the liver.

Experimental Tumors—*ELD (Ehrlich Ascites Carcinoma)*—Two groups of four mice each (ABYXdba strain), weighing 20–25 g., were inoculated intraperitoneally with 10^6 living tumor cells of the ELD type. In one group, Compound IV (as the hydrochloride in water solution) was injected intraperitoneally daily at doses of 80 mg./kg. body weight on the 3rd day after inoculation and for 6 consecutive days. The other group was kept as the control. Observation and weight control continued for 6 weeks. After 10 days, the control group showed clear tumor development with a remarkable increase in weight. In the treated group, no signs of tumor development were observed and there was no appreciable change in weight. Upon sacrificing the animals in both groups, living tumor cells were found in the controls; in the treated group, no tumor cells were found.

TA_3 (Mammary Carcinoma)—Two groups of four mice, weighing 16–18 g. each, were inoculated with 10^6 cells of the TA_3 type. On the 3rd day after inoculation and for 6 consecutive days, one group of four mice was treated intraperitoneally with 80 mg./kg. of Compound IV (as the hydrochloride in water solution). The other group was left untreated as a control. After 10 days, the control animals showed development of the transplanted tumor accompanied by an increase in weight (20–22 g.). In the treated mice, no remarkable change in weight was observed. After sacrificing the animals in both groups, no tumor cells were found in treated animals; in the controls, living tumor cells were present.

Regression of well-established experimental tumors by purely chemical means is seldom seen (14). Thus, testing the compound's effect on established tumors was of interest.

Treatment of established ascites tumors of the ELD type (14–18 days postinoculation with 2×10^6 living tumor cells) by daily doses of 80 mg./kg. for 4 consecutive days showed marked regression in the tumor sizes and cell counts, *e.g.*, the number counted before treatment was 900×10^6 cells/ml., and after treatment the number found was 26×10^6 cells/ml. After sacrificing the treated animals, masses of dead cells were found on the wall of the abdominal cavity.

Established mammary tumors, TA_3 type (8–10 days postinoculation with 10^6 living tumor cells) were treated with 80 mg./kg. of the compound for 4 days. Marked regression in tumor size and cell count was observed. For example, a mouse bearing a tumor cell count of 171×10^6/ml. showed a posttreatment cell count of 15×10^6/ml. The treated cells showed vacuolization and dispersion. This was contrary to control, nontreated cells which usually aggregate in colonized groups. This observed intracellular dispersion could be attributed to the electrostatic interaction between the polarized thiaxanthone molecule [due to electron delocalization (15), measured dipole moment for the compound 5.8 Debye units] and the tumor cells which carry high electronegative charges (16). This property provides a clue for the selective attack on tumor cells.

Preliminary studies in human leukemia (myeloblastic and monocytic types) *in vitro* showed pronounced effect of the compound toward the leucocytes.

The observed antitumor activity of the compound could be rationalized on the basis that the thiaxanthone system serves as a target-seeking device or carrier to bring the tetralin part of the molecule to the tumor cells, since tetralin tends to fix molecular oxygen in an oxygenation process (17). This would affect the glycolytic rate in the cell through oxidation of the sulfhydryl (—SH) enzymes engaged in this metabolic process. If cell division depends on the presence of small quantities of sulfhydryl, then the division could be inhibited by keeping the sulfhydryl in an oxidized condition by the presence of such oxygen carriers. Furthermore, the tetrahydronaphthalene system could undergo biological transformation to a naphthoquinone-type structure which depresses cell division. Also, the thiaxanthone system could act through complexing with DNA strands in the tumor cells, thus inhibiting DNA-dependent RNA synthesis. Biochemical studies are underway to determine the possibility of complex formation with this compound.

EXPERIMENTAL[2]

2′,3′-Cyclohexeno-5′-nitrodiphenylsulfide-2-carboxylic Acid (V)—*Method A*—To a mixture of 5-amino-7-nitrotetralin (10 g.) and sulfuric acid (40 ml., 50%) at 0° was added dropwise a solution of sodium nitrite (5 g. in 30 ml. water). The diazonium solution was then poured into a stirred solution of thiosalicylic acid (7 g. in 100 ml. 35% NaOH), heated on a steam bath under stirring for 3 hr., and cooled, and the supernate was then decanted. The residue was boiled with water and filtered while hot, and the filtrate was acidified with acetic acid. The separated product was purified by redissolving it in warm ammonium hydroxide solution and filtering. The filtrate was acidified with acetic acid and filtered. The product was dried to give 11 g. of V (69%), and it was recrystallized from benzene–alcohol, m.p. 210–212°.

Anal.—Calc. for $C_{17}H_{15}NO_4S$: C, 62.07; H, 4.59; N, 4.25; S, 9.73. Found: C, 62.18; H, 4.63; N, 4.42; S, 10.12.

Method B—A mixture of 5-iodo-7-nitrotetralin (2.4 g.), thiosalicylic acid (1.2 g.), sodium carbonate (1 g.), amyl alcohol (15 ml.), and 0.2 g. copper powder was refluxed for 20 hr. Five milliliters of sodium hydroxide solution was then added and the alcohol was steam distilled. The residue was boiled with excess water (25 ml.) and filtered, and the filtrate was acidified after cooling with dilute hydrochloric acid. The formed product weighed 1.90 g. (74%) after drying. Upon recrystallization from benzene–alcohol, it had a melting point of 210–212°, with no depression in the melting point when mixed with the product obtained by Method A.

2′,3′-Cyclohexeno-5′-aminodiphenylsulfide-2-carboxylic Acid (VI)—The nitro Compound V (3 g.) was stirred on a water bath with acetic acid (30 ml.), and then iron powder (3 g.) was added portionwise. After addition of half of the iron, 10 ml. acetic acid was added. Heating was continued for 2 hr. The mixture was filtered while hot, and the residue was washed with additional hot 50% acetic acid. The combined filtrate was poured into ice water. The formed precipitate was collected, washed with water, and dried to give 2.10 g. (74%) of VI. It was recrystallized from ethanol, m.p. 214–216°.

Anal.—Calc. for $C_{17}H_{17}NO_2S$: C, 68.27; H, 5.73; N, 4.68. Found: C, 68.08; H, 5.69; N, 4.65.

1-Amino-3,4-cyclohexenothiaxanthone (VII)—Sixteen grams of phosphoric acid was heated at 190°; then 2 g. of VI was added portionwise, and heating at this temperature was continued for 2 hr. Then the mixture was cooled and poured into ice water. The formed precipitate was collected, washed with hot ammonium hydroxide solution and then water, and dried. It gave 1.7 g. (90%) of VII. Upon recrystallization from benzene, it melted at 198–200°.

Anal.—Calc. for $C_{17}H_{15}NOS$: C, 72.56; H, 5.37; N, 5.37. Found: C, 72.78; H, 5.43; N, 5.46.

1-(β-Diethylaminoethylamino)-3,4-cylohexenothiaxanthone (IV)—A mixture of VII (2 g.) and β-chlorodiethylaminoethylamine (1.5 ml.) was heated at 180° for 4 hr. It was boiled with 25 ml. water for 0.5 hr., and then 4 ml. of concentrated hydrochloric acid was added; it was heated and filtered while hot. The filtrate was basified with sodium hydroxide solution; the formed precipitate was collected, washed with water, and then dried. It gave 2.26 g. of V (82%). Upon recrystallization from ethanol, it melted at 94–96°; IR: 1630 (C=O), 3340 (—NH—), 3017 (cyclohexyl), and 680 (—S—) $cm.^{-1}$.

Anal.—Calc. for $C_{23}H_{28}N_2OS$: C, 72.29; H, 7.41; N, 7.36; S, 8.43. Found: C, 72.34; H, 7.48; N, 7.39; S, 8.51.

The hydrochloride was prepared by dissolving the base in dry ether and allowing a stream of hydrogen chloride gas to pass through the solution, whereby it separated as a deep-orange product, m.p. 202–204°. It was highly hygroscopic and soluble in water.

[2] All melting points were taken in open capillaries using a Gallenkamp melting-point apparatus and are uncorrected. Microanalyses were performed at the National Research Center (microanalytical unit) and Spang Microanalytical Laboratory, Ann Arbor, Mich.

2′-Nitro-4′,5′-cyclohexenodiphenylsulfide-2-carboxylic Acid (VIII)—*Method A*—A mixture of 6-amino-7-nitrotetralin (6 g.) and concentrated hydrochloric acid (20 ml.) in 10 ml. of water was stirred at 0°, and then a solution of sodium nitrite (2.5 g. in 10 ml. water) was added. The diazonium solution was added portionwise to a stirred solution of thiosalicylic acid (3.5 g. in 50 ml. 20% NaOH solution) and then heated on a steam bath for 3 hr. After cooling, the supernatant layer was decanted and the residue was boiled with water. This was filtered while hot, and the filtrate was acidified after cooling with acetic acid. The product was redissolved in hot ammonium hydroxide solution, filtered, and then acidified with acetic acid. The collected product was dried to give 5.83 g. of VIII (64%). Upon recrystallization from benzene–alcohol, it melted at 162–164°.

Anal.—Calc. for $C_{17}H_{15}NO_4S$: C, 62.07; H, 4.59; N, 4.25; S, 9.73. Found: C, 62.32; H, 4.68; N, 4.37; S, 9.92.

Method B—A mixture of 6-iodo-7-nitrotetralin (3 g.), thiosalicylic acid (1.5 g.), amyl alcohol (30 ml.), sodium carbonate (1.3 g.), and 0.3 g. of copper powder was refluxed for 17 hr., and then 6 ml. of 50% NaOH was added. The alcohol was removed through steam distillation. The residue was boiled with 50 ml. water and filtered, and the filtrate was acidified with dilute hydrochloric acid. The formed product was collected, washed with water, and dried to give 2.4 g. of VIII. Upon recrystallization from benzene–alcohol, it melted at 162–164°, with no depression in melting point when mixed with the product prepared by Method A.

1,2-Cyclohexeno-4-nitrothiaxanthone (IX)—A mixture of VIII (2 g.) and phosphorus oxychloride (10 ml.) was refluxed for 1 hr. Then the excess of the oxychloride was removed under reduced pressure, and the residue was refluxed with 1 *N* HCl (50 ml.) for 30 min. The formed precipitate was filtered, washed with hot ammonia solution and then with water, and dried to give 1.5 g. of IX (78%). Upon recrystallization from benzene, it melted at 167–169°.

Anal.—Calc. for $C_{17}H_{13}NO_3S$: C, 65.58; H, 4.20; S, 10.29. Found: C, 65.67; H, 4.26; S, 10.38.

1,2-Cyclohexeno-4-aminothiaxanthone (X)—Compound IX (1 g.) and concentrated hydrochloric acid (5 ml.) in 20 ml. of ethyl alcohol were refluxed on a steam bath, and 1 g. of iron powder was added portionwise. Reflux continued for 4 hr. Then the mixture was cooled and the formed product was filtered. Sodium hydroxide solution (50%) was added to the filtrate to give 0.6 g. of X. It was recrystallized from benzene, m.p. 182–183°. The compound was identical to that previously prepared (5) as an intermediate in the synthesis of II.

2′,3′-Cyclohexeno-4′-nitrophenylsulfide-2-carboxylic Acid (XI)—A mixture of 5-amino-8-nitrotetralin (3 g.) and 50% sulfuric acid (20 ml.) was stirred at 0°. A solution of sodium nitrite (1 g.) in 15 ml. of water was added dropwise. Then the diazonium solution was added gradually to a solution of 1.6 g. of thiosalicylic acid in 50 ml. of 50% NaOH and heated on a water bath. After 2 hr., the mixture was cooled and the supernate was decanted. The residue was boiled with water and filtered, and the filtrate was acidified with acetic acid. The obtained product was dissolved in dilute ammonia and filtered. The filtrate was acidified, and the product was dried to give 2.8 g. of XI. Upon recrystallization from benzene–alcohol, it melted at 220°.

Anal.—Calc. for $C_{17}H_{15}NO_4S$: C, 62.07; H, 4.59; N, 4.25. Found: C, 61.78; H, 4.82; N, 4.51.

2′,3′-Cyclohexeno-4′-aminodiphenylsulfide-2-carboxylic Acid (XII)—A solution of IX (2 g.) in 25 ml. of acetic acid was stirred on a steam bath, and 2 g. of iron powder was added portionwise. Then 20 ml. of water was added. Heating was continued for 3 hr. The hot mixture was filtered and washed with dilute acetic acid. The filtrate was cooled and poured into ice water; the formed product was collected, washed with water, and dried to give 1.2 g. of XII. After recrystallization from benzene, it melted at 217–218°; IR: 3010 (cyclohexyl) and 690 (—S—) $cm.^{-1}$.

Anal.—Calc. for $C_{17}H_{17}NO_2S$: C, 68.34; H, 5.73; N, 4.69. Found: C, 68.42; H, 5.78; N, 4.76.

2-Amino-3,4-cyclohexenothiaxanthone (XIII)—To 10 g. of polyphosphoric acid heated at 170° was added 1 g. of XII; then heating was continued for 1 hr. After cooling, the mixture was poured into ice water. An excess of ammonia solution was added, and the solution was filtered. The formed product was washed with hot water and dried to give 0.70 g. of XIII, m.p. 235–237° [lit. (5) m.p. 239–240°].

Spectrofluorometric Determination of Carbidopa [L-(−)-α-Hydrazino-3,4-dihydroxy-α-methylhydrocinnamic Acid] in Plasma

S. VICKERS▲ and E. K. STUART

Abstract □ A spectrofluorometric assay is described for carbidopa utilizing *p*-dimethylaminobenzaldehyde. The fluorophore is dimethylaminobenzalazine which fluoresces intensely in chloroform saturated with trichloroacetic acid. The assay was applied to the analysis of carbidopa in monkey plasma.

Keyphrases □ Carbidopa—spectrofluorometric determination, monkey plasma □ L-(−)-α-Hydrazino-3,4-dihydroxy-α-methylhydrocinnamic acid—spectrofluorometric determination, monkey plasma □ Spectrophotofluorometry—analysis of carbidopa in monkey plasma

Carbidopa [L-(−)-α-hydrazino-3,4-dihydroxy-α-methylhydrocinnamic acid] is an inhibitor of aromatic amino acid decarboxylase, and it is able to potentiate levodopa in the treatment of Parkinson's disease (1–3). Carbidopa decreases the peripheral decarboxylation of dopa but not the conversion of dopa to dopamine in the brain, since carbidopa does not penetrate the blood–brain barrier (4).

To measure levels of carbidopa in plasma after oral administration of the drug in therapeutic doses, a sensitive assay was required. A fluorometric method was developed which depends upon the formation of dimethylaminobenzalazine, chloroform solutions of which fluoresce in the presence of trichloroacetic acid.

EXPERIMENTAL

Analytical Method—Trichloroacetic acid[1], chloroform[2], *p*-dimethylaminobenzaldehyde[3], and anhydrous magnesium sulfate[1] were used in these studies.

Plasma (2 ml.) was mixed with aqueous 10% trichloroacetic acid (3 ml.) and centrifuged (15 min.). The supernate was removed (as much as possible) and shaken with chloroform (2 ml.) for 15 min.; the aqueous layer was removed (as much as possible) and mixed with 0.4% ethanolic *p*-dimethylaminobenzaldehyde (2 ml.). The solution was heated at 70° for 45 min., cooled, and shaken with chloroform (3 ml.) for 10 min. The chloroform layer was removed following centrifugation, and anhydrous magnesium sulfate (10 mg.) was added. After centrifugation, the solution was analyzed spectrophotometrically in a spectrophotofluorometer[4] using quartz cells (10-mm. lightpath). Carbidopa analyzed in this manner exhibited a maximum value of fluorescence at an excitation wavelength of 466 nm. and an emission wavelength of 546 nm.

Table I—Reproducibility of the Fluorescence Assay for Carbidopa[a]

Carbidopa, mcg./2 ml.	Arbitrary Fluorescence Units ± *SD*
2	10.5 ± 0.7
1	4.9 ± 0.4
0.5	2.3 ± 0.3
0.1	0.4 ± 0.05

[a] Four experiments.

Identification of Fluorophore—Carbidopa (0.55 g.) was dissolved in the least amount of 1 *N* HCl possible, and ethanol (10 ml.) was added. This solution was added to an ethanolic solution (10 ml.) of *p*-dimethylaminobenzaldehyde (0.74 g.). After 30 min. at 70°, solid sodium acetate was added until precipitation occurred. The precipitate was filtered and recrystallized from dimethylformamide to yield 346 mg. material, m.p. 274–275°.

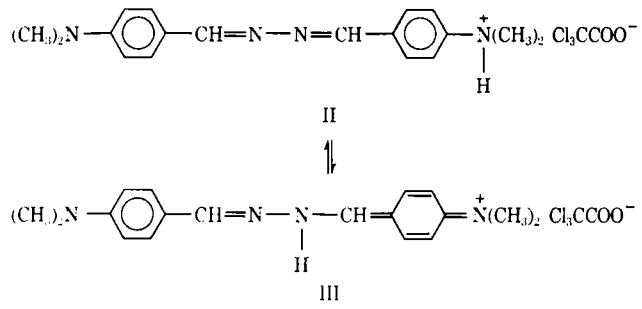
Animal Experiments—Five female rhesus monkeys (3–4 kg.) were dosed orally with an aqueous solution of carbidopa. Three received a dose of 20 mg./kg. and two received a dose of 2 mg./kg. Plasma was drawn at 1, 2, and 4 hr., and levels of carbidopa were measured with a calibration curve constructed by using normal plasma spiked with known amounts of carbidopa and plotting the fluorescence of the chloroform solution (after correcting for the blank value) *versus* the concentration of carbidopa in plasma.

RESULTS

Eighty nanograms of carbidopa/2 ml. of plasma could be detected by this method. The sensitivity of the method could be increased by using larger volumes of plasma since this caused no concomitant increase in background fluorescence. To test the reproducibility of the method, plasma samples (2 ml.) containing carbidopa (1, 0.5, 0.25, and 0.05 mcg./ml.) were analyzed (Table I). The intensities of the fluorescence obtained in these experiments were compared to those of standard solutions of the azine in chloroform saturated with trichloroacetic acid. It was determined that the reaction and the extraction of the product were essentially complete (93.5% ± 4.4 *SD*) over the 0.1–2-mcg. range of carbidopa/ml. of plasma. A water bath temperature of 70° and a 45-min. incubation were optimum conditions for maximum intensity of fluorescence. The latter was reduced when ethyl acetate or butanol was substituted for chloroform. Magnesium sulfate, unlike sodium chloride or hydrochloric acid, did not decrease the sensitivity of the assay. Trichloroacetic acid served a dual purpose: precipitating

Table II—Identification of Dimethylaminobenzalazine by Comparative TLC

Solvent System	R_f of Fluorescent Product	R_f of Authentic Dimethylaminobenzalazine
Benzene–acetic acid (3:2)	0.05	0.05
Benzene–acetic acid (2:3)	0.1	0.1
Benzene–acetic acid (4:1)	Origin	Origin
Benzene–acetone–water–acetic acid–butanol (equal parts)	0.92	0.92
Ethanol–acetic acid (1:1)	0.81	0.78



Scheme I—Ion-pair formation between dimethylaminobenzalazine and trichloroacetic acid

protein and increasing the fluorescence intensity of the product. There was no advantage in using trichloroacetic acid concentrations greater than 10%.

Carbidopa was shown to form dimethylaminobenzalazine (mixed melting point 274°) when reacted with dimethylaminobenzaldehyde. The structure of the product was confirmed by the use of mass spectroscopy and comparative TLC (Table II), which also did not indicate the presence of another product.

Anal.—Calc. for $C_{18}H_{22}N_4$: C, 73.45; H, 7.48; N, 19.05. Found: C, 73.52; H, 7.85; N, 18.98.

The recovery of the product and the reproducibility of the assay at levels anticipated after clinical doses[5] of carbidopa in man were found to be satisfactory.

Interfering Substances—No interference was produced by dopa, dopamine, phenylhydrazine, tryptamine, or tyrosine at levels of 3, 1, 1, 10, and 10 mcg./ml. of plasma, respectively. The 3-*O*-methyl derivative of carbidopa will interfere, but this was not detected as a metabolite of carbidopa. Hydrazine will also interfere, and the method forms the basis for a very sensitive assay for hydrazine. However, hydrazine has not been identified as a metabolite of carbidopa[6].

Plasma Levels of Carbidopa in Monkeys—Levels of carbidopa were measured in the plasma of monkeys dosed with carbidopa (see *Experimental*). Maximum levels were usually achieved within 2 hr. (Table III). These doses gave plasma levels which were in the range described by the calibration curve, *i.e.*, 0.1–2 mcg./2 ml. plasma (Table I).

[5] Plasma levels of radioactivity in man (nine subjects) after administration of a single 50-mg. oral dose of carbidopa-^{14}C when expressed as equivalents of carbidopa ranged from 0.05 to 0.9 mcg./ml. (unpublished results of the authors).

[6] Unpublished observations of the authors.

Table III—Levels of Carbidopa[a] in Monkey Plasma after an Oral Dose

Monkey	Dose, mg./kg.	Carbidopa in Monkey Plasma—Hours 1	2	4
1	20	0.7	2.0	0.3
2	20	1.6	0.5	0.2
3	20	2.6	1.8	0.8
4	2	0.15	0.05	<0.03
5	2	<0.03	0.03	0.18

[a] Expressed as micrograms of carbidopa per milliliter of plasma.

DISCUSSION

In the present investigation, carbidopa formed the corresponding azine with dimethylaminobenzaldehyde without preliminary hydrolysis; it was not possible to detect the hydrazone. Structure III (5) may be the isomeric form of II that is responsible for the fluorescence properties of dimethylaminobenzalazine (Scheme I). This follows a similar suggestion made by Glazko *et al.* (6) to explain the observation that solutions of reserpine in ethylene dichloride become strongly fluorescent in the presence of trichloroacetic acid.

Effect of Stimulation and Acetylcholine on ^{32}P and ^{14}C Incorporation into Phospholipids of Eel Electroplax

PHILIP ROSENBERG

Abstract □ Incorporation of ^{32}P and ^{14}C into phosphatidylinositol and phosphatidylcholine was increased when electroplax of the Sachs organ of the electric eel was exposed to 10^{-4} *M* concentrations of acetylcholine or physostigmine or when the cells were stimulated. In contrast, there was no significant effect on the specific activities of sphingomyelin, phosphatidylserine, phosphatidylethanolamine, or phosphatidic acid. The concentration of total phospholipids was unaltered. These results support the proposals that the neurotransmitter action of acetylcholine is associated with an increased turnover of phospholipids.

Keyphrases □ Acetylcholine—effects on ^{32}P and ^{14}C incorporation into eel electroplax phospholipids □ Electroplax, eel—stimulation and acetylcholine effects on ^{32}P and ^{14}C incorporation □ Radiolabeled phosphorus and carbon—effects of stimulation and acetylcholine on incorporation into eel electroplax phospholipids □ Stimulation—effects on ^{32}P and ^{14}C incorporation into eel electroplax phospholipids

Various functions have been proposed for phospholipids in bioelectrically excitable tissues including their possible involvement in the control of membrane resistance and capacitance, in the genesis of bioelectricity, as receptors for various drugs, and in active transport (1–7). Earlier studies from this laboratory, however, showed that axonal conduction and normal permeability were maintained in the squid giant axon even after extensive splitting of its phospholipids by phospholipases A and C (8–10). It was of interest to extend these studies to a synaptic-containing preparation since some investigators related the action of synaptic transmitters to an interaction with membrane phospholipids (6, 11–14). The isolated single electroplax used in the present study has acetylcholine as the neurotransmitter at the thousands of synapses present on each cell, and the conducting membrane can be stimulated either directly or indirectly *via* the nerves. The phospholipid composition of this preparation was recently reported (15) from this laboratory, and the postsynaptic and action potentials were noted to be blocked when more than one-third of the phosphatidylcholine of the cell was hydrolyzed by phospholipase A. As a further test of the possible involvement of phospholipids in the bioelectrical functioning of the electroplax, the incorporation of ^{32}P and ^{14}C into the phospholipids of control, stimulated, and acetylcholine- and physostigmine-treated electric tissue was measured.

MATERIALS AND METHODS

Cells from the Sachs organ were incubated in 7 ml. of eel Ringer's solution (pH 7) of the following composition (m*M*): NaCl, 160; KCl, 5; $CaCl_2$, 2; $MgCl_2$, 2; NaH_2PO_4, 0.3; Na_2HPO_4, 1.2; and glucose, 10. In addition, each milliliter of the solution contained 25 μc. of ^{32}P-H_3PO_4[1] (>99% radiochemical purity) and 2.5 μc. of U-^{14}C-D-glucose[1] (>95% radiochemical purity, U = uniformly labeled). For the stimulation experiments, slices of Sachs organ, 1 cell thick and 15–30 cells long (1–2 g.), were incubated in this solution for 1 hr., after which the rows were stimulated with supramaximal voltages 5–10 times/sec. for 2 hr. with a 10-min. rest period every 20 min. In control experiments, the action potentials decreased no more than 20% during this 2-hr. period. Extracellular silver–silver chloride electrodes inserted into each end of the row were used for stimulating and recording electrical activity. Depending on the direction of the current, the innervated (conducting) membrane of the cell was either stimulated directly or indirectly *via* the nerve endings. Control slices were incubated for 3 hr. without stimulation.

In other experiments, 30 single isolated cells (~2 g.) from the Sachs organ were exposed for 6 hr. to eel Ringer's solution containing acetylcholine and physostigmine (10^{-4} *M* of each) or physostigmine (10^{-4} *M*) in addition to the radioactive compounds. This concentration of physostigmine decreases the action potential very slowly, taking several hours to block conduction, whereas acetylcholine plus physostigmine blocks electrical activity within 1 or 2 min. Control cells were exposed for the same length of time to a similar solution not containing acetylcholine or physostigmine. After incubation, lipid extracts of the tissues were prepared using chloroform–methanol (1:3, followed by 2:1) and were spotted on a two-dimensional thin-layer chromatogram used for the separation of the individual phospholipids (8–10, 15). Each phospholipid spot was visualized with iodine vapors, scraped off of the chromatogram, eluted with 4 ml. of chloroform–methanol (1:1), and divided into two equal samples. Both samples were evaporated to dryness, after which phosphorus was determined in one sample (16) and 10 ml. of scintillator fluid[2] was added to the other sample. This latter sample was counted in a scintillation spectrometer[3] with the windows set to count ^{14}C and ^{32}P simultaneously. An automatic external standard was used to monitor counting efficiency, and all samples were corrected for background, for radioactive decay of ^{32}P, and for the approximately 15% of the ^{32}P counts that appeared in the ^{14}C channel. A small portion (5%) of the original lipid extract was used for the determination of total lipid phosphorus. Elution of phospholipids from silica gel with chloroform–methanol may not completely extract the phospholipids (17–19); therefore, it is essential that all results be reported as specific activities, that is, counts per minute per micromole of phosphorus.

RESULTS

All treatments caused a significant increase in ^{32}P and ^{14}C incorporation into phosphatidylinositol and phosphatidylcholine (Tables I and II). No significant changes were seen in the specific activities of sphingomyelin, phosphatidylserine, phosphatidylethanolamine, or phosphatidic acid. Although there appeared to be a tendency toward an increase with phosphatidic acid, these results are probably the least reliable because of the very small amounts of phosphatidic acid present. In the initial experiments, it appeared that a large incorporation of ^{14}C into sphingomyelin was occurring, which would have been most unusual considering the known metabolic stability of this phospholipid in other membrane systems. Later it was found that this radioactivity was associated with a nonphosphorus-containing compound, which plated out on the sphingomyelin spot and adjacent area. By careful separation of supernates and phases during each step of the lipid extraction, especially at the stage of washing with pure solvent upper phase, it was possible to decrease markedly the amount of this contaminant, although the sphingomyelin values still probably represent maximum values.

IS	10 ± 3	111 ± 19**	320 ± 10**	14 ± 3	2 ± 1	89 ± 21

[a] Single cells were exposed to 2.5 μc. U-^{14}C-glucose/ml. of incubation mixture for 6 hr., while rows of cells were exposed for 3 hr. Abbreviations are given in Table I. [b] Each value (mean ± standard error) is based upon three experiments. ** = $p < 0.01$ compared to controls, and * = $p < 0.05$ compared to controls.

In four experiments, single cells were exposed to 2.5 μc. *N*-methyl-^{14}C-choline[1]/ml. of incubation mixture. More than 90% of the radioactivity incorporated into the phospholipids was found in phosphatidylcholine, a small amount was found in sphingomyelin, and phosphatidylethanolamine and phosphatidylserine remained nonradioactive. This is in agreement with earlier findings that choline is incorporated as a unit into lecithin (20–23).

Studies similar to those in the Sachs organ were also carried out on rows of cells from the Main organ, but the results were more variable and the ^{32}P incorporation was very low.

Total lipid phosphorus values of the tissues were not affected by stimulation or exposure to acetylcholine (Table III). The values for the Sachs organ are slightly higher and the values for Main organ are slightly lower than those previously found (15). The absolute values will, however, vary considerably, depending on the area of the Sachs and Main organs used. The closer to the head end of the eel the tissue samples are taken from, the more tightly packed are the cells and, therefore, the higher are the values for phosphorus per unit weight.

DISCUSSION

All experimental conditions studied caused depolarization of the innervated membrane of the electroplax. It is, however, unlikely that the results are due to an increased penetration and, therefore, an increase in the specific activity of ^{32}P-H_3PO_4 or U-^{14}C-glucose within the cell. If that were the case, one would expect to see increased specific activity of ^{32}P and ^{14}C in all phospholipids, whereas only an increased incorporation into phosphatidylcholine and phosphatidylinositol was found.

Acetylcholine, physostigmine, and stimulation cause an influx of sodium into the cell and an efflux of potassium, which may then be followed by an increase in active transport of sodium. The effects of these treatments on phospholipid metabolism may be associated with ionic changes occurring as a result of depolarization. Depending on conditions, ionic alterations may either decrease or increase ^{32}P incorporation into brain phospholipids (24, 25). The application of acetylcholine and physostigmine to a wide variety of tissues increases incorporation into both phosphatidic acid and phosphatidylinositol and may be due to a stimulation of active transport processes (26–31). In the electric organ, however, it has been reported (32) that phospholipids do not act as intermediates in the transport adenosine triphosphatase system.

The Main organ of the electric eel showed very low ^{32}P incorporation, probably because of the permeability barriers to the penetration of phosphorus in this tissue. The cells are much closer together in the Main organ than in the Sachs organ, so that it is not possible to dissect out single cells. By comparing the results shown in Tables I and II, one can see that even in the Sachs organ the incorporation of ^{14}C is much greater than the incorporation of ^{32}P, even though the specific activity of ^{32}P used in the incubation mixture was much higher than that of ^{14}C. Phosphorus does not readily penetrate through neuronal membranes (33–36), which could explain these findings.

Table III—Total Lipid Phosphorus Values for Sachs and Main Electric Organ[a]

Treatment	Sachs Organ		Main Organ
	Single Cells	Rows of Cells	Rows of Cells
Control	0.80 ± 0.05 (3)	1.33 ± 0.04 (3)	2.85 ± 0.15 (12)
ACh + Physo	0.78 ± 0.02 (3)	—	2.80 ± 0.19 (3)
Physo	0.73 ± 0.06 (3)	—	2.72 ± 0.19 (3)
DS	—	1.26 ± 0.05 (3)	2.91 ± 0.16 (6)
IS	—	1.20 ± 0.04 (3)	—

[a] All results are presented as micromoles per gram wet weight (means ± standard errors), with numbers of experiments shown in parentheses. ACh = 10^{-4} *M* acetylcholine, Physo = 10^{-4} *M* physostigmine, DS = direct stimulation, and IS = indirect stimulation.

The results with phosphatidylinositol resemble those seen by Larrabee and coworkers (13, 14) on the sympathetic ganglia. An increased incorporation of ^{32}P and ^{14}C into the phospholipids of the electroplax was observed irrespective of whether one stimulated the conducting membrane directly or *via* the nerve endings, which would indicate a site of action not exclusively localized to the synaptic region. In contrast, the increased incorporation observed previously (13, 14) appeared to be due exclusively to the transmitter, acetylcholine, acting on the postsynaptic cell. Acetylcholine acts only at the synapses of the electroplax; however, depolarization of these thousands of synapses causes a short-circuiting and depolarization of the entire conducting membrane.

The increased turnover of phosphatidylinositol in the electroplax, as a result of stimulation or the action of acetylcholine, is in agreement with suggestions that both excitation and the action of acetylcholine are mediated *via* an increase in phosphatidylinositol of polyphosphoinositide metabolism (6, 12). The increased turnover of phosphatidylcholine is of special interest in relationship to the proposal of Watkins (11) that acetylcholine, due to its structural similarity to the polar head group of phosphatidylcholine, may compete with this phospholipid for binding to a receptor protein. In fact, DeRobertis (37) suggested that the acetylcholine receptor of the electric organ is a proteolipid. If acetylcholine displaces phosphatidylcholine from a receptor proteolipid, the phospholipid may be more readily available to metabolic enzymes, thereby giving rise to the increased ^{32}P and ^{14}C incorporation values found in this study.
