Abstract □ The use of a continuous flowing stream apparatus to follow tablet dissolution was studied. A dissolution chamber using a commercially available filter unit was designed to follow tablet dissolution through use of either a sodium-ion electrode or a spectrophotometric analytical module. The effect of variation of flow rate on the dissolution profile and the ability of the apparatus to differentiate between the common tablet parameters of hardness and drug potency were shown.

Keyphrases □ Tablet dissolution—determination in continuous-flow equipment using sodium-ion electrode or UV spectrophotometry differentiation between parameters of hardness and drug potency □ Dissolution equipment, tablets—continuous-flow system using sodium-ion electrode or UV spectrophotometry, differentiation between parameters of hardness and drug potency □ Sodium-ion electrode system—used to determine tablet dissolution in continuous-flow system

The importance of *in vitro* testing of tablet and capsule dissolution and its relationship to drug availability are accepted facts. The correlation of *in vitro* to *in vivo* data shows the need for a versatile and flexible apparatus which, through adjustment of its parameters to the variance in dissolution profiles of different tablets, can succeed in matching such data. A second but equally important consideration is a reduction in the time and labor required for such *in vitro* analysis. By using the technique of continuous analysis in flowing streams to monitor dissolution, the entire profile can be recorded and experimental error can be reduced to a minimum.

In recent years, equipment for studying the dissolution of solid dosage forms under conditions of continuous flow has been presented. The arguments for using a continuous-flow method and the theoretical considerations involved have been documented (1, 2). These authors suggested that the continuous-flow

acetate degrades significantly in the absence of water. When 0.5% water is added, the stability picture remains essentially the same, indicating that the water's contribution to degradation is offset by the partial protection it affords against solid-state oxidation. As more water is added, however, the degradation rate increases linearly with water concentration, indicating that the contribution of solid-state oxidation has plateaued and the effects of hydrolysis are becoming more evident.

The vitamin A acetate report (5) provides another example of the usefulness of the concepts and models presented in this paper. In discussing the theory behind their presentation, the authors (5) stated: "If vitamin A degrades by functional dependence of water content, then a $(1 + a)$ order reaction may be expressed as $dC_a/dt = -K \cdot C_A \cdot C^a_{H_2O}$ [their Eq. 1] where C denotes concentration and the subscripts denote vitamin A acetate and water." From their data, they reached the conclusion that the apparent value of a is 2–3, a relatively high order.

If one assumes that zero-order kinetics prevail for the water-dependent degradation (a reasonable assumption, since vitamin A acetate is relatively water insoluble), then their Eq. 1 reduces to our Eq. 1 when the value of a is unity. A slightly different interpretation of their data yields values of a that are close to unity and confirm the validity of the model in Fig. 3. That interpretation is as follows.

From the sharp break in the slope in Fig. 8, it is evident that the 0–0.5% range of water concentration is atypical. That is, their Eq. 1 assumes a continuous function and, for their system, the function can be considered continuous only between 0.5 and 2.0% added water. Therefore, the "water added" concept should, in our opinion, start from their 0.5% mark. Thus, their 0.5, 1.0, 1.5, and 2.0 values for "percent water added" should (more correctly) be taken as 0, 0.5, 1.0, and 1.5%, respectively. For example, their 1.5% is, more correctly, 1.0% (*i.e.*, 1.5 − 0.5). Recalculating their data using the corrected values of water added yields the following values for a: 85°, 0.90; 70°, 0.87; 55°, 1.45; 25°, 1.46; and 5°, 1.42. Considering the complexity of the system, experimental values of 0.87–1.46 (average = 1.2) against a theoretical value of unity is good confirmation of the validity of the model in Fig. 3.

CONCLUSION

Stability data for solid dosage forms, gathered under suitably controlled conditions, can often be successfully interpreted using the schematic models presented in Figs. 1–3.

Sodium-Ion Electrode: Continuous Monitoring of Tablet Dissolution *via* Flowing Streams

T. E. NEEDHAM, Jr., L. A. LUZZI▲, and W. D. MASON

Abstract □ The use of a continuous flowing stream apparatus to follow tablet dissolution was studied. A dissolution chamber using a commercially available filter unit was designed to follow tablet dissolution through use of either a sodium-ion electrode or a spectrophotometric analytical module. The effect of variation of flow rate on the dissolution profile and the ability of the apparatus to differentiate between the common tablet parameters of hardness and drug potency were shown.

Keyphrases □ Tablet dissolution—determination in continuous-flow equipment using sodium-ion electrode or UV spectrophotometry differentiation between parameters of hardness and drug potency □ Dissolution equipment, tablets—continuous-flow system using sodium-ion electrode or UV spectrophotometry, differentiation between parameters of hardness and drug potency □ Sodium-ion electrode system—used to determine tablet dissolution in continuous-flow system

The importance of *in vitro* testing of tablet and capsule dissolution and its relationship to drug availability are accepted facts. The correlation of *in vitro* to *in vivo* data shows the need for a versatile and flexible apparatus which, through adjustment of its parameters to the variance in dissolution profiles of different tablets, can succeed in matching such data. A second but equally important consideration is a reduction in the time and labor required for such *in vitro* analysis. By using the technique of continuous analysis in flowing streams to monitor dissolution, the entire profile can be recorded and experimental error can be reduced to a minimum.

In recent years, equipment for studying the dissolution of solid dosage forms under conditions of continuous flow has been presented. The arguments for using a continuous-flow method and the theoretical considerations involved have been documented (1, 2). These authors suggested that the continuous-flow

methodology should have sufficient flexibility to be useful in studying intrinsic dissolution characteristics of a sample while maintaining reproducibility and the ability to detect small differences in formulation.

The described apparatus differs from previously presented systems in that it allows a choice of analytical module using an inexpensive, universally available dissolution cell. A sodium-ion electrode may be mounted in a flow cell and employed as a sensor in addition to a spectrophotometric sensor as used previously. The sodium-ion electrode has limitations, some of which were documented in these laboratories (5).

The reproducibility of the apparatus, as well as its ability to detect differences in tablet hardness and to analyze and differentiate between tablets of different drug potency, is evaluated in this report.

EXPERIMENTAL

Materials—Both commercial and specially manufactured tablets were used. Only one batch number each of sodium warfarin[1], sodium butabarbital[2], and sodium bicarbonate[3] tablets was used. The sodium salicylate tablets were manufactured in these laboratories using a 16-station rotary tablet press[4] equipped with an induced die feeder. Standard concave punches [0.95 cm. (0.375 in.)] were used. These tablets were compressed from the following formulation: sodium salicylate[5], 50 mg.; fast flow lactose[6], 216.5 mg.; microcrystalline cellulose[7], 43.5 mg.; starch[8], 35.0 mg.; and stearic acid[5], 5.0 mg., to produce 350-mg. tablets. The tablets were compressed to three different hardnesses as determined by an electronic hardness tester[9]. The reported hardnesses are averages found after testing 50% of the tablets from each run.

The dissolution medium consisted of a buffer mixture (3) of potassium hydroxide[5] and dibasic potassium phosphate[5] at pH 8 with an adjusted sodium-ion concentration of 10^{-3} *M*.

Apparatus and Instrumentation—The apparatus (Fig. 1) was designed for use with either a sodium-ion electrode or UV spectrophotometer as the analytical module. The dissolution cell is a commercially available filter unit[10], using a standard 0.22-μ filter to prevent disintegrated tablet particles from leaving the cell. A peristaltic pump[11] was used to push the solvent at a constant flow rate from the reservoir through the dissolution cell and analytical system. The flow lines were made from Tygon tubing [formula B44-3, 0.15 cm. (0.06 in.) i.d.]. All flow rates were determined periodically by collecting samples of the liquid that had passed through the dissolution cell. All studies reported were carried out at ambient temperatures (25 ± 1°).

The analytical system used was either a spectrophotometer with an adapted time drive to record absorbance as a function of time or a sodium-ion electrode system with connected recorders (Fig. 1). While the use of a flow cell to hold a sodium-ion electrode was previously reported (4), Fig. 2 illustrates the unit designed to incorporate the sodium-ion electrode into the system. It consists of a cylindrical Teflon block with a horizontal channel to carry the dissolution medium past the sodium-ion and reference electrodes and on to the second analytical module or disposal vessel. Both the sodium-ion and reference electrodes are set into the block vertically such that the tip of each protrudes into the channel and no air space is left along the side or at the tip of the electrodes. A micro sodium-ion electrode was used and found to have a response equivalent to the full-size sodium-ion electrode previously reported (5). The analytical modules were connected singly or in series to the dissolution cell.

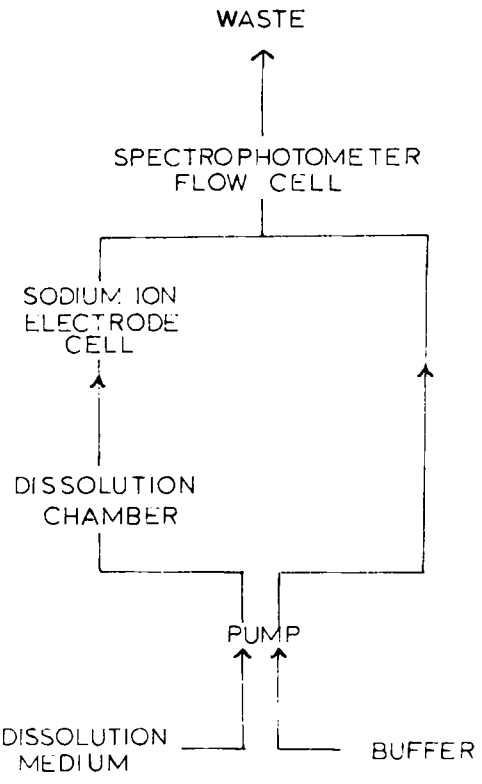

Figure 1—*Schematic representation of automated flow system.*

Samples were diluted to the analytical range of the spectrophotometer by mixing with a fixed ratio of solvent. The diluent was also used in the case of sodium butabarbital to adjust the pH to that level where the Beer–Lambert law was valid. Use of a buffered 0.001 *M* sodium-ion base solution, calibration of the sodium-ion electrode, and correlation of the sodium-ion electrode reading to spectrophotometric and atomic absorption readings were explained in a previous paper (5). Since all tablets exhibited significant differences in their dissolution profiles in the first 18 min. with a slow

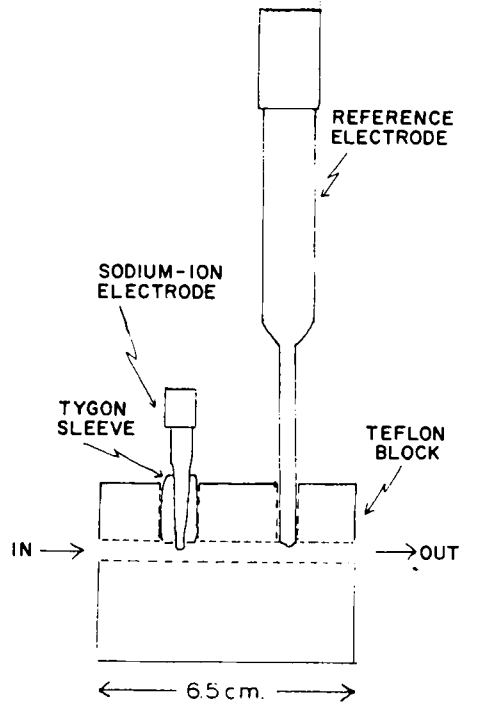

Figure 2—*Side view of sodium-ion electrode cell.*

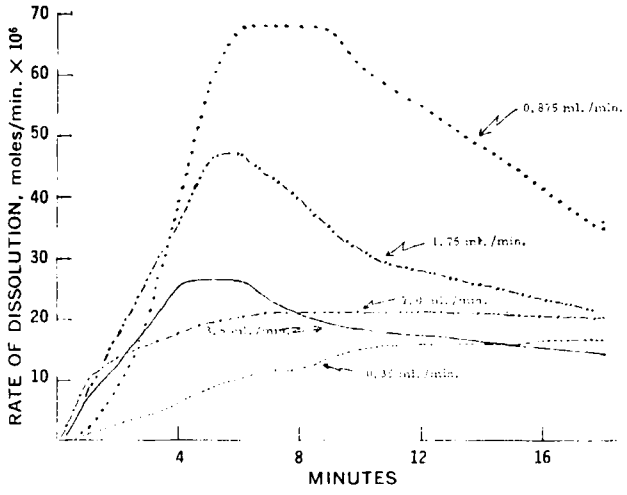

Figure 3—*Rate of dissolution of sodium butabarbital tablets at pH 8.0 as a function of flow rate.*

return to the blank concentration after that time, only the first 18 min. of each profile is presented.

Procedure—At the beginning of each tablet dissolution run, the analytical system was equilibrated to its baseline with the dissolution medium and the dissolution chamber was disassembled and dried. A weighed tablet was placed in the chamber, a new filter was set in, and the apparatus was closed. The pump was started and the changes in concentration were recorded as a function of time. The solution was discarded after being pumped through the analytical module. Variance in the rate of dissolution between tablets of the same batch was found to be comparable to the USP (6), Levy (7, 8) beaker, and magnetic basket (9, 10) methods of dissolution testing. All reported dissolution curves are the average of at least four separate determinations.

RESULTS AND DISCUSSION

Most dissolution data presented in this paper were collected using the sodium-ion electrode analytical module. However, dissolution profiles were obtained for sodium salicylate and sodium butabarbital using the spectrophotometer only and a combination of the spectrophotometer and sodium-ion electrode recorder module attached in series after the dissolution cell. The spectrophotometer produced results comparable to those seen by Tingstad and Riegelman (2). In fact, when the spectrophotometer and sodium-ion electrode recorder module were used in series to follow the dissolution of the same tablet, curves characteristic of that tablet were comparable.

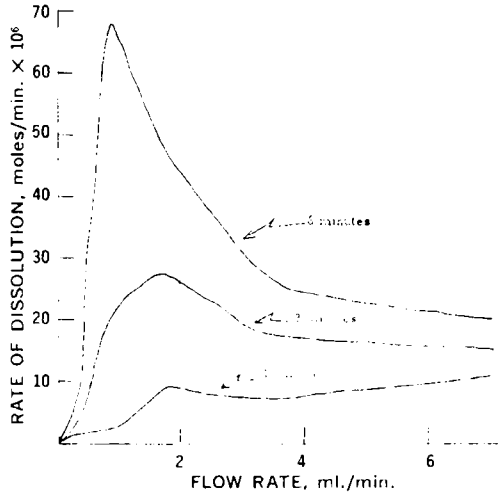

Figure 4—*Effect of flow rate on the rate of dissolution at increasing time intervals.*

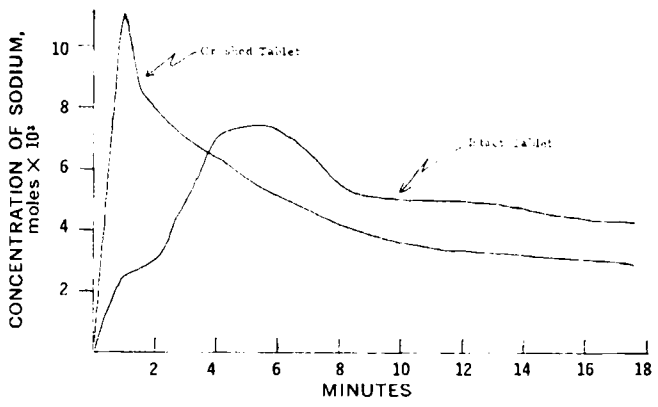

Figure 5—*Comparison of crushed and intact sodium butabarbital tablets at pH 8.0 and a flow rate of 3.5 ml./min.*

When using the continuous-flow dissolution apparatus in Fig. 1, one obtains a continuous readout of logarithm concentration of the drug in the dissolution medium *versus* time. The data can be presented in a number of ways that permit evaluation of the tablet dissolution. The obvious presentation, as previously reported (1, 2), consists of multiplying the concentration by the volume flow rate of the solution through the apparatus to obtain the instantaneous dissolution rate as a function of time. Figure 3 shows the effect of the volume flow rate on the instantaneous dissolution rate–time plot for sodium butabarbital tablets from the same batch. The importance of the proper flow rate selection can be seen. The flow rate should be coordinated with the characteristics of the tablet being studied to produce the most meaningful results. Figure 3 shows that as the volume flow rate was increased from 0.35 to 0.875 ml./min., the instantaneous dissolution rate during the first 18 min. increased. This is analogous to increasing the stirring rate when using the beaker method. Further increase in the volume flow rate above 0.875 ml./min. resulted in a decrease in the instantaneous dissolution rate.

In Fig. 4, the changing effect of flow rate on the instantaneous rate of dissolution at several different times can be seen. At 1 min. elapsed time, the faster flow rates have produced the fastest rates of dissolution. However, as the time of dissolution increased through 3 min., 6 min., and greater, the instantaneous dissolution rate increased for the slower flow rates until it peaked at 0.875 ml./min. This produces what seems to be a contradiction in that the greater the rate of flow the higher should be the rate of dissolution. However, further examination of the data reveals several possible explanations. Visual observation of the tablets at increasing elapsed times of dissolution indicates that this flowing stream method produces a "peeling" away of the outer layers of the tablets examined and a much slower disintegration than that seen in other dissolution methods using larger volumes of medium. Thus, the change in surface area would be small and the rate of dissolution of the drug would be maximized to a constant such that the dissolution taking place at the faster flow rates would be limited.

In addition, although the effects of the higher flow rates were not

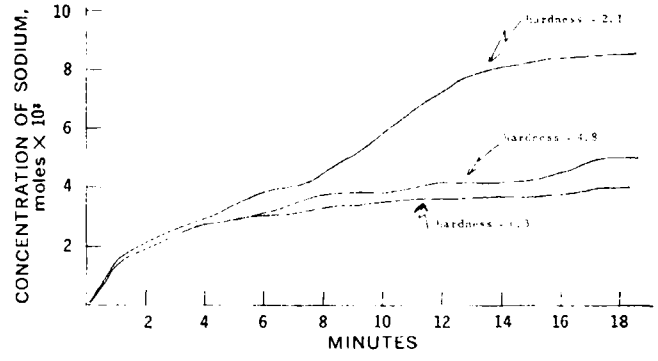

Figure 6—*Effect of hardness on the dissolution of sodium salicylate tablets at pH 8.0 and a flow rate of 0.75 ml./min.*

studied in detail, it would seem that the decrease in the dissolution rate could occur due to excessive turbulence of the dissolution medium inside the confined space of the chamber and/or the compression of the tablet against the upper filter. So ultimately the concentration of drug appearing in solution at the slower flow rates exceeds the correction made for rate of flow in calculation of the instantaneous dissolution rate. This behavior is substantiated by the fact that if the dissolution of a tablet is allowed to run to completion, the tablet being dissolved at a slower flow rate returns to the baseline before that being dissolved at the higher rate.

It was also observed that the dependence of the dissolution rate on volume flow rate varied with hardness, strength, and formulation of the tablet. With each different type of tablet, the flow rate had to be empirically determined to provide the most revealing dissolution rate. In addition to the nature of the tablet, the limitations of the analytical module must be considered in selecting the volume flow rate. The concentration of the dissolving drug must be maintained within the linear calibration range of the sodium-ion electrode or spectrophotometer.

The ability of the dissolution apparatus to monitor common variables is shown in Figs. 5 and 6. In Fig. 5, the dissolution profile for a sodium butabarbital tablet is compared to the dissolution profile for a tablet from the same batch that had been crushed to a powder before placement in the dissolution apparatus. As expected, the initial dissolution rate was greatly increased when the disintegration phase was eliminated. This observation is in agreement with the data by Tingstad and Riegelman (2). Figure 6 illustrates the ability of the apparatus to differentiate between tablets of exactly the same formulation but of different hardnesses. The sodium salicylate tablets used were prepared in these laboratories and, as expected, a rate of dissolution increasing in rank order of decreasing tablet hardness was seen.

The versatility of this apparatus is further illustrated with the dissolution of sodium warfarin tablets. A flow rate of 0.75 ml./min. allows the instrument to differentiate among 5-, 10-, and 25-mg. tablets. The dissolution of sodium bicarbonate tablets was also followed by adjustment of the flow rate to 3.5 ml./min.

The use of a flowing stream dissolution apparatus in conjunction with either the sodium-ion electrode or spectrophotometric module provides an automated means of following tablet dissolution quickly and accurately. The apparatus differentiates between the common tablet parameters of hardness and drug potency and provides a variability adjustment through flow rate. In conclusion, this apparatus provides a quick and accurate means of analyzing *in vitro* tablet dissolution.

Effect of Adverse Storage Conditions on Vacuum-Holding Ability of Large-Volume Parenteral Containers

MARTIN B. PINCKNEY, Jr.*, LOUIS A. LUZZI▲, and JAMES C. PRICE

Abstract □ The ability of large-volume vacuum-packed parenteral containers to maintain vacuum under adverse conditions of temperature and agitation was examined. It was the intent of the study to examine the possible effects of accelerated aging during travel and storage. Containers were stressed by being subjected to alternating high and low temperatures for 30 days (24-hr. intervals) and by shaking for 30 days at temperatures up to 50°. Preliminary tests were carried out to establish a statistically significant number of experiments. It was found, in all cases, that the vacuum seal was maintained under these conditions. It is concluded that such factors as decomposition of ingredients and faulty glassware should be suspected if vacuum loss is found with these types of containers.

Keyphrases □ Parenteral containers, large volume—effects of temperature and agitation on vacuum-holding ability □ Large-volume parenteral containers—effects of temperature and agitation on vacuum-holding ability □ Vacuum retention—effects of temperature and agitation on large-volume parenteral containers □ Containers, large-volume parenteral—effects of temperature and agitation on vacuum-holding ability

In the last decade, there has been a surge of interest regarding the safety of parenteral preparations. Recent reports have been concerned with particulate matter (1–4), sterility control (5, 6), and contamination during opening, preparation, and use (7–9).

That serious problems can still occur with this type of preparation is indicated by recent references to septicemias caused by microbial contamination (10–12). Some of these infections have been attributed to improper use or handling of the parenteral product itself (10). Other problems have been caused by introduction of contaminants during administration (11, 12).

One possible source of contamination is the failure of the closure during storage. A means of testing for

closure failure has not been reported in the literature. In vacuum-packed parenterals, this possibility can be examined by measuring the vacuum retained under various stressing storage conditions. This report describes the vacuum-holding ability of large-volume parenterals under storage conditions somewhat more severe than would be encountered during normal use.

EXPERIMENTAL

Description of Systems Tested[1]—The systems examined were: Type A, a vacuum-packed nonfiltered air system; and Type B, a vacuum-packed filtered air system (9). Both systems contained lactated Ringer's solution in 250- and 500-ml. sizes, and only one lot number was used for each size. Headspace and fill volume in both types of container were found to vary less than 1% of the total container volume for each size container reported.

Temperature Fluctuation Tests—Each described system was exposed to four temperature ranges, which were chosen as extreme test conditions and were designed to approximate or exceed the maximum and minimum conditions encountered during transit or storage. Temperature ranges employed were 25–40°, 5–40°, 5–25°, and 5–50°.

The filled containers were initially maintained in a constant-temperature circulating bath at the lower temperature for 24 hr. and then transferred to another constant-temperature circulating bath at the higher temperature for 24 hr. Each set of containers was alternated at the indicated temperatures for 8 days. At the end of the tests, the containers were adjusted to room temperature[2] to establish equilibrium and were examined for vacuum retention.

Agitation Tests—Shaking at constant elevated temperatures was performed to study the effects of agitation on vacuum loss. The filled containers were placed in a temperature-controlled shaker[3] and run at the highest shaking speed [approximately 380 oscillations/min. with an oscillatory amplitude of 2.54 cm. (1 in.)]. The size of the container holders built into the shaker necessitated the use of 500-ml. containers for the agitation tests (Tables I and II). Sets of containers were agitated at 30, 40, and 50° for 30 days; the bottles were then removed from the shaker, adjusted to room temperature, and tested for vacuum.

[1] Systems included are those marketed by Cutter Laboratories, Berkeley, CA 94710, and by Baxter Laboratories, Inc., Morton Grove, IL 60053.

[2] Accomplished by placing the bottles in a 25° water bath for 24 hr. and then passing room temperature air (*via* an electric fan) over the bottles for 2–4 days; room temperature for these tests was 23.5–24.5°.

Table II—Effect of Agitation for 30 Days on Vacuum-Holding Ability of 500-ml. Vacuum-Packed Parenterals

Agitation Temperature	Type of Container	Number Each of Test and Control Containers	Test Containers, avg. ml. Water to Relieve Vacuum	Control Containers, avg. ml. Water to Relieve Vacuum
30°	A[a]	21	88.9	88.5
30°	B[b]	23	75.9	75.0
40°	A	12	78.6	78.0
40°	B	12	77.5	78.6
50°	A	12	74.2	74.3
50°	B	12	73.3	75.0

[a] Type A containers from Lot N20F3. [b] Type B containers from Lot TU9617C.

Controls—Containers from the same lot were stored at room temperature and were examined at the same time as the test containers in both the temperature fluctuation and agitation studies to assure that "aging" of the bottles would not be a variable factor in the studies. Pairing controls with test containers in each lot eliminated the possibility of lot-to-lot variation.

Vacuum Measuring Apparatus—The apparatus consisted of a 250-ml. buret equipped with attached tubing terminating with an administration needle; the buret was equipped with an automatic refilling device (Fig. 1).

Container vacuum was measured by filling the 250-ml. buret with water and inserting the administration needle through the recommended puncture site of the parenteral container. Water from the buret was allowed to pass into the inverted intravenous container until the partial vacuum had been satisfied. Liquid levels in the container and buret were maintained at the same level by adjusting the container height. Water drawn from the buret into the vacuum was accurately read to 1.0 ml. and estimated to 0.5 ml. The larger the quantity of water drawn into the bottle, the greater was the vacuum that had existed prior to puncture. As a control, at least 25 containers of both types were examined for void space and fill volume.

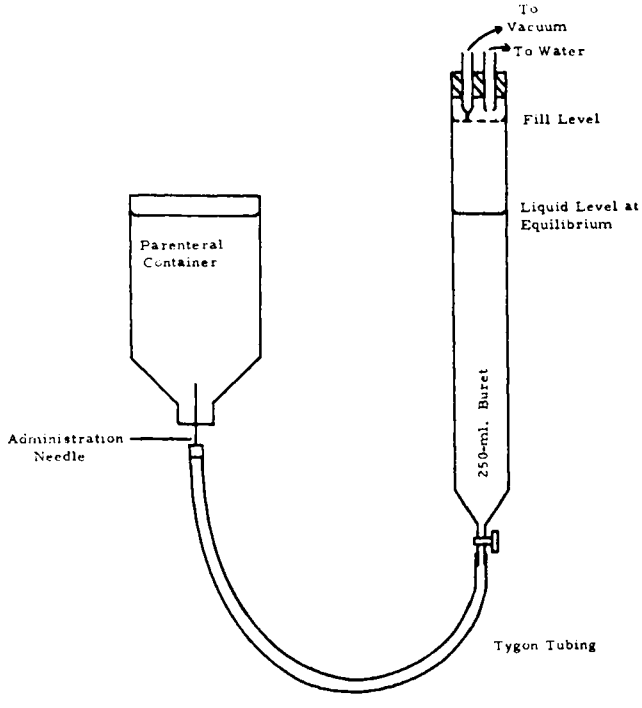

Figure 1—*Apparatus used to examine vacuum.*

Use of the water-filled buret technique eliminated the possibility of errors due to air leakage about the site of cannulation. If air entered, it would pass by the needle, go up through the liquid in the inverted container, and become visible as bubbles.

RESULTS AND DISCUSSION

The results from the experiments are shown in Tables I and II. Statistical evaluation of these data yields evidence that temperature fluctuation and agitation treatments have no detrimental effect on vacuum seal.

The greatest difference detected between average vacuums for test and control groups was found in the temperature fluctuation experiments. Table I shows that the 5–40°, 500-ml. Type A group had average vacuums of 85.75 ml. water for the test bottles and of 88.99 ml. water for the control bottles. A standard "pooled" or two-sample t test on this test-control pair of samples indicated that the differences were insignificant since the calculated t value is 2.0 or less than 2.413 at the 1% level.

The natural variation in vacuum from bottle to bottle among the Type A and Type B control samples is given by their standard deviations: 4.54 ml. water for Type A and 4.37 ml. water for Type B. When using the F test, it was found that there was no significant difference in the vacuum variance between the two types of control samples.

It is apparent from analysis that the conditions imposed upon the test containers did not affect the vacuum in these systems. The test conditions were strenuous to the point where they exceeded the normally expected environments to which the containers would be exposed. It may be concluded that normally expected amounts of agitation experienced in transport or fluctuations in temperature as in transport or storage are not primarily responsible for a loss of vacuum in these types of containers. When loss of vacuum is suspected, other factors such as decomposition of ingredients and faulty glassware or stoppers should be considered.

Semiautomated Spectrophotofluorometric Determination of Trimethoprim in Biological Fluids

S. A. KAPLAN▲, R. E. WEINFELD, and T. L. LEE

Abstract □ A semiautomated spectrophotofluorometric method for the determination of trimethoprim in blood, urine, and tissue is described. The initial extraction procedures are performed manually. The subsequent alkaline permanganate oxidation and the chloroform extraction of the fluorescent trimethoxybenzoic acid are performed by the automated system at a rate of 30 specimens/hr. The fluorescence is measured by a microflow cell in a spectrophotofluorometer. The method exhibits the same specificity and precision as the manual procedure, with a sensitivity limit in blood of 0.2 mcg./ml.

Keyphrases □ Trimethoprim in blood, urine, and tissue—semiautomated spectrophotofluorometric analysis □ Spectrophotofluorometry—analysis, semiautomated, trimethoprim in biological fluids

Trimethoprim[1] [2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine, I] is an inhibitor of dihydrofolate reductase which potentiates the activity of sulfonamides against a wide variety of bacterial species (1, 2). The previously reported manual method for determining I in blood and urine (3) met the requirements for specificity, sensitivity, accuracy, and precision. However, the generation of a large number of specimens required

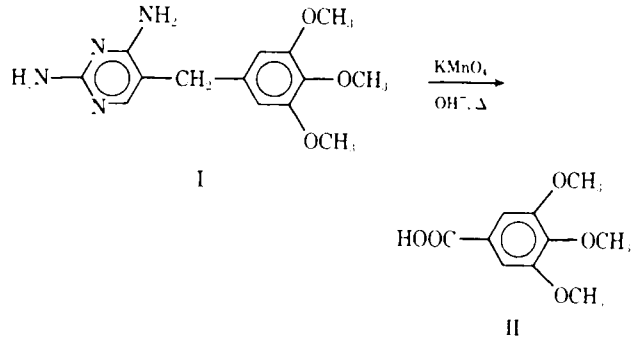
Semiautomated Spectrophotofluorometric Determination of Trimethoprim in Biological Fluids

S. A. KAPLAN▲, R. E. WEINFELD, and T. L. LEE

Abstract □ A semiautomated spectrophotofluorometric method for the determination of trimethoprim in blood, urine, and tissue is described. The initial extraction procedures are performed manually. The subsequent alkaline permanganate oxidation and the chloroform extraction of the fluorescent trimethoxybenzoic acid are performed by the automated system at a rate of 30 specimens/hr. The fluorescence is measured by a microflow cell in a spectrophotofluorometer. The method exhibits the same specificity and precision as the manual procedure, with a sensitivity limit in blood of 0.2 mcg./ml.

Keyphrases □ Trimethoprim in blood, urine, and tissue—semiautomated spectrophotofluorometric analysis □ Spectrophotofluorometry—analysis, semiautomated, trimethoprim in biological fluids

Trimethoprim[1] [2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine, I] is an inhibitor of dihydrofolate reductase which potentiates the activity of sulfonamides against a wide variety of bacterial species (1, 2). The previously reported manual method for determining I in blood and urine (3) met the requirements for specificity, sensitivity, accuracy, and precision. However, the generation of a large number of specimens required



Scheme I

[1] Trimethoprim is an active ingredient in Bactrim, F. Hoffmann-La Roche and Co., Basle, Switzerland.

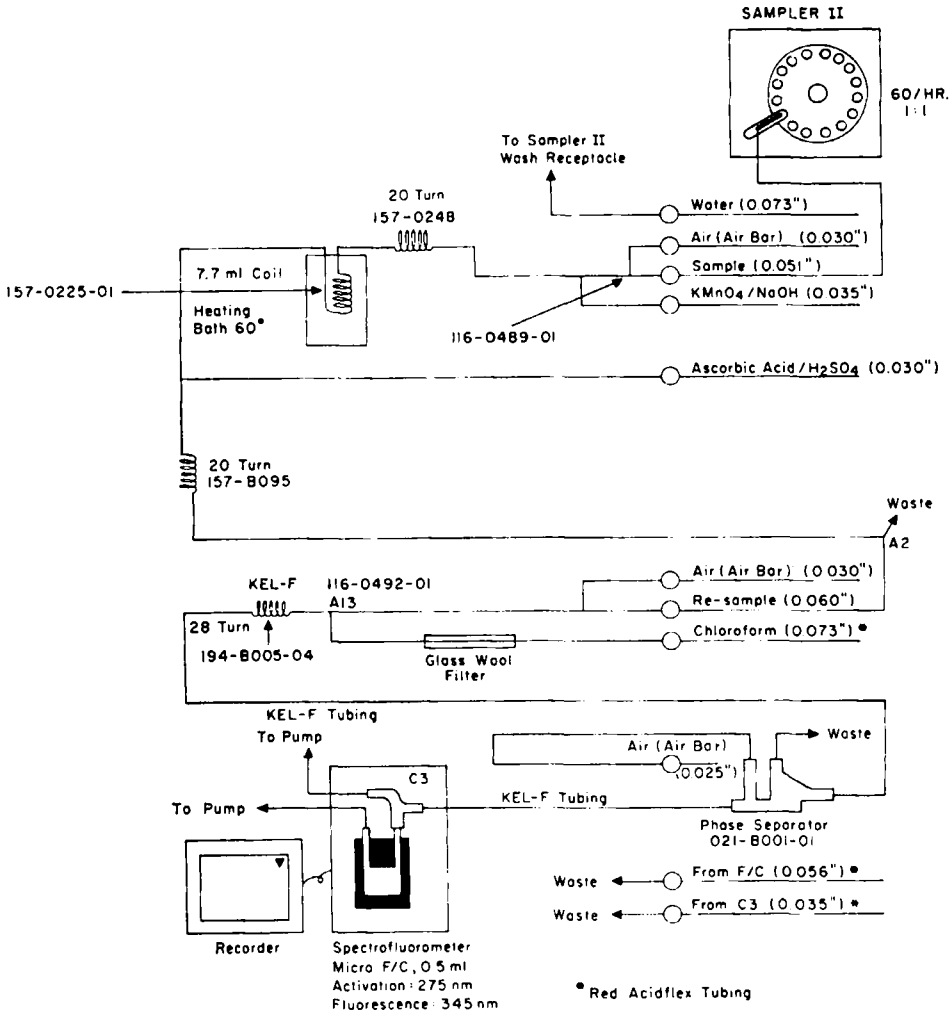


Figure 1—*Flow diagram for the automated determination of trimethoprim. Pump tubing is given with the internal diameter; Tygon tubing was used, except where noted. Technicon part numbers are also indicated.*

speed of analysis. Studies were undertaken to modify the manual spectrophotofluorometric method to make it compatible with continuous-flow automated techniques.

The manual procedure involves the extraction of I from biological specimens at pH 11.0 with chloroform, back-extraction into dilute sulfuric acid, and oxidation with alkaline potassium permanganate at 60° for 20 min. to the fluorescent trimethoxybenzoic acid, II (Scheme I). Following removal of excess permanganate with formaldehyde and subsequent acidification with 1 *N* sulfuric acid, II is extracted into chloroform and the fluorescence is measured at an activation wavelength of 275 nm. and a fluorescence wavelength of 345 nm.

Several modifications of the manual procedure were required to design an automated system using continuous-flow techniques. The manual, 20-min. oxidation step at 60° had to be shortened to approximately 4 min. at 60° for the automated system, and a 12% ascorbic acid solution in 1 *N* sulfuric acid was substituted for the 35% formaldehyde solution to destroy the excess potassium permanganate. The resulting clear acidified aqueous solution was extracted with chloroform in the automated procedure and, following phase separation, the organic phase was passed through the microflow cell of a fluorescence spectrophotometer[2] at the appropriate wavelengths. The finalized automated manifold utilizes automated analysis components[3] and allows for an analysis rate of 30 specimens/hr.

EXPERIMENTAL[4]

Reagents All chemicals are either reagent grade or USP: sodium carbonate, 0.2 *N* aqueous solution; sulfuric acid, 0.01 and 1 *N* aqueous solutions; potassium permanganate, 0.1 *M* in 0.1 *N* NaOH; ascorbic acid USP; 12% (w/v) ascorbic acid solution in 1 *N* H_2SO_4 (prepared fresh daily); and chloroform.

Standards—All standard solutions should be stored in a refrigerator and prepared fresh monthly. The following were used: trimethoprim, 100 mcg./ml. (dissolve 10.0 mg. of I in 0.01 *N* H_2SO_4 in a 100-ml. volumetric flask), and diluted standards of I ranging from 0.05 to 4.0 mcg./ml. in 0.01 *N* H_2SO_4. The standards are required for establishing external standard curves and for preparing internal standards.

[2] Perkin-Elmer.

[3] Technicon AutoAnalyzer II.

[4] The equipment and instruments used were: Technicon Sampler II, Technicon Instruments Corp., Tarrytown, NY 10591; Technicon proportioning pump model III; Techne thermostatic bath model TWB-5 with circulation pump, fitted with special cover for use with Technicon glassware, Techne, Inc., Princeton, NJ 08540; Perkin-Elmer model 204 fluorescence spectrophotometer with 150-w. xenon lamp light source, xenon lamp power supply, and R212 photomultiplier, Perkin-Elmer Corp., Norwalk, CT 06850; Technicon recorder with chart speed of 45.7 cm. (18 in.)/hr.; recorder interface accessory, Perkin-Elmer No. 010-0130; flow cell, rectangular, quartz, 0.5-ml. chamber capacity, 10-mm. light path, Perkin-Elmer No. 220-1461; and Technicon AutoAnalyzer II glassware.

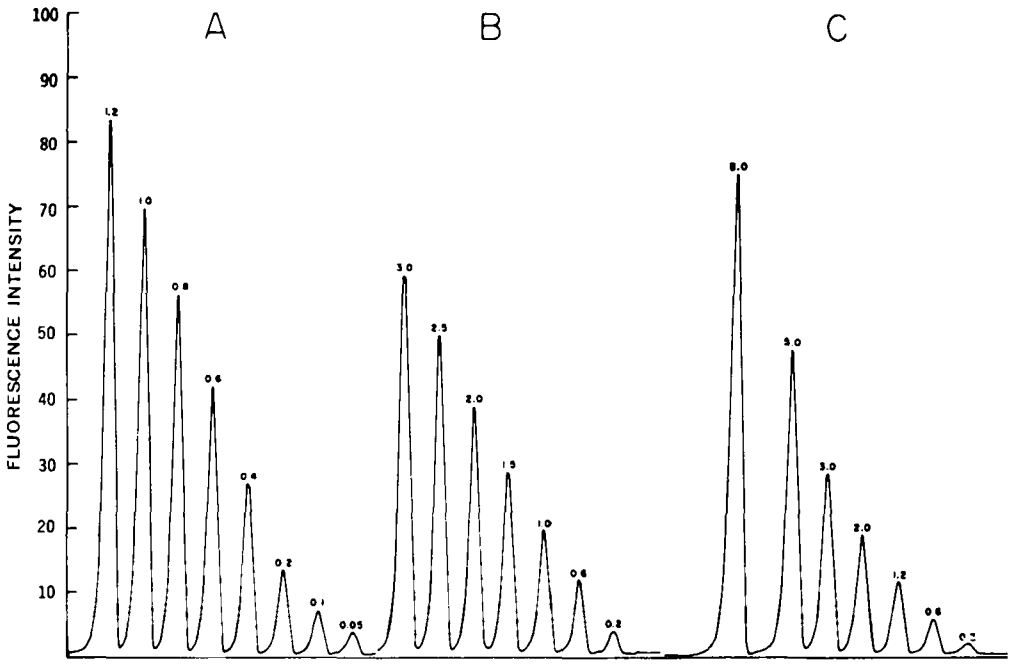

Figure 2—*Chart recordings relating trimethoprim concentration and fluorescence intensity. Instrument sensitivities were: A, 8 × 1; B, 6 × 1; and C, 5 × 1. Flow cell had 0.5-ml. capacity; recorder chart speed was 45.7 cm. (18 in.)/hr.*

Sample Preparation (Manual Extraction)—Pipet 1.0 ml. of blood, urine[5], or 10 ml. tissue homogenate[6] into a 40-ml. glass-stoppered, round-bottom centrifuge tube. Add 5 ml. of 0.2 *N* sodium carbonate solution for blood and urine specimens, and mix[7]. Extract the mixture with 10 ml. chloroform by shaking *slowly* for 15 min. on a mechanical reciprocating shaker. Centrifuge samples for 10 min. at 2000 r.p.m. with stoppers removed, and aspirate aqueous and most of the protein interface. Transfer a fixed aliquot of chloroform (7 or 8 ml.) to a 40-ml. glass-stoppered centrifuge tube, and extract with 5.0 ml. of 0.01 *N* sulfuric acid for blood[5] or tissue and with 10.0 ml. of 0.01 *N* sulfuric acid for urine due to higher concentrations of I[8] in urine. Shake for 10 min. at moderate speed, and centrifuge for 10 min. with stoppers removed. Transfer approximately 95% of the acid phase to 15-ml. glass-stoppered tubes and retain for automated analysis. Control (drug-free) blood, to which 5 or 10 mcg. of I[8] has been added, is analyzed along with the unknown specimens and serves as the internal drug standard. In the case of urine specimens, 30 mcg. of I is added.

Automated Analysis Procedure—The flow diagram for the automated manifold is presented in Fig. 1. Approximately 1 hr. prior to pumping any reagents, the spectrophotofluorometer, heating bath[9], and recorder (not the chart drive) should be turned on. The reagents are then pumped through the system for about 10 min., prior to establishing a reagent blank baseline on the recorder. The sampling cam used is 60/hr. [sample–wash ratio (1:1)] with a water wash cup between extracted samples. Sample cups[10] are used for extracts, standards, and washes.

Prior to introducing unknown extracts, two external standards of I are analyzed in the desired range (0.05–1.6 mcg./ml. for blood or 0.2–4.0 mcg./ml. for urine). The spectrophotofluorometer is adjusted to about 40% of full scale for a midconcentration standard using the instrument sensitivity control. The entire series of external standards of I can then be analyzed[11], placing a water wash cup between each sample.

The acid extracts are transferred to sample cups and placed on the sampler tray, with a water wash between extracts. When analyses of several hours are anticipated, the internal drug standard extract

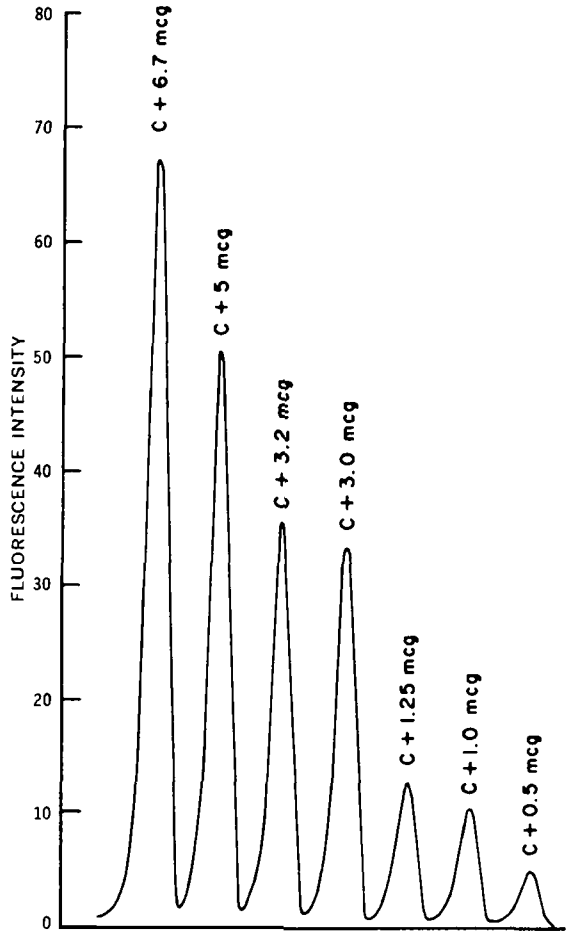

Figure 3—*Chart recording of indicated amounts of trimethoprim added to control (C) blood and analyzed by the described procedure. Acid extract volume = 5 ml.; instrument sensitivity was at 8 × 1.*

[5] Plasma, spinal fluid, or other biological fluids can also be analyzed by the same procedure.

[6] Homogenize a weighed tissue specimen directly with 0.2 *N* sodium carbonate solution. Use approximately 10 ml. sodium carbonate solution/g. tissue.

[7] In the analysis of urine, it is suggested that the pH of this mixture be checked so that the resultant pH is 11.0. Add additional sodium carbonate solution, if required.

[8] If necessary, the acid extracts can be further diluted with 0.01 *N* sulfuric acid to bring them into the range of the standard curve.

[9] Heating bath filled with ethylene glycol.

[10] Technicon.

[11] For routine analyses, it is unnecessary to run the entire standard curve. Duplicate determinations of the midconcentration standard are satisfactory for calculating percent recovery of the internal standard samples.

Table I—Concentration of Trimethoprim in Blood Determined by Manual and Automated Methods

Sample	Methods: Automated (A), mcg./ml.	Manual (B) Using Ascorbic Acid, mcg./ml.	Manual (C) Using Formaldehyde, mcg./ml.	Ratios: A/B	A/C	B/C

Mean ± *SE*				0.971 ± 0.014	0.963 ± 0.015	0.993 ± 0.016

should be reevaluated several times to check for any significant change in instrumental response.

The manifold (Fig. 1) performs the following steps. Acid extracts are aspirated from the sampler into the system, segmented with air, and mixed with alkaline potassium permanganate solution in a 20-turn coil. Oxidation is accomplished by passing the sample stream into a 7.7-ml. capacity coil (2.0 mm. i.d.) placed in a heating bath at 60°. The sample stream is then mixed with the ascorbic acid–sulfuric acid solution in a 20-turn coil to remove the excess potassium permanganate and acidify the stream, which is then debubbled, resampled through the pump, and resegmented with air. Chloroform is pumped directly with red pump tubing[12] through a glass-wool filter and mixed with the sample stream in a 28-turn coil[13] [0.10 cm. (0.040 in.) i.d.] to accomplish extraction of II into the chloroform. The mixture is passed through a four-point phase separator[3] with Teflon insert. The lower chloroform phase is resegmented with air and transferred through tubing to the flow cell in the spectrophotofluorometer. The sample stream is debubbled prior to entrance to the flow cell where the fluorescence of the chloroform stream is measured. The total time of analysis from sample aspiration to appearance on the recorder is about 12 min.

At the conclusion of the day's analyses, all tubing carrying aqueous reagents are washed through with water, while tubing carrying solvents are washed through with methanol and pumped with air until dry.

RESULTS

Standard Curves—Recorder tracings of external standards of I obtained by the automated procedure are shown in Fig. 2. Spectrophotofluorometer sensitivity settings are indicated in each case. Extracts of control blood specimens to which known amounts of I were added and a series of unknown human blood specimens following administration of the drug analyzed by the automated procedure are shown in Figs. 3 and 4. Extracts of control urine specimens to which known amounts of I were added and a series of unknown human urine specimens analyzed by the automated procedure are shown in Fig. 5. A plot of concentration of I (external and internal drug standards) *versus* fluorescence intensity is shown in Fig. 6 for the 0.05–1.2-mcg./ml. range and in Fig. 7 for the 0.2–4-mcg./ml. range. The fluorescence is linear up to 8 mcg./ml. of I, which is equivalent to approximately 4.10 mcg./ml. of II[14] under the described conditions.

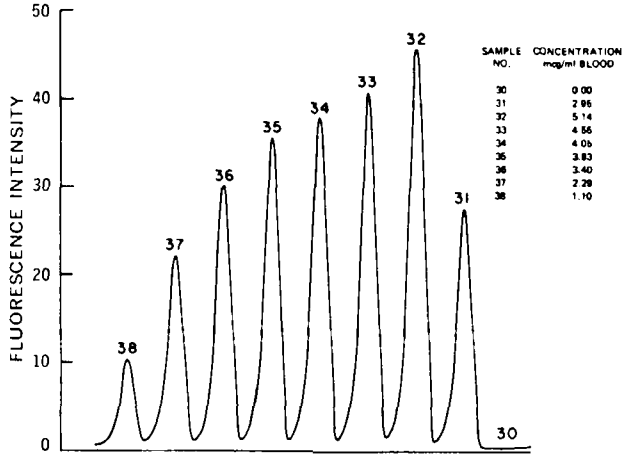

Figure 4—*Chart recording and corresponding concentrations of trimethoprim blood specimens following a single oral dose of the combination trimethoprim and sulfamethoxazole (400 and 2000 mg., respectively) formulation in man. Specimens correspond to 0, 1, 2, 3, 4, 6, 8, 12, and 24 hr. Acid extract volume = 5.0 ml.; instrument sensitivity was at 8 × 1.*

Extracts with a fluorescence intensity higher than the 8 mcg./ml. of I standard (or higher than the most concentrated standard being analyzed) must be diluted with 0.01 *N* sulfuric acid and rerun to bring the fluorescence into the linear portion of the standard curve.

Calculations—The fluorescence intensity at the apex of each peak is read directly from the chart recording. Reagent or control blood fluorescence is subtracted to give the net fluorescence due to I present. The concentration of I in the unknown specimens is di-

[12] Acidflex, Technicon.
[13] Kel-F, Technicon.
[14] Trimethoprim is oxidized to trimethoxybenzoic acid to the extent of about 70%; thus, the theoretical yield of 5.85 mcg./ml. trimethoxybenzoic acid is not attained.

Table II—Concentration of Trimethoprim in Urine Determined by Manual and Automated Methods

Sample	Methods: Automated (A), mcg./ml.	Manual (B) Using Ascorbic Acid, mcg./ml.	Manual (C) Using Formaldehyde, mcg./ml.	Ratios: A/B	A/C	B/C

10	75.4	75.3	75.1	1.00	1.00	1.00
11	45.7	41.3	47.2	1.11	0.97	0.88
12	162.2	160.9	179.4	1.01	0.90	0.90
13	36.5	38.0	35.0	0.96	1.04	1.09
Mean ± *SE*				1.037 ± 0.022	0.999 ± 0.022	0.972 ± 0.033

rectly proportional to the internal drug standard carried through the entire procedure. If further dilutions are necessary to bring the unknown extracts into the concentration range of the standards, they must be considered in calculating the final results. For urine specimens, dilution will be encountered more frequently since a much wider range of I values are encountered as compared to blood specimens.

The reproducibility of the automated steps of the procedure was determined by performing 34 replicate samplings of a 0.6 mcg./ml. I standard solution, at the spectrophotofluorometric sensitivity setting of 8 × 1 required for blood level studies, and was found to be 0.60 mcg./ml. ● 0.030 (*SD*).

The precision of the overall method including the manual sample preparation, manual extraction steps, automated steps, and fluorescence measurements was determined by the preparation and analysis of an internal drug standard, 10 mcg. I/ml. blood. This evaluation was based on the determination of the internal standard, in duplicate, by the automated section of the procedure on 11 separate days. The results of these analyses show that the precision of a single determination is approximately ±9.1%. This value was developed from analysis of variance which estimated both the variation within a day and between days. Comparable data evaluation based on single-day multiple determinations of drug internal standards using the manual method was reported to be ±6.2% (3).

Specimens of blood and urine containing I were analyzed by the manual and automated procedures to compare results. The published manual procedure (3) using formaldehyde to remove the excess potassium permanganate and the manual version of the automated procedure substituting 12% ascorbic acid were compared. This was necessary to demonstrate that the use of ascorbic acid in the automated procedure did not alter the chemical basis of the assay.

The results for 24 separate blood specimens analyzed by the three methods are shown in Table I, and results for 13 separate urine specimens containing a wide range of I concentrations are shown in Table II. Correlation of the results of these assays was tested by fitting a line to the joint determinations (A *versus* B, A *versus* C, and B *versus* C) and developing a 95% confidence region for the intercept and slope. The confidence limits for the intercept when the slope is fixed at unity are shown in Table III.

Significant differences would be reflected in confidence limits of the same sign. However, in those instances where this occurs, the calculated significance appears to be marginal (Table III).

Control bloods and urines exhibited no increase in fluorescence

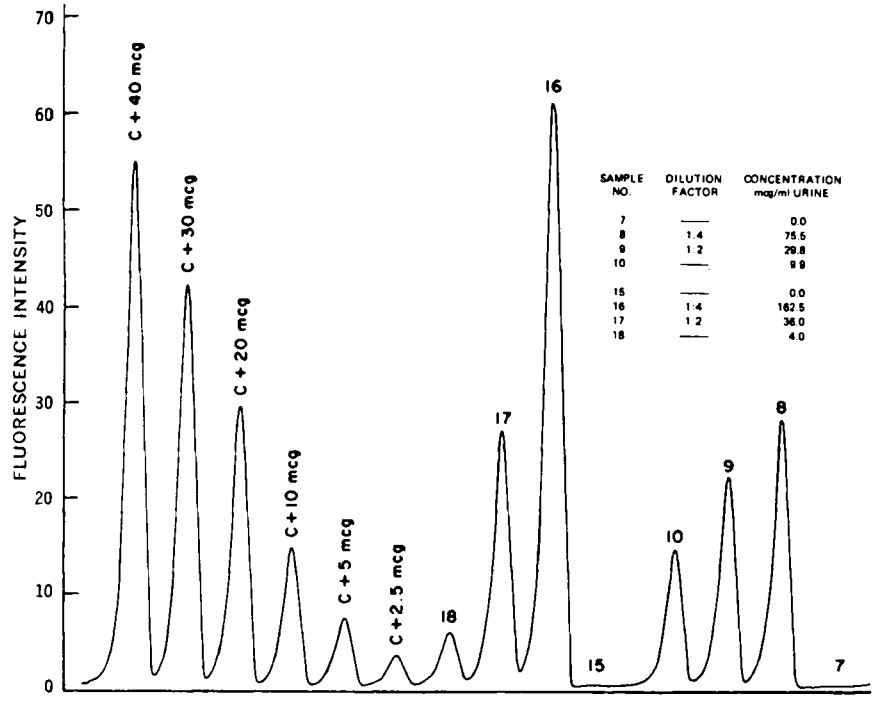

Figure 5—*Chart recording and corresponding concentrations of trimethoprim urine specimens following a single oral dose of the combination trimethoprim and sulfamethoxazole (400 and 2000 mg., respectively) formulation in two subjects and urine internal standards of the indicated amounts of trimethoprim added. Specimens correspond to control, 0–24, 24–48, and 48–72 hr. in each subject. Acid extract volume = 10.0 ml. (with appropriate dilutions); instrument sensitivity was at 6 × 1.*

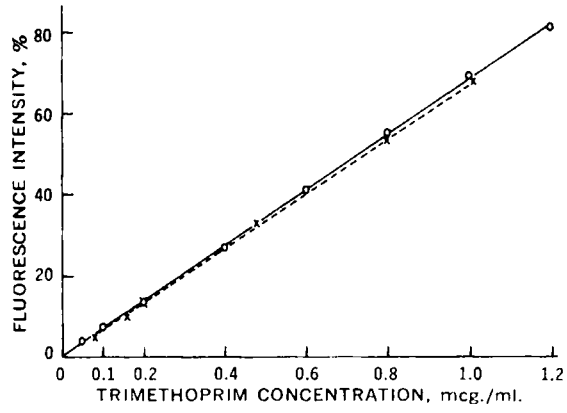

Figure 6—*Plot of trimethoprim standards (direct and recovered from blood) versus fluorescence intensity by automated procedure. Trimethoprim concentration, mcg./ml. acid expected. Instrument sensitivity was at 8 × 1. Key: O—O, direct standards; and ×- - -×, added to blood.*

compared to a reagent blank when analyzed by the automated procedure. No shifting of baseline was noted for control bloods, urines, and reagent blank.

The specificity of the automated procedure is the same as that previously reported for the manual procedure (3). In both the automated and manual procedures, it was demonstrated that physiological components of human plasma or blood do not interfere with the determination of I. Sulfonamides normally administered along with trimethoprim do not interfere with the analytical procedure (3).

DISCUSSION

The direct automation of the manual procedure for the determination of trimethoprim in blood and urine presented several major problems. Use of formaldehyde in the automated system resulted in the formation of the particulate brown manganese dioxide which clogged the mixing coil after several specimens passed through the system. Attempts to break up the precipitate proved difficult due to the large amounts formed. The same procedure was attempted using a solution of sodium bisulfite in place of formaldehyde. Although this process eliminated much of the precipitate problem, the resulting dissolved sulfur dioxide interfered with the fluorescence of II in the chloroform. To overcome this problem, a solution of sodium tetrachloromercurate was unsuccessfully used to complex the large amounts of sulfur dioxide produced (4). Ascorbic acid proved to be an excellent reagent for removing excess potassium permanganate from the reaction mixture. A 12% aqueous solution of ascorbic acid produced negligible particulate manganese dioxide, which was completely dissolved after several turns through the mixing coil. Preparation of the ascorbic acid in 1 *N* sulfuric acid proved to be more efficient than sequentially adding each reagent to the reaction mixture.

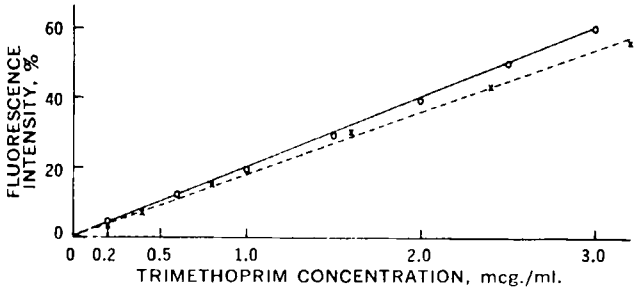

Figure 7—*Plot of trimethoprim standards (direct and recovered from blood) versus fluorescence intensity by automated procedure. Trimethoprim concentration, mcg./ml. acid expected. Instrument sensitivity was at 6 × 1. Key: O—O, direct standards; and ×- - -×, added to blood.*

Table III -Confidence Intervals

Fluid Analyzed	Method Y	Method X	95% Confidence Interval for Intercept when Slope = 1	Correlation Coefficient (*r* Value)
Blood	A	B	(−0.26, 0.01)	0.987
Blood	A	C	(−0.09, −0.02)	0.994
Blood	B	C	(−0.05, 0.16)	0.985
Urine	A	B	(0.7, 7.0)	0.997
Urine	A	C	(−15.0, 3.8)	0.990
Urine	B	C	(−18.4, −0.5)	0.987

Working with Kel-F tubing yielded better results than Teflon tubing, particularly for the extraction coil and less importantly for the transfer lines, due to their surface tension properties.

In developing the automated manifold for I, it was found that the use of AutoAnalyzer II glassware (mixing coils, injection fittings, phase separators, and tubing) resulted in superior overall reproducibility as compared with AutoAnalyzer I components. The former system was the most efficient regarding reagent consumption, reproducibility of bubble pattern, and phase separation and is considered the system of choice.

Development of a fully automated manifold for the determination of trimethoprim is being investigated. This will involve direct extraction of the buffered biological fluid with chloroform on the manifold and back-extraction of the chloroform with dilute sulfuric acid prior to the automated procedure described.

SUMMARY

A semiautomated spectrophotofluorometric method for the determination of trimethoprim in blood and other biological specimens is described. The automated procedure has the same specificity and precision as the manual procedure and allows for the analysis of 30 specimens/hr.

Subphase Exchange Apparatus for Monomolecular Film Studies

A. W. MALICK*, A. FELMEISTER†, and N. D. WEINER*▲

Abstract □ An apparatus for studying monomolecular films, by which the subphase can be changed without disturbing the film, was developed and the effectiveness of the apparatus was studied. Almost 100% of the subphase could be replaced when 1500 ml. of the subphase was exchanged over 20 min. By studying dipalmitoyl lecithin monolayers with and without subphase exchange (the π–A curves in both cases were the same), it was established that the films are not disturbed during the subphase exchange operation. The effect of subphase exchange on human serum albumin films of different concentrations was studied. The films became condensed when a water subphase was exchanged with water, apparently because of loss of some protein from the surface. This effect was more pronounced when films were spread using larger amounts of human serum albumin. The loss of less protein when less human serum albumin was spread was attributed to better spreading. The films also became condensed when a sodium chloride subphase solution was replaced with sodium chloride solution of the same concentration. However, the effect was less pronounced as compared to the water exchange with water. The π–A plots of human serum albumin films, in which the water subphase was exchanged with sodium chloride solution, were superimposable on the π–A plots of films spread on sodium chloride solution without exchange. Films of malate dehydrogenase formed using different amounts of this enzyme were studied after the buffer subphase was changed with a buffer solution of the same concentration. The exchange of this subphase had no effect on the π–A plots of any malate dehydrogenase film.

Keyphrases □ Monomolecular films—apparatus for changing subphase without disturbing film, dipalmitoyl lecithin, human serum albumin, and malate dehydrogenase films □ Films, monomolecular—apparatus for changing subphase without disturbing film □ Dipalmitoyl lecithin films—used to study subphase-changing apparatus □ Human serum albumin films—used to study subphase-changing apparatus □ Malate dehydrogenase films—used to study subphase-changing apparatus

Monomolecular films represent a relatively simple type of membrane model having a well-defined organized structure. They provide a convenient and promising method of studying molecules in a fixed orientation, as well as in a single layer where orientation can be changed by compression of the monomolecular film. As such, they constitute an important model system for the study of many natural phenomena involving surfaces of an oriented array of molecules.

Monomolecular films have been extensively used as structural models of the cell membrane. These model membranes cannot be expected to mimic fully a cell membrane. Their simplicity can also be considered a serious shortcoming to their use as a general model for biological membrane function. What can realistically be expected from studies with model membranes is some insight into the molecular mechanism of specific functions, as well as some knowledge of the function of specific areas within the heterogeneous makeup of biological membranes. Nevertheless, they provide considerable insight into the structure and function of biomembranes.

Monolayer studies involving proteins and enzymes present unique difficulties. For example, estimation of catalytic activity of surface-spread enzymes is difficult because of possible contamination by adsorbed unspread molecules beneath the film or by protein molecules dissolved in the bulk. There is a need for assaying enzymes *in situ*, but the dangers of contaminating the film with unspread globular protein from the subsolution are great (1). Ideally, the assay should be carried out while the molecules are adsorbed at the interface in question without manipulation or transfer of the film (2).

About 25–56% of protein spread on water was reported (3) to escape to the bulk, leaving 75–44% in the surface. Mechanical agitation was applied (3) under the film to assist the molecules adsorbed under the film to escape to the bulk. The amount of protein escaping to the bulk, of course, depends on many factors including the amount of protein applied, method of spreading, and spreading time.

To determine the activity of a surface-spread enzyme, the fraction of the enzyme that is adsorbed just below the surface or that escapes into the bulk phase must first be removed. In previous studies, this was accomplished by removing the surface-spread enzyme from the environment of the subphase either by transferring the enzyme monolayer to metal slides or by removing it with filter paper or a silk net. Alternatively, monolayers have been compressed to a fiber and then transferred to the substrate (3).

To investigate the effects of varying film pressures (varying degree of unfolding) on the activity of surface-spread acetylcholinesterase, a special four-compartment trough was devised (3) to provide a subphase free of dissolved or adsorbed enzyme. The protein was spread on one compartment between two barriers, and vigorous stirring was applied to the underlying solution to remove adsorbed unspread molecules from beneath the film. The film was then transferred by sliding the barriers to another compartment with a clean subphase containing the substrate. The surface pressure was measured in this second compartment using a platinum blade suspended from a tension transducer. When the film was moved, the whole apparatus was shifted so that the blade was always in contact with the film.

A three-compartment trough was utilized in a similar manner (4). The film was spread over one compartment and then was moved to the second compartment, with the help of a movable frame, where the subsolution was vigorously stirred. Then the film was moved to the third compartment onto fresh subsolution by shifting the frame.

A circular, multicompartment, Teflon trough was introduced (5) which allowed the shifting of mono-

layers over different subphases by moving together two barriers resting on the trough edge. A Wilhelmy balance was shifted with the film. The walls separating the compartments were lower than the edges so that the monolayers could be moved from one compartment to the other. The different compartments could be filled or emptied independently.

In all of these methods, the monolayer itself has to be transferred from the subphase on which the film is initially spread. This procedure may disturb the film and introduce additional uncertainties into the study.

The purpose of this study was to develop an apparatus that could be used to free the subphase under a spread film of dissolved constituents or contaminants without moving or disturbing the film. Such an apparatus would be of great use in studying the activity of surface-spread enzymes free of dissolved enzymes. It would also be useful for studying adsorption–desorption of ions and ion-exchange processes using lipid and protein monomolecular films.

EXPERIMENTAL

Materials—Synthetic L-α-dipalmitoyl lecithin[1], procine heart malate dehydrogenase[1] (260 units/mg. as a suspension in 70% ammonium sulfate), and crystalline human serum albumin[2] were used.

The organic solvents used, all spectrograde, were checked for surface-active impurities by compression on the film balance after addition of small amounts of these solvents onto the subphase. About 3 ml. of the solvent was placed on the surface (surface area of trough = 315.0 cm.^{2}) and, after 25 min., the surface area was reduced to 105.0 cm.^{2} by shifting the barrier. No surface pressure was observed for any solvent used. The inorganic chemicals used, all reagent grade, were also checked for surface impurities. Sodium chloride was roasted at 700° for 8 hr. Surface tension measurements of sodium chloride solutions and tromethamine–hydrochloric acid solutions before and after compression showed these solutions to be free of surface-active impurities.

The water used was deionized by passing tap water through a mixed resin bed of a demineralizer[3] and then distilling it in an all-glass still.

Apparatus—The Teflon-coated trough (525-ml. capacity) is removable to facilitate cleaning. The precision lead screw, which drives the reinforced Teflon barrier, allows for changes in surface area of the trough as small as 0.0125 cm. The barrier can be disengaged from the lead screw for rapid sweeping of the surface. The Teflon used for the trough and barrier has an advantage over the traditional wax-coated glass in that it is chemically inert as well as hydrophobic and oleophobic. The surface balance[4] is enclosed in a Plexiglas cabinet to minimize possible surface contamination by dust and grease from the environment.

Surface pressure values were measured by the Wilhelmy plate method (6). The platinum plate, roughened to ensure wetting, was suspended from a torsion balance[5] which can measure surface pressure changes as small as 0.1 dyne/cm.

The described surface balance was modified (Fig. 1) to allow for subphase exchange as required. The liquid used to replace the subphase liquid in the trough was placed in the 2.5-l. separator A, which served as a reservoir. During the operation, the stopper P of the separator was kept tightly closed so that it was air tight, whereas the Teflon stopcock B was kept open. The level of the stem D of the separator was adjusted by raising or lowering the separator A, by adjusting the ring stand supporting the separator, or by raising or lowering the vessel C using the adjustable jack E. The mouth of the vessel C was kept covered by aluminum foil to avoid contamination from the air. The level of the stem D controlled the level of the liquid in vessel C, which, in turn, controlled the level of the liquid in the trough H of the surface balance. The reservoir A and the vessel C worked somewhat like an animal feeder. As soon as the level of the liquid started to drop in vessel C, it was replenished by liquid from reservoir A. This served to maintain the liquid level in C constant, which, in turn, maintained the level in the trough constant. The flow of liquid to the trough could be stopped by closing stopcock F.

The inlet glass tube G was placed in one corner of the trough on the side from which compression was started, and the outlet glass tube I was placed in another corner on the opposite side. The barrier was so positioned that the inlet glass tube G did not interfere with the movement of the barrier during compression. The liquid level was so adjusted that the liquid level in the trough was slightly above the brim of the trough throughout the operation.

To control and maintain a certain flow of liquid through the system (trough), the stopcock J was adjusted and its position was kept fixed afterward. To start or stop the flow of liquid through the system, stopcock L was opened or closed, respectively. To measure the rate of flow, the outflowing liquid from the polyethylene tube K was collected in a graduated vessel M.

In all experiments, the subphase exchange was started 10 min. after spreading the film and the film was compressed 5 min. after stopping the flow. The subphase exchange was completed in 20 min. in all cases. Flow rates were controlled so that either 900 or 1500 ml. was exchanged in this period. At these rates, no visual disturbance of the film was observed. To ensure that the apparatus was free of surface-active impurities, water in the trough was replaced with 2000 ml. of water from separator A and the surface tension was checked at full trough area and after compression to one-third trough area. The apparatus was found to be free of any surface-active contaminants by this method.

Dipalmitoyl lecithin monolayers were studied with and without subphase exchange to establish that there was no film loss during the subphase exchange procedure.

To determine the amount of liquid required to replace the subphase, a 0.01% aqueous solution of benzoic acid in the trough was exchanged with water from separator A. The absorbance of benzoic acid solution samples taken from the trough at different intervals was read at 273 nm., and the concentration of benzoic acid was determined from a standard curve. Percentages of original benzoic acid concentration in the trough *versus* volume of liquid replaced in the trough plots were then constructed for two different flow rates.

Preparation of Spreading Solutions—*Dipalmitoyl Lecithin*—Dipalmitoyl lecithin (22.5 mg., mol. wt. 734) was dissolved in ethanol–hexane (5:95 v/v) to make 50 ml. of solution. In all experiments with dipalmitoyl lecithin, 0.07 ml. of this solution was spread on a tromethamine–hydrochloric acid buffer (pH 7.4) subphase.

Human Serum Albumin—Crystalline human serum albumin (24.2 mg.) was dissolved in water to make 50 ml. of solution. It was stored in the freezer and was thawed to room temperature immediately before use. In the various experiments, 0.038 and 0.07 ml. of this solution were spread on either water or 10% sodium chloride solution by the Trurnit (8) method.

Malate Dehydrogenase—An appropriate volume of the suspension was dissolved in 5 ml. of the tromethamine-hydrochloric acid buffer solution (pH 7.4) to yield a concentration of 1 mg./ml. This solution was stored in the freezer and thawed to room temperature just before use. In the various experiments, 0.07 and 0.1 ml. of this solution were spread on a tromethamine-hydrochloric acid buffer subphase (pH 7.4) by the Trurnit (8) method. The pH 7.4 for malate dehydrogenase studies was chosen because the highest activity of malate dehydrogenase is reported to occur in the physiological range of pH 7.3–7.5 (7).

In the case of proteins, different volumes of the same spreading solution were delivered to spread films of different protein concentrations.

Procedure—Before spreading the film-former solution, the surface of the subphase was swept several times with the barrier to clean the surface. The surface was checked for cleanliness by taking readings at full trough area and after compressing to one-third trough area. The same reading in both positions ensured that the surface was clean. The platinum plate was then lowered into position and allowed to remain beneath the surface while a known volume of the film-forming substance was spread with a micrometer syringe[6], which can deliver volumes as small as 0.001 ml. accurately. In all experiments, compression was initiated 35 min. after the film was spread, allowing the system to come to "equilibrium" and also ensuring complete evaporation of the spreading solvents for phospholipids. The area available to the film molecules was then reduced in small increments, and surface pressure readings were taken 1 min. after each area change. Compression was usually continued until the film collapsed.

Solutions of dipalmitoyl lecithin were applied onto the subphase by allowing small drops to fall from the syringe held a few millimeters above the surface. The proteins were spread by the Trurnit (8) method. A 5-mm. diameter glass rod was bent so that it could be placed in the trough on its own base. The vertical limb of the glass rod was 40 mm. long and had a hemispherical top. Before spreading, the glass rod was thoroughly washed and then placed in the trough. The protein solutions were applied from the micrometer syringe on the glass rod top at a slow, steady rate. The syringe was always held directly above the top of the glass rod. The glass rod was then washed by applying drops of the same solution being used as the subphase, with the help of a clean dropper. The number of drops was kept constant for all readings. The washing ensured that no protein was left sticking to the portion of the glass rod outside the subphase. The glass rod was so positioned that it could remain in place during the compression cycle.

Two different amounts of each protein were spread to demonstrate the effects of: (*a*) subphase exchange on different protein concentrations, and (*b*) protein concentration on area per unit weight of the protein.

The 35-min. period between spreading and compression also allowed enough time for subphase exchange when required.

All experiments were carried out at room temperature (25 ± 2°).

RESULTS AND DISCUSSION

A plot of the original benzoic acid concentration in the trough *versus* volume of water replaced in the trough is shown in Fig. 2. It was observed that when 900 ml. of water was replaced over 20 min., the benzoic acid concentration in the trough was reduced by 92%. In the first 250-ml. change of subphase, 57% loss in concentration occurred. Figure 2 also shows a plot of benzoic acid concentration *versus* volume of water replaced in the trough when 1500 ml. of water was used to replace the subphase solution over the same 20-min. period; almost 100% (>99%) of the subphase solution was replaced. The major loss in benzoic acid concentration (69%) again occurred with the replacement of the first 250 ml. It is important to note that for a given volume of subphase exchanged, the amount of benzoic acid solution replaced is dependent on the rate of exchange of the subphase; *i.e.*, the rate of benzoic acid loss is greater at a faster rate of subphase replacement. Thus, to achieve reproducible results, it is necessary to work at a fixed rate of exchange of the trough liquid. With the apparatus and technique used, essentially 100% exchange of the subphase solution in the surface balance trough can be achieved.

Figure 3 shows π–A plots of spread films of dipalmitoyl lecithin on water without subphase exchange and of dipalmitoyl lecithin films on water when the subphase was exchanged with 900 and 1500 ml. of water. The π–A plots in all these cases are identical, indicating that there was no leakage of the film under the movable barriers or any disturbance of the film during the subphase exchange operation. These experiments indicate that this apparatus can be used to replace the subphase under an insoluble lipid film without affecting the film characteristics.

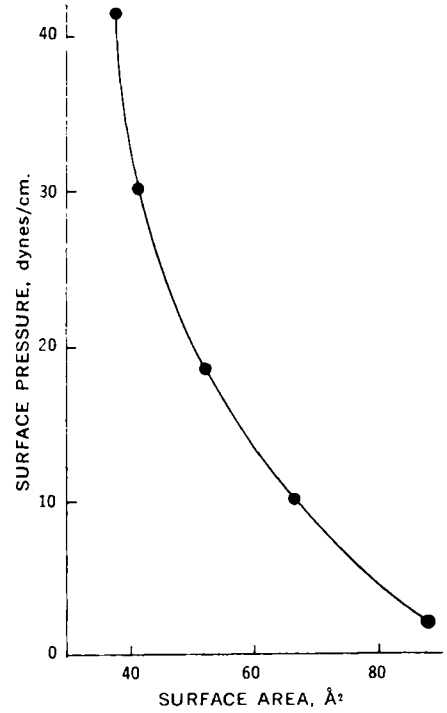

Figure 3—π–A *curves of dipalmitoyl lecithin spread on water. Key:* ●, *no subphase replacement;* ●, *subphase replaced with 900 ml. water; and* ●, *subphase replaced with 1500 ml. water.*

In the protein studies, human serum albumin films were spread by the Trurnit (8) method either on water or on 10% sodium chloride solution; in certain experiments, the subphase was exchanged. In all experiments, the human serum albumin formed stable films which gave reproducible π-A plots. Figure 4 shows π-A plots of human serum albumin films (0.0184 mg.) on a water subphase and on a 10% sodium chloride solution subphase. The two plots are parallel, but the film on the 10% sodium chloride subphase has a much larger area per milligram at all surface pressures; *i.e.*, it is more expanded than the film spread on water. The expansion effect was also observed when a larger amount of human serum albumin was spread (0.0339 mg.) on the 10% sodium chloride solution subphase (Fig. 5). These data suggest that more complete spreading occurred with both concentrations of protein in the presence of 10% sodium chloride.

In the case of proteins, the presence of charges on the molecules must be given consideration concerning their ability to spread. According to Crisp (9), better spreading of protein on solutions of high ionic strength can readily be understood if it is recognized that the electrical potential set up by the charged film inhibits further adsorption of additional charged protein molecules at the interface. A decrease in this potential occurs as the concentration of electrolyte in the solution is increased. Charge repulsions between molecules in the plane of the film are reduced also as the ionic strength increases, because with it the dielectric constant of the subphase increases. Cheeseman and Davies (10) attributed the facilitation of spreading and unfolding of protein molecules by salt solutions to the diminution of intramolecular cohesion, because of reduced electrostatic attraction between ionizable groups as the effect of the ionic charges are canceled. Some investigators (11) stated that ions exert their effect by altering the structure of water, thus weakening the tendency of protein to form hydrophobic bonds and so facilitating uncoiling of the protein molecule. Spreading protein on a high salt concentration subphase may simply reduce the solubility of the protein considerably (salting-out effect), thus minimizing the loss of protein into the subphase by diffusion (12). Therefore, salts would be expected to cause a marked increase in surface area of protein films *via* one or all of the mechanisms previously described, although it cannot be said with certainty which is responsible for the observed expansion of human serum albumin films on the salt solution subphase.

Figure 4 shows the effect of change of subphase with water on films of human serum albumin (0.0184 mg.) spread on water. Exchange of the subphase results in a slight shift of the π-A plots to smaller surface areas. The difference, while small, is significant. The same effect is observed when the subphase of human serum albumin films spread on 10% sodium chloride solution is replaced by 1500 ml. of a sodium chloride solution of the same concentration.

The effect of subphase exchange is much more pronounced when a larger amount of the protein is spread. Figure 5 shows the effect of subphase exchange on films of human serum albumin when 0.0339 mg. of the protein was spread. When the subphase of the film spread on water was replaced by water, the π-A profile shifted to smaller areas. This suggests that when the subphase is exchanged, some protein is lost. Cheeseman and Davies (10) postulated that, when proteins are spread on substrates in which they are soluble, an unstable equilibrium may be established. The monolayer proper consists of completely or almost completely unfolded molecules, beneath which exists an adsorbed layer of relatively unmodified molecules. These molecules are held in the interfacial region by salt linkages or hydrogen bonding, and some of this unmodified protein is forced into the subphase. It is possible that this adsorbed layer of relatively less unfolded protein molecules under the monolayer may be swept away and removed as the subphase is replaced by fresh subphase. This would, in turn, result in a reduction in surface area at all given surface pressures.

When the effect of subphase exchange on the two amounts of spread human serum albumin is compared, it can be seen that there is a very small effect on the π-A plots when 0.0184 mg. is spread (Fig. 4) while the effect is quite significant when 0.0339 mg. is spread (Fig. 5). This may be due to better spreading in the former case since the protein molecules under this condition have more area available at the interface for unfolding, allowing relatively more molecules to unfold completely and form a more stable monolayer with fewer unmodified molecules adsorbed under it. In this case, more molecules would be held securely at the interface and thus less protein would be removed by subphase exchange. At higher concentrations of protein, molecules would have less area available for unfolding and thus more molecules would be adsorbed under the film. These adsorbed molecules would be more easily removed when the subphase is exchanged.

Figure 5 also shows the effect of exchanging the subphase with sodium chloride solution when 0.0339 mg. human serum albumin was spread on the sodium chloride subphase solution. This reduction in surface area is less than when the water subphase is changed

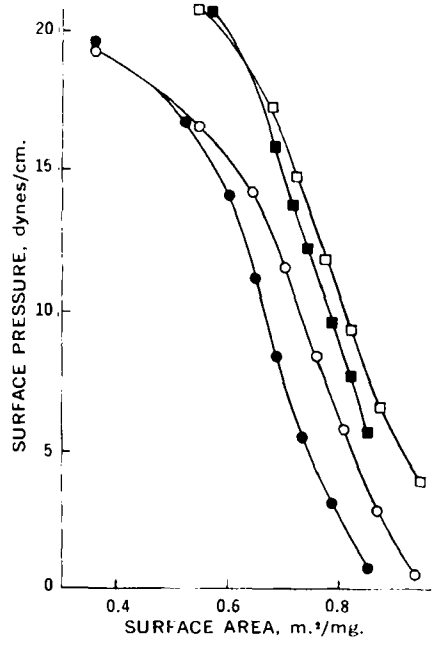

Figure 5-- π-A *curves for 0.0339 mg. human serum albumin. Key:* ○, *spread on water;* ●, *spread on water and subphase replaced with 900 and 1500 ml. water;* □, *spread on 10% (w/v) sodium chloride solution; and* ■, *spread on 10% (w/v) sodium chloride solution and subphase replaced with 1500 ml. 10% (w/v) sodium chloride solution.*

with water. This may be due to the better spreading of the protein on the salt solution as well as to its reduced solubility in the subphase as compared to water. The π–A plots for human serum albumin films are essentially the same when both 0.0339 and 0.0184 mg. of protein are spread (Figs. 4 and 5). This demonstrates that the area per unit weight of the human serum albumin film is almost independent of the amount of protein spread within the range studied.

The effect of exchanging the water subphase with sodium chloride solution on films of 0.0339 mg. human serum albumin is shown in Fig. 6. The π–A plots of the film after the exchange of subphase are superimposable on the π–A plot of 0.0339 mg. human serum albumin spread on 10% sodium chloride solution. The film is expanded as compared to the film on the water subphase. This suggests that when sodium chloride solution is exchanged for the water subphase, the salt either allows the protein molecule in the film to unfold more completely or forces any protein molecule adsorbed under the film into an area determining position at the interface. If the latter is true, these data would also indicate that, in a water subphase, any protein molecule not in an area determining position is adsorbed at or close to the interface rather than dispersed uniformly throughout the solution. If the protein is dispersed uniformly throughout the subphase rather than being primarily in the unstirred layers close to the interface, much of it would be swept away during subphase change and the π–A curves would not be superimposable.

The effect of replacing the subphase with water when 0.0339 mg. of human serum albumin was spread on 10% sodium chloride solution is also shown in Fig. 6. There is a significant reduction in surface area, but the π–A plot is parallel to the π–A plot of the human serum albumin film spread on the sodium chloride solution. However, the π–A plot does not quite coincide with the plot of the film spread on water alone. This may be due to better spreading of the protein initially on the sodium chloride solution subphase, which would tend to reduce the amount of protein lost when the subphase is exchanged. Moreover, since the protein solubility is greater in water than in sodium chloride solution, some protein would be expected to be lost following the exchange. This could account for the reduction in the surface area of the film as shown in Fig. 6.

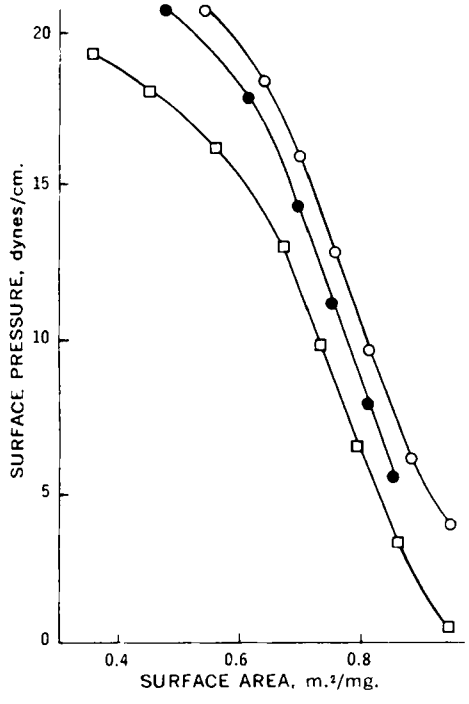

Figure 6—π–A *curves for 0.0339 mg. human serum albumin. Key:* ○, *spread on 10% (w/v) sodium chloride solution;* ○, *spread on water and subphase replaced with 1500 ml. 10% (w/v) sodium chloride solution;* ●, *spread on 10% (w/v) sodium chloride solution and subphase replaced with 1500 ml. water; and* □, *spread on water.*

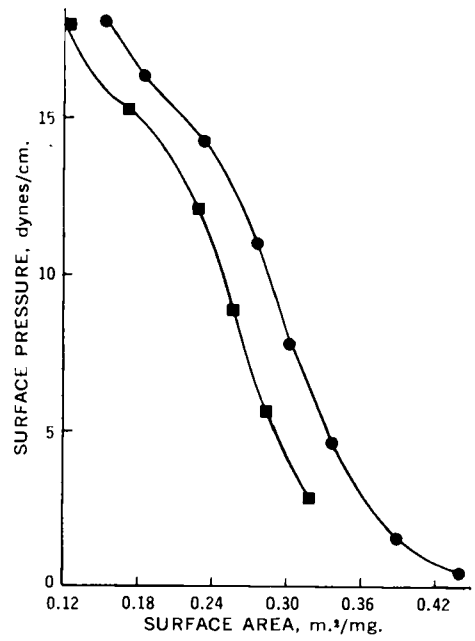

Figure 7—π–A *curves of malate dehydrogenase films on pH 7.4 tromethamine–hydrochloric acid buffer solution. Key:* ●, *0.07 mg. spread on buffer;* ●, *0.07 mg. spread on buffer and subphase replaced with 900 and 1500 ml. buffer;* ■, *0.10 mg. spread on buffer; and* ■, *0.10 mg. spread on buffer and subphase replaced with 900 and 1500 ml. buffer.*

The malate dehydrogenase films were spread on pH 7.4 tromethamine–hydrochloric acid buffer solution. In some experiments, the subphase was exchanged with a buffer solution of the same composition. The malate dehydrogenase films were spread by the Trurnit (8) method and, in all experiments, malate dehydrogenase formed stable films which gave reproducible π–A curves.

Figure 7 shows π–A plots of 0.1 and 0.07 mg. malate dehydrogenase spread on the buffer solution. The π–A plots of the two different amounts of malate dehydrogenase are not superimposable, and the curve representing the larger amount of enzyme spread is more condensed. However, the two plots are parallel, and both show an inflection point at about 15.7 dynes/cm. surface pressure. Beyond this inflection point, at smaller surface areas, the films become less compressible.

The reason why the area per molecule at all surface pressures is greater when a smaller amount of malate dehydrogenase is spread might be due to better spreading of the film under this condition, since more area is available to the molecules and better unfolding and less enzyme loss to the subphase would result. Thus, in the case of malate dehydrogenase films, the area per unit weight of protein is dependent on the amount spread.

Figure 7 also shows the effect of replacing the tromethamine–hydrochloric acid buffer subphase with 900 and 1500 ml. of a buffer solution of the same composition on 0.07 and 0.1 mg. malate dehydrogenase films. The change of subphase has no effect on either concentration of malate dehydrogenase films. This shows that both the 0.1- and 0.07-mg. malate dehydrogenase films are very stable, and no enzyme is lost by replacing the subphase. Thus, it appears that the difference in surface area observed when different amounts of this enzyme are spread is the result of differences in the degree of unfolding only, rather than dissolution or adsorption of protein below the film surface.

The study demonstrates the effectiveness of this apparatus in exchanging the subphase under monomolecular films of lipids and proteins without significantly disturbing the films or modifying their π–A characteristics.

NOTES

Cardiovascular Effects of Digoxin–Phenelzine Interaction in Rabbits

JEFFREY S. BOHRMAN* and EMMANUEL B. THOMPSON▲

Abstract □ The potential toxicity of combining phenelzine, an MAO inhibitor, and digoxin, a cardiac glycoside, was studied in rabbits. Cardiovascular responses following concurrent administration of these drugs and the administration of these drugs 20 and 60 min. apart, respectively, revealed that phenelzine and digoxin evoked arrhythmias in about 50% of all rabbits tested without markedly altering the arterial blood pressure. Spontaneous heart rate in these animals was found to be lower than control values. The incidence of arrhythmia decreased as the time interval between the administration of both drugs was increased from 20 to 60 min. An increase in the number of days of pretreatment with phenelzine resulted in the use of a higher dose of digoxin to evoke arrhythmia.

Keyphrases □ Digoxin–phenelzine interactions—cardiovascular effects in rabbits, dose–time relationships □ Phenelzine–digoxin interactions—cardiovascular effects in rabbits, dose–time relationships □ Interactions, digoxin–phenelzine—cardiovascular effects in rabbits, dose–time relationships □ Drug interactions digoxin–phenelzine in rabbits

The administration of digoxin in combination with phenelzine is occasionally employed in clinical practice. However, when an antidepressant drug such as phenelzine, a monoamine oxidase (MAO) inhibitor, is administered concurrently with a cardiac glycoside such as digoxin, an interaction may occur. A digitoxigenin–biogenic amine interaction was reported (1) to play a significant role in the development of digitoxigenin toxicity and lethality. Drugs not belonging to the class of MAO inhibitors but that deplete brain monoamines were found to protect mice and rats against digitoxigenin lethality. On the basis of the preceding information, it can be surmised that digoxin toxicity may be enhanced with concurrent phenelzine administration.

This preliminary investigation was undertaken to determine if concurrent digoxin phenelzine administration would result in enhanced toxicity and if such toxicity was dose related and/or time dependent in terms of the two drugs administered together.

EXPERIMENTAL

Cardiovascular Studies of Phenelzine and Digoxin—Adult, female, albino rabbits, weighing 1.96–4.9 kg., were anesthetized with sodium pentobarbital[1], 25 mg./kg. i.v.; supplemental doses of 0.2 ml. sodium pentobarbital were injected as needed. Carotid arterial blood pressure was recorded using a pressure transducer[2], while heart rate was determined from limb lead II electrocardiographic records. All monitored parameters were recorded on an ink-writing oscillograph[3].

Studies of certain cardiovascular responses to either phenelzine (2.5, 5, and 10 mg./kg.) or digoxin (0.125 and 0.250 mg./kg.) administered individually by jugular vein served as the control basis for comparison with concurrent administration of both drugs. At least six rabbits were used in each experiment. Control readings of spontaneous heart rate and arterial blood pressure were recorded at 10-min. intervals prior to the injection of the first drug. Following each drug administration, readings were made at intervals of 0.5, 1.0, 5.0, and 10.0 min. and then every 10 min. thereafter; three nearly similar readings were obtained before a subsequent dose was administered. Replicate observations were made in the same animal (*i.e.*, 0.125 mg./kg. digoxin was given noncumulatively in the same animal three times before attempting the next dose, 0.25 mg./kg., for the next three trials).

Drug Interaction–Time Course—The following three time-spaced studies of phenelzine and digoxin were conducted: (*a*) drugs concurrently injected intravenously; (*b*) drug administration 20 min.

	5.0 + 0.250[d]	2	250 ± 7	235 ± 5	205 ± 25	234 ± 16	1/2

[a] Statistically significant from control values ($p < 0.05$). [b] Concurrent administration. [c] Digoxin administered 20 min. after phenelzine. [d] Digoxin administered 60 min. after phenelzine.

apart, with phenelzine being given first followed by digoxin 20 min. later; and (*c*) a similar pattern of drug administration 60 min. apart. The dose levels of digoxin and phenelzine used were 0.125 or 0.25 mg./kg. and 2.5 or 5.0 mg./kg., respectively.

Effects of Phenelzine Pretreatment on Digoxin-Induced Arrhythmias—Six rabbits were pretreated with phenelzine intraperitoneally for varying times, one each for 3, 4, and 5 consecutive days and three for 7 days. Pretreatment days with phenelzine were varied to determine long- and short-term effects of this drug when interacting with digoxin. Two dose levels of phenelzine were tested: 2.5 and 5 mg./kg. The first three rabbits received 0.125 mg./kg. i.v. of digoxin on a cumulative basis every 20 min. until arrhythmias developed. Similarly, the other three animals received digoxin, 0.25 mg./kg. A control study of six other rabbits pretreated with normal saline in the same dose regimen described for phenelzine was also conducted. These rabbits were similarly challenged with digoxin.

RESULTS

Spontaneous Effects of Digoxin—Of the two doses of digoxin tested in anesthetized rabbits, only 0.25 mg./kg. produced a sustained decrease in spontaneous heart rate (Table I). The heart rate of animals receiving 0.125 mg./kg. was slowed significantly only at 5 min. after administration and returned to a near preinjection value by 30 min.

A prompt elevation of arterial blood pressure was noted following administration of 0.25 mg./kg. digoxin but was not significant 30 min. later (Table II). Only one out of the 15 observations recorded at the dose level of 0.125 mg./kg. showed a transient arrhythmia following digoxin administration while the dose of 0.25 mg./kg. produced a 50% incidence of arrhythmia (Table I). In almost all of these observations, the arrhythmia was of the ventricular type; onset was noted about 1 min. after injection and the duration was approximately 10 min.

Spontaneous Effects of Phenelzine—All doses of phenelzine, except 2.5 mg./kg., produced varying degrees of reduction of spontaneous heart rate in 5–10 min. (Table I). With each injection of phenelzine, a transient hypotensive effect was noted, generally followed by hypertensive response. The hypertensive response to 2.5 mg./kg. was minimal in some rabbits and nonexistent in others (Table II). There was an increase in pulse pressure with this hypertensive response, which was sustained for approximately 5 to 10 min. by doses of 5 and 10 mg./kg., respectively. The incidence and severity of the ventricular arrhythmias that occurred after injection of phenelzine varied directly with increasing dose (Table I). Most of these arrhythmias were short lived, lasting only about 5 min.

Interactions of Phenelzine and Digoxin—The immediate response to concurrent intravenous administration of phenelzine and digoxin appeared to be bradycardia. This decrease in spontaneous heart rate was statistically significant 5 min. after drug treatment when both phenelzine and digoxin were administered 20 min. apart (Table I). This decrease in heart rate was evident up to 30 min. after drug treatment. The drug combination generally caused a fall in arterial blood pressure, and such a hypotensive response was significant when higher doses of phenelzine and digoxin were administered 20 min. apart (Table II). Phenelzine–digoxin administration evoked arrhythmias of very short duration in 45% of the animals tested.

In these time-dependent studies, the frequency of occurrence of arrhythmias appeared to be inversely related to the prolongation of the time interval between injection of phenelzine and digoxin.

Table II—Effects on Arterial Blood Pressure following Interactions of Phenelzine and Digoxin in Rabbits

Treatment	Dosage, mg./kg.	Number of Observations	Mean Arterial Blood Pressure ± *SE*

6	7	5.0	0.750	~0.025
7–12	7	—[b]	0.38 ± 0.15[c]	-

[a] Level of significance relative to the saline controls. [b] Saline controls. [c] Mean value ± *SE*.

When digoxin was administered 20 and 60 min. after phenelzine, the incidence of arrhythmias was observed in 50 and 33%, respectively, of the animals.

Phenelzine Pretreatment on Digoxin Toxicity—Six rabbits pretreated with varying doses of phenelzine and for varying times responded to injected digoxin with a bigeminal type of ventricular arrhythmia. Because of the variability in the autonomic response of these rabbits to phenelzine pretreatment, it was sometimes necessary to administer a large loading dose for a longer period followed by a smaller sustaining dose for a shorter period, and vice versa. By increasing the number of pretreatment days to 5 and 7, respectively, the amount of the cardiac glycoside required to evoke arrhythmias was similarly altered (Table III). Each injection of digoxin produced an immediate decrease in the heart rate and a slight hypotensive effect.

DISCUSSION

These studies point out certain potential cardiovascular dangers inherent with concurrent phenelzine–digoxin administration. The results in rabbits showed that a dose–time relationship existed for both spontaneous heart rate and arterial blood pressure. While spontaneous heart rate decreased significantly after 0.125 and 0.25 mg./kg. i.v. digoxin, the systolic arterial pressure was significantly increased at the 0.25-mg./kg. dose level. This increase in arterial blood pressure might have been caused by increased peripheral vascular resistance due to the well-known vasoconstrictor action of digitalis on the resistance vessels of the systemic circulation (2–5). Rabbits injected with phenelzine alone, 5 and 10 mg./kg., showed instantaneous bradycardia, which may partly be a reflex response to elevated blood pressure and partly be due to a possible vagal action (6).

The fact that phenelzine and digoxin when administered alone caused a significant decrease from control values in spontaneous heart rate, but failed to do so significantly when given together, may suggest a partial explanation for their potential toxicity in combination. A potential for increased automaticity in the heart muscle may have been created, with consequent precipitation of arrhythmias. Table I shows that the low incidence of arrhythmias occurred at the digoxin dose of 0.125 mg./kg. but was greatly increased when this dose was given in combination with 2.5 mg./kg. phenelzine. The transient hypotension, occurring immediately after phenelzine injection, may have been caused by a temporary decrease in peripheral sympathetic tone with a consequent decrease of peripheral vascular resistance (7). The subsequent rise in arterial blood pressure suggests sympathetic activity, perhaps due to increased catecholamine levels. In terms of dose–time relationships, spontaneous heart rate was significantly decreased for the dosages of 5 and 10 mg./kg. phenelzine whereas all doses did not significantly depress heart rate 20 min. after injection ($p = 0.6$). Arrhythmia frequency produced by phenelzine increased with increasing dose (Table I). However, when varying the intervals between injections of phenelzine and digoxin, it was observed that administration of these drugs 20 min. apart was as toxic as concurrent injection as seen by the incidence of arrhythmias. This incidence was decreased when both drugs were given 60 min. apart (Table I).

Pretreatment of rabbits with phenelzine for some days appears to modify the dose of digoxin needed to produce arrhythmias. An increase in the number of pretreatment days correspondingly caused a significant increase in the arrhythmogenic dose of digoxin (Table III). The dose levels of digoxin and the length of phenelzine pretreatment period seem to be important factors in modifying the toxicity of concurrent administration. These findings may be relevant to those occasional clinical situations in which depressed patients with advanced cardiac failure are given doses of digitalis concurrently with a mood elevator such as phenelzine.

Natural Coumarins VII: Isolation and Structure of a New Coumarin, Peuruthenicin, from *Peucedanum ruthenicum* M.B.

T. O. SOINE*▲, A. ZHELEVA†, M. M. MAHANDRU‡, P. ERHARDT*, and L. BUBEVA-IVANOVA†

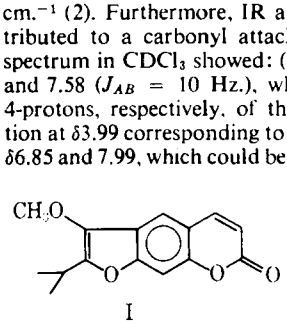
Abstract □ The roots of the Bulgarian umbellifer, *Peucedanum ruthenicum* M.B., yielded a novel naturally occurring coumarin, which was assigned the trivial name of peuruthenicin. It was identified as 6-carbomethoxy-7-hydroxycoumarin through both spectral (mass, NMR, IR, and UV) and chemical (degradative and synthetic) evidence. The latter consisted of alkaline hydrolysis to known umbelliferone-6-carboxylic acid (IV) and synthesis of peuruthenicin by methyl esterification of IV which had been obtained by chromate oxidation of marmesin.

Keyphrases □ Peuruthenicin (6-carbomethoxy-7-hydroxycoumarin)—isolation from *Peucedanum ruthenicum* M.B., structure determination □ Coumarins, natural—isolation of peuruthenicin (6-carbomethoxy-7-hydroxycoumarin) from *Peucedanum ruthenicum* M.B., structure determination □ 6-Carbomethoxy-7-hydroxycoumarin (peuruthenicin)—isolation from *Peucedanum ruthenicum* M.B., structure determination □ *Peucedanum ruthenicum* M.B.—isolation and structure identification of peuruthenicin (6-carbomethoxy-7-hydroxycoumarin)

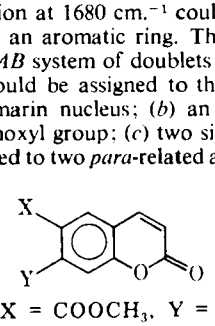
Previously (1), a phytochemical examination of *Peucedanum ruthenicum* M.B., a native Bulgarian umbellifer, showed the presence of the furanocoumarin peucedanin (I) in the roots and the flavonol glycoside rutin in the flowers. Further examination of the root extract provided a new compound, assigned the trivial name peuruthenicin, which has been structurally characterized.

DISCUSSION

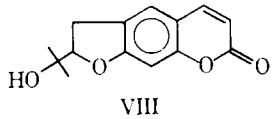
Peuruthenicin was obtained as cream-colored needles, m.p. 196–197°, for which the molecular ion derived from the mass spectrum and the supporting elemental analyses suggested the molecular formula $C_{11}H_8O_5$. Its UV spectrum suggested a possible coumarin chromophore. The IR spectrum was also compatible with a coumarin-type structure, since it showed a typical carbonyl absorption at 1740 cm.$^{-1}$ and the typical 3,4-double bond absorption at 1630 cm.$^{-1}$ (2). Furthermore, IR absorption at 1680 cm.$^{-1}$ could be attributed to a carbonyl attached to an aromatic ring. The NMR spectrum in $CDCl_3$ showed: (*a*) an *AB* system of doublets at δ6.25 and 7.58 (J_{AB} = 10 Hz.), which could be assigned to the 3- and 4-protons, respectively, of the coumarin nucleus; (*b*) an absorption at δ3.99 corresponding to a methoxyl group; (*c*) two singlets at δ6.85 and 7.99, which could be assigned to two *para*-related aromatic protons; and (*d*) a low field singlet at δ11.08, which could be assigned to chelated hydroxyl. The mass spectrum (Scheme I) indicated the facile loss of methanol from the molecular ion to provide a metastable ion (*m/e* 160.85), supported base peak at *m/e* 188. This behavior is well known for *ortho*-substituted methyl benzoates, particularly for the methyl salicylate type of moiety (3). Therefore, on the basis of the assembled spectral and analytical data, two possible structures could be entertained for peuruthenicin, namely II and III.



I



II: X = $COOCH_3$, Y = OH
III: X = OH, Y = $COOCH_3$
IV: X = COOH, Y = OH
V: X = H, Y = OH
VI: X = $COOCH_3$, Y = OCH_3
VII: X = COOH, Y = OCH_3



VIII

Alkaline hydrolysis of peuruthenicin gave a carboxylic acid, m.p. 258° dec., which failed to depress the melting point of an authentic sample of umbelliferone-6-carboxylic acid (IV) prepared by chromate oxidation of marmesin (VIII) as described previously (4). This acid also provided umbelliferone (V) when thermally decarboxylated to locate firmly the site of the phenolic hydroxyl group. Peuruthenicin, on treatment with diazomethane, provided a methyl ether, m.p. 168°, which was apparently identical to 6-carbomethoxy-7-methoxycoumarin (VI) (4).

The physical and chemical data strongly suggested that peuruthenicin was a novel naturally occurring coumarin with Structure II rather than III. This structure was validated by esterification of IV with methanolic sulfuric acid to give the methyl ester (II), which proved to be identical in all respects (UV, IR, NMR, and mass spectrum) with peuruthenicin.

Furthermore, VI was subjected to alkaline hydrolysis to provide VII, m.p. 237–239°, isomeric with II. Its NMR spectrum was distinctly different from that of II and showed two doublets at δ6.30 and 7.70 ($J_{3,4}$ = 10 Hz.) characteristic of the protons at the 3- and 4-positions, two *para*-related aromatic protons as singlets at δ6.91 and 8.23, and a methoxyl singlet at δ3.83.

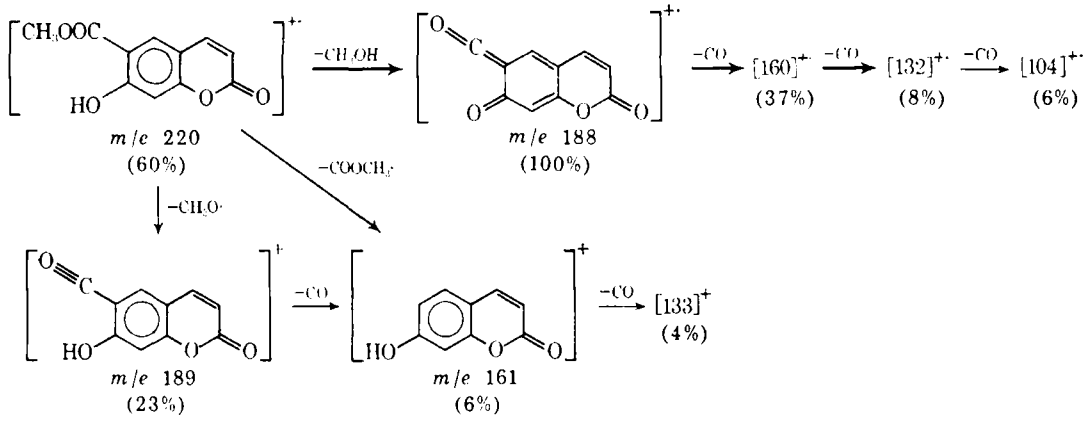
Although the present study was not concerned with the biosynthesis of peuruthenicin, it may well be that it is derived through a bio-oxidative transformation of peucedanin (I) or the corresponding ketone, oreoselone. Studies presently underway are exploring this possibility.

EXPERIMENTAL[1]

Isolation of Peuruthenicin—One kilogram of the roots of *P. ruthenicum* M.B., ground to a No. 20 powder, was extracted with methanol at room temperature using successively 10, 8, and 6 l. of solvent[2]. The extract was then filtered until clear and evaporated to give a gummy residue. This residue, when treated with 1 l. of water, gave a cloudy suspension which was extracted with ether (3 × 300

[1] Melting points were determined using a Reichert hot-stage apparatus and are uncorrected. Unless otherwise stated, IR spectra were measured in chloroform on a Perkin-Elmer 157G grating spectrophotometer, UV spectra were measured in 95% ethanol on a Cary 14 spectrophotometer, and 60- and 100-MHz. NMR spectra were measured in $CDCl_3$ (tetramethylsilane as internal standard) on HA 100 or R 12 NMR spectrometers. Only significant bands from these spectra are cited. Mass spectra (Scheme I) were determined using an AEI-MS 12 mass spectrometer as well as a Hitachi Perkin-Elmer RMU-6D instrument; in each case the source temperature was 150° and the ionizing voltage was 70 ev. Elemental analyses were obtained from M-H-W Laboratories, Garden City, Mich. Evaporation refers to evaporation under reduced pressure. TLC separations were carried out on plates coated with Merck kieselgel G and a solvent system consisting of benzene–toluene–ethyl acetate–formic acid (10:5:4:1). The drying agent for ethereal solutions was anhydrous sodium sulfate, and substances stated to be identical were thus established by comparison of melting points; IR, NMR, and mass spectra; and TLC behavior.

[2] That peuruthenicin was not an artifact formed by possible esterification of umbelliferone-6-carboxylic acid because of the methanol solvent was shown by extraction of the original plant material with several different solvents: benzene, petroleum ether, ether, chloroform, acetone, ethanol, and methanol. Each extract, without further treatment, was spotted on a TLC plate and developed with the benzene–toluene–ethyl acetate–formic acid solvent described. There was no doubt that peuruthenicin was the original coumarin in each extract since the R_f value of peuruthenicin is 0.60 and that of the acid is 0.4.



Scheme I—Mass spectral fragmentation of peuruthenicin. Heavy arrows indicate that the proposed fragmentation pathway is supported by the appearance of a metastable ion.

ml.). The combined ethereal extracts were dried and evaporated, and the residue was successively extracted with 200-ml. portions of boiling petroleum ether (b.p. 40–60°). The extracts, in sequence, were examined by TLC, which revealed that the first 10 extracts contained mainly peucedanin but that the following five extracts contained a 1:1 mixture of peucedanin and an unknown coumarin (*i.e.*, peuruthenicin). The latter extracts were combined, concentrated to about 100 ml., and held at 0° for 12 hr., at which time a crystalline precipitate of peucedanin had been deposited. This was removed by filtration and the filtrate was reduced to a volume of 50 ml. and then kept at 0° for an additional 15 days, during which time an amorphous precipitate formed and was collected by filtration. Recrystallization of this precipitate from methanol gave peuruthenicin (1 g.) as cream-colored needles, m.p. 196–197°; UV $\lambda_{max}^{C_2H_5OH}$ (log ϵ): 218 (4.30), 224 (4.28), 245 (4.46), 292 (3.99, shoulder), 3.03 (4.06), 323 (4.16), and 332 nm. (4.15); IR ν_{max}: 1740, 1680, and 1630 cm.$^{-1}$; mass spectrometry: *m/e* 220, 189, 188, 161, 160, 133, 132, and 104.

Anal.—Calc. for $C_{11}H_8O_3$: C, 60.0; H, 3.6; M (mass spectrum), 220. Found: C, 60.1; H, 3.7; M, 220.

Alkaline Hydrolysis of Peuruthenicin—Peuruthenicin (200 mg.) was dissolved in dioxane (40 ml.) and treated with aqueous 20% sodium hydroxide (80 ml.) under reflux for 30 min. The cooled mixture was then diluted to approximately 500 ml. with water, acidified with diluted sulfuric acid, and extracted with chloroform. The chloroform extract was dried and evaporated to yield 80 mg. of white crystals, m.p. 258° dec., identical to umbelliferone-6-carboxylic acid (IV) as determined by melting point, mixed melting point, and spectral comparison with the oxidative product of marmesin.

Decarboxylation of Alkaline Hydrolysis Product—The preceding acid (50 mg.) was heated at 265° for 2 hr. under a sublimation unit; the collected sublimate was shown to have a melting point of 230° and was identical to authentic umbelliferone.

Methylation of Alkaline Hydrolysis Product—The preceding acid (59 mg.) was dissolved in acetone (5 ml.) and treated for 20 min. with excess ethereal diazomethane generated from *N*-nitrosomethylurea in the usual way (5). Evaporation of the reaction mixture and crystallization of the residue from methanol gave white crystals (60 mg.), m.p. 167° [lit. (4) m.p. 168°]; IR ν_{max}: 1740–1720 and 1622 cm.$^{-1}$; NMR: δ6.30 and 7.66 (doublets, *AB* system, J_{AB} = 10 Hz., 3-H and 4-H), 8.00 (singlet, 5-H), 6.87 (singlet, 8-H), and 3.97 and 3.90 (singlets, $COOCH_3$ and OCH_3).

Umbelliferone-6-carboxylic Acid (IV)—Marmesin (1 g.) was oxidized, according to a published method (4), with 3% sulfuric acid and potassium dichromate to yield umbelliferone-6-carboxylic acid (300 mg.), m.p. 259°, identical with the product of alkaline hydrolysis of peuruthenicin as shown previously.

Synthesis of Peuruthenicin—Umbelliferone-6-carboxylic acid (90 mg.), methanol (5 ml.) and concentrated sulfuric acid (0.1 ml.) were heated together for 48 hr. under reflux. The resulting mixture was cooled, neutralized with 5% aqueous potassium hydroxide, and diluted with water until no further precipitate formed. The precipitate was collected and fractionated by preparative TLC to give cream-colored crystals (47 mg.), m.p. 196°, identical with the peuruthenicin obtained from natural sources.

7-Methoxycoumarin-6-carboxylic Acid (VII)—Peuruthenicin methyl ether (VI) (50 mg.) was dissolved in acetone (2 ml.) and treated with 5% aqueous potassium hydroxide (2 ml.) at room temperature for 7 hr. and then heated under reflux for 15 min. The cooled mixture, upon acidification with diluted sulfuric acid and dilution with water, yielded a precipitate which was collected and subjected to preparative TLC separation. The principal product was removed from the plates by scraping and, when extracted with methanol, yielded a white crystalline material (35 mg.), m.p. 237–239°; IR ν_{max}: 1730 and 1630 cm.$^{-1}$; NMR (in pyridine): δ6.30 and 7.70 (doublets, *AB* system, J_{AB} = 10 Hz., 3-H and 4-H), 8.23 (singlet, 5-H), 6.91 (singlet, 8-H), and 3.83 (singlet, OCH_3).

Lysergic Acid Analogs: 5-Phenylnicotinamides and Nipecotamides

FATIMA N. JOHNSON▲, S. P. BATTISTA, and DOROTHY REID

Abstract □ A series of 5-phenylnicotinamides and 1-methyl-5-phenylnipecotamides was synthesized as simplified lysergic acid analogs. Pharmacological evaluation showed that, in general, these compounds are CNS depressants. The nipecotamides, although more toxic, possess MED_{50} values comparable to those found for the analogous 9,10-dihydrolysergamides. The nicotinamides, however, showed greatly reduced activity when compared to the lysergamides.

Keyphrases □ Lysergic acid analogs—synthesis and pharmacological screening of 5-phenylnicotinamides and nipecotamides □ 5-Phenylnicotinamides—synthesis, screened for CNS activity □ Nipecotamides—synthesis, screened for CNS activity □ CNS activity—synthesis and screening of 5-phenylnicotinamides and nipecotamides

The potent and diverse pharmacological activity of ergot alkaloids has generated considerable interest in the synthesis of simplified analogs (1). The synthesis and pharmacological evaluation of some 5-phenylnicotinamides (I*a*–I*d*) and 1-methyl-5-phenylnipecotamides (II*a*–II*d*) are reported here. These compounds may be viewed as representing rings A and D of the ergolene system (III). It has been reported that the hallucinogenic activity of *N,N*-diethyllysergamide (LSD, IV*b*), may reside in that portion of the molecule that includes aromatic ring A and the nitrogen atom of ring D (2).

In connection with another study (3), numerous lysergamides (IV) and their 9,10-dihydro derivatives (V) were prepared. It became of interest to compare compounds of type II with the analogous 9,10-dihydrolysergamides (V). The choice of substituents R_1 and R_2 in Compounds I and II was dictated by the pharmacological results obtained previously (3).

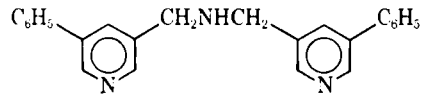
d: R_1 = H, R_2 = $C(CH_3)_3$



VI

RESULTS AND DISCUSSION

The common starting material for I and II was 5-phenylnicotinic acid, obtained from the hydrolysis of 5-phenylnicotinonitrile. The nitrile was prepared by the hydrogenolysis of 2-chloro-5-phenylnicotinonitrile over palladium-on-charcoal. When the literature procedure (4) was followed using palladium chloride, a substantial quantity of 3,3′-iminobis(methylene-5-phenylpyridine) (VI) was formed as a by-product. The desired product, 5-phenylnicotinonitrile, was obtained in unsatisfactory yield and was difficult to purify.

Compounds I*a*–I*d* (Table I) were obtained in good yield from 5-phenylnicotinic acid by a new, efficient amidation procedure (3), using the appropriate amine and phosphorus oxychloride in a 4–8-min. reaction period. Catalytic reduction of the methobromides of I*a*–I*d* gave the corresponding nipecotamides (II*a*–II*d*) (Table II). The synthesis of lysergamides (IV*a* and IV*b*) and 9,10-dihydrolysergamides (V*a*–V*d*) was described previously (3).

The general pharmacological activity of all compounds listed in Table III was measured in a modified Irwin mouse profile (5, 6), using male albino mice weighing 22 ± 2 g. Administration was made intravenously to two animals per dose at each of four or more dose levels. Following administration of a compound, observations were made on approximately 50 discrete components of behavior and appearance, response to external stimuli and neuromuscular integrity, and performance (6). The LD_{50} and MED_{50} (minimum effective dose) values were calculated using the moving average method of Thompson (7) and Weil (8).

[a] Hydrochlorides were administered intravenously in aqueous solution; free bases and maleates required polyethylene glycol 200 or dilute hydrochloric acid for solubilization.

nervous system (CNS) depression and, in particular, a decreased respiratory rate. A comparison of the results obtained for Va–Vd with the simplified analogs IIa–IId showed very similar pharmacological activity on the Irwin screen even though the absolute stereochemistry at chiral centers 3 and 5 of IIa–IId is unknown. The absolute stereochemistry at the analogous positions 8 and 10 of the 9,10-dihydrolysergamides has been established (9). However, IIa–IId were considerably more toxic than Va–Vd by a factor of at least 2–3.

The nicotinamides (Ia–Id), on the other hand, showed greatly reduced activity when compared to the lysergamides, but the presence of the pyridine ring makes for a less valid comparison with lysergamides.

EXPERIMENTAL[1]

5-Phenylnicotinonitrile—A mixture of 20.7 g. of 2-chloro-5-phenylnicotinonitrile (4), 120 ml. of dimethylformamide, 25.5 ml. of triethylamine, and 1.5 g. of 5% palladium-on-charcoal was hydrogenated at room temperature in a Parr apparatus at 3.9 kg./cm.^{2} for 1 hr. The mixture was filtered and the filtrate was concentrated to dryness. The residue was partitioned between dichloromethane and 50 ml. of 2 *N* NaOH. The organic extract was washed twice with 5% HCl and several times with water, dried over magnesium sulfate, and evaporated to dryness *in vacuo*. The residue was recrystallized from *n*-hexane, yielding 12.1 g. (69%) of 5-phenylnicotinonitrile, m.p. 72–74° [lit. (4) m.p. 75–76°].

When the literature procedure (4) was followed using palladium chloride as a catalyst, 3,3′-iminobis(methylene-5-phenylpyridine) (VI) was isolated from the 5% HCl wash of the organic extract described previously. The acidic solution was made basic with 2 *N* NaOH, and the liberated base was extracted into methylene chloride. The dried extract (magnesium sulfate) was evaporated to dryness under vacuum, and the viscous residue was recrystallized from ether and then from acetonitrile, m.p. 98–99°. The NMR ($CDCl_3$) spectrum revealed the presence of 10 aromatic protons at δ 7.47 (multiplet); six pyridine protons at δ 7.85 (multiplet), 8.52 (doublet), and 8.72 (doublet); four methylene protons at δ 3.91 (singlet); and a D_2O-exchangeable proton (NH) at δ 2.25. Mass spectrometric analysis revealed a molecular ion peak at *m/e* 351 (calculated molecular weight 351.4).

Anal.—Calc. for $C_{24}H_{21}N_3$: C, 82.02; H, 6.02; N, 11.96. Found: C, 82.09; H, 6.04; N, 12.00.

5-Phenylnicotinic Acid—A solution of 5.7 g. of 5-phenylnicotinonitrile in 120 ml. of concentrated hydrochloric acid was heated at reflux overnight. The reaction mixture was poured into ice and made basic by the addition of 2 *N* NaOH. The basic solution was then acidified with glacial acetic acid. The fine, white precipitate was filtered, washed repeatedly with water, and air dried. The crude product was recrystallized from about 800 ml. of ethanol, yielding 5.2 g. (82%) of 5-phenylnicotinic acid, m.p. 264–266° [lit. m.p. 260–263° (4) and 267–269° (10)].

5-Phenylnicotinamides (Ia–Id)—A solution of 0.048 mole of the appropriate amine in 20 ml. of chloroform and 1 ml. (0.011 mole) of phosphorus oxychloride were added concurrently to a refluxing slurry of 1.1 g. (0.005 mole) of 5-phenylnicotinic acid in 80 ml. of chloroform. After being kept at reflux for an additional 2 min., the solution was cooled to room temperature, washed with 50 ml. of 1 *M* NH_4OH and with water, dried over magnesium sulfate, and evaporated to dryness *in vacuo*. The residue was then crystallized from the appropriate solvent (Table I). Table I includes melting points and yields, and elemental analysis data are given in Table IV.

[1] Melting points were determined on a Mel-Temp apparatus and are uncorrected. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn. The structures of all novel compounds were confirmed by NMR spectroscopy. NMR spectra were obtained on a Varian A-60 instrument.

of Compounds Ia–Id were prepared by bubbling methyl bromide through a solution of the appropriate 5-phenylnicotinamide in ethyl acetate for 3–6 hr. The quaternary salts were not recrystallized prior to use. The methobromides separated very cleanly and in high yields from the reaction medium (Table I). They were filtered, washed thoroughly with cold ethyl acetate, air dried, and converted directly to the corresponding 1-methyl-5-phenylnipecotamide by the general procedure described here.

A solution of 1.5 g. of the methobromide in 75 ml. of ethanol containing 75 mg. of platinum oxide was hydrogenated at room temperature for 3–6 hr. at an initial pressure of 0.7 kg./cm.^{2}. The mixture was filtered and the filtrate was evaporated to dryness. The residue was dissolved in methylene chloride, washed with 2 *N* NaOH and water, dried over magnesium sulfate, and concentrated *in vacuo*. The residue was crystallized from the appropriate solvent or dissolved in ether, treated with anhydrous hydrogen chloride to yield the corresponding hydrochloride, and then recrystallized. The recrystallization solvents, melting points, and yields are listed in Table II, and elemental analysis data are given in Table IV.

Phase Separation of Cellulose Derivatives: Effects of Polymer Viscosity and Dielectric Constant of Nonsolvent

SALEH A. H. KHALIL

Abstract □ In systems containing either cellulose acetate butyrate or ethylcellulose, the intrinsic viscosity of the polymer in the appropriate solvent had no effect on the phase type separated. The latter was dependent on the dielectric constant of the nonsolvent added. Nonsolvents possessing relatively high dielectric constants produced a flocculate phase, while either a coacervate or gel was formed after the addition of nonsolvents of lower dielectric constant.

Keyphrases □ Cellulose derivatives (cellulose acetate butyrate and ethylcellulose)—effects of polymer viscosity and dielectric constant of nonsolvent on phase separation □ Phase separation, cellulose derivatives—effects of polymer viscosity and dielectric constant of nonsolvent □ Nonsolvents—effect on phase separation of cellulose acetate butyrate and ethylcellulose

Starting from a polymer solution in a suitable solvent, the addition of an appropriate concentration of a nonsolvent may produce phase separation. The type of phase separating may be a flocculate, gel, or coacervate (liquid–liquid phase separation). While factors such as pH and electrolytes were reported to govern the phase type in polyelectrolyte systems (1, 2), no studies have been made on nonelectrolytic polymers. Phase separation of cellulose derivatives is of special interest in pharmacy because of its application to microencapsulation of pharmaceuticals (3, 4). The present article reports the effect of various solvent–nonsolvent systems on the type of phase separating in two polymers: ethylcellulose and cellulose acetate butyrate. An attempt was made to study the effect of solvent–nonsolvent systems on the phase type as determined by the viscosity of the polymer (in the appropriate solvent) and the dielectric constant of the nonsolvent added.

EXPERIMENTAL

Materials—The ethylcellulose[1] used had a 48% ethoxyl content. Cellulose acetate butyrate[2], 171-2 grade, had a 17% butyryl content. All solvents and nonsolvents were analytical reagent grade or pure reagents.

Methods—*Determination of Phase Type*—To a solution of the polymer in the appropriate solvent, placed in glass-stoppered centrifuge tubes, the nonsolvent was gradually added until a visual phase change was noted. The stoppered tubes were equilibrated at 25 ± 0.1° for completion of phase separation (4–6 hr.). The separated phase was examined and classified as a flocculate, gel, or coacervate. The latter was found microscopically to exhibit coacervate droplets (10–25 μ in diameter) which rapidly coalesced to a clear oily layer upon standing. The gel phase showed no coacervate droplets and was highly viscous, frequently adhering to the walls of the container.

of Compounds Ia–Id were prepared by bubbling methyl bromide through a solution of the appropriate 5-phenylnicotinamide in ethyl acetate for 3–6 hr. The quaternary salts were not recrystallized prior to use. The methobromides separated very cleanly and in high yields from the reaction medium (Table I). They were filtered, washed thoroughly with cold ethyl acetate, air dried, and converted directly to the corresponding 1-methyl-5-phenylnipecotamide by the general procedure described here.

A solution of 1.5 g. of the methobromide in 75 ml. of ethanol containing 75 mg. of platinum oxide was hydrogenated at room temperature for 3–6 hr. at an initial pressure of 0.7 kg./cm.^{2}. The mixture was filtered and the filtrate was evaporated to dryness. The residue was dissolved in methylene chloride, washed with 2 *N* NaOH and water, dried over magnesium sulfate, and concentrated *in vacuo*. The residue was crystallized from the appropriate solvent or dissolved in ether, treated with anhydrous hydrogen chloride to yield the corresponding hydrochloride, and then recrystallized. The recrystallization solvents, melting points, and yields are listed in Table II, and elemental analysis data are given in Table IV.

Phase Separation of Cellulose Derivatives: Effects of Polymer Viscosity and Dielectric Constant of Nonsolvent

SALEH A. H. KHALIL

Abstract □ In systems containing either cellulose acetate butyrate or ethylcellulose, the intrinsic viscosity of the polymer in the appropriate solvent had no effect on the phase type separated. The latter was dependent on the dielectric constant of the nonsolvent added. Nonsolvents possessing relatively high dielectric constants produced a flocculate phase, while either a coacervate or gel was formed after the addition of nonsolvents of lower dielectric constant.

Keyphrases □ Cellulose derivatives (cellulose acetate butyrate and ethylcellulose)—effects of polymer viscosity and dielectric constant of nonsolvent on phase separation □ Phase separation, cellulose derivatives—effects of polymer viscosity and dielectric constant of nonsolvent □ Nonsolvents—effect on phase separation of cellulose acetate butyrate and ethylcellulose

Starting from a polymer solution in a suitable solvent, the addition of an appropriate concentration of a nonsolvent may produce phase separation. The type of phase separating may be a flocculate, gel, or coacervate (liquid–liquid phase separation). While factors such as pH and electrolytes were reported to govern the phase type in polyelectrolyte systems (1, 2), no studies have been made on nonelectrolytic polymers. Phase separation of cellulose derivatives is of special interest in pharmacy because of its application to microencapsulation of pharmaceuticals (3, 4). The present article reports the effect of various solvent–nonsolvent systems on the type of phase separating in two polymers: ethylcellulose and cellulose acetate butyrate. An attempt was made to study the effect of solvent–nonsolvent systems on the phase type as determined by the viscosity of the polymer (in the appropriate solvent) and the dielectric constant of the nonsolvent added.

EXPERIMENTAL

Materials—The ethylcellulose[1] used had a 48% ethoxyl content. Cellulose acetate butyrate[2], 171-2 grade, had a 17% butyryl content. All solvents and nonsolvents were analytical reagent grade or pure reagents.

Methods—*Determination of Phase Type*—To a solution of the polymer in the appropriate solvent, placed in glass-stoppered centrifuge tubes, the nonsolvent was gradually added until a visual phase change was noted. The stoppered tubes were equilibrated at 25 ± 0.1° for completion of phase separation (4–6 hr.). The separated phase was examined and classified as a flocculate, gel, or coacervate. The latter was found microscopically to exhibit coacervate droplets (10–25 μ in diameter) which rapidly coalesced to a clear oily layer upon standing. The gel phase showed no coacervate droplets and was highly viscous, frequently adhering to the walls of the container.

Table I—Effect of Solvent–Nonsolvent Systems on the Phase Type Separated in 5% (w/v) Cellulose Acetate Butyrate[a]

Nonsolvent	Dielectric[b] Constant (at 20°)	Solvent[c] Acetone (0.37)	Cyclohexanone (0.55)	Methylene Chloride (0.49)
Water	80.4	F	—	—
Methanol	33.7	F	F	F
Ethanol	25.7	F	F	F
n-Butanol	17.8	F	F	F
Hexane	1.9	C	C	C
Petroleum ether (b.p. 40–60°)	1.9	G	G	G

[a] Phase types are: F = flocculate, C = coacervate, and G = gel. [b] Values obtained from "Handbook of Chemistry and Physics," 50th ed., R. C. Weast, Ed., Chemical Rubber Co., Cleveland, Ohio, 1969, pp. E61–E63. [c] The figures in parentheses are the determined intrinsic viscosities of the polymer solution in the appropriate solvent. Values were determined at 25 ± 0.1°.

Determination of Intrinsic Viscosity—The intrinsic viscosity of the polymer in the appropriate solvent was determined at 25 ± 0.1° using a viscometer[3]. The polymer concentration range was 0.1–0.6 g./100 ml.

RESULTS AND DISCUSSION

Tables I and II show the various phases that separated upon the addition of several nonsolvents to 5% w/v solutions of the polymer in different solvents. The phase types produced were independent of the initial polymer concentration in the range used (1–5% w/v). The slight difference observed in the intrinsic viscosities of the polymers (and possibly a change in the molecular configuration) had no effect on the phase type separated. Of the six nonsolvents tested, only two showed a different effect on phase type while four produced the same phase (flocculate). Thus, it was not the nonsolvent *per se* that produced the effect but some other inherent property. It is suggested that the dielectric constant of the nonsolvent has a decisive role in determining the phase type. Nonsolvents possessing relatively high dielectric constants (the first four nonsolvents in Table I) yielded the same phase (flocculate). However, hexane and petroleum ether produced either a coacervate or gel phase, since these nonsolvents have a much lower dielectric constant (about 1.9). These observations were the same in both polymer systems.

In general, the reported results suggest that care should be taken in selecting the nonsolvent during microencapsulation of drugs by phase separation of polymeric nonelectrolytes. A previous report (5) showed that the *in vitro* release of ferrous sulfate from cellulose-coated formulations, prepared by phase separation, was dependent on the phase type separated.

[3] Ostwald type.

Table II—Effect of Solvent–Nonsolvent System on the Phase Type Separated in 5% (w/v) Ethylcellulose[a]

Nonsolvent	Dielectric[b] Constant (at 20°)	Solvent[c] Acetone (0.41)	Ethanol (0.53)	Toluene (0.62)
Water	80.4	F	F	—
Hexane	1.9	C	C	C
Petroleum ether (b.p. 40–60°)	1.9	G	G	G

[a] Phase types are: F = flocculate, C = coacervate, and G = gel. [b] Values obtained from "Handbook of Chemistry and Physics," 50th ed., R.C. Weast, Ed., Chemical Rubber Co., Cleveland, Ohio, 1969, pp. E61–E63. [c] The figures in parentheses are the determined intrinsic viscosities of the polymer solution in the appropriate solvent. Values were determined at 25 ± 0.1°.

SUMMARY

1. Three phase types are produced in the phase separation of systems containing either cellulose acetate butyrate or ethylcellulose. These phase types are flocculate, gel, and coacervate.

2. The intrinsic viscosity of the polymer, in the appropriate solvent, had no effect on the phase type separated.

3. The dielectric constant of the nonsolvent added appears to control the phase type. A flocculate phase was formed upon the addition of nonsolvents possessing relatively high dielectric constants. Either a coacervate or gel phase was produced with nonsolvents having a much lower dielectric constant.

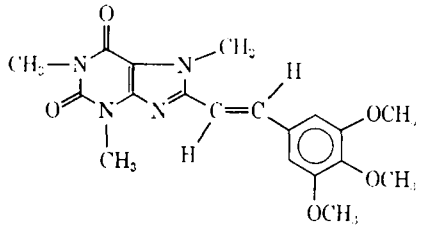
Photo-Induced Isomerization of 8-(3,4,5-Trimethoxystyryl)caffeine as Possible Route of Drug Decomposition

JOSE PHILIP▲ and DALE H. SZULCZEWSKI

Abstract □ *trans*-8-(3,4,5-Trimethoxystyryl)caffeine, dissolved in methanol or chloroform, rapidly isomerizes to an equilibrium mixture of *trans*-*cis*-isomers in the presence of visible light. Geometric isomerization was established by catalytic hydrogenation of both reactant and product to yield 8-(3,4,5-trimethoxyphenethyl)-caffeine.

Keyphrases □ 8-(3,4,5-Trimethoxystyryl)caffeine—decomposition by photoisomerization □ Caffeine derivatives—decomposition of 8-(3,4,5-trimethoxystyryl)caffeine by photoisomerization □ Photoisomerization—decomposition of 8-(3,4,5-trimethoxystyryl)caffeine

trans-8-(3,4,5-Trimethoxystyryl)caffeine (I) is a caffeine derivative being evaluated for use as a cerebral stimulant. Past work (1–4) indicated that photoisomerization about an ethylenic double bond is a general reaction. Since this investigational drug is a styryl derivative containing an ethylenic moiety, it is possible that photo-induced isomerization could occur and cause subsequent developmental problems. The effect of visible light on the drug was investigated to obtain information in this area.



I

RESULTS AND DISCUSSION

Dilute solutions (c 0.00189%) of I were prepared and exposed to visible light for varying periods. Sequential UV spectra (Fig. 1) of such solutions changed very rapidly during initial exposure (0.5 hr.), after which they became essentially constant. Almost the same behavior was noted with either chloroform or methanol as the solvent. UV spectra of solutions stored at the same temperature in the dark did not change.

To determine the nature of the process responsible for the observed changes, reaction products were isolated for identification. Preparative TLC was without value in this regard since the products and reactant had the same R_f value in available chromatographic systems.

A quantity of crystalline reaction product (II) was obtained by exposing a solution of I in chloroform to the point of spectral redundancy. Its molecular weight, determined by mass spectroscopy and elemental analysis, was identical to that of the drug, thereby indicating that the drug and product are isomers.

Confirmation that this isomerization involved geometric conversion was obtained by saturating the olefinic double bond presumed to be present in the reaction product to obtain 8-(3,4,5-trimethoxyphenethyl)caffeine (III), a compound previously obtained[1] from I by the same hydrogenation procedure (Scheme I).

[1] D. Schweiss, Parke, Davis & Co., Ann Arbor, MI 48105, personal communication.

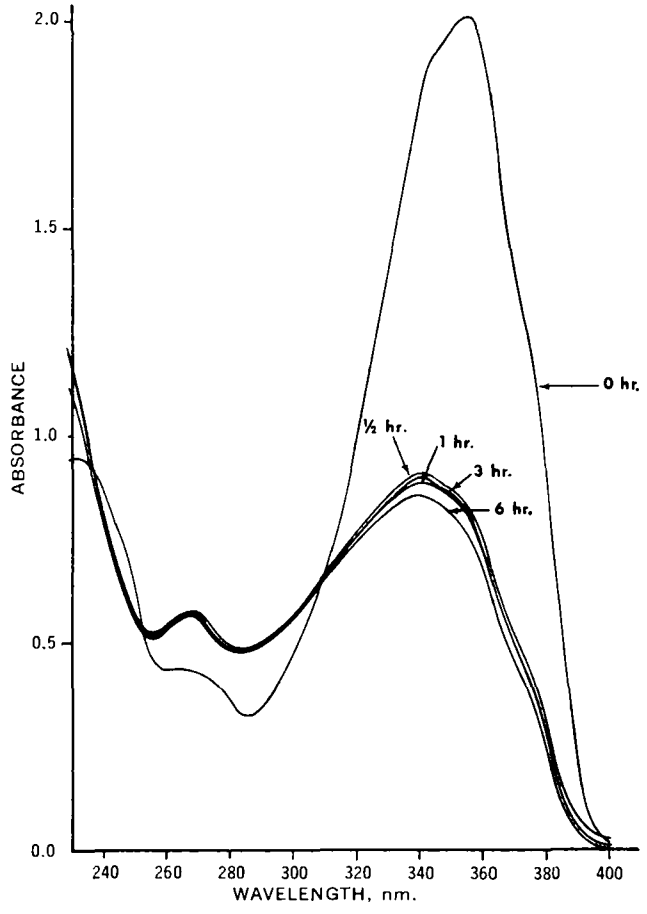


Figure 1– *Sequential UV spectra of I in methanol kept in the light cabinet. Exposure time (hours) is noted.*

Analysis of the UV spectra of a methanolic solution of I exposed to light to spectral redundancy indicated that an equilibrium mixture (80% *cis*–20% *trans*) is eventually formed. This finding was substantiated by similarly exposing the *cis*-isomer and noting that its spectrum changed to that corresponding to an 84:16 *cis*–*trans* mixture.

EXPERIMENTAL[2]

Initial Observations—One hundred milliliters of a 0.00189% solution of I in methanol was prepared and placed in a 100-ml. volumetric flask. The flask was placed in the light cabinet, and aliquots were removed periodically for UV determination.

Preparation and Identification of Reaction Product—One gram of I was dissolved in 3 l. of chloroform and kept in a light cabinet at 45°. The reaction was followed by obtaining repetitive UV spectra: when they ceased to change, the chloroform was removed and the residue was recrystallized twice from chloroform–methanol and finally from acetonitrile, m.p. 187–189° (I, m.p. 245–247°).

[2] The equipment was as follows: Cary model 14 S/W, steel light cabinet equipped with several 100-w. incandescent bulbs, Perkin-Elmer model 457 grating IR spectrophotometer, Varian A-60 NMR spectrometer; and Finnigan model 1015 quadrupole mass spectrometer.

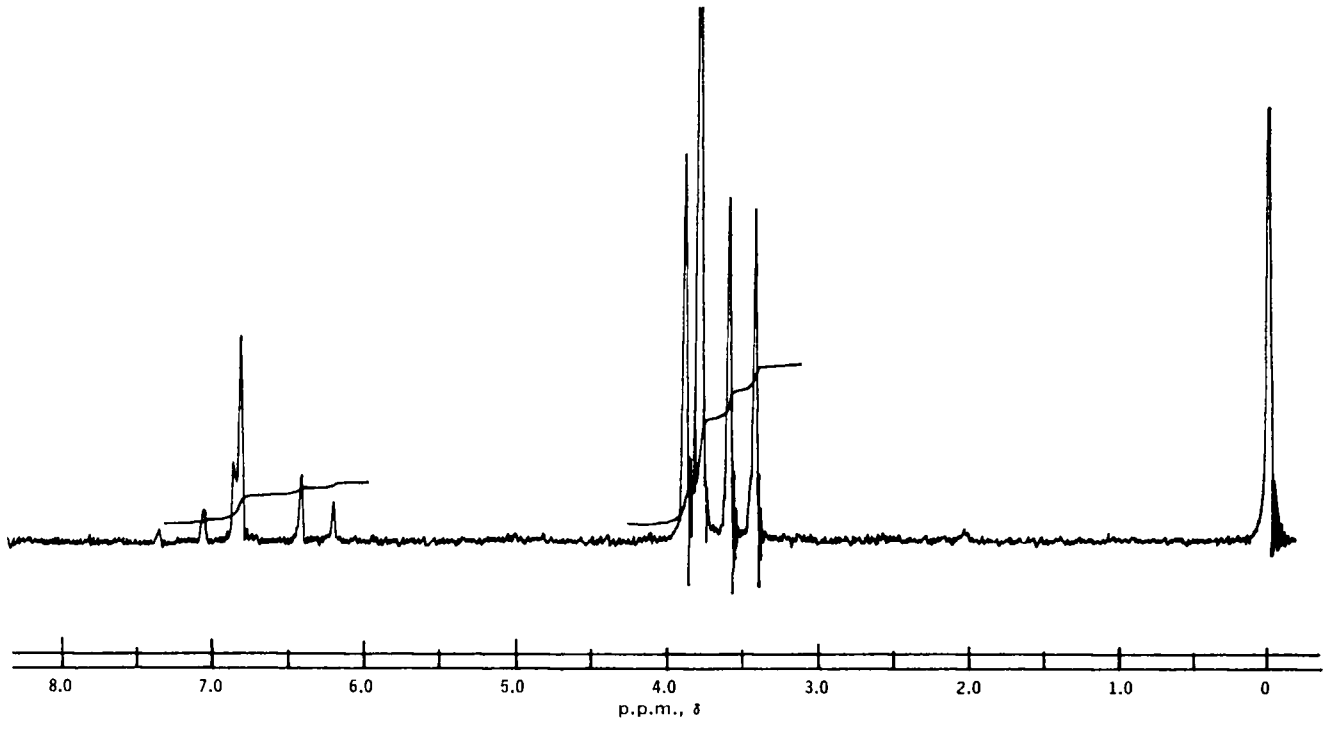

Figure 2—*NMR spectrum of II in $CDCl_3$.*

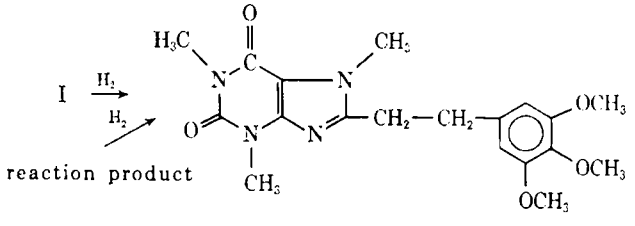
Anal.—Calc. for $C_{19}H_{22}N_4O_5$: C, 59.10; H, 5.70; N, 14.50. Found: C, 59.16; H, 5.65; N, 14.59.

The UV spectrum[3] showed $\lambda_{max}^{methanol}$ 327 and 268 nm. (ϵ 1.30 × 10^4 and 1.084 × 10^4, respectively).

The NMR spectrum (Fig. 2) showed a singlet at 3.75 (9H) p.p.m., assigned to the methoxy methyl protons; singlets at 3.41 (3H), 3.58 (3H), and 3.87 (3H) p.p.m., assigned to the three *N*-methyl group protons; and doublets centered at 6.95 (1H) and 6.31 (1H) p.p.m. (J = 13 Hz.), assigned to the vinyl protons[4].

Reduction of I and II Approximately 0.6 g. compound was suspended in 75 ml. of acetic acid in a Parr machine. Then 0.1 g. of 20% palladium-on-carbon was added. The hydrogen pressure was kept at 50 p.s.i. and the solution was shaken for 5 min. Then the solution was filtered and the solvent was evaporated. The residue was then suspended in 50 ml. of water, and the solution was made neutral by adding ammonium hydroxide. The precipitate was filtered and then recrystallized from ethanol. The reduction



III

Scheme I

products of I (A) and II (B) had identical properties and were identified as 8-(3,4,5-trimethoxyphenethyl)caffeine (III).

Properties of A and B are as follows:

	A	B
Melting point	141–143°	141–143°
UV (methanol) $\epsilon\lambda^{276}$	1.20×10^4	1.23×10^4
IR	identical spectra	

Anal.—Calc. for $C_{19}H_{24}N_4O_5$: C, 58.75; H, 6.23; N, 14.42. Found: (A) C, 58.35; H, 6.54; N, 14.18. (B) C, 58.24; H, 6.17; N, 14.32.

Determination of the Composition of Spent Reaction—The composition of the spent reaction was established by analysis of the UV spectrum obtained when the methanolic solution of the *trans*-isomer was exposed to spectral redundancy. The absorptivity (a) (1%, 1 cm.) at λ342 of the mixture was found to be 450, which corresponds to an 80:20 mixture (*cis-trans*), *i.e.*:

$$\%\ trans = \frac{a\,(1\%,\ 1\ cm.)_{obs} - 318}{659} \qquad \text{(Eq. 1)}$$

where 318 = $a\,(1\%,\ 1\ cm.)_{\lambda342}^{cis}$ and 659 = $\Delta a(1\%,\ 1\ cm.)_{\lambda342} = a(1\%,\ 1\ cm.)_{\lambda342}^{trans} - a(1\%,\ 1\ cm.)_{\lambda342}^{cis}$.

When a 0.002% solution of the *cis*-isomer was similarly exposed to a spectral redundancy, the a(1%, 1 cm.) at λ342 was found to be 425. This, in turn, indicates the composition of the equilibrium mixture to be 84:16, in reasonable agreement with that determined by starting with the *trans*-isomer.

CONCLUSION

Exposure of dilute solutions of *trans*-8-(3,4,5-trimethoxystyryl)-caffeine in methanol or chloroform to visible light results in rapid *trans-cis* isomerization; *trans-cis* isomerization proceeds with the ultimate formation of an equilibrium mixture containing approximately 82% *cis*-18% *trans*.

(2) D. Schulte-Frahlinde, H. Blume, and H. Güsten, *J. Phys. Chem.*, **66**, 2486(1962).

[3] The UV parameters are in accord with previous observations (5–7) made on UV properties of *cis*- and *trans*-stilbenes in that the *trans*-isomer has the greater molar absorptivity and a maximum at longer wavelength than the *cis*-isomer (355 and 327 nm., respectively). Also, the molar absorptivity at 268 nm. is greater for the *cis*-isomer than for the *trans*-isomer, which is in accord with expectation.

[4] The coupling constant in I (15 Hz.) is less than normal for a vinyl hydrogen but is within the limit of 5–30 Hz. In I (*trans*), there is conjugation from the benzene ring through the vinyl system and then through the purine moiety. This reduces bond order between the carbons and thus the value of J. In II (*cis*), steric hindrance prevents both the benzene ring and purine ring from being simultaneously coplanar with the ethylene system and thus should markedly reduce conjugation. This, in turn, raises bond order in the ethylene and thereby increases J. The overall result is to bring the values of J for the *cis*- and *trans*-isomers closer together than normal.

Application of Conformation-Dependent Antibodies: Enhancement of Enzyme Activity of L-Glutamate Dehydrogenase [L-Glutamate NAD(P) Oxidoreductase (Deaminating) EC 1.4.1.3]

BRIAN J. JOHNSON▲ and DAVID H. KEMPNER

Abstract □ By using a nonprecipitating system, it was found that the enzyme activity of L-glutamate dehydrogenase [L-glutamate NAD(P) oxidoreductase (deaminating) EC 1.4.1.3] (I) is enhanced by the addition of small amounts of anti-I-serum. It is suggested that this enhancement is due to the ability of conformation-dependent antibodies to maintain L-glutamate dehydrogenase in a more favorable conformation and thereby influence the rate of conversion of sodium α-ketoglutarate to sodium glutamate.

Keyphrases □ L-Glutamate dehydrogenase [L-glutamate NAD(P) oxidoreductase (deaminating) EC 1.4.1.3]—immunochemical properties □ Antibodies, L-glutamate dehydrogenase [L-glutamate NAD(P) oxidoreductase (deaminating) EC 1.4.1.3] produced—specificity □ Enzyme activity—enhancement of L-glutamate dehydrogenase

It has been shown that the enzymatic activity of L-glutamate dehydrogenase [L-glutamate NAD(P) oxidoreductase (deaminating) EC 1.4.1.3] (I) is dependent upon the conformation of the molecule (1–7). Immunochemical studies with this enzyme, using a precipitating system, showed that rabbit antibodies possess specificities not only for the primary structure but also for the conformation of the antigen (8, 9).

The effect of conformation-dependent antibodies on their homologous antigens is of interest. With respect to I, it was reported (10) that normal rabbit serum activates purified preparations of human and bovine I by about 40% in reactions using α-ketoglutarate and glutamate as substrates. It was also reported (10) that anti-I-serum enhanced the enzyme activity of I using α-ketoglutarate as substrate. It was, therefore, of interest to extend the reported investigations by studying the effect produced by these conformation-dependent antibodies over a period of time on the enzyme activity.

EXPERIMENTAL

Nicotinamide adenine dinucleotide reduced (NADH), α-ketoglutarate, and bovine liver L-glutamate dehydrogenase [L-glutamate NAD(P) oxidoreductase (deaminating) EC 1.4.1.3] were purchased[1]; the latter material was obtained as a crystalline suspension in ammonium sulfate. Compound I was prepared for use by dialyzing against a standard buffer solution (0.03 *M* Na_2HPO_4–0.01 *M* NaH_2PO_4–1×10^{-3} *M* disodium edetate), pH 7.4.

Immunochemistry—Ten rabbits were treated at weekly intervals with 5 mg. of I. The first 3 weeks they were injected intradermally, using complete Freunds adjuvant as the suspension medium. The rabbits were bled the following week using the standard heart puncture technique. Thereafter, the rabbits were bled and immunized on alternate weeks. Incremental amounts of I were added to 1-ml. aliquots of the antiserum obtained from each rabbit. These mixtures were incubated at 37° for 1 hr. and then stored at 4° for 48 hr. Each rabbit antiserum gave a precipitin reaction, and the amount of protein precipitated was quantitated by analysis for nitrogen (Kjeldahl).

Each rabbit antiserum gave a precipitin reaction, and the amount of protein precipitated was quantitated by analysis for nitrogen (Kjeldahl).

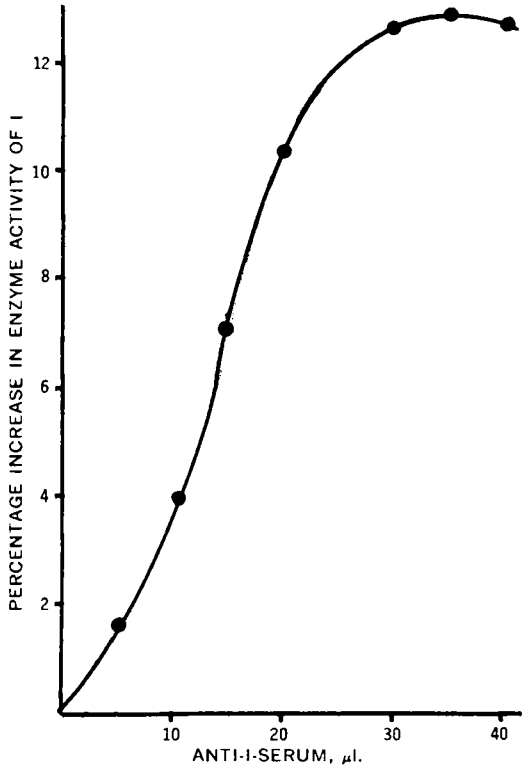

Figure 1—*Percentage increase in enzyme activity of I in the presence of anti-I-serum.*

[1] Sigma Chemical Co.

Table I—Percentage Increases in Enzyme Activity of I for Each Animal Tabulated against Length of Time from Initial Immunization

Animal Number	Time from Initial Immunization, Weeks						
	4	6	8	10	12	14	16
1	0	0	3	11	8.5	10	14
2	0	6.8	5.2	8	4.5	6.5	10.5
3	7	4	2.6	4.2	9	6.5	9.8
4	—	6	14	7.5	11.7	14.5	17.5
5	4.5	7	7.5	7	13	14.5	31
6	2.5	18	23	17.5	7	6	0
7	7	6	14	7	15	6	5
8	6.5	12	23	12	15	13	3
9	5	10	21	11	7	14.5	10
10	3.5	9	9.5	12	10	2	7

Preimmunized serum was treated with I and run under identical conditions to those described for the antiserum. No precipitin reactions were observed.

Enzyme Assays—In a typical assay the concentration of I in a solution was determined by measurement of the absorbance at 280 nm., where $E_{max} = 1.0 \times 10^6\ M^{-1}\ cm.^{-1}$ for a molecular weight of 1.0×10^6. To 3 ml. of phosphate buffer (0.03 *M* Na_2HPO_4–0.01 *M* NaH_2PO_4–1×10^{-3} disodium edetate), pH 7.4, 1.0×10^{-4} *M* NADH, 2×10^{-3} *M* sodium α-ketoglutarate, and 1×10^{-1} *M* NH_4Cl was added 5 μl. of a solution of I (0.5 mg./ml.). The enzyme activity at 23° was obtained by measuring the decrease in the absorbance of the solution at 340 nm. The determination of the enzyme activity of I in the presence of antibody obtained from each rabbit and for each bleeding was performed in exactly the same manner as that already described. However, the solution containing I and 20 μl. of the specified antiserum were incubated at 37° for 1 hr. and then cooled to 23° before proceeding with the assay. Controls using I with and without preimmunized serum were run simultaneously with the conditions identical to those described for the antiserum enzyme assays.

RESULTS

Antiserum from each rabbit and from each bleeding gave a positive precipitin reaction; however, controls using nonimmunized serum produced no precipitation. Initially, it was necessary to ascertain the optimum amount of antibody required to produce the largest change in enzyme activity without precipitation occurring. For this purpose, incremental amounts of antiserum were added to the standard aliquot of I and the increase in activity was ascertained. Typically, it was found that a maximum increase in enzyme activity occurred in the presence of 35 μl. of antiserum (Fig. 1). However, a small amount of precipitate was obtained under these conditions. An investigation to ascertain the largest amount of antiserum permissible before precipitation occurred was conducted. From these results (Fig. 2), it was evident that the largest amount of antiserum that could be used and still maintain solution was 20 μl. By using these conditions, it was found that practically every antiserum tested produced an enhancement of the activity of the enzyme I as measured by the increase in the rate of conversion of sodium α-ketoglutarate to sodium glutamate (Table I). No enhancement of enzyme activity was obtained with nonimmunized serum.

DISCUSSION

Unlike the previous report (10), no enhancement of the enzyme activity of I was found in the presence of nonimmunized serum. However, by using the nonprecipitating system described, the reported enhancement of the enzyme activity of I by use of small amounts of rabbit anti-I-serum was corroborated. The rationale was that within the heterogeneous mixture of antibodies formed to the antigenic challenge of I, a definite population is conformation dependent. It is suggested that these antibodies are capable of maintaining I in a more favorable conformation to influence the rate of conversion of sodium α-ketoglutarate to sodium glutamate. However, it is evident from Table I that the concentration of the conformation-dependent antibodies varies with the length of time of immunization. A similar observation has been made of the concentrations of various antibody populations produced by rabbits upon continuous immunization with type III and type VIII pneumococci (11). It also has to be concluded that the antigenic determinants of I must be clearly different from those that constitute the enzyme active site.

Biological and Phytochemical Evaluation of Plants XIII: Preliminary Estimation of Analgesic Activity of Rhazinilam, a Novel Alkaloid Isolated from *Aspidosperma quebracho-blanco* Leaves

P. S. BENOIT▲, G. ANGRY, R. L. LYON, H. H. S. FONG, and N. R. FARNSWORTH

Abstract □ A novel alkaloid, rhazinilam, from *Aspidosperma quebracho-blanco* leaves exhibited mild analgesic activity in mice.

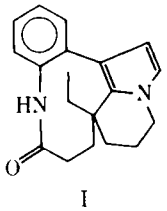
Keyphrases □ Rhazinilam—alkaloid from *Aspidosperma quebracho-blanco* tested for analgesic activity in mice □ *Aspidosperma quebracho-blanco* leaves—isolated alkaloid rhazinilam tested for analgesic activity in mice □ Analgesic activity—rhazinilam screened in mice

Previously, the isolation and structure elucidation of the lactam alkaloid, rhazinilam (I), from the leaves of *Aspidosperma quebracho-blanco* was reported[1] (2, 3). Since a literature search did not reveal any pharmacological studies on rhazinilam, it was subjected to pharmacological evaluations and was found to exhibit mild analgesic activity in mice.

EXPERIMENTAL

The procedure utilized for the evaluation of analgesic activity was essentially that described by Koster *et al.* (4), with some modifications of Taber *et al.* (5). In the screening procedure, groups of three male CD-1 mice[2], weighing 20–25 g., which had been previously starved for 18–24 hr., were injected with 10 ml./kg. i.p. of a 0.6% aqueous acetic acid solution and then placed into observation jars. The drug or the vehicle was administered by gavage 30 min. prior to administration of the acetic acid solution. Five minutes following the acid injection, the total number of writhes exhibited by the three mice during 10 min. was counted. Each day, one control (vehicle treated) and several test groups of mice were studied. At a dose of 10 mg./kg., rhazinilam reduced writhing by 15% when compared to controls.

When it had been determined by preliminary experimentation that rhazinilam possessed antiwrithing activity at a relatively low dosage level, the ED_{50} values by various routes of administration were determined. Five groups of five mice each were studied. One group was treated with the vehicle, and the other four groups received graded doses of the drug. The number of writhes exhibited in 10 min. by the drug-treated group was calculated as a percent of the number of writhes exhibited by the control group. From these data, a dose–response curve was plotted on double-cycle, semilog paper with percent response as the ordinate and log dose as the abscissa. The ED_{50} value was read directly from the curve and then determined by a programmed computer method. For comparison, similar experiments were conducted with aspirin.



I

Table I—ED_{50} Values for Aspirin and Rhazinilam Administered by Different Routes

Drug	Route	ED_{50}, mg./kg.	Number of ED_{50} Values
Aspirin	Oral	112.4	5
Aspirin	Subcutaneous	37.0	1
Aspirin	Intraperitoneal	15.0	1
Rhazinilam	Oral	313.0	1
Rhazinilam	Oral	310.0	1
Rhazinilam	Subcutaneous	140.0	1
Rhazinilam	Intraperitoneal	46.0	1

RESULTS

The results of these studies are presented in Table I. Aspirin produced ED_{50} values of 112.4 mg./kg. p.o., 37.0 mg./kg. s.c., and 15.0 mg./kg. i.p. Rhazinilam produced ED_{50} values of 311.5 mg./kg. p.o., 140 mg./kg. s.c., and 46.0 mg./kg. i.p.

From these preliminary data, it appears that rhazinilam possesses mild analgesic activity in the acetic acid writhing test. Lack of a supply of rhazinilam, which is a minor alkaloid of *Aspidosperma quebracho-blanco* leaves, precluded further study.

Influence of Polysorbate 20 and Sodium Cholate on Uptake of *p*-Hydroxybenzoates by the Frog, *Rana pipiens*

C. W. WHITWORTH[▲] and H. W. JUN

Abstract □ The frog, *Rana pipiens*, was found to take up certain *p*-hydroxybenzoates when partially immersed in a solution of these substances. The order of decreasing uptake rates for the benzoates was butyl, propyl, ethyl, and methyl. The presence of a nonionic surfactant, polysorbate 20, reversed the order; however, a biological surfactant, sodium cholate, appeared to increase the rate of uptake of the parabens. The process was first order.

Keyphrases □ Polysorbate 20—influence on uptake of *p*-hydroxybenzoates by frog □ Sodium cholate—influence on uptake of *p*-hydroxybenzoates by frog □ *p*-Hydroxybenzoates—influence of polysorbate 20 and sodium cholate on uptake by frog □ Surfactants—influence of polysorbate 20 and sodium cholate on uptake of *p*-hydroxybenzoates by frog

The purpose of this study was to screen a number of drugs for uptake by the frog and, for those found, to determine the effect of two types of surfactants on the process. The screened drugs included the weak bases procaine, acetanilid, and 4-aminoantipyrine and the weak acids phenobarbital, sulfacetamide, and four benzoic acid esters. Of these drugs, only the benzoates were taken up to any detectable degree. Previously, salicylic acid was shown (1) to be taken up readily, mainly in the undissociated form, from solution by the frog, thus conforming to the proposed pH–partition theory of passive absorption of some drugs as offered by Shore *et al.* (2). This study supports the evidence of this theory since the frog took up the higher molecular weight benzoates which had greater oil solubility more readily than the ones with lower molecular weight.

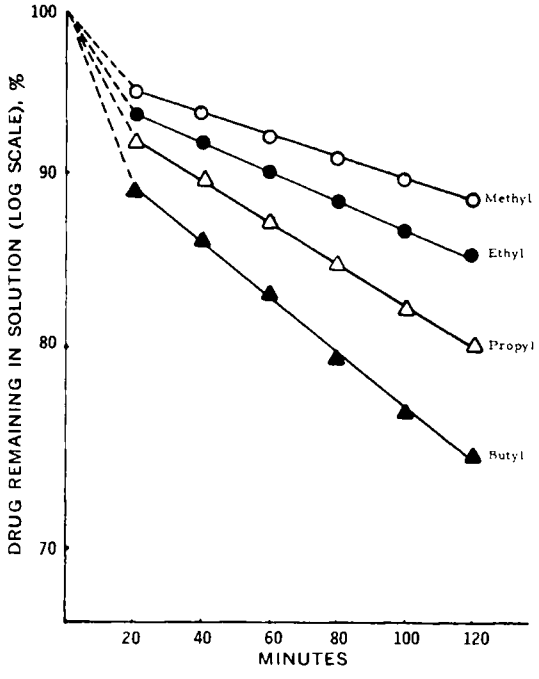

Figure 1—*Plot of average percent of parabens remaining in solution over 2 hr. when five frogs were each placed in 500 ml. of aqueous drug solution. Each solution was initially 5.0 × 10⁻⁵ M in the paraben.*

Table I Rate Constants (min.⁻¹ × 10⁴)

Additive	Paraben			
	Methyl	Ethyl	Propyl	Butyl
None (control)	1.53	1.92	2.84	3.78
Polysorbate 20 (0.5%)	1.74	1.42	0.747	0.625
Polysorbate 20 (1.0%)	1.42	1.21	0.671	0.499
Sodium cholate (5.0×10^{-5} *M*)	1.64	2.06	3.18	4.48

EXPERIMENTAL

The technique employed in this study was used previously (1, 3, 4). Five frogs, 30–35 g. each, were used in the determinations. Each frog was placed in 500 ml. of drug solution contained in a 2-l. beaker which permitted immersion to the neck. At 20-min. intervals, about 5 ml. of drug solution was withdrawn and assayed for drug content and returned to the container to maintain uniform volume. The solutions were buffered to pH 4.0 with hydrochloric acid in 0.05 *M* glycine. This pH is well tolerated by frogs and was used in previous studies (1, 3, 4) to minimize the effect of ionization changes

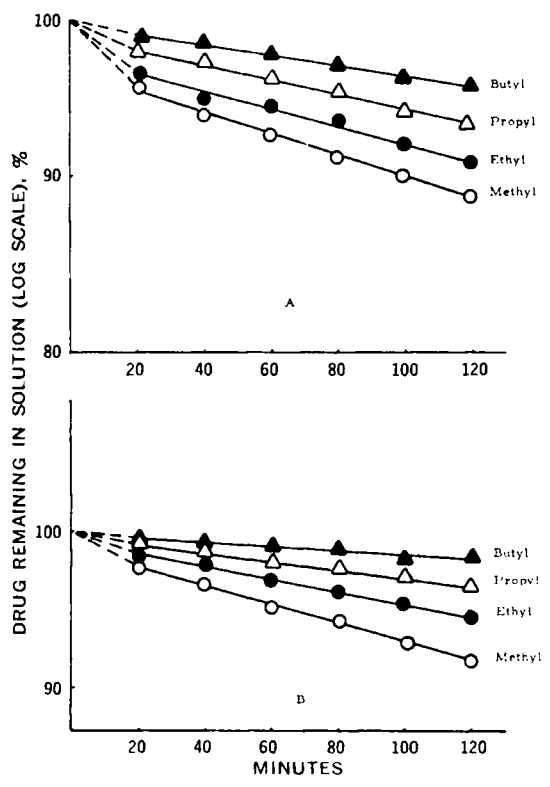

Figure 2—*Plot of average percent of parabens remaining in solution over 2 hr. when five frogs were each placed in 500 ml. of aqueous drug solution, each containing a paraben in a concentration of 5.0 × 10⁻⁵ M and polysorbate 20 (0.5%, upper curves A; 1%, lower curves B).*

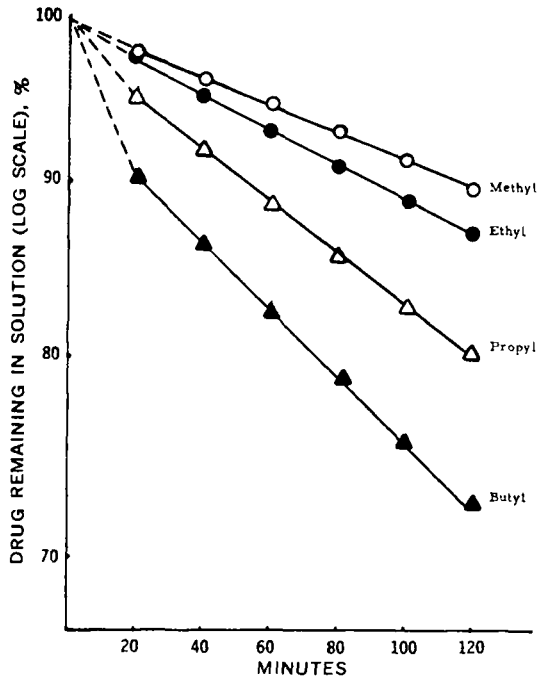

Figure 3—*Plot of average percent of parabens remaining in solution over 2 hr. when five frogs were each placed in 500 ml. of aqueous drug solution, each containing a paraben in a concentration of 5.0 × 10^{-5} M and sodium cholate, 5.0 × 10^{-5} M.*

on drug uptake. Distilled water was used as the solvent, and the solutions of parabens were 5.0 × 10^{-5} *M*. The concentration of benzoate remaining in solution was determined by absorbance readings[1] at a wavelength of 255 nm.

The partition coefficient was determined by allowing each paraben to equilibrate with stirring for 3 hr. at 25° between 100 ml. of *n*-hexane–distilled water (50:50), adjusted to a pH of 2.0 with hydrochloric acid. The aqueous layer was assessed for paraben content, and the partition coefficient was calculated from:

$$P = \frac{\text{concentration in } n\text{-hexane}}{\text{concentration in water}} \qquad \text{(Eq. 1)}$$

RESULTS AND DISCUSSION

As seen in Figs. 1–3, the data can be linearized satisfactorily by plotting the log of the percent of paraben remaining in solution against time, thus indicating a first-order process. In each case, however, the relationship does not become linear until after the first 20 min. During this initial period, the frog takes up the drug considerably faster than during the remainder of the 2 hr., as noted in a previous study (4).

The linear equation is:

$$\log C = -\frac{kt}{2.303} + \log C_0 \qquad \text{(Eq. 2)}$$

where C = percent of benzoate remaining in solution, C_0 = initial percent of benzoate in solution (100), k = rate constant, and t = time in minutes. The rate constants were calculated from the slope, $-K/2.303$, of the line and show the rate of disappearance of drug.

Figure 1 shows that the frog, *Rana pipiens*, takes up the parabens with higher molecular weights more readily than those with lower molecular weights, in the order butyl > propyl > ethyl > methyl.

[1] Beckman DU spectrophotometer.

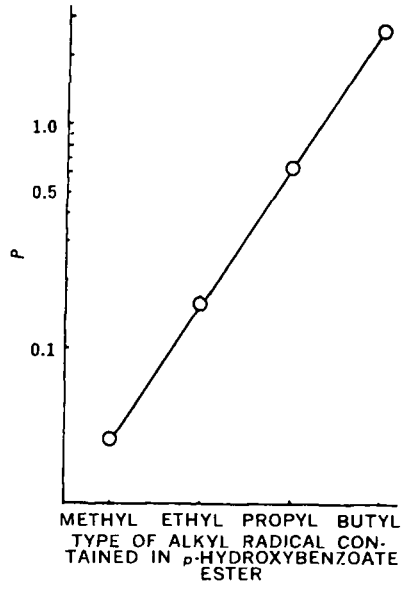

Figure 4—*Partition coefficient* (P) *of parabens at pH 2.0.* P = *concentration in* n-*hexane/concentration in water.*

This is consistent with previous findings (1) that the greater the lipid solubility of the drug the greater is the rate of uptake by the frog for these drugs. Figure 4 shows paraben partition coefficient data which correlate molecular weight and lipid solubility.

Surfactants have been shown to influence drug absorption (4, 5). Figure 2 shows the effect of two concentrations of polysorbate 20 on the uptake of parabens. This nonionic surfactant decreased the uptake of most of the parabens and also reversed the order of the sorption process with respect to molecular weight (Table I).

Sodium cholate is a bile salt having surfactant properties, and its effect on the uptake of parabens by the frog is seen in Fig. 3. A comparison of rate constants (Table I) indicates that sodium cholate slightly increased the rate of uptake of each paraben.

The mechanisms by which such additives influence drug uptake is not well understood. The effect of polysorbate 20 in decreasing uptake is perhaps due to complexation. The surface tension-lowering ability of the sodium cholate probably increases drug uptake by permitting better wetting action by the drug solution on the skin of the frog. Bile salts were found to increase the permeability of everted rat intestine to salicylate (6).

The frog, *Rana pipiens*, has been found to take up relatively few types of drugs using an immersion technique. The partition coefficient of the drugs taken up plays an important role in determining the rate.

Acetaminophen Prodrug: 2-(*p*-Acetaminophenoxy)tetrahydropyran

A. J. REPTA▲ and J. HACK

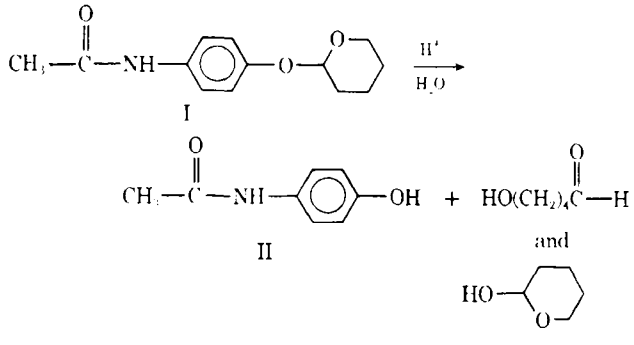
Abstract □ The synthesis and chemistry of 2-(*p*-acetaminophenoxy)-tetrahydropyran, a prodrug of acetaminophen, are described. The utilization of a prodrug approach to the formulation of chewable acetaminophen tablets is discussed. Although the compound studied has many desired properties for use in chewable tablets, its aqueous solubility is very low so the dissolution rate may be rate determining in the release of acetaminophen.

Keyphrases □ Acetaminophen—synthesis of 2-(*p*-acetaminophenoxy)tetrahydropyran as a prodrug for chewable formulations, chemical properties □ 2-(*p*-Acetaminophenoxy)tetrahydropyran—synthesized as a prodrug of acetaminophen, hydrolysis, effects of temperature, ionic strength, pH, taste properties □ Acylals—synthesis of 2-(*p*-acetaminophenoxy)tetrahydropyran as a prodrug of acetaminophen for chewable formulations

The analgesic–antipyretic drug acetaminophen has been formulated in numerous dosage forms. However, there apparently has been no attempt to produce a chewable form, probably because of its unpleasant taste.

Since taste is known to be relatively specific and its intensity is concentration dependent, the taste problem should be overcome, at least in part, by preparing derivatives of acetaminophen that are much less soluble and thereby reduce the concentration of the drug at the taste buds. Alternatively, it should also be possible to alter the structure of the drug to produce a more acceptable taste.

For either approach to be successful, any chemical derivative employed should release the drug in the GI tract in the active form which would then be available for absorption. If the approach is to have merit, the rate of release of the drug under acid conditions must be much more rapid than the release rate at the relatively neutral pH of the mouth. If the prodrug form releases the drug rapidly in the mouth, the organoleptic sensations produced would be similar to those of the drug alone and no advantage would be realized. Therefore, the conversion of the prodrug to the active material must be greatly accelerated by the acid contents of the stomach.



Scheme I

The acylal class of organic compounds possesses chemical properties that appear to meet these criteria. For this study, 2-(*p*-acetaminophenoxy)tetrahydropyran (I) was selected to determine its feasibility as a prodrug of acetaminophen (II) suitable for a chewable dosage form (Scheme I).

The synthesis and chemistry of some 2-(aryloxy)tetrahydropyrans were reported previously (1, 2). Such substances are easily prepared by reaction of various phenols with dihydropyran in the presence of acid catalysts. The hydrolysis of the acylals was shown to be acid catalyzed at low pH but independent of pH at near neutral to alkaline conditions (1–3). The products of hydrolysis were reported to be the phenol, δ-hydroxyvaleraldehyde, and 2-(hydroxy)tetrahydropyran (1, 4)[1].

In previous studies, the rate of hydrolysis of compounds similar to I was dependent on the dielectric constant of the hydrolysis medium, and mechanisms were suggested (2, 3).

While much work has been done on the chemistry of such compounds, the acylal approach in the formulation of prodrugs apparently has not been used.

To determine whether the hydrolysis of 2-(*p*-acetaminophenoxy)tetrahydropyran would likely result in the rapid and complete release of acetaminophen under conditions similar to those encountered in the GI tract, the rate of hydrolysis was studied as a function of pH, temperature, and ionic strength. Some physical properties were also investigated.

EXPERIMENTAL[2]

Synthesis of I—A suspension containing II (4 g., 0.026 mole), dihydropyran (50 ml., 0.6 mole), and methylene chloride (40 ml.), saturated with hydrogen chloride gas, was prepared in a 250-ml., loosely stoppered flask. This suspension was stirred magnetically at room temperature until all suspended material was dissolved and a clear colorless solution was obtained. This normally occurred within 2–4 hr.

The solution obtained was transferred to a rotary evaporator, and some of the solvent and other volatiles were removed at room temperature and reduced pressure using an aspirator. Evaporation under these conditions was continued until most solvent was removed and a viscous suspension of a heavy white precipitate was obtained. About 10 ml. of anhydrous ether was added to the residue to facilitate its removal from the flask.

The solid white precipitate was separated by vacuum filtration, washed twice with 20-ml. portions of anhydrous ether, and dried for 30 min. at room temperature in a vacuum oven at a pressure of 1–2 mm. Hg. The solid obtained (5.5 g., 88% yield) melted at 112–113°.

[1] No reports on toxicity of these agents were located. However, it seems likely that the valeraldehyde would probably be oxidized to glutaric acid which presents no problem of toxicity.

[2] The equipment used included the Cary models 14 and 15 spectrophotometers and a Corning model 12 pH meter. Temperatures were controlled by using a water bath thermostated at the desired temperature ±0.1°. All reagents were of reagent grade, and the water was distilled from acid permanganate solution in an all-glass still.

Table I—Observed Rate Constants for Hydrolysis of I at 25° at Various pH and Ionic Strengths

Ionic Strength, μ	k_{obs} (sec.$^{-1}$) at pH 1.11	2.0	3.0	4.135	5.0
0.1	6.73×10^{-2}	6.51×10^{-3}	6.6×10^{-4}	5.63×10^{-5}	7.9×10^{-6}
0.3	7.11×10^{-2}	9.63×10^{-3}	6.7×10^{-4}	—	—
0.5	7.53×10^{-2}	11.55×10^{-3}	8.8×10^{-4}	—	—
0.8	7.70×10^{-2}	13.8×10^{-3}	—	—	—
1.0	—	—	10.0×10^{-4}	—	—

The NMR[3] spectrum of a solution of the solid in dimethyl sulfoxide was consistent with the formula of Compound I.

Anal.—Calc. for $C_{13}H_{17}NO_3$: C, 66.4; H, 7.3; N, 6.0. Found[4]: C, 66.6; H, 7.5; N, 6.2.

TLC of a solution of I in 2-butanone showed only one spot, at R_f 0.55, and differential scanning calorimetry[5] indicated only one endotherm, at 112–113°. The melting point as conventionally determined[6] was ~113° (uncorrected).

TLC—The TLC system employed to separate I and II utilized a polyamide layer[7] with dry 2-butanone as the developing solvent. Detection was accomplished by UV light at 254 nm. The system was sensitive to 0.1 mcg. II. The R_f values were: I, 0.75; and II, 0.55. No spots indicating the presence or nature of the products of the tetrahydropyran product were detectable. The hydrolysis of a 0.1% solution of I was followed at pH 2.95, μ = 0.1. At various times over several hours, a sample of the solution was withdrawn and added to pH 7 buffer to quench the hydrolytic reaction. The resulting solution was then spotted on the plate and developed.

Kinetic Studies—The kinetics of the hydrolysis of I were followed by UV at 290 nm. At this wavelength, the absorbance increased with time.

Since I did not dissolve rapidly in aqueous solutions, a 0.03 *M* stock solution of I in acetonitrile was prepared. Approximately 150 μl. of the stock solution was placed in a 2-cm. cell. The desired buffer (6.5 ml.), equilibrated at the desired temperature, was then added. The cell was closed, inverted carefully and rapidly to assure mixing, and placed in the spectrophotometer, and the absorbance changes were then followed.

Normally the reactions were followed to completion. At a higher pH value and a slower reaction, the reaction was followed for only about 5–6 half-lives. In all cases, an apparent but minor problem of solubility was encountered. As the reaction proceeded, the dihydropyran and/or derivatives that resulted from hydrolysis appeared to separate from the solution, and this occurrence resulted in small changes in the apparent absorbance. To correct for the problem of changing absorbance, all kinetic data were plotted using the Guggenheim method.

All buffers used were prepared from reagent grade materials, and the ionic strength was adjusted by the addition of sodium or potassium chloride.

RESULTS AND DISCUSSION

The hydrolysis of I was followed over a pH range of 1–5 at μ = 0.1 and 25° in aqueous solutions containing 2–3% acetonitrile. It can be seen from Fig. 1 that the hydrolysis of I is hydrogen-ion catalyzed. The solid line in Fig. 1 is drawn with a slope of unity. The good fit of the experimental points to the line shows that the catalysis is first order in [H^+]. Although the reaction was not studied extensively or quantitatively at pH > 5, due to the very slow rate of hydrolysis, the rate began to reach a plateau in the region of pH > 6–7. This finding is in accord with previous studies on related systems (3, 4).

To be certain that the hydrolysis of I to yield II was neat and complete, the reaction at 25°, pH 3.0, and μ = 0.1 was followed by TLC. The TLC method was able to separate I and II. The reaction was followed as a function of time, and it was found that the hydrolysis was complete and that there was no detectable degradation of II under these conditions as indicated by the presence of a single TLC spot, which corresponded to II, at the end of the reaction.

The rate of hydrolysis of I was followed as a function of acetate concentration (0.1–1.0 *M*) in buffers at 25°, pH 3.0, μ = 0.1; no buffer catalysis was observed.

Ionic strength, on the other hand, affected the rate greatly. The observed rate constants as a function of ionic strength at pH 1.1–5 are shown in Table I. The rate was increased by increasing ionic strength, and the magnitude of the effect increased with increasing pH. These observations seem to be in agreement with the suggested mechanism of hydrolysis for related compounds (3, 4).

The effect of temperature on k_{obs} was studied at pH 3.0 and μ = 0.1; k_{obs} (sec.$^{-1}$)($\times 10^4$) was found to be 2.3 (288°K.), 6.6 (298°K.), and 21.8 (310°K.). The energy of activation of the reaction was about 19.5 kcal./mole degree, which is again in agreement with values determined for related systems (2, 3).

While the half-life of hydrolysis at 25°, pH 3.0, and μ = 0.1 was a rather slow 17.5 min., the rate at 37° resulted in a half-life of only 5 min. Since the environment of the stomach would be similar to the conditions of the *in vitro* study at 37°, it would be expected that the

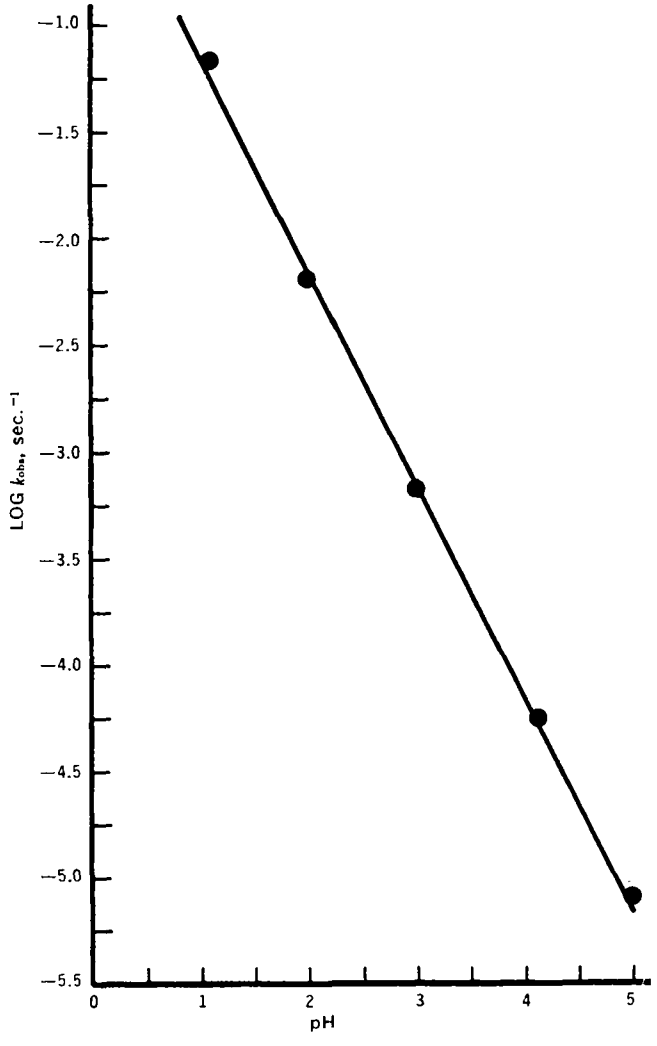


Figure 1—*The pH–rate profile for hydrolysis of I at 25° and μ = 0.1.*

[3] Varian model T-60 NMR spectrometer.
[4] Elemental analysis was performed at the Medicinal Chemistry Department, University of Kansas, Lawrence, Kans.
[5] Perkin-Elmer model DSC-1B differential scanning calorimeter.
[6] Thomas–Hoover capillary melting-point apparatus.
[7] Polygram Sil N-HR precoated on plastic sheets, available from Brinkmann Instruments, Inc.

release of II from I in the stomach would be about 95% complete in 25 min. In the mouth, however, the half-life would be expected to be 1 hr. or more since a pH > 5 would be normal. Thus, there should not be a sufficient amount of II released in the mouth to cause the taste problem associated with II, yet it should be rapidly released in the stomach. When small amounts of II were placed on the tongues of volunteers, they reported the lack of any significant taste associated with the material.

The solubility of I in distilled water at 25° was only 0.002 mole/l., while the solubility of II under the same conditions was about 0.1 mole/l. (5). By applying the approach of Hussain (6) in the calculation of time required for 50% dissolution, it can be calculated that, for a material with an average particle size of 100 μ, about 19 min. would be required for 50% dissolution at 25°. Thus, the rate-determining step in the release of II would be the rate of dissolution at pH 3. Therefore, the solubility of I may limit its usefulness as a chewable tasteless prodrug form of II.

To establish whether the lack of taste associated with I is due solely to its limited solubility, saturated solutions of I in both 40 and 30% alcohol in water were prepared. These solutions were tasted by volunteers who again reported no objectionable taste, which suggested that I was relatively free of taste problems.

CONCLUSIONS

The prodrug of acetaminophen investigated appears to be suitable, from the taste standpoint, for use in a chewable tablet.

In vitro studies of the hydrolysis of I in aqueous solution showed that the rates of hydrolysis of I were sufficiently rapid to ensure release of acetaminophen in the stomach. However, the low solubility of I suggests that the rate-determining step in the release of acetaminophen would be the dissolution rate of the prodrug rather than its hydrolytic rate. Therefore, on the basis of these data, it appears that 2-(*p*-acetaminophenoxy)tetrahydropyran may not be especially suited for use in chewable tablets, although other uses may exist.

Synthesis and Pharmacological Screening of 1-Chloro-3-(2-propynyloxy)-2-propanols and 2-[(2-Propynyloxy)methyl]oxiranes

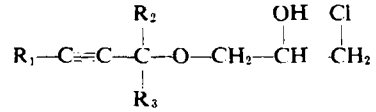
R. B. FUGITT, G. S. WU, and L. C. MARTINELLI▲

Abstract □ Some researchers have found that an ethynyl group is essential for optimal anticancer activity of carbamate esters. In addition, it has been observed that bisepoxides are generally more potent anticancer agents than monoepoxides. These observations led to the syntheses and screening of the title compounds, ethynyl derivatives of oxiranes and their synthetic precursors, since the presence of both an ethynyl group and an oxirane group in a molecule may lead to significant anticancer activity. One compound, 2-[(2-butynyloxy)methyl]oxirane, showed confirmed, but weak, activity in the P-388 test system employed.

Keyphrases □ 1-Chloro-3-(2-propynyloxy)-2-propanols—synthesis and pharmacological screening as possible anticancer agents □ 2-[(2-Propynyloxy)methyl]oxiranes synthesis and pharmacological screening as possible anticancer agents □ Oxiranes, ethynyl derivatives and synthetic precursors—synthesis and screening as possible anticancer agents □ Anticancer agents, potential—synthesis and screening of 1-chloro-3-(2-propynyloxy)-2-propanols and 2-[(2-propynyloxy)methyl]oxiranes

The possibility that the ethynyl group could act as a biological alkylating agent prompted the synthesis and screening of the title compounds as possible cytotoxic agents. It has been reported (1) that the presence of an acetylene group is essential for the oncolytic action of a series of ethynylmethyl carbamate esters.

The requirements of an ethynyl group for oncolytic activity in ethynylmethyl carbamates, as well as a generally observed lower anticancer activity for mono-



halohydrins

release of II from I in the stomach would be about 95% complete in 25 min. In the mouth, however, the half-life would be expected to be 1 hr. or more since a pH > 5 would be normal. Thus, there should not be a sufficient amount of II released in the mouth to cause the taste problem associated with II, yet it should be rapidly released in the stomach. When small amounts of II were placed on the tongues of volunteers, they reported the lack of any significant taste associated with the material.

The solubility of I in distilled water at 25° was only 0.002 mole/l., while the solubility of II under the same conditions was about 0.1 mole/l. (5). By applying the approach of Hussain (6) in the calculation of time required for 50% dissolution, it can be calculated that, for a material with an average particle size of 100 μ, about 19 min. would be required for 50% dissolution at 25°. Thus, the rate-determining step in the release of II would be the rate of dissolution at pH 3. Therefore, the solubility of I may limit its usefulness as a chewable tasteless prodrug form of II.

To establish whether the lack of taste associated with I is due solely to its limited solubility, saturated solutions of I in both 40 and 30% alcohol in water were prepared. These solutions were tasted by volunteers who again reported no objectionable taste, which suggested that I was relatively free of taste problems.

CONCLUSIONS

The prodrug of acetaminophen investigated appears to be suitable, from the taste standpoint, for use in a chewable tablet.

In vitro studies of the hydrolysis of I in aqueous solution showed that the rates of hydrolysis of I were sufficiently rapid to ensure release of acetaminophen in the stomach. However, the low solubility of I suggests that the rate-determining step in the release of acetaminophen would be the dissolution rate of the prodrug rather than its hydrolytic rate. Therefore, on the basis of these data, it appears that 2-(*p*-acetaminophenoxy)tetrahydropyran may not be especially suited for use in chewable tablets, although other uses may exist.

epoxides compared to bisepoxides (2), prompted the investigation of the anticancer activity of ethynyl-substituted oxiranes. It seemed reasonable that the ethynyl group might also be acting as a biological alkylating site and that ethynyl derivatives of oxiranes might, therefore, possess significant anticancer activity. The halohydrins were prepared as intermediates to the oxiranes and were also screened since they may be converted *in vivo* to their corresponding oxiranes.

EXPERIMENTAL

Chemistry[1]—Table I gives the experimental data for the individual compounds, and Tables II and III give their NMR and IR spectral characteristics. NMR spectra[2] were taken in deuteriochloroform containing 1% tetramethylsilane as a standard. The IR spectra[3] were taken as thin films between sodium chloride plates.

The 1-chloro-3-(2-propynyloxy)-2-propanols were synthesized by acid-catalyzed condensation, similar to a published procedure (4), of the appropriate alcohol with epichlorohydrin. In the cases of the two tertiary alkynols and phenylpropargyl alcohol, phosphoric acid was employed (Procedure B) to eliminate the excessive tarring and lowered yields experienced when sulfuric acid was used (Procedure A). The 2-[(2-propynyloxy)methyl]oxiranes were prepared from the acetylenic halohydrins in good yield using a published method (4).

Synthesis of 1-Chloro-3-(2-propynyloxy)-2-propanols—*Procedure A, Compounds I–III*—Concentrated sulfuric acid (2 ml./mole epichlorohydrin) was added dropwise at room temperature to a flask containing a stirred mixture of 1 equivalent of epichlorohydrin and 2 equivalents of the acetylenic alcohol. The reaction vessel was equipped with a reflux condenser protected by a drying tube. The reaction solution was warmed to 100–110° for 24–48 hr. when it began to darken appreciably. After cooling, 1.5 equivalents of powdered barium carbonate was added; after stirring for 1–2 hr., the salts were removed by filtration. Unchanged epichlorohydrin was removed by a water aspirator, and the residual oil was carefully fractionated *in vacuo* to give the product. When the alcoholic starting material is sufficiently water insoluble to resist emulsification, the acid catalyst may also be removed by diluting the reaction mixture with methylene chloride and washing it with water.

Procedure B, Compounds IV–VI—These compounds were prepared as in Procedure A with the following modifications. Concentrated phosphoric acid (10 ml.) is substituted for every 2 ml. of con-

XII	H	2.60	$CH_2(CH_2)_3CH_2$				1.60	3.64	3.08	2.67	3250	3035	2100	1260

centrated sulfuric acid used in Procedure A, and the reaction solution is heated an additional 4–24 hr.

Synthesis of 2-[(2-Propynyloxy)methyl]oxiranes, Compounds VII–XII– Freshly powdered sodium hydroxide (1.5 equivalents) was added to an ice-cold solution of the 1-chloro-3-(2-propynyloxy)-2-propanol dissolved in a volume of absolute ether equal to 10 times the weight of sodium hydroxide used. The reaction vessel was stoppered and allowed to stir magnetically overnight. The suspended inorganic salts were removed by filtration, the ether solution was concentrated on a rotary evaporator, and the residual oil was distilled *in vacuo*.

Biological[1]–The experimental animals were BDF_1 mice inoculated intraperitoneally (i.p.) or intracerebrally (i.c.) with L-1210 or P-388 tumor systems. The test compounds (all were racemic mixtures) were administered at 400, 200, 100, and 50 mg./kg. body weight i.p. in sonified saline or saline with polysorbate 80. Doses were administered, beginning on Day 1, either daily for nine doses or every 4th day for three doses, and test results were evaluated at Day 30. Evaluations were made as mean survival time and are expressed as % T/C (test/control), with a value of 125 or greater representing activity in these systems.

RESULTS AND DISCUSSION

Chemistry–The possibility exists that condensation of the acetylenic alcohol with epichlorohydrin may occur at both the primary and secondary carbons of the epichlorohydrin to give a γ-halohydrin in addition to the desired β-halohydrin. This inconvenient side reaction was observed in only one instance, in the case of 2 butyn-1-ol. Apparently, the reaction conditions used for the conversion of the β-halohydrin to the oxirane are insufficient to convert also the γ-halohydrin to the corresponding oxetane, since oxetane has not been observed in the IR or NMR of any 2-[(2-propynyloxy)-methyl]oxirane. Isolation of the lower boiling β-halohydrin in pure form is achieved by careful fractional distillation of the reaction mixture *in vacuo*.

Biological–The compounds were tested against L-1210 and P-388 leukemia according to the standard protocol of The Division of Cancer Treatment, National Cancer Institute, National Institutes of Health. The 1-chloro-3-(2-propynyloxy)-2-propanols (I–VI) showed no significant activity as indicated by changes in the mean survival time of the test animals over that of the control animals (% T/C < 125). The activity of oxirane VII, 2-[(2-butynyloxy)methyl]oxirane (NSC 153427), was confirmed by duplicate screening in the intraperitoneal P-388 test system (% T/C 129 and 134) when administered daily, at doses as low as 44 mg./kg. body weight, for nine doses. Oxirane XI, 2-{[(3-phenyl-2-propynyl)oxy]methyl}oxirane (NSC 156628), showed unconfirmed preliminary activity in intraperitoneal P-388 (% T/C 133) and intracerebral P-388 (% T/C 154) when administered daily for nine doses (400 and 100 mg./kg., respectively). The other oxiranes were devoid of activity but did exhibit slightly larger % T/C values than their corresponding β-halohydrins.

The marginal activity exhibited by only one oxirane, VII, and perhaps oxirane XI does not appear to support the hypothesis that the ethynyl group can act as a biological alkylating agent in these compounds. Further work will be conducted in this area, however, before final conclusions are made.

Search for Potential Oral Hypoglycemic Agents: Synthesis and Activity of 2-(*N*-Alkylaminomethyl)indolizines

A. U. DE▲ and B. P. SAHA

Abstract □ Some 2-(*N*-alkylaminomethyl)indolizines were synthesized and biologically evaluated; however, they showed very weak oral hypoglycemic activity. One compound of this series possessed anti-Parkinson activity and another had marginal anti-inflammatory activity.

Keyphrases □ 2-(*N*-Alkylaminomethyl)indolizines—synthesized and screened as potential oral hypoglycemic agents □ Indolizines, 2-(*N*-alkylaminomethyl)—synthesized and screened as potential oral hypoglycemic agents □ Hypoglycemic agents, oral, potential—synthesis and screening of 2-(*N*-alkylaminomethyl)indolizines

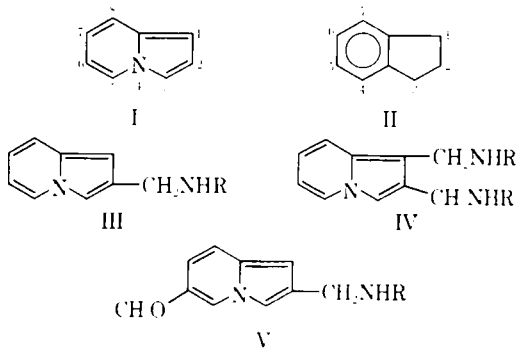
The alkaloids vincamine, vindoline, and vindolinine obtained from plants of the genus vinca, commonly known as periwinkles, have been reported to cause varying degrees of blood sugar lowering (1–4). All of these alkaloids are structurally different from the common hypoglycemic agents like sulfonylureas and biguanides and thus provide a new lead in this area (4).

DISCUSSION

The structures of these alkaloids consist of several ring systems like those of indolizine, quinolizine, indole, and quinoline. Since indolizine ring systems (I) are a rare occurrence in natural products, their presence in vinca alkaloids is of particular interest. It appears from the literature that no indolizine derivative has yet been tested as a potential oral hypoglycemic agent.

Indolizine derivatives have been reported to exhibit hypotensive, anti-inflammatory, central nervous system depressant, anticholinergic, antiedema, estrogenic, and anabolic activities (5–11). In addition, both the pyridine and the pyrrole ring systems, the structural components of the indolizine ring linked through the common nitrogen atom, have furnished various pharmacologically active compounds through their derivatives. Moreover, the indolizine ring system may be regarded as structurally equivalent to the hydrindene ring system (II) through isosteric replacement of one angular carbon atom of the hydrindene ring with a nitrogen atom. From the point of chemical reactivity, indolizine and hydrindene rings have one common feature: the 1- and 3-positions of both ring systems are active in their many derivatives (12–14). Presumably, these may combine with the active receptor site through these positions and evoke biological responses.

The significance of the hydrindene ring system for oral hypoglycemic activity (15) and various other activities (16, 17) has been already established. Earlier, the authors synthesized and biologically evaluated a few hydrindene derivatives as potential oral hypoglycemic agents; however, the results were not encouraging (18, 19). The interesting features of the indolizine ring system have shifted emphasis to indolizine derivatives as potential oral hypoglycemic agents. With this objective, the synthesis and biological evaluation of a few compounds (III, IV, and V) have been undertaken. These derivatives were chosen to keep the 1- and/or 3-positions free so as to retain their reactivity in the biological system.



In this article, only the synthesis and biological activity of 2-(*N*-alkylaminomethyl)indolizines (III) are described. The synthesis and activity of other indolizine derivatives (IV and V) will be described in a subsequent report.

Indolizine-2-carboxylic acid (III*a*) was prepared by the condensation of α-picoline with ethyl bromopyruvate according to the method of Borrows and Holland (20), who obtained a buff-colored product. But in this case, a greenish product of the same melting point as reported earlier (20) was obtained. All attempts to convert this acid to the corresponding acid chloride failed. As such, the acid was converted to the corresponding methyl indolizine-2-carboxylate (III*b*) by the reaction of diazomethane with a suspension of the acid (III*a*) in ether instead of dioxane (20). The ester was condensed with the respective amines to give 2-(*N*-alkylcarboxamido)indolizines (III*c*) and then reduced with lithium aluminum hydride to 2-(*N*-alkylaminomethyl)indolizines (III) in dry ether (Scheme I). On standing, the colors of the carboxamides (III*c*) and the amine (III) changed to dark brown. UV absorption characteristics are recorded in Table I.

Table I—UV Absorption Characteristics

Compound	λ_{max}, nm. (in Alcohol)	ϵ_{molar}
III*a*	290, 300, 342	1972, 2173, 2124
III*b*	291, 301, 342	2358, 2668, 2581
III*c* (R = ethyl)	288, 300, 341	1406, 1438, 1363
III (R = ethyl)	284, 296, 346	2610, 2870, 1866

ACTIVITY

Of the four compounds synthesized, 2-(*N*-*n*-butylaminomethyl)-indolizine (III: R = *n*-butyl) and 2-(*N*-*n*-propylaminomethyl)-indolizine (III: R = *n*-propyl) exhibited one-fourth of the activity of tolbutamide at 250 mg./kg. body weight in normal, overnight-fasted rabbits. The blood sugar was estimated at 0, 2, and 4 hr. Because of this weak hypoglycemic acitivity, further investigations were suspended. However, 2-(*N*-ethylaminomethyl)indolizine (III: R = ethyl) demonstrated anti-Parkinson activity as determined by the oxotremorine model in mice. The activity was seen at doses that were very close to lethality. The minimum effective dose (MED) was 50 mg./kg. i.p., and the lethal dose (LD_{50}) in mice was 140 mg./kg.

				H 8.91	9.09
				N 13.87	13.58

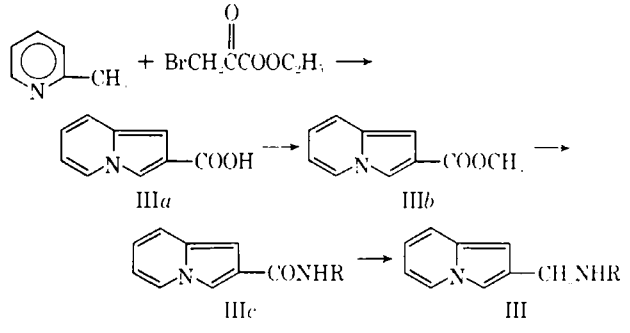
i.p. Thus, further studies were suspended. On the other hand, 2-(*N*-*n*-propylaminomethyl)indolizine (III: R = *n*-propyl) demonstrated marginal anti-inflammatory activity but only at rather large oral doses in rats. Due to this weak activity, further studies were not undertaken. All of these compounds showed no microbiological activity.

EXPERIMENTAL[1]

Methyl Indolizine-2-carboxylate (III*b*)—To a suspension of indolizine-2-carboxylic acid (III*a*, 10 g.) in dry ether (250 ml.), an ethereal solution of diazomethane was added in the usual way. The reaction was allowed to continue overnight, and the resulting solution was filtered. The solvent was removed when a yellowish product was obtained, which crystallized from dilute ethanol as colorless plates, m.p. 98–99°.

2-(*N*-Alkylcarboxamido)indolizines (III*c*)—Methyl indolizine-2-carboxylate (III*b*, 1 mole) and the appropriate alkylamine (1.5 moles) were heated in a hard glass, sealed tube on a water bath for 12–16 hr. After cooling, the reaction mass was poured into water, either filtered or extracted with benzene, and washed with water. The crude product was either crystallized from dilute ethanol or benzene–petroleum ether (b.p. 60–80°) or distilled under reduced pressure to yield white to pale-yellow solids (Table II).

2-(*N*-Alkylaminomethyl)indolizines (III)—2-(*N*-Alkylcarboxamido)indolizine (III*c*, 1 mole) was reduced with lithium aluminum hydride (0.6 mole) in sodium-dried ether for 16 hr. and worked up in the usual way. The crude amines were purified by distillation to yield colorless products (Table III).



Scheme I

[1] All melting points are uncorrected. Absorption characteristics were recorded on a Spectromom 201 spectrophotometer made in Hungary.

Insect Repellency of Substituted *N,N*-Diethylbenzamidines

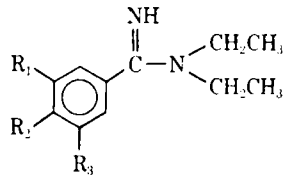
DANIEL D. GARNER* and LORRIN R. GARSON▲

Abstract □ The synthesis of *N,N*-diethylbenzamidine, *N,N*-diethyl-3-trifluoromethylbenzamidine, *N,N*-diethyl-4-trifluoromethylbenzamidine, and *N,N*-diethyl-3,5-di(trifluoromethyl)benzamidine is described; the compounds were designed to produce long-lasting insect repellent activity. The repellency of these agents on cloth against *Aedes aegypti* (L.) mosquitoes is reported.

Keyphrases □ *N,N*-Diethylbenzamidines, substituted—synthesized and evaluated as potential insect repellents □ Insect repellents, potential—synthesis and evaluation of substituted *N,N*-diethylbenzamidines □ Repellents, insect—synthesis and evaluation of substituted *N,N*-diethylbenzamidines

Associated with efforts to develop long-lasting insect repellents and prompted by the remarkable efficacy elicited by *N,N*-diethyl-*m*-toluamidine (I) (1), four additional amidines were synthesized and evaluated as repellents. Although Compound I exhibited a higher degree of repellency than the standard repellent 2-ethyl-1,3-hexanediol[1], a drying action on the skin of some volunteers was produced by this agent. Since this adverse effect may have been a manifestation of the strong basicity of I, the design of III–V included structural features to effect reduced basicity.

Volatility has long been associated with insect repellent activity (2); the lower activity of I compared to *N,N*-diethyl-*m*-toluamide could be due to the latter's higher volatility as indicated by the boiling points [*i.e.*, *N,N*-diethyl-*m*-toluamide, b.p. 111°/1.0 mm. (3); I, b.p. 148°/1.0 mm. (1)]. An inverse linear relationship was shown (4) between insect repellency and boiling point for ring-substituted *N,N*-diethylbenzamides. By assuming that this relationship is also applicable to the corresponding amidine series, II–IV were designed to obtain an agent with the optimal volatility associated with maximum effectiveness as a repellent. Also of significance is the fact that II is a nitrogen isostere of *N,N*-diethylbenzamide, an excellent repellent (5).



Compound	R_1	R_2	R_3
I	H	H	CH_3
II	H	H	H
III	H	H	CF_3
IV	H	CF_3	H
V	CF_3	H	CF_3

EXPERIMENTAL[2]

***N,N*-Diethylbenzamidine (II)**—By employing the method described for the preparation of I (1), 24.9 g. (0.540 mole) of absolute ethanol, 75 ml. of anhydrous ether, and 44.0 g. (0.427 mole) of benzonitrile were combined and cooled to −7°. After the addition of 37.8 g. (1.04 moles) of hydrogen chloride, the reaction mixture was stirred for 14 hr. Ethyl benzimidate hydrochloride (VI) was collected by filtration, washed with ether, and dried *in vacuo* for 2 hr., yielding 53.7 g. (67.7%). The hydrochloride (0.289 mole) was allowed to stand for 1 week with 63.2 g. (0.864 mole) of diethylamine in 200 ml. of absolute ethanol. Then the reaction mixture was distilled *in vacuo*, leaving a dark-brown residual liquid.

The crude material was dissolved in 500 ml. of 10% sodium bicarbonate and divided into two portions, and each was extracted with ether (4 × 50 ml.). The aqueous phase was brought to a higher pH (pH 11–13) by adding sodium hydroxide until a second layer appeared, at which time the basic solution was extracted with ether (4 × 100 ml.). The ether solutions from the second extraction were combined, dried over magnesium sulfate, and filtered; the ether was removed by distillation *in vacuo*, yielding a yellow residual liquid. The crude product was purified by distillation *in vacuo*, employing a short-path, microdistillation apparatus, yielding 20.7 g. (40.6%) of pure II, b.p. 62–63° (0.2 mm.); n_D^{25} 1.5322; IR (chloroform): 1575 cm.$^{-1}$ (C=N); UV (95% ethanol): 205 nm. (ε 14,100).

Anal.—Calc. for $C_{11}H_{16}N_2$: C, 74.96; H, 9.15; N, 15.89. Found: C, 75.07; H, 9.17; N, 15.81.

***N,N*-Diethyl-3-trifluoromethylbenzamidine (III)**—Ethyl 3-trifluoromethylbenzimidate hydrochloride was prepared in an analogous manner to VI, using 14.6 g. (0.317 mole) of absolute ethanol, 43.0 g. (0.251 mole) of *m*-trifluoromethylbenzonitrile, and 18.3 g. (0.502 mole) of hydrogen chloride, yielding 49.5 g. (77.7%) of the salt. The salt was allowed to react in a similar manner as described in the preparation of II, using 42.8 g. (0.585 mole) of diethylamine. The product was purified by distillation *in vacuo*, yielding 19.4 g. (40.8%) of colorless III, b.p. 66–68° (0.1–0.2 mm.); n_D^{25} 1.4814; IR (chloroform): 1572 cm.$^{-1}$ (C=N); UV (95% ethanol): 205 nm. (ε 14,500).

Anal.—Calc. for $C_{12}H_{15}F_3N_2$: C, 59.01; H, 6.19; F, 23.34; N, 11.47. Found: C, 59.22; H, 6.16; F, 23.23; N, 11.46.

***N,N*-Diethyl-4-trifluoromethylbenzamidine (IV)**—Ethyl 4-trifluoromethylbenzimidate hydrochloride was prepared in a similar manner to VI, using 17.0 g. (0.369 mole) of absolute ethanol, 50.0 g. (0.292 mole) of *p*-trifluoromethylbenzonitrile, and 23.5 g. (0.644 mole) of hydrogen chloride, yielding 65.4 g. (88.3%) of the benzimidate salt. Compound IV was prepared using 56.6 g. (0.774 mole) of diethylamine and the salt. The product was distilled *in vacuo*, yielding 23.6 g. (37.5%) of yellow-colored IV, b.p. 74–76° (0.05 mm.); n_D^{25}/1.4824; IR (chloroform): 1580 cm.$^{-1}$ (C=N); UV (95% ethanol): 208 nm. (ε 13,700).

Anal.—Calc. for $C_{12}H_{15}F_3N_2$: C, 59.01; H, 6.19; F, 23.34; N, 11.47. Found: C, 58.95; H, 6.24; F, 23.52; N, 11.41.

***N,N*-Diethyl-3,5-di(trifluoromethyl)benzamidine (V)**—In a comparable manner to VI, ethyl 3,5-di(trifluoromethyl)benzimidate hydrochloride was prepared using 12.1 g. (0.263 mole) of absolute ethanol, 50.0 g. (0.209 mole) of 3,5-di(trifluoromethyl)benzonitrile, and 15.0 g. (0.411 mole) of hydrogen chloride, yielding 66.1 g. (98.4%) of the salt. A mixture of 66.1 g. (0.205 mole) of the benzimidate salt, 200 ml. of isopropyl alcohol, and 46.5 g. (0.636 mole) of diethylamine was stirred at 75° for 5 days. Then the mixture was distilled *in vacuo*, leaving a red residual solid.

The crude material was shaken with water buffered at pH 7, the undissolved material was removed, and the aqueous phase was extracted with ether (3 × 100 ml.). The insoluble material was dissolved in 500 ml. of an aqueous sodium hydroxide solution (pH 12) and, after the appearance of a second layer following the addition of more sodium hydroxide, the basic solution was extracted with

[1] Rutgers 612.

[2] Boiling points are uncorrected. IR and UV spectra were obtained with the Perkin-Elmer models 137B and 202 spectrophotometers, respectively. Analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn.

ether (3 × 100 ml.). The ether solutions from the second extraction were combined, dried over magnesium sulfate, and filtered, and the ether was removed by distillation *in vacuo*, yielding a purple residual liquid. The crude product was purified by distillation *in vacuo*, employing a microdistillation apparatus (24-cm. Vigreux column), yielding 10.9 g. (17.0%) of pure V, b.p. 60 65° (0.01–0.02 mm.); n_D^{25} 1.4465; IR (chloroform): 1580 cm.$^{-1}$ (C=N); UV (95% ethanol): 208 nm. (ϵ 15,000).

Anal.—Calc. for $C_{13}H_{14}F_6N_2$: C, 50.00; H, 4.52; F, 36.51; N, 8.97. Found: C, 50.07; H, 4.57; F, 36.23; N, 8.76.

Evaluation of Repellency—To minimize contact with the skin, Compounds II–V were evaluated as repellents against *Aedes aegypti* (L.) mosquitoes employing a standard cloth method (6); *N,N*-diethyl-*m*-toluamide was included in the tests as a standard for comparison. One-third square foot of a cotton stocking was treated with 1 g. of the compound in solution (10% solution in a volatile solvent, usually acetone). Two hours after treatment, the stocking, on the arm of a human subject, was exposed for 1 min. in a cage of mosquitoes. If less than five mosquitoes bit the subject through the stocking, the test was repeated at 24 hr. and then weekly thereafter until five bites were received in 1 min.

RESULTS AND DISCUSSION

As tested, Compounds II–V were found to be effective on cloth against *Aedes aegypti* (L.) mosquitoes for 7 days as compared to *N,N*-diethyl-*m*-toluamide and *N,N*-diethylbenzamide, which are effective under the same conditions for more than 21 days. To our knowledge, Compounds I–V are the only amidines that have been evaluated as insect repellents. The effectiveness of these specific agents and the structural similarities between amidines and amides and imides, which were found (7) to be the largest single class of compounds effective for 5 hr. or more upon dermal application, indicate that amidines as a class possess considerable potential as insectifugal agents.

Metabolism and Anticonvulsant Activity of Deuterated *N*-Demethyldiazepam

FRANCA MARCUCCI, EMILIO MUSSINI, PAOLA MARTELLI, AMALIA GUAITANI, and SILVIO GARATTINI▲

Abstract □ The substitution of the hydrogen at the C_3-position of *N*-demethyldiazepam with deuterium shortens the anticonvulsant activity in mice from 20 to 5 hr. This pharmacological effect may be partly explained by a decrease in the ability of deuterated *N*-demethyldiazepam to protect mice from pentylenetetrazol-induced convulsions in contrast to the effect exerted by the C_3-unlabeled analog. Furthermore, the weaker pharmacological action of deuterated *N*-demethyldiazepam may in part be due to the lesser accumulation of the hydroxylated metabolite, oxazepam, in the brain of mice treated with deuterated *N*-demethyldiazepam than with the unlabeled analog. The lesser accumulation of oxazepam from deuterated *N*-demethyldiazepam than from the unlabeled analog is due to a reduced C_3-hydroxylation of this compound by liver microsomal enzymes, as shown by experiments *in vitro*.

Keyphrases □ Diazepam, *N*-demethyl, deuterated—metabolism and anticonvulsant activity, mice □ *N*-Demethyldiazepam, deuterated—metabolism and anticonvulsant activity, mice □ Anticonvulsant activity—deuterated *N*-demethyldiazepam, metabolism, mice □ Oxazepam—accumulation after administration of deuterated *N*-demethyldiazepam, mice

N-Demethyldiazepam, a major metabolite of diazepam, possesses pharmacological properties similar to the parent compound (1, 2). In the liver microsomal system, it undergoes a process of hydroxylation in position C_3 with the formation of oxazepam (3). The administration of *N*-demethyldiazepam in mice results in an accumulation of oxazepam in brain (4) where it is retained for several hours. Because oxazepam exerts

an anticonvulsant activity comparable to that of *N*-demethyldiazepam, the consequence of C_3-hydroxylation in mice is a prolonged action of the administered drug due to accumulation of oxazepam in the brain.

Several drugs are oxidized by liver microsomal enzymes at a specific carbon–hydrogen bond. If breaking of the carbon–hydrogen bond is rate limiting in the oxidative process, substitution of hydrogen by deuterium at the suspected site of oxidation may result in a decreased rate of oxidation.

The purpose of this study was to evaluate the consequence of such C_3-substitution in *N*-demethyldiazepam on the metabolism and pharmacological activity in mice.

EXPERIMENTAL

The deuterated *N*-demethyldiazepam[1] (7-chloro-1*H*-3,3-dideutero-5-phenyl-1,4-benzodiazepin-2-one) had 84% of dideuterated molecules. Male, albino Swiss mice, weighing 20–25 g., were used in all experiments.

Drug Administration—*N*-Demethyldiazepam and deuterated *N*-demethyldiazepam were administered by the tail at 5 mg./kg. i.v. Drugs were dissolved in a solvent containing propylene glycol–glycofurol–benzyl alcohol–water (30:30:2:48).

The ED_{50} was determined using male, albino Swiss mice and is the dose (in micrograms per kilogram) protecting 50% of the mice from the mortality induced by phenylenetetrazol at 120 mg./kg. i.p. The method of Litchfield and Wilcoxon (5) was used for calculating the confidence limits. The ED_{50} for *N*-demethyldiazepam was 198 mcg./kg. (confidence limits of 177–221 mcg./kg.), and for deuterated *N*-demethyldiazepam it was 288 mcg./kg. (confidence limits of 252–329 mcg./kg.). The ED_{50} was calculated from data obtained 5 min. between drug and pentylenetetrazol administration, when the injected drug, according to previous observations (4), is practically unmetabolized.

Chemical Determinations—The preparation of brain extracts was made according to the method previously described (6). GLC analyses were carried out by using a gas chromatograph[2] equipped with a ^{63}Ni electron-capture detector (voltage of 42 v.). The stationary phase was 3% OV-17 on Gas Chrom Q (100–120 mesh) packed into a 1-m. glass column (2 mm. i.d., 4 mm. o.d.). The flow rate of the carrier gas (nitrogen) was 33 ml./min., and the column temperature was 245°.

Preparations of Liver Microsomes—Albino Swiss mice were given 40 mg./kg. i.p. of phenobarbital in 0.9% NaCl twice a day for 4 days. This treatment is known to increase the hydroxylation of *N*-demethyldiazepam by liver microsomal enzymes (7). After the last injection, the animals were deprived of food for 24 hr. and then sacrificed by decapitation. The livers were removed, chilled in ice, and homogenized in ice-cold 1.15% potassium chloride solution (1:4 w/v). The homogenate was centrifuged[3] at 105,000×*g* for 1 hr. The precipitated liver microsomes were suspended in 1.15% potassium chloride solution. Protein determinations were performed according to Lowry *et al.* (8).

Table II—Brain Levels of *N*-Demethyldiazepam and Its Metabolite, Oxazepam, after Administration (5 mg./kg. i.v.) of Unlabeled and Labeled *N*-Demethyldiazepam to Mice

N-Demethyldiazepam	Hours after Treatment	Benzodiazepine Brain Level, mcg./g. ± *SE*		Mice Protected against Pentylenetetrazol (120 mg./kg. i.p.), %
		N-Demethyldiazepam	Oxazepam	
Unlabeled	1	4.52 ± 0.18	2.37 ± 0.02	100
Labeled	1	5.66 ± 0.25	0.21 ± 0.01	100
Unlabeled	3	0.62 ± 0.01	3.93 ± 0.07	100
Labeled	3	3.50 ± 0.20	0.38 ± 0.01	66
Unlabeled	10	<0.002	0.75 ± 0.02	100
Labeled	10	0.74 ± 0.04	0.09 ± 0.007	16
Unlabeled	20	<0.002	0.09 ± 0.01	33
Labeled	20	0.09 ± 0.01	0.04 ± 0.02	0

Incubation *In Vitro*—The incubation mixture, as previously reported (3), consisted of 2.5 ml. of microsomal suspension equivalent to 1 g. of liver, NADP (1.5 μmoles), glucose 6-phosphate (50 μmoles), glucose 6-phosphate dehydrogenase (0.5 unit), magnesium chloride (35 μmoles), nicotinamide (50 μmoles), 1.4 ml. of 0.2 *M* phosphate buffer (pH 7.4), 300 mcg. of deuterated or nondeuterated *N*-demethyldiazepam, 0.45 ml. of 1.15% potassium chloride, and water to obtain a final volume of 5 ml. The mixtures were incubated in a metabolic shaker[4] at 37° under air for 30 min. Recovery studies of *N*-demethyldiazepam and oxazepam, both deuterated and nondeuterated, were performed with microsomal boiled mixtures containing ingredients identical to those in the experimental samples.

Determination of Substrates and Metabolites—At the end of the incubation time, 5 ml. of the mixture was extracted twice with 10 ml. of fresh peroxide-free ether. The combined ether extracts were dried, redissolved in a suitable volume of acetonitrile, and then submitted to the GLC procedure previously described (6). This procedure allows the simultaneous determination of the formed metabolite and the disappearance of the added substrate.

RESULTS

Table I shows the relative rate of hydroxylation *in vitro* of *N*-demethyldiazepam bearing hydrogen or deuterium in position 3. It is evident that more oxazepam is formed from *N*-demethyldiazepam than from the deuterated analog. However, the recovery of the added substrate is incomplete with the deuterated *N*-demethyldiazepam, suggesting alternative metabolic pathways or a tighter binding to liver microsomes.

Table II summarizes the findings obtained *in vivo*. Mice injected with deuterated *N*-demethyldiazepam showed higher levels of this compound in the brain compared to animals receiving the hydrogenated compound. Conversely, the brain levels of oxazepam, the hydroxylated metabolite, were much lower with deuterated than with hydrogenated *N*-demethyldiazepam. Because of the lower levels of brain oxazepam, the duration of the antipentylenetetrazol activity exerted by the deuterated compound is much shorter than for the C_3-unlabeled drug.

DISCUSSION

The present study indicates that the substitution of the hydrogen at the C_3-position of *N*-demethyldiazepam with deuterium resulted in a shortening of the anticonvulsant activity in mice. This finding

[1] Received as a gift from Prof. G. C. Jommi, Laboratory of Organic Chemistry, Department of Sciences, Milan University, Milan, Italy.
[2] Model GI, Carlo Erba, Milan, Italy.
[3] Rotor 40 ft., Beckman model L ultracentrifuge.
[4] Dubnoff.

may be partly explained by the fact that deuterated *N*-demethyldiazepam is less effective than the hydrogenated analog as an inhibitor of the mortality induced by pentylenetetrazol in mice. The ED_{50} was 198 mcg./kg. for *N*-demethyldiazepam and 288 mcg./kg. for the deuterated analog.

However, there is also a decreased accumulation of the hydroxylated metabolite, oxazepam, in the brain of mice treated with the deuterated analog compared to the C_3-unlabeled *N*-demethyldiazepam. This finding is in agreement with previous studies indicating that the long duration of action of diazepam and *N*-demethyldiazepam in mice is related to the formation and persistence of brain oxazepam (9). The lack of accumulation of oxazepam from C_3-deuterated *N*-demethyldiazepam is due to a reduced C_3-hydroxylation of this benzodiazepine *in vitro* compared to the C_3-unlabeled compound, as shown by the experiments utilizing liver microsomal enzymes.

The deuterated *N*-demethyldiazepam may be less hydroxylated than the C_3-unlabeled analog for one of the following reasons: (*a*) slower rate of cleavage of the carbon–deuterium bond, (*b*) lower affinity for the active site of the enzymes involved in the hydroxylation, and (*c*) more stable complex with the enzyme. While these possibilities are open to experimental investigations, it remains established that the presence of oxazepam in the brain is the main factor accounting for the prolonged antipentylenetetrazol effect exerted by diazepam or *N*-demethyldiazepam in mice.

Effect of Hydroxy Group on Coacervate Formation by Sodium Hydroxybenzoates with Benzalkonium Chloride

Keyphrases ☐ Coacervate formation, sodium hydroxybenzoates and benzalkonium chloride—effect of position of hydroxy group ☐ Hydroxybenzoates—coacervate formation with benzalkonium chloride, phase transition diagrams, effect of hydroxy position

Sir:

Shah *et al.* (1) reported coacervate formation by sodium salicylate (sodium *o*-hydroxybenzoate) with benzalkonium chloride.

The phase transition diagram of this system (Fig. 1) illustrates two main regions: a biphasic coacervate system (I) and a monophasic equilibrium solution (II). The biphasic coacervate system shows two distinct regions. In one region (B) the coacervate phase has a higher density than the equilibrium liquid and it settles to the bottom of the container, and in the other region (T), the coacervate phase is lighter than the equilibrium liquid and floats on the top of the liquid.

This communication reports the effect of the presence and position of the hydroxy group on coacervate formation between hydroxybenzoates and benzalkonium chloride.

The coacervate systems are obtained by mixing various concentrations of sodium *m*-hydroxybenzoate, sodium *p*-hydroxybenzoate, and sodium benzoate with benzalkonium chloride in water. Figure 1 is the superimposed phase transition diagram of sodium *o*-, *m*-, and *p*-hydroxybenzoates. The phase regions for the hydroxybenzoates are equivalent, differing only in the positions of the boundary lines, and are as identified previously (1). Figure 2 shows a phase transition diagram of the sodium benzoate and benzalkonium chloride coacervate system.

The sodium benzoate system (Fig. 2) shows a lighter coacervate phase (T) throughout the biphasic coacervate region. The systems near the upper and lower transition lines showed the property of birefringence during flow. The coacervate phase in all three systems was observed to be isotropic under examination with a polarizing microscope.

From our previous (1) and present data, it is our belief that the density of the coacervate phase is a function of the molecular weight of the anionic electrolyte, the amount of this electrolyte associated with the micellar aggregation, and the size of the micelles.

may be partly explained by the fact that deuterated *N*-demethyldiazepam is less effective than the hydrogenated analog as an inhibitor of the mortality induced by pentylenetetrazol in mice. The ED_{50} was 198 mcg./kg. for *N*-demethyldiazepam and 288 mcg./kg. for the deuterated analog.

Effect of Hydroxy Group on Coacervate Formation by Sodium Hydroxybenzoates with Benzalkonium Chloride

Keyphrases ☐ Coacervate formation, sodium hydroxybenzoates and benzalkonium chloride—effect of position of hydroxy group ☐ Hydroxybenzoates—coacervate formation with benzalkonium chloride, phase transition diagrams, effect of hydroxy position

Sir:

Shah *et al.* (1) reported coacervate formation by sodium salicylate (sodium *o*-hydroxybenzoate) with benzalkonium chloride.

The phase transition diagram of this system (Fig. 1) illustrates two main regions: a biphasic coacervate system (I) and a monophasic equilibrium solution (II). The biphasic coacervate system shows two distinct regions. In one region (B) the coacervate phase has a higher density than the equilibrium liquid and it settles to the bottom of the container, and in the other region (T), the coacervate phase is lighter than the equilibrium liquid and floats on the top of the liquid.

This communication reports the effect of the presence and position of the hydroxy group on coacervate formation between hydroxybenzoates and benzalkonium chloride.

The coacervate systems are obtained by mixing various concentrations of sodium *m*-hydroxybenzoate, sodium *p*-hydroxybenzoate, and sodium benzoate with benzalkonium chloride in water. Figure 1 is the superimposed phase transition diagram of sodium *o*-, *m*-, and *p*-hydroxybenzoates. The phase regions for the hydroxybenzoates are equivalent, differing only in the positions of the boundary lines, and are as identified previously (1). Figure 2 shows a phase transition diagram of the sodium benzoate and benzalkonium chloride coacervate system.

The sodium benzoate system (Fig. 2) shows a lighter coacervate phase (T) throughout the biphasic coacervate region. The systems near the upper and lower transition lines showed the property of birefringence during flow. The coacervate phase in all three systems was observed to be isotropic under examination with a polarizing microscope.

From our previous (1) and present data, it is our belief that the density of the coacervate phase is a function of the molecular weight of the anionic electrolyte, the amount of this electrolyte associated with the micellar aggregation, and the size of the micelles.

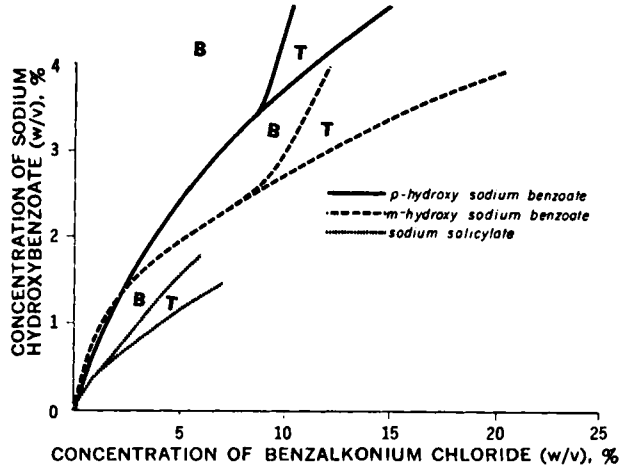

Figure 1—*Superimposed phase transition diagrams of sodium* o-, m-, *and* p-*hydroxybenzoates–benzalkonium chloride coacervate systems at 24°. (Data for sodium* o-*hydroxybenzoate from* Reference 1.)

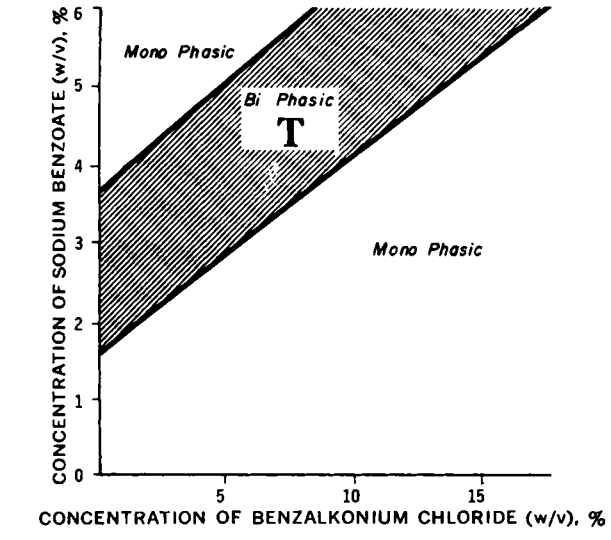

Figure 2—*Phase transition diagram of sodium benzoate–benzalkonium chloride coacervate system at 24°. Dark area [T] represents the region of coacervate formation at the top, and light area represents the region of no coacervate formation.*

In the case of the sodium hydroxybenzoate and benzalkonium chloride coacervate system, the denser coacervate phase, on heating, becomes lighter and moves to the top of the equilibrium liquid.

The increase in benzalkonium chloride concentration at constant salt concentration results in either a lighter coacervate phase or a monophasic solution (Fig. 1). Since benzalkonium chloride is lighter than water, an increase in micellar aggregation results in a lighter coacervate phase and hence the coacervate moves to the top of the equilibrium liquid. Figure 1 also shows the similarity in patterns of phase transition diagrams of all three salts of hydroxybenzoate, and they follow the same order as the degree of solubility (*o*-hydroxybenzoate being least soluble and *p*-hydroxybenzoate being most soluble). The sodium benzoate system did not form a denser coacervate phase; this is probably because of the structural changes in the micelle size and/or shape resulting from the absence of a hydroxyl group.

Cholinergic Activity of Pilocarpine Methiodide: A Reinvestigation

Keyphrases ☐ Pilocarpine methiodide—cholinergic activity reinvestigated ☐ Cholinergic activity—pilocarpine methiodide ☐ Quaternary salts—cholinergic activity of pilocarpine methiodide

Sir:

While most compounds possessing cholinergic activity are quaternary amine derivatives, several tertiary amines are known to possess significant cholinergic activity. Pilocarpine is perhaps the most widely known example of a tertiary amine derivative possessing therapeutically useful cholinergic activity. The cholinergic activity, or lack thereof, of the quaternary methiodide salt of pilocarpine has been a point of interest for some time. Wojciechowski and Ecanow (1, 2) prepared a series of quaternary salts of pilocarpine and later reported (3) that pilocarpine methiodide lacks muscarinic activity. Hanin *et al.* (4) confirmed this report while presenting the correct chemical structure of the methiodide.

During studies designed to clarify the structural and conformational requirements for cholinergic activity of pilocarpine (5, 6), we examined the effects of pilocarpine methiodide on the ileum of the guinea pig. We confirmed the earlier reports that the quaternary salt lacks muscarinic activity but, more significantly, observed (5) that this salt possesses the ability to antagonize the muscarinic effects of acetylcholine. Subsequent to our observation, Ben Bassat *et al.* (7) reported the cholinergic antagonist activities of a large number of quaternary salts of pilocarpine but, curiously, neither reported any data regarding the methiodide salt nor mentioned previous studies on this compound. In view of these facts, we feel it of importance that we report our observations.

The methiodide of pilocarpine was prepared from pilocarpine in the standard manner, and the physical data (elemental analyses, IR and NMR data, and specific rotation) were consistent with the earlier reports. Antagonism of the muscarinic actions of acetylcholine

Binding of Sulfonylureas to Serum Albumin

Keyphrases ☐ Protein binding, human and bovine serum albumin—sulfonylureas, dynamic dialysis technique ☐ Sulfonylureas—binding to human and bovine serum albumin, dynamic dialysis technique ☐ Drug–protein binding—sulfonylureas ☐ Dialysis, dynamic—used to study sulfonylurea binding to serum albumin

Sir:

A recent paper (1) concerned the binding of the sulfonylureas, tolbutamide, chlorpropamide, and acetohexamide, to serum proteins. We have studied the binding of tolbutamide and chlorpropamide to serum albumin and find that there are substantial differences between our results and those of Judis (1). In this communication we present some results for comparison and attempt to reconcile the differences.

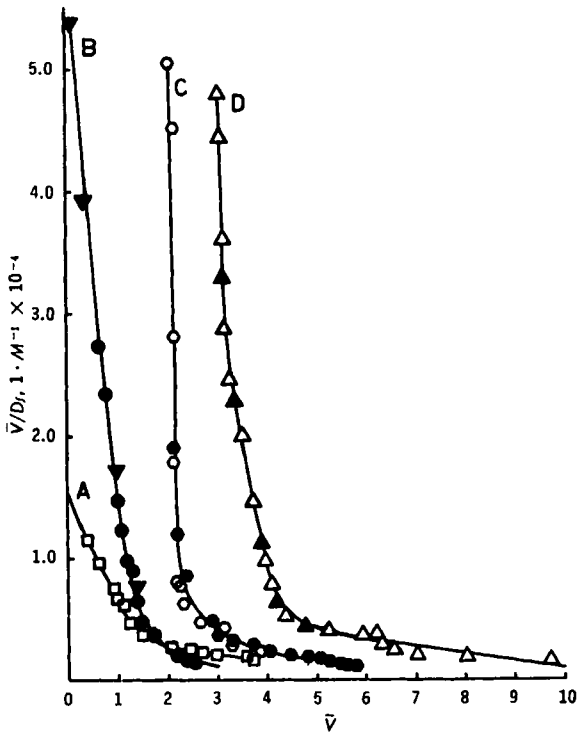

Figure 1—*Scatchard plots for the binding of tolbutamide to serum albumin in 0.067 M buffer at pH 7.4 and 37°. Key: open symbols, 1% albumin; closed symbols, 2% albumin; A, 1% human serum albumin in tromethamine buffer; B, 2% human serum albumin in tromethamine buffer; ●, ▼, Judis' (1) results (40°); C, human serum albumin in phosphate buffer; and D, bovine serum albumin in phosphate buffer. All points are experimental while the solid lines were computed from the binding parameters.*

The drug–protein interaction was characterized using a dynamic dialysis technique. The method and apparatus were based on those described by Meyer and Guttman (2). A concentration of 1 or 2% serum albumin was used, buffered to pH 7.4 with 0.067 *M* phosphate buffer. The volume and frequency of sampling were such that the concentration of drug in the outer compartment never exceeded 5% of the free concentration in the protein compartment to ensure that dialysis proceeded under sink conditions.

Tolbutamide was estimated by two separate methods: (*a*) in buffer, by direct UV spectrophotometry at 228 nm., and (*b*) in solutions containing protein and/or other interfering materials, by a modification of the colorimetric procedure of Alessandro *et al.* (3). Chlorpropamide was estimated spectrophotometrically at 231 nm.

The decline in drug concentration, D_t, within the dialysis bag was followed as a function of time. From a knowledge of the intrinsic dialytic rate constant and the instantaneous dialysis rate at any time, t, the free concentration in the protein compartment was estimated. The instantaneous rate of dialysis was obtained by fitting the plot of D_t *versus* time to an equation of the form:

$$D_t = D_t^0 + at + bt^2 + ct^3 + dt^4 \ldots \quad \text{(Eq. 1)}$$

on the guinea pig ileum was measured by known procedures (8). A pA_2 value (9) of 2.2 was determined. While the degree of antagonism observed is much weaker than that observed for atropine [pA_2 = 9.0 (10)], it is significant that these effects have not been previously reported.

The effects of pilocarpine methiodide on eel acetylcholinesterase were studied[1], and weak, uncompetitive inhibition was observed ($K_i = 1.64 \times 10^{-4}$).

Binding of Sulfonylureas to Serum Albumin

Keyphrases ☐ Protein binding, human and bovine serum albumin—sulfonylureas, dynamic dialysis technique ☐ Sulfonylureas—binding to human and bovine serum albumin, dynamic dialysis technique ☐ Drug–protein binding—sulfonylureas ☐ Dialysis, dynamic—used to study sulfonylurea binding to serum albumin

Sir:

A recent paper (1) concerned the binding of the sulfonylureas, tolbutamide, chlorpropamide, and acetohexamide, to serum proteins. We have studied the binding of tolbutamide and chlorpropamide to serum albumin and find that there are substantial differences between our results and those of Judis (1). In this communication we present some results for comparison and attempt to reconcile the differences.

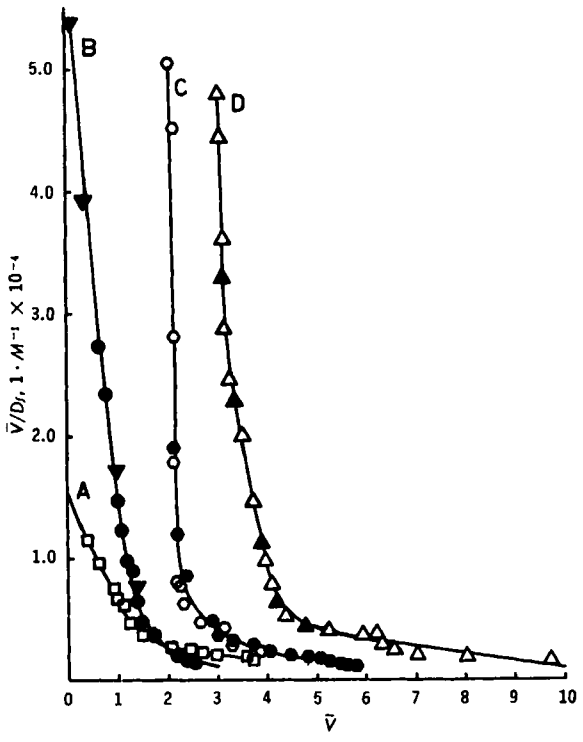

Figure 1—*Scatchard plots for the binding of tolbutamide to serum albumin in 0.067 M buffer at pH 7.4 and 37°. Key: open symbols, 1% albumin; closed symbols, 2% albumin; A, 1% human serum albumin in tromethamine buffer; B, 2% human serum albumin in tromethamine buffer; ●, ▼, Judis' (1) results (40°); C, human serum albumin in phosphate buffer; and D, bovine serum albumin in phosphate buffer. All points are experimental while the solid lines were computed from the binding parameters.*

The drug–protein interaction was characterized using a dynamic dialysis technique. The method and apparatus were based on those described by Meyer and Guttman (2). A concentration of 1 or 2% serum albumin was used, buffered to pH 7.4 with 0.067 *M* phosphate buffer. The volume and frequency of sampling were such that the concentration of drug in the outer compartment never exceeded 5% of the free concentration in the protein compartment to ensure that dialysis proceeded under sink conditions.

Tolbutamide was estimated by two separate methods: (*a*) in buffer, by direct UV spectrophotometry at 228 nm., and (*b*) in solutions containing protein and/or other interfering materials, by a modification of the colorimetric procedure of Alessandro *et al.* (3). Chlorpropamide was estimated spectrophotometrically at 231 nm.

The decline in drug concentration, D_t, within the dialysis bag was followed as a function of time. From a knowledge of the intrinsic dialytic rate constant and the instantaneous dialysis rate at any time, t, the free concentration in the protein compartment was estimated. The instantaneous rate of dialysis was obtained by fitting the plot of D_t *versus* time to an equation of the form:

$$D_t = D_t^0 + at + bt^2 + ct^3 + dt^4 \ldots \quad \text{(Eq. 1)}$$

Table I—Binding Parameters for the Interaction of Chlorpropamide and Tolbutamide with Human and Bovine Serum Albumin at pH 7.4 and 37° in 0.067 *M* Buffer

Drug	Protein	Buffer	n_1	$k_1 \times 10^{-4}$, l. mole^{-1}	n_2	$k_2 \times 10^{-2}$, l. mole^{-1}
Tolbutamide	Human serum albumin, 1 and 2%	Phosphate	2.27	21.86	8.21	1.71
	Human serum albumin, 1%	Tromethamine	1.42	0.97	8.81	1.85
	Human serum albumin, 2%	Tromethamine	1.20	4.95	8.29	1.45
	Human serum albumin, 2%	Tromethamine	1.36[a]	4.06[a]	—	—
	Bovine serum albumin, 1%	Phosphate	2.98	24.82	8.12	3.39
Chlorpropamide	Human serum albumin, 1%	Phosphate	2.19	4.51	8.22	1.71
	Human serum albumin, 2%	Tromethamine	1.64[a]	1.09[a]	—	—
	Bovine serum albumin, 1 and 2%	Phosphate	1.94	4.67	8.93	4.14

[a] Values calculated by Judis (1) (40°).

where D_t^0 is the initial concentration of drug in the protein solution and *a*, *b*, *c*, and *d* are constants. This was achieved by treating the data by polynomial regression to produce four normal equations (4), which were solved by using a program for the solution of a symmetrical matrix and a programmable calculator[1]. Differentiation of Eq. 1 yields the instantaneous rate.

Data for the binding of tolbutamide to both human and bovine serum albumin are shown as Scatchard plots in Fig. 1. The results of Judis (1) determined by equilibrium dialysis and in the presence of tromethamine buffer are included for comparison. It is apparent that the latter results indicate a much weaker interaction than our own. In an attempt to reconcile these differences, binding experiments were repeated using 0.067 *M* tromethamine buffer in place of phosphate in both 1 and 2% human serum albumin. These data are also included in Fig. 1, and our results in 2% human serum albumin are in good agreement with those reported (1). However, these data indicate a much weaker interaction than occurs in phosphate buffer. Furthermore, the degree of interaction in tromethamine buffer shows a marked dependence on the human serum albumin concentration, as evidenced by the large difference between the plots for 1 and 2% protein. No such dependence was observed using phosphate buffer with either human or bovine serum albumin (Fig. 1). This dependence implies that the components of tromethamine buffer itself interact with the protein and compete with tolbutamide for binding sites.

If potentially competitive species are present in the buffer, one might expect quite strong competition because of the high molar concentration of buffer relative to that of tolbutamide. Scatchard plots for the binding of chlorpropamide to human and bovine serum albumin (Fig. 2) show a similar effect. Again the degree of interaction is considerably less in tromethamine buffer than in phosphate.

The Scatchard plots are not linear but curved. Such curvature is generally considered to be indicative of binding to more than one class of sites (5). The curvature results from the combination of two or more linear plots representing the binding to each class of sites. In such cases, simple extrapolation or evaluation of the slope from the linear portion of the curve may give inaccurate estimates of the binding constant for all classes of sites, unless the association constants for the various classes are very widely separated. These aspects have been overlooked by many authors, and linear extrapolation is probably still the means most frequently used to determine binding constants.

Hart (6) reported a mathematical treatment for the estimation of binding constants from curved Scatchard plots. By using Hart's treatment and a multiple linear regression analysis (4) and program similar to that described here, the experimental data were fitted to a model for two classes of sites. Binding parameters for the various systems are shown in Table I. In phosphate buffer, the association constant (k_1) for the binding of tolbutamide to the primary sites (n_1) on human serum

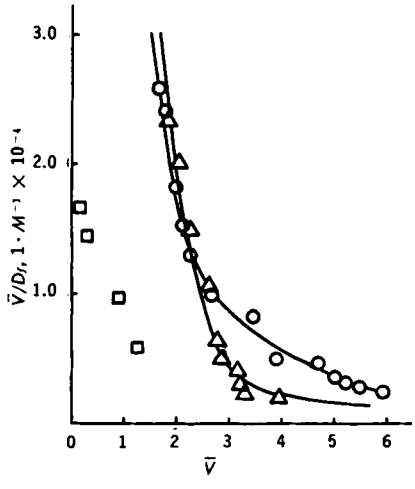

Figure 2—*Scatchard plots for the binding of chlorpropamide to serum albumin in 0.067* M *buffer at pH 7.4 and 37°. Key: △, 1% human serum albumin in phosphate buffer; □, Judis' (1) results for 2% human serum albumin in tromethamine buffer (40°); and ○, 1% bovine serum albumin in phosphate buffer. All points are experimental while the solid lines were computed from the binding parameters.*

[1] Diehl Combitron S.

albumin was four times greater than that using tromethamine buffer and 2% human serum albumin and about 20 times that determined for tromethamine and 1% human serum albumin. Furthermore, the number of sites in the first class (n_1) in phosphate buffer was substantially greater than in tromethamine. In the second class of sites, the association constant (k_2) and the number of sites (n_2) did not appear to show a strong dependence on the buffer used or the protein concentration. This suggests that tromethamine buffer did not interfere with binding in the second class and that binding to these sites possibly occurs by a less specific mechanism.

A comparison of the binding parameters obtained by Judis (1) and ourselves for the binding of tolbutamide to 2% human serum albumin in tromethamine buffer demonstrates the effect of neglecting the existence of the second class of sites. Although both sets of data are in good agreement on the Scatchard plot (Fig. 1), estimation of the primary association constant (k_1) from the slope of the linear portion of the plot does not correct for the slope contribution due to the second class of sites. This leads to an underestimate of the association constant on the order of 20% or 9000 l. mole^{-1} and a larger number of primary binding sites.

In the case of chlorpropamide, determination of binding in the presence of tromethamine buffer leads to a reduction in the number of binding sites and a fourfold reduction in the association constant relative to values obtained in phosphate buffer. Thus, as with tolbutamide, tromethamine strongly suppresses the binding.

These data illustrate the effects that buffers and other materials may have on the extent of protein binding *in vitro*. In such studies it is important to characterize the binding at several buffer or protein concentrations to test that the observed binding is a real effect rather than an artifact dependent on the particular buffer used. This also applies to salts which may be added to suppress the Donnan effect in equilibrium dialysis experiments. These considerations are also relevant to competitive binding studies. When the buffer system itself acts as a competitor and is present in high concentrations relative to the other competitors, the significance of the results is somewhat difficult to assess.

Judis (1) used two graphical methods (7, 8) to present his data, and there is excellent agreement between them. However, this is to be expected since the two methods are closely related. The plot used by Sandberg *et al.* (7) does not normalize the concentrations of bound small molecules for variations in total protein concentration and is for use chiefly when the protein concentration is not precisely known. The method used by Eichman *et al.* (8) is the well-known Scatchard plot, and in this case the results are normalized for variations in protein concentration. The only difference between the two is that, in the method of Sandberg *et al.*, the intercepts on the ordinate and abscissa are nkP_t and nP_t, respectively, where P_t is the concentration of protein. The value of n cannot be estimated without a knowledge of the protein concentration. In all other respects, both plots are essentially mathematically identical. Thus, any variation occurring in the value of n or k must only be the result of the errors expected in deriving information from graphical data.

Binding of Sulfonylureas to Serum Albumin: A Response

Keyphrases ☐ Sulfonylureas—binding to serum albumin ☐ Protein binding—sulfonylureas to serum albumin ☐ Binding, protein—sulfonylureas to serum albumin ☐ Dialysis, equilibrium and dynamic—explanation of differences found studying sulfonylurea binding to serum albumin

Sir:

Crooks and Brown (1) suggested substantial disagreements between their findings and mine (2). Disagreement between the results is complicated by the fact that a different method was used in each article. Equilibrium dialysis is an old, established method for studying protein binding, and there is a substantial literature of findings with this experimental approach. The new method used by Crooks and Brown, dynamic dialysis, first described by Meyer and Guttman (3) has not been used as extensively as equilibrium dialysis.

Disagreement with the results (2) also may have occurred because Crooks and Brown did not repeat the experiments using equilibrium dialysis or the same methods for analysis, such as radiochemical assay. No data are offered (1) regarding the analytical work, interfering substances, sensitivity of the assays, or specificity of the analyses. Therefore, comparison of data may or may not be valid.

The data in their Fig. 1 (curve B) lead to the conclusion that using tromethamine buffer and 2% human serum albumin results in agreement with our findings.

albumin was four times greater than that using tromethamine buffer and 2% human serum albumin and about 20 times that determined for tromethamine and 1% human serum albumin. Furthermore, the number of sites in the first class (n_1) in phosphate buffer was substantially greater than in tromethamine. In the second class of sites, the association constant (k_2) and the number of sites (n_2) did not appear to show a strong dependence on the buffer used or the protein concentration. This suggests that tromethamine buffer did not interfere with binding in the second class and that binding to these sites possibly occurs by a less specific mechanism.

A comparison of the binding parameters obtained by Judis (1) and ourselves for the binding of tolbutamide to 2% human serum albumin in tromethamine buffer demonstrates the effect of neglecting the existence of the second class of sites. Although both sets of data are in good agreement on the Scatchard plot (Fig. 1), estimation of the primary association constant (k_1) from the slope of the linear portion of the plot does not correct for the slope contribution due to the second class of sites. This leads to an underestimate of the association constant on the order of 20% or 9000 l. mole^{-1} and a larger number of primary binding sites.

In the case of chlorpropamide, determination of binding in the presence of tromethamine buffer leads to a reduction in the number of binding sites and a fourfold reduction in the association constant relative to values obtained in phosphate buffer. Thus, as with tolbutamide, tromethamine strongly suppresses the binding.

These data illustrate the effects that buffers and other materials may have on the extent of protein binding *in vitro*. In such studies it is important to characterize the binding at several buffer or protein concentrations to test that the observed binding is a real effect rather than an artifact dependent on the particular buffer used. This also applies to salts which may be added to suppress the Donnan effect in equilibrium dialysis experiments. These considerations are also relevant to competitive binding studies. When the buffer system itself acts as a competitor and is present in high concentrations relative to the other competitors, the significance of the results is somewhat difficult to assess.

Judis (1) used two graphical methods (7, 8) to present his data, and there is excellent agreement between them. However, this is to be expected since the two methods are closely related. The plot used by Sandberg *et al.* (7) does not normalize the concentrations of bound small molecules for variations in total protein concentration and is for use chiefly when the protein concentration is not precisely known. The method used by Eichman *et al.* (8) is the well-known Scatchard plot, and in this case the results are normalized for variations in protein concentration. The only difference between the two is that, in the method of Sandberg *et al.*, the intercepts on the ordinate and abscissa are nkP_t and nP_t, respectively, where P_t is the concentration of protein. The value of n cannot be estimated without a knowledge of the protein concentration. In all other respects, both plots are essentially mathematically identical. Thus, any variation occurring in the value of n or k must only be the result of the errors expected in deriving information from graphical data.

Binding of Sulfonylureas to Serum Albumin: A Response

Keyphrases ☐ Sulfonylureas—binding to serum albumin ☐ Protein binding—sulfonylureas to serum albumin ☐ Binding, protein—sulfonylureas to serum albumin ☐ Dialysis, equilibrium and dynamic—explanation of differences found studying sulfonylurea binding to serum albumin

Sir:

Crooks and Brown (1) suggested substantial disagreements between their findings and mine (2). Disagreement between the results is complicated by the fact that a different method was used in each article. Equilibrium dialysis is an old, established method for studying protein binding, and there is a substantial literature of findings with this experimental approach. The new method used by Crooks and Brown, dynamic dialysis, first described by Meyer and Guttman (3) has not been used as extensively as equilibrium dialysis.

Disagreement with the results (2) also may have occurred because Crooks and Brown did not repeat the experiments using equilibrium dialysis or the same methods for analysis, such as radiochemical assay. No data are offered (1) regarding the analytical work, interfering substances, sensitivity of the assays, or specificity of the analyses. Therefore, comparison of data may or may not be valid.

The data in their Fig. 1 (curve B) lead to the conclusion that using tromethamine buffer and 2% human serum albumin results in agreement with our findings.

The only variable was the dialysis method, that is, equilibrium dialysis (2) and dynamic dialysis (1). These findings are essentially an indication that the two dialytic methods may give equivalent results. Curve D, representing results using bovine serum albumin are not relevant since bovine serum albumin was not used in my work. Curve A, for 1% human serum albumin, suggests that binding characteristics change with protein concentration. Curve C, representing human serum albumin in phosphate buffer, suggests that protein concentration is of no consequence in phosphate buffer, although it is in tromethamine buffer. Figure 1 (1) thus leads to the conclusions that results with tromethamine buffer are different from those obtained with phosphate buffer and that protein concentration is of consequence in tromethamine buffer but not in phosphate buffer. These conclusions are not in disagreement with my findings because I made no claims about the generality of results in tromethamine buffer.

Figure 2 (1) is very difficult to interpret as presenting conflicting data because it represents data of experiments using 1% human serum albumin in phosphate and 1% bovine serum albumin in phosphate while only 2% human serum albumin was used in my work. In the experiments (2), the sulfonylureas usually were bound to the extent of 80% or higher at all concentrations of sulfonylurea used with the exception of the highest ($81–84 \times 10^{-6}$ mole) at which 40–60% binding was found, which is a rather substantial interaction.

A comment (1) was made that estimation of binding constants from extrapolation of the linear portion of Scatchard plots may be inaccurate. There is no disagreement on this point. The binding constants (2) were approximations because of this reason and, more basically, because of the limited number of data points. However, there is reasonable agreement in Table I between the n value for tolbutamide with 2% human serum albumin in tromethamine and that determined by Crooks and Brown. The difference between the n values for tolbutamide with 2% human serum albumin in tromethamine (2) and in *Reference 1* is less than that shown in Meyer and Guttman's paper (3) comparing k_1 for their kinetic method and literature values for ultrafiltration.

I cannot accept the conclusion of Crooks and Brown that there is questionable significance to my data on drugs competing with the binding of sulfonylureas to human serum albumin. Given that tromethamine may bind to human serum albumin, the amount of tromethamine was constant in each cell and the reduction in binding caused by the presence of competitor drugs was beyond that possibly caused by tromethamine. The reduction in binding caused by these competitor drugs was significant, and the results clearly have qualitative significance. Quantitative conclusions in terms of the amount of reduction in binding of sulfonylureas to human serum albumin caused by a number of moles of competitor drug would not be absolute if tromethamine also acts as a competitor drug; but with a constant amount of tromethamine in each system, the quantitative conclusions would be relative.

I believe Crooks and Brown (2) make two important contributions which do not represent disagreement with my findings (1) but actually extend our knowledge of binding of sulfonylureas to human serum albumin and, perhaps, protein binding in general. First, buffer systems may have significant effect on binding and more than one buffer system should be employed to ascertain these effects. Second, protein concentration may affect binding characteristics, although this finding is not new. Brunkhorts and Hess (4) found differences in binding parameters at different concentrations of albumin in studies of the interaction of the latter with cortisol. Perhaps this phenomenon, not yet satisfactorily explained, may be more general than is now appreciated.

Importance of Considering Variables when Using Magnetic Basket Dissolution Apparatus

Keyphrases □ Magnetic basket dissolution apparatus—effect of basket mesh size and revolution speed □ Dissolution apparatus, magnetic basket—effect of basket mesh size and revolution speed

Sir:

In several recent articles (1, 2), the versatility and adaptability of the magnetic basket were demonstrated. This apparatus was initially developed to yield reproducible dissolution profiles for capsules. The adaptability of the magnetic basket apparatus to tablet dissolution was also discussed (2). By using several sets of specially formulated tablets as the control, the magnetic basket was shown to differentiate between the common tablet parameters of hardness, particle size, and formulation changes, thereby illustrating its possible use in quality control. However, to use the concept of the magnetic basket as a means of correlating *in vitro* dissolution with the *in vivo* performance of a drug, further adaptability of the basket must be considered. Since the above-mentioned tablet parameters are not appreciably changed and remain constant after initial clinical testing demonstrates the effectiveness of the dosage form, the dissolution system must be able to show further versatility in its ability to provide an *in vitro* dissolution profile which approximates the *in vivo* behavior of the drug. Adjustment of the *in vitro* conditions, such as propeller height and revolutions per minute, or a change in the mesh or size of the basket

The only variable was the dialysis method, that is, equilibrium dialysis (2) and dynamic dialysis (1). These findings are essentially an indication that the two dialytic methods may give equivalent results. Curve D, representing results using bovine serum albumin are not relevant since bovine serum albumin was not used in my work. Curve A, for 1% human serum albumin, suggests that binding characteristics change with protein concentration. Curve C, representing human serum albumin in phosphate buffer, suggests that protein concentration is of no consequence in phosphate buffer, although it is in tromethamine buffer. Figure 1 (1) thus leads to the conclusions that results with tromethamine buffer are different from those obtained with phosphate buffer and that protein concentration is of consequence in tromethamine buffer but not in phosphate buffer. These conclusions are not in disagreement with my findings because I made no claims about the generality of results in tromethamine buffer.

Figure 2 (1) is very difficult to interpret as presenting conflicting data because it represents data of experiments using 1% human serum albumin in phosphate and 1% bovine serum albumin in phosphate while only 2% human serum albumin was used in my work. Importance of Considering Variables when Using Magnetic Basket Dissolution Apparatus

Keyphrases □ Magnetic basket dissolution apparatus—effect of basket mesh size and revolution speed □ Dissolution apparatus, magnetic basket—effect of basket mesh size and revolution speed

Sir:

In several recent articles (1, 2), the versatility and adaptability of the magnetic basket were demonstrated. This apparatus was initially developed to yield reproducible dissolution profiles for capsules. The adaptability of the magnetic basket apparatus to tablet dissolution was also discussed (2). By using several sets of specially formulated tablets as the control, the magnetic basket was shown to differentiate between the common tablet parameters of hardness, particle size, and formulation changes, thereby illustrating its possible use in quality control. However, to use the concept of the magnetic basket as a means of correlating *in vitro* dissolution with the *in vivo* performance of a drug, further adaptability of the basket must be considered. Since the above-mentioned tablet parameters are not appreciably changed and remain constant after initial clinical testing demonstrates the effectiveness of the dosage form, the dissolution system must be able to show further versatility in its ability to provide an *in vitro* dissolution profile which approximates the *in vivo* behavior of the drug. Adjustment of the *in vitro* conditions, such as propeller height and revolutions per minute, or a change in the mesh or size of the basket

would seem to be the means of achieving this approximation.

To test this hypothesis partially, two new magnetic baskets were built. The first conformed to the original specifications (1) but was made of 16-mesh instead of the original 8-mesh stainless steel wire. The second basket was constructed with 8-mesh wire and had larger dimensions: an inner diameter of 12 mm. and a length of 38 mm. instead of the 11 × 25-mm. dimensions of the original basket.

A tablet and capsule were selected to be tested. Pentobarbital tablets were prepared in our laboratories, which allowed control of the ingredient and manufacturing variables. Commercially prepared sodium butabarbital capsules were selected since a previous publication (1) showed that capsules manufactured in an automated manner show less variance than hand-packed capsules.

The pentobarbital tablets were tested in the three different size baskets and showed no clogging of the pores in any case. At least five tablets of the same formulation and hardness were run in each basket. The T_{50} percent values increased in the expected order as the dimensional and pore size of the baskets decreased. The T_{50} values of 10, 14, and 21 min. were found for the bigger basket, regular basket, and smaller pore basket, respectively. In varying the revolutions per minute of the stirring propeller from 60 through 150 for the pentobarbital tablets in the regular basket, a distinct difference can be seen. The T_{50} at 150 and 120 r.p.m. is very close at an average of 2.5 and 3.25 min. Decreasing the revolutions per minute to 90 and to 60 shows a significant reduction and difference, with the T_{50} equal to 7.5 and 14 min., respectively.

A comparison of the dissolution of the sodium butabarbital capsules in the three baskets shows little difference between the bigger and regular baskets, with the T_{50} equal to 26 and 29 min., respectively. The smaller pore basket did show an increase in the T_{50} to 38 min. The difference in the T_{50} in the regular basket as a function of revolutions per minute was small at 150 and 120, producing average times of 15 and 16 min., respectively. Decreases in propeller speed to 90 and 60 r.p.m. showed T_{50}'s of 21 and 30 min., respectively.

In conclusion, the adjustment of basket pore size and propeller revolutions per minute can produce significantly different dissolution profiles, which should be considered when comparing *in vitro* dissolution results from the magnetic basket in quality control or as a means of correlating *in vitro–in vivo* data.

REVIEWS

The Prostaglandins, Volume I. Edited by Peter W. Ramwell. Plenum, New York, NY 10011, 1973. 526 pp. 17 × 25.5 cm. Price $22.50.

Respected scientists have collaborated in this treatise to report on the present status of prostaglandin data and hypotheses in chemistry, physiology, and pharmacology. The chemistry of prostaglandins is presented in a functional manner. The chemical, metabolic, physiological, and pharmacological implications of altering bonds, specific groups, and steroidal configurations on this complex molecule are discussed. Methods of *in vitro* and *in vivo* synthesis of the primary prostaglandins and analogs from various chemicals are described.

Prostaglandins synthetase, its assay, and the hypotheses regarding physiological production of various prostaglandins *in vivo* are discussed. Working hypotheses are presented and defended by data for the physiological role of various prostaglandins in peripheral, central, and autonomic neurotransmission; renal, respiratory, GI, ocular, cardiovascular, lipid, and endocrine homeostasis; and male and female reproductive function. Data and hypotheses for possible roles of various prostaglandins in pathological states such as hypertension, asthma, inflammation, anaphylaxis, glaucoma, ocular trauma, and endocrine disorders are presented.

The possibilities of treating neurological, respiratory, GI, cardiovascular, renal, and lipid diseases with exogenous prostaglandins are explored. Results of using PGE_2 and $PGF_{3\alpha}$ for induction of term labor by the intravenous route and for induction of artificial abortions by the intravenous, subcutaneous, vaginal, extraovular, and intraamniotic routes are presented to demonstrate the practicability of prostaglandins for terminating pregnancy at all stages of gestation. In this rapidly developing field of research and development involving the chemist, physiologist, pharmacologist, and clinician, this volume is valuable to scientists in all of these disciplines in summarizing what often appear to be conflicting data and applying them to hypotheses.

would seem to be the means of achieving this approximation.

To test this hypothesis partially, two new magnetic baskets were built. The first conformed to the original specifications (1) but was made of 16-mesh instead of the original 8-mesh stainless steel wire. The second basket was constructed with 8-mesh wire and had larger dimensions: an inner diameter of 12 mm. and a length of 38 mm. instead of the 11 × 25-mm. dimensions of the original basket.

A tablet and capsule were selected to be tested. Pentobarbital tablets were prepared in our laboratories, which allowed control of the ingredient and manufacturing variables. Commercially prepared sodium butabarbital capsules were selected since a previous publication (1) showed that capsules manufactured in an automated manner show less variance than hand-packed capsules.

The pentobarbital tablets were tested in the three different size baskets and showed no clogging of the pores in any case. At least five tablets of the same formulation and hardness were run in each basket. The T_{50} percent values increased in the expected order as the dimensional and pore size of the baskets decreased. The T_{50} values of 10, 14, and 21 min. were found for the bigger basket, regular basket, and smaller pore basket, respectively. In varying the revolutions per minute of the stirring propeller from 60 through 150 for the pentobarbital tablets in the regular basket, a distinct difference can be seen. The T_{50} at 150 and 120 r.p.m. is very close at an average of 2.5 and 3.25 min. Decreasing the revolutions per minute to 90 and to 60 shows a significant reduction and difference, with the T_{50} equal to 7.5 and 14 min., respectively.

A comparison of the dissolution of the sodium butabarbital capsules in the three baskets shows little difference between the bigger and regular baskets, with the T_{50} equal to 26 and 29 min., respectively. The smaller pore basket did show an increase in the T_{50} to 38 min. The difference in the T_{50} in the regular basket as a function of revolutions per minute was small at 150 and 120, producing average times of 15 and 16 min., respectively. Decreases in propeller speed to 90 and 60 r.p.m. showed T_{50}'s of 21 and 30 min., respectively.

In conclusion, the adjustment of basket pore size and propeller revolutions per minute can produce significantly different dissolution profiles, which should be considered when comparing *in vitro* dissolution results from the magnetic basket in quality control or as a means of correlating *in vitro–in vivo* data.

Liquid Scintillation Counting, Volume 2. Edited by M. A. CROOK, P. JOHNSON, and B. SEALES. Heyden and Son Ltd., New York, N.Y., 1972. 327 pp. 17 × 26 cm. Price $21.50.

"Liquid Scintillation Counting, Volume 2" contains the proceedings of the International Symposium of Liquid Scintillation Counting, held at Brighton, England, in September 1971. The papers presented at that symposium are, in general, concerned with the biomedical applications of liquid scintillation counting techniques. There are 27 papers included in the book; four on Basic Theory of the Chemistry and Physics of Scintillators and Scintillation Counting; four on Historical Developments and Miscellaneous Problems; six on Methods of Sample Preparation of Inorganic Materials, Including Cerenkov Counting; six on Methods of Sample Preparation of Organic Materials Including Biological Systems; and seven papers on Data Processing.

This book, for the most part, presents material that deals with day-to-day problems associated with the liquid scintillation technique and should be a welcome addition to the library of users of internal liquid scintillation counters. Rapkin's article on the "History of the Development of the Modern Liquid Scintillation Counter" was very interesting and gives much information that will be helpful to potential purchasers of liquid scintillation counters.

Two other articles of general interest should be mentioned. Birks and Poullis reevaluated a wide range of scintillation solutions as to their relative pulse height under conditions which correspond closely to conditions used in current internal scintillation counting. Although carbon tetrachloride was the only quenching agent involved in their investigations, the article contains information as to the preferred solvent system for use depending on the degree of quenching present in the system. Scales presents information on undesirable luminescence in liquid scintillation samples of biological origin. He discusses methods of elimination of luminescence and points out the need for careful sample preparation technique.

For the most part, articles in the book deal with specific problems of biomedical interest and problems associated with data processing. On the whole, the book contains information which will lead to the solution of many day-to-day problems; information which, for the most part, is very difficult to find in other sources.

A Guide to Drug Eruptions. By W. BRUINSMA. American Elsevier, 52 Vanderbilt Ave., New York, NY 10017, 1973. viii + 103 pp. 14.5 × 22.5 cm. Price $9.95.

This guide's stated purpose is "...to give information on clinical data which might be helpful in locating the responsible drug...." The objective has been achieved in part. However, the author is somewhat a victim of a problem identified in the introduction, namely, "Exact knowledge of incidence figures even for the common type of reaction to drugs is rarely available. For the great majority of drugs these data are widely scattered and difficult to obtain."

The resulting compilation is somewhat superficial. However, considering that the subject of skin eruptions is complex, the data are difficult to obtain, and reporting systems are poor, the book does serve as a useful departure point and as a *guide* for health-care practitioners having need of this kind of information.

Drugs: Annotated Bibliography and Guide. By A. M. AJAMI. G. K. Hall & Co., 70 Lincoln St., Boston MA 02111, 1973. xxiv + 205 pp. 16 × 24 cm. Price $16.50.

The title of this publication is somewhat misleading. The thrust of the book is abuse drugs and the drug culture rather than the more general area indicated by the title.

Abstracts of 539 articles divided into five sections are given. The bibliography was developed as part of a natural science college course and, as such, articles were selected to reflect various positions on numerous aspects of drug abuse. Rather than focus on one thesis, the articles were selected to provide a broad overview of uses, opinions, and considerations related to drugs.

How to Divide Medical Words. By RICHARD V. LEE and DORIS J. HOFER. Southern Illinois University Press, Carbondale, IL 62901, 1972. 229 pp. 11 × 15.5 cm. Price $4.50.

Divided into two sections, this reference books provides a listing of the correct spelling of a number of medical words and a substantially longer listing of the correct division of such words. While the correct spelling is available in a number of sources, finding the correct way to divide medical and pharmaceutical terminology sometimes can be difficult. Since it is priced reasonably, this book should be a useful addition to the reference sources available to persons involved with the preparation of technical publications.

Biosynthesis, A Specialist Periodical Report. T. A. GEISSMAN, Senior Reporter. The Chemical Society, Burlington House, London WIV OBN, England, 1972. 249 pp. 13 × 21.5 cm. Price £ 6.50.

This is the first volume of a series of the well-regarded Specialist Periodical Reports dealing with the synthesis of organic compounds in living organisms. An introductory chapter on the methodology of biosynthetic experimentation provides a general background to the specific topics discussed in the following sections. The four specific sections include the biosynthesis of terpenoid compounds; triterpenes, steroids, and carotenoids; phenolic compounds; and alkaloids.

This volume covers the literature of 1970 and 1971, with reference to earlier work where necessary for clarity.

Scales presents information on undesirable luminescence in liquid scintillation samples of biological origin. He discusses methods of elimination of luminescence and points out the need for careful sample preparation technique.

For the most part, articles in the book deal with specific problems of biomedical interest and problems associated with data processing. On the whole, the book contains information which will lead to the solution of many day-to-day problems; information which, for the most part, is very difficult to find in other sources.

A Guide to Drug Eruptions. By W. BRUINSMA. American Elsevier, 52 Vanderbilt Ave., New York, NY 10017, 1973. viii + 103 pp. 14.5 × 22.5 cm. Price $9.95.

This guide's stated purpose is "...to give information on clinical data which might be helpful in locating the responsible drug...." The objective has been achieved in part. However, the author is somewhat a victim of a problem identified in the introduction, namely, "Exact knowledge of incidence figures even for the common type of reaction to drugs is rarely available. For the great majority of drugs these data are widely scattered and difficult to obtain."

The resulting compilation is somewhat superficial. However, considering that the subject of skin eruptions is complex, the data are difficult to obtain, and reporting systems are poor, the book does serve as a useful departure point and as a *guide* for health-care practitioners having need of this kind of information.

Drugs: Annotated Bibliography and Guide. By A. M. AJAMI. G. K. Hall & Co., 70 Lincoln St., Boston MA 02111, 1973. xxiv + 205 pp. 16 × 24 cm. Price $16.50.

The title of this publication is somewhat misleading. The thrust of the book is abuse drugs and the drug culture rather than the more general area indicated by the title.

Abstracts of 539 articles divided into five sections are given. The bibliography was developed as part of a natural science college course and, as such, articles were selected to reflect various positions on numerous aspects of drug abuse. Rather than focus on one thesis, the articles were selected to provide a broad overview of uses, opinions, and considerations related to drugs.

How to Divide Medical Words. By RICHARD V. LEE and DORIS J. HOFER. Southern Illinois University Press, Carbondale, IL 62901, 1972. 229 pp. 11 × 15.5 cm. Price $4.50.

Divided into two sections, this reference books provides a listing of the correct spelling of a number of medical words and a substantially longer listing of the correct division of such words. While the correct spelling is available in a number of sources, finding the correct way to divide medical and pharmaceutical terminology sometimes can be difficult. Since it is priced reasonably, this book should be a useful addition to the reference sources available to persons involved with the preparation of technical publications.

Biosynthesis, A Specialist Periodical Report. T. A. GEISSMAN, Senior Reporter. The Chemical Society, Burlington House, London WIV OBN, England, 1972. 249 pp. 13 × 21.5 cm. Price £ 6.50.

This is the first volume of a series of the well-regarded Specialist Periodical Reports dealing with the synthesis of organic compounds in living organisms. An introductory chapter on the methodology of biosynthetic experimentation provides a general background to the specific topics discussed in the following sections. The four specific sections include the biosynthesis of terpenoid compounds; triterpenes, steroids, and carotenoids; phenolic compounds; and alkaloids.

This volume covers the literature of 1970 and 1971, with reference to earlier work where necessary for clarity.

The Child With Down's Syndrome (Mongolism). By DAVID W. SMITH and ANN ASPER WILSON. Saunders, West Washington Square, Philadelphia, PA 19105, 1973. 106 pp. 18 × 26 cm. Price $5.75.

This publication was designed for parents, physicians, and persons concerned with the education and care of the child with Down's syndrome, frequently referred to as mongolism. The causes, characteristics, and acceptance of the Down's syndrome-affected child are emphasized.

The discussions are understandable, straightforward, and frank. For instance, in a discussion of the serious physical conditions that

Liquid Scintillation Counting, Volume 2. Edited by M. A. CROOK, P. JOHNSON, and B. SEALES. Heyden and Son Ltd., New York, N.Y., 1972. 327 pp. 17 × 26 cm. Price $21.50.

"Liquid Scintillation Counting, Volume 2" contains the proceedings of the International Symposium of Liquid Scintillation Counting, held at Brighton, England, in September 1971. The papers presented at that symposium are, in general, concerned with the biomedical applications of liquid scintillation counting techniques. There are 27 papers included in the book; four on Basic Theory of the Chemistry and Physics of Scintillators and Scintillation Counting; four on Historical Developments and Miscellaneous Problems; six on Methods of Sample Preparation of Inorganic Materials, Including Cerenkov Counting; six on Methods of Sample Preparation of Organic Materials Including Biological Systems; and seven papers on Data Processing.

This book, for the most part, presents material that deals with day-to-day problems associated with the liquid scintillation technique and should be a welcome addition to the library of users of internal liquid scintillation counters. Rapkin's article on the "History of the Development of the Modern Liquid Scintillation Counter" was very interesting and gives much information that will be helpful to potential purchasers of liquid scintillation counters.

Two other articles of general interest should be mentioned. Birks and Poullis reevaluated a wide range of scintillation solutions as to their relative pulse height under conditions which correspond closely to conditions used in current internal scintillation counting. Although carbon tetrachloride was the only quenching agent involved in their investigations, the article contains information as to the preferred solvent system for use depending on the degree of quenching present in the system. Scales presents information on undesirable luminescence in liquid scintillation samples of biological origin. He discusses methods of elimination of luminescence and points out the need for careful sample preparation technique.

For the most part, articles in the book deal with specific problems of biomedical interest and problems associated with data processing. On the whole, the book contains information which will lead to the solution of many day-to-day problems; information which, for the most part, is very difficult to find in other sources.

The Child With Down's Syndrome (Mongolism). By DAVID W. SMITH and ANN ASPER WILSON. Saunders, West Washington Square, Philadelphia, PA 19105, 1973. 106 pp. 18 × 26 cm. Price $5.75.

This publication was designed for parents, physicians, and persons concerned with the education and care of the child with Down's syndrome, frequently referred to as mongolism. The causes, characteristics, and acceptance of the Down's syndrome-affected child are emphasized.

The discussions are understandable, straightforward, and frank. For instance, in a discussion of the serious physical conditions that

may accompany Down's syndrome, *e.g.*, intestinal blockage and defective heart development, it is emphasized that decisions for corrective measures must be left to the parents and that they have the right to refuse such measures.

The genetic "mistake" which leads to Down's syndrome is discussed in detail and is illustrated very effectively. This and all discussions should be easily understood without any scientific or technical background.

A large portion of the book is concerned with the physical, mental, and social characteristics of Down's syndrome. While it is obviously impossible to make predictions about a particular child, general patterns of development are discussed, accompanied by graphs. It is emphasized that seeking professional assistance as soon as possible allows for the greatest assurance that a Down's syndrome child will achieve the highest level of development. Results of research and programs in this area have indicated that attention, education, and therapy between the age of 3 and 5 apparently have a substantial effect on the child's future development. This is perhaps related to motivation; between 3 and 5, the child can master certain motor and learning skills. After that age, the Down's child begins to lose ground on normal children and may be subject to a sense of frustration.

Overall, this book is readable and informative without overwhelming the reader with peripheral information.

. . . It is not to mere clinical experience that we must look for a revelation of the laws of disease. The laws of chemistry were not discovered in blazing fires or crumbling rocks; the laws of hydrostatics and hydraulics were not revealed in torrents, tides, or ocean currents, nor those of pneumatics and electricity in winds, whirlwinds, and thunderstorms; much less could it be rationally expected that the laws of pathology should be discovered amid the much greater complexity and more multitudinous conflicts of elements presented to the physician at the bedside of a diseased or dying patient. It is in the laboratory, and by artificially contrived experiments that the clue has ever been spun and the torch lighted to guide through the labyrinths which hide the arcana of nature. . . .

R. Cresson Stiles (1865)

Much of our present knowledge on the biochemical and morphological basis of the secretory process derives from studies on the adrenal medulla. The usefulness of this organ as a model for investigating both hormonal and neuronal release mechanisms was reviewed by Stjärne (1). The isolated perfused bovine adrenal gland has been more extensively used than adrenals of other species. Serrão and Da Costa (2) demonstrated that the cytological details as well as the catecholamine content of the isolated bovine adrenal medulla are well preserved even after prolonged perfusion (1–2 hr.) with physiological solutions. Since preservation of cellular structures in isolated organs is an indispensable condition for pharmacological investigations, the extensive use of the bovine adrenal gland as a model for studying the various aspects of neuroendocrine secretion seems justified.

Mammals are unique among vertebrates in that most chromaffin cells in the adult are confined within the adrenal medulla, which in turn is encapsulated by the adrenal cortex. The adrenal medulla derives from the neuroectoderm and is a neuroendocrine transducer, secreting its products in response to a neural input primarily from the preganglionic cholinergic fibers of the greater thoracic splanchnic nerves. Every chromaffin cell is said to be innervated (3). The adrenal

medulla has a rich dual blood supply, receiving blood that has drained the adrenal cortex and is rich in adrenal cortical steroids in addition to having its own direct arterial blood supply. Each chromaffin cell is said to be oriented with one end abutting on an arterial capillary and the other on a veinule (3), thus conveniently receiving biosynthetic precursors and releasing end-products, respectively. The anatomical relationship of the adrenal cortex and medulla is not without physiological significance. The role of the adrenocortical steroids in induction of medullary protein and phenethanolamine-*N*-methyltransferase synthesis and in determination of the relative distribution and anatomical disposition of epinephrine- and norepinephrine-containing cells of the medulla (4) was thoroughly reviewed by Pohorecky and Wurtman (5) and Wurtman *et al.* (6). However, although the cortex plays a significant regulatory role on the biosynthetic activity of the adrenal chromaffin cells, it appears to exert no immediate influence on the secretory process of catecholamines from the adrenal medulla (7, 8).

The details of the fine structure of the adrenal chromaffin cell of various species were described by several authors (9–22). The cytoplasm of the chromaffin cell contains a large number of what appear to be membrane-bound granules, 1000–3000 Å in diameter (23). The granules are reportedly bound by a unit membrane approximately 75 Å thick (4, 13), showing a trilaminar appearance (19). Fixation with glutaraldehyde and silver methenamine (10) results in the differential staining of three types of adrenal medullary cells: norepinephrine-containing cells showing black granules, epinephrine-containing cells showing light-gray granules, and a third cell type intermediate in appearance between epinephrine and norepinephrine cells. There is also evidence that epinephrine and norepinephrine granules may coexist within the same chromaffin cell, along with "precursor granules" whose content was chemically identified to be dopamine (9). The origin of the so-called chromaffin granules is a matter of conjecture. Small immature granules are said to be observed in the region of the Golgi apparatus (23), and "prosecretory" granules are reported to have been seen within the Golgi complex (17, 20); it has been suggested that the Golgi apparatus is directly involved in the formation of the chromaffin granules (9).

The adrenal medulla is the ancestral homolog of autonomic ganglia. The extensive investigations of Marley and Paton (24) and Marley and Prout (25) elucidated much of our present knowledge of the physiology and pharmacology of the splanchnic–adrenal medullary junction and the electrical properties of the chromaffin cell membrane. These authors studied the response of the adrenal chromaffin cells to nervous excitation and reported on properties such as threshold to nerve excitation, fatigue, spatial and temporal recruitment, and the effect of drugs (*e.g.*, ganglionic blocking agents, eserine, and cocaine) on these parameters (24, 25). Douglas *et al.* (26, 27) further extended these observations by studying the effect of medullary secretagogues (*e.g.*, acetylcholine, nicotine, pilocarpine, histamine, 5-hydroxytryptamine, angiotensin, and bradykinin) and antagonists (*e.g.*, atropine and hexamethonium) on the membrane potential of adrenal chromaffin cells, as well as the influence of the ionic environment on this parameter. These studies demonstrated the presence of both nicotinic and muscarinic receptors on the adrenal chromaffin cell membrane (26).

THEORIES OF CATECHOLAMINE RELEASE FROM ADRENAL MEDULLA[1]

The catecholamine hormones of the adrenal medulla are stored in high concentrations in the gland. In the rat, the adrenal medulla contains as much stored epinephrine as is secreted in 7 days (28, 29). The biochemical basis underlying the storage mechanism of the catecholamines was reviewed elsewhere (29–31). In brief, the catecholamines are believed to be bound in a non-diffusible form as a complex with adenosine triphosphate (ATP) and protein (32) or with ATP, calcium, magnesium, and RNA (33). The high concentration of catecholamines in the granules is believed to be maintained by an active uptake of amines across the membrane of the granules, which counteracts the loss of amines that occurs by outward diffusion (29).

In the past decade and particularly with the advent of the electron microscope and the introduction of biochemical techniques of subcellular fractionation, considerable progress has been made toward the understanding of the cellular storage of catecholamines and the manner of their release from the adrenal medullary cell (34–36). Several different mechanisms have been proposed to account for secretion from the adrenal medulla at a cellular level. As early as 1918, Cramer (37) proposed that the adrenal medullary granules were released as a whole from the adrenal gland (38). Round opaque particles, 300–700 Å in diameter and resembling chromaffin granules in appearance, were demonstrated in the canaliculi and intercellular spaces between the chromaffin cells of the adrenal medulla (19). In some cases where the particles were present at the free cell surface, small groove-like impressions occurred in the plasma membrane of the chromaffin cell (19). Similar findings of extracellular synaptic vesicles in the mouse heart were reported (39), as well as groove-like bays in the axolemma which were proposed to serve as points of exit of the granules from the nerve ending. Granule

[1] *Added in press*—A role for cyclic AMP in catecholamine secretion from the adrenal medulla was recently suggested (A. M. Poisner, *3rd Int. Catecholamine Symp.*, Strasbourg, France, 1973). Three of the criteria for second messenger status [E. W. Sutherland, G. A. Robison, and R. W. Butcher, *Circulation*, **37**, 279(1968)] have been met for cyclic AMP in adrenal medullary secretion: (*a*) cyclic AMP is present in the adrenal medulla in high concentrations and its level increases when secretion is stimulated *in vivo* [A. Guidotti and E. Costa, *5th Int. Congr. Pharmacol.*, **1972**, Abstract 541; *Fed. Proc.*, **31**, Abstract 1923(1972)]; (*b*) cyclic AMP and dibutyryl cyclic AMP can initiate catecholamine release from the adrenal medulla [M. J. Peach, *Proc. Nat. Acad. Sci. USA*, **69**, 834(1972)]; and (*c*) phosphodiesterase inhibitors, such as theophylline, which raise levels of cyclic AMP also cause catecholamine secretion from the adrenal medulla [M. J. Peach, *Proc. Nat. Acad. Sci. USA*, **69**, 834(1972); A. M. Poisner, *Biochem. Pharmacol.*, **22**, 469 (1973)]. Recent evidence also was presented indicating that cyclic AMP is involved in the release of norepinephrine from sympathetic nerve endings [G. F. Wooten, N. B. Thoa, I. J. Kopin, and J. Axelrod, *Mol. Pharmacol.*, **9**, 178(1973)]. The means by which cyclic AMP can initiate or mediate adrenal catecholamine secretion include mobilization of intracellular calcium or activation of protein kinases which may phosphorylate critical cell components, such as secretory granules, plasma membrane, or microtubules (A. M. Poisner, *3rd Int. Catecholamine Symp.*, Strasbourg, France, 1973), or chemical constituents of these structures, such as adrenal actomyosin or the microtubule protein, tubulin, recently identified in the adrenal medulla [D. A. Redburn, A. M. Poisner, and F. E. Samson, Jr., *Brain Res.*, **44**, 615(1972); S. L. Twomey and A. M. Poisner, *ibid.*, **46**, 341(1972)].

extrusion from rat anterior pituitary cells following injection of leutinizing hormone-releasing factor was also recently demonstrated (40). Biochemical data do not support the theory of release of intact granules nor similar suggestions of apocrine or holocrine secretion from the adrenal medulla (41, 42), as will become evident from the ensuing discussion.

Based on cell fractionation studies, Hillarp (43) proposed the existence of at least three different pools of catecholamines in the adrenal chromaffin cell. One pool was the chromaffin granule which contained catecholamines in association with ATP with a molar ratio of 4:1. This ratio suggested that ATP served as the anion paired with the basic catecholamines, forming a complex which is an integral part of the intragranular mechanism of catecholamine storage (30). The second pool consisted of granules in which catecholamines were stored without ATP; the third pool consisted of the "free" cytoplasmic amines which, together with the pool of amines in the granules lacking ATP, comprised about 20% of all the catecholamines in the chromaffin cell, an amount that can sustain secretory activity for a prolonged time (44). Since ATPase activity was present in the chromaffin granule fraction (45), Hillarp (45) and Hillarp *et al.* (46) suggested that when the chromaffin cell is stimulated, the ATPase associated with the chromaffin granules may be activated in some way, enabling it to attack the ATP of the catecholamine storage complex, thus freeing the amines which would then diffuse or be transported out of the granules, into the cytoplasm, and ultimately out of the cell.

Blaschko and Welch (34) had earlier speculated that liberation of acetylcholine at the splanchnic–adrenal medullary junction might result in an increased permeability of the membrane of the chromaffin cell that would lead to a loss of "free" amines present in the cytoplasmic sap and that the role of the chromaffin granules was to replenish the cytoplasmic pool of catecholamines released during the secretory activity. In support of Hillarp's (45) suggestion of a critical role of granular ATP splitting in the release of catecholamines from their granules is the finding that ATP metabolites appeared in the adrenal effluent from stimulated glands (47, 48), and the observation that acetylcholine evoked catecholamine secretion by promoting calcium influx into the chromaffin cell (49)—a cation known to be an activator of certain ATPases and, consequently, to play a critical role in excitation–contraction coupling in muscle (50, 51). However, this hypothesis of *intracellular* release of catecholamines from the chromaffin granules followed by diffusion of the hormones to the cell exterior lost some of its credibility when Douglas *et al.* (52) noted that ATP metabolites present in the venous effluent from the adrenal were attributable to hydrolysis of ATP by endothelial enzymes and that, under appropriate experimental conditions, ATP is extruded unhydrolyzed to the cell exterior during catecholamine release from the gland (53). These observations led to the conclusion that splitting of intragranular ATP is not a critical step in the secretory process. Direct evidence against the hypothesis of intracellular release of catecholamines was provided by the finding that the secretion of the soluble contents of the chromaffin granule, including the soluble intragranular protein chromogranin A (effective hydrodynamic radius approximately 62 Å), took place without simultaneous secretion of the cytoplasmic enzyme lactate dehydrogenase (hydrodynamic radius approximately 37 Å) (29, 54).

Although it is now generally recognized that the free cytoplasmic catecholamine pool demonstrated in cell fractionation studies results largely as an artifact of the homogenization procedure (29), and although the hypothesis of intracellular release of catecholamines has largely been superseded by other hypotheses, certain drugs such as acetaldehyde (55), dextroamphetamine (56, 57), *l*-amphetamine (58), and tyramine (58) are capable of releasing adrenal catecholamines from their storage sites into the cytoplasm of the chromaffin cell, from where the amines may diffuse to the extracellular space. Furthermore, spontaneous (resting) secretion of adrenal catecholamines is believed to utilize, at least in part, the intracellular release mechanism (58).

Exocytosis Hypothesis—This hypothesis was first proposed by De Robertis and Vaz Ferreira (18) in 1957 to explain their observations on structural changes in the adrenal medulla following stimulation of the splanchnic nerves. It was described later by De Robertis (59):

> *When the gland is stimulated through the splanchnic nerve the first changes that occur in the catecholamine-containing vesicles (or granules) are the following: the granule attaches to the plasma membrane and it swells; at this moment there is no clear distinction between the clear zone on the outside and the dense granule inside; then there is a decrease in the amount of material contained in the granule. The material flows out but the membrane of the granule remains within the adrenal cell.*

This type of secretion was initially called "reverse pinocytosis" (18) but, more recently, the term "exocytosis" was introduced (60). Although this hypothesis received additional morphological support (12, 17, 19, 22, 61–65), it was disclaimed by others (66, 67). Electron microscopic evidence for exocytosis also has been reported for glandular tissue containing membrane-bound secretory granules other than the adrenal medulla (*e.g.*, 64, 68–74).

Support for the exocytosis hypothesis derives heavily from biochemical evidence. That secretion from the adrenal medulla may take place by exocytosis is based mainly on the finding that several water-soluble constituents of the catecholamine storage granules appear simultaneously in the effluent from the gland. Thus, catecholamines, adenine nucleotides (48), the specific soluble protein chromogranin (75, 76), and soluble dopamine-β-hydroxylase (77) have been shown to be released from the adrenal medulla by various stimuli, sometimes in the same proportions in which they occur in the granules. Furthermore, neither water-insoluble constituents of the granules, such as cholesterol and phospholipids (78), nor cytoplasmic material, such as tyrosine hydroxylase, phenethanolamine-*N*-methyltransferase (77), or lactate dehydrogenase (29, 54), accompany the catecholamines secreted from the adrenal

medullary cells upon stimulation. The presence in the adrenal medullary chromaffin granule of a high content of lysolecithin (29, 79), a potent lytic agent (29, 80), led to the postulate that this lipid participates in the fusion of the secretory granule to the plasma membrane of the chromaffin cell during exocytosis (80).

The role of calcium ions in stimulus–secretion coupling will be discussed in a later section. However, one finding warrants mentioning since it provides a plausible basis for the explanation of the molecular mechanisms underlying exocytosis. Calcium appears to be almost universally involved as the link that couples excitation and secretion (81). Quarles and Folch-Pi (82) studied the effect of calcium on the distribution of gangliosides in an organic–aqueous biphasic system. They showed that when calcium is in the upper organic phase at concentrations below 5 m*M* or above 160 m*M*, all of the ganglioside distributes in the organic phase. At calcium concentrations between 5 and 160 m*M*, the ganglioside partitions to the aqueous phase. When contaminated with protein, the ganglioside was induced by calcium to localize at the interface of the aqueous–organic phases. Since the chromaffin granules are composed of ganglioside and protein (29) and since the chromaffin cell consists of an aqueous (cytoplasm) phase and an organic (lipid and protein) phase (the plasma membrane), Simpson (83) proposed a similar situation to exist *in vivo*. Accordingly, a depolarizing stimulus to the chromaffin cell membrane would lead to an influx of calcium into the cell (49), resulting in a calcium concentration at the inner aspect of the cell membrane that is high enough to allow the collision between the granule (ganglioside) and the plasma membrane (organic phase) to persist, particularly since protein is present in both the granule and the cell membrane. Calcium could then activate membrane phospholipase A or granule lysolecithin, thus facilitating the fusion of the granule to the plasma membrane (79). Simpson (83) further proposed that when the stimulus to the chromaffin cell is terminated, the calcium concentration at the inner aspect of the plasma membrane of the chromaffin cell starts to decline; the granule (ganglioside) would repartition to the aqueous (cytoplasmic) phase and secretion would dwindle. To explain resting (spontaneous) secretion, Simpson (83) postulated that the very low calcium concentration found at the inner aspect of the chromaffin cell membrane at rest would increase the effectiveness of ganglioside (granule)–lipid (cell membrane) contact, in an analogous way to the *in vitro* situation described by Quarles and Folch-Pi (82).

The fate of the membranes of the chromaffin granules that remain in the chromaffin cell following discharge of their catecholamine content (64, 65, 84, 85) is a matter for conjecture. Although empty ghost granules have been seen electron microscopically in sections of medullary tissue from stimulated adrenal glands (59), it is not known whether these membranes become recharged with catecholamines, protein, ATP, and cations or whether they are phagocytized by the intracellular autophagic vacuoles and become broken down by lysosomal enzymes (29, 65). Evidence has been presented (64, 65, 71–74) for the adrenal chromaffin cells as well as for the adenohypophyseal and neurohypophyseal cells that the granule membrane incorporated into the cell surface during exocytosis is removed by a process of vesiculation resembling micropinocytosis. In this process the exocytotic pits pinch off to form intracellular microvesicles, thus conserving not only the area of the plasmalemma but also its chemical characteristics associated with permeability, excitability, and the receptor function (64, 65). Kopin and Silberstein (86) suggested that the large norepinephrine vesicles in adrenergic neurons discharge their contents when the nerve ending is depolarized; once their soluble protein contents are exhausted, they may be transformed into the smaller storage vesicles and be concerned primarily with synthesis and storage of the transmitter reserve.

Although the exocytosis hypothesis for the release of neurotransmitters, hormones, and other macromolecules (80, 81, 83) has received considerable biochemical support, it does not explain a number of observations. Exocytosis certainly cannot be the mechanism by which the secretory products of the adrenal cortex, the fetal pancreas, or the parietal cells of the stomach are released, since the secretory products of these structures are not sequestered in membrane-bound granules (87–89). Furthermore, the exocytosis hypothesis cannot possibly account for the explosive and almost instantaneous release of transmitters, hormones, or macromolecules upon stimulation of cells containing these secretory products. Thus, catecholamines are released from the adrenal medulla within 1–2 sec. of splanchnic nerve stimulation (48), and epinephrine releases amylase from its storage granules in the parotid gland in less than 10 sec. (90). Likewise, insulin is released very rapidly from the pancreas following glucose stimulation (91). Schramm (80) emphasized that fusion of the zymogen granule with the cell membrane cannot explain the *rate* of enzyme secretion, and no experimental evidence indicates any temporal relationship between fusion, cleavage, and healing of the plasma membrane during exocytosis (64, 65, 71–74) and the rate of hormone, enzyme, or neurotransmitter secretion. Finally, the exocytosis hypothesis cannot explain the findings of Hubbard and Kwanbunbumpen (92) who demonstrated that there was no electron microscopic evidence of an increase in the number of discharging vesicles fused to the axolemma under conditions of increased quantal release of transmitter at the neuromuscular junction of the rat diaphragm.

Microtubule Hypothesis—The many serious and fundamental shortcomings of the exocytosis hypothesis prompted Whittaker (93–95) to propose the possible existence of a complex interconnecting system of tubules within secretory cells which may facilitate the discharge of secretory products to the cell exterior. According to Whittaker (95), "there might well be an intercommunicating system of fine tubules—hard to see by normal histological methods—composed of protein and another macromolecule that could open or close in response to ionic changes induced by action potentials." Such a system of microtubules would provide a possible pathway for release of all types of secretions, including the nongranule-bound secretions of the parietal cells, the adrenal cortex, and the fetal rabbit pancreas. In

addition, if the secretory tubules were to be considered as possessing a dynamic function as well as a structural one, they would provide a basis for the interpretation of the rate of egress of secretory products from secretory cells—perhaps the major shortcoming of the exocytosis hypothesis.

The possibility that secretion may take place within a structured environment of secretory tubules is supported by morphological observations. In negative staining, fine interconnections between isolated synaptic vesicles were demonstrated by Whittaker (93). Amsterdam and Schramm (96) showed that isolated zymogen granules are sometimes linked by thin tubules not visible in conventional sections of whole cells when examined under the electron microscope. Tubular connections may also account for the presynaptic projections and fine filaments sometimes seen in electron micrographs of nerve tissue (97). The existence of narrow tubules connecting the secretory granules to the plasma membrane was also proposed by Gray (97) and Sandborn (98). Electron microscopic evidence for the existence of neurotubules in axons was presented (98); De Iraldi and De Robertis (99) showed that these neurotubules appear to originate in the region of the Golgi complex in the soma and function in the rapid transport of material down the axon. Similar findings were reported by Davison (100). According to von Euler (101), "electron microscope pictures often show granules arranged in sequences, in rows with a kind of connecting tube or link between them" and that "practically every good picture shows at least a few granules which have such a connection between them." Von Euler (101) also observed "chains of two or three vesicles" in negatively stained preparations of suspensions of granules.

Kopin and Silberstein (86) described a situation in adrenergic neurons in which the secretory vesicles would move along, rather than within, microtubular structures which would serve as tracks to channel the vesicles toward the cell membrane of the terminal varicosities. In the adrenal cortex, there is evidence that the smooth endoplasmic reticulum forms an anastamosing system of tubular elements which plays a role in the extrusion of steroids to the cell exterior (88). Tubular connections running to the surface of the cell have been proposed to exist in cholinergic nerves (94), mast cells (102), and β-cells of the pancreas (91). The parietal cell of the stomach shows secretory canaliculi forming a sinuous tubular channel which opens into the lumen of the gastric gland (87). Furthermore, a system of cytoplasmic tubules, which is sometimes continuous with the canaliculus, has been identified in these cells (87).

Biochemical evidence for the existence of a microtubular secretory apparatus within secretory cells is rapidly accumulating, particularly since the introduction of colchicine, the vinca alkaloids, and cytochalasin-B as drug tools for the study of cell movement and intracellular transport systems. Colchicine binds specifically to microtubular protein (103), depolymerizes the microtubules of mitotic spindles, thus arresting mitosis, and unites with the protein subunits of neurotubules, causing a disruption of their organization (104). Similar effects were reported for the vinca alkaloids (105, 106). Vinblastine-induced precipitation of microtubular protein was reported by Marantz *et al.* (107). Cytochalasin-B is known to destroy neurofilaments specifically and to inhibit a wide variety of cellular movements, including changes in cell shape during differentiation and development (108). Cytochalasin-B was shown to interact with actomyosin from rabbit striated muscle, causing a decrease in viscosity of the actomyosin and an inhibition of actin-induced activation of heavy meromyosin ATPase activity by direct interaction with actin (109).

Reports are increasing on the inhibitory effects of colchicine, vinblastine, vincristine, and cytochalasin-B on secretory activity in secretory cells—a property invariably attributed to their disrupting effect on microtubules and microfilaments. Thus, colchicine and vinblastine inhibit the transport of amine storage granules in adrenergic neurons (110) and inhibit the release of norepinephrine and dopamine-β-hydroxylase from sympathetic nerves (111), a property also shared by cytochalasin-B (111). Release of catecholamines from the bovine adrenal medulla is inhibited by colchicine, vinblastine, and vincristine (112). Vincristine also was shown to inhibit the release of growth hormone and prolactin from the pituitary gland (113). Insulin secretion from the pancreas is blocked by colchicine (91), which also blocks thyroxine and iodine secretion from the thyroid gland (114, 115). Histamine release from mast cells (116) and leukocytes (117) and release of lysosomal hydrolases by phagocytes (118) are also inhibited by colchicine. Degranulation associated with phagocytosis (119) and melanin granule movement in melanophores (120) are likewise inhibited by colchicine. Cytochalasin-B inhibits latex-induced or zymosan-induced phagocytic activity in leukocytes, as well as phagocytosis of bacteria by polymorphonuclear leukocytes (121). Vincristine frequently produces signs of skeletal and smooth muscle toxicity consistent with diminished transmitter release (122).

In all of these systems, translocation of the secretory product or granule or vesicle movement appears to involve a microtubule system (123, 124) sensitive to the disrupting effect of colchicine, the vinca alkaloids, or cytochalasin-B—agents that labilize microtubular structures. On the other hand, the microtubule stabilizer deuterium oxide (125–127) has been shown to potentiate nicotine-induced catecholamine release from the adrenal gland (112) and histamine release from mast cells induced by compound 48/80 (116).

The proposal by Poisner and Bernstein (112) that the inhibitory effect of colchicine and vinblastine on evoked adrenal catecholamine secretion is due to disruption of secretory microtubules was contested by Trifaró *et al.* (128) and Douglas and Sorimachi (129, 130). They claimed that the inhibitory action of the alkaloids was attributable to an anticholinergic effect, since these agents inhibited the acetylcholine-induced release of catecholamines but did not block secretion evoked by high potassium concentrations (128–130). However, acetylcholine and potassium may act by different mechanisms to evoke catecholamine release from the adrenal medulla, as evidenced by the findings that lanthanum (131) and certain local anesthetics (132) block the secretory effect of acetylcholine more effectively than that of potassium. Furthermore, it is well documented that

colchicine can block the release of secretory products induced by noncholinergic stimuli in various tissues. For example, *in vitro* release of adrenocorticotropin from the adenohypophysis induced by high potassium concentration is blocked by colchicine (133). Similarly, glucose-induced release of insulin from isolated pancreatic islet β-cells is also blocked by colchicine (91). This alkaloid also blocks release of thyroxine and iodine from the thyroid induced by either thyroid-stimulating hormone or dibutyryl cyclic adenosine-3′,5′-monophosphate (cyclic AMP) by binding to a 6S colchicine-binding protein in the soluble fraction of homogenates (114), which is similar to the protein identified in other systems as a microtubular subunit (103, 134–138).

Recent investigations disclosed the presence of an actomyosin-like contractile protein in a number of secretory cells. Thus, a Mg^{+2}- or Ca^{+2}-activated ATPase was identified in isolated synaptic vesicles of rat brain (139, 140), and a similar ATPase was isolated from whole brain of the rat and cat (141) and characterized as having properties similar to those of muscle actomyosin and exhibiting an affinity for colchicine binding (142). A contractile protein was also isolated from human platelets (143) which was postulated to play a role in release of histamine and serotonin from these cells. Poisner (144) demonstrated the existence of an actomyosin-like protein in the bovine adrenal medulla, which could participate in the secretory mechanism of catecholamines.

Such findings have generated a number of theories relating the presence of actomyosin-like activity, the existence of microtubules, and the secretory process (78, 91, 104, 112, 114, 145). Poisner and Bernstein (112) crystallized these theories into a unitary thesis which postulates that "microtubules assist in the transport of secretory granules to the cell surface by a mechanism involving mechanicochemical transduction comparable to the contraction of actomyosin, and the final discharge mechanism also includes a contractile process with an actomyosin-like protein in the granule membrane, perhaps with the microtubules serving to orient the membranes at the surface to permit the active ejection of secretory product."

In view of the almost universal requirement for calcium in release of secretory products (81 and to be discussed later), Whittaker (94), referring to the possible role of microtubules in secretion, postulated that "if the walls of such tubules were made up of a macromolecule which changed configuration in the presence of calcium ions in such a way as to enlarge the lumen of the tubules, a basis might be provided for the well known essential role of calcium ions in excitation-secretion coupling." Because of the similarities between microtubule protein and actin (104), it is entirely possible that the "macromolecules" postulated by Whittaker (94) may actually constitute the contractile actomyosin isolated from secretory cells (139–144).

Rahwan (146) and Rahwan *et al.*[2] recently demonstrated by electron microscopy the existence of tubular connections between catecholamine granules in sections of mouse adrenal medulla. These authors advanced a theory for secretion from the adrenal medulla based on the postulate that the hormones may exist in the form of intratubular *droplets* within the chromaffin cell. A stimulus to the adrenal chromaffin cell would lead to an influx of calcium from the extracellular space (81) or translocation of calcium from intracellular pools (57) into the cytoplasm. The free intracellular calcium, either as ionic calcium or as a complex with intracellular phosphate (147), would activate an actomyosin-like protein in the contractile membranes of the secretory tubules, possibly by binding to a troponin-like factor (145), resulting in a peristaltic wave which would end in the egress of the catecholamines to the exterior of the cell (146)[2]. The isolation of intact chromaffin *granules* from homogenates of adrenal medulla does not necessarily militate against the postulate of the existence of the catecholamines within the chromaffin cell in the form of intratubular *droplets* (146)[2], since it is conceivable that when the gland is homogenized the fragmented tubules may undergo healing and vesicle formation in a manner analogous to the formation of synaptosomes[2].

ROLE OF CALCIUM IN STIMULUS–SECRETION COUPLING IN ADRENAL MEDULLA

A number of comprehensive reviews covered various aspects of the role of extracellular calcium in the release of neurotransmitter substances, hormones, and other secretory products (44, 47, 81, 83, 145, 148, 149). The role of intracellular calcium in stimulus–secretion coupling has only recently been recognized and will be reviewed here. In general, calcium appears to play a critical and almost universal role in the release of secretory material. Furthermore, a relationship between calcium and cyclic AMP as intracellular messengers in secretion was discussed by Rasmussen (124). In the adrenal medulla, however, stimulation of the chromaffin cells does not result in an increase in intracellular cyclic AMP concentrations (124), and the role of this cyclic nucleotide, if any, in catecholamine secretion from the adrenal medulla is not known (124) despite the dependence of the secretory mechanism of this gland on calcium (81).

Role of Extracellular Calcium—Calcium-deprived perfusion solutions depress or abolish the secretory response of the adrenal medulla to a variety of secretagogues including acetylcholine, carbachol, other nicotinic and muscarinic agents, histamine, serotonin, polypeptides such as bradykinin and angiotensin I, some sympathomimetic amines, ouabain, and excess potassium (33, 150–159). Furthermore, Douglas and Rubin (150) showed that the secretory response of the adrenal medulla to acetylcholine varies directly with the concentration of calcium in the perfusion medium. Acetylcholine, potassium, histamine, angiotensin I, bradykinin, serotonin, nicotine, carbachol, and pilocarpine have been shown to depolarize the chromaffin cell membrane (26). An increased influx of radiolabeled calcium into chromaffin cells occurs during stimulation (49, 160, 161), and Douglas and Rubin (150, 162–164) proposed that acetylcholine owes its stimulant effect on

[2] R. G. Rahwan, J. L. Borowitz, and E. J. Hinsman, unpublished data (manuscript in preparation).

the chromaffin cell to some action increasing the permeability of the plasma membrane to calcium in the extracellular fluid. The effect of acetylcholine on the permeability of the chromaffin cell is thought to occur through depolarization (44, 148). However, the finding that acetylcholine can still evoke catecholamine secretion from the adrenal medulla perfused with a sodium-free medium or a medium containing isotonic potassium sulfate indicates that depolarization is not tightly coupled with secretion as long as calcium is present in the extracellular environment (44, 148, 162). Additional evidence that depolarization and secretion can be dissociated was provided by Douglas *et al.* (27) who demonstrated that acetylcholine or excess potassium still depolarized the chromaffin cell when the extracellular fluid was calcium free or contained excess magnesium—conditions that inhibit secretion (150, 157, 162). However, in the work of Douglas *et al.* (27), the depolarization of the chromaffin cell in response to acetylcholine in the absence of extracellular sodium was not totally abolished but fell to about 30% of the control value. Moreover, prolonged perfusion with sodium-free medium abolishes the secretory response of the adrenal medulla to carbamylcholine and to high potassium concentrations (165)—agents that depolarize the chromaffin cell membrane (26). Although Banks *et al.* (165) suggested that sodium has some regulatory effect on the entry of calcium into chromaffin cells during stimulation, Rubin (81) argued that the prolonged perfusion with sodium-free medium used by Banks *et al.* (165) may result in a nonspecific deleterious effect to the chromaffin cell rather than a specific effect on calcium entry. However, sodium-deficient perfusion solutions cause an increase in spontaneous adrenal medullary secretion (150, 162, 165), and sodium deficiency has been shown to increase the entry of calcium into cells (165, 166).

An increased uptake (49) and exchange (160) of calcium by the chromaffin cell occurs during acetylcholine stimulation, and magnesium markedly inhibits calcium exchangeability between the gland and the perfusion medium (161) and also inhibits medullary secretion (162). Likewise, local anesthetics block the influx of calcium as well as the secretory response of the adrenal medulla (57, 161, 167). Rubin *et al.* (161) suggested that local anesthetics and magnesium interfere with calcium entry into the chromaffin cell by competition at a common membrane site. However, Rahwan *et al.* (57) presented evidence that magnesium may also interfere with the action of calcium at an intracellular calcium receptor site in the adrenal chromaffin cell.

Role of Intracellular Calcium—Despite substantial evidence of the importance of extracellular calcium in stimulus–secretion coupling in the adrenal medulla, in some instances drugs have been shown to evoke release of catecholamines from the perfused adrenal gland in the absence of calcium in the perfusion fluid. Thus, reserpine (33, 152), tyramine (152), phenylethylamine (152), barium (163), potassium thiocyanate (168), strontium (163), caffeine (56, 57, 169), aminophylline (169), acetaldehyde (55), chlorpromazine (56, 57), and dextroamphetamine (56–58) have all been shown to release catecholamines from the adrenal gland in the absence of extracellular calcium. Likewise, the reintroduction of calcium to the perfusion medium following perfusion with calcium-free medium evokes catecholamine release from the adrenal medulla (150, 162), despite the fact that under normal conditions excess calcium added to a perfusion medium already containing calcium does not augment secretion in the absence of a depolarizing agent (163).

The dissociation of extracellular calcium and the secretory effect of some secretagogues do not militate against the role of calcium in secretion. Indeed, it is becoming increasingly apparent that intracellular calcium may be of importance in stimulus–secretion coupling. In animal cells the concentration of calcium in the cytoplasm is in the range of 10^{-5}–10^{-8} *M* (124, 170–172). The demonstration by Borowitz *et al.* (173) that the adrenal chromaffin cell has a high content of calcium distributed among the various intracellular organelles raised the possibility that this intracellular calcium may play a role in catecholamine secretion in much the same way as has been demonstrated for muscle contraction (50). Thus, agents that release catecholamines from the adrenal medulla in the absence of extracellular calcium may still be dependent on a critical intracellular calcium pool for their secretory effect. In fact, Rahwan and Borowitz (56) and Rahwan *et al.* (57) showed that, under calcium-free perfusion conditions, chlorpromazine induced catecholamine release from bovine adrenal glands by mobilizing mitochondrial calcium reserves, caffeine evoked catecholamine secretion by mobilizing calcium from the endoplasmic reticulum as well as the mitochondria, and dextroamphetamine released adrenal catecholamines initially by a calcium-free mechanism followed by an enhanced secretory effect consequent upon mobilization of calcium from the endoplasmic reticulum. Furthermore, catecholamine release induced by chlorpromazine, caffeine, and dextroamphetamine in calcium-free medium generally paralleled ^{40}Ca and ^{45}Ca efflux from radiocalcium-labeled adrenal glands (57), suggesting that the calcium released to the exterior of chromaffin cells under these conditions represents in part the free intracellular levels of calcium that mediate catecholamine secretion (57) and in part the intragranular calcium involved in the catecholamine storage complex (174). The finding that magnesium significantly inhibited catecholamine secretion from the adrenal medulla induced by chlorpromazine, caffeine, or dextroamphetamine under calcium-free perfusion conditions (57) offers rather conclusive evidence that mobilization of intracellular calcium by these secretagogues is the triggering event in stimulus–secretion coupling and establishes an intracellular site for competition between calcium and magnesium (57).

Jaanus and Rubin (175) demonstrated that the total calcium content of the adrenal cortex may be divided into three roughly equal fractions: extracellular, cellular extractable, and cellular nonextractable. The extracellular calcium pool was presumed to be of importance for maintaining the more critical cellular calcium pools. During prolonged perfusion with calcium-free solution, approximately one-third of the total calcium content of the cortex was still retained by the gland. The locus of this nonextractable cellular calcium was assumed to

be the mitochondria and could be depleted only by treatment of the gland with 2,4-dinitrophenol, an uncoupling agent that releases calcium from the mitochondria (176). The cellular extractable calcium pool was assumed to be bound to or near the surface of the cortical cell or localized in some readily exchangeable intracellular site (175). The role of these different calcium pools in adrenocorticotropin-induced corticosteroid secretion was discussed by Jaanus and Rubin (175). The secretory response of the adrenal cortex to low concentrations of adrenocorticotropic hormone was found to be dependent upon extracellular calcium (177, 178), whereas high concentrations of adrenocorticotropin evoked corticosteroid release in the absence of extracellular calcium (179). It has been reported that the secretory effect of adrenocorticotropin on the adrenal cortex is dependent upon some critical intracellular calcium pool (175, 179).

Additional evidence for a role of intracellular calcium as a coupling link in the secretory process was provided by Williams (180). He showed that secretion from the thyroid gland induced by thyroid-stimulating hormone may be dependent upon mobilization of intracellular calcium.

To emphasize further the emerging significance of intracellular calcium in cellular processes, it has been reported that in certain tissues where adenyl cyclase and cyclic AMP mediate the effect of a specific peptide hormone, although the hormone-induced stimulation leads to an influx of calcium into the cells, the addition of extracellular cyclic AMP does not stimulate calcium uptake even though it mimics hormone action (124). Such findings indicate that the action of the cyclic nucleotide is either independent of calcium or utilizes an intracellular calcium pool (124). Evidence that cyclic AMP causes mobilization of calcium from intracellular pools has been presented by numerous investigators (181–184). Based on this and other information, Rasmussen (124) postulated that the increase in intracellular cyclic AMP, subsequent to interaction of a hormone with adenyl cyclase, would result in mobilization of calcium from one or more intracellular pools and/or prevention of uptake of cytoplasmic calcium into intracellular organelles.

Although the adrenal medullary chromaffin cell has been impaled by microelectrodes (26, 27), there is as yet no report on the effect of intracellularly injected calcium on catecholamine secretion. Such studies should provide direct evidence for the role of intracellular calcium in stimulus–secretion coupling. Miledi and Slater (185) found calcium to be ineffective in evoking release of transmitter when injected intracellularly into the squid giant axon. In their study, Miledi and Slater (185) deprived the squid giant synapse preparation of calcium and then tested the effect of ionophoretic application of calcium at different spots along the synapse. The transmitter-releasing effect of calcium was found to be very sharply localized at specific spots along the stretch of presynaptic axon lying adjacent to the postsynaptic axon. To test the effect of intracellularly injected calcium, the pipet was inserted into the presynaptic axon at a *single* spot which was previously shown to be sensitive to extracellular application of calcium. When injection of calcium into the presynaptic axon resulted in no release of transmitter, Miledi and Slater (185) concluded that for calcium to evoke transmitter release the cation acts through a membrane reaction whose reactive sites are accessible only from the outside of the membrane. However, Miledi and Slater (185) conceded that such a conclusion "remains tentative because time was too short to test its validity fully." These authors (185) further stated that: "Usually we could not test more than one 'intracellular spot,' and it is clear that many spots must be tested in view of the sharp localization required for effective ionophoretic application of calcium from the outside." The question of whether intracellularly injected calcium can release secretory products remains to be answered.

The importance of calcium ions in spontaneous (resting) secretion of catecholamines from the adrenal medulla is not clear. Although some investigators reported spontaneous catecholamine secretion to be very low in the absence of calcium in the perfusion fluid (150, 154, 158), others showed that resting secretion from the adrenal medulla was unaffected when the perfusion fluid was switched from one containing 2.2 m*M* calcium to one containing no calcium (57). The spontaneous secretion of catecholamines from the adrenal medulla is presumed to reflect what is released by exocytosis initiated by spontaneous release of acetylcholine at the splanchnic–adrenomedullary junction as well as what diffuses out of the chromaffin granules and into the cytoplasm (58). This was shown to be the case by Schneider (58), since addition of hexamethonium to the fluid perfusing adrenal glands in a concentration that completely blocks the effect of acetylcholine released by the preganglionic cholinergic fibers resulted in approximately a 40% reduction of spontaneous catecholamine release, equivalent to the reduction observed when calcium was eliminated from the perfusion fluid. These results indicate that extracellular calcium has no effect on spontaneous catecholamine secretion other than that mediated by inhibition of exocytosis (58).

Spontaneous secretion clearly does not cease in the absence of extracellular calcium and, furthermore, is not abolished by either local anesthetics (57, 161) or magnesium (57, 162) whether or not calcium is present in the extracellular fluid. The finding that magnesium does not inhibit resting secretion when adrenal glands are perfused with calcium-free medium (57) casts doubt as to the importance of intracellular calcium in spontaneous catecholamine secretion, particularly since magnesium was shown to compete with calcium at an intracellular site (57). Furthermore, ouabain, which raises intracellular calcium levels by presumably inhibiting calcium efflux from cells, does not potentiate resting secretion from the adrenal medulla in the absence of extracellular calcium (154). On the other hand, Douglas and Ishida (186) reported that cooling increases resting secretion of vasopressin from the neurohypophysis perfused with a calcium-free medium, and cooling has been shown to inhibit calcium uptake by intracellular organelles including the endoplasmic reticulum of the adrenal chromaffin cell (168). Since calcium uptake by intracellular organelles is presumed to be one mechanism for termination of secretory

activity (discussed later), it is not unlikely that cytoplasmic calcium may play a role in spontaneous secretion and that interference with intracellular sequestration of this cation may enhance resting secretion. Furthermore, calcium was shown to be released from the adrenal chromaffin cells (57) and from isolated chromaffin granules (187) during spontaneous secretion even in the absence of extracellular calcium (57). Whether this extruded calcium is involved in resting secretion, as has been postulated for evoked adrenomedullary secretion (57), must await further research.

PARALLELISM BETWEEN STIMULUS–SECRETION COUPLING IN ADRENAL MEDULLA AND EXCITATION–CONTRACTION COUPLING IN MUSCLE

Over the past few years, the striking similarities between the processes of stimulus-secretion coupling in secretory cells and excitation-contraction coupling in muscle have become increasingly apparent (57, 81, 145). Thus, all secretory systems studied have shown that the release of the secretory product is critically dependent on extracellular (81) or intracellular (57, 175, 180) calcium ions. Furthermore, studies of many secretory systems, including neurons and endocrine and exocrine cells, have shown that discharge of stored product does not occur when synthesis of ATP is blocked (188–190) or when granule ATPase is inhibited (78, 191). These facts, in addition to the isolation and characterization of an actomyosin-like contractile protein from a number of secretory cells (139–144), have emphasized the similarities between secretion and muscle contraction which were recently reviewed by Poisner (145).

The early finding that the adrenal chromaffin granules contained ATP and ATPase activity (45), coupled with the demonstration that the ATP–Mg^{+2}-dependent pump which concentrates catecholamines in these granules (30) has many characteristics of the calcium pump in muscle (192), led Hillarp (45) to suggest that when the chromaffin cell is stimulated, the ATPase associated with the chromaffin granules may hydrolyze the ATP of the ATP–Mg^{+2} intragranular storage complex, thus releasing the catecholamines from the granules. Although this hypothesis was refuted on other grounds (discussed previously), its significance also was made doubtful when it was demonstrated that calcium did not evoke catecholamine release from isolated adrenal medullary chromaffin granules (78). However, Poisner (145) speculated on the failure of calcium to facilitate release of catecholamines from isolated chromaffin granules *in vitro* as being possibly due to the absence of an active calcium-sensitive protein comparable to the troponin–tropomyosin complex in muscle (193). The possibilities that such a protein may constitute an integral part of the membranes of the tubules involved in secretion and that it may be lost during the homogenation and isolation procedures (145) are thought provoking. Furthermore, the finding that radioactive calcium entering the chromaffin cell during stimulation readily penetrates the chromaffin granule (160) is suggestive of a pooling of calcium in the vicinity of the secretory elements of the chromaffin cell for the purpose of triggering catecholamine release.

MECHANISMS OF TERMINATION OF SECRETORY RESPONSE OF ADRENAL MEDULLA

Since parallels between secretion and muscle contraction have been described with respect to release of secretory products from whole cells and from isolated granules, and since the molecular mechanisms of release of catecholamines have, in fact, been proposed to be contractile in nature[2] (84, 112, 145), further biochemical similarities between secretion and contraction can be outlined.

One very important aspect of the contractile system in muscle is that the concentration of ionized calcium in the myoplasm is maintained at low levels, and the sarcoplasmic reticulum has been shown to possess an ATP-activated uptake mechanism which reduces free intracellular calcium levels (194). It would be expected that secretory cells would also have some active mechanisms for keeping cytoplasmic levels of free ionized calcium low. Indeed, Borowitz (195) demonstrated that calcium is readily bound to subcellular organelles of the adrenal medulla. Poisner and Hava (168) reported that microsomes from the adrenal medulla can bind calcium in the presence of ATP and that this ATP-activated binding of calcium is inhibited by agents [*e.g.*, quinidine, amytal, thiocyanate, strontium, barium, and *p*-hydroxymercuribenzoate (168)] that are known to block calcium uptake by muscle microsomes (196, 197).

Recently, Haugaard *et al.* (198) demonstrated an active uptake of calcium by mitochondria in cardiac muscle, and they speculated on the role of this uptake mechanism in the regulation of contraction and relaxation of the myocardial cell. A similar ATP-activated calcium uptake mechanism in mitochondria of adrenal medullary chromaffin cells was described (168), which was inhibited by azide, oligomycin, and 2,4-dinitrophenol.

The adrenal medullary chromaffin granules may also play a role in the termination of an evoked secretory response. The fact that calcium readily penetrates the chromaffin granule during stimulation (160), coupled with the demonstration that the ATP–Mg^{+2}-dependent pump in the granule has many properties of the calcium pump in muscle (192), would indicate that the chromaffin granule may act as an active sequestrating organelle for calcium. The adrenal chromaffin granules have also been shown to take up calcium during catecholamine synthesis, since stimulation of the adrenal glands with acetylcholine in the presence of 3,4-dihydroxyphenylalanine (dopa) and ^{45}Ca resulted in a greater accumulation of ^{45}Ca in the granule fraction than stimulation in the absence of dopa (174). Furthermore, a relatively large amount of the intragranular calcium was found to be held in a nondiffusible form and was considered part of the binding complex for catecholamines in the adrenal medulla (174). It is possible, therefore, that uptake of calcium into the chromaffin granule may serve the dual purpose of terminating the secretory response (81) and of participating in the synthesis and storage of new catecholamines (174) to replenish the granules following an evoked secretion of their contents.

Termination of the secretory response or of muscle contraction could conceivably also be brought about by an active pumping of calcium out of the cell against a concentration gradient. This could be achieved by means of the outwardly directed membrane sodium–calcium pump, similar to the one described by Blaustein and Hodgkin (199) and by Reuter and Seitz (200). An indirect confirmation of such a mechanism derives from the finding that ouabain, which blocks the membrane sodium–calcium pump and increases the concentration of intracellular calcium, enhances both spontaneous and carbachol-induced catecholamine secretion from the adrenal medulla (154) and exhibits positive inotropic effects on the myocardium.

The described mechanisms for the termination of the secretory response of the adrenal medulla received further confirmation from Borowitz (167) who showed that the secretory response to acetylcholine, which is normally terminated in a few seconds after the removal of the stimulus, is prolonged under conditions that promote an influx of large amounts of calcium into the chromaffin cell—such as high concentration of extracellular calcium. The slow removal (either by intracellular binding or by efflux) of the relatively large amounts of calcium from the adrenal medullary cells may account for the prolonged catecholamine release under these conditions (167). Local anesthetics block the influx of calcium as well as the secretory response of the adrenal medulla (57, 161, 167) and also inhibit contractility and associated calcium movements in both striated and smooth muscles (201, 202).

Drugs and other factors that release intracellular calcium or block its uptake into intracellular organelles have profound effects on muscle by initiating contraction or delaying relaxation (50, 203). In an analogous sense, it would be expected that agents or factors that increase the intracellular calcium-ion concentration in the adrenal medullary chromaffin cell could initiate the release of catecholamines or, alternatively, potentiate or prolong an evoked secretory response. From the close parallelism between muscle and the adrenal medulla with respect to calcium binding, as already described, it might be predicted that drugs or factors that affect muscle function by influencing calcium mobility would have the same type of effect on adrenal medullary secretion: catecholamine release would be analogous to muscle contraction, and termination of the secretory response would correspond to relaxation (168). Indeed, agents such as caffeine (56, 57), barium, thiocyanate, sulfhydryl reagents, and ouabain (145, 168), all of which increase the level of free calcium in the cytoplasm by influencing intracellular calcium movements and binding, have been shown to potentiate or evoke adrenal medullary secretion and also to contract muscle (145). Furthermore, anoxia, nitrogen, and cyanide (190) increase spontaneous or evoked catecholamine release from the adrenal medulla, and cooling enhances the secretion of vasopressin from the neurohypophysis in the absence of extracellular calcium (186). These observations could be related to a diminished mitochondrial or microsomal calcium uptake (168)—mechanisms that may well be responsible for the termination of the secretory response (145, 168).

PHARMACOLOGICAL MECHANISMS OF STIMULUS–SECRETION COUPLING IN ADRENAL MEDULLA

Somlyo and Somlyo (203) broadly classified the mechanisms of smooth muscle contraction into "electromechanical coupling" (regulation of the contractile system by changes in the membrane potential, action potential frequency, or both) and "pharmacomechanical coupling" (the action of compounds on the contractile system independent of the membrane potential and action potential). Evidence that similar mechanisms apply to skeletal and cardiac muscle is extensive (50, 198, 204). Since, as previously discussed, similar molecular mechanisms appear to underlie the processes of excitation–contraction coupling in muscle and stimulus–secretion coupling in the adrenal medulla and other secretory cells (78, 81, 145, 168), a similar classification of the mechanisms of stimulus–secretion coupling was proposed by Rahwan *et al.* (57). The terms electromechanical coupling and pharmacomechanical coupling could justifiably be retained for this purpose, since there is mounting evidence that the process of secretion may indeed involve a contractile mechanism[2] (145, 146). The possible subcellular mechanisms by which drugs may evoke secretion are as follows:

A. Electromechanical coupling (dependent upon extracellular calcium): membrane depolarization, leading to increased permeability to inorganic ions, and an influx of extracellular calcium into the secretory cell
B. Pharmacomechanical coupling (dependent upon intracellular calcium):
   1. Release of calcium from the endoplasmic reticulum
   2. Inhibition of calcium uptake by the endoplasmic reticulum
   3. Release of calcium from mitochondria
   4. Inhibition of calcium uptake by mitochondria
   5. Release of calcium from cell membrane storage sites
   6. Inhibition of calcium binding by the cell membrane
   7. Inhibition of calcium efflux from the cell by inhibition of the membrane sodium–calcium pump
C. Mechanisms independent of extracellular or intracellular calcium:
   1. Direct interaction with intracellular contractile proteins
   2. Inhibition of hypothetical "inhibitory factor" (troponin?)
   3. Interference with the intragranular or intratubular storage mechanism
   4. Displacement of secretory product from intragranular or intratubular storage by false transmitter-type effect
D. Physical damage to cell membranes or membranes of intracellular organelles of the secretory cell, leading to passive diffusion of calcium and/or secretory product

It is conceivable that secretagogues like acetylcholine, nicotine, carbachol, pilocarpine, potassium, hista-

mine, serotonin, bradykinin, and angiotensin I evoke catecholamine secretion from the adrenal medullary cell by electromechanical coupling (57), involving depolarization of the chromaffin cell membrane, with a dependency on extracellular calcium (26, 27, 150, 155, 156). On the other hand, drugs that evoke catecholamine secretion from the adrenal medulla in the absence of extracellular calcium [*e.g.*, caffeine, aminophylline, chlorpromazine, dextroamphetamine, reserpine, tyramine, phenylethylamine, barium, strontium, thiocyanate, and acetaldehyde (33, 55, 57, 58, 152, 163, 168, 169)] could conceivably exert their secretory effect by pharmacomechanical coupling (57), with a dependency on intracellular calcium.

In addition to electromechanical and pharmacomechanical coupling, other alternative mechanisms for drug-induced catecholamine secretion from the adrenal medulla should be considered, such as interference with the catecholamine storage mechanism (independent of both extracellular and intracellular calcium) or physical damage to biological membranes. For example, acetaldehyde releases catecholamines from the adrenal medulla presumably by a direct interaction between the aldehyde and the chromaffin granule protein, resulting in a possible alteration of the chromaffin granule membrane structure (55), or by an interaction between the aldehyde and the catecholamines forming the tetrahydroisoquinoline derivatives which act as "false transmitters" (205). Both interpretations are consistent with the finding of Schneider (55) that acetaldehyde-induced catecholamine secretion from the adrenal gland and from isolated chromaffin granules, which occurs in the absence of calcium in the perfusion or incubation medium, is not accompanied by the release of intragranular or cytoplasmic proteins. Rahwan (146) and Rahwan *et al.*[2] (57) reported that chlorpromazine evoked catecholamine secretion from the adrenal medulla by physical disruption of, and mobilization of calcium from, the mitochondria of the chromaffin cells. Chlorpromazine-induced mitochondrial structural damage in the adrenal medulla was also reported by Mäkelä and Vapaatalo (206). It is conceivable that the reserpine-induced catecholamine release from the adrenal medulla, which occurs in the absence of extracellular calcium (33, 152), may represent a calcium-independent mechanism based on interference with the intragranular storage mechanism (30). Tyramine may also release adrenal catecholamines by a mechanism that does not require calcium (152), analogous possibly to its ability to displace norepinephrine from storage granules in adrenergic nerve endings (207). This is supported by the finding that tyramine-induced adrenal catecholamine secretion is not accompanied by release of intragranular protein or dopamine-β-hydroxylase (58). Similar results were reported by Schneider (58) for the effect of *l*-amphetamine on the adrenal medulla. Likewise, the initial phase of the secretory effect of dextroamphetamine on the adrenal medulla was reported by Rahwan *et al.* (57) to be calcium independent and to involve a tyramine-like displacement of catecholamines from their storage sites into the cytoplasm from where the amines could be recovered.

It is likely that pharmacomechanical mechanisms of secretion may represent the primary means by which some drugs evoke secretion even in the presence of extracellular calcium (57). It is also conceivable that electromechanical and pharmacomechanical mechanisms may be operative simultaneously under physiological conditions where calcium is present in the cellular environment.

Effects of Disopyramide on Electrophysiological and Mechanical Properties of the Heart

BILLY K. YEH▲, PEI-KUN SUNG, and BENJAMIN J. SCHERLAG

Abstract □ Studies were performed in whole dog and in isolated superfused canine Purkinje fiber–papillary muscle preparations to investigate mechanisms responsible for the antiarrhythmic effects of disopyramide. Two human left atrial appendages were also studied *in vitro*. Disopyramide had a potent quinidine-like effect which may explain the antiarrhythmic properties of disopyramide. While disopyramide is perhaps at least twice as potent as quinidine in suppressing experimentally induced arrhythmias, disopyramide also has at least proportionally more depressant effect on cardiac mechanical performance in the dog heart.

Keyphrases □ Disopyramide—effects on electrophysiological and mechanical properties of the heart, *in vitro*, *in vivo* □ Antiarrhythmic activity, disopyramide—effects on electrophysiological and mechanical properties of the heart, *in vitro*, *in vivo* □ Quinidine-like activity—effects of disopyramide on *in vitro* and *in vivo* electrophysiological and mechanical properties of the heart □ Cardiac effects, electrophysiological and mechanical—disopyramide

The use of quinidine and quinidine-like drugs in the treatment of both supraventricular and ventricular arrhythmias, due to a variety of etiologies, remains one basic form of therapy for cardiac arrhythmias. The pharmacology of a new antiarrhythmic agent disopyramide[1], [2-(diisopropylamino)ethyl]-α-phenyl-2-pyridineacetamide, has been compared with that of quinidine (1). It was found that disopyramide was at least twice as potent as quinidine in abolishing arrhythmias induced experimentally by repetitive electrical stimulation, by local application of aconitine nitrate, by coronary artery ligation, and by ouabain infusion. The acute toxicity of disopyramide was reported to be relatively low, the intravenous therapeutic ratio in dogs being about 10 (1).

These data led to limited clinical trials of disopyramide (2). According to Katz *et al.* (2), disopyramide converted 11 of the 19 subjects with various arrhythmias to normal sinus rhythm; two patients (one with chronic atrial fibrillation and one with frequent premature ventricular contractions) who did not respond to quinidine therapy were subsequently converted by disopyramide at doses less than 50% of the quinidine dosage. At present, larger scale clinical trials of disopyramide are underway[2]. This paper reports the effects of disopyramide on the electrophysiological properties of the dog heart and human atrial tissue to elucidate the antiarrhythmic actions of disopyramide. Also the effects of disopyramide on canine cardiac mechanical performance were evaluated so that the effects of disopyramide on the electrophysiological and mechanical parameters in the dog heart could be correlated.

EXPERIMENTAL

***In Vivo* Studies**—The cardiac effects of intravenous injections of disopyramide were evaluated in six adult mongrel dogs anesthetized with sodium pentobarbital (30 mg./kg.) and maintained on controlled respiration. Arterial blood pressure was recorded continuously using a transducer[3]. An electrode catheter was introduced into the right atrium for pacing and recording. His bundle electrograms were recorded by use of another bipolar electrode catheter positioned near the A–V node as previously described (3). Thus, the A–V conduction time could be divided into three time segments: intraatrial, A–V nodal, and intraventricular. Cardiac pacing at various rates was used to stress A–V conduction. The effects of right vagal stimulation (2 msec., 5 v., 20 Hz.) on sinus rate, A–V conduction, and ventricular automaticity were also evaluated in each experiment.

A micromanometer catheter was introduced into the left ventricle *via* a common carotid artery for recording intraventricular pressure. Left ventricular dP/dt was obtained using an operational amplifier. In addition, a strain-gauge arch was sutured on the right ventricular wall for monitoring a representative segment of myocardial contractile force (4).

After control records were obtained during normal sinus rhythm and atrial pacing at various rates, disopyramide (10 mg./ml. dissolved in normal saline) was administered slowly by vein at a dose of 3 mg./kg. Serial recordings of sinus rate, A–V conduction, ventricular automaticity, blood pressures, left ventricular pressures and dP/dt, and myocardial segment contractility were monitored up to 2 hr. after drug injection.

Two hours after the injection of the first dose of disopyramide, a second dose of 5 mg./kg. was given to all animals. Thus, each animal received a cumulative dose of 8 mg./kg. of disopyramide. Serial recordings of sinus rate, cardiac conduction, ventricular automaticity, blood pressures, and ventricular mechanical performance were again obtained up to 2 hr. after the second dose of disopyramide.

In three dogs, the effects of the intravenous injection of quinidine, 5 and 8 mg./kg., were evaluated and compared to disopyramide injections.

***In Vitro* Studies**—Seven canine Purkinje fiber–papillary muscle preparations and two human left atrial appendages (one obtained from a 56-year-old man who underwent coronary bypass surgery and the other obtained from a teen-aged boy who underwent corrective surgery for tetralogy of Fallot) were studied. Intracellular and extracellular recordings were obtained by conventional electrophysiological techniques under control conditions, during drug infusion (1 or 2 mg./l.), and after washing out the drug. Doses of disopyramide up to 2 mg./kg. have been used in man, and it was thought that the concentration range of the drug used in these studies would be within the clinical therapeutic level. The preparations were superfused with modified Tyrode's solution (K = 4.0 meq./l.) at 37°.

		5 mg./kg.				**8 mg./kg.**	
Quinidine group	132 ± 10	129 ± 6	134 ± 11	140 ± 20	145 ± 19	139 ± 22	140 ± 18

[a] Values are mean ± *SE.* * = $p < 0.05$; ** = $p < 0.01$; + = $p < 0.001$.

The preparations were driven at a fixed rate of between 60 and 100/min. in canine preparation and of between 30 and 60/min. in human atrial preparations. The refractory period and the membrane responsiveness were studied by applying an extra stimulus (with adjustable delays) during the repolarization phase of every 10th driven beat.

Statistical Analysis—Paired *t* tests were performed to determine changes induced by the drugs in the same preparation. Nonpaired *t* tests were used to determine whether the differences observed between two groups were statistically significant. The *p*-values were expressed as nonsignificant (>0.05) and significant at three levels (<0.05, <0.01, and <0.001).

RESULTS

***In Vivo* Studies**—*Effects of Disopyramide on Automaticity*—A depression of sinus automaticity was noticed after disopyramide injection. Table I compares the effects of disopyramide and quini-

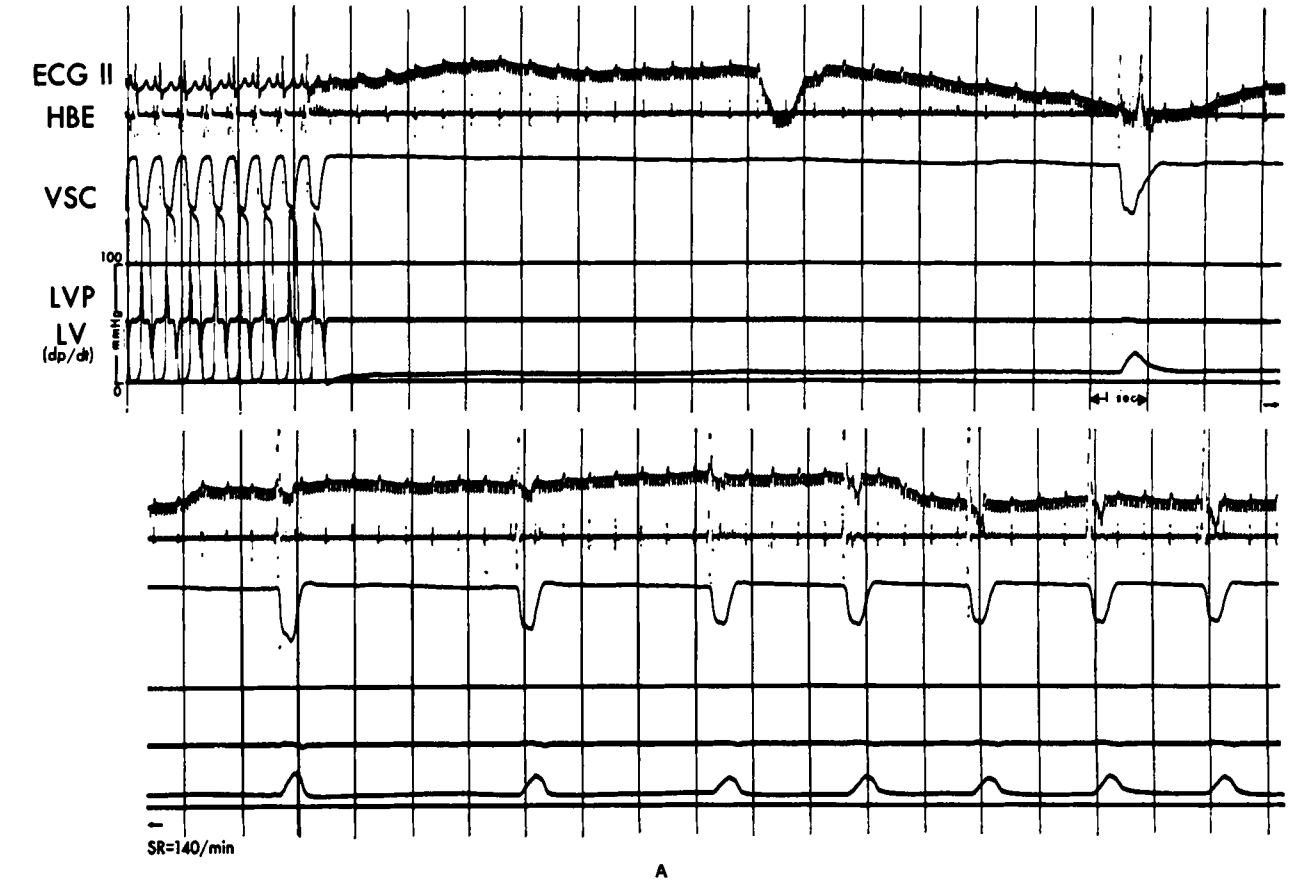

Figure 1—*Atropine-like activity of disopyramide revealed by vagal stimulation. Tracings from top to bottom are: surface ECG lead II, His bundle electrogram (HBE), right ventricular segmental contractility (VSC) recorded by a strain-gauge arch, left ventricular pressure (LVP), and the first derivative of LVP (LV, dP/dt). A shows the control right vagal stimulation (5 v., 20 Hz.) resulting in sinus arrest, with an escape time of 14 sec. and a slow idioventricular rhythm of 30/min. B shows responses to the same vagal stimulation 15 min. after 3 mg./kg. disopyramide. There was some slowing of the sinus rate during vagal stimulation and no ventricular automaticity was seen, due to inhibition of ventricular pacemakers by supraventricular conducted beats.*

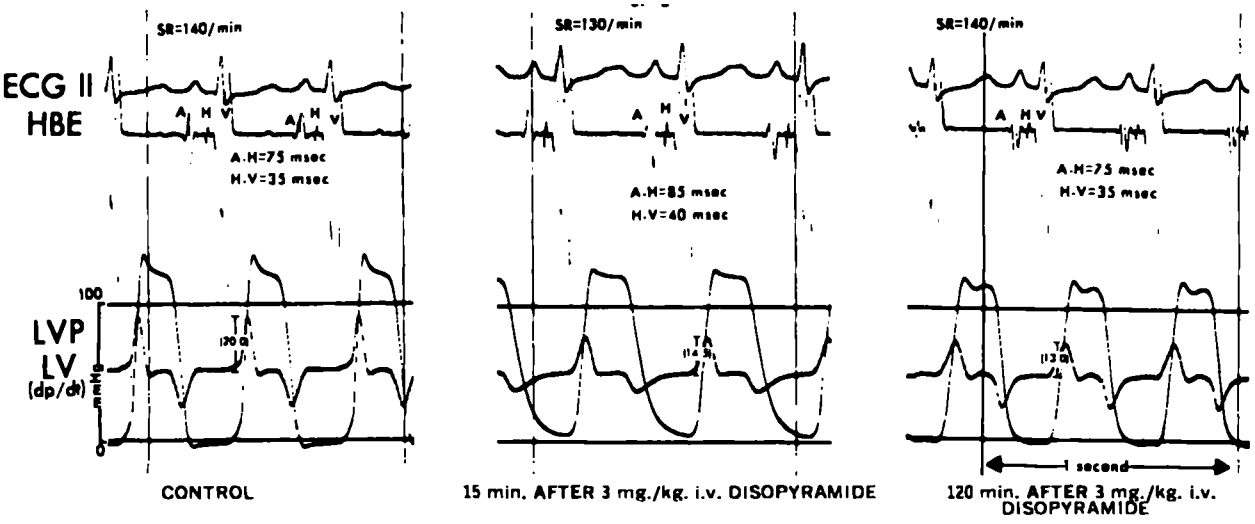

Figure 2—*Effects of disopyramide on sinus rate, A–V conduction, and left ventricular pressures. The top tracing is surface ECG lead II. The labels in the His bundle electrogram (HBE) are: A, activation of atrial septum near the A–V node; H, His bundle electrogram; and V, ventricular electrogram. The left panel is the control. Disopyramide, 3 mg./kg., caused some slowing of the sinus rate associated with A–V nodal and intraventricular conduction delay. Disopyramide also caused a decrease of systolic pressure and* dP/dt *and a rise in end diastolic pressure of the left ventricle. This dog recovered from the electrophysiological effects of disopyramide within 2 hr., while the depression of left ventricular mechanical performance was still evident.*

dine on sinus rate. It is evident that disopyramide had a greater depressant effect than quinidine on sinus automaticity and that this depressant effect lasted longer than 2 hr.

Disopyramide also had a much more potent vagolytic effect than quinidine. Ventricular automaticity could not be evaluated after disopyramide because vagal stimulation failed to cause sinus arrest (Fig. 1). This inhibition of the vagal effect on sinus automaticity by disopyramide lasted more than 2 hr. after a 3-mg./kg. i.v. injection of disopyramide. No such vagolytic effect was observed after administration of quinidine, even at the 8-mg./kg. dose.

Effects of Disopyramide on Cardiac Conduction—At both dose levels (3 and 5 mg./kg.), disopyramide caused significant conduction delay in both the A–V node and the specialized ventricular conduction system, although there was an associated decrease in sinus rate (Figs. 2 and 3). The lower dose of quinidine (5 mg./kg.) had no effect on cardiac conduction; the higher dose (8 mg./kg.) caused a slight depression of both A–V nodal and intraventricular conduction, which, however, was not as marked as those induced by 3 mg./kg. disopyramide. The depression of A–V nodal conduction lasted somewhat longer than the depression of intraventricular conduction with both disopyramide and quinidine (8 mg./kg.). Table II summarizes the results obtained using His bundle recordings.

The direct depressant effect of disopyramide on A–V conduction overwhelmed its vagolytic effect. Wenckebach cycles developed at a mean pacing rate of 340 beats/min. under control conditions and of 284 beats/min. 3 min. after 3 mg./kg. disopyramide. This depression of A–V nodal conduction persisted for about 1 hr. and disappeared by the end of the 2nd hr. Quinidine, 5 mg./kg., caused a similar qualitative depression of A–V nodal conduction, but this effect was only revealed by pacing.

Effects of Disopyramide on Arterial Blood Pressure—No change in mean arterial blood pressure was noticed after the injection of 3 mg./kg. disopyramide. However, higher doses of disopyramide (5 mg./kg.) caused an average 11-mm. Hg decrease in mean blood pressure. Compared to "equiantiarrhythmic" doses, quinidine had a more potent depressor effect (a 16-mm. Hg decrease in mean blood pressure was noted after 5 mg./kg. quinidine) than disopyramide (Table III).

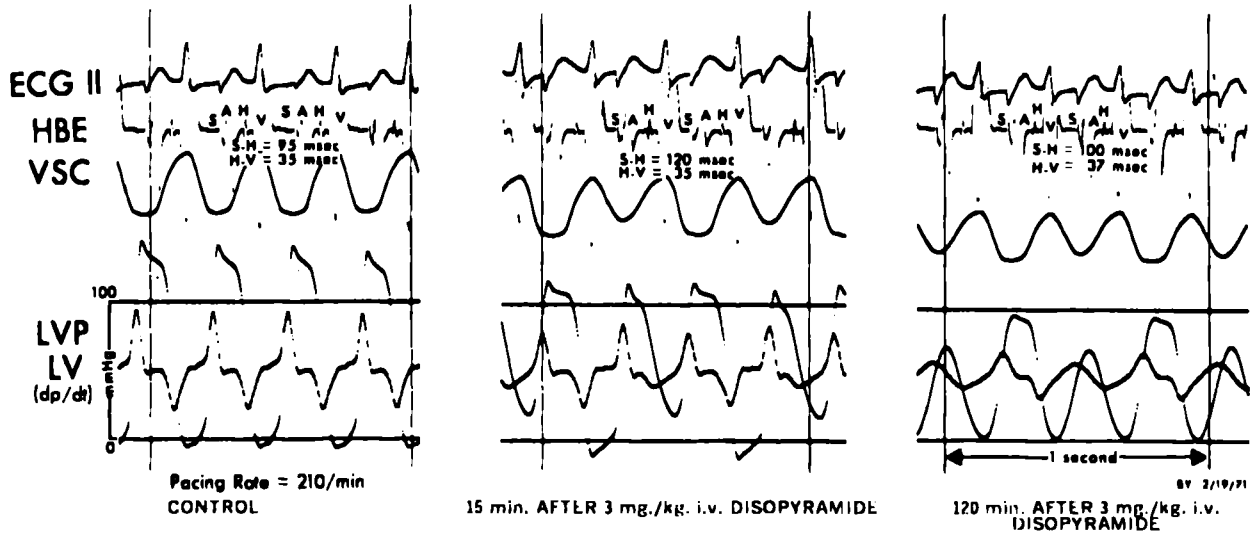

Figure 3—*Effects of 3 mg./kg. i.v. disopyramide on the dog heart. Comparisons were made with the heart rate controlled by atrial pacing at a fixed rate, 210/min. S is the stimulus artifact, and other labels are similar to those in previous figures. The left panel is the control. The middle panel shows the prolonged supraventricular conduction time (S–H interval) and depression of ventricular function (decrease in ventricular systolic pressure and* dP/dt *and alternate contractions) 15 min. after disopyramide injection. The right panel again shows the recovery of the depressant electrophysiological effects of disopyramide, with depression of ventricular mechanical performance remaining.*

[a] * = $p < 0.05$; ** = $p < 0.01$.

Effects of Disopyramide on Ventricular Performance—Both disopyramide and quinidine caused a depression in left ventricular systolic pressure and an increase in end diastolic pressure. These changes in left ventricular pressures lasted about 2 hr. Similar but less evident depression of ventricular contractility was observed with strain-gauge recordings (Fig. 3). Disopyramide was found to have a much more pronounced depressant effect than quinidine on the maximum *dP/dt* of the left ventricle. This depressant effect persisted longer than 2 hr. (Fig. 2). Thus, the depressant effect of disopyramide on cardiac mechanical performance persisted when the electrophysiological effects of the drug had disappeared (Table IV).

Depression of ventricular mechanical performance by disopyramide and quinidine was also demonstrated by pacing. The ability of the ventricular muscle to respond mechanically to pacing was impaired, and "pulsus alternans" developed at a lower driving rate after injection of the drugs (Fig. 3).

***In Vitro* Studies**—Superfusion with Tyrode's solution containing disopyramide (1–2 mg./l.) significantly prolongated the action potential duration, decreased the rate of maximum depolarization (*dV/dt*) maximum, and caused conduction delay without significantly affecting the resting potential or the overshoot (Figs. 4 and 5). Therefore, the electrophysiological properties of disopyramide can be classified as "quinidine-like." The prolongation in action potential duration probably was the first electrophysiological change noted, and it became evident after 20 min. of superfusion with 1 mg./l. disopyramide. The maximal depressant effects of disopyramide were reached within 1 hr., and some drug effects persisted even after a 30-min. washout period. Table V shows data obtained from one canine preparation.

Depression of electrophysiological parameters occurred earlier and was more pronounced when 2 mg./l. disopyramide was used. Qualitatively similar responses were seen in human atrial tissues, but the human atrial muscle fibers seemed to be more resistant to the depressant effects of disopyramide than were the canine Purkinje fibers (Fig. 6).

As expected, the membrane responsiveness curves were shifted to the right after perfusion with disopyramide. This shift in membrane responsiveness was also associated with a significant depression of maximum *dV/dt* after complete repolarization when higher doses of disopyramide were used (Fig. 7).

No spontaneous automaticity was observed in human left atrial

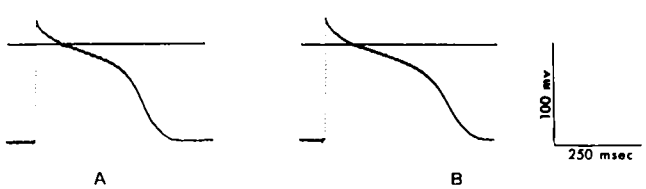

Figure 4—*Effects of 1 mg./l. disopyramide on the action potential duration of a canine Purkinje fiber driven at a cycle length of 630 msec. The control (A) action potential duration was 400 msec. Thirty minutes after exposure to disopyramide (B), the action potential had increased to 450 msec.*

Table V—Electrophysiological Effects of 1 mg./l. Disopyramide on Canine Purkinje–Muscle Preparations[a]

[a] The values are the mean ± *SE* for seven experiments.

preparations. The canine Purkinje-papillary muscle preparations also had slow spontaneous phase 4 depolarization, so the effects of disopyramide on automaticity could not be properly evaluated in these *in vitro* preparations. However, judging from the decrease in inward sodium current caused by the drug, disopyramide might have a depressant effect in preparations exhibiting a high spontaneous rate.

DISCUSSION

Disopyramide in doses of 3 or 5 mg./kg. i.v. caused a slowing of sinus rate in intact dogs, presumably through the decrease of the slope of phase 4 depolarization of sinoatrial pacemakers. Disopyramide, 1 or 2 mg./l., caused a shift of membrane responsiveness curves to the right. These direct quinidine-like properties of disopyramide are consistent with its clinical effectiveness in the suppression or abolition of arrhythmias due to enhanced phase 4 depolarization.

Disopyramide also prolonged action potential duration and increased the effective refractory period. Both effects of disopyramide can result in the abolition of premature "contractions"; if the premature depolarization reaches a refractory tissue, it will not elicit an effective response and the premature contraction will be suppressed. The prolongation of the action potential and refractory period could also account for a beneficial therapeutic response in arrhythmias resulting from reentrant mechanisms. Disopyramide would be effective if the slowing of conduction induced by the drug were proportionally less than the prolongation in the effective refractory period, *i.e.*, if the conduction speed in the circus pathway were relatively accelerated by the drug. In Purkinje–muscle preparations, disopyramide caused a greater prolongation of the refractory period than conduction velocity (*cf.*, Table V); thus, it may abolish arrhythmias caused by unidirectional conduction delay and reentry.

These data indicate that disopyramide is a quinidine-like drug, and its antiarrhythmic properties could be explained on the basis of: (*a*) a possible depression of unduly enhanced phase 4 depolarization, (*b*) decreased membrane responsiveness, and (*c*) prolongation of the refractory period.

The electrophysiological effects of disopyramide obtained from our microelectrode studies are qualitatively similar to those reported by Sekiya and Vaughan Williams (5). However, quantita-

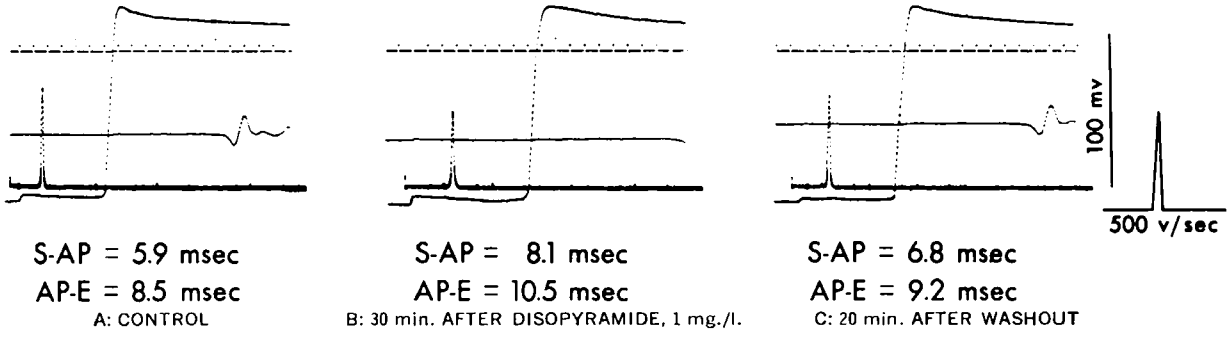

Figure 5—*Effects of 1 mg./l. disopyramide on resting potential, maximum rate of depolarization* (dV/dt *max*), *and conduction velocity in a canine Purkinje fiber-papillary muscle preparation. A is the control. The top tracing is the zero reference line with time marks of 1 and 10 msec. The second tracing shows the surface electrogram (E) recorded from the distal end of the specialized ventricular conduction system. The third tracing shows the* dV/dt *max of the action potential, and the bottom tracing shows the action potential (AP) recorded from a Purkinje fiber in the proximal end of the same strand of specialized ventricular conduction system. Stimulus artifact (S) can be seen at the beginning of the third and the fourth tracings. B shows that 1 mg./l. disopyramide decreased the maximum rate of rise of the action potential and conduction velocity, without affecting either the resting potential or the overshoot. These effects of disopyramide are largely reversible, and C shows the improvement of* dV/dt *max and conduction velocity after washout. Calibrations for voltage and* dV/dt *are indicated on the right side of the figure.*

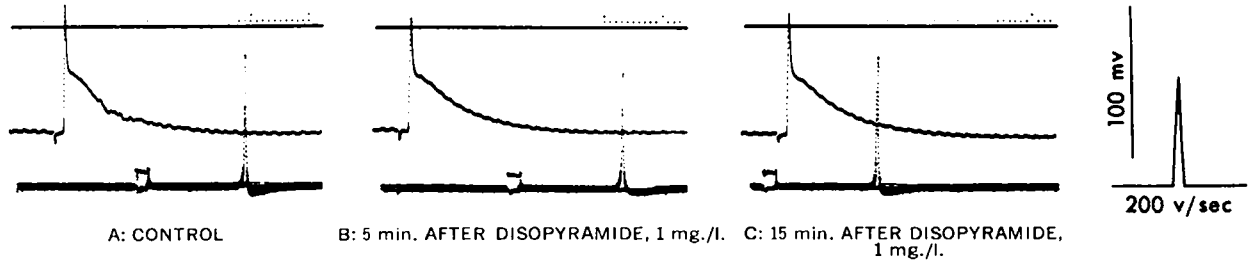

Figure 6—*Effects of disopyramide on the action potential of a human atrial muscle fiber. A is the control. The top tracing is the zero reference line showing time marks of 10 and 100 msec. The square pulse on the bottom tracing shows the stimulus intensity (10% above threshold), and the maximum rate of depolarization* (dV/dt *max*) *is also registered. Note that 1 mg./l. disopyramide caused a slight and transient depolarization, associated with a decrease in* dV/dt *max and overshoot (B). The atrial cell recovered quickly despite the continued presence of disopyramide in the perfusate (C).*

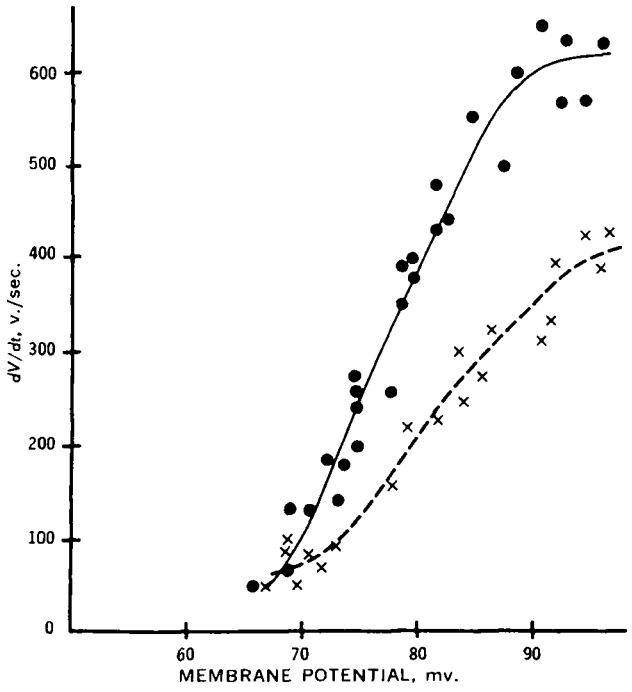

Figure 7—*Effects of disopyramide on membrane responsiveness in dog Purkinje fibers. The control curve is one characteristic of a normal Purkinje fiber, with the maximum rate of rise* (dV/dt) *of about 600 v./sec. It is evident that 2 mg./l. disopyramide caused a shift of the membrane responsiveness curve to the right, and there was also depression of* dV/dt *to around 400 v./sec., while the maximum resting potential remained unchanged (90–95 mv.). The measurements were made 45 min. after exposure to disopyramide. Key:* ●—●, *control; and* ×- - -×, *after 2 mg./l. disopyramide.*

tively speaking, the dog Purkinje fibers used in the present study are perhaps at least 5 times more sensitive to the depressant effect of disopyramide than the rabbit atrial muscle fibers. This is consistent with our own data showing that human atrial muscle fibers are more resistant to disopyramide than dog Purkinje fibers. These differences in sensitivity to disopyramide, if not due to species difference, could be explained by the well-known fact that the specialized ventricular conduction system is more sensitive to drugs than ordinary cardiac muscle fibers.

Like quinidine, disopyramide also depresses myocardial contractility and left ventricular function. It would be an undesirable property if the depressant effect of disopyramide on myocardial performance, which outlasts its electrophysiological effects in the dog heart, is also found in man.

Pharmacokinetics of Iodochlorhydroxyquin in Man

D. B. JACK and W. RIESS▲

Abstract □ A method of extracting iodochlorhydroxyquin from plasma and quantitating by GLC was developed and used to study the pharmacokinetics in man. A clearcut dose–plasma concentration relationship was obtained, and no evidence of accumulation was found.

Keyphrases □ Iodochlorhydroxyquin—pharmacokinetics in man, dose–plasma concentration relationships, GLC determination □ Quinolines (iodochlorhydroxyquin)—GLC analysis of human plasma samples, pharmacokinetics □ Pharmacokinetics—iodochlorhydroxyquin half-life, dose–plasma concentration relationships, GLC determination □ GLC—analysis of iodochlorhydroxyquin in human plasma samples

Recently two publications (1, 2) appeared dealing with the GLC of halogenated quinolines using flame-ionization detection. Neither publication was concerned with the analysis of extracts derived from biological material.

To study the pharmacokinetics of iodochlorhydroxyquin, 5-chloro-7-iodo-8-hydroxyquinoline, a sensitive and specific method of analysis was needed; the presence of two halogen atoms in the molecule made GLC using an electron-capture detector an obvious choice. Acetylation at the 8-position of the quinoline ring system provided a derivative of sufficient volatility to allow 50-ng./ml. concentrations to be measured.

EXPERIMENTAL

By using the developed method, the kinetics in man were studied as follows.

Single-Dose Administration—Six volunteers were given single oral doses of 250 and 1500 mg. of iodochlorhydroxyquin powder[1]

[1] Iodochlorhydroxyquin was administered as a powder with the addition of 7% *N*-stearoyl-*N'*,*N'*-diethylethylenediamine (Sapamine). This formulation is available commercially as Entero-Vioform.

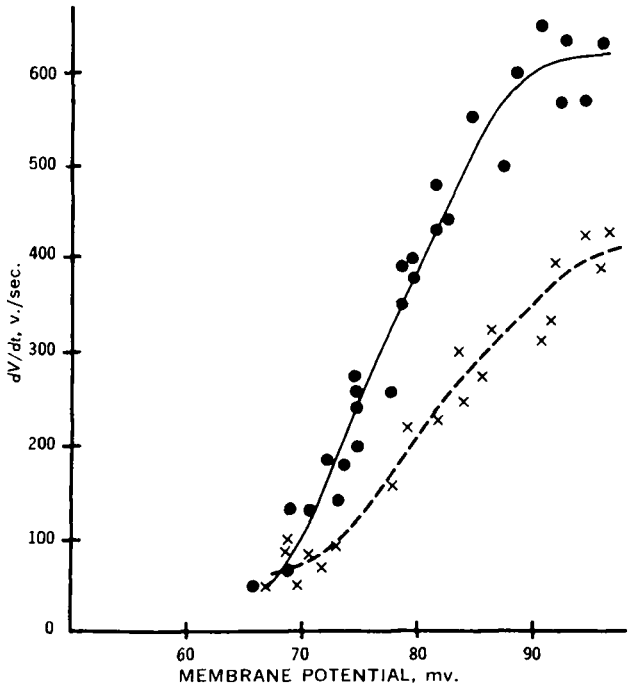

Figure 7—*Effects of disopyramide on membrane responsiveness in dog Purkinje fibers. Pharmacokinetics of Iodochlorhydroxyquin in Man

D. B. JACK and W. RIESS▲

Abstract □ A method of extracting iodochlorhydroxyquin from plasma and quantitating by GLC was developed and used to study the pharmacokinetics in man. A clearcut dose–plasma concentration relationship was obtained, and no evidence of accumulation was found.

Keyphrases □ Iodochlorhydroxyquin—pharmacokinetics in man, dose–plasma concentration relationships, GLC determination □ Quinolines (iodochlorhydroxyquin)—GLC analysis of human plasma samples, pharmacokinetics □ Pharmacokinetics—iodochlorhydroxyquin half-life, dose–plasma concentration relationships, GLC determination □ GLC—analysis of iodochlorhydroxyquin in human plasma samples

Recently two publications (1, 2) appeared dealing with the GLC of halogenated quinolines using flame-ionization detection. Neither publication was concerned with the analysis of extracts derived from biological material.

To study the pharmacokinetics of iodochlorhydroxyquin, 5-chloro-7-iodo-8-hydroxyquinoline, a sensitive and specific method of analysis was needed; the presence of two halogen atoms in the molecule made GLC using an electron-capture detector an obvious choice. Acetylation at the 8-position of the quinoline ring system provided a derivative of sufficient volatility to allow 50-ng./ml. concentrations to be measured.

EXPERIMENTAL

By using the developed method, the kinetics in man were studied as follows.

Single-Dose Administration—Six volunteers were given single oral doses of 250 and 1500 mg. of iodochlorhydroxyquin powder[1]

[1] Iodochlorhydroxyquin was administered as a powder with the addition of 7% *N*-stearoyl-*N'*,*N'*-diethylethylenediamine (Sapamine). This formulation is available commercially as Entero-Vioform.

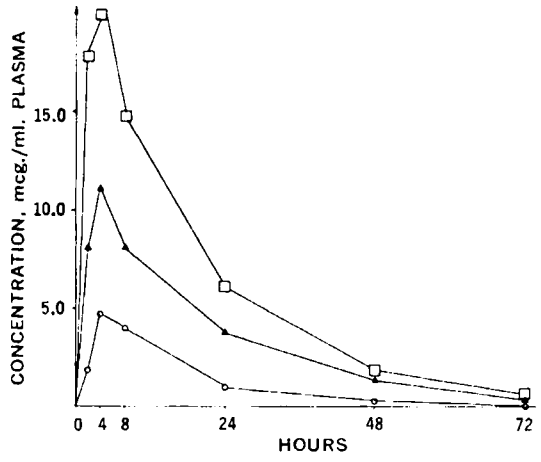

Figure 1—*Mean plasma levels of iodochlorhydroxyquin (micrograms per milliliter) after single oral doses of 250* (○), *750* (▲), *and 1500* (□) *mg. iodochlorhydroxyquin powder (six subjects per dose).*

in a crossover study, three subjects beginning with the 250-mg. and three with the 1500-mg. dose with 2 weeks between the two administrations.

Another group of six volunteers took a single oral dose of 750 mg. Blood was withdrawn from all subjects immediately before and 2, 4, 8, 24, 48, and 72 hr. after administration.

Multiple-Dose Administration—Six volunteers were given 500 mg. of iodochlorhydroxyquin powder three times daily at 8:00 a.m., 2:00 p.m., and 8:00 p.m. for 7 days followed by 250 mg. three times daily at the same times for an additional 7 days. Blood samples were withdrawn immediately before the first dose of the day on Days 1–5 and 8–12 and at 8:00 a.m. on the first 4 days following the end of administration.

Heparin[2] was added to all samples, which were then immediately centrifuged, and the plasma was stored at −20° until analysis.

Methods and Apparatus—GLC was carried out using a chromatograph[3] equipped with an electron-capture detector (^{63}Ni source) operated with a pulse space of 150 μsec. A 3.04-m. (10-ft.) glass column, 0.31 cm. (0.125 in.) i.d. filled with 3% OV-17 on Gas Chrom Q, 100 120 mesh[4], was used. The column oven temperature was kept at 205° with the injector block and detector oven temperatures at 230 and 340°, respectively. Nitrogen at a flow of 50 ml./min. was used as carrier gas. Under these conditions, the retention times of the internal standard 5,7-dichloro-8-acetoxyquinoline and of 5-chloro-7-iodo-8-acetoxyquinoline were 6.0 and 14.6 min., respectively.

Extraction—To correct for losses during the extraction, 5,7-dichloro-8-hydroxyquinoline (1000 ng.) was added to each plasma sample (up to 2 ml. used) before extraction. Water (14 ml.) was then added and the sample was extracted three times with 2-ml. portions of methylene chloride–ether (1:4). After centrifugation, the organic phase was removed and evaporated, and 200 μl. of acetic anhydride and 50 μl. of pyridine were added. The sample was placed in a water bath at 70° for 1 hr. and, after the addition of 4

ml. of water, extracted with 3 × 1 ml. ethyl acetate. The ethyl acetate was washed once with 2 ml. of saturated sodium bicarbonate, evaporated, and redissolved in 100 μl. ethyl acetate for injection.

In cases where more than 0.5 ml. of plasma was taken, it was necessary to add a TLC step. The ethyl acetate extract (100 μl.) was applied to a silica gel plate with a reference compound on either side, and the plate was developed in hexane–ether (1:3). The reference compound may be the 8-acetoxy derivative of either the 5,7-dichloro or 5-chloro-7-iodo compound, since they both have the same R_f value in this system. After development, the appropriate region is noted, scraped off, shaken with 1 ml. of saturated sodium bicarbonate, and extracted (3 × 0.5 ml.) with ethyl acetate. After centrifugation, the organic phase is evaporated and redissolved in 100 μl. ethyl acetate for injection. The use of 5,7-dichloro-8-hydroxyquinoline, both as an internal standard for the extraction and as the 8-acetoxy derivative for GLC, permitted the amount of iodochlorhydroxyquin present in the sample to be calculated from the peak area ratio of the two acetoxy derivatives. Plasma samples were prepared with added iodochlorhydroxyquin and analyzed using this method (Table I).

[a] Dose not taken the evening before.

RESULTS AND DISCUSSION

Single-Dose Administration—The results of the single-dose study are given in Table II and illustrated in Fig. 1. Maximum plasma concentrations were reached around 4 hr. after administration for the three doses studied and then decreased with an apparent half-life of between 11 and 14 hr. (Fig. 2).

For the average plasma concentration curves, the time of maximal concentrations observed and the half-life values obtained allow the calculation of the range of the absorption rate constant, k_a, which was found to be between 0.63 and 0.69 $hr.^{-1}$.

The areas under the plasma curves can be calculated and standardized for the body weight of the individual according to the following formula:

$$\text{standard area} = \frac{Wi}{75}\int_0^{72\text{ hr.}} c\,dt \text{ (mcg./ml.)(hr.)} \quad \text{(Eq. 1)}$$

where Wi = individual body weight, and 75 kg. is taken as the standard body weight. The area under the plasma curve values so obtained (Table III) clearly reflect the different dosages. Comparison of the area under the plasma curve values of Subjects G–M showed no statistically significant difference in the relative absorption of the two dosages of 250 and 1500 mg.

Metabolic studies using ^{14}C-iodochlorhydroxyquin showed that approximately 25% of a 750-mg. oral dose was excreted in the urine over 72 hr., demonstrating a substantial absorption of the drug from the GI tract. Urine samples collected in this study were examined using the GLC method, and no free iodochlorhydroxyquin was found. Heating the urine samples for 1 hr. at 60° in hydrochloric acid liberated some iodochlorhydroxyquin, which accounted for less than 1% of the administered dose. No attempt was made to estimate glucuronide-conjugated iodochlorhydroxyquin. These findings agree well with a study (3) where 12–24% of the administered dose (250 mg.) was found in the urine over 10 hr. No free iodochlorhydroxyquin was found.

Multiple-Dose Administration—The plasma levels measured immediately before the first dose of the day are given in Table IV and illustrated in Fig. 3. Equilibrium between the amount absorbed and the amount eliminated per 24-hr. period appears to be reached by the 5th day of treatment at the latest. After discontinuation of administration, the plasma levels fall to undetectable values after approximately 3 days, which is in accord with the single-dose findings. Urine samples collected over 1 hr. immediately before the first dose of the day were analyzed when no free iodochlorhydroxyquin was found. No evidence of the accumulation of iodochlorhydroxyquin in the plasma was found.

SUMMARY

A GLC method, capable of measuring plasma levels as low as 50 ng./ml. of iodochlorhydroxyquin, was developed. Volunteers given single oral doses of 250, 750, and 1500 mg. of iodochlorhydroxyquin powder exhibited a clear dose–plasma concentration relationship. Calculation of the area under the plasma concentration curves showed that the relative absorption of the three doses was similar. The half-life was between 11 and 14 hr. Volunteers given orally 3 × 500 mg. of the powder daily for 7 days followed by 3 × 250 mg. daily for an additional 7 days had blood samples withdrawn 24 hr. after the daily dose. Equilibrium between the amount absorbed and the amount eliminated per 24-hr. period appeared to be reached by the 5th day of administration. After discontinuation of treatment, the plasma levels fell to undetectable levels after 3 days, a finding that agreed well with the results of the single-dose study. No evidence of the accumulation of iodochlorhydroxyquin was found.

Blood Level Profile in Man following Chronic Oral Administration of Flurazepam Hydrochloride

S. A. KAPLAN▲, J. A. F. de SILVA, M. L. JACK, K. ALEXANDER, N. STROJNY, R. E. WEINFELD, C. V. PUGLISI, and L. WEISSMAN

Abstract □ The blood level profile of flurazepam and its major metabolites was determined in man following the oral administration of 30 mg. daily for 2 weeks. The levels of the intact drug were below the sensitivity limit of the assay (<3–4 ng./ml.). The hydroxyethyl metabolite was measurable only during the early hours after a 30-mg. oral dose and was not detectable after 24 hr. The major metabolite in blood was *N*-desalkyl-flurazepam, which reached steady-state (plateau) levels after 7 days. The half-life of elimination of the *N*-desalkyl metabolite ranged from 47 to 100 hr. No measurable amounts of the *N*-desalkyl-3-hydroxy metabolite were seen in blood.

Keyphrases □ Flurazepam hydrochloride and metabolites—blood level profile in man following 14 days administration, half-lives □ Blood level profile—flurazepam hydrochloride and metabolites after 14 days administration, man □ Biotransformation—flurazepam hydrochloride after chronic administration, blood level profile including metabolites, half-lives □ Benzodiazepines, flurazepam hydrochloride—biotransformation, blood level profile, metabolites

Flurazepam[1], 7-chloro-1-[2-(diethylamino)ethyl]-5-(*o*-fluorophenyl)-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one dihydrochloride (I), was synthesized by Sternbach *et al.* (1) and is marketed as a hypnotic for the treatment of insomnia (2). Studies on the metabolism of flurazepam (3) showed that it was extensively metabolized in both man and dog to yield measurable amounts of the hydroxyethyl (II) and *N*-desalkyl (III) metabolites in the blood. The latter was further metabolized to the 3-hydroxy analog (IV), which appeared in trace amounts in urine as a glucuronide conjugate. In addition, they showed that both flurazepam and the hydroxyethyl metabolite were metabolized extensively in the dog to an acidic compound, flurazepam-*N*-yl-acetic acid (V), by the oxidation of the alcohol side chain to a carboxylic acid. Flurazepam-*N*-yl-acetic acid is a minor urinary metabolite in man.

The characterization of these metabolites and the synthesis of authentic reference compounds were reported previously (4, 5). The objective of the present study was to define the blood level profile of flurazepam and its major biotransformation products when the drug is administered once daily for 14 days at the usually recommended therapeutic dose of 30 mg./day.

PROCEDURE

Blood levels of flurazepam and its major biotransformation products were analyzed by a spectrofluorometric method (6), which involves selective extraction of flurazepam and its metabolites (II, III, and IV) from blood buffered to pH 9.0 into ether, back-extraction into 6 *N* HCl, and hydrolysis to their benzophenones followed by cyclization to the highly fluorescent 9-acridanone derivatives. These derivatives are extracted into ether and separated by TLC, and their fluorescence is determined in methanol–0.1 *N* HCl (80:20) (after elution from the silica gel) at their respective activation and emission maxima.

The sensitivity of the assay is of the order of 3–10 ng. of each compound/ml. of blood using a 4-ml. specimen per analysis. The spectrofluorometric assay does not specifically differentiate *N*-desalkyl-flurazepam from the *N*-desalkyl-3-hydroxy metabolite if present, since they both give rise to the same 9-acridanone derivative (6). However, the presence of *N*-desalkyl-flurazepam as the major metabolite in the blood of these subjects was confirmed by electron-capture GLC analysis[2], which completely resolves the *N*-

SUMMARY

A GLC method, capable of measuring plasma levels as low as 50 ng./ml. of iodochlorhydroxyquin, was developed. Volunteers given single oral doses of 250, 750, and 1500 mg. of iodochlorhydroxyquin powder exhibited a clear dose–plasma concentration relationship. Calculation of the area under the plasma concentration curves showed that the relative absorption of the three doses was similar. The half-life was between 11 and 14 hr. Volunteers given orally 3 × 500 mg. of the powder daily for 7 days followed by 3 × 250 mg. daily for an additional 7 days had blood samples withdrawn 24 hr. after the daily dose. Equilibrium between the amount absorbed and the amount eliminated per 24-hr. period appeared to be reached by the 5th day of administration. After discontinuation of treatment, the plasma levels fell to undetectable levels after 3 days, a finding that agreed well with the results of the single-dose study. No evidence of the accumulation of iodochlorhydroxyquin was found.

Blood Level Profile in Man following Chronic Oral Administration of Flurazepam Hydrochloride

S. A. KAPLAN▲, J. A. F. de SILVA, M. L. JACK, K. ALEXANDER, N. STROJNY, R. E. WEINFELD, C. V. PUGLISI, and L. WEISSMAN

Abstract □ The blood level profile of flurazepam and its major metabolites was determined in man following the oral administration of 30 mg. daily for 2 weeks. The levels of the intact drug were below the sensitivity limit of the assay (<3–4 ng./ml.). The hydroxyethyl metabolite was measurable only during the early hours after a 30-mg. oral dose and was not detectable after 24 hr. The major metabolite in blood was *N*-desalkyl-flurazepam, which reached steady-state (plateau) levels after 7 days. The half-life of elimination of the *N*-desalkyl metabolite ranged from 47 to 100 hr. No measurable amounts of the *N*-desalkyl-3-hydroxy metabolite were seen in blood.

Keyphrases □ Flurazepam hydrochloride and metabolites—blood level profile in man following 14 days administration, half-lives □ Blood level profile—flurazepam hydrochloride and metabolites after 14 days administration, man □ Biotransformation—flurazepam hydrochloride after chronic administration, blood level profile including metabolites, half-lives □ Benzodiazepines, flurazepam hydrochloride—biotransformation, blood level profile, metabolites

Flurazepam[1], 7-chloro-1-[2-(diethylamino)ethyl]-5-(*o*-fluorophenyl)-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one dihydrochloride (I), was synthesized by Sternbach *et al.* (1) and is marketed as a hypnotic for the treatment of insomnia (2). Studies on the metabolism of flurazepam (3) showed that it was extensively metabolized in both man and dog to yield measurable amounts of the hydroxyethyl (II) and *N*-desalkyl (III) metabolites in the blood. The latter was further metabolized to the 3-hydroxy analog (IV), which appeared in trace amounts in urine as a glucuronide conjugate. In addition, they showed that both flurazepam and the hydroxyethyl metabolite were metabolized extensively in the dog to an acidic compound, flurazepam-*N*-yl-acetic acid (V), by the oxidation of the alcohol side chain to a carboxylic acid. Flurazepam-*N*-yl-acetic acid is a minor urinary metabolite in man.

The characterization of these metabolites and the synthesis of authentic reference compounds were reported previously (4, 5). The objective of the present study was to define the blood level profile of flurazepam and its major biotransformation products when the drug is administered once daily for 14 days at the usually recommended therapeutic dose of 30 mg./day.

PROCEDURE

Blood levels of flurazepam and its major biotransformation products were analyzed by a spectrofluorometric method (6), which involves selective extraction of flurazepam and its metabolites (II, III, and IV) from blood buffered to pH 9.0 into ether, back-extraction into 6 *N* HCl, and hydrolysis to their benzophenones followed by cyclization to the highly fluorescent 9-acridanone derivatives. These derivatives are extracted into ether and separated by TLC, and their fluorescence is determined in methanol–0.1 *N* HCl (80:20) (after elution from the silica gel) at their respective activation and emission maxima.

The sensitivity of the assay is of the order of 3–10 ng. of each compound/ml. of blood using a 4-ml. specimen per analysis. The spectrofluorometric assay does not specifically differentiate *N*-desalkyl-flurazepam from the *N*-desalkyl-3-hydroxy metabolite if present, since they both give rise to the same 9-acridanone derivative (6). However, the presence of *N*-desalkyl-flurazepam as the major metabolite in the blood of these subjects was confirmed by electron-capture GLC analysis[2], which completely resolves the *N*-

desalkyl metabolite from the *N*-desalkyl-3-hydroxy metabolite. The specimens from Days 14, 15, and 16 in Subjects 2, 3, and 4 were analyzed by the GLC procedure and clearly showed that the *N*-desalkyl-3-hydroxy metabolite was not present in the blood and confirmed that the *N*-desalkyl metabolite was the major blood component present. Therefore, the metabolite levels represented as the *N*-desalkyl metabolite by the fluorometric assay are due only to this component in these subjects.

Four adult healthy male volunteers (age and weight listed here) were selected for this study:

chloride at approximately 10 p.m. for 14 days. Ten milliliters oxalated blood specimens were obtained as follows: Days 1, 7, and 14—just prior to drug administration and at 1, 3, 6, 12, and 24 hr. postadministration; Days 2 through 6 and 8 through 13—just prior to drug administration (24 hr. postadministration); and Days 15, 16, 17, 19, 21, 28, and 35—at 10 p.m. (1, 2, 3, 5, 7, 14, and 21 days following the last administration on Day 14).

All blood specimens were frozen immediately and maintained frozen until analyzed.

RESULTS AND DISCUSSION

The blood level data are tabulated in Tables I–IV for Subjects 1–4. The blood levels of the N-desalkyl metabolite in each subject are summarized in Fig. 1. The overall blood level profile parameters are summarized in Table V.

Blood levels of flurazepam were generally below 2 ng./ml. Only Subject 1 exhibited trace amounts of flurazepam of 3–4 ng./ml. on Day 14 of the study.

Blood levels of the hydroxyethyl metabolite were seen in the early hour samples measured on Days 1, 7, and 14 (Tables I–IV). The elimination rate of the hydroxyethyl metabolite was very rapid (data insufficient for half-life calculation), and this metabolite was not evident in the blood 24 hr. postadministration.

The N-desalkyl metabolite was the major detectable blood component following flurazepam hydrochloride administration (Fig. 1). The half-lives of elimination of this component from the blood were calculated to be 64, 47, 51, and 100 hr. for Subjects 1, 2, 3, and 4, respectively.

Subjects 2 and 4 exhibited a typical steady-state blood level profile of the N-desalkyl metabolite. In both subjects, the blood levels appeared to reach a plateau on Days 7–10 of the study. Subject 2 exhibited a minimum steady-state level (24 hr. postdosing), ranging between 33 and 42 ng./ml. The corresponding range for Subject 4 was 84–114 ng./ml. These values correlate well with the "calculated" minimum steady-state levels of 28 and 88 ng./ml. for Subjects 2 and 4, respectively (Table V). The calculated value was obtained using the observed half-life and the 24-hr. blood level on Day 1 for each subject. This close correlation of actual and calculated minimum steady-state levels indicates that the levels of the N-desalkyl metab-

Flurazepam (I):				
Blood levels	Barely detectable on Day 14, only at 3–4 ng./ml.	N.D.[b]	N.D.	N.D.

[a] Body weight. [b] N.D. = not detectable <2–3 ng./ml.

olite reach a predictable steady-state plateau within 7–10 days upon chronic drug administration. The actual minimum steady-state blood levels were approximately four- to sixfold greater than the 24-hr. blood level observed on Day 1.

The daily 24-hr. blood levels of the *N*-desalkyl metabolite in Subjects 1 and 3 were more variable than those found in Subjects 2 and 4. The correlation of the actual 24-hr. blood levels and the calculated steady-state level was fair in Subject 1, with the calculated value falling at the lower end of the actual 24-hr. blood level range (Table V). Subject 1 exhibited 24-hr. blood levels from Days 10 to 14, which were approximately five- to sixfold greater than the observed Day 1 level, which is consistent with the findings in Subjects 2 and 4. The actual 24-hr. levels in Subject 3 were lower than the calculated minimum steady-state levels.

The blood level profile following the oral administration of 30 mg. of flurazepam hydrochloride every 24 hr. indicates that: (*a*) the blood level of flurazepam was <2 ng./ml. in blood, (*b*) the hydroxyethyl metabolite was present in the blood in the early hours following each administration and was rapidly eliminated, and (*c*) the *N*-desalkyl metabolite was the major blood component.

The blood level profiles indicate that the *N*-desalkyl metabolite was eliminated with half-lives of 64, 47, 51, and 100 hr. in the four subjects studied. In three subjects, blood levels of this metabolite exhibited a "typical," predictable minimum steady-state profile: *i.e.*, the actual and calculated steady-state levels correlated well. This would suggest that the physiological disposition of the *N*-desalkyl metabolite follows apparent first-order kinetic patterns. The minimum steady-state levels observed, commencing 7–10 days following the onset of a once every 24-hr. dosing regimen, were approximately five- to sixfold greater than the 24-hr. levels observed on Day 1.

SUMMARY

Following the oral administration of 30 mg. of flurazepam hydrochloride in man every 24 hr. for 14 days, blood samples were analyzed for flurazepam and its major metabolites. The method used for the analysis of flurazepam was not sufficiently sensitive to measure the concentration of unchanged drug in blood (<2 ng. flurazepam/ml. of blood was present). The hydroxyethyl metabolite was present in the blood shortly after each administration and was rapidly eliminated. The *N*-desalkyl metabolite was the major metabolite in blood. It was eliminated with half-lives of 47–100 hr. in the four subjects. It exhibited a typical minimum steady-state profile, with plateau levels reached after 7–10 days of dosing, approximately five- to sixfold greater than the 24-hr. levels observed on Day 1.

Calculating Absorption Rate Constants for Drugs with Incomplete Availability

LEWIS J. LEESON[▲] and HOWARD WEINTRAUB*

Abstract □ A mathematical analysis was made of the type of results to be expected, by the classic pharmacokinetic treatment of plasma level data, when, in addition to absorption, the drug is simultaneously lost to an extravascular compartment *via* either a parallel first- or zero-order process. Equations are presented for both the presence and absence of a lag time before onset of the parallel process. A procedure is proposed which allows the true first-order absorption rate constant to be determined for some models, as well as the elucidation of the applicable model.

Keyphrases □ Drugs with incomplete availability—considerations in calculating absorption rate constants, plasma level data and simultaneous loss to extravascular compartment, equations for both presence and absence of lag time □ Absorption rate constants, drugs with incomplete availability—mathematical treatment of plasma level data and simultaneous loss to extravascular compartment, equations for both presence and absence of lag time □ Pharmacokinetics—calculation of absorption rate constants for drugs with incomplete availability, plasma level data and simultaneous loss to extravascular compartment, equations for both presence and absence of lag time

In a recent publication, Notari *et al.* (1) demonstrated that methods commonly employed to calculate absorption rate constants from the time course of drug in the blood do not result in the correct value if the drug is simultaneously lost to an extravascular compartment by a parallel first-order process. It is well recognized in chemical kinetics that the classical kinetic treatment of reaction data, in which a compound degrades *via* two or more first-order pathways, yields an apparent rate constant for loss of material which is a sum of the rate constants for the individual processes. However, to the best of these authors' knowledge, the application of this principle to pharmacokinetic considerations was not recognized prior to the publication of Notari *et al.* (1). More recently, Perrier and Gibaldi (2) expanded on Notari's concept, which deals primarily with chemical degradation of drugs in solution, to include the case of both a granulation and a nondisintegrating dosage form moving along the GI tract to a point where absorption no longer occurs. They also considered the case where the competing parallel reaction was zero order and introduced the concept of a lag time occurring prior to the onset of either parallel reaction. These authors (2) concluded that the nature of the rate constant obtained with a parallel first-order reaction was dependent upon the lag time. They also reported that in the case of a parallel zero-order reaction, although the computer-generated data showed curvature, when plotted according to the Wagner–Nelson (3) or Loo–Riegelman (4) method, the normal experimental error encountered in real situations could mask this. As a result, one would tend to accept the curves as linear and employ the slope to obtain an absorption rate constant.

The cases of parallel first-order and zero-order competitive processes with various lag times have been considered, and a mathematical interpretation is presented for the nature of the curves obtained both by the method of feathering and by the Wagner–Nelson (3) procedure. In the case of the parallel first-order loss of drug to extravascular compartment, it is concluded that these methods yield plots which tend to be curved until the onset of the lag time, at which time they become linear and are all parallel. In the case of a parallel zero-order process, one encounters curves that could be interpreted as linear, with the apparent linear relationships being a function of the lag time. In addition, a method was developed which in some cases allows an investigator to determine the correct absorption rate constant with concomitant recognition of the nature of the parallel process.

All of this work has been limited to the one-compartment open model with first-order absorption. However, parallel considerations for more complex models are possible in a manner similar to that presented in this report.

EXPERIMENTAL

In this analysis, the simple one-compartment open model is represented as shown in Scheme I, where k_1 and k_2 are the absorption

$$\underset{\text{absorption compartment}}{A} \xrightarrow{k_1} \underset{\text{plasma compartment}}{B} \xrightarrow{k_2} \underset{\text{elimination compartment}}{C}$$

Scheme I

and elimination rate constants, respectively. Two variations on this scheme were considered. In Case 1, drug in Compartment A is simultaneously being removed to an extravascular compartment by a first-order rate process with a rate constant of k_3. In Case 2, drug is being removed from Compartment A *via* a zero-order rate process with a rate constant of k_0. These are shown in Scheme II.

Case 1

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$
$$\downarrow k_3$$
$$D$$

Case 2

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$
$$\downarrow k_0$$
$$D$$

Scheme II

All calculations were performed on a programmable desk calculator[1]. The rate constants employed were those suggested by Perrier and Gibaldi (2) ($k_1 = 0.693$, $k_2 = 0.0693$, $k_3 = 0.5$, and $k_0 = 25$)[2]. Lag times were varied from 0 to 3 hr. In most cases only the final forms of the equations employed are presented[3].

[1] Wang model 700.

[2] k_1, k_2, and k_3 are first-order rate constants with dimensions of reciprocal hours; k_0 is a zero-order rate constant with dimensions of units per hour.

[3] Interested parties may obtain the derivations by communication with the authors.

RESULTS AND DISCUSSION

Case 1—It may be shown that the relationship governing the time course of drug in the body in the absence and presence of a lag time is defined by Eqs. 1 and 2, respectively:

$$C_p = \frac{k_1 A_0}{(K - k_2)V}[\exp(-k_2 t) - \exp(-Kt)] \quad \text{(Eq. 1)}$$

$$C_p = \frac{k_1 A_0 \exp(-k_1 t1)}{(K - k_2)V}\{\exp[-k_2(t - t1)] - \exp[-K(t - t1)]\} + \frac{B_{t1}}{V}\{\exp[-k_2(t - t1)]\} \quad \text{(Eq. 2)}$$

where k_1 and k_2 are the absorption and elimination rate constants, respectively; k_3 is the parallel nonabsorption first-order rate constant; t is time; $t1$ is lag time; C_p is the plasma concentration; A_0 is the amount of drug in the dosage form; B_{t1} is the amount of drug in Compartment B at lag time $t1$; K is the sum of the two parallel first-order rate constants ($k_1 + k_3$); and V is the volume of distribution. The similarity between Eq. 1 and that for the one-compartment open model with first-order absorption and no parallel reaction (Eq. 6) is obvious when one substitutes 0 for k_3 in Eq. 1. Equation 2 is applicable only from the onset of the lag time.

In the treatment of experimentally obtained data, one plots log C_p as a function of time and determines k_2 from the log-linear phase. The absorption rate constant is then evaluated by either the method of feathering or the Wagner–Nelson procedure. Under conditions of nonparallel reactions occurring, both methods yield essentially the same results. The type of data obtained from these techniques when one does encounter parallel competing reactions, both with and without lag times, was examined.

Feathering Method (Method of Residuals)—Where there is no lag time, one would employ Eq. 1. It is, therefore, obvious that after onset of the log-linear phase, C_p would be expressed in terms of Eq. 3:

$$C_p = \left[\frac{k_1 A_0}{(K - k_2)V}\right]\exp(-k_2 t) \quad \text{(Eq. 3)}$$

Thus, ΔC_p, which represents the difference in C_p between Eqs. 1 and 3 at any given time, would be expressed as shown in Eq. 4:

$$\Delta C_p = \left[\frac{k_1 A_0}{(K - k_2)V}\right]\exp(-Kt) \quad \text{(Eq. 4)}$$

It is then apparent that Eq. 4 represents a log-linear relationship which, when plotted, has a slope equal to K. This is implicit in what was stated by Notari *et al.* (1) and Perrier and Gibaldi (2).

In the case where there is a finite lag time, $t1$, C_p in the post-absorptive phase comes from Eq. 2 and is shown as Eq. 5:

$$C_p = \left[\frac{k_1 A_0 \exp(-k_1 t1)}{(K - k_2)V} + \frac{B_{t1}}{V}\right]\exp[-k_2(t - t1)] \quad \text{(Eq. 5)}$$

However, when t is less than $t1$, C_p is defined in terms of the classical one-compartment open model with first-order absorption as shown in Eq. 6:

$$C_p = \frac{k_1 A_0}{(k_1 - k_2)V}[\exp(-k_2 t) - \exp(-k_1 t)] \quad \text{(Eq. 6)}$$

Therefore, ΔC_p prior to the onset of the lag time is represented mathematically by Eq. 7, where M and N are constants. It is readily seen that Eq. 7 is not a log-linear relationship:

$$\Delta C_p = M\exp(-k_2 t) + \exp(-k_1 t) \quad \text{(Eq. 7)}$$

$$M = \frac{k_1 A_2 \exp(k_2 - k_1)t1}{(K - k_2)V} + \frac{B_{t1}\exp(k_2 t1)}{V} - N \quad \text{(Eq. 7a)}$$

$$N = \frac{k_1 A_0}{(k_1 - k_2)V} \quad \text{(Eq. 7b)}$$

In the range where t is between $t1$ and the onset of the log-linear phase, C_p is as defined in Eq. 2 and ΔC_p is defined by Eq. 8:

$$\Delta C_p = \left[\frac{k_1 A_0 \exp(k_2 t1)}{(K - k_2)V}\right]\exp(-Kt) \quad \text{(Eq. 8)}$$

It is again obvious that a plot of log ΔC_p *versus* t, according to Eq. 8, will be linear with a slope from which K may be obtained.

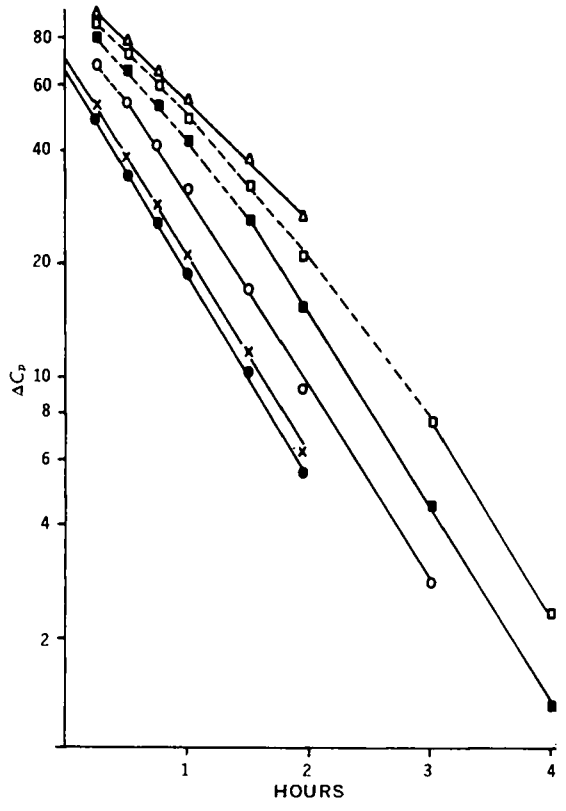

Figure 1—*Plot of* ΔC_p versus *time for data where competing first-order process is operative, calculated according to the method of residuals. Key:* ●, *no lag;* ×, *0.5-hr. lag;* ○, *1-hr. lag;* ■, *2-hr. lag;* □, *3-hr. lag; and* △, *no competitive process (control).*

From this discussion, therefore, it is apparent that when a lag time occurs prior to the onset of a parallel first-order reaction, the feathering technique results in a line that is initially curved followed by a straight portion from which the apparent absorption rate constant (K) is obtained. This value, while not the true absorption rate constant, would be the same whether or not there was a lag time occurring before onset of the competing process. Data of this type are shown in Fig. 1, employing the rate constant suggested by Perrier and Gibaldi (2).

Wagner–Nelson Technique—In the Wagner–Nelson (3) method, one first determines the fraction of drug absorbed, and the absorption rate constant is evaluated from a plot of log fraction unabsorbed as a function of time. The fraction absorbed is determined by dividing the amount of drug absorbed at any time period (D/V) by the total amount of drug absorbed (D_∞/V). The fraction unabsorbed is then expressed by the relationship ($1 - D/D_\infty$).

It may be shown that the total amount of drug absorbed is represented by a sum of the drug absorbed up to the lag time *via* the equation for a one-compartment open model with first-order absorption (Eq. 6), plus the drug absorbed from the onset of the lag time until the onset of the log-linear phase. This is expressed by Eq. 9:

$$D_\infty = D_{t1} + \left(\frac{k_1}{K}\right)A_{t1} = A_0\left[1 - \frac{k_3}{K}\exp(-k_1 t1)\right] \quad \text{(Eq. 9)}$$

where D_{t1} represents the amount of drug absorbed up to the lag time and $[(k_1/K)A_{t1}]$ represents the amount of drug absorbed from the lag time until absorption ceases. The term A_{t1} represents the amount of drug in Compartment A at the onset of the lag time.

Correspondingly, the amount of drug absorbed at any time after the lag time is represented by Eq. 10 where the constants are as designated previously:

$$D = A_0\left\{\left[1 - \frac{k_3}{K}\exp(-k_1 t1)\right] - \left[\frac{k_1}{K}\exp(k_2 t1)\right]\exp(-Kt)\right\} \quad \text{(Eq. 10)}$$

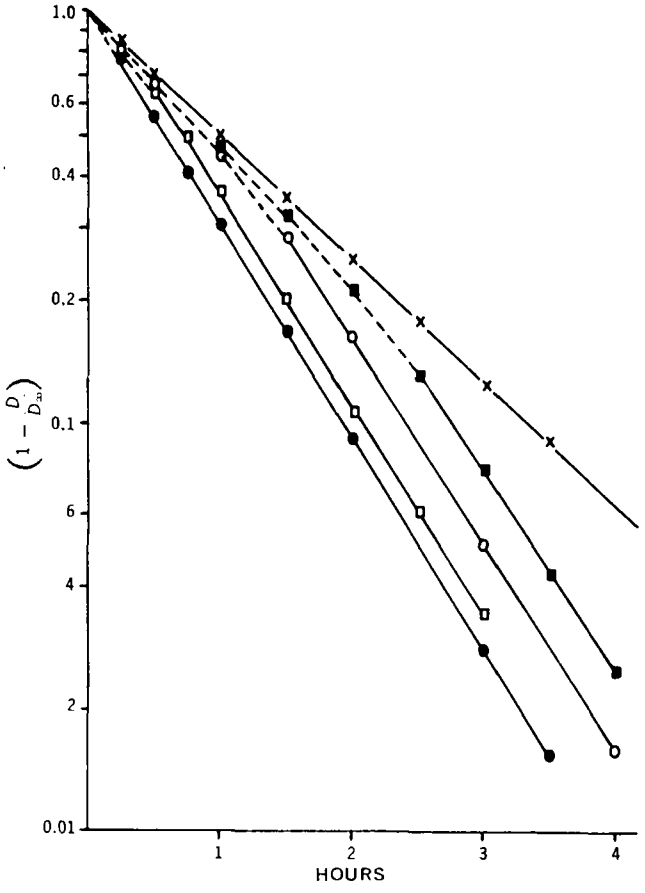

Figure 2—*Plot of Wagner-Nelson calculations* versus *time for data where competing first-order process is operative. Key:* ×, *control (no competition);* ●, *0.5-hr. lag;* □, *1-hr. lag;* ○, *2-hr. lag; and* ■, *3-hr. lag.*

Therefore, if there is no lag time, $D_{t1} = 0$ and the expression $(1 - D/D_\infty)$ may be represented as seen in Eq. 11:

$$(1 - D/D_\infty) = \exp(-Kt) \qquad \text{(Eq. 11)}$$

Equation 11 represents a log-linear relationship from which K may be determined, again in agreement with both Notari *et al.* (1) and Perrier and Gibaldi (2).

Where there is a lag time occurring prior to $t = t1$, the expression $(1 - D/D_\infty)$ is represented by Eq. 12 and is not a log-linear relationship:

$$(1 - D/D_\infty) = \frac{K\exp(-k_1t) - k_3\exp(-k_1t1)}{k_3\exp(-k_1t1) - K} \qquad \text{(Eq. 12)}$$

Between the onset of the lag time and completion of absorption, the expression $(1 - D/D_\infty)$ is represented by Eq. 13 and would be log-linear with the slope related to K:

$$(1 - D/D_\infty) = \left[\frac{k_1\exp(k_3t1)}{K - k_3\exp(-k_1t1)}\right]\exp(-Kt) \qquad \text{(Eq. 13)}$$

This discussion indicates that a Wagner-Nelson (3) plot will be comparable to one obtained by the feathering technique in that the plot will be curved prior to the lag time. After the onset of the lag time and independent of its magnitude, one obtains a straight line from which the identical, apparent first-order absorption rate constant (K) is obtained. Plots of this type are shown in Fig. 2, again employing Perrier and Gibaldi's rate constants. On initial inspection, the results appear to be different from those reported by Perrier and Gibaldi in their Fig. 1. However, if one considers the fact that they limited their results to $(1 - D/D_\infty)$ values of greater than 0.1, in some cases the true log-linear phase was not attained. In addition, for the purpose of emphasis, they intentionally fit all of their data linearly. This masked the cases where there were parallel log-linear relationships. Therefore, Fig. 2 in this publication and Fig. 1 of Perrier and Gibaldi are, in fact, the same.

Parallel Zero-Order Reaction—The relationships between plasma concentration and time resulting from the model designated as Case 2 are somewhat more complex than with Case 1 and are shown by Eq. 14 for the case where $t1 = 0$ and by Eq. 15 when there is a finite lag time:

$$C_p = \left[\frac{k_0}{k_2V} + \frac{k_1A_0 + k_0}{V(k_1 - k_2)}\right]\exp(-k_2t) - \left[\frac{k_1A_0 + k_0}{V(k_1 - k_2)}\right]\exp(-k_1t) - \frac{k_0}{k_2V} \qquad \text{(Eq. 14)}$$

$$C_p = \left[\frac{k_0}{k_2V} + \frac{k_1A_0\exp(-k_1t1) + k_0}{V(k_1 - k_2)}\right]\exp[-k_2(t - t1)] - \left[\frac{k_1A_0\exp(-k_1t1) + k_0}{V(k_1 - k_2)}\right]\exp[-k_1(t - t1)] - \frac{k_0}{Vk_2} + \frac{B_{t1}}{V}\exp[-k_2(t - t1)] \qquad \text{(Eq. 15)}$$

In these expressions, the constants are all as previously designated. Equations 14 and 15 may be expressed in a number of ways for which an equivalency is not immediately apparent. Moreover, Eq. 15 applies only after onset of the lag time.

Upon first examination of Eqs. 14 and 15, there appears to be an error in the fact that when time is equal to infinity C_p does not go to zero but becomes a finite negative value, as indicated by the constant (k_0/k_2V) present in both equations. Upon considering the situation, however, one recognizes that Eqs. 14 and 15 only apply up to a certain critical time, t_c, at which point there remains no drug in Compartment A. From this point on, the plasma concentration is defined as shown in Eq. 16 where B_c is equal to the concentration in Compartment B at t_c:

$$C_p = \frac{B_c}{V}\exp(-k_2t) \qquad \text{(Eq. 16)}$$

The term t_c is shown in Eq. 17:

$$t_c = \frac{1}{k_1}\ln\left(\frac{k_0}{k_1A_0 + k_0}\right) \qquad \text{(Eq. 17)}$$

B_c may be determined using the value for t_c and Eq. 14 or 15.

Feathering Technique—It is apparent that if one employs the feathering technique in the case of a parallel zero-order reaction with no lag time, the differences between Eqs. 14 and 16 at various times do not result in a log-linear relationship. Thus, a plot of log ΔC_p as a function of time would be curved. Correspondingly, when a lag time does occur, prior to its onset the difference between the equation for the one-compartment open model (Eq. 6) and Eq. 16 would also result in a ΔC_p-time relationship which is not log-linear. After t reaches $t1$, the ΔC_p values will be comparable to those in the case where there is no lag time. Thus, the data obtained by the feathering technique would be expected to give results that do not indicate the true absorption rate constant, in spite of the fact that in one exponential term there is a k_1 and not a pseudoconstant. However, as indicated by Perrier and Gibaldi (2), the normal error encountered in this type of data could be such as to make it appear to be log-linear. Such plots are shown in Fig. 3, and we agree with Perrier and Gibaldi that the data could be drawn linear, especially with values resulting from *in vivo* studies. They might also be considered to be curved initially followed by linearity. It should be mentioned, however, that there could exist values of k_1, k_2, and k_0 of such a magnitude as to result in an obviously curved relationship.

Wagner-Nelson Method—It may be demonstrated that the expression $(1 - D/D_\infty)$ is represented by rather complex functions both in the presence and absence of a finite lag time (Eqs. 18 and 19, respectively):

$$(1 - D/D_\infty) = \frac{M' - N'[1 - \exp(k_1t)] + k_0t}{M} \qquad \text{(Eq. 18)}$$

$$M' = A_0 + \frac{k_0}{k_1}\left(\ln\frac{k_0}{k_1A_0 + k_0}\right) \qquad \text{(Eq. 18}a\text{)}$$

$$N' = \frac{k_1A_0 + k_0}{k_1} \qquad \text{(Eq. 18}b\text{)}$$

$$(1 - D/D_\infty) = \frac{M^* - N^* \{1 - \exp[-k_1(t - t1)]\} + k_0(t - t1)}{M'} \quad \text{(Eq. 19)}$$

$$M^* = A_{t1} + \frac{k_0}{k_1}\left(\ln \frac{k_0}{k_1 A_{t1} + k_0}\right) \quad \text{(Eq. 19a)}$$

$$N^* = \frac{k_1 A_{t1} + k_0}{k_1} \quad \text{(Eq. 19b)}$$

It is apparent from an examination of both of these relationships that a Wagner–Nelson plot in the event of Case 2 would not result in a straight line. Once again, however, as proposed by Perrier and Gibaldi and as seen in Fig. 4, the data obtained could appear to be either log-linear or initially curved followed by an apparent log-linear relationship.

Evaluating True Absorption Rate Constant and Correct Model—Based on what has been stated to this point, if one obtains plasma level data resulting from a one-compartment open model with first-order absorption and treats them *via* either a feathering or the Wagner–Nelson method, various plots may result. If one obtains what appears to be an initial curvature followed by an apparent linear portion, it may be assumed that after a finite lag time the drug is also being lost from the absorption compartment *via* either a parallel first-order or zero-order process. However, if the lag time is less than 30 min., it probably would not be detected nor be sufficiently distinguishable from a lag time that is due to a dosage form effect such as the opening of a gelatin capsule or the removal of a coating from a sugar- or film-coated tablet. However, assuming that there is a lag time prior to the onset of the parallel secondary process, the true absorption rate constant may be determined by treatment of the data obtained prior to the onset of the lag time. A suggested technique is as follows.

If one considers what is occurring prior to the onset of the lag time, it is obvious that during this period the total amount of drug in the body may be represented by Eq. 20, where A_0 represents the amount of drug in the dosage form and k_1 is the true first-order absorption rate constant:

$$D = A_0[1 - \exp(-k_1 t)] \quad \text{(Eq. 20)}$$

Correspondingly, the D/V obtained from the Wagner–Nelson method is represented by Eq. 21:

$$\frac{D}{V} = \frac{A_0}{V}[1 - \exp(-k_1 t)] \quad \text{(Eq. 21)}$$

Thus, if one were to select two values of D/V at two different time intervals prior to onset of the lag time, where $t_1 = n$ and $t_2 = 2n$, the corresponding expressions for D/V could be shown as Eqs. 22 and 23:

$$\frac{D}{V}(2n) = \frac{A_0}{V}[1 - \exp(-2nk_1)] \quad \text{(Eq. 22)}$$

$$\frac{D}{V}(n) = \frac{A_0}{V}[1 - \exp(-nk_1)] \quad \text{(Eq. 23)}$$

Dividing Eq. 22 by Eq. 23, one obtains Eq. 24, which may be modified to give Eq. 25:

$$\frac{D_{2n}}{D_n} = \frac{[1 - \exp(-2nk_1)]}{[1 - \exp(-nk_1)]} = \frac{[1 + \exp(-nk_1)][1 - \exp(-nk_1)]}{[1 - \exp(-nk_1)]} \quad \text{(Eq. 24)}$$

$$\left(\frac{D_{2n}}{D_n} - 1\right) = \exp(-nk_1) \quad \text{(Eq. 25)}$$

It is apparent from Eq. 25 that if one plots the log of the fraction $\{[D/V(2n)/D/V(n)] - 1\}$ as a function of n, a straight line will result with a slope equal to $-k_1/2.303$. Another characteristic of data plotted *via* Eq. 25 is that the line resulting from such a plot will intercept the y axis at 1 (on semilog paper) when $n = 0$. When time is equal to or greater than $t1$, the relationship is no longer linear if the parallel reaction is zero order. If the parallel reaction is first order, after the onset of the lag time one obtains a second straight line with a slope equal to $-K/2.303$. Thus, using the n–$2n$ technique (Eq. 25), one is able to differentiate between Case 1 and Case 2 when there is a finite lag time. Plots of this type are shown in Figs. 5 and 6.

In addition to the situation described, if one obtains plasma level data resulting from the one-compartment open model with first-order absorption and treats them *via* either feathering or the Wagner–Nelson method, an apparent log-linear relationship through all data points may indicate one of the following three possibilities:

1. There is complete availability of the drug with no side reactions occurring, and the slope of the log-linear plot is related to the true absorption rate constant.

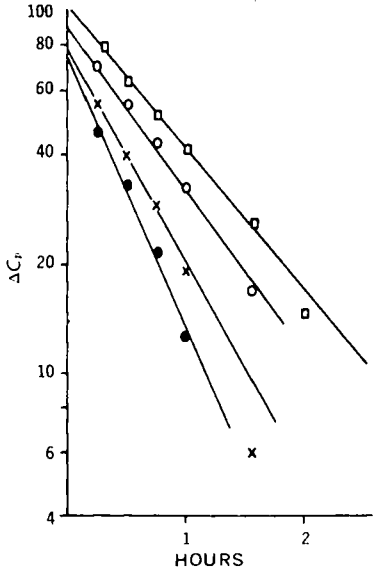

Figure 3 *Plot of* ΔC_p versus *time for data where competing zero-order process is operative, calculated according to the method of residuals* (k_0 = *25 units/hr.*). *Key:* ●, *0.5-hr. lag;* ×, *1.0-hr. lag;* ○, *2.0-hr. lag; and* □, *3.0-hr. lag.*

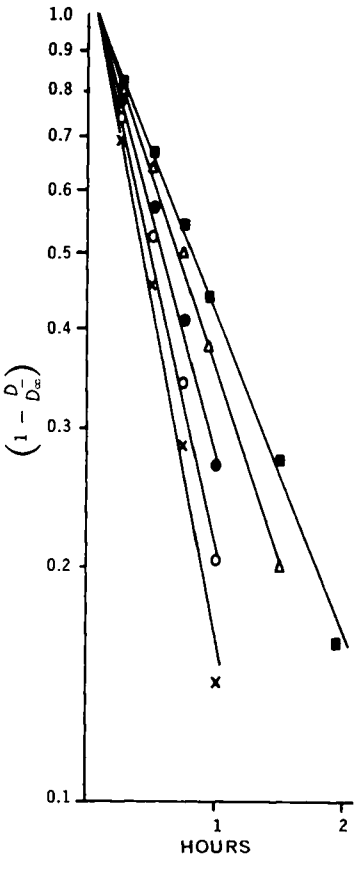

Figure 4—*Plot of Wagner–Nelson calculations* versus *time for data where competing zero-order process is operative* (k_0 = *25 units/hr.*). *Key:* ×, *no lag;* ○, *0.5-hr. lag;* ●, *1-hr. lag;* △, *2-hr. lag; and* ■, *3-hr. lag.*

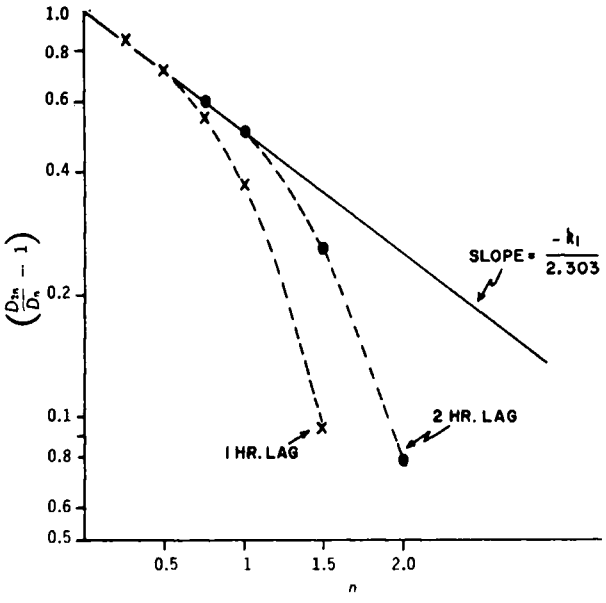

Figure 5—*Plot of data calculated according to* n–2n *method (see text for explanation)* versus *time for a competitive zero-order process* (k_0 = *25 units/hr.*). *Key:* ×, *1-hr. lag; and* ●, *2-hr. lag.*

2. In addition to absorption, there is a parallel first-order reaction occurring simultaneously with no lag time and the slope of the line represents the sum of the first-order rate constants for both the absorption and the competing process.

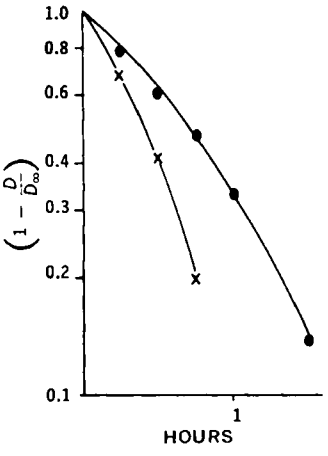

Figure 7—*Plot of Wagner–Nelson calculations* versus *time for an all-or-none competitive phenomenon. Key:* ×, *50% drug available; and* ●, *75% drug available.*

3. There is a parallel zero-order reaction process occurring, either with or without a lag time, but the data are such a magnitude as to appear linear. The apparent first-order absorption rate constant obtained is a complex function of the true rate constant and zero-rate constant.

Applying the *n–2n* technique for determining the true first-order absorption rate constant will result in linear relationships in both possibilities 1 and 2, with the resulting slope being identical to that obtained *via* the Wagner–Nelson or feathering method. Therefore, this procedure cannot differentiate between possibilities 1 and 2, and one does not get a measure of the true first-order absorption rate constants in the case of possibility 2. The plot, however, in the case of possibility 3 demonstrates a marked degree of curvature if there is no lag time. If there is a finite lag time, the data up to this time are linear, passing through $y = 1$ (on semilog paper) at $n = 0$.

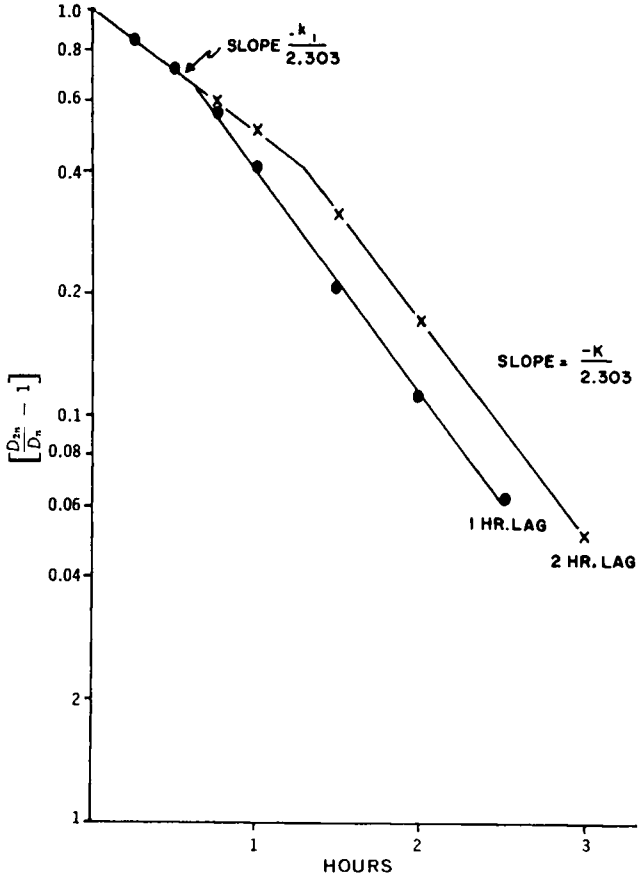

Figure 6—*Plot of data calculated according to* n–2n *method* versus *time for a competitive first-order process* (k_1 = *0.5*). *Key:* ●, *1-hr. lag; and* ×, *2-hr. lag.*

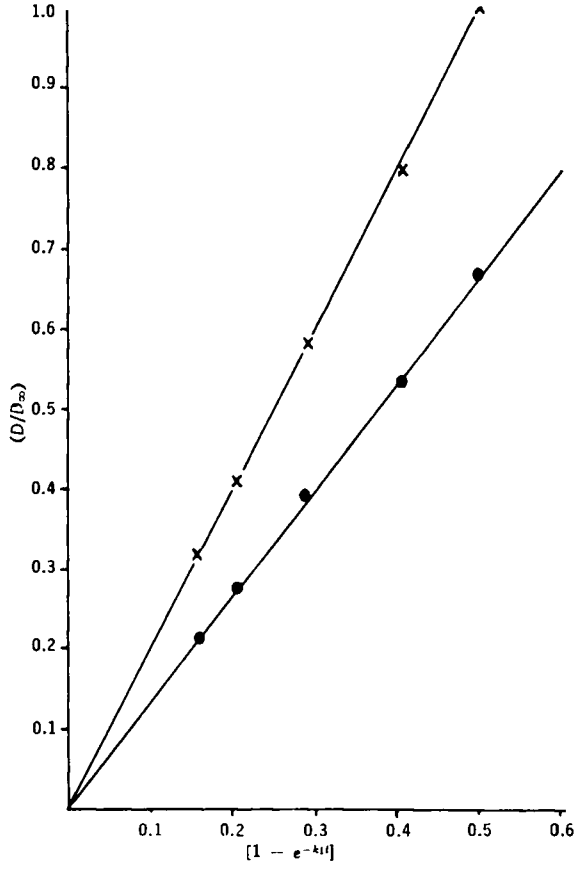

Figure 8—*Plot for determining availability (see text for explanation) for all-or-none phenomenon. Key:* ×, *50% drug available; and* ●, *75% drug available.*

In addition, $t1$ is approximately twice the last n value to fall on the line. Such results allow one to differentiate between this case and the other two (Fig. 5).

This discussion has indicated that the n–$2n$ method may be used to distinguish between parallel zero-order and parallel first-order reactions which may be occurring with no lag time and parallel zero-order and parallel first-order reactions which may be occurring with finite lag times. However, it is not able to distinguish between the parallel first-order reaction with no lag time and the case of no parallel reaction occurring. In addition, one is unable to make an evaluation of the true first-order absorption rate constant in the case of a parallel first-order reaction with no lag time.

Notari *et al.* (1) have indicated a technique for determining the true first-order absorption rate constant. This is done by multiplying K by the fraction of the drug absorbed. However, data other than merely plasma levels (*e.g.*, urinary excretion) would be required to estimate the fraction of drug absorbed. Unfortunately, in many instances, one obtains only plasma level data. The n–$2n$ technique for determining the true first-order absorption rate constant, although not requiring any additional measurements, does necessitate the occurrence of a finite lag time. In addition, if one does have a finite lag time with a parallel first-order process and determines the true absorption rate constant, the fraction of drug available after onset of the lag time may be determined from a ratio of (k_1/K). Correspondingly, the true fraction available (f) is defined by Eq. 26:

$$f = 1 - \frac{k_3}{K} \exp(-k_1 t1) \qquad \text{(Eq. 26)}$$

$$k_3 = K - k_1 \qquad \text{(Eq. 26}a\text{)}$$

In such a case, one is able to evaluate the availability employing *only* plasma level measurements.

"All or None" Phenomena—The previous discussion omitted consideration of the "all or none" phenomena proposed by Perrier and Gibaldi (2). This refers to the case of a nondisintegrating dosage form moving through the GI tract where absorption is occurring and suddenly reaching an area where absorption ceases. Treatment of these data *via* the Wagner–Nelson method results in a non-log-linear relationship. This is because of the considerations in Eqs. 27–30, where f is the fraction of drug absorbed and the other constants are as previously defined:

$$\frac{D}{V} = \frac{A_0}{V}[1 - \exp(-k_1 t)] \qquad \text{(Eq. 27)}$$

$$\frac{D_\infty}{V} = f\left(\frac{A_0}{V}\right) \qquad \text{(Eq. 28)}$$

$$\frac{D}{D_\infty} = \frac{[1 - \exp(-k_1 t)]}{f} \qquad \text{(Eq. 29)}$$

$$[1 - D/D_\infty] = \frac{f - 1 + \exp(-k_1 t)}{f} \qquad \text{(Eq. 30)}$$

It may be seen from Eq. 30 that the expression $(1 - D/D_\infty)$ is not a log-linear relationship when f is less than 1. Plots of this type are shown in Fig. 7 for f values of 0.5 and 0.75. However, if one employs the n–$2n$ technique, the true first-order absorption rate constant would be obtained in these cases. In addition, once k_1 has been evaluated, from Eq. 29 it is seen that from a plot of D/D_∞ against $(1 - e^{-k_1 t})$ the fraction absorbed may be determined as the reciprocal of the slope (Fig. 8). Therefore, employing Eqs. 25 and 29, one may test for the existence of the all-or-none phenomena.

In conclusion, as indicated by Perrier and Gibaldi, the occurrence of incomplete availability will in most cases result in an incorrect measure of the true absorption rate constant. The one exception to their generalization is the case of a poorly designed formulation which would only release a certain fraction of its drug, even if it remained at an absorption site for an infinite length of time. In this instance, the value obtained for the absorption rate constant will be the correct one.

Because the data in this report were computer generated rather than experimentally determined, one could suggest that *in vivo* results would not allow the detection of some of the anomalies reported here. However, on occasion these authors have encountered curvature of a log $(1 - D/D_\infty)$ or ΔC_p plot, and an awareness of the concepts proposed by Notari *et al.* (1) or Perrier and Gibaldi (2) would have allowed for an alternative data treatment. In addition, this report proposes an alternative technique for treating data generated by the Wagner–Nelson (3) or Loo–Riegleman (4) techniques which could allow detection of the fraction of drug absorbed in some of the models proposed by Perrier and Gibaldi.

Competitive Inhibition of Drug–Protein Interaction in Eye Fluids and Tissues

THOMAS J. MIKKELSON*, SUKHBIR S. CHRAI, and JOSEPH R. ROBINSON▲

Abstract □ Binding of drugs to proteins in fluids and tissues of the eye previously was shown to modify significantly the bioavailability of a number of drugs. This adverse effect is particularly important in the precorneal portion and anterior chamber of the eye, since tears and aqueous humor are turned over at relatively rapid rates, removing both free and bound forms of the drug. In addition, rapid drainage of instilled solutions also removes substantial drug quantities. The drug–protein interaction can be minimized through the use of competitive inhibitors of protein binding. These agents occupy binding sites normally bound by drug, increasing free drug concentration. *In vitro* experiments with eye fluids and tissues, as well as *in vivo* studies in rabbits, support the concept of competitive inhibition as a means of significantly improving drug bioavailability. These experiments are principally concerned with competitive inhibition in the precorneal portion of the eye. Pilocarpine nitrate, a miotic drug with low binding affinity for albumin, shows a 10-fold increase in biological activity in the presence of the competitive inhibitor cetylpyridinium chloride. This increase in response is suggested to be due, in part, to competitive inhibition of drug–protein interaction. Competitive inhibition of drug binding in tears and the precorneal portion of the eye can be applied successfully without the attendent problems when the concept is applied to blood proteins. Tear proteins have apparently less substrate carrier function as compared to blood proteins, there is less total protein in tears as compared to blood, and the amount of drug plus inhibitor applied to the eye is small. Thus, side effects due to undesired substrate displacement are not present when rather nonspecific competitive inhibitors are used in ophthalmic systems. Extrapolation of the pilocarpine nitrate data to drugs with higher protein binding affinities suggests that substantial increases in drug activity can be expected through competitive inhibition of drug–protein interactions in eye fluids and tissues.

Keyphrases □ Drug–protein interactions in eye fluids and tissues—effect of competitive protein binding inhibitors on drug availability □ Protein binding—effect of competitive inhibitors on drug availability, eye fluids and tissues □ Ophthalmic bioavailability—effect of competitive protein binding inhibitors on drug–protein interactions in eye fluids and tissues □ Bioavailability, ophthalmic—effect of competitive protein binding inhibitors on drug–protein interactions in eye fluids and tissues

An earlier report (1) from this laboratory described the importance of drug binding to proteins in tissues and fluids of the eye. Tears, cornea, and, in some circumstances, aqueous humor contain appreciable quantities of protein, which bind drugs and reduce their effective free concentrations. Since both tears and aqueous humor are turned over at relatively rapid rates, removing both free and bound forms of the drug, the influence of drug–protein binding on drug bioavailability is significant. The present report is concerned with a proposed method for competitive inhibition of drug–protein interaction through the use of rather nonspecific "biologically inert" inhibitors. A substantial increase in drug activity in the presence of these inhibitors is observed and offers an attractive method to improve drug bioavailability in the eye.

The concept of competitive inhibition of drug–protein binding to increase free drug concentration is not new (2). Synergistic behavior of drug effects is considered to be in some instances a result of competitive displacement of a strongly bound drug (2). Suggestions of the use of substrates for intentional competitive inhibition have been made (3), but apparently no specific application has been reported. There are several reasons why systemic application of competitive inhibition to increase drug activity has not been successful: (*a*) blood proteins normally serve as carriers for numerous substrates, so a competitive inhibitor must be highly specific for sites on the protein or displacement of normal substrates will occur followed by undesirable side effects; and (*b*) the enormous amount of protein present in blood requires that large amounts of the inhibitor be used to cause successful competitive inhibition. Thus, application of competitive inhibition of drug–protein binding in the blood is very limited, and no successful application of the concept to an *in vivo* situation could be found.

However, when the proposal is considered with respect to the eye, it has much greater potential. The relative isolation of the eye coupled with the limited protein content and the lack of extensive carrier function of this protein, as compared to blood protein, makes the concept of competitive inhibition of drug–protein interaction an attractive, workable proposal for increasing drug bioavailability (4). This report is concerned with the feasibility of competitive inhibition of drug–protein binding in eye fluids and tissues.

EXPERIMENTAL

Materials—Water was distilled from alkaline permanganate in an all-glass distillation apparatus. Cellulose dialysis tubing[1] and crystalline rabbit serum albumin[2] were used.

Adult, male albino rabbits[3], New Zealand strain, were the experimental animals. No special pretreatment methods or diets were incorporated into the *in vivo* procedures.

The following chemicals were used: methylprednisolone[4], sulfisoxazole[5], and *N*-1-naphthylethylenediamine dihydrochloride[6]. All other chemicals were either USP or reagent grade and were used as received.

Equilibrium Dialysis—The cells and procedures used were described previously (1). Protein solutions or eye fluid and tissue samples were placed in one half-cell chamber, with or without the competitive inhibitor, and the drug solution was placed in the other half of the dialysis cell. The dialysis membrane preparation and the drug and dialysis solution preparation were described previously (1).

Assays—Analytical procedures were described previously (1).

Miosis–Time Studies—A complete description of procedures used in the pupillary diameter measurement was given previously (1). The competitive inhibitor was added directly to the drug solution prior to instillation into the rabbit eye.

RESULTS

***In Vitro* Demonstration of Competitive Inhibition of Drug–Protein Interaction**—A commonly used method to illustrate competitive inhibition of drug–protein interactions is equilibrium dialysis. The increase in free drug concentration in the presence of a competitive inhibitor reflects competitive inhibition. This is illustrated in Fig. 1 for sulfisoxazole and rabbit serum albumin, using sodium lauryl sulfate and polyoxyethylene (23) lauryl ether[7] as competitive inhibitors. Sodium lauryl sulfate is an effective competitive inhibitor in this system, whereas polyoxyethylene (23) lauryl ether is not. Figure 2 shows where polyoxyethylene (23) lauryl ether is a successful inhibitor of the binding of methylprednisolone to rabbit serum albumin. These examples illustrate the structural and charge requirements for successful competitive inhibition of a particular drug–protein interaction. Ideally, the competitive inhibitor should bind to the same site normally occupied by the drug molecule and exhibit a greater affinity for that site than the drug. A further description of structural requirements for competitive inhibitors is available (4) and will be discussed subsequently.

An extensive search for an optimum competitive inhibitor for a particular drug was not conducted in the present study. The study objective was to show successful competitive inhibition in ophthalmic systems. For this purpose, a competitive inhibitor was selected on the general basis that it should have a similar charge type as the drug in question and an affinity for albumin that is substantially larger than that of the drug. With respect to this last point, an inhibitor was chosen that had reasonable aqueous solubility and, at the same time, possessed a hydrophobic chain for stabilization of the drug–protein complex when formed. All of these requirements seem to be met with the surfactant class of compounds. Competitive inhibition of drug binding to rabbit serum albumin was used as a qualitative yardstick to select competitive inhibitors.

Since all competitive inhibitors reported in this study are surface active and can associate to form micelles in aqueous solution, consideration was given to the concentration of surfactant used. Micelle formation would considerably increase the complexity of these systems and make interpretation of the results more difficult (5–7).

The concentration of surfactant used in all *in vivo* experiments was below the reported (8) critical micelle concentration (CMC). However, considering the decrease in CMC that results from addition of salts and buffer components, it is probable that the instilled solutions were above the CMC. Upon instillation of the drug solution, there is a dilution with tears and an elevation in solution temperature to that of the body, which, when coupled with tear turnover, should reduce the micellar influence.

Competitive inhibition of drug–protein binding in ocular tissues and fluids is also possible and can be demonstrated. Figure 3 shows the binding of methylprednisolone to the components of human tears in the presence and absence of polyoxyethylene (23) lauryl ether. The sizable decrease in fraction of methylprednisolone bound to tear protein in the presence of polyoxyethylene (23) lauryl ether is apparent and, when extrapolated to a living system, suggests a considerable increase in bioavailability for this drug. The increase in bioavailability to the eye is particularly significant when it is realized that solution drainage from the eye is very rapid and that the rate of tear turnover is quite large (1, 9).

Key: A, drug only; B, drug plus 0.01% sodium lauryl sulfate; and C, drug plus 0.01% polyoxyethylene (23) lauryl ether.*

A significant decrease in fraction bound is also observed for drugs that are not highly bound to proteins (1), such as the miotic drug pilocarpine nitrate. Figure 4 illustrates the fraction of pilocarpine bound to the components of plasmoid aqueous humor in the presence and absence of the competitive inhibitor cetylpyridinium chloride. In the presence of cetylpyridinium chloride, the data points fall on the abscissa axis, showing that complete inhibition of binding occurs. Plasmoid aqueous humor was obtained by paracentesis and has the property of being very rich in proteins as compared to normal aqueous humor. Cetylpyridinium chloride is commonly used as a preservative in drug delivery systems, but its structural features make it an efficient competitive inhibitor for binding of certain cationic drugs to proteins.

***In Vivo* Demonstration of Competitive Inhibition of Drug–Protein Interaction**—Successful competitive inhibition of drug–protein binding in eye fluids and tissues should result in an increase in free drug concentration and an increase in the corneal transport rate of the drug in question. The elevated concentration of free drug should be demonstrable in an *in vivo* system through either an increased biological response to the drug or actual measurement of drug concentrations.

To demonstrate the increased biological response, the miotic drug pilocarpine nitrate was selected and pupillary diameter change was used as the biological response. Figure 5 shows miosis–time profiles for several concentrations of pilocarpine nitrate, with and without cetylpyridinium chloride, in albino rabbits. Several interesting aspects to these curves will be explored in a separate publication,

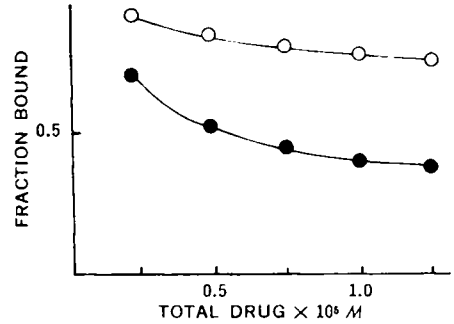

Figure 3—*Equilibrium dialysis experiments on the extent of methylprednisolone binding to the components of human tears in the presence and absence of polyoxyethylene (23) lauryl ether. Key: ○, drug only; and ●, drug plus polyoxyethylene (23) lauryl ether. The data points are mean values from three separate determinations, and standard deviations are within ±7% of the mean values.*

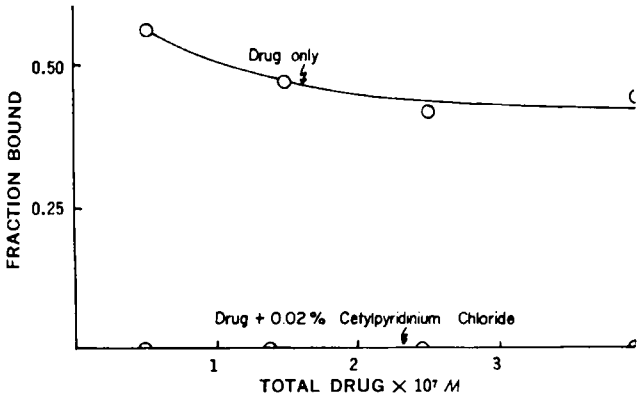

Figure 4—*Equilibrium dialysis studies of tritiated pilocarpine nitrate binding to plasmoid aqueous humor in the presence and absence of 0.02% cetylpyridinium chloride. The data points for the cetylpyridinium chloride study fall on the abscissa axis since there was no binding. but only the relationship between dose and maximum response is of interest here.

Addition of cetylpyridinium chloride to the pilocarpine nitrate solution prior to instillation increases the miotic effect at all concentrations tested. In Fig. 6, the maximum change in pupillary diameter was used as the biological response to generate a dose-response relationship. The log dose-response curve appears to be sigmoidal in shape, with the upper limit being set by either saturation of all existing receptor sites or the smallest pupillary diameter attainable while the lower end is no response at all. An upper limit was not reached due to several factors associated with the pilocarpine nitrate solution, such as approaching the solubility limit of the drug in the buffer at the 5×10^{-1} *M* dosage concentrations and encountering other severe, concomitant drug responses at the higher dosing levels. Nevertheless, the log dose-response relationship is linear over several orders of magnitude.

As can be seen from Fig. 6, the activity of pilocarpine nitrate was increased by a factor of 10 when 0.02% cetylpyridinium chloride was added to the system. Thus, 10 times less drug is required to achieve the same pupillary diameter when the competitive inhibitor is added to the drug solution. Instillation of cetylpyridinium chloride by itself had no effect on pupillary diameter.

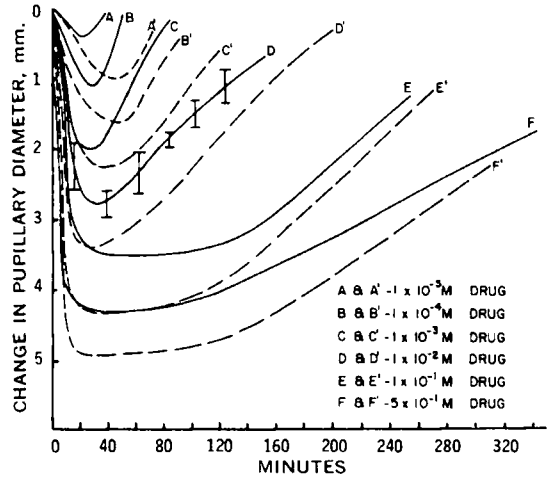

Figure 5—*Miosis-time profiles for various concentrations of pilocarpine nitrate, with and without 0.02% cetylpyridinium chloride. Key: ——, pilocarpine nitrate alone; ---, pilocarpine nitrate plus competitive inhibitor. Standard deviation lines are shown for the 1 × 10^{-2} M drug case only for the sake of clarity. All other lines have similar standard deviations. Each concentration line represents a minimum of four separate determinations in four different animals. Each line was constructed on the basis of 15–40 experimental points.*

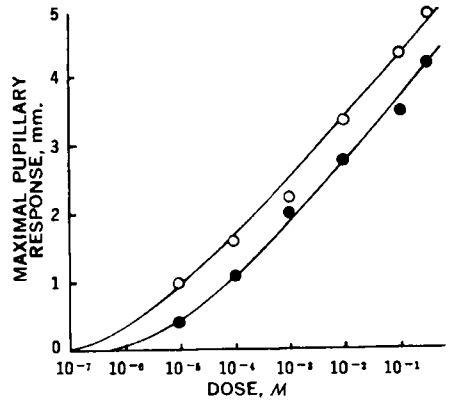

Figure 6—*Maximal miotic response of the rabbit eye to pilocarpine nitrate, with and without 0.02% cetylpyridinium chloride, as a function of dose. Key: ●, drug alone; and ○, drug plus 0.02% cetylpyridinium chloride.*

Examination of the corneal surface with fluorescein solution and UV light, following repeated application of this concentration of cetylpyridinium chloride for several days, showed no visual damage to the epithelial layer of the cornea.

DISCUSSION

Very small amounts of an instilled drug are transported across the cornea, due in part to the rapid drainage of an instilled solution and to rapid tear turnover (9). Both of these processes cause removal of drug from the precorneal area. If a drug undergoes extensive binding to proteins in tears or to precorneal eye tissue, the amount of free drug available to exert a local effect or to be absorbed across the cornea is reduced significantly. Moreover, the very efficient removal of both free and bound forms of the drug from this area is responsible for a considerable loss in drug and a reduction in drug activity. Similarly, binding of drug to the cornea reduces the transport rate of drug through the cornea, which, when coupled with the turnover of aqueous humor, can greatly reduce the concentration of drug in the anterior chamber of the eye. Therefore, competitive inhibition of this drug-protein binding, especially in the precorneal area, should result in a considerable increase in the bioavailability of drugs that are normally bound to proteins.

The *in vivo* data presented show that addition of certain substrates to ophthalmic drug solutions increases the rate of corneal transport for these drugs as evidenced by miotic increases. The *in vitro* equilibrium dialysis data demonstrate that these substrates are able to serve as competitive inhibitors of drug-protein binding. It is our belief that a portion or all of the absorption rate enhancement through the addition of "biologically inert substances" to the drug solution is through competitive inhibition of drug-protein interaction. The data strongly support the suggestion that enhanced corneal penetration of drugs by addition of certain substrates is through a competitive inhibition mechanism. However, the data do not preclude all other possible mechanistic interpretations.

Because of the structural requirements for competitive inhibition of drug-protein binding, all substrates used were surface active and fall in the surfactant class of compounds. That surfactants can influence the extent of corneal absorption of drugs is well known (10), but this influence has not been attributed to competitive inhibition of drug-protein binding.

Surfactant influence on drug absorption in various parts of the body (11, 12) including the eye (10, 13, 14) is well established. What is not well established is the mechanism for this effect. Such factors as drug solubilization above the CMC, wetting of the membrane surface, and structural modification of the membrane have all been indicated in promoting or retarding drug absorption through biological membranes (5, 6, 15). However, the influence of premicellar concentrations on drug transport has not been studied thoroughly, and any influence on drug transport rate is generally ascribed to changes in the membrane.

It is our belief that competitive inhibition of drug-protein binding is at least partially responsible in many cases of enhanced drug transport. For example, it has been shown that surfactants induce

structural changes in proteins (16) and in biological membranes (13) which, in terms of membrane transport, can be interpreted as an enlargement of either the effective pore size in the membrane or the area of the membrane, thus leading to a rate enhancement. An alternative explanation is that the protein modification leads to a decrease in available binding sites and, hence, less protein binding of the drug.

Consider the possible alternative mechanisms of enhanced corneal transport in more detail. The influence of detergents on proteins varies considerably as a function of pH, detergent structure and concentration, and type of protein. Some detergents such as sodium lauryl sulfate induce large changes in the protein (17, 18), and their competitive inhibition activity in equilibrium dialysis experiments is usually ascribed to this protein denaturation. With sodium lauryl sulfate, this influence exists both above and below the CMC. However, some surfactants do compete for drug binding sites in the classical sense (16). In the present study, several surfactants were used but the principal agent was cetylpyridinium chloride. This compound was used in all experiments at a concentration of 0.02%. Neither the data in this report nor the data in the literature elucidate the mechanism of its competitive inhibitory activity. Thus, whether this agent is merely competing for the binding sites normally occupied by the drug or is removing the binding sites through an unfolding mechanism is unknown. Irrespective of the mechanism, the net result of the interaction, namely, competitive inhibition of drug–protein binding, is the important point. The remaining question is whether competitive inhibition in tears is responsible for the entire effect or is it necessary to include alteration of the epithelial layer of the cornea. If inclusion of corneal tissue changes is necessary, what is the mechanism of transport *via* this change? Is it competitive inhibition *via* protein denaturation or is it a physical enhancement as described earlier?

The *in vivo* activity of pilocarpine nitrate plus 0.02% cetylpyridinium chloride can be significantly decreased by addition of albumin to the drug–cetylpyridinium chloride solution, suggesting that drug–protein binding can alter the availability of free drug (1). However, raising the concentration of cetylpyridinium chloride in the drug–albumin solution restores the biological activity so that a fully reversible system can be established and the reversibility is controlled either by albumin or cetylpyridinium chloride. This supports competitive inhibition in the tear film as a contributing factor in the enhancement of drug activity.

Further support for competitive inhibition of drug binding as a principal mechanism was obtained using the anionic steroid fluorometholone. Addition of cetylpyridinium chloride to an albumin–fluorometholone solution in an equilibrium dialysis experiment does not raise the free drug concentration, as expected, since the steroid is of neutral charge as compared to cetylpyridinium chloride and would therefore occupy different sites. In a similar vein, cetylpyridinium chloride does not promote corneal absorption of this drug[8]. If changes in the corneal tissue by addition of cetylpyridinium chloride were responsible for promoting or inhibiting drug penetration, it is expected that all drugs would be affected, albeit to different extents. It is, of course, possible that the different drugs penetrate the cornea *via* different routes, *i.e.*, intercellular *versus* intracellular, and the membrane changes caused by cetylpyridinium chloride do not influence the pathway through which fluorometholone is absorbed.

Data supporting a corneal membrane effect for cetylpyridinium chloride and other agents are given by Green and Tonjum (13). Using *in vitro* corneal transport studies, they showed that application of surfactants such as cetylpyridinium chloride and benzalkonium chloride to the cornea, prior to application of a fluorescein solution, results in an increased penetration of fluorescein. Based on electron micrographs, the mechanism of enhanced penetration was ascribed to an increased intercellular space area in the outermost epithelial layer of the cornea, analogous with the effects of ouabain as well as high endothelial pressure, both of which lead to an increased rate of drug penetration.

There are major differences in experimental technique between the study of Green and Tonjum (13) and the present work, and it is important to consider these differences in trying to assign a mechanism of action. Green and Tonjum used concentrations of cetylpyridinium chloride that were well above the CMC (8). A conclusion as to whether or not they were above the CMC with benzalkonium chloride cannot be reached without knowing the specific structure of the quaternary ammonium compound used. In addition to the differences in initial cetylpyridinium chloride concentration, there was a difference in contact time and concentration during this contact time. Green and Tonjum soaked the excised cornea in the surfactant solution for 2 min. prior to application of the fluorescein solution. This approach yields a significantly higher effective surfactant concentration than do experiments on an intact animal, where tear and instilled solution drainage as well as tear turnover significantly alter the surfactant concentration (9). Thus, concentrations of cetylpyridinium chloride above the CMC as well as the higher effective concentration for longer periods might as well lead to membrane changes that do not occur at lower concentrations in *in vivo* experiments.

Due to the differences in the experimental techniques of Green and Tonjum and the present study, a definite conclusion as to mechanisms apparently cannot be made. It is, of course, possible to interpret the results of Green and Tonjum in terms of competitive inhibition; *i.e.*, the increased intercellular area is merely a form of protein unfolding and therefore binding sites are masked as opposed to the more physical interpretation of a greater area for drug penetration.

In summary, it would appear that competitive inhibition of drug–protein binding is at least partly responsible for an increase in drug transport rate when some surfactants or competitive inhibitors of drug–protein binding are incorporated into the drug delivery system. It is probable, based on the work by Green and Tonjum (13), that cetylpyridinium chloride and similar substrates under suitable conditions owe part of their drug transport potentiation property to changes in the epithelial layer of the cornea, although the specific mechanism is unknown.

All work described in this report was carried out on healthy eyes. Diseased eyes will show a significant increase in precorneal protein binding and are better candidates for competitive inhibition of drug–protein binding.

Effect of Various Steroids and ACTH on Distribution of Zoxazolamine in Rats

P. KOUROUNAKIS[▲], S. SZABO*, and H. SELYE

Abstract □ A study was performed on rats given pregnenolone-16α-carbonitrile (I), triamcinolone, fludrocortisone acetate, corticosterone, estradiol, or ACTH to investigate correlations between the *in vivo* effects upon zoxazolamine paralysis and the concentrations of this drug in plasma, brain, liver, kidney, heart, spleen, muscle, and fat. Pretreatment with the steroids or ACTH altered the organ concentrations of zoxazolamine but not the relationships between the interorgan concentrations. Protection by I was associated with a simultaneous reduction of zoxazolamine in plasma, brain, and most of the other organs (catatoxic mechanism) as compared with controls killed when paralysis disappeared in the pretreated group. The protective actions of ACTH and triamcinolone were often accompanied by high concentrations of zoxazolamine in plasma and most of the organs (syntoxic mechanism) when compared with controls sacrificed at spontaneous termination of the pharmacological response. Fludrocortisone seemed to protect through both phenomena. Corticosterone and estradiol were ineffective under the same conditions, eliciting no changes in the plasma clearance or organ concentrations of the drug.

Keyphrases □ Steroids (pregnenolone-16α-carbonitrile, triamcinolone, fludrocortisone acetate, corticosterone, and estradiol)—effect on plasma and organ concentrations of zoxazolamine □ ACTH—effect on plasma and organ concentrations of zoxazolamine □ Zoxazolamine, plasma concentrations—effect of steroids and ACTH, resistance–plasma concentration correlations

Numerous observations (1–3) have confirmed that steroids and certain other pharmacological agents play a decisive role in altering drug activity, thereby influencing the resistance of the body against the most varied types of injury. These adaptive steroids have been classified according to their mechanism of protective action into: (*a*) syntoxic steroids, which improve host tissue tolerance by permitting coexistence with the toxic agent (*e.g.*, by suppressing nonspecific inflammatory or allergic reactions against it); and (*b*) catatoxic steroids, which enhance the detoxication of endogenous or exogenous toxicants *via* induction, activation, decreased degradation of drug-metabolizing enzymes, and/or accelerated substrate elimination. Of the many steroids studied, it has been found that pregnenolone-16α-carbonitrile (I) exerts the greatest protective effect *in vivo*. This compound is a known hepatic microsomal enzyme inducer (4, 5). Biochemical studies have shown that protection offered by catatoxic steroids (*e.g.*, I and spironolactone) is usually accompanied by a significant reduction of drug concentrations in plasma (6, 7). To obtain the best catatoxic effect, the steroids have to be administered at least 3 days before the toxicant. However, in some cases, even posttreatment offers significant protection (8).

Recent studies (6, 7) showed that the protective effect of I and spironolactone against zoxazolamine and methyprylon can be considered as catatoxic and that of triamcinolone and ACTH can be considered as syntoxic. On the basis of these findings, it was established that these phenomena are characterized by the following relationships:

catatoxic	$C_{cd} < C_1$	$C_{cd} \simeq C_2$
syntoxic	$C_{cd} \simeq C_1$	$C_{cd} > C_2$

where:

C_{cd} = plasma concentration of the drug in pretreated animals at the termination of the pharmacological response

C_1 = plasma concentration of the drug in not yet recovered controls killed when the pharmacological response has disappeared in the pretreated group

C_2 = plasma concentration in recovered controls sacrificed at the termination of the pharmacological response

In previous experiments (6), estradiol was found to be very active against dicumarol. Although unusual, this is not an altogether surprising observation since estradiol can affect the response to other drugs (9–12). The protection offered by syntoxic compounds (*e.g.*, triamcinolone and ACTH) is difficult to explain, although altered drug distribution may be involved. The concentrations of zoxazolamine in some organs and the correlation between the plasma and brain concentrations of this drug were reported by others (13, 14). Changes in distribution of zoxazolamine in the central nervous system (CNS) and plasma as a function of time or chlordane pretreatment were also studied (15). However, it appears that there have been no investigations on the concentrations of this drug in other organs and on the effect, if any, of steroid pretreatment.

In addition to experiments on possible changes in the organ concentrations, it seemed of interest to determine whether: (*a*) the two adaptive steroid groups also produce characteristic alterations in drug distribution; (*b*) changes in the drug plasma concentrations are reflected in the brain, liver, kidney, heart, muscle, and fat; and (*c*) the characteristic relationships for syntoxic and catatoxic steroids, based on plasma concentrations, are applicable to drug concentrations in the parameters just mentioned.

EXPERIMENTAL

Female Sprague-Dawley rats[1], averaging 100 g. (range of 90–110 g.), were used and maintained on laboratory food[2] and tap water *ad libitum*. The animals were divided into three groups. The controls (Groups 1 and 2) were given 1 ml. of water twice daily *per os* for 3 days and once (1 hr. before zoxazolamine) on the 4th day. The rats of the remaining group received I[3] (3β-hydroxy-20-oxo-5-

[a] The plasma concentrations of zoxazolamine in the recovered and not yet recovered controls are compared with the plasma concentrations of the drug in the pretreated rats: * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.005$, and NS = not significant. [b] Killed when the pretreated group regained the righting reflex. [c] Figures in parentheses indicate number of animals. [d] Killed when the righting reflex was regained.

pregnene-16α-carbonitrile), triamcinolone[4], corticosterone[5], fludrocortisone (9α-fluorocortisol) acetate[3], estradiol[6] (1 mg. in 1 ml. water, homogenized with a trace of polysorbate 80, twice daily *per os* for 3 days and once on the 4th day), or depot ACTH[7] (5 I.U. = 50 mcg., subcutaneously) 24 hr. before the toxicant. Zoxazolamine[8] (10 mg./100 g. body weight in 1 ml. water, homogenized with a few drops of polysorbate 80) was administered intraperitoneally to all rats on the 4th day.

Blood samples were collected from the unrecovered control and pretreated animals when the latter regained the righting reflex and from the second control group at spontaneous recovery. Specimens were immediately taken from the liver (left lateral lobe), brain (severed just above the first cervical vertebra), kidney, heart (blood was drained by pressing the organ immediately after removal), spleen, muscle (biceps femoris, quadratus femoris, and rectus abdominis), and adipose tissues (subcutaneous, mesenteral, and perirenal). These specimens were then placed in an ice-cold 0.9% NaCl solution (ratio 1:2) and homogenized.

Zoxazolamine was extracted from plasma, organ, muscle, or adipose tissue homogenates into ethylene dichloride and from the organic solvent into hydrochloric acid. The drug concentrations were measured spectrophotometrically at 278 nm., the λ_{max} of zoxazolamine (13). Drug-free plasma from pretreated and unpretreated animals was used for preparing standards and blanks.

RESULTS AND DISCUSSION

Table I shows that the zoxazolamine concentrations decreased approximately in the following order: liver, heart, spleen, muscle,

Fludrocortisone	148 ± 12 (8)	93 ± 12** (7)
Estradiol	143 ± 12 (6)	141 ± 18 NS (8)
ACTH	156 ± 6 (6)	80 ± 6*** (7)

[a] ** = $p < 0.01$, *** = $p < 0.005$, and NS = $p > 0.05$. [b] Figures in parentheses indicate number of animals.

and plasma. Neither the steroids, nor ACTH, nor time had any influence on these parameters. Essentially similar drug concentrations were found in the brain, fat, and kidney; these concentrations lay between those of the heart and liver. The results on the zoxazolamine concentrations in plasma and brain are in agreement with other comparative studies (14–16). The changes in drug concentrations in the spleen were not significantly altered by time or pretreatment.

In I- or fludrocortisone-pretreated rats, the concentrations of zoxazolamine in most organs were greatly reduced as compared with unrecovered controls (sacrificed when the righting reflex was regained in the former); they were similar to those in the second control group (killed at spontaneous recovery). There were considerable differences between the drug concentrations in the organs of the two controls. In the estradiol series, the differences between the zoxazolamine concentrations in the controls were not significant. This was expected because the duration of paralysis was similar in both groups (Table II).

The relationship for catatoxic activity is obviously common to drug concentrations in the plasma, brain, liver, heart, muscle, and spleen of I- or fludrocortisone-pretreated rats. Fludrocortisone was the only agent that caused a significant reduction of zoxazolamine in the spleen as compared with concentrations of the drug in the unrecovered controls.

The zoxazolamine concentrations in the various organs of the ACTH- or triamcinolone-pretreated animals were similar to those in the paralyzed controls; however, the pretreated groups showed lower drug concentrations in the liver, which could possibly be ascribed to the increase of hepatic glycogen. The ACTH- or triamcinolone-pretreated rats generally had higher drug concentrations in all organs than the recovered controls. The zoxazolamine concentrations were significantly increased in the plasma of the triamcinolone group as well as in the liver, brain, kidney, fat, and plasma of the ACTH-pretreated animals. Some changes in the other parameters were evident, but the differences were not significant. These findings show that the changes characteristic of syntoxic activity (of ACTH) manifest themselves not only in plasma drug concentrations but also in most of the organs examined. In triamcinolone-pretreated rats, there was a tendency for this relationship to be fulfilled. However, of all the parameters, only the plasma concentrations clearly indicated a syntoxic phenomenon.

The zoxazolamine concentrations in the organs of the corticosterone- or estradiol-pretreated animals usually lay between those of the corresponding two control groups, but the differences were not significant.

The brain: plasma concentrations of zoxazolamine were generally the same in pretreated and unpretreated rats (Table III), but there was a significant difference between the fludrocortisone group and the corresponding controls. This could indicate that the steroids and ACTH, unlike fludrocortisone, did not modify the permeability of the blood–brain barrier.

Generally, the liver:plasma concentrations of zoxazolamine varied in the pretreated and unpretreated groups. This may have been due to intense biotransformation of the drug in the liver and/or to increased glycogen in certain cases. As seen in Table III, the only exceptions were estradiol-pretreated animals and their corresponding controls, which showed none of these characteristics. Differences between the liver weights of pretreated and unpretreated rats could not have accounted for the variations in the hepatic concentrations of zoxazolamine.

Previous studies (17–19) established that the metabolic degradation of zoxazolamine is increased after induction of hepatic microsomal enzymes. In I-pretreated rats, the general decline of zoxazolamine concentrations in various organs after microsomal enzyme induction (4, 5) does not seem to alter drug distribution significantly in the body. The decrease of zoxazolamine paralysis (Table II) is well correlated with reduced drug concentrations in the brain (Table I). On the other hand, the protection offered by ACTH and triamcinolone can be considered as syntoxic since the plasma and brain concentrations of zoxazolamine are higher in pretreated animals than in recovered controls (killed at the same clinical stage). The organism is rendered less sensitive to the toxicant through a mechanism that has not yet been clarified (*e.g.*, interactions at receptor sites). Here the possibility of alterations in drug distribution may be excluded, as the findings indicate.

The *in vivo* protection offered by fludrocortisone (Table II) seems to be due to more than merely increased drug metabolism through hepatic microsomal enzyme induction. This is evident from the present results (Table I) and from *in vitro* studies on liver homogenates (20). The syntoxic effect of fludrocortisone is indicated by the seemingly reduced permeability of the blood–brain barrier. It is suggested that fludrocortisone has a dual action (catatoxic and syntoxic), because the mild fall in the plasma concentration of zoxazolamine in itself could not account for marked *in vivo* protection.

Under the experimental conditions, corticosterone and estradiol were neither catatoxic nor syntoxic, judging from the unaltered drug concentrations in the various organs. The failure of corticosterone to offer protection was previously demonstrated in methyprylon-intoxicated rats (7).

The present results indicate that the various steroids and ACTH generally modify the organ concentrations of zoxazolamine but not its organ distribution. Thus, the syntoxic effects of triamcinolone and ACTH (6, 7, 21) are not mediated through altered drug distribution. Fludrocortisone appears to be catatoxic (*e.g.*, increased zoxazolamine biodegradation) and syntoxic (*e.g.*, reduced permeability of the blood–brain barrier).

Finally, the effects of catatoxic and syntoxic steroids upon zoxazolamine concentrations in plasma are generally associated with altered drug concentrations in various organs. The latter changes

Table III—Effect of Various Steroids and ACTH on the Brain:Plasma and Liver:Plasma Ratios of Zoxazolamine

Drug Absorption Kinetics in Goldfish

SAMUEL H. YALKOWSKY▲, O. S. CARPENTER, GORDON L. FLYNN, and THOMAS G. SLUNICK

Abstract □ A model is presented for relating turnover time in goldfish to the concentration of drug in the bathing solution. The model, based on passive transport and the existence of a critical concentration of drug within the fish being required for turnover, was applied to the dose–response data of eight homologous esters of *p*-aminobenzoic acid. Absorption rate constants, relative membrane water partition coefficients, and critical concentrations were evaluated for the methyl through hexyl esters. Heptyl aminobenzoate was only effective in saturated solution. No turnover could be produced by the octyl ester which has a solubility below the critical concentration required for activity.

Keyphrases □ Goldfish—drug absorption kinetics, model and equations relating turnover time and alkyl *p*-aminobenzoate concentration □ Drug absorption kinetics—relationship between turnover time (goldfish) and drug concentration (alkyl *p*-aminobenzoates), model, equations □ *p*-Aminobenzoic acid esters—model and equations relating drug concentration and goldfish turnover time □ Dose–response data—alkyl *p*-aminobenzoate-induced turnover of goldfish

The relationship between the concentration of drug in a bulk solution containing a goldfish and the turnover time of the fish has been studied in several laboratories (1–12) over the past few years. Levy and Gucinski (1) developed a model which relates turnover time to the passive transport rate of the drug across the appropriate membrane of the fish. Their model, while frequently useful, does not account for the commonly observed threshold concentrations of drug, *i.e.*, the minimum concentration producing turnover. Nightingale and Gibaldi (8) recently extended the Levy–Gucinski model to cover situations where a measurable threshold concentration exists. Unfortunately, their derivation appears to predict a dependency on fish volume and on bathing solution volume. This report presents an alternative derivation which overcomes certain difficulties of previous mathematical models.

The equations developed will be used to interpret the dose–response data obtained for several normal alkyl esters of *p*-aminobenzoic acid.

THEORETICAL

In the course of these experiments and in the work of previous investigators, a linear relationship was observed between drug concentration and goldfish turnover time. The linearity and intercept of the reciprocal turnover time–concentration data can be explained by a model based on the following assumptions:

1. Absorption of the drug is passive and is, therefore, a reversible and unsaturable process.
2. Permeability characteristics of the membrane are unchanged during the experiment and unaffected by drug concentration.
3. Drug metabolism or active excretion is negligible during the experiment. There is no development of drug tolerance.

follow the patterns demonstrated for catatoxic and syntoxic phenomena in plasma (6, 7).

Drug Absorption Kinetics in Goldfish

SAMUEL H. YALKOWSKY▲, O. S. CARPENTER, GORDON L. FLYNN, and THOMAS G. SLUNICK

Abstract □ A model is presented for relating turnover time in goldfish to the concentration of drug in the bathing solution. The model, based on passive transport and the existence of a critical concentration of drug within the fish being required for turnover, was applied to the dose–response data of eight homologous esters of *p*-aminobenzoic acid. Absorption rate constants, relative membrane water partition coefficients, and critical concentrations were evaluated for the methyl through hexyl esters. Heptyl aminobenzoate was only effective in saturated solution. No turnover could be produced by the octyl ester which has a solubility below the critical concentration required for activity.

Keyphrases □ Goldfish—drug absorption kinetics, model and equations relating turnover time and alkyl *p*-aminobenzoate concentration □ Drug absorption kinetics—relationship between turnover time (goldfish) and drug concentration (alkyl *p*-aminobenzoates), model, equations □ *p*-Aminobenzoic acid esters—model and equations relating drug concentration and goldfish turnover time □ Dose–response data—alkyl *p*-aminobenzoate-induced turnover of goldfish

The relationship between the concentration of drug in a bulk solution containing a goldfish and the turnover time of the fish has been studied in several laboratories (1–12) over the past few years. Levy and Gucinski (1) developed a model which relates turnover time to the passive transport rate of the drug across the appropriate membrane of the fish. Their model, while frequently useful, does not account for the commonly observed threshold concentrations of drug, *i.e.*, the minimum concentration producing turnover. Nightingale and Gibaldi (8) recently extended the Levy–Gucinski model to cover situations where a measurable threshold concentration exists. Unfortunately, their derivation appears to predict a dependency on fish volume and on bathing solution volume. This report presents an alternative derivation which overcomes certain difficulties of previous mathematical models.

The equations developed will be used to interpret the dose–response data obtained for several normal alkyl esters of *p*-aminobenzoic acid.

THEORETICAL

In the course of these experiments and in the work of previous investigators, a linear relationship was observed between drug concentration and goldfish turnover time. The linearity and intercept of the reciprocal turnover time–concentration data can be explained by a model based on the following assumptions:

1. Absorption of the drug is passive and is, therefore, a reversible and unsaturable process.
2. Permeability characteristics of the membrane are unchanged during the experiment and unaffected by drug concentration.
3. Drug metabolism or active excretion is negligible during the experiment. There is no development of drug tolerance.

Table I—Comparison of Kinetic Equations for Goldfish Turnover

Model	Relation between $1/t$ and C_B		C_B^e	
Levy–Gucinski (1)	$\frac{1}{t} = \frac{k_1' V_B C_B}{V_F C_F}$	(Eq. 11)	$C_B^e = 0$	(Eq. 12)
Nightingale–Gibaldi (8)	$\frac{1}{t} = \frac{k_1' V_B C_B}{V_F C_F^*} - \frac{k_1' + k_2'}{2}$	(Eq. 13)	$C_B^e = \frac{k_1' + k_2'}{2k_1'} \frac{V_F C_F^*}{V_B}$	(Eq. 14)
This work	$\frac{1}{t} = \frac{k_1}{C_F^*} C_B - \frac{k_2}{2}$	(Eq. 8)	$C_B^e = \frac{k_2}{2k_1} C_F^*$	(Eq. 9)
			$C_B^r = \frac{k_2}{k_1} C_F^*$	(Eq. 10)

4. The end-point is observed immediately after a critical concentration of drug within the fish, C_F^*, is reached. This value is assumed to be independent of the concentration of drug in the bathing solution.

5. The concentration of drug in the bathing solution is unchanged during the experiment.

The first four of these assumptions are essentially equivalent to the assumptions made by Nightingale and Gibaldi (8). The fifth assumption is intuitively agreeable since only a negligible fraction of the total drug present is absorbed by the fish. This latter assumption simplifies both the calculations and the results considerably.

The application of these assumptions to the absorption of drug by goldfish leads to the following differential equation:

$$\frac{dC_F}{dt} = k_1 C_B - k_2 C_F \qquad \text{(Eq. 1)}$$

where C_B and C_F are the concentrations of drug in the bulk or bathing solution and in the fish, respectively; t is time; and k_1 and k_2 are the rate constants for passive absorption and elimination, respectively. The solution to Eq. 1 is:

$$C_F = \frac{k_1}{k_2} C_B + A e^{-k_2 t} \qquad \text{(Eq. 2)}$$

where A is a constant of integration.

Since it is known that $C_F = 0$ at $t = 0$, the constant A must be equal to $-(k_1/k_2)C_B$, and Eq. 2 becomes:

$$e^{-k_2 t} = \left(\frac{\frac{k_1}{k_2} C_B - C_F}{\frac{k_1}{k_2} C_B} \right) \qquad \text{(Eq. 3)}$$

Converting to natural logarithms gives:

$$k_2 t = -\ln \left(\frac{\frac{k_1}{k_2} C_B - C_F}{\frac{k_1}{k_2} C_B} \right) \qquad \text{(Eq. 4)}$$

which can be approximated by:

$$\frac{1}{k_2 t} = \frac{1}{2\left(\frac{X-1}{X+1}\right) + \frac{2}{3}\left(\frac{X-1}{X+1}\right)^3 + \frac{2}{5}\left(\frac{X-1}{X+1}\right)^5 + \dots} \qquad \text{(Eq. 5)}$$

Table II—Solubilities of *n*-Alkyl *p*-Aminobenzoates in Water at 24°

Ester	Solubility, mole/l.
Methyl	8.3×10^{-3}
Ethyl	4.83×10^{-3}
Propyl	2.03×10^{-3}
Butyl	7.35×10^{-4}
Pentyl	1.79×10^{-4}
Hexyl	3.1×10^{-5}
Heptyl	7.0×10^{-6}
Octyl	1.3×10^{-6}

where $X = (k_1 C_B/k_2)/(k_1 C_B/k_2 - C_F)$. For $1 < X < 100$[1], all but the first term in the denominator can be ignored and Eq. 5 becomes:

$$\frac{1}{k_2 t} = \left(\frac{2C_F}{2\frac{k_1}{k_2} C_B - C_F} \right)^{-1} \qquad \text{(Eq. 6)}$$

or[2]:

$$\frac{1}{t} = \frac{k_1 C_B}{C_F} - \frac{k_2}{2} \qquad \text{(Eq. 7)}$$

If, in Eq. 7, t is the turnover time, t^*, then C_F, according to the fifth assumption, must be equal to the threshold concentration of the drug in the fish, C_F^*. Thus, the reciprocal turnover time can be expressed as:

$$\frac{1}{t^*} = \frac{k_1}{C_F^*} C_B - \frac{k_2}{2} \qquad \text{(Eq. 8)}$$

Equation 8 describes a straight line of slope (k_1/C_F^*) and an extrapolated intercept $-(k_2/2)$, which relates reciprocal turnover time to the concentration of drug in the bathing solution. The extrapolated concentration intercept, C_B, of Eq. 8 is determined (by setting $1/t = 0$) to be related to the threshold concentration in the fish, C_F^*, by:

$$C_B^e = \frac{k_2}{2k_1} C_F^* \qquad \text{(Eq. 9)}$$

The existence of a bath concentration that will show no activity over any period of time is well documented in the literature. The value of C_B^e for a particular drug is well defined and consistently observed. Independent studies (4, 5, 7) showed the value of C_B^e for ethanol in goldfish to be between 1 and 2% by volume.

If the series in Eq. 5 is not truncated after the first term, the function deviates from linearity and the real intercept, $(k_1/k_2)\ C_B^r$, approaches C_F^* as $1/t$ approaches zero, *i.e.*:

$$C_B^r = \frac{k_2}{k_1} C_F^* \qquad \text{(Eq. 10)}$$

Figure 1 shows the theoretical relationship between $1/t$ and concentration as described by the exact Eq. 4 and the approximate Eq. 8.

[1] Most of the data to be discussed is within this region.

[2] If one lets $(k_1 C_B)/(k_2 C_F) = p$, then Eq. 4 becomes:

$$\frac{1}{k_2 t} = \frac{1}{\ln\left(\frac{p}{p-1}\right)} \qquad \text{(Eq. 4a)}$$

Equation 4*a* was solved for the following integral values of p between 2 and 100 (p = 2, 3, 4, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 100). The results fit the following least-squares equation with a correlation coefficient of 1.000:

$$\frac{1}{k_2 t} = 1.00\,p - 0.52 \qquad \text{(Eq. 4b)}$$

which is approximately equivalent to:

$$\frac{1}{t} = \frac{k_1 C_B}{C_F} - \frac{k_2}{2} \qquad \text{(Eq. 7)}$$

As can be seen in Fig. 1, the approximate Eq. 7 shows good agreement with the exact solution in p for $2 < p < 100$. However, there is significant deviation from linearity and $1/t \to 0$ as $p \to 1$, *i.e.*, as $k_1/k_2\ C_B \to C_F^*$.

These results differ from those of Levy and Gucinski (1) and Nightingale and Gibaldi (8) in several respects. The final equations and the concentration intercepts of the three derivations (in the present notation) are summarized in Table I. The major difference between the equation developed here and the other equations found in the table is that the latter appear to be dependent upon the volume of the fish, V_F, and the volume of the bathing solution, V_B. The independence of goldfish turnover time on fish size was demonstrated by DiSanto and Wagner (7) using ethanol and in these laboratories for various esters of *p*-aminobenzoic acid[3]. As long as the volume of the bathing solution is greater than about 50 times the volume of the fish, the turnover time is independent of solution volume. Both Eqs. 11 and 13 predict that reciprocal turnover time will increase linearly with increasing solution volume at a constant concentration. However, if k_1' is converted to units based on concentration rather than amounts by $k_1' = k_1(C_F/C_B)$, the slope of the Nightingale–Gibaldi Eq. 13 becomes identical to the slope of the present Eq. 8. The differences in the intercepts of Eqs. 8 and 13 are simply a reflection of the mathematical approximations involved in the two treatments.

If the value of C_F^* refers to the aqueous portion of the fish, it is possible to make one further simplifying assumption; namely, that $k_1 = k_2$. In other words, as is implicit in the first assumption, there is no directional specificity in the membrane barriers. With this simplification the extrapolated concentration intercept, C_B^e, of a reciprocal turnover times *versus* concentration plot is equal to one-half the critical concentration within the fish required to produce turnover:

$$C_B^e = {}^1/_2 C_F^* \qquad \text{(Eq. 15)}$$

Equation 15 is consistent with the fact that C_B^e is equal to ${}^1/_2 C_B^r$ (Fig. 1) and the hypothesis (Eq. 10) that the threshold concentration in the bulk, C_B^r, must be equal to the critical concentration within the fish.

If C_F^* is the total fish concentration of drug, this discussion is still qualitatively applicable. Since over 80% of the goldfish is aqueous, $k_1 \approx k_2$ and, thus, $2C_B^e \approx C_B^r$. The equilibrium constants of several simple semipolar compounds between gudgeons and water were determined (13) to be 0.94 for methanol, 0.86 for ethanol, 0.79 for isopropanol, 0.88 for acetone, and 0.84 for methyl acetate. Likewise, the data of Nightingale (9) indicate a goldfish–water partition coefficient of 0.92 for 4-aminoantipyrine. From these values, it can be seen that the approximation of k_2/k_1 by unity will be off by less than 20% for these compounds. Further verification of the equivalency of the two rate constants is found in reported results (3, 9, 11, 14) that have shown experimentally that $C_B^r \approx C_F^*$ or $k_1 \approx k_2$.

Thus, Eq. 8 can be rewritten as:

$$\frac{1}{t} = \frac{k_1}{C_F^*}C_B - \frac{k_1}{2} = \left(\frac{C_B}{C_F^*} - \frac{1}{2}\right)k_1 \qquad \text{(Eq. 16)}$$

EXPERIMENTAL

Materials—Methyl *p*-aminobenzoate, ethyl *p*-aminobenzoate, and butyl *p*-aminobenzoate were used as received. The remaining esters were synthesized from the appropriate alcohol[4] and *p*-nitrobenzoyl chloride[5] as described previously (15, 16).

Aqueous Solubility—The aqueous solubility of these esters was determined at 24 ± 1° by UV spectroscopy of stock solutions which were equilibrated for at least 3 days.

Bathing Solutions—All bathing solutions were prepared from the stock saturated solutions by dilution.

Measurement of Turnover Time—Goldfish, *Carassius auratus*, between 5.08 and 7.62 cm. (2 and 3 in.) in length, were purchased locally. The shorter turnover time was determined by placing a single fish in 200 ml. of bathing solution. The longer times were determined by placing several fish in a larger volume. In all cases, the end-point was taken as the time it took the fish to become unable to bring itself to an upright position after being turned onto its side by a glass rod, *i.e.*, lose its righting reflex.

RESULTS AND DISCUSSION

Solubility—The 24° solubilities of the eight esters studied are listed in Table II. Past butyl, the solubility decreases by factor of 5.0 for each additional methylene group; the solubilities of shorter homologs decrease more slowly with chain length. The solubilities of the *n*-alkyl *p*-aminobenzoates were already interpreted in terms of other physical properties of these compounds (16).

Turnover Time—Mean turnover times obtained as a function of concentration for the various *n*-alkyl *p*-aminobenzoates are given in Table III. With the exception of the four values discussed below, all of the values are the average of 10 individual experimental points. The asterisks represent conditions under which at least three out of 10 fish did not turn over within 48 hr. These data are shown graphically in Figs. 2 and 3. The graphs are presented in terms of fractional saturation, C/S, rather than the more conventional concentration, C, for two reasons: (*a*) all of the data in Table III, which range from 1×10^{-6} to 8×10^{-3} M, can be plotted simultaneously, and (*b*) a direct comparison of the esters can be made on a so-called "equal thermodynamic scale" (17).

In Fig. 2, reciprocal turnover time is plotted against fractional saturation. The minimum turnover time observed is about 0.4 min., and this value was obtained for saturated solutions of the lower esters. Furthermore, these points fall well below the least-squares line through the other data. The authors believe that these deviations from predicted behavior are related to the time required for the establishment of a quasi-steady-state concentration gradient across the membrane barriers. This lag time for turnover is then the minimum attainable turnover time.

The bulk of the data in Fig. 2 falls on lines having positive concentration intercepts. The equations for the least-squares lines (all points weighted according to the reciprocal of their variance) for each ester are given in Table IV. Dividing the slope of the solubilities of the esters enables concentration to be expressed in moles per liter instead of fractional saturation. It is necessary to weight the data as already described to obtain more accurate values for the intercepts. The scatter in the reciprocal turnover time produced by the higher concentrations of drug precluded accurate determination of the intercepts by nonweighted regression analysis of all of the data. This same difficulty was noted by Nightingale and Gibaldi (8) for 4-aminoantipyrine-induced turnover. They overcame this difficulty by ignoring the data for the higher drug concentrations in determining the intercept.

The log–log curves of Fig. 3 are also revealing. All of the curves approach an infinite slope as $C_B \to C_B^r$; but for $C_B \gg C_B^r$, the

slopes all approach unity. If there were no intercept in the $1/t$ *versus* C data, the log-log plots would have a slope of -1.0 throughout the range studied.

From the equations in Table IV, the values of the kinetic parameters, k_2, $(k_1/C_B{}^s)$, and $(k_2/k_1)C_B{}^s$, can be obtained for each ester, and they are listed in Table V. It is possible to determine a range for $C_B{}^0$ from the raw material data in Table III. These ranges are also in agreement with the data in Table V.

The low solubility of the heptyl ester is responsible for the lack of conclusive estimates of its kinetic parameters. The inability of the octyl ester to produce turnover, even from saturated solutions, suggests that its solubility is below the threshold concentration. Likewise, the nonyl ester was found to be totally inactive.

The data indicate quite clearly that k_2 values decrease and $k_1/C_B{}^s$ values increase with increasing chain length of the *p*-aminobenzoate ester moiety. However, these changes are small compared to the dramatic decreases in $k_2C_B{}^s/k_1$ that accompany assension of the homologous series. Unfortunately, the proposed model does not enable the definitive mathematical separation of k_1 and $C_B{}^s$. If it is assumed that $k_1 = k_2$ as described, it is evident that $C_B{}^s$ is highly dependent upon chain length. On the other hand, if it is assumed that the intrinsic activities of all of the esters are identical, it is

Hexyl	$1/t = (-0.000570 \pm 0.000846) + (0.135 \pm 0.0103) + 3.1 \times 10^{-5} \times C$	7	0.981

obvious from the data that k_1 cannot equal k_2. These two assumptions are consistent with one another if equal concentrations of the esters have equal activities only in some lipid or membrane portion of the fish; *i.e.*, at turnover, C_M^* is the same for each ester. Since the membrane water partition coefficient of each ester is given by:

$$PC = \frac{C_M}{C_W} \approx \frac{C_M}{C_F} \approx \frac{C_M^*}{C_F^*} \qquad \text{(Eq. 17)}$$

and if C_M^* is assumed independent of chain length, the relative partition coefficients of the esters are approximately proportional to the reciprocal of their critical fish concentrations, C_F^*. Interpretation of the changes in k_1, k_2, C_F^*, and PC that accompany changes in alkyl chain length will be published later.

As a further test of its validity, the turnover times produced by various concentrations of 4-aminoantipyrine (Table I of *Reference 8*) were analyzed according to the model. To get meaningful estimates of the intercepts, only the data for the lower concentrations of drug were considered.

The resulting least-squares line was then used to calculate the kinetic parameters. These values (Table VI) were in good agreement with values determined independently by Nightingale (9) and Anello and Levy (11).

Table V—Kinetic Parameters for *n*-Alkyl *p*-Aminobenzoate-Induced Turnover of Goldfish

CONCLUSIONS

The equations derived in this report not only describe the dose–response data for alkyl benzoate-induced turnover of goldfish but also provide a convenient means of estimating the following parameters: (*a*) elimination rate constant, and (*b*) the critical or threshold concentration of each drug required to produce turnover.

Table VI—Values of Kinetic Parameters for 4-Aminoantipyrine-Induced Overturn of Goldfish

Parameter	From Eq. 8 and Dose–Response Data	Literature Values	Reference
k_1	6.54×10^{-3} min.$^{-1}$	2.3×10^{-3} min.$^{-1}$	11
k_2	6.54×10^{-3} min.$^{-1}$	3.3×10^{-3} min.$^{-1}$	11
C_F*	6.67 mg.%	6.8 mg.%	9

The proposed model for the action of homologous narcotic drugs on goldfish was tested using *n*-alkyl *p*-aminobenzoates. The experimental data were interpretable by the derived equations. Apparent discrepancies between the model and high concentration data were accounted for by recognizing that there is a finite lag time for turnover.

Literature data for 4-aminoantipyrine-induced narcosis of goldfish were also interpretable by the model.

Correlation of Viscoelastic Functions for Pharmaceutical Semisolids: Comparison of Creep and Oscillatory Tests for Oil-in-Water Creams Stabilized by Mixed Emulsifiers

G. M. ECCLESTON▲, B. W. BARRY, and S. S. DAVIS*

Abstract □ Liquid paraffin-in-water emulsions stabilized by mixed emulsifiers of a surfactant (cetrimide or cetomacrogol) and a long-chain alcohol were used as model systems to represent pharmaceutical semisolids. They were examined in their linear viscoelastic regions using creep and oscillatory (Weissenberg rheogoniometer) techniques. Storage and loss compliances (J' and J'') over the frequency range 2.5×10^{-8} to 1.5×10^{-1} Hz. were calculated from creep data using numerical formulas. The transformed compliances were used to derive the other oscillatory functions, the storage and loss moduli (G' and G''), the storage and loss viscosities (η' and η''), and the loss tangent (tan δ) at the same frequencies. The agreement between transformed functions and those obtained directly from oscillatory measurements at frequencies ranging from 7.91×10^{-4} to 1.5×10^{-1} Hz. was generally good. Discrepancies at the extremities of this range were a result of the practical difficulties involved when creep measurements are made at very short times (representing high frequencies) and evaporation of water from the parallel plates of the rheogoniometer during low frequency dynamic experiments. Neither small strain technique alone covered the entire frequency or time range necessary for an exhaustive study of semisolids. Creep data were unavoidably inaccurate at high frequencies, and the limitations of the rheogoniometer gear box prevented oscillatory measurements from being made at extremely low frequencies. The unification of data from oscillatory and creep measurements so as to provide a dynamic description over an extended frequency range (10^{-8}–25 Hz.) is discussed. The variations of each function with frequency are considered with reference to linear viscoelastic theory; the limiting values and the shapes of the plots at low frequencies agreed well with the theoretical values for viscoelastic liquids. It was concluded that such interconversion techniques are applicable and valuable for interpreting the rheological behavior of a pharmaceutical system.

The rheological properties of semisolid preparations affect all stages of manufacture, and they should be considered in quality control. The release of medicaments from semisolid vehicles is sometimes related to these properties, so a knowledge of the rheological effects of changes in formulation may also be important for bioavailability studies.

In the past, a major difficulty encountered in the rheological evaluation of semisolid ointments and creams was how to obtain a true measure of consistency. The approach described frequently in the literature is to use a continuous shear technique and then to attempt to correlate derived parameters, *e.g.*, spur points or yield values, with the qualitative terms "consistency

Table VI—Values of Kinetic Parameters for 4-Aminoantipyrine-Induced Overturn of Goldfish

Parameter	From Eq. 8 and Dose–Response Data	Literature Values	Reference
k_1	6.54×10^{-3} min.$^{-1}$	2.3×10^{-3} min.$^{-1}$	11
k_2	6.54×10^{-3} min.$^{-1}$	3.3×10^{-3} min.$^{-1}$	11
C_F*	6.67 mg.%	6.8 mg.%	9

The proposed model for the action of homologous narcotic drugs on goldfish was tested using *n*-alkyl *p*-aminobenzoates. The experimental data were interpretable by the derived equations. Apparent discrepancies between the model and high concentration data were accounted for by recognizing that there is a finite lag time for turnover.

Literature data for 4-aminoantipyrine-induced narcosis of goldfish were also interpretable by the model.

Correlation of Viscoelastic Functions for Pharmaceutical Semisolids: Comparison of Creep and Oscillatory Tests for Oil-in-Water Creams Stabilized by Mixed Emulsifiers

G. M. ECCLESTON▲, B. W. BARRY, and S. S. DAVIS*

Abstract □ Liquid paraffin-in-water emulsions stabilized by mixed emulsifiers of a surfactant (cetrimide or cetomacrogol) and a long-chain alcohol were used as model systems to represent pharmaceutical semisolids. They were examined in their linear viscoelastic regions using creep and oscillatory (Weissenberg rheogoniometer) techniques. Storage and loss compliances (J' and J'') over the frequency range 2.5×10^{-8} to 1.5×10^{-1} Hz. were calculated from creep data using numerical formulas. The transformed compliances were used to derive the other oscillatory functions, the storage and loss moduli (G' and G''), the storage and loss viscosities (η' and η''), and the loss tangent (tan δ) at the same frequencies. The agreement between transformed functions and those obtained directly from oscillatory measurements at frequencies ranging from 7.91×10^{-4} to 1.5×10^{-1} Hz. was generally good. Discrepancies at the extremities of this range were a result of the practical difficulties involved when creep measurements are made at very short times (representing high frequencies) and evaporation of water from the parallel plates of the rheogoniometer during low frequency dynamic experiments. Neither small strain technique alone covered the entire frequency or time range necessary for an exhaustive study of semisolids. Creep data were unavoidably inaccurate at high frequencies, and the limitations of the rheogoniometer gear box prevented oscillatory measurements from being made at extremely low frequencies. The unification of data from oscillatory and creep measurements so as to provide a dynamic description over an extended frequency range (10^{-8}–25 Hz.) is discussed. The variations of each function with frequency are considered with reference to linear viscoelastic theory; the limiting values and the shapes of the plots at low frequencies agreed well with the theoretical values for viscoelastic liquids. It was concluded that such interconversion techniques are applicable and valuable for interpreting the rheological behavior of a pharmaceutical system.

The rheological properties of semisolid preparations affect all stages of manufacture, and they should be considered in quality control. The release of medicaments from semisolid vehicles is sometimes related to these properties, so a knowledge of the rheological effects of changes in formulation may also be important for bioavailability studies.

In the past, a major difficulty encountered in the rheological evaluation of semisolid ointments and creams was how to obtain a true measure of consistency. The approach described frequently in the literature is to use a continuous shear technique and then to attempt to correlate derived parameters, *e.g.*, spur points or yield values, with the qualitative terms "consistency

change" or "body." However, data from such experiments are often misleading and should be treated with caution. All continuous shear techniques measure the complex phenomenon of structure breakdown which, in turn, is a function of the test method. The material constants necessary to define viscoelastic (semisolid) materials, *e.g.*, Newtonian viscosity and modulus of elasticity, are not derived.

To obtain true measures of consistency, it is necessary to employ fundamental experiments in which the semisolids are examined in their rheological ground states, *i.e.*, when the method of testing does not significantly disrupt static structures. Small strain rheological experiments such as creep and oscillatory techniques are included in this category and have been used to investigate the rheological behavior of an extensive range of cosmetic and pharmaceutical materials (1–31). A suitable instrument for creep testing is the concentric cylinder reaction air turbine viscometer (22, 31–33). Oscillatory experiments may be performed using the Weissenberg rheogoniometer coupled to a Solartron digital transfer function analyzer and mechanical reference synchronizer (26).

For an exhaustive study of semisolids, it is usually necessary to employ both types of small strain experiment, because neither method alone determines viscoelastic properties over the required wide time or frequency range. Creep measurements essentially provide information at long times (equivalent to low frequencies that are inaccessible to the rheogoniometer) whereas the high frequency (short time) range is accessible only to dynamic experiments. Thus, a difficulty arises when attempts are made to compare the results of past studies, because a description of the mechanical behavior of the systems may be given by transient functions at long times such as compliances expressed as functions of time, $J(t)$, and by oscillatory functions at short times, such as storage and loss compliances expressed as functions of frequency, $J'(\omega)$ and $J''(\omega)$.

However, fundamental parameters may be mathematically interconverted using linear viscoelastic theory. It is then possible to transform any one viscoelastic function derived in shear to any other, provided that the former is known over a sufficiently wide range of time or frequency. Thus, the comparison problem may be solved if functions are transformed so as to provide a unified parameter applicable at both high and low frequencies. Since the necessary exact calculations are often difficult and tedious, various approximation methods are usually employed (34–36). A comparatively simple numerical approximation for converting transient to dynamic data was described by Schwarzl (36).

The present investigation had two objectives:

1. To determine whether the conversion of creep data to dynamic functions is feasible for model pharmaceutical systems using Schwarzl's transformation formulas. If so, it may also be possible to derive dynamic data at very low frequencies, and oscillatory data may also be produced within the rheogoniometer's frequency range without using this expensive instrument.

2. To assess the accuracy involved in this method of transforming data in the light of the many variables normally involved in creep and oscillatory experiments. These include the different viscometer geometries (parallel plate and concentric cylinder), the dissimilar times for which the emulsions remain in each viscometer before and during the experiments, that no allowance is made for end effects in creep or for evaporation effects (particularly from parallel plates) and the possibility that internal structure breaks down to different extents when the two viscometers are loaded.

Liquid paraffin-in-water emulsions containing cetostearyl alcohol and the surfactants cetrimide or cetomacrogol were chosen as model ionic and nonionic systems to represent pharmaceutical and cosmetic semisolids in general. These preparations have already been examined in detail by both fundamental methods, and information is available as to the effects of small changes in formulation on each type of viscoelastic function (13, 17, 20). To cover the consistency range usually found in pharmaceutical formulations, two emulsions were prepared from each mixed emulsifier, one a "soft" semisolid and the other a "stiff" material.

EXPERIMENTAL

Materials—Cetostearyl alcohol, liquid paraffin, water, cetrimide[1], and cetomacrogol[2] were as described previously (13, 17, 37).

Preparation of Systems—Liquid paraffin-in-water emulsions were made by a standardized procedure according to the formulas in Table I (13). Prior to testing, emulsions were stored for sufficient time at 25 ± 0.5° to ensure that consistency build-up was complete and that the systems were not changing in rheological properties during the test. The microscopic and macroscopic appearances of each formulation were already described (1, 13, 14, 17, 18).

Creep Tests—Creep experiments were performed at 25 ± 0.5° using a concentric cylinder reaction air turbine viscometer (22, 31, 33). Approximate linearity checks were made at short times, and the creep curves were recorded in the linear viscoelastic regions. Each creep stress was applied for a minimum of 90 min., by which time the strain or compliance responses for the samples were essentially linear with time. Creep curves were analyzed into discrete spectra using a method similar to that of Warburton and Barry (38). To check the accuracy of the analysis, a computer program was written to regenerate values of $J(t)$ from the discrete spectral values. Agreement between experimental and reconstituted values for $J(t)$ was better than 2% full-scale deflection, even at long times.

Oscillatory Tests—Oscillatory tests were performed at 25 ± 0.5°[3]. The instrument was employed with parallel plates, 7.5 cm. in diameter, and the platen gap was set to 6.35×10^{-2} cm. The torsion bar constant was 2.207×10^{3} dyne cm./2.54×10^{-3} cm. movement. Initial tests for linearity were performed (20), and the systems were examined in their linear viscoelastic regions by applying sinusoidally varying shear strains at frequencies ranging from 7.91×10^{-4} to 25 Hz. (n Hz. = $2\pi n$ rad./sec.). At each frequency, the amplitude ratio and the phase shift, a, were determined and were employed to calculate the storage modulus (G') and the dynamic viscosity (η') using Walters' equations for parallel plate geometry (39, 40). The other viscoelastic functions, G'', η'', J', and J'', were calculated from G' and η' using Eqs. 1–4 (34):

$$G'' = \eta'\omega \quad \text{(Eq. 1)}$$

$$\eta'' = G'/\omega \quad \text{(Eq. 2)}$$

$$J' = G'/(G'^2 + G''^2) \quad \text{(Eq. 3)}$$

$$J'' = G''/(G'^2 + G''^2) \quad \text{(Eq. 4)}$$

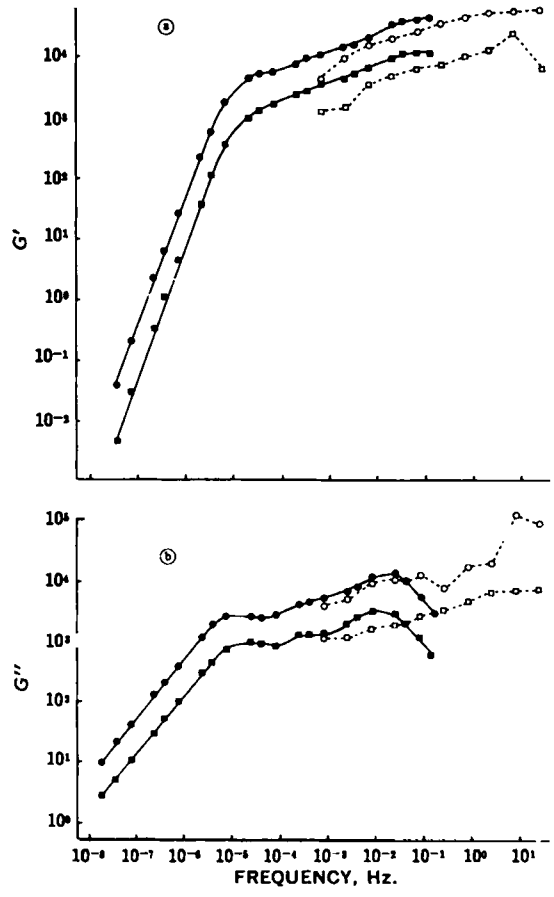

Figure 2—*Cetrimide emulsions C8 and C14, showing the variation of: (a) storage modulus, G', and (b) loss modulus, G'' (dynes cm.$^{-2}$), with frequency (Hz.). Key: □, C8, and ○, C14, values derived from oscillatory experiments using a rheogoniometer; and ■, C8, and ●, C14, theoretical values derived by transformation of creep data.*

A description of these functions was given previously (20, 21). The storage modulus, G', and the storage compliance, J', are associated with energy stored and recovered per cycle of deformation; the loss modulus, G'', and the loss compliance, J'', are measures of energy lost or dissipated as heat during this time. The dynamic viscosity, η', is another useful way of describing dissipative effects and is the real part of a complex viscosity. The imaginary part, η'', is related to stored energy. The loss tangent, tan a, is a useful parameter because, although it conveys no physical magnitude and is dimensionless, it is a measure of the ratio of energy lost to energy stored in a cyclic deformation.

Numerical Calculation of Storage and Loss Compliances from Creep Compliance—Schwarzl (36) published a number of formulas of increasing complexity but decreasing relative error with which to calculate the storage compliance, $J'(\omega)$, and the loss compliance, $J''(\omega)$, from the creep compliance, $J(t)$. Equations 5 and 6 are the most accurate for calculating J' and J'', respectively, if infinite series are to be avoided:

$$J'(\omega) \sim J(t) + 0.000715[J(32t) - J(16t)] - 0.0185[J(16t) - J(8t)] + 0.197[J(8t) - J(4t)] - 0.778[J(4t) - J(2t)] - 0.181[J(t) - J(t/2)] - 0.0494[J(t/4) - J(t/8)] \quad \text{(Eq. 5)}$$

Table I—Composition of Emulsions (in Grams)

	C8[a]	C14	N7	N16
Liquid paraffin	100	100	100	100
Water	300	300	300	300
Cetostearyl alcohol	28.8	50.4	25.2	57.6
Cetrimide	3.2	5.6	—	—
Cetomacrogol	—	—	2.8	6.4

[a] C represents cetrimide (cationic) emulsions, N represents cetomacrogol (nonionic) emulsions, and the associated numerals refer to the approximate percentage of mixed emulsifier (surfactant plus alcohol) present.

$$J''(\omega) \sim -0.470[J(4t) - J(2t)] + 1.674[(J(2t) - J(t)] + 0.198[J(t) - J(t/2)] + 0.620[J(t/2) - J(t/4)] + 0.012[J(t/4) - J(t/8)] + 0.172[J(t/8) - J(t/16)] + 0.043[J(t/32) - J(t/64)] + 0.012[J(t/128) - J(t/256)] \quad \text{(Eq. 6)}$$

where ω (rad. sec.$^{-1}$) = $1/t$ sec.

The values of $J(t)$ required for the calculations may be read directly from the experimental creep curve and inserted into Eqs. 5 and 6. However, as the curves had already been analyzed into discrete spectra, a computer program was written which converted discrete spectral results into the values of $J(t)$ specified in the equations. It then processed the conversion of this data into $J'(\omega)$ and $J''(\omega)$. Since the discrete analysis was available, these transformed data were checked and found to be accurate, using exact interrelationships (34).

The other oscillatory functions were calculated from the transformed values of J' and J'' using Eqs. 2 and 7–9 (34):

$$G' = J'/(J'^2 + J''^2) \quad \text{(Eq. 7)}$$

$$G'' = J''/(J'^2 + J''^2) \quad \text{(Eq. 8)}$$

$$\tan a = G''/G' \quad \text{(Eq. 9)}$$

RESULTS

The results of discrete spectral analyses of the creep curves are in Table II. Figures 1–4 show plots of the loss tangents and the storage and loss compliances, moduli, and viscosities *versus* frequency for cetrimide emulsions. The same functions for cetomacrogol emulsions are illustrated in Figs. 5–8. Each figure contains the appro-

Table II—Discrete Spectral Analysis of Creep Curves [Three Voigt Unit, Residual Spring, and Residual Dashpot Model (38)]

priate function derived by direct oscillatory measurements at frequencies ranging from 10^{-4} to 25 Hz. and the same function calculated from the creep data in Table II using Eqs. 5–9. Transformed data are plotted over the frequency range 10^{-6}–1.5×10^{-1} Hz.

DISCUSSION

In general, agreement between experimental storage and loss parameters obtained using the rheogoniometer and the same functions calculated from creep data using Schwarzl's (36) transformations is good (Figs. 1–8). The significance of this is apparent when considering both the nature of the mathematical approximations and the many variables involved in the experiments (see introductory material). This agreement between the data provides strong evidence that the basic assumption made in previous work is valid; that is, that neither small strain technique destroys static structure and thus the systems are examined essentially in their rheological ground states during both types of measurement.

Creep data imply that the emulsions were of a slightly higher consistency during transient experiments than when observed in oscillation. Thus, in Figs. 1–8 a slight trend is apparent whereby transformed compliances are lower and transformed viscosities and moduli are higher than the corresponding parameters derived directly from oscillatory experiments. The most likely explanation of this trend involves two factors.

1. The loading process in the rheogoniometer destroys slightly more structure because of the relatively high shear rates and shear strains applied when parallel plates are brought together.
2. Neglect of the "end effect" in creep calculations increases the value used for the mean shear stress. If the end effect were allowed for, the rheological parameters would move closer to the relevant oscillatory data.

At high frequencies, data were transformed from values of $J(t)$ taken within a few seconds of creep. It is not possible to measure accurately these compliances because of the inertias of the viscometer and recorder. Thus, in this region, data for transformed functions are often scattered and tend to deviate from the experimental points. At the other end of the frequency range, oscillatory measurements involve errors, mainly because of evaporation from the parallel plates during the comparatively long experimental time (20, 21). Sometimes these points are also scattered. However, these discrepancies are slight and the accuracy of the transformation is excellent in view of the many experimental variables and the mathematical approximations made.

Since the transformed dynamic functions were similar to those obtained from direct dynamic measurements over the frequency range 7.91×10^{-4} (cetrimide) or 7.91×10^{-3} (cetomacrogol) to 1.5×10^{-1} Hz., it was deduced that transformed data extrapolated to low frequencies are also representative of the values that would be obtained if it were possible to conduct oscillatory experiments in this frequency range. In practice, one cannot perform reliable oscillatory experiments at frequencies below approximately 10^{-4} Hz. because of the limitations of the rheogoniometer and the transfer function analyzer and because of evaporation effects from parallel plates.

Thus, it is concluded that the described transformation procedure provides reasonably accurate dynamic functions at intermediate frequencies so that it is possible to obtain dynamic data without an oscillatory instrument. This procedure also enables oscillatory functions to be calculated at frequencies lower than those accessible to an oscillatory instrument.

Now that it has been established that transformation procedures are applicable to pharmaceutical materials and an understanding has been reached of the limitations of both creep and oscillatory experiments with regard to frequency range, it is possible to suggest a practical procedure for examining the viscoelastic properties of such formulations. In this process, data are selected from both types of experiment in the time–frequency range where each method is most accurate. This involves using high frequency values obtained from direct oscillatory measurements and low frequency values realized when creep data are transformed. Typical examples are shown in Fig. 9, where data taken from Figs. 2 and 3 are collated to provide single plots of the variations of G' and η' with frequency. To obtain smooth plots, less emphasis is given to high frequency transformed functions and to low frequency oscillatory values. The functions in the other graphs (Figs. 1–8) can be similarly processed to obtain smooth plots (not shown here). The advantage of this unification procedure is that one now obtains a clear rheological description over the entire frequency range by means of a single type of response function.

Although a viscoelastic material may be rheologically defined by any one of the viscoelastic functions used in this work, it is considered valuable to examine several functions because different types of viscoelastic behavior often exhibit different degrees of prominence in the various plots. For both ionic and nonionic preparations, as the mixed emulsifier concentration increased, consistencies rose as coherent viscoelastic networks formed in the continuous phases (1).

This is shown throughout the entire frequency range by increases in the experimental and transformed viscosities and moduli and decreases in the compliances as the cetrimide and cetomacrogol mixed emulsifier concentrations rise from 8 to 14 and 7 to 16%, respectively. The loss tangent decreases with concentration, indicating that, when networks build up, the elastic component increases to a greater extent than the viscous component. The trends exhibited by the functions plotted in Figs. 1–9 are similar to those shown by uncrosslinked viscoelastic polymers (34) and conform with a generalized Maxwell model analogy described previously (20). At high frequencies, elastic behavior dominates because there is little time available for viscous deformation, and values of G' and J' are high and low, respectively. As the time period increases, viscous behavior becomes increasingly prominent, and J' rises and G' falls with decrease in frequency. Plots of both functions alter generally in the 8×10^{-5}–1×10^{-4}-Hz. frequency region (Figs. 1, 2, 5, 6, 9).

Although η'' is not usually used to describe viscoelastic deformation, plots are included here to complete the data (Figs. 3*b* and 7*b*). These also change, exhibiting pronounced maxima in this region. These variations are significant, because they occur at frequencies that correspond to creep times (~1600–2000 sec.) only slightly greater than the longest retardation times obtained by the discrete spectral analyses of the curves (*cf.*, Table II). They indicate that retarded elastic effects no longer operate and further deformation at low frequencies is due to viscous flow. Thus, at very low frequencies (much less than 10^{-5} Hz.), G' and η'' fall rapidly and J' flattens, as the energy stored per cycle becomes negligible compared to that dissipated. Viscoelastic theory predicts that, at these low frequencies, G' plots should approach zero with a slope of 2 and J'

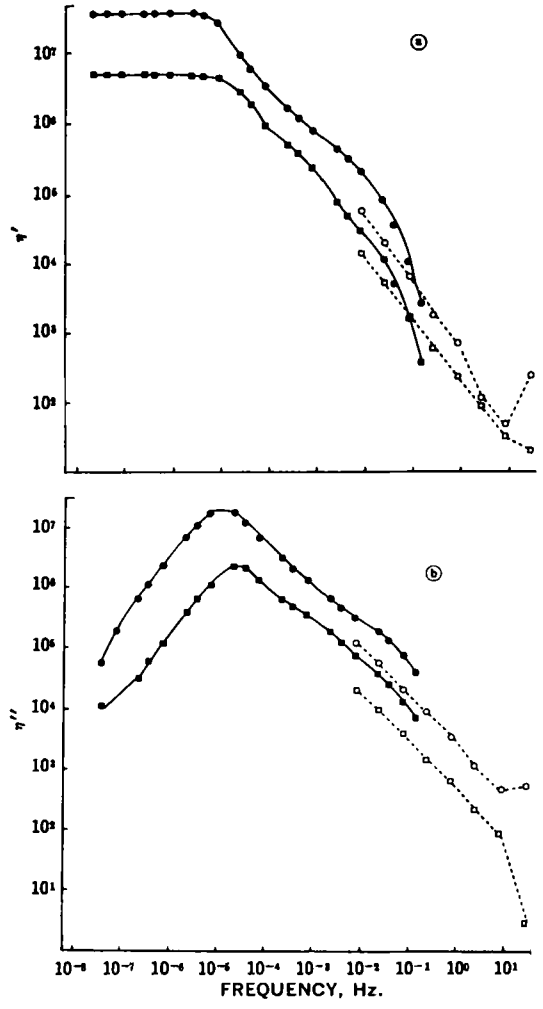

Figure 7—*Cetomacrogol emulsions N7 and N16, showing the variation of: (a) dynamic viscosity, η', and (b) imaginary part of a complex viscosity, η'' (poises), with frequency (Hz.). Key: □, N7, and ○, N16, values derived from oscillatory experiments using a rheogoniometer; and ■, N7, and ●, N16, theoretical values derived by transformation of creep data.*

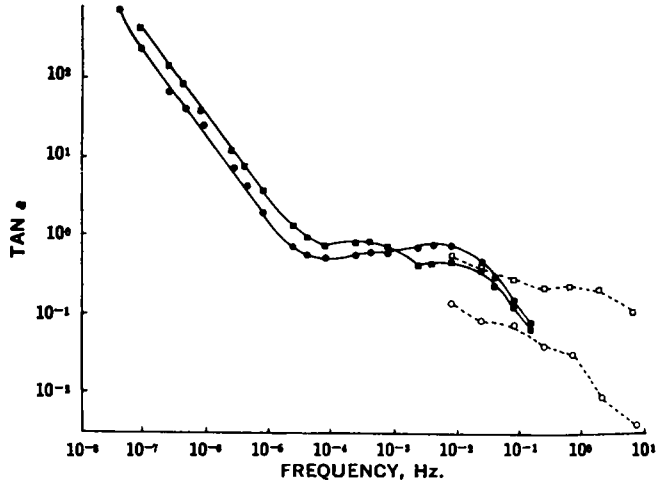

Figure 8—*Cetomacrogol emulsions N7 and N16, showing the variation of loss tangent, tan a, with frequency (Hz.). Key: □, N7, and ○, N16, values derived from oscillatory experiments using a rheogoniometer; and ■, N7, and ●, N16, theoretical values derived by transformation of creep data.*

plots should approach J_e, the total recoverable (elastic) compliance in creep. The results summarized in Table III show that agreement between such theoretical and transformed data is good. At high frequencies, G' values should approach G_0, the instantaneous elastic modulus derived in creep. The values in Table II indicate that this condition is met quite closely. Such agreement is especially satisfactory in the light of the experimental limitations involved in short time creep testing, *i.e.*, the inertial effects of the viscometer and the difficulty in applying a truly instantaneous stress.

Plots of the dissipative functions η', G'', and J'' also inflect at frequencies close to 10^{-5}–10^{-4} Hz.; at lower frequencies, dissipative mechanisms predominate and G'' reduces, J'' increases, and η' flattens out. In regions where G' changes relatively slowly with frequency (greater than approximately 10^{-4} Hz.), the behavior is predominately elastic and G'' is slightly less and J'' is slightly greater than the corresponding storage parameters. In addition, when η' flattens, G'' rises steeply, and when η' increases rapidly, G'' shows little variation. At the very low frequencies that correspond to long creep times, η' approaches the creep residual viscosity, η_0, and J'' and G'' slopes are close to -1 and $+1$, respectively, as predicted by viscoelastic theory (Table III).

Plots of the variation of tan a with frequency (Figs. 4 and 8) are of considerable practical interest because each emulsion has a characteristic curve containing maxima and minima. Loss tangent plots have been referred to as "consistency spectra" because of their similarities with the spectra obtained from spectrophotometry (29). At very low frequencies (less than 10^{-5} Hz.), tan a is large and, as predicted by theory, it is inversely proportional to the frequency so the plots in this region have slopes of -1 (Table III). In the frequency region where all other plots change ($\sim 10^{-4}$ Hz.), spectra flatten with tan a values close to unity. In the intermediate and high frequency regions, all spectra contain at least three minima which are possibly related to retardation mechanisms.

CONCLUSIONS

1. Liquid paraffin-in-water emulsions stabilized by mixed emulsifiers of the cetrimide or cetomacrogol surfactants–cetostearyl alcohol type were used as model systems to represent pharmaceutical semisolids. They were examined in their linear viscoelastic regions using creep (concentric cylinder reaction air turbine viscometer) and oscillatory (parallel plate Weissenberg rheogoniometer) techniques.

2. Storage and loss compliances (J' and J'') for frequencies ranging from 2.5×10^{-6} to 1.5×10^{-1} Hz. were calculated from creep data using numerical formulas (29). These were used to de-

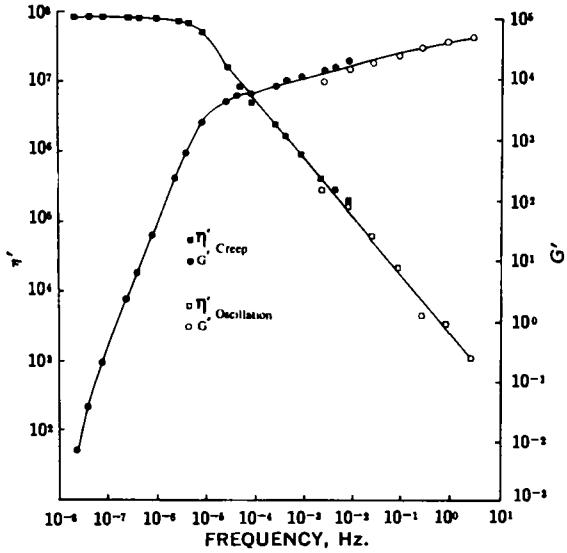

Figure 9—*Cetrimide emulsion C8. Unified plots of the variations of storage modulus, G' (dynes cm.$^{-2}$), and dynamic viscosity, η' (poises), with frequency (Hz.). Low frequency values were derived by transformation of creep data, and high frequency values were derived from oscillatory experiments using a rheogoniometer.*

Table III—Relationships between Viscoelastic Data

Data	Emulsions C8	C14	N7	N16
Slope of G' plots at low frequencies (theoretical value = 2 dynes cm.$^{-2}$ Hz.$^{-1}$)	2.1	2.1	2.1	2.1
Slope of G'' plots at low frequencies (theoretical value = 1 dyne cm.$^{-2}$ Hz.$^{-1}$)	1.0	1.0	1.0	1.0
Comparison of slope of J' plots at low frequencies and (in parentheses) J_e derived in creep (dyne^{-1} cm.^{2})	5.0×10^{-6} (4.3×10^{-6})	1.5×10^{-6} (1.7×10^{-6})	1.0×10^{-5} (1.1×10^{-5})	3.0×10^{-6} (2.4×10^{-6})
Comparison of η' derived at low frequencies and (in parentheses) η_0 derived in creep (poises)	2.0×10^{7} (2.0×10^{7})	7.9×10^{7} (7.9×10^{7})	4.8×10^{6} (4.4×10^{6})	3.8×10^{7} (4.1×10^{7})
Slope of consistency spectra plots at low frequencies (theoretical value = −1 Hz.$^{-1}$)	−1.1	−1.1	−1.0	−1.1
Comparison of residual shear modulus G_0 derived in creep and (in parentheses) G' at 7.91 and 25 Hz., respectively ($\times 10^4$ dynes cm.$^{-2}$)	1.1 (2.3, 0.6)	4.0 (4.9, 5.0)	0.65 (0.45, 0.05[a])	3.7 (1.9, 7.5)

[a] Low value due to nonlinear response at 25 Hz.

termine the other dynamic functions, G', G'', η', η'', and tan a, at the same frequencies.

3. The transformed dynamic functions were compared with the same functions obtained directly from oscillatory measurements at frequencies ranging from 7.91×10^{-4} to 1.5×10^{-1} Hz. for cetrimide emulsions and from 7.91×10^{-3} to 1.5×10^{-1} Hz. for cetomacrogol emulsions. Agreement was excellent at most frequencies; discrepancies at the extremes of the range were because of unavoidable experimental variables. This good agreement suggests that dynamic descriptions of pharmaceutical semisolids may be obtained at intermediate frequencies using a creep viscometer when an expensive rheogoniometer with associated transfer function analyzer is not available.

4. Neither small strain technique alone covered the entire time scale necessary for an exhaustive study of pharmaceutical semisolids. Creep data were unavoidably inaccurate at high frequencies, and oscillatory measurements could not be made at very low frequencies. To solve this problem, it was shown that creep and oscillatory data may be collated and unified so as to provide smooth plots of the variation of each dynamic function over an extended frequency range (10^{-8}–25 Hz.). This unification procedure uses high frequency values obtained from oscillatory measurements and low frequency values transformed from creep experiments.

5. The variations of each dynamic function with frequency over the entire frequency range were discussed with reference to linear viscoelastic theory. The limiting values and the shapes of the plots agreed well with the theoretical values for viscoelastic liquids.

NOMENCLATURE

C = cetrimide (cationic) emulsions
G' = storage shear modulus
G'' = loss shear modulus
G_0 = residual shear modulus (creep)
J = creep shear compliance
J' = storage shear compliance
J'' = loss shear compliance
J_e = total elastic shear compliance (creep)
J_0 = residual shear compliance (creep)
J_1,J_2,J_3 = shear compliances of Voigt units 1, 2, and 3, respectively (creep)
N = cetomacrogol (nonionic) emulsion
a = phase angle
n = frequency of oscillation (hertz)
t = time (second)
η' = real component of complex dynamic viscosity; dynamic viscosity
η'' = imaginary component of complex dynamic viscosity
η_0 = residual shear viscosity (creep)
η_1,η_2,η_3 = shear viscosities of Voigt units 1, 2, and 3, respectively (creep)
τ_1,τ_2,τ_3 = retardations times of Voigt units 1, 2, and 3, respectively (creep)
ω = frequency of oscillation (rad. sec.$^{-1}$)

Effect of Sodium Taurodeoxycholate on Biological Membranes: Release of Phosphorus, Phospholipid, and Protein from Everted Rat Small Intestine

STUART FELDMAN▲, MARK REINHARD, and CHARLES WILLSON

Abstract □ Sodium taurodeoxycholate accelerates the release of total phosphorus, lipid phosphorus, and protein from isolated everted rat small intestinal sacs. The effect occurs at concentrations of the physiological surfactant above the CMC. The effect of sodium taurodeoxycholate on components of the biological membrane can be related to an increase in permeability of the everted intestine to phenol red in the presence of various concentrations of the surfactant. The interaction of the surfactant with the biological membrane may produce an acceleration of the loss of structural integrity of the preparation, resulting in an increased permeability to phenol red.

Keyphrases □ Sodium taurodeoxycholate—effect on biological membranes, release of phosphorus, phospholipid, and protein from the everted rat small intestine, loss of structural integrity proposed □ Membranes, biological, everted rat small intestine—effect of sodium taurodeoxycholate on release of phosphorus, phospholipid, and protein □ Surfactants—effect of sodium taurodeoxycholate on release of phosphorus, phospholipid, and protein from the everted rat small intestine □ Permeability, everted rat small intestine—effect of sodium taurodeoxycholate on transport of phenol red, release of phosphorus, phospholipid, and protein from membrane, loss of structural integrity proposed

Previous investigators (1–7) showed an increase in drug absorption across biological membranes in the presence of physiological surfactants. An increase was found in the rate of transfer of salicylate (1) and salicylamide (2) across the everted rat small intestine in the presence of micellar sodium taurodeoxycholate. Absorption of orally administered riboflavin in man increased upon coadministration of sodium deoxycholate, an unconjugated bile salt (3). The GI absorption of phenol red in the rat increased when phenol red was administered with sodium deoxycholate (4). Increased absorption of a number of drugs in the presence of bile salts was reported (5, 6) using an *in situ* perfusion technique. The influence of sodium taurodeoxycholate on the pharmacological effect (time required to produce overturn) of pentobarbital and ethanol in goldfish was studied (7). All these effects are presumably due to an alteration in the permeability of the biological membrane to these drugs by the physiological surfactant.

The exact mechanism of action of the physiological surfactants in increasing the permeability of biological membranes has not been elucidated, although it was postulated (1, 2, 4) that the mechanism may involve changes in membrane structure, possibly by solubilizing lipid components of the membrane. Bile salts were shown to solubilize phospholipids (8), a major component of biological membranes (9).

In a later study (10), the addition of lecithin, a phospholipid, or a mixture of fatty acids and esters to the micellar bile salt solution resulted in a reduction of the permeability effect of the bile salt on the everted rat intestine to salicylate ion. It was, therefore, decided to

investigate the effect of sodium taurodeoxycholate on the release of components from biological membranes, using the everted rat small intestine as a model biological membrane.

EXPERIMENTAL

Materials—Sodium taurodeoxycholate[1] was certified as chromatographically pure. All other reagents were analytical grade.

Modified Krebs bicarbonate buffer, with no potassium dihydrogen phosphate included, was made by dissolving the sodium chloride, potassium chloride, and sodium bicarbonate in distilled water. The pH of the solution was adjusted to pH 7.4 with dry ice. When sodium taurodeoxycholate was included in the buffer, it was dissolved before the pH was adjusted with dry ice. In all cases the sodium-ion concentration was adjusted to 150 m*M* by the proper addition or omission of sodium chloride.

The Fiske–Subba Row (11) reagent was prepared by adding 0.125 g. of 1-amino-2-naphthol-4-sulfuric acid, with mechanical stirring, to 50 ml. of freshly prepared 15% sodium bisulfite (anhydrous), followed by 0.25 g. of anhydrous sodium sulfite. The solution was filtered, stored in a dark bottle in a refrigerator, and freshly prepared weekly.

Preparation of Everted Rat Intestinal Sacs—The procedure developed by Crane and Wilson (12) was used with the following modifications. Male, Sprague–Dawley descent rats[2], weighing 250–350 g. and fasted for 20–24 hr. (water allowed *ad libitum*), were anesthetized with ether. A midline abdominal incision was made, the entire small intestine was removed, and the rat was sacrificed. The intestine was rinsed with several portions of normal saline and cut 15 cm. from the pylorus. The 15-cm. portion was discarded and the intestine was everted over a glass rod. Four consecutive sacs were made by stretching the intestine with an 8-g. weight and tying off consecutive 5-cm. segments. The segments were separated and filled with 1 ml. of buffer at pH 7.4 through a syringe and blunt needle. The sacs were then individually incubated in a mucosal solution at 37° consisting of 20 ml. of buffer alone or buffer containing various concentrations of sodium taurodeoxycholate. The mucosal solution was oxygenated continuously with a mixture of 95% oxygen–5% carbon dioxide. One-milliliter samples of the mucosal solution were taken at 30-min. intervals for 2 hr.

Intestinal Transfer Rate Measurements—The Crane and Wilson (12) procedure was used with the modifications previously described (1). Two segments of everted intestine, each 10 cm. in length, were taken. Each segment was attached to a cannula as previously described (1) and was suspended in 80 ml. of mucosal solution, which consisted of buffer at pH 7.4 containing 0.1 mg./ml. phenol red in the presence or absence of various concentrations of sodium taurodeoxycholate. Samples of the serosal solutions were taken at appropriate intervals and assayed for phenol red content.

Assay Procedure—*Total Phosphorus*—The assay procedure described by Bartlett (13) was used with slight modifications. The mucosal samples were diluted to 10 ml. with distilled water. One-milliliter aliquots were taken and placed in 15-ml. conical centrifuge tubes, and 0.5 ml. of 10 *N* sulfuric acid was added to each tube. The tubes were placed in an oven at 160° for 3 hr. After the initial 3-hr. heating period, 3 drops of 30% hydrogen peroxide were added to each tube and the tubes were returned to the oven for another 3 hr. at 160°. After the samples were allowed to cool, 4.4 ml. of distilled water, 0.2 ml. of 5% ammonium molybdate, and 0.2 ml. of Fiske–Subba Row reagent were added. The samples were then heated for 10 min. at 100° and allowed to cool, and the solution was read at 830 nm. on a colorimeter[3] equipped with a red-sensitive phototube. A calibration curve was made by dissolving a known amount of potassium dihydrogen phosphate in distilled water and diluting appropriately to various concentrations of phosphorus equivalents. Each solution was assayed for phosphorus content by the assay previously described, and a calibration curve was constructed. Sodium taurodeoxycholate did not interfere with the assay procedure.

Phospholipid Phosphorus—Phospholipids in the mucosal solution were assayed by a modification of the Zilversmit and Davis (14) method. To 1 ml. of the mucosal solution in a centrifuge tube, 3 ml. of 10% trichloroacetic acid was added drop by drop with swirling. The tubes were allowed to stand for 2 min. and then were centrifuged at approximately 2000 r.p.m. for 5 min. The supernate was decanted and the precipitate was washed twice with 3-ml. portions of 10% trichloroacetic acid. After centrifugation and decantation of the supernate, 1 ml. of distilled water and 0.5 ml. of 10 *N* sulfuric acid were added to each tube and the assay procedure for total phosphorus was followed as outlined previously.

Protein Determinations—Protein determinations of the mucosal samples were made by the method of Lowry *et al.* (15). The solutions were read[3] at 750 nm. against an appropriate blank. Sodium taurodeoxycholate did not interfere with the assay procedure.

Phenol Red Assay—The serosal samples were diluted appropriately with distilled water alkalinized with 3 *N* sodium hydroxide, filtered[4] if necessary, and assayed for phenol red spectrophotometrically at 560 nm. Neither sodium taurodeoxycholate nor "blank" serosal fluid interfered with the assay procedure.

RESULTS AND DISCUSSION

The effect of sodium taurodeoxycholate on the release of total phosphorus from the everted rat intestine as a function of bile salt concentration and time is shown in Table I. At all time periods studied, with increasing concentrations of sodium taurodeoxycholate there was an increase in the total amount of phosphorus released from the everted intestinal sac. Comparison of the total amount of phosphorus released at 2 hr. after incubation reveals that at all concentrations of sodium taurodeoxycholate above 2.5 m*M* the amount of phosphorus in the mucosal fluid was significantly[5] different than that of control values. No statistical difference existed between control studies and the 1 m*M* concentration of sodium taurodeoxycholate as determined by the Student *t* test (16).

Since a possible mechanism for the increase in permeability of the everted rat intestine to drugs after exposure of the membrane to bile salts involves the interaction of the surfactant with lipid components of the biological membrane, the release of lipid-associated phosphorus from the everted intestinal sac in the presence of various concentrations of sodium taurodeoxycholate was measured. The results (Table II) show an increase in the amount of lipid phosphorus released from the everted rat intestine at 2 hr. after incubation in mucosal solutions containing sodium taurodeoxycholate in concentrations above 2.5 m*M* when compared to the control buffer and 1 m*M* bile salt solution.

Since biological membranes consist of both lipid and protein, it

was important to determine if sodium taurodeoxycholate had an effect on the protein composition of the everted rat intestinal sac. The released protein was measured as bovine serum albumin equivalents (Table III). Table III lists the milligrams of protein released from the everted intestinal sac at 60 and 120 min. after incubation as a function of sodium taurodeoxycholate concentration. As can be seen from the data, with increasing concentration of sodium taurodeoxycholate there was an increase in the total amount of protein released.

The next phase of the study examined the influence of sodium taurodeoxycholate on the transfer of a drug across the everted rat small intestine. This was done to determine if any correlation existed regarding the release of membrane components and the alteration in permeability of the membrane to a drug substance. Phenol red was chosen as the model drug, and the effect of various concentrations of sodium taurodeoxycholate on the transfer of the drug across the everted rat intestine was examined (Table IV). The total amount of phenol red transferred across the intestinal segments at 60 and 120 min. increased with increasing concentrations of sodium taurodeoxycholate. The increase in the amount of phenol red transferred in 2 hr. was significantly different from control values for all bile salt concentrations except 1 m*M* sodium taurodeoxycholate.

The data presented in Table V show the ratio of the total amount of membrane component released after a 2-hr. exposure to various concentrations of sodium taurodeoxycholate compared to the amount released in control studies. The increase in the release of membrane phosphorus, lipid phosphorus, and protein corresponded to the increased permeability of the everted intestine to phenol red. In all cases except for the protein experiments, the amount of membrane component released in the presence of 1 m*M* sodium taurodeoxycholate was not significantly different from control values as determined by the Student *t* test (16). Similar findings can be seen in the phenol red permeability measurements. The ratio of total amount of membrane component released after a 2-hr. exposure to various concentrations of sodium taurodeoxycholate plotted against the ratio of total amount of phenol red transferred in 2 hr. for each bile salt concentration is presented in Fig. 1. At 2.5, 5, and 10 m*M* concentrations of sodium taurodeoxycholate, a relationship between total phosphorus, lipid phosphorus, or protein released from the membrane and permeability of the membrane to phenol red appears to exist.

The critical micelle concentration (CMC) of sodium taurodeoxycholate is approximately 1.2 m*M* at 37° (17). Thus, it appears that the effect of the bile salt on the release of membrane phosphorus and lipid phosphorus occurs at concentrations of the surfactant above the CMC. This effect on permeability at concentrations of surfactant above the CMC was reported previously (1, 2, 10) and occurred in the transfer of phenol red in the present study.

A previous report (10) presented data to show that the addition of phospholipid or fat digestion products to micellar bile salt solutions results in a decreased permeability response by the everted rat intestine in the presence of the bile salt. To determine whether the addition of phospholipid to the micellar bile salt solution would have an effect on the release of membrane components, 10 m*M* egg lecithin was added to 10 m*M* sodium taurodeoxycholate and the release of protein from the intestinal sac was measured. The results are presented in Fig. 2 and clearly show that the addition of lecithin to the micellar bile salt solution results in a decreased amount of protein released when compared to the bile salt alone. This is in good agreement with results from previous permeability experiments (10).

Table III—Protein Release from Everted Rat Small Intestine as a Function of Time and Mucosal Concentration of Sodium Taurodeoxycholate

Solution	Protein, mg.[a,b] 60 min.	120 min.
Buffer	3.61 ± 0.14	5.44 ± 0.12
1 m*M*[c]	3.71 ± 0.17	6.55 ± 0.12
2.5 m*M*[c]	5.99 ± 0.11	9.69 ± 0.15
5 m*M*[c]	7.22 ± 0.23	11.7 ± 0.11
10 m*M*[c]	10.5 ± 0.20	12.1 ● 0.21

[a] Mean of five determinations ± *SD*. [b] Calculated as bovine serum albumin equivalents. [c] Sodium taurodeoxycholate.

Table IV—Cumulative Amount (Micrograms) Phenol Red Transferred at 60 and 120 min. in the Presence of Various Concentrations of Sodium Taurodeoxycholate

Solution[a]	Cumulative Amount, mcg.[b] 60 min.	120 min.
Control (7)	36.5 ± 3.8	118 ± 12
1 m*M*[c] (4)	39.2 ± 2.8	120 ± 1.8
2.5 m*M*[c] (5)	45.7 ± 3.4	179 ± 13.1
5 m*M*[c] (5)	52.2 ± 13.2	211 ± 8.3
10 m*M*[c] (6)	54.9 ± 6.0	229 ± 38

Table V—Ratio of Total Amount of Membrane Component Released after a 2-hr. Exposure to Various Concentrations of Sodium Taurodeoxycholate

Solution	Ratio (Sodium Taurodeoxycholate/Control) Total Phosphorus	Lipid Phosphorus	Protein	Phenol Red
1 m*M*[a]	1.14[b]	1.55[b]	1.20	1.02[b]
2.5 m*M*[a]	1.46	2.26	1.78	1.52
5 m*M*[a]	1.88	4.56	2.16	1.79
10 m*M*[a]	2.11	6.82	2.22	1.94

[a] Sodium taurodeoxycholate. [b] Not significantly different than control values ($p > 0.05$).

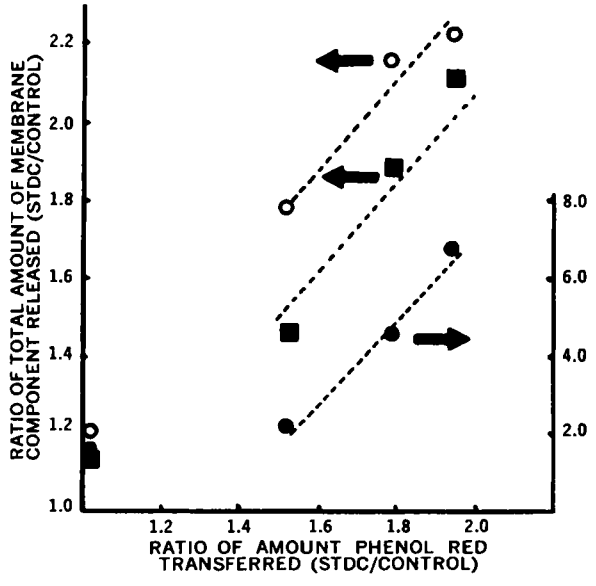

Figure 1—*Plot of the ratio of membrane total phosphorus* (■), *lipid phosphorus* (●), *and protein* (○) *released in 2 hr. in various concentrations of sodium taurodeoxycholate* (*STDC*) *to that in controls* versus *the ratio of phenol red transferred in 2 hr. in various concentrations of sodium taurodeoxycholate to that of controls.*

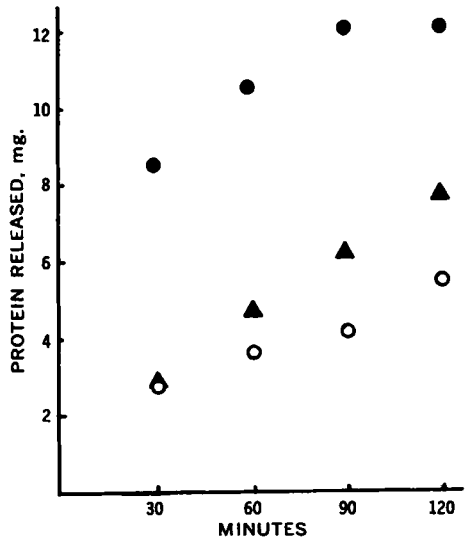

Figure 2—*Plot of total amount of protein released from the everted rat intestinal sac* versus *time in the presence of sodium taurodeoxycholate, 10 mM* (●); *sodium taurodeoxycholate, 10 mM + egg lecithin, 10 mM* (▲); *and control buffer* (○).

It appears that sodium taurodeoxycholate alters the composition of the everted rat intestinal membrane by producing an efflux of membrane components from the everted sac preparation. A similar effect by detergents on a microsomal fraction from mammalian brain was reported by Bradford *et al.* (18). These workers found that sodium deoxycholate, digitonin, and cetrimonium (cetyltrimethylammonium) bromide increased the percentage of protein, cholesterol, and phospholipid phosphorus recovered in the supernatant liquid of microsomal suspensions from brain tissue. The mechanism of action was postulated to involve interaction of the surfactant with the membrane lipo-protein complex. Moreover, Bradford *et al.* (18) did not observe significant increases in recovery of protein, phospholipid phosphorus, or cholesterol until the CMC of each surfactant was exceeded.

The alteration of the biological membrane in the presence of micellar concentrations of sodium taurodeoxycholate appears to be responsible for the increased permeability of the everted rat intestinal membrane to certain drugs after exposure to the physiological surfactant. The exact mechanism of the interaction is still unknown but most likely involves interaction of the bile salt with the protein and/or phospholipid components of the membrane. Recent work (19, 20) suggests a strong possibility for the observed effects; an increase in clearance values of polar drugs across the everted rat intestine over a 2-hr. period as compared to the initial 30-min. values was observed. The increase in rate of clearance of the compounds was partly due to a loss of functional integrity of the preparation. Compounds demonstrating initial clearance values of >1 ml./hr. showed little change in permeability over the entire 2 hr.

Previous studies with sodium taurodeoxycholate show little alteration in the permeability of the everted rat intestine to salicylamide (2) after exposure of the preparation to the bile salt, while a significant effect was noted with salicylate (1) and riboflavin (3). The clearance of salicylamide is 2.8 ml./hr., salicylate clearance is 0.7 ml./hr., and riboflavin clearance is approximately 0.3 ml./hr. (19). Phenol red has an initial 30-min. clearance value of 0.1 ml./hr. Therefore, the effect of the physiological surfactant on the biological membrane is consistent with the previously reported data (19, 20). Furthermore, Levine *et al.* (21) reported a progressive loss of structural integrity of everted rat intestinal sacs after eversion and incubation in oxygenated buffer. It is possible that the effect of sodium taurodeoxycholate on the permeability of the everted rat intestine to polar water-soluble drugs may be due to an acceleration by the surfactant of the loss of structural integrity of the preparation. This remains to be confirmed.

Effects of Cryogenine on Adjuvant-Induced Arthritis and Serum Turbidity in Rats

DONALD S. KOSERSKY*, JOHN K. BROWN, and MARVIN H. MALONE▲

Abstract □ Daily oral administration of 100 mg./kg. of cryogenine significantly suppressed the inflammation and the development of disseminated lesions in rats with adjuvant-induced (*Mycobacterium butyricum*) polyarthritis. Significant anti-inflammatory effects continued for 10 days after cessation of therapy (20 days after pedal injection of adjuvant). Cryogenine also partially prevented the decreased growth rate and decreased serum turbidity documented for untreated rats with adjuvant-induced polyarthritis. This profile of activity was similar to that established for 10 mg./kg. daily of hydrocortisone but unlike that for 2 mg./kg. daily of mercaptopurine. Cryogenine appeared equipotent (milligrams per kilogram) to phenylbutazone in inhibiting adjuvant-induced polyarthritis.

Keyphrases □ Cryogenine—effects on adjuvant-induced arthritis and serum turbidity in rats □ Arthritis, adjuvant induced—effect of cryogenine on inflammation and serum turbidity, rats □ Anti-inflammatory activity—effects of cryogenine on adjuvant-induced arthritis and serum turbidity in rats

Adjuvant-induced polyarthritis in rats produced by pedal injection of a killed *Mycobacterium* species suspended in a vehicle of light liquid petrolatum (1) has many similarities to human rheumatoid arthritis (2). While the initial edema and soft tissue thickening in the injected hindfoot may be due partially to irritation, the subsequent swelling in the injected foot and disseminated polyarthritis in the contralateral foot, front limbs, and tail appear to be immunological events (3). In 1967, Kaplan *et al.* (4) reported that chronic oral administration of cryogenine was effective in inhibiting this adjuvant-induced polyarthritis. This study was qualitative rather than quantitative since it was conducted in a very limited number of rats for a limited time and monitored only by caliper measurements of medial foot thickness. Therefore, a quantitative study appeared indicated when an adequate supply of this rare alkaloid became available.

Omaye *et al.* (5) reported that erythrocyte sedimentation rate is significantly increased by adjuvant-induced polyarthritis in a two-step process (significant elevation within 6 days after pedal injection and maximum elevation around Day +15 when secondary lesions develop). This phenomenon was paralleled by increases in total white cell count associated with lymphopenia and neutrophilia. In the same study, orally administered cryogenine and phenylbutazone appeared equipotent (milligrams per kilogram) in moderating these hematological changes.

The interrelationships between lysozyme activity and serum turbidity in rats with adjuvant-induced polyarthritis also were investigated (6). Increased lysozyme levels and decreases in serum turbidity (determined by the stability of serum protein against heat denaturation) were found to be correlated with the severity of the polyarthritic condition. Therapeutically useful anti-inflammatory drugs were shown to reverse both of these parameters. Weissman (7) proposed that degradative enzymes released from lysosomes may denature native connective tissue. The denatured products in turn may then induce an immune response like that seen in adjuvant-induced polyarthritis. Therefore, the present study also attempts to establish the effect of cryogenine and various prototype agents on serum turbidity.

EXPERIMENTAL

Adjuvant-Induced Polyarthritis—Adult female rats of the Sprague–Dawley strain, weighing approximately 200 g., were allowed to acclimatize in this laboratory for 1 week with free access to food pellets[1] and tap water. The animals were randomized into nine treatment groups of 10 rats each, and the test drugs[2] (suspended or dissolved in aqueous 0.25% agar) were orally administered (5 ml./kg.) daily beginning on Day −1 and continuing through Day +20. Both control groups received only the agar dosing vehicle. The oral route was selected to minimize counterirritant effects associated with parenteral injection (8). On Day 0, each rat to receive adjuvant was anesthetized with 30 mg./kg. i.p. of sodium pentobarbital; then 0.05 ml. of a sterile 5-mg./ml. homogenized suspension of heat-killed, desiccated *Mycobacterium butyricum*[3] in light mineral oil was injected into the left hindfoot, using a sterile micrometer syringe and a sterile disposable needle. To prevent external leakage of the injected material and to minimize vascular involvement, the 25-gauge needle was inserted through the radial foot pad and directed medially into the metatarsal region, keeping the needle's path as near to the skin surface as possible. Paw volume was measured up to an india ink line across the lateral malleolus by displacement of mercury similar to the technique described by Van Arman *et al.* (9). These plethysmographic determinations were made every 3 days for both the injected foot and the contralateral foot through Day +30. The inhibitory effects of the various drug treatments were estimated using Eq. 1 (1):

$$\text{percent inhibition} = 100\,\{1 - [(a - x)/(b - y)]\} \quad \text{(Eq. 1)}$$

where y = mean foot volume of the adjuvant control rats (receiving adjuvant injection but no drug treatment) immediately prior to adjuvant administration, b = mean foot volume of adjuvant control rats on a particular day, x = mean foot volume of drug-treated rats immediately prior to adjuvant injection, and a = mean foot volume of drug-treated rats on a particular day.

A subjective scoring system was also used to evaluate the polyarthritis. Every 3rd day the severity of the arthritic lesions in each of the four limbs was rated on a scale of 0–4. Criteria for grading included: severity and extent of edema and erythema of the periarticular tissue plus the degree of enlargement, distortion, and ankylosis of the joints. Therefore, the score for any one animal at any one time could range from 0 to a maximum of 16.

Serum Turbidity—Another 36 rats of the same stock were randomized into nine groups and treated with adjuvant and drugs as already described. However, on Day +20, they were lightly

[a] Mean foot volume is not significantly different from that of the adjuvant control group ($p > 0.05$).

anesthetized with ether and exsanguinated by cardiac puncture. To 0.1 ml. of nonhemolyzed serum, 2.9 ml. of 0.067 *M* Sørensen phosphate buffer[4] in saline (pH 5.2) was added and gently agitated. The mixture was allowed to stabilize at room temperature for 15 min. before being incubated in a constant-temperature water bath at 69° for 30 min. After removal, the sample was cooled in an ice bath and read in a spectrophotometer[5] at a wavelength of 645 nm. (10). Two separate determinations were made per rat.

RESULTS AND DISCUSSION

Adjuvant-Induced Polyarthritis—In the adjuvant control rats, marked inflammatory swelling was noted in the injected paw within 2 hr. after adjuvant injection. Paw volume increased in a linear fashion until a plateau effect was achieved between Days +6 and +12; thereafter volume again increased in a linear fashion through Day +30 (Table I). None of the test agents prevented the acute inflammatory reaction seen immediately following adjuvant injection. If one discounts the Day +3 foot volume readings, which still may reflect trauma and irritation due to the injection, all test drugs inhibited to some degree the subsequent inflammatory processes. With the exception of mefenamic acid, significant inhibition of inflammation in the injected foot was achieved with all test drugs during the dosing period and after cessation of dosage. Significant inhibition of inflammation in the injected foot was documented for mefenamic acid only at Days +6 and +9.

By Day +12, the development of secondary lesions was noted in the adjuvant control animals (increased vascularity of the ears, muzzle, and tail accompanied by swelling of the front and contralateral hindpaws). This secondary involvement increased in severity through Day +30, with the volume of the contralateral foot increasing in a near linear fashion. The initial reaction in the contralateral paw was a diffuse erythematous swelling of the dorsum of the tarsal region and the ankle joint, generally accompanied by a fusiform swelling of the digits. Nodular lesions eventually developed in the ears, muzzle, and tail. Inflammation in the contralateral paw as measured by volume (Table II) was significantly suppressed during the medication period by all drugs except indomethacin (all days) and phenylbutazone (Day +15). While indomethacin also lacked significant effect after cessation of therapy, some beneficial anti-inflammatory effects persisted for the other drugs through Day +30, especially in rats treated with paramethasone and to a lesser extent with phenylbutazone and mercaptopurine. Contralateral feet of the paramethasone-treated rats appeared grossly equivalent to the feet of untreated control animals at the termination of the 30-day observation period. The anti-inflammatory effects in the contralateral feet of animals treated with cryogenine, mefenamic acid, and hydrocortisone were not well sustained after cessation of drug dosage.

The arbitrary scoring system used in Table III should provide an index reflecting the total degree of polyarthritic involvement since both the fore- and hindpaws were rated. Only cryogenine, hydrocortisone, and mercaptopurine appeared to provide significant early protection (Day +12), while all test drugs except indomethacin appeared to protect against the development of secondary lesions (Day +21). All medicaments except indomethacin and mefenamic acid provided some continuing protection after the cessation of therapy (Day +30). The oral doses used were selected to be equiactive based on other anti-inflammatory testing in this laboratory using this rat stock; however, the present results indicate that the test compounds were not equiactive against adjuvant-induced polyarthritis at these doses.

Body Weight Changes—The mean weight of all animals was 218 g. at 0 time. The adjuvant control group achieved only a mean net gain of 5 g. in body weight during the entire observation period. There was a significant loss of mean weight (−11 g.) during the first 3 days following adjuvant injection, after which there was a

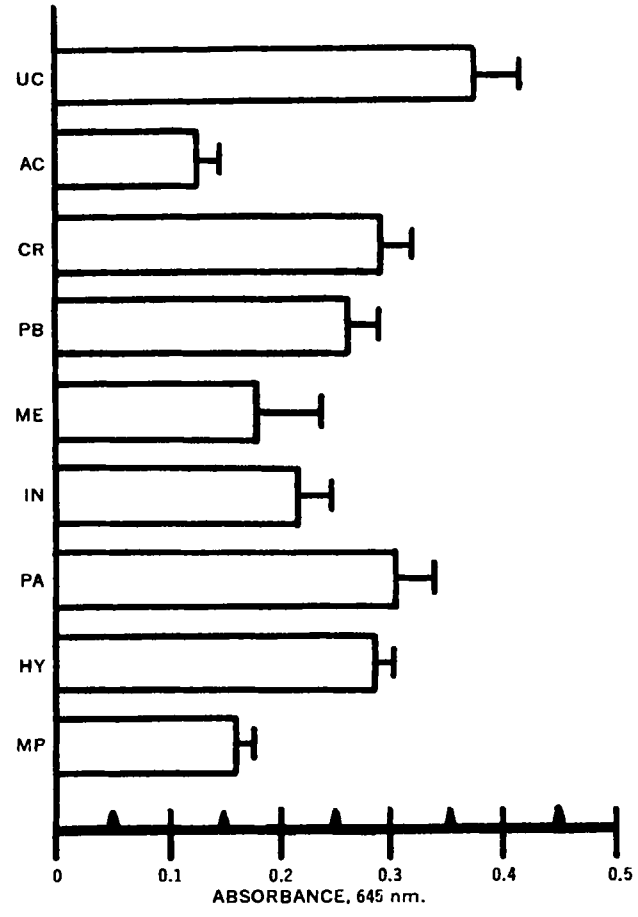

Figure 1—*Serum turbidity (absorbance + 1 SE) on Day +20 of untreated controls (UC) relative to adjuvant controls (AC) plus the effects on serum turbidity of adjuvant-treated rats receiving daily oral administration of cryogenine (CR), phenylbutazone (PB), mefenamic acid (ME), indomethacin (IN), paramethasone (PA), hydrocortisone (HY), and mercaptopurine (MP).*

Table II—Drug Effects on Volume of the Contralateral Paw in Adjuvant-Induced Polyarthritis

Treatment (Day −1 to Day +20)	Daily Oral Dose, mg./kg.	Mean Foot Volume, ml. ± *SE* (Percent Inhibition Inflammation) Day +15	Day +18	Day +21	Day +24	Day +30
Untreated control	—	1.19 ± 0.02	1.22 ± 0.02	1.24 ± 0.04	1.25 ± 0.05	1.26 ± 0.06
Adjuvant control	—	1.50 ± 0.10 (0)	1.67 ± 0.15 (0)	1.78 ± 0.16 (0)	1.87 ± 0.21 (0)	2.00 ± 0.21 (0)
Cryogenine	100	1.27 ± 0.03 (94)	1.31 ± 0.03 (88)	1.33 ± 0.05 (86)	1.37 ± 0.06 (82)	1.61 ± 0.04 (56)[a]
Phenylbutazone	100	1.30 ± 0.02 (74)[a]	1.31 ± 0.02 (81)	1.32 ± 0.02 (83)	1.35 ± 0.04 (80)	1.48 ± 0.04 (68)
Mefenamic acid	25	1.19 ± 0.02 (113)	1.26 ± 0.01 (94)	1.29 ± 0.01 (90)	1.39 ± 0.02 (75)	1.74 ± 0.04 (37)[a]
Indomethacin	1	1.34 ± 0.05 (71)[a]	1.43 ± 0.05 (62)[a]	1.45 ± 0.07 (66)[a]	1.41 ± 0.09 (75)[a]	1.69 ± 0.10 (46)[a]
Paramethasone	0.5	1.10 ± 0.01 (126)	1.17 ± 0.02 (102)	1.15 ± 0.02 (105)	1.18 ± 0.01 (100)	1.22 ± 0.06 (95)
Hydrocortisone	10	1.26 ± 0.02 (90)	1.29 ± 0.04 (88)	1.31 ± 0.04 (86)	1.44 ± 0.04 (68)[a]	1.56 ± 0.04 (59)[a]
Mercaptopurine	2	1.20 ± 0.03 (103)	1.21 ± 0.02 (100)	1.26 ± 0.03 (92)	1.34 ± 0.05 (80)	1.41 ± 0.03 (75)

[a] Mean foot volume is not significantly different from that of the adjuvant control group ($p > 0.05$).

slow recovery to preinjection weight by Day +12. Body weight then fluctuated within a narrow range during the remaining days of the study. These results are similar to those of Glenn *et al.* (11) and intermediate between the results of Pearson (12), who noted a normal weight gain, and of Newbould (1), who reported severe weight losses.

Considering the three compounds in Table III that provided consistent protection at Days +12, +21, and +30, and considering the patterns of body weight change documented in Table IV, cryogenine closely resembles hydrocortisone. Cryogenine partially prevented the acute loss of body weight noted in the adjuvant controls at Day +3 and thereafter the cryogenine-treated animals consistently gained weight, although at a slower rate than the untreated controls (mean gain of 21 g. by Day +30 as compared to 41 g. for the controls). Rats medicated with mercaptopurine progressively lost body weight through Day +9, and these animals still averaged 10 g. lighter than their starting weight by Day +30. Of the remaining partially protective compounds (Day +21 and/or Day +30) in Table III, the weight change pattern of the animals receiving paramethasone (Table IV) resembles that described for mercaptopurine. Such decreases in total body weight may contribute indirectly to the apparent "anti-inflammatory" effects recorded in Tables I and II but should not distort the arthritic index data in Table III. The weight change effects of mefenamic acid generally resembled the pattern described for cryogenine and hydrocortisone, while the pattern with phenylbutazone differed slightly in that the Day +3 weight loss seen with the adjuvant controls was generally blocked.

Table III—Drug Effects on the Arthritic Index in Rats with Adjuvant-Induced Polyarthritis

Treatment (Day −1 to Day +20)	Daily Oral Dose, mg./kg.	Mean Arthritic Index (Percent Inhibition) Day +12	Day +21	Day +30
Untreated control	—	0	0	0
Adjuvant control	—	3.3 (0)	6.5 (0)	10.2 (0)
Cryogenine	100	2.0 (39)[a]	3.2 (51)[a]	6.2 (39)[a]
Phenylbutazone	100	2.9 (12)	3.6 (45)[a]	6.7 (34)[a]
Mefenamic acid	25	2.4 (27)	4.0 (38)[a]	8.6 (16)
Indomethacin	1	3.1 (6)	4.7 (28)	7.3 (28)
Paramethasone	0.5	2.4 (27)	2.4 (63)[a]	3.6 (65)[a]
Hydrocortisone	10	1.7 (48)[a]	3.3 (49)[a]	3.9 (62)[a]
Mercaptopurine	2	2.3 (30)[a]	2.6 (60)[a]	4.9 (51)[a]

[a] Mean arthritic index is significantly different from that of the adjuvant control group ($p < 0.05$).

The adjuvant control animals resented handling, developed coarse ruffled fur, and began to vocalize and assume defensive fighting postures when paired with a fellow rat. Animals receiving cryogenine appeared quite healthy, displayed normal spontaneous motor activity, and did not show aggressive or defensive behavior patterns when paired with another rat. This tranquil attitude may be due to the weak ataractic activity documented for parenterally administered cryogenine (13) but is more likely due to the anti-inflammatory capacity of cryogenine providing relative freedom from the polyarthritic pain.

Serum Turbidity—As shown in Fig. 1, there was a significant ($p < 0.05$) decrease in serum turbidity in adjuvant control animals as compared to the untreated controls. While the immunosuppressive mercaptopurine was effective in all phases of adjuvant-induced polyarthritis studied (Days +12, +21, and +30, Table III), this effect was accompanied by severe losses in total body weight, and the serum turbidity in mercaptopurine-treated rats at Day +21 was not significantly different from the depressed levels documented for the adjuvant controls. Paramethasone, cryogenine, hydrocortisone, and phenylbutazone had a significant but intermediate degree of effect in preventing the adjuvant-induced decrease in serum turbidity, but the acute loss of body weight produced by paramethasone seems to place this compound in a different pharmacological category than the other three agents.

In studies with intact and adrenalectomized rats using both proliferative (cotton-pellet granuloma) and exudative (carrageenin-induced pedal edema) models of inflammation, DeCato (14) suggested that the anti-inflammatory efficacy of cryogenine may be due, in part, to the release of endogenous corticosteroids. This hypothesis is supported by the limited effectiveness of cryogenine (relative to phenylbutazone) in preventing UV-induced erythema in guinea pigs, a pharmacological model of inflammation that is

Table IV—Drug Effects on Whole Body Weight of Rats with Adjuvant-Induced Polyarthritis

Treatment (Day −1 to Day +20)	Daily Oral Dose, mg./kg.	Mean Body Weight, g. Day 0	Day +3	Day +6	Day +12	Day +18	Day +21	Day +24	Day +30
Untreated control	—	228	232[a]	234[a]	235[a]	253[a]	253[a]	258[a]	269[a]

unresponsive to corticosteroid-like agents (15). The results of the present study do not conflict with this theory and do establish that the anti-inflammatory activity of cryogenine probably is not due to a mercaptopurine-like immunosuppressive capacity.

Structure–Side-Effect Sorting of Drugs II: Skin Sensitization

ERIC J. LIEN▲ and GEDY A. GUDAUSKAS*

Abstract □ A computerized sorting program was used to sort out 120 drugs that have been reported to cause skin sensitization from a data bank of 540 clinically useful drugs. Based on an analysis of functional groups, a number of unique common denominators were found for skin sensitization due to covalent bond formation with body proteins. These include potential epoxide-forming groups such as an electron-deficient benzene ring, a vinyl group, hydroxylamine and *N*-oxide precursors, drugs capable of forming a benzylic radical, β-lactam derivatives, and α,β-unsaturated ketones. By using multiple-regression analysis, the quantitative structure–activity relationship for skin-sensitizing properties of 3-alkyl catechols and 2,4-dinitrobenzene derivatives are also reported.

Keyphrases □ Side effects, computer sorting of 540 drugs—skin sensitization related to structure □ Computer sorting of side effects of 540 drugs—skin sensitization related to structure □ Structure–activity relationships—features related to skin sensitization effects, result of computer sorting of 540 drugs □ Skin sensitization effects—related to structural features, result of computer sorting of 540 drugs □ Drug sorting by side effects—structure–activity relationships

As a continuation and extension of an effort to sort and correlate side effects of drugs with their chemical structures (1), attention was focused on the problem of skin sensitization. Numerous drugs are known to cause dermatitis, urticaria, eczema, photosensitization, or other signs of skin sensitization following either systemic or topical applications. The main purpose of this study was to utilize a computerized sorting program to list as many as possible of the drugs known to cause various types of skin sensitization and to find out the common structural features. Attempts were made to categorize these drugs on the basis of functional group analysis and the types of possible chemical reactions with proteins. It is hoped that the findings will not only suggest working hypotheses for skin sensitization by various drugs but will also provide some rational chemical basis of skin sensitization. Quantitative structure–activity analysis was applied to a series of catechols and dinitrobenzene derivatives where quantitative data on series of compounds were available.

METHOD

The computerized sorting program was described previously (1). The following descriptive terms of signs were sorted out from the data bank: skin sensitization, lesions, necrosis, rashes, eruptions, reactions, irritations, opacities, dermatitis, photosensitivity, and urticaria. The results are given in Tables I and II.

The method of least squares was used to derive the equations correlating the physicochemical parameters with the delayed contact skin-sensitizing activity. The biological data and the physicochemical constants used are assembled in Table III.

RESULTS AND DISCUSSION

Skin-Sensitizing Drugs—A total of 120 drugs or drug groups from the data bank of 540 drugs have been reported to cause various types of skin sensitization (2–8). In analyzing the common structural features, many of these drugs were found to contain a benzene ring

unresponsive to corticosteroid-like agents (15). The results of the present study do not conflict with this theory and do establish that the anti-inflammatory activity of cryogenine probably is not due to a mercaptopurine-like immunosuppressive capacity.

or other aromatic ring systems bearing electron-withdrawing groups (Table I). The electron-withdrawing groups may stabilize the epoxide formed by drug-metabolizing enzymes. It has been shown (9) that drug-metabolizing enzymes in the liver cause the formation of active epoxides from bromobenzene, *o*-dibromobenzene, *m*-dibromobenzene, and naphthalene (10). These epoxides may then alkylate body protein or cause tissue damage in liver, kidney, bone marrow, *etc.* (11, 12). Other compounds such as various isomers of octene (13), styrene (14), and chlordane (15) also have been shown to form epoxides *in vivo*. The carbon–carbon double bond in diethylstilbestrol, carbamazepine, and novobiocin may be responsible for the skin sensitization *via* epoxide formation.

The second group of drugs that has been reported to cause skin sensitization contain either a primary aromatic amine moiety with the *para*-position blocked or a tertiary aliphatic amino group (Table II). Compounds with the structure of X—C_6H_5—NH_2 form the highly reactive and toxic hydroxyamino and nitroso compounds (16–18), which may then react with proteins to form antigens. Schwarz and Speck (19) demonstrated that hydroxyamino derivatives of sulfanilamide play a role in photosensitivity. They were able to sensitize guinea pigs with these oxidation products of sulfanilamide and then to provoke a reaction by exposure to sulfanilamide and light and vice versa.

In contrast to the sulfanilamides, when patients known to be photoallergic to chlorothiazides were skin tested to the oxidation products 4-amino-6-chlorobenzenedisulfonamide and 4-hydroxyamino-6-chlorobenzenedisulfonamide, no positive reactions were elicited in patch and intracutaneous tests and in irradiated patch and intracutaneous tests with these compounds (20). Therefore, the exact mechanism by which drugs like chlorothiazides induce skin sensitization remains to be investigated. Since the positions *meta* and *para* to the chloro atom are blocked by the thiazide ring, the formation of an epoxide is not likely.

The nitro group in chloramphenicol is also known to undergo reduction to give an amino group (21). This minor metabolic path-

[a] C = the geometric mean dose (moles) for threshold skin reaction 4 weeks after the animals received the last sensitizing injection; taken from Table I of *Reference 30*. [b] Based upon the experimental value of 0.88 for pyrocatechol and use of π = 0.50 for each CH_3 or CH_2 unit (36). [c] C = the geometric mean dose (moles) for threshold skin reaction (homologous) 47 days after sensitization; taken from Table I of *Reference 33*. [d] Experimental values from *Reference 33*. [e] Calculated by taking advantage of the additive–constitutive nature of the Hansch π constant. The following π values are used: 1,3-dinitrophenyl = 1.49; SCN = 1.01; I = 0.92; Br = 0.75; Cl = 0.59; F = 0.01; and SO_3H = −4.38; taken from *Reference 35*, phenoxyacetic acid system, and *Reference 36*. [f] Volume in Å^3 from *Reference 33*. [g] R = reactivity coefficient with bovine serum albumin (BSA), R = (hapten)/(DNP–BSA) − 1, where DNP = dinitrophenol. For the experimental procedure, see *Reference 33*.

way may be responsible for the skin sensitization. Another possible way of forming a covalent bond between chloramphenicol and a protein would be *via* a benzylic free radical, as suggested by Hansch and Kerley (22) (*vide infra*).

The third group of drugs contains substituents which may stabilize a benzylic radical (22). This group includes drugs such as chloramphenicol and quinine (Scheme I).

It is also known that various aliphatic tertiary amino compounds form *N*-oxides in many biological systems (Scheme II) (16, 24, 26). Since these *N*-oxides can be isolated fairly easily, they probably are not as reactive as *N*-nitroso or *N*-hydroxyamine derivatives. Nevertheless, it has been reported that in several cases *N*-oxides are more active than their corresponding tertiary amines (27).

[a] n = number of data points (compounds used in the regression analysis). [b] r = correlation coefficient. [c] s = standard deviation. [d] 95% confidence interval.

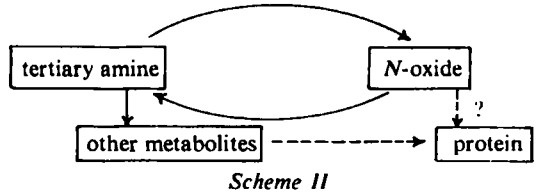
Some *N*-oxides also have been postulated as inducers of spontaneous cancer. These *N*-oxides may also be important intermediates in drug metabolism (27).

The fourth group of drugs causing skin sensitization and/or anaphylactic shock contains drugs with a β-lactam moiety. The four-membered β-lactam ring may open up and form a new peptide linkage with body protein (Scheme III) (28). All of the penicillins and cephalosporins belong to this group.

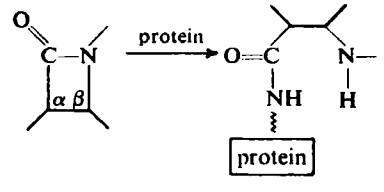
The fifth group of drugs which can form covalent bonds with proteins and cause skin sensitization includes those possessing an α,β-unsaturated ketone function. The examples found from the data bank are cortisone, digoxin, griseofulvin, and spironolactone. These drugs can conceivably undergo nucleophilic attack by any nucleophiles ($\ddot{N}u$) such as —SH, —O^-, and —$\ddot{N}H_2$ (Scheme IV) (29).

The sixth group of skin-sensitizing drugs contains polyiodinated benzene derivatives, *e.g.*, ipodate, iothalamic acid, and diiodohydroxyquin. Polyiodinated benzene derivatives are readily deiodinated *in vivo* (30, 31). Although the exact mechanism is not known, this process possibly may go through a free radical intermediate. The iodine radical, the phenyl radical, or the iodide ion produced may act as a hapten and react with protein.

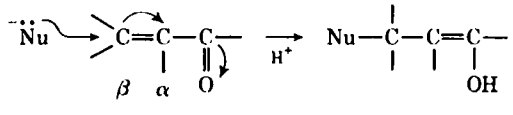
Miscellaneous Compounds—Drugs like kanamycin and paromomycin contain primary amino groups and sugar moieties. It



Scheme II



Scheme III



Scheme IV

does not appear likely that these molecules would form covalent bonds with body protein. Whether the skin sensitization caused by these drugs is due to the trace amount of fermentation by-products by *Streptomyces* or not remains to be studied.

Other drugs like phenacemide, phenacetin, phenelzine, and barbiturates are also known to cause sensitization. No well-established biotransformations or chemical reactions are available to explain the coupling between these compounds and proteins. It is possible that small amounts of reactive metabolites may be responsible for the skin sensitization reported. Identification of these metabolites will be essential for the establishment of the mechanism.

Quantitative Structure–Activity Relationship—The equations correlating the skin-sensitizing properties with the physicochemical constants are summarized in Table IV. The biological data are from Baer *et al.* (32) and Godfrey and Baer (33). It has been suggested that the mechanism of sensitization by compounds of the catechol type results from conversion to a quinone, which then spontaneously couples to protein (34). Equations 1 and 2 clearly indicate that the major variation in the skin-sensitization activity of the 3-alkyl catechol is primarily due to the lipophilic character (log P) or the length of the side chain, as indicated by the log P from octanol–water. However, because all of the substituents are straight-chain alkyl groups, there is a strong correlation between the log P and the chain length. A better selection of substituents with different steric and lipophilic character may delineate which parameter is more important in contributing to the skin sensitization. The $(\log P)^2$ is significant at the 99 percentile level as indicated by an F-test ($F_{1,7} = 15.05$, $F_{1,7,99} = 12.2$). About 97% of the variance ($r^2 = 0.97$) in the data can be accounted for by the parabolic equation of log P (Eq. 2). The optimum lipophilic character for maximum sensitization is defined by log P_0 (37, 38). The log P_0 of 17.96 from Eq. 2 is considerably higher than that of pentadecylcatechol (log $P = 8.38$), the active principle of poison ivy. The fairly wide 95% confidence interval of log P_0 is primarily due to the fact that the highest log P in the series is only 10.38. Nevertheless, the statistical analysis points to the deviation from linearity.

For the 2,4-dinitrobenzene derivatives, Eqs. 3–6 are obtained. Among the parameters examined, the molar volume of the substituent (V_x) gives a slightly better correlation than log P (octanol–water) or the reactivity coefficient (R) with bovine serum albumin. Pure hydrocarbon is known to yield less satisfactory correlation with biological activity than the solvents that are capable of forming hydrogen bonds. This becomes very evident when one compares Eqs. 3 and 5. The log P of 2,4-dinitrobenzenesulfonyl chloride in octanol–water is not available because it reacts with alcohols, and that of 2,4-dinitrobenzenesulfonic acid in isooctane–water is not available because of the very low solubility in the hydrocarbon. As a consequence, six data points are included in Eq. 5, but only five data points are in Eqs. 3 and 6. It is difficult to assess whether Eq. 6 is really better than Eq. 5. Intercorrelation between the volume of the substituent (V_x) and log P_{octanol} is also apparent ($r = 0.98$). The analysis is in agreement with the original authors' conclusion (33) regarding the importance of the steric nature of the substituent. The results also show that if a proper solvent system is chosen, one can get practically the same correlation by using log P instead of the steric parameter. A better selection of substituents with no interdependence between log P and V_x will be necessary to evaluate the contribution of these two parameters to skin sensitization.

Since the phototoxic reaction does not involve the conjugation of hapten with protein (39, 40), it is not included in this study. For the general discussion of allergic drug reactions, a recent article by MacFarlane (41) is available.

GLC Determination of Probenecid in Biological Fluids

ANTHONY G. ZACCHEI▲ and LINDA WEIDNER

Abstract □ A highly specific and quantitative GLC method for the determination of probenecid in biological fluids is described. The method is adaptable to automation with an automatic sample injector and a peak area integrator. The procedure involves the addition of an internal standard (*N*-dibutyl analog of probenecid) to plasma or urine samples followed by extraction at pH 1 into benzene. The extracted acids are converted to methyl esters for GLC analysis by reaction with ethereal diazomethane. The sensitivity of the method is such that 250 ng. of material can be detected in 1 ml. of plasma. GLC–mass spectrometry techniques confirmed that the developed method measures the parent drug probenecid.

Keyphrases □ Probenecid in biological fluids—GLC analysis □ GLC—analysis, probenecid in biological fluids

The use of the uricosuric agent, probenecid (I), for the treatment of gout and for the inhibition of the active transport of many substances necessitated the development of a rapid and sensitive quantitative method for the detection of I. Various spectrophotometric methods (1–3) have been reported; however, these methods lack the required specificity and sensitivity. A recently described GLC method (4) has several disadvantages; specifically, no internal standard is employed and the sensitivity is about 2 mcg./ml.

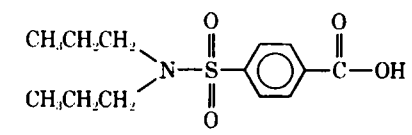
This report describes a very sensitive and specific GLC method for probenecid determinations, under conditions where only probenecid was administered, using an internal standard (*N*-dibutyl analog of probenecid, II). The method has the added advantage of being adaptable to automation.

EXPERIMENTAL

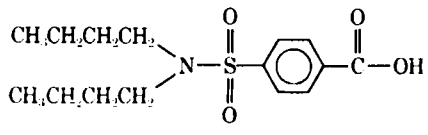
Reagents and Chemicals—The chemicals and reagents used were: probenecid, the *N*-dibutyl analog of probenecid, benzene, methylene chloride, and 0.5 *M* diazomethane (generated from *N*-nitroso-*N*-methylurea).

Instrumentation—*GLC*—A gas chromatograph[1] equipped with a flame-ionization detector and a 183 × 6-mm. glass column containing 1% OV-17 (phenyl methyl silicone gum) on Supelcoport, 90–100 mesh, was used. The column, detector, and injection port temperatures were 225, 240, and 245°, respectively. Helium was used as the carrier gas at a flow rate of 48–50 ml./min.

A gas chromatograph[2] equipped with a flame-ionization detector and a 183 × 6-mm. glass column containing 1% OV-17 on Supelcoport, 80–100 mesh, was employed for the automated GLC analysis. The column, detector, and injection port temperatures were 209, 276, and 265°, respectively. Helium was used as a carrier gas at a flow rate of 50 ml./min. Injections were performed automatically[3]. Peak areas were calculated automatically by an integrator[4].



I



II

GLC–Mass Spectrometry—All mass spectra were obtained on a mass spectrometer[5] using the GLC inlet with a 183 × 6-mm. glass column packed with 1% OV-17 on Supelcoport, 80–100 mesh. The gas chromatograph was operated isothermally at 230° with a helium flow rate of 30 ml./min. The mass spectrometry ionizing and accelerating potentials were 70 ev. and 3.5 kv., respectively. The source and injection port temperatures were both 270°.

Measurement of I in Biological Samples—Compound I was determined in biological samples as follows. One milliliter of plasma or 3.0 ml. of urine was added to a 50-ml. glass-stoppered centrifuge tube containing 15 mcg. of internal standard (in 1.0 ml. of phosphate buffer, pH 7), 1 ml. of 2 *N* hydrochloric acid, and 25 ml. of benzene. The tube was shaken for 10 min. and centrifuged, and at least 20 ml of the organic phase was transferred to a similar tube containing 2 ml. of 0.1 *N* sodium hydroxide. After shaking for 5 min., the tube was centrifuged and the organic phase was removed by aspiration. The pH of the aqueous phase was adjusted to 1 by the addition of 0.2 ml. of 2 *N* HCl, and the free acids were extracted into 5 ml. of methylene chloride (Vortex, 1 min.). After centrifuga-

	B	120	84	108	108	120		

[a] Values in the A rows represent micrograms recovered; values in the B rows represent percent recovery.

tion, the aqueous phase was removed by aspiration and the methylene chloride phase was transferred to a 13-ml. conical centrifuge tube and then treated with 100 μl. of an ethereal solution of diazomethane. After 5 min., the tube was placed in a warm water bath in a hood; all solvent and unreacted reagent were allowed to evaporate under nitrogen. The residue was dissolved in 100 μl. of ethyl acetate and appropriate aliquots, usually 5 μl., were injected into the gas chromatographs. The retention times of the methyl esters of I and the *N*-dibutyl internal standard (II) were 4.6 and 6.6 min., respectively.

Standard water, urine, and plasma curves were constructed by plotting the peak height ratios (I/II) or peak area ratios (I/II) *versus* weight ratios (I/II). The peak height ratio obtained from an unknown was then used to determine the amount of I present. The standard samples were run simultaneously with the unknown samples as previously described. Recoveries of I added to plasma or urine in amounts of 0.2–60 mcg. ranged from 84 to 120% for analyses performed over several months. The mean recovery was 100.55 ± 6.37% over the entire concentration range.

Absorption and Excretion Studies—Drug (I), in capsule form or in saline solution as the sodium salt, was administered to purebred beagle dogs of both sexes. Drug (I) in gelatin capsules was administered to normal human subjects. Probenecid was administered to the dogs at a dose of 19 mg./kg. as the free drug or in combination with pivampicillin (33 mg./kg.) and ampicillin (23.3 mg./kg.). Similar dosage formulations were administered to human subjects.

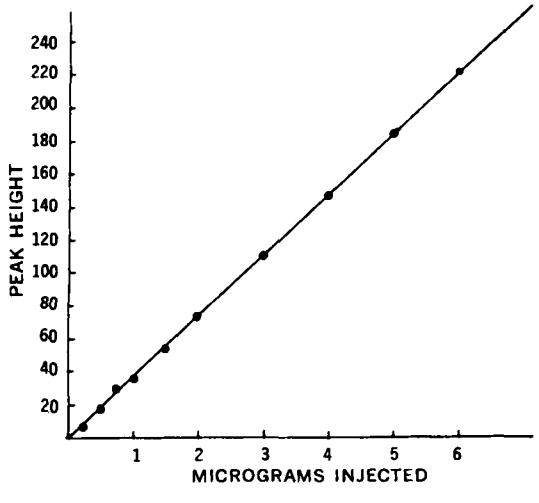

Figure 2—*Relationship between peak height and amount injected. Five microliters was injected in each case.*

Animals and human subjects were fasted prior to drug administration. Urine was collected from animals housed in individual metabolism cages and was frozen as collected in dry ice-cooled containers. Blood was collected in heparinized syringes, and the plasma was separated by centrifugation and frozen until assayed. The plasma and urine samples were analyzed as previously described.

RESULTS AND DISCUSSION

Figure 1 presents gas chromatograms of the following samples: (*a*) pure probenecid methyl ester and the corresponding *N*-dibutyl analog, (*b*) probenecid and the *N*-dibutyl analog added to control

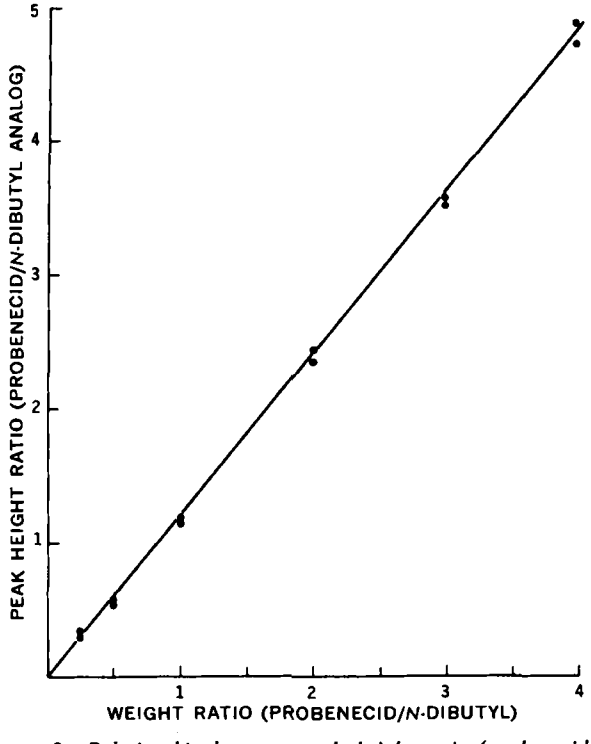

Figure 3—*Relationship between peak height ratio (probenecid/N-dibutyl analog) and weight ratio (probenecid/N-dibutyl analog). Five microliters was injected in each case out of 100 μl. following appropriate recovery (water, plasma, or urine).*

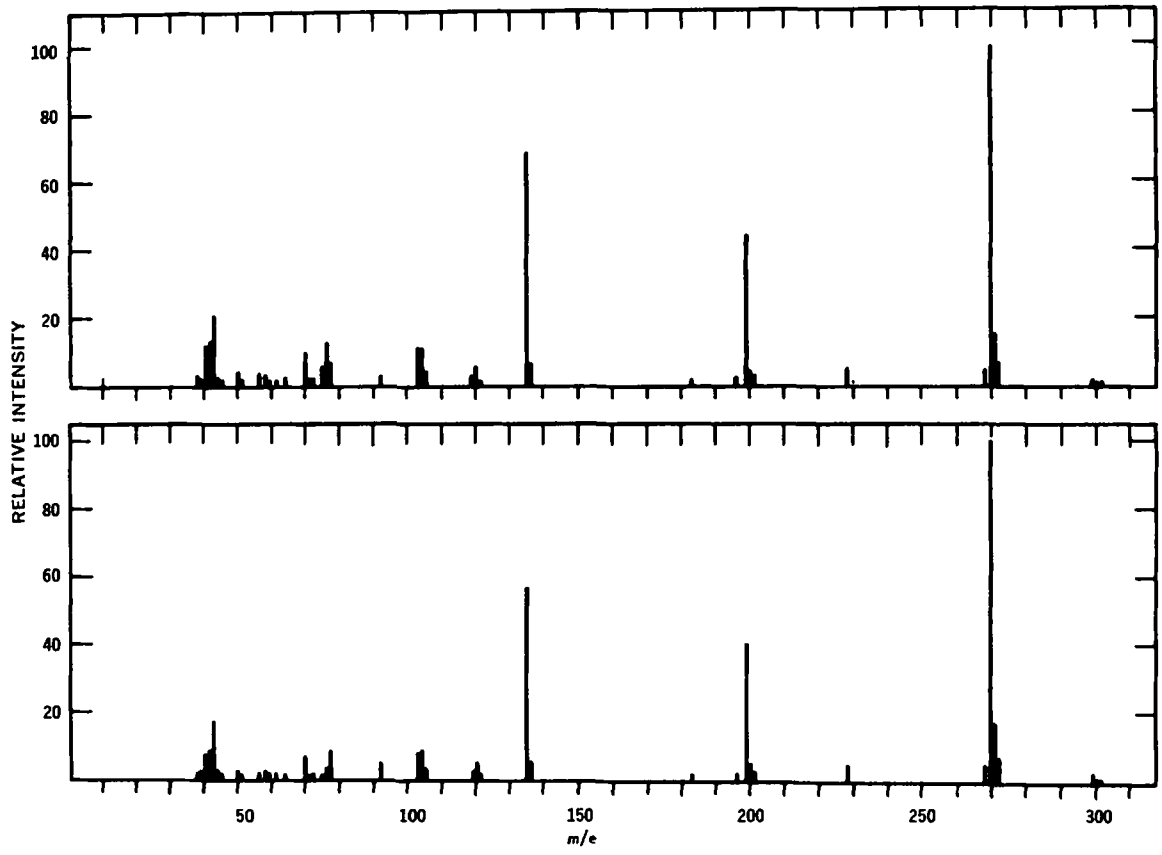

Figure 4—*Mass spectra for probenecid methyl ester (top) and the material obtained from dog plasma (bottom).*

plasma and carried through the GLC procedure, and (*c*) material obtained from biological specimens after the addition of the *N*-dibutyl internal standard. As stated previously, the methyl ester of probenecid had a retention time of 4.6 min. and the corresponding internal standard had a retention time of 6.6 min. Gas chromatograms of control samples did not exhibit any peaks with retention similar to probenecid methyl ester or the methyl ester of the internal standard. A linear relationship is observed when peak height (or peak area) is plotted *versus* amount injected (Fig. 2). A typical standard peak height ratio (I/II) *versus* weight ratio (I/II) is presented in Fig. 3. The slope of the straight line is 1.20. Values for the slope ranged from 1.03 to 1.25, depending upon specific analysis over 6 months. A summary of the recovery results of I obtained with dog plasma in the range of 0.2–60 mcg. added to the initial tube is presented in Table I. As evident, the GLC procedure for probenecid in biological fluids is very sensitive and exhibits a high degree of precision and accuracy.

Table II—Plasma Levels of Probenecid following Administration of Probenecid to Dogs (Intravenous or Oral, 19 mg./kg.)

8.0	22.8	38.3	29.3	39.3	21.8	45.6
24.0	3.0	10.5	3.7	12.3	3.6	13.9
$t_{1/2}$	5.5	8.0	6.0	9.8	7.6	9.4

[a] Group A, dogs received probenecid intravenously, 19 mg./kg.; Group B, dogs received probenecid intravenously, 19 mg./kg., and ampicillin intravenously, 23.3 mg./kg.; and Group C, dogs received probenecid orally, 19 mg./kg., and pivampicillin orally, 33.3 mg./kg.

This GLC method was applied to numerous samples of biological origin, specifically with respect to dog and human urine and plasma. The samples analyzed also contained ampicillin and pivampicillin, neither of which had any effect on the GLC assay of probenecid. Typical probenecid levels in dog plasma are seen in Table II.

Confirmation of specificity of analysis was obtained when representative unknown biological specimens were analyzed by combined GLC–mass spectrometry using the technique previously described. Figure 4 presents a comparison of the mass spectrum of the synthetic methyl ester of probenecid with the mass spectrum of the material isolated from biological origin following oral administration of drug (I). The details of the fragmentation pattern of probenecid were reported previously (4–6); the mass spectra were identical in all respects. The molecular ion (*m/e* 299) represents ~2% of the intensity of the base peak (*m/e* 270), which results from cleavage of the side chain beta to the nitrogen. The characteristic metastable ions at 192.6, 173.8, and 146.8 were observed.

CONCLUSION

A sensitive, specific, and accurate GLC method for the determination of probenecid in biological fluids is presented. The method is adaptable to automation with the use of an automatic sample injector and a peak area integrator. The use of an internal standard eliminates any errors in quantitation as a result of sample manipulation (7). The sensitivity of the method is such that 250 ng. of material can be detected in 1 ml. of plasma. No interference in the GLC method was observed with ampicillin or pivampicillin. GLC–mass spectrometry results from various analyzed samples confirmed the specificity and identity of probenecid.

5-Fluorouracil and Derivatives in Cancer Chemotherapy III: *In Vivo* Enhancement of Antitumor Activity of 5-Fluorouracil (FU) and 5-Fluoro-2′-deoxyuridine (FUDR)

JOHNSON JATO* and J. J. WINDHEUSER▲

Abstract □ The antitumor activity of 5-fluorouracil (FU) and 5-fluoro-2′-deoxyuridine (FUDR) has been enhanced in mice in the presence of deoxyribose donors such as 2′-deoxyuridine (UDR). Based upon *in vitro* data, it appears that the enhancement is due to the conversion of 5-fluorouracil to 5-fluoro-2′-deoxyuridine in blood and the stabilization of 5-fluoro-2′-deoxyuridine due to the presence of 2′-deoxyuridine.

Keyphrases □ 5-Fluorouracil (FU)—antitumor activity enhanced by deoxyribose donors (2′-deoxyuridine), mice □ 5-Fluoro-2′-deoxyuridine (FUDR)—antitumor activity enhanced by deoxyribose donors (2′-deoxyuridine), mice □ Antitumor activity, 5-fluorouracil (FU) and 5-fluoro-2′-deoxyuridine (FUDR)—enhanced in presence of deoxyribose donors (2′-deoxyuridine), mice □ Cancer chemotherapy—enhancement of 5-fluorouracil (FU) and 5-fluoro-2′-deoxyuridine (FUDR) activity by deoxyribose donors (2′-deoxyuridine), mice

A previous article (1) reported the *in vivo* stabilization of 5-fluoro-2′-deoxyuridine (FUDR) and its formation from 5-fluorouracil (FU) in the presence of nucleosides. The speculation was made that these findings could have marked effects on the clinical use of 5-fluorouracil and 5-fluoro-2′-deoxyuridine in cancer chemotherapy. Following the synthesis of 5-fluoro-2′-deoxyuridine (2), it was shown that the nucleoside was 10^3 times as effective as 5-fluorouracil *in vitro* (3). However, the relatively high anticipated effectiveness of 5-fluoro-2′-deoxyuridine as compared to 5-fluorouracil has not been borne out in clinical use. It was suggested (4) that the lower activity observed was due to the *in vivo* cleavage of 5-fluoro-2′-deoxyuridine to the pyrimidine base and the phosphorylated sugar moiety. The stabilization of 5-fluoro-2′-deoxyuridine by 2′-deoxyuridine (UDR) in blood (1) led to the speculation that this approach could lead to a marked clinical enhancement of 5-fluoro-2′-deoxyuridine activity. This article reports the effect of combining 5-fluorouracil and 5-fluoro-2′-deoxyuridine with 2′-deoxyuridine in protecting mice against L-1210 leukemia and adenocarcinoma 755.

EXPERIMENTAL

Materials and Instruments—The following were used: 5-fluorouracil[1], 5-fluoro-2′-deoxyuridine[1], 2′-deoxyuridine[2], deoxycytidine[2] (CDR), and 5-trifluoromethyl-2′-deoxyuridine[3] (F_3TDR). All other substances used were either reagent grade or of the highest purity available.

A spectrophotofluorometer[4], a TLC scanner[5] modified to contain pendrive motor and range offset, and an *x-y* recorder were used.

***In Vitro* Analysis of 5-Fluorouracil and 5-Fluoro-2′-deoxyuridine**—Drugs and additives in known initial concentrations in blood were dialyzed and evaporated by the method of Windheuser *et al.* (5). The dry samples were dissolved in a constant volume of ethanol. The samples were applied to a fluorescent TLC plate, which had previously been activated at 110° and ruled to restrict the lateral motion of the spots to within the range of the scanner optic. The components were resolved by multiple-pass discontinuous development (6). The developer for the process was composed of ethyl acetate–ethanol–10% ammonium hydroxide (200:5:2). The dried plates were scanned in the direction of development for fluorescence quenching at an activation maximum of 280 nm. and a fluorescence maximum of 530 nm., using a spectrophotofluorometer[4] with a thin-film scanner attachment. Quantities of substances present in the blood were computed by appropriate comparison of sample and standard peak areas obtained by planimetry. The method exhibited sufficient sensitivity to detect 10 ng. of 5-fluorouracil and 5-fluoro-2′-deoxyuridine.

***In Vivo* Mouse Studies**—*L-1210 489 Leukemia*—A standardized suspension prepared from 7-day-old tumors from BDF_1 mice was injected intraperitoneally. The volume was adjusted to provide 1×10^6 cells/injection. Twenty-four hours after the transplant, the mice were divided into groups of 10 and each group was injected intraperitoneally for 7 days with one of the drug regimens listed in Table I.

The number of mice per group that died from the leukemia, as confirmed by autopsies, was recorded daily until all animals were dead. An average lifespan, that is, the average number of days that mice in each group survived after tumor transplant, was computed. The T/C value, which is the ratio of the lifespan of the experimental group to that of the control group, was calculated. An increase in lifespan representing the percent increase of the lifespan of each group relative to the control was determined from the T/C (Table I). The increase in lifespan is used as a measure of the effectivness of the drug regimen.

Adenocarcinoma 755—Donor BDF_1 mice bearing 10-day-old tumors were sacrificed, and the tumors were removed with sterile surgical instruments inside a tissue culture hood. Then the tumors

Following the synthesis of 5-fluoro-2′-deoxyuridine (2), it was shown that the nucleoside was 10^3 times as effective as 5-fluorouracil *in vitro* (3). However, the relatively high anticipated effectiveness of 5-fluoro-2′-deoxyuridine as compared to 5-fluorouracil has not been borne out in clinical use. It was suggested (4) that the lower activity observed was due to the *in vivo* cleavage of 5-fluoro-2′-deoxyuridine to the pyrimidine base and the phosphorylated sugar moiety. The stabilization of 5-fluoro-2′-deoxyuridine by 2′-deoxyuridine (UDR) in blood (1) led to the speculation that this approach could lead to a marked clinical enhancement of 5-fluoro-2′-deoxyuridine activity. This article reports the effect of combining 5-fluorouracil and 5-fluoro-2′-deoxyuridine with 2′-deoxyuridine in protecting mice against L-1210 leukemia and adenocarcinoma 755.

EXPERIMENTAL

Materials and Instruments—The following were used: 5-fluorouracil[1], 5-fluoro-2′-deoxyuridine[1], 2′-deoxyuridine[2], deoxycytidine[2] (CDR), and 5-trifluoromethyl-2′-deoxyuridine[3] (F_3TDR). All other substances used were either reagent grade or of the highest purity available.

A spectrophotofluorometer[4], a TLC scanner[5] modified to contain pendrive motor and range offset, and an *x-y* recorder were used.

***In Vitro* Analysis of 5-Fluorouracil and 5-Fluoro-2′-deoxyuridine**—Drugs and additives in known initial concentrations in blood were dialyzed and evaporated by the method of Windheuser *et al.* (5). The dry samples were dissolved in a constant volume of ethanol. The samples were applied to a fluorescent TLC plate, which had previously been activated at 110° and ruled to restrict the lateral motion of the spots to within the range of the scanner optic. The components were resolved by multiple-pass discontinuous development (6). The developer for the process was composed of ethyl acetate–ethanol–10% ammonium hydroxide (200:5:2). The dried plates were scanned in the direction of development for fluorescence quenching at an activation maximum of 280 nm. and a fluorescence maximum of 530 nm., using a spectrophotofluorometer[4] with a thin-film scanner attachment. Quantities of substances present in the blood were computed by appropriate comparison of sample and standard peak areas obtained by planimetry. The method exhibited sufficient sensitivity to detect 10 ng. of 5-fluorouracil and 5-fluoro-2′-deoxyuridine.

***In Vivo* Mouse Studies**—*L-1210 489 Leukemia*—A standardized suspension prepared from 7-day-old tumors from BDF_1 mice was injected intraperitoneally. The volume was adjusted to provide 1×10^6 cells/injection. Twenty-four hours after the transplant, the mice were divided into groups of 10 and each group was injected intraperitoneally for 7 days with one of the drug regimens listed in Table I.

The number of mice per group that died from the leukemia, as confirmed by autopsies, was recorded daily until all animals were dead. An average lifespan, that is, the average number of days that mice in each group survived after tumor transplant, was computed. The T/C value, which is the ratio of the lifespan of the experimental group to that of the control group, was calculated. An increase in lifespan representing the percent increase of the lifespan of each group relative to the control was determined from the T/C (Table I). The increase in lifespan is used as a measure of the effectivness of the drug regimen.

Adenocarcinoma 755—Donor BDF_1 mice bearing 10-day-old tumors were sacrificed, and the tumors were removed with sterile surgical instruments inside a tissue culture hood. Then the tumors

[a] Each increase in lifespan value represents the average for 10 mice.

were placed in ice-cold saline and cut into pieces about 2 mm. in diameter. Two pieces were transplanted bilaterally subcutaneously on the dorsal side of each BDF_1 mouse by means of a trochar.

Twenty-four hours after transplant, the mice were divided into groups of 10. Each group received, by intraperitoneal injections for 7 days, one of the drug regimens listed in Table II. These regimens were the same as those used for the L-1210 experiment, modified where necessary to minimize any observed toxic manifestations.

Twelve days after transplant, the diameter of each tumor was measured in two directions and the mean tumor radius for each group was calculated. The corresponding tumor volume was calculated, assuming a spherical shape. The volumes thus obtained for each experimental group were divided by the corresponding volumes for the control group to obtain the T/C. The percent inhibition of tumor growth was given by Eq. 1:

$$\text{percent inhibition} = 100\left(1 - \frac{T}{C}\right) \qquad \text{(Eq. 1)}$$

5-Trifluoromethyl-2′-deoxyuridine	2.03×10^{-3}	—	—

The percent inhibition is a measure of the effectiveness of the drug regimen.

RESULTS AND DISCUSSION

***In Vitro* Blood Studies**—During efforts to develop analytical procedures for the determination of 5-fluoro-2′-deoxyuridine *in vivo*, using the dialysis method previously reported (5) for 5-fluorouracil, it was found that when 5-fluoro-2′-deoxyuridine was added to whole human blood samples only about 37% was recovered as 5-fluoro-2′-deoxyuridine after 24 hr. Attempts to increase recovery of 5-fluoro-2′-deoxyuridine by enzyme deactivation procedures, such as pH adjustment, protein precipitation, and increased temperature, failed. A survey of the literature indicated that the cleavage was thought to be mediated by nucleoside phosphorylase (7) and that inhibitors such as 5-trifluoromethyl-2′-deoxyuridine might be of some value.

Preliminary data indicated that the addition of 5-trifluoromethyl-2′-deoxyuridine did enhance the recovery of 5-fluoro-2′-deoxyuridine from "spiked" blood (Table III). Although the recovery was not quantitative, it is readily apparent that increased 5-trifluoromethyl-2′-deoxyuridine concentration appeared to reduce 5-fluoro-2′-deoxyuridine cleavage.

Since one would expect the presence of both 5-fluorouracil and 5-fluoro-2′-deoxyuridine in actual clinical samples, experiments were carried out with spiked blood containing 5-fluorouracil, 5-fluoro-2′-deoxyuridine, and 5-trifluoromethyl-2′-deoxyuridine. The results (Table IV) were startling in that 5-fluorouracil recoveries, which previously had been shown to be 95%, were very low and the 5-fluoro-2′-deoxyuridine concentration was increased to more than 208% of that initially added. These findings indicate that 5-trifluoromethyl-2′-deoxyuridine not only inhibits 5-fluoro-2′-deoxyuridine cleavage but is involved in a deoxyribosyl transfer giving rise to the reaction shown in Scheme I. This is, undoubtedly, an oversimplification of a complex enzyme-mediated reaction since a repetition in pH 7.4 buffered saline failed to show any conversion of 5-fluorouracil to 5-fluoro-2′-deoxyuridine in the presence of 5-trifluoromethyl-2′-deoxyuridine.

These findings led to the consideration that the mechanism of action of so-called nucleoside phosphorylase inhibitors actually functioned in part by reversal of the cleavage equilibrium. It was further rationalized that compounds of similar structures such as 2′-deoxyuridine and deoxycytidine should function in an analogous manner in blood. The effect of 5-trifluoromethyl-2′-deoxyuridine, 2′-deoxyuridine, and deoxycytidine on 5-fluoro-2′-deoxyuridine

$$FU + F_3TDR \rightleftharpoons FUDR + F_3T$$

Scheme I

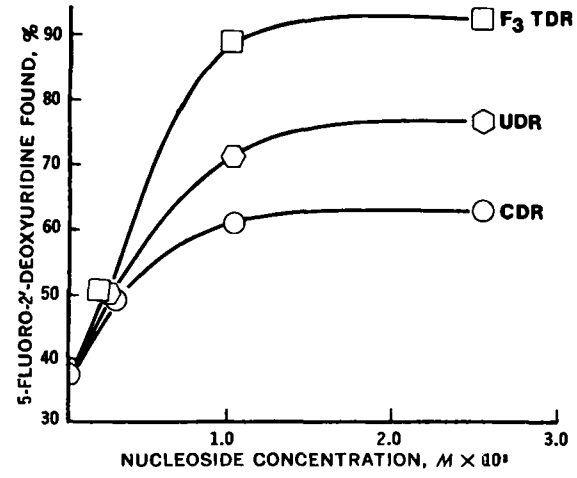

Figure 1—*5-Fluoro-2'-deoxyuridine found in blood in the presence of various concentrations of added nucleosides after 24-hr. dialysis. (Initial 5-fluoro-2'-deoxyuridine concentration was 5.1 × 10⁻⁴ M.)*

cleavage is summarized in Fig. 1. In all three cases, the apparent cleavage of 5-fluoro-2'-deoxyuridine was reduced as nucleoside concentration increased. A similar experiment was conducted to determine the interaction of 5-fluorouracil with 5-trifluoromethyl-2'-deoxyuridine, 2'-deoxyuridine, and deoxycytidine to form 5-fluoro-2'-deoxyuridine. The results (Fig. 2) clearly show that in all cases there was significant conversion of 5-fluorouracil to 5-fluoro-2'-deoxyuridine. The sugar moiety alone, deoxyribose, did not react with 5-fluorouracil.

The importance of these interactions to the clinical use of 5-fluorouracil and 5-fluoro-2'-deoxyuridine is immediately apparent.

***In Vivo* Mouse Studies**—The preliminary *in vitro* studies raised the question that, if the reduced activity of 5-fluoro-2'-deoxyuridine was truly due to *in vivo* cleavage to 5-fluorouracil and deoxyribose, could this reaction be reversed *in vivo* by the coadministration of a suitable nucleoside. Of the three compounds tested *in vitro*, 2'-deoxyuridine appeared to be the most promising candidate for the following reasons:

1. 2'-Deoxyuridine is of lower order toxicity and has no antitumor activity of its own.

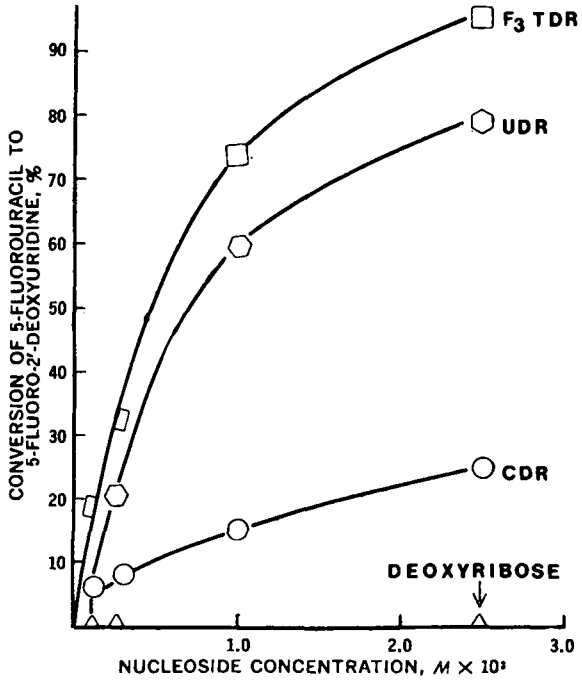

Figure 2—*Percent conversion of 5-fluorouracil to 5-fluoro-2'-deoxyuridine at various concentrations of four deoxyribosyl donors in blood during 24-hr. dialysis. (Initial 5-fluorouracil concentration was 4.1 × 10⁻⁴ M.)*

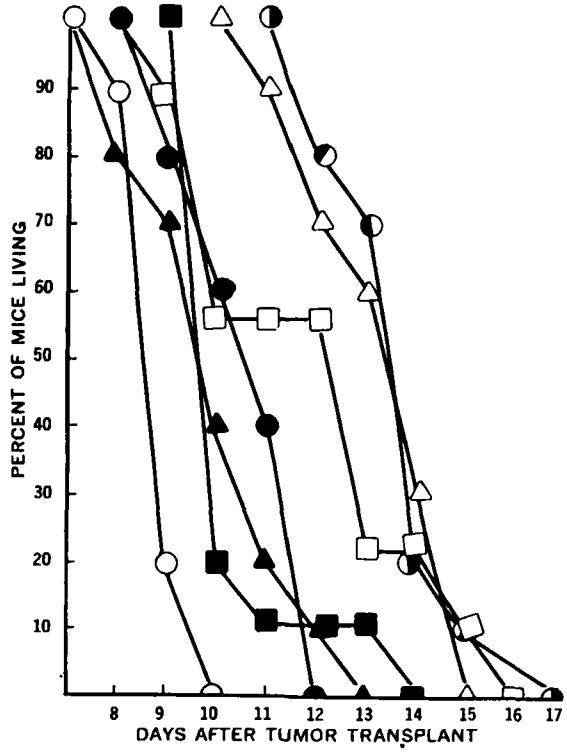

Figure 3—*Survival of mice during chemotherapy of L-1210 leukemia with 5-fluorouracil, 5-fluoro-2'-deoxyuridine, and their combinations with 2'-deoxyuridine. Key: ◑, 5-fluorouracil (10 mg./kg./day) plus 2'-deoxyuridine (200 mg./kg./day); △, 5-fluorouracil (20 mg./kg./day); □, 5-fluoro-2'-deoxyuridine (45 mg./kg./day) plus 2'-deoxyuridine (200 mg./kg./day); ●, 5-fluorouracil (10 mg./kg./day); ▲, 2'-deoxyuridine (200 mg./kg./day); ■, 5-fluoro-2'-deoxyuridine (45 mg./kg./day); and ○, control, 0.9% sodium chloride solution.*

2. Although 5-trifluoromethyl-2'-deoxyuridine appears to be the most active in preventing or reversing cleavage, it is an antitumor agent and toxic.

3. Deoxycytidine is less effective in preventing 5-fluoro-2'-deoxyuridine cleavage.

Based upon the concentration–conversion ratios from Figs. 1 and 2, it appears that 2'-deoxyuridine exhibits its maximum "anti-cleavage" activity at a concentration approximately 5 times that of the 5-fluoro-2'-deoxyuridine and remains invariant thereafter. Based upon an average dose of 40 mg./kg. 5-fluoro-2'-deoxyuridine, a standard dose of 200 mg./kg. 2'-deoxyuridine was used in all combinations.

Chemotherapy of Mouse L-1210 489 Leukemia with Combinations of 5-Fluorouracil or 5-Fluoro-2'-deoxyuridine and 2'-Deoxyuridine—As noted under *Experimental*, 70 mice (divided into seven groups of 10 each) were inoculated with a standardized suspension of L-1210 leukemia cells. The animals were randomized into groups and subjected to various drug regimens alone and in combination with 200 mg./kg. 2'-deoxyuridine. The drugs were administered once a day by intraperitoneal injection, using normal saline as a control. The drug activity was determined grossly by recording a survivial time of each animal (Table I).

Although fluorinated pyrimidines are considered to be less effective against leukemias than against other forms of cancer, such as solid tumors, the data obtained here indicate that their effectiveness can be enhanced by the presence of 2'-deoxyuridine in the drug regimen. For example, the addition of 2'-deoxyuridine to the 12.5-mg. regimen of 5-fluorouracil quadrupled its effectiveness against L-1210 leukemia. The addition of 2'-deoxyuridine to the 10-mg. regimen enhanced its effectiveness over 2.5 times.

Autopsies of mice given these drugs, singly or in combination with 2'-deoxyuridine, indicated that death was partly due to toxicity. However, enhancement of 5-fluorouracil activity at the lower dose levels, such as 10 mg./kg./day, by the addition of 2'-deoxyuridine is significant. Further clarification of the optimum dosage level is necessary.

An alternative way of presenting the survival data is shown in Fig. 3. The percentage of animals alive in each group was computed for each day of the experiment, and this information was graphed. The data indicate the superiority of the drug combinations to the single drugs.

Chemotherapy of Mouse Adenocarcinoma 755 with Combinations of 5-Fluorouracil or 5-Fluoro-2′-deoxyuridine and 2′-Deoxyuridine—Experiments dealing with solid tumors were carried out using adenocarcinoma 755. The tumor was grown in BDF_1 mice and transplanted to 70 normal mice. After allowing 24 hr. for the tumors to acclimate to the host, drug therapy was started using drugs alone or in combination with 200 mg./kg. 2′-deoxyuridine. Therapy was continued for 7 days using daily intraperitoneal injections. Twelve days after the tumor transplants, the average tumor volumes were determined for each group. The results given in Table II compare the tumor volumes of the treated groups to those of saline controls.

The reduction in tumor volumes of the mice treated with 10 mg./kg. 5-fluorouracil and 200 mg./kg. 2′-deoxyuridine and 40 mg./kg. 5-fluoro-2′-deoxyuridine and 200 mg./kg. 2′-deoxyuridine as compared to each drug alone or to the control is dramatic. Although there is an apparent tumor inhibition due to 2′-deoxyuridine alone, the apparent diminutions are not significant. Based on the data, it can be shown that the drug–2′-deoxyuridine combinations are synergistic and not simply additive.

The loss in weight of the mice appears to correlate with the percent tumor inhibition. This may be indicative of increased toxicity because of the higher effective titer of 5-fluoro-2′-deoxyuridine in the body due to the presence of the deoxyribosyl donor. There are some indications that the loss in weight was partly associated with the mouse colony used. Further toxicity studies are being carried out and will be reported later.

These *in vivo* data tend to support the *in vitro* findings that 5-fluorouracil is converted to 5-fluoro-2′-deoxyuridine by deoxyribosyl transfer in the presence of an excess donor compound such as 2′-deoxyuridine, and the activity therefore is enhanced. Also the apparent stabilization of 5-fluoro-2′-deoxyuridine has a dramatic effect on antitumor activity. In light of the present results, the observation by Birnie *et al.* (4) of great toxicity in the use of uridine with 5-fluoro-2′-deoxyuridine may be explained in terms of the exchange reaction where one product is the very toxic 5-fluorouridine.

SUMMARY AND CONCLUSIONS

In vitro experiments in human blood showed that deoxyribonucleosides such as 5-trifluoromethyl-2′-deoxyuridine, 2′-deoxyuridine, and deoxycytidine can react with 5-fluorouracil to form 5-fluoro-2′-deoxyuridine. A prediction that deoxyribosyl transfer reaction can enhance the antitumor activity of 5-fluorouracil and 5-fluoro-2′-deoxyuridine was tested *in vivo* in mice. When survival time and decreased tumor growth are used as measures of effectiveness, results from mouse leukemia L-1210 and adenocarcinoma 755 indicate that 5-fluorouracil or 5-fluoro-2′-deoxyuridine coadministered with excess 2′-deoxyuridine has higher antitumor activity than either of the pure drugs alone.

The data are consistent with the prediction of enhanced antitumor activity due to the deoxyribosyl transfer reaction, although other contributory mechanisms are possible.

Deoxyribosyl transfer reactions may provide a rationale for efficacy of some drug combinations used clinically.

Further work to determine toxicity and efficacy of the combinations is underway.

Liquid Crystalline Phases in Aerosol Formation II: Influence of Liquid Crystalline Phases on Foam Stability

G. JEDERSTRÖM*, L. RYDHAG, and S. FRIBERG▲

Abstract □ Aerosol foam stability was determined by visual observation of time-dependent change in foams of different propellant compositions. Compositions that contained both a liquid crystalline phase and a liquid phase gave rise to foams with pronounced stability compared with those where only a liquid phase was present.

Keyphrases □ Aerosol foams—effect of liquid crystalline phases on foam stability □ Foam stability, aerosols—effect of liquid crystalline phases □ Propellant compositions—effect of liquid crystalline phases on foam stability

The stability of thin films is of importance for foam stability and the stability of emulsions against coagulation from the flocculated state. Extensive research has been undertaken in order to understand the reasons for the stability of such films. Generally, the Derjaguin, Landau, Verwey, and Overbeek (DLVO) theory (1, 2) has been applied to the phenomena (3, 4), giving four factors (3): (*a*) the Laplace capillary suction pressure, (*b*) the electrical double-layer repulsion, (*c*) the long-range Van der Waals pressure, and (*d*) "steric hindrance" of close-packed monolayers.

The last factor is not based on theory but is "vaguely described as the resistance from close-packed monolayers to lateral flow" (3).

The DLVO theory is obviously insufficient for an explanation of emulsion stability against coagulation when the continuous phase is nonpolar; the stability of water/oil emulsions shows no dependence on the surface potential (5).

The importance of chemical associations of different emulsifiers was observed early (6, 7), and recently attempts have been made (8) to relate the stability of aerosol foams to the formation of "molecular complexes." This hypothesis was criticized (9); it was demonstrated that molecular complexes formed by the emulsifiers bore no relation to emulsion stability. The importance lies in the presence of liquid crystalline phases (10, 11) in which the emulsifiers, water, and the oil phase are all associated into an ordered structure.

The importance of the association into liquid crystalline phases for foam stability was also demonstrated recently (12). Stable foams actually may be prepared from hydrocarbons when small amounts of water are present, associated into a liquid crystalline phase with the surfactants (13). The importance of liquid crystalline phases for the stability of foams from aqueous solutions (14) and also for the rate of thinning of thin films (15) has been shown independently.

Since the technical and pharmaceutical importance of these facts is obvious, an investigation into the application of these mechanisms to aerosol foam formulations was conducted. The phase equilibria of the propellant compositions were published earlier (16) (Fig. 1).

EXPERIMENTAL

Materials—The water was twice distilled. 1-Aminooctane[1] (C_8NH_2) (purity by GLC >99%), octanoic acid[2] (C_8OOH), and a propellant[3] were used.

Foam Stability—The acid, amine, and water were weighed into glass containers which were sealed and cooled to −20°. The liquid crystalline phase involved in the experiments does not solidify at temperatures above −28°, so no crystallization problems occurred. At that temperature (−20°), the propellant ($C_2F_4Cl_2$) was added and the pressurized packaging, the aerosol, was formed as the temperature slowly rose to 20°. The container[4] was shaken before spraying to obtain as homogeneous conditions as possible between phases

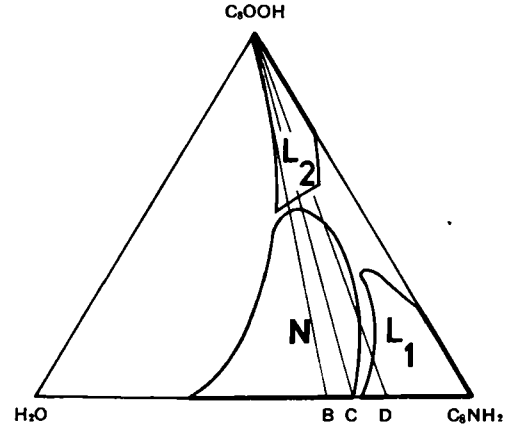

Figure 1—*Phase regions in the water (H_2O)–octylamine (C_8NH_2)–octanoic acid (C_8OOH) system. The lines ending at B, C, and D denote series used in the aerosol experiments. L_1 and L_2 = liquid isotropic phases. N = liquid crystalline, lamellar, "neat" phase.*

in the aerosol. The aerosol foams were extended into conical test tubes to facilitate the determination of drainage rates. The samples were photographed, and the foam height was measured on the photographs as a function of time.

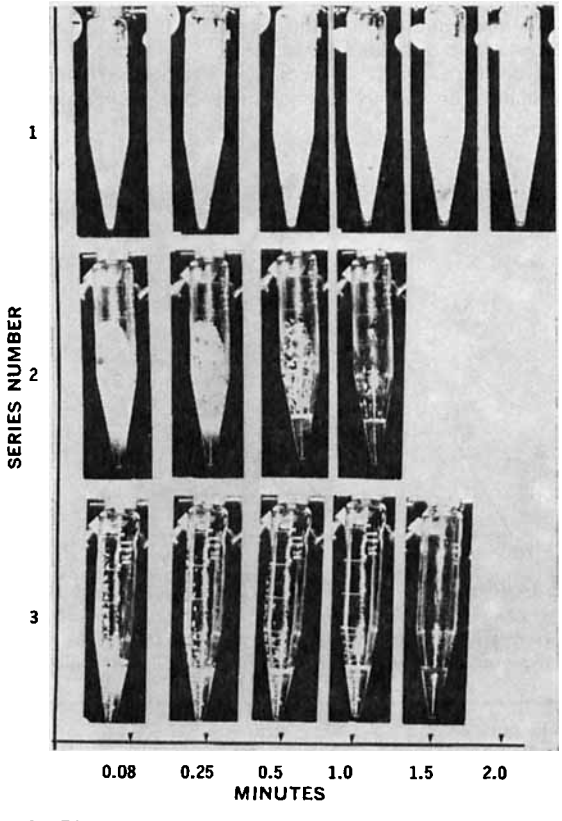

Figure 3—*Photographs showing the foam height as function of time.*

RESULTS

Phase Equilibria—The phase regions when the propellant is added to compositions C_8OOH-B, C_8OOH-C, and C_8OOH-D in Fig. 1 are given in Fig. 2, where the actual compositions prior to foam extrusion are marked on the diagram (Table I). The phase regions and their determining factors were described previously (16).

Foam Stability—Figure 3 demonstrates the general features of the photographs obtained. There usually was a pronounced difference between stable and unstable foams; the height of the former was reduced to less than half the initial value in less than 10 sec. while the corresponding time for the latter was several minutes. The foam in Series 1 showed no change over 2 min. while the others completely collapsed in 10 sec.

Diagrams of foam height *versus* time on a linear scale (Fig. 4) consequently show two groups of curves; one group for stable foams and one group at zero height for unstable foams. A logarithmic time scale was used to compare fast and slow foam height decay in identical diagrams.

Figure 5 shows the foam height for Samples 1–6 marked in Fig. 2*a*. The four samples containing a liquid crystal in the aerosol prior to addition of the propellant gave rise to stable foams. The foams from the two samples in which there were no liquid crystals were unstable, with half-lives of less than 10 sec.

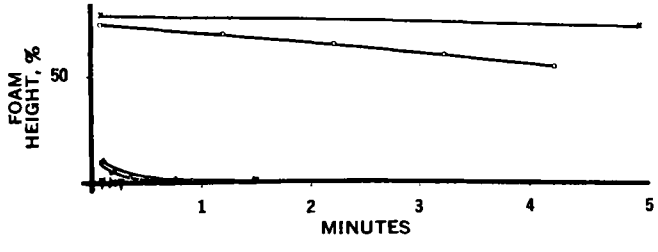

Figure 4—*Foam height* versus *time in a linear scale (compositions according to Fig. 2b). Key (Series): △, 1; ○, 2; ×, 3; □, 4; ▽, 5; and ☆, 6.*

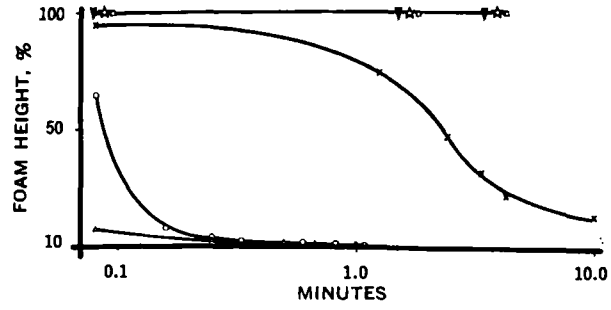

Figure 5—*Foam height* versus *logarithm of time* (*compositions according to Fig. 2a*). *Key (Series):* ×, *1;* ☆, *2;* ▼, *3;* □, *4;* ○, *5; and* △, *6.*

The second series in Fig. 2*b* contained six samples. Of the three with liquid crystals present in the aerosol composition (16) (exclusive of propellant), the one without acid gave rise to unstable foams and the other two to stable foams (Fig. 6). All samples containing no liquid crystals produced unstable foams. The samples in Series D showed the same general pattern; the foams from the two samples containing a liquid crystalline phase, prior to addition of propellant, were more stable than any of the other samples (Fig. 7). Sample 3 was not extremely stable, with a half-life of about 20 sec., but the difference from the samples with no liquid crystalline phase was distinct; all of the latter had half-lives of less than 5 sec.

DISCUSSION

The results were analyzed with regard to both the practical subject of reliable compositions for foam aerosol packings and the theory of stability of thin films.

Composition Method—*In all cases, foams from samples originally* containing only liquid phases gave completely unstable foams. The samples that contained a liquid crystalline phase prior to addition of the propellant gave rise to extremely stable foams with two exceptions. These two samples both had original compositions close to the phase limit and, furthermore, no liquid crystalline phase could be found in the collapsed foam. This probably was due to the fact that the phase diagrams in Figs. 1 and 2 were obtained under equilibrium, while the system was not in equilibrium when foamed. Original compositions close to the phase limit could well be expected to change their composition to outside the phase region during the foaming process.

It is also necessary that parts of the propellant should be incorporated into the liquid crystalline phase. Such a condition automatically implies stability only for compositions a few percent inside the liquid propellant region.

In themselves, these results indicated a simple method for the reliable evaluation of foam stabilizers for aerosol foams. Essentially, the composition prior to addition of propellant should contain a liquid crystalline phase and this phase should be able to ininclude some of the propellant. This method will help avoid problems associated with impurities in the emulsifier which are encountered in practice. Variations in impurity level may well change the limits of the liquid crystal region, causing an unstable foam. This problem can be avoided by using initial compositions that are *centrally* positioned in the liquid crystalline region, where compositions would be expected to show optimal resistance to changes in the properties of the emulsifiers due to variations in composition.

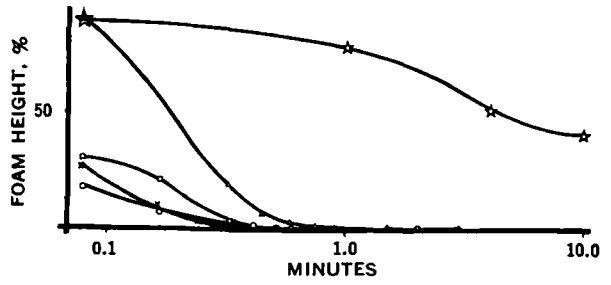

Figure 7—*Foam height* versus *logarithm of time* (*compositions according to Fig. 2c*). *Key (Series):* ○, *1;* □, *2;* △, *3;* ☆, *4; and* ×, *5.*

Stability of Thin Films—A thin film is never in the state of lowest free energy. The reason why it is stable is the presence of one or several minima in the potential energy *versus* thickness function. These energy minima may sometimes be extremely shallow. The presence of an energy minimum implies a small rise of the free energy in the system for small changes in its dimensions.

The final bursting of a thin film in equilibrium takes place due to small disturbances of it. In case these small changes in dimensions are not sufficiently self-damping, bursting takes place. An increase in energy when the film is disturbed may be related to the surface free energy, γ, and to the potential energy, V, which depends on the thickness of the film. According to Vrij (17), the change in free energy:

$$\Delta G = \iint \left\{ {}^1/_2\gamma \sum_{ij=1}^{2} \left(\frac{\partial z_i}{\partial x_j}\right)^2 + {}^1/_2 d^2 V/dh^2 \sum_{i=1}^{2} z_i^2 \right\} \prod_{j=1}^{2} dx \qquad \text{(Eq. 1)}$$

where z denotes vertical changes in the upper ($i = 1$) or lower ($i = 2$) plane of the horizontal film. The indexes j indicate the two Cartesian horizontal coordinates in these planes.

In hydrocarbons or even polar organic solvents, the surface energy is low and has a minor importance; the first term in Eq. 1 is of little importance. This is one reason why foams from hydrocarbons have not been taken into account (3) when the stability of thin films was treated. The present results, which show the importance of the presence of a liquid crystalline phase, may help explain the stability of thin films in hydrocarbons by focusing attention on the connection between the characteristic structure of liquid crystals and the second term in Eq. 1.

The lyotropic liquid crystalline phases are mainly lamellar or form a hexagonal array of cylinders. The reason why foams from hydrocarbons are stable when two-phase systems, solution–liquid crystalline phase, are formed is probably to be found in the fact that the structure of the thin film consists of a central part of liquid crystalline structure surrounded by layers of a nonpolar liquid. In such a structure, the surface energy of the system has no importance whatsoever for the stability. The hydrocarbon surface of the film has low surface energy which does not change with the geometric dimensions.

Changing the geometrical dimensions of the film will, on the other hand, require considerable energy additions due to the fact that the liquid crystalline phase spontaneously forms ordered structures. If z_1 and z_2 have the same size in Eq. 1, the alteration in the geometry is bending of the film. The change is resisted by viscous forces only. These are of a different magnitude from those found in a solution, but intuitively the influence of changes of this kind is of less importance than those encountered when z_1 and z_2 have different signs. That implies a thinning of the film, which means that the layers or cylinders constituting the liquid crystal must be moved on top of each other. Such a mechanism includes either a transport of amphophilic molecules through the lipid layer part of the liquid crystalline phase or a simultaneous motion of a high number of molecules. Both of these mechanisms require a high free energy and have small probability in a liquid crystalline phase compared to conditions in a liquid phase.

The investigations will be continued on systems of mixed emulsifiers.

Aggregations of Certain Nucleosides in Aqueous Solutions from Osmometric Measurements: Theory

HANNA N. BORAZAN

Abstract □ Two models, the mononuclear and multinuclear, are proposed for self-aggregating systems such as dilute aqueous solutions of 2′-deoxyadenosine, 2′-deoxyguanosine, uridine, cytidine, and thymidine, which are characterized by two linear slopes in plots of their osmolal *versus* total molal concentrations. Their first slopes indicate a monomeric behavior and a formation of critical micelle-like concentrations. By correlating the results of both models on a semiempirical basis, theoretical curves were generated that agree with previous experimental work. Equilibrium constants, osmotic coefficients, and concentrations of various associated forms can be calculated.

Keyphrases □ Nucleosides in aqueous solution, self-aggregation—osmometric measurements, theoretical curves compared to experimental data, calculation of equilibrium constants, osmotic coefficients, and species concentrations □ Osmometric measurements—self-aggregation of nucleosides in aqueous solution, theoretical curves compared to experimental data □ Aggregation of nucleosides in aqueous solution—osmometric measurements, theoretical curves compared to experimental data

The thermoelectric osmometer developed by Goyan and Johnson (1, 2) has been improved and used to study dilute aqueous solutions of caffeine and other substances of pharmaceutical interest (3). The measured osmotic property plotted against molal concentration resulted in two linear slopes for many substances. The point of break was sharp whenever it occurred and was regarded as evidence of a critical micelle concentration (CMC). The molal concentration where this break occurs is a critical concentration in that it is a property of a substance. It evidently has been overlooked by other workers, probably because of the difficulty of exploring the concentration range between 0.01 and 0.10 *M*. Later, Borazan (4) and Borazan and Goyan (5) extended past work (6, 7) into this region of concentration and included other compounds. The characteristic break between linear slopes was found for very dilute solutions of 2′-deoxyadenosine, 2′-deoxyguanosine, uridine, cytidine, and thymidine.

This paper presents some theoretical considerations in an effort to explain experimental results reported previously (3–5). An attempt is also made to recalculate equilibrium constants that might hold over a wider range of concentration than those given previously (8, 9).

THEORY

An attempt is made to explain the two intersecting linear slopes determined experimentally, when plotting a colligative property *versus* molal concentration (3–5), by using a simple mathematical model:

$$nA = A_n \qquad \text{(Eq. 1}a\text{)}$$

$$K = (A_n)/(A)^n \qquad \text{(Eq. 1}b\text{)}$$

The osmolal, o, and total molal, m, concentrations are given by the equations:

$$o = (A_n) + (A) \qquad \text{(Eq. 2)}$$

$$m = n(A_n) + (A) \qquad \text{(Eq. 3)}$$

In Eqs. 1–3, A represents the monomer and A_n represents the associated form. Parentheses indicate molal concentration. By

Aggregations of Certain Nucleosides in Aqueous Solutions from Osmometric Measurements: Theory

HANNA N. BORAZAN

Abstract □ Two models, the mononuclear and multinuclear, are proposed for self-aggregating systems such as dilute aqueous solutions of 2′-deoxyadenosine, 2′-deoxyguanosine, uridine, cytidine, and thymidine, which are characterized by two linear slopes in plots of their osmolal *versus* total molal concentrations. Their first slopes indicate a monomeric behavior and a formation of critical micelle-like concentrations. By correlating the results of both models on a semiempirical basis, theoretical curves were generated that agree with previous experimental work. Equilibrium constants, osmotic coefficients, and concentrations of various associated forms can be calculated.

Keyphrases □ Nucleosides in aqueous solution, self-aggregation—osmometric measurements, theoretical curves compared to experimental data, calculation of equilibrium constants, osmotic coefficients, and species concentrations □ Osmometric measurements—self-aggregation of nucleosides in aqueous solution, theoretical curves compared to experimental data □ Aggregation of nucleosides in aqueous solution—osmometric measurements, theoretical curves compared to experimental data

The thermoelectric osmometer developed by Goyan and Johnson (1, 2) has been improved and used to study dilute aqueous solutions of caffeine and other substances of pharmaceutical interest (3). The measured osmotic property plotted against molal concentration resulted in two linear slopes for many substances. The point of break was sharp whenever it occurred and was regarded as evidence of a critical micelle concentration (CMC). The molal concentration where this break occurs is a critical concentration in that it is a property of a substance. It evidently has been overlooked by other workers, probably because of the difficulty of exploring the concentration range between 0.01 and 0.10 *M*. Later, Borazan (4) and Borazan and Goyan (5) extended past work (6, 7) into this region of concentration and included other compounds. The characteristic break between linear slopes was found for very dilute solutions of 2′-deoxyadenosine, 2′-deoxyguanosine, uridine, cytidine, and thymidine.

This paper presents some theoretical considerations in an effort to explain experimental results reported previously (3–5). An attempt is also made to recalculate equilibrium constants that might hold over a wider range of concentration than those given previously (8, 9).

THEORY

An attempt is made to explain the two intersecting linear slopes determined experimentally, when plotting a colligative property *versus* molal concentration (3–5), by using a simple mathematical model:

$$nA = A_n \qquad \text{(Eq. 1}a\text{)}$$

$$K = (A_n)/(A)^n \qquad \text{(Eq. 1}b\text{)}$$

The osmolal, o, and total molal, m, concentrations are given by the equations:

$$o = (A_n) + (A) \qquad \text{(Eq. 2)}$$

$$m = n(A_n) + (A) \qquad \text{(Eq. 3)}$$

In Eqs. 1–3, A represents the monomer and A_n represents the associated form. Parentheses indicate molal concentration. By

assigning values at intervals of 0.01 M to (A), it is easy to calculate corresponding values of (A_n) for selected values of K. When the values for o are plotted against m and compared directly with the experimental curves (3–5), the resulting curves are similar to those obtained from experimental data. In all of the graphs, the first parts were very similar to ideal solutions showing no association. This is due to the fact that the concentration of the n-mer is so low that it cannot be detected. When K is taken to be 1 or 10 and n to be 2 or 3, a few of the curves calculated in this way approximate a few of the intersecting straight lines. However, points near the intersection deviate from either line by more than can be accounted for on the basis of experimental error, except when the two slopes differ very little. To simulate the realistic slope change and an intersection in the concentration range studied with n equal to 4, it is necessary to assign large values for K. As reported previously (6, 7, 10–12), in systems of this type K is lower than 20 in most cases, and the free energy is on the order of magnitude of thermal kinetic energy. Therefore, a K value in the neighborhood of 10 with n equal to 3 seems to be a reasonable limit. With these values, a deviation of points near the intersection from straight lines is about 3 ohms. This deviation is outside the limit of experimental error by a factor of nearly 10. These facts clearly indicate that this simple mathematical model cannot be used.

A more sophisticated approach along the same lines was undertaken with the aid of a computer[1]. Based upon the assumption that two monomers react to form a dimer and that the dimer reacts with another monomer to form a trimer, *etc.*, four different association constants were postulated. The values 2, 4, 6, and 8 were assigned to K_1, K_2, K_3, and K_4 in rotation. The resulting 256 curves were calculated and plotted by the computer.

When the experimental slopes (5) are converted to the osmolal system by dividing by 924 from the sucrose standardization, all initial slopes for single pure substances in water show an experimental value of unity within the limits of experimental error. All computer-generated curves based on four K values, where $K_1 = 2$, show an initial slope of 0.98 based on the first plotted point and 0.96 or 0.95 based on the second point, regardless of the values assigned to K_2, K_3, and K_4. Higher values of K_1 produce lower slopes, indicating the need to try smaller values for the initial association constants.

A study of the lines generated with four association constants showed that K_4 played a minor role. It can be concluded from this study that association constants are very small and that certain combinations of K values can produce almost two linear intersecting slopes in the range of concentrations studied, with the first slopes having values approximately equal to one, thus resembling reported experimental curves (5).

In an effort to calculate equilibrium constants for the successive aggregation processes from the experimental curves reported, two models are proposed here.

Mononuclear Aggregation—A solute molecule, say A', can serve as a nucleus for other molecules of the same solute:

$$A' + A = A'A \qquad \text{(Eq. 4a)}$$

$$A'A + A = A'A_2 \qquad \text{(Eq. 4b)}$$

$$\vdots$$

$$A'A_{j-1} + A = A'A_j \qquad \text{(Eq. 4c)}$$

$$\vdots$$

$$A'A_{\sigma-1} + A = A'A_\sigma \qquad \text{(Eq. 4d)}$$

where σ is the maximum number of multiple equilibria. In the model presented here, it is assumed that no interactions among various associated forms take place and that the binding sites on the nucleus molecule are dependent; *i.e.*, the binding of a monomer to a nucleus can influence the binding of another monomer to the same nucleus. Therefore, the following equations can be written:

$$K_1 = (A'A)/(A')(A) \qquad (A'A) = K_1(A')(A) \qquad \text{(Eq. 5)}$$

$$K_2 = (A'A_2)/(A'A)(A) \qquad (A'A_2) = K_2(A'A)(A) \qquad \text{(Eq. 6)}$$

$$K_j = (A'A_j)/(A'A_{j-1})(A) \qquad (A'A_j) = K_j(A'A_{j-1})(A) \qquad \text{(Eq. 7)}$$

$$K_\sigma = (A'A_\sigma)/(A'A_{\sigma-1})(A) \qquad (A'A_\sigma) = K_\sigma(A'A_{\sigma-1})(A) \qquad \text{(Eq. 8)}$$

Combining Eqs. 5 and 6:

$$(A'A_2) = K_1K_2(A')(A)^2 \qquad \text{(Eq. 9)}$$

If one carries the same technique of substitutions for the consecutive processes, the following equation can be derived:

$$(A'A_j) = K_1K_2 \ldots K_j(A')(A)^j \qquad \text{(Eq. 10)}$$

Under the assumption that no self-association takes place below the critical concentrations, (C_0), based upon experimental results, and if (C_0) and $(A_0 - C_0)$ are considered as the total concentrations of the reactant species, A' and A, respectively, where (A_0) is the total concentration of the solute, then the following can be defined:

$$(C_0) = (A') + (A'A) + (A'A_2) + \ldots + (A'A_j) + \ldots + (A'A_\sigma) \qquad \text{(Eq. 11)}$$

$$= (A') + \sum_{j=1}^{\sigma} (A'A_j)$$

By substitution from Eq. 10 of $(A'A_j)$ in Eq. 11:

$$(C_0) = (A')\left[1 + \sum_{j=1}^{\sigma}\left(\prod_{j=1}^{j} K_j\right)(A)^j\right] \qquad \text{(Eq. 12)}$$

where:

$$\prod_{j=1}^{j} K_j = K_1K_2 \ldots K_j$$

$$(A_0 - C_0) = (A) + (A'A) + \ldots + j(A'A_j) + \ldots + \sigma(A'A_\sigma) \qquad \text{(Eq. 13)}$$

$$= (A)\left[1 + (A')\sum_{j=1}^{\sigma} j\left(\prod_{j=1}^{j} K_j\right)(A)^{j-1}\right]$$

and:

$$o = (A') + (A) + (A'A) + \ldots + (A'A_j) + \ldots + (A'A_\sigma) \qquad \text{(Eq. 14)}$$

$$= (A') + (A) + \sum_{j=1}^{\sigma} (A'A_j)$$

where o represents osmolal concentration.

The second linear slope, S_2 (5), can be expressed:

$$S_2 = [o - (C_0)]/(A_0 - C_0) = \frac{\text{second experimental slope}}{\text{sucrose slope}} \qquad \text{(Eq. 15)}$$

By substitution from Eqs. 14, 11, and 13 of o, C_0, and $(A_0 - C_0)$, respectively, in Eq. 15:

$$S_2 = \left[1 + (A')\sum_{j=1}^{\sigma} j\left(\prod_{j=1}^{j} K_j\right)(A)^{j-1}\right]^{-1} \qquad \text{(Eq. 16)}$$

set:

$$\left[1 + \sum_{j=1}^{\sigma}\left(\prod_{j=1}^{j} K_j\right)(A)^j\right] = \phi(K_j, A) \qquad \text{(Eq. 17)}$$

and:

$$\sum_{j=1}^{\sigma} j\left(\prod_{j=1}^{j} K_j\right)(A)^{j-1} = \frac{\partial\phi}{\partial(A)} \qquad \text{(Eq. 18)}$$

Substituting for the summation of terms, Eq. 18, by the partial derivative into Eq. 16:

$$\frac{\partial\phi}{\partial(A)} = \frac{1}{(A')}\left(\frac{1 - S_2}{S_2}\right) \qquad \text{(Eq. 19)}$$

Combining Eqs. 17 and 12 and substituting into Eq. 19:

$$\left(\frac{(C_0)S_2}{1 - S_2}\right)\frac{\partial\phi}{\partial(A)} = \phi \qquad \text{(Eq. 20)}$$

[1] The approach was suggested by Professor Leo Brewer, University of California, Berkeley. An IBM 360 computer was programmed by Mr. Phillip Johnson, University of California San Francisco Information Service, who contributed much of his own time and thought to this portion of the work.

Table I—Equilibrium Constants of Self-Association of the Nucleosides Together with Their Progression Constant

Nucleoside	Progression[a] Constant, α_s, molal	β_1, molal^{-1}	β_2, molal^{-1}	β_3, molal^{-1}
2′-Deoxyadenosine	0.0272	4.07	12.20	36.60
2′-Deoxyguanosine	0.0193	5.77	17.30	51.80
Uridine	0.330	0.33	1.00	3.00
Cytidine	0.338	0.40	1.20	3.60
Thymidine	0.238	0.55	1.65	4.95

[a] Progression constant $= \dfrac{\text{second slope} \times \text{critical concentration}}{\text{sucrose slope} - \text{second slope}}$, according to Eq. 21. The data were taken from *Reference 5*. The slope of standard solution of sucrose is 923.7 ohms molal^{-1}.

The critical concentration, (C_0), is supposed to be a constant quantity for a particular molecule; therefore:

$$\frac{(C_0)S_2}{1 - S_2} = \text{constant} = \alpha_s \qquad \text{(Eq. 21)}$$

Equation 20 has the following solution:

$$\phi = e^{(A)/\alpha_s} \qquad \text{(Eq. 22)}$$

The function ϕ can be expressed as a power series in $(A)/\alpha_s$, and according to Eq. 17:

$$\phi = 1 + K_1(A) + K_1K_2(A)^2 + \ldots + K_1 \ldots K_j(A)^j + \ldots + K_1 \ldots K_\sigma(A)^\sigma$$
$$= 1 + \frac{(A)}{\alpha_s} + \frac{1}{2!}\left(\frac{(A)}{\alpha_s}\right)^2 + \ldots + \frac{1}{j!}\left(\frac{(A)}{\alpha_s}\right)^j + \ldots + \frac{1}{\sigma!}\left(\frac{(A)}{\alpha_s}\right)^\sigma + \ldots + \frac{1}{\infty!}\left(\frac{(A)}{\alpha_s}\right)^\infty \qquad \text{(Eq. 23)}$$

If the number of multiple equilibria, σ, is large enough, one can deduce with reasonable approximation, for low concentration of A, the following by comparing coefficients of (A) from Eq. 23:

$$K_1 = 1/\alpha_s \qquad K_j = 1/j\,\alpha_s \qquad \text{(Eq. 24a)}$$

$$K_2 = 1/2\,\alpha_s \qquad K_\sigma = 1/\sigma\,\alpha_s \qquad \text{(Eq. 24b)}$$

Multinuclear Aggregation—According to this model, the binding of a monomer to $(j - 1)$-mer to produce j-mer induces an identical, independent binding probability for another monomer; any of the equivalent subunits in the j-mer can serve as a binding site for another monomer and so on. Therefore, one would expect that the overall equilibrium constants are increasing and related to one intrinsic binding constant, k.

Based upon configurational probabilities for these completely independent and identical sites, the following can be derived (13):

$$A + A = A_2 \qquad k/\sigma = \beta_1 \qquad \text{(Eq. 25a)}$$

$$A_2 + A = A_3 \qquad \left(\frac{2}{\sigma - 2 + 1}\right) k = \beta_2 \qquad \text{(Eq. 25b)}$$

$$\vdots$$

$$A_j + A = A_{j+1} \qquad \left(\frac{j}{\sigma - j + 1}\right) k = \beta_j \qquad \text{(Eq. 25c)}$$

$$\vdots$$

$$A_\sigma + A = A_{\sigma+1} \qquad \sigma k = \beta_\sigma \qquad \text{(Eq. 25d)}$$

Since no simple way is available for one to derive the precise values of k and σ, the progression constant, α_s, described by Eq. 21 was sought intuitively as a possible common constant between the overall equilibrium constants in the two models. It is, therefore, assumed empirically that the reciprocal of the progression constant which determines the first and highest equilibrium constant in the first model could also determine the highest but the last equilibrium constant in the second model. It is also assumed that the last equilibrium constant for the mononuclear aggregation model, K_σ (when all binding sites are occupied except one), may be the real intrinsic binding constant, k, in the second model. Accordingly, the following are set:

$$K_1 = \beta_\sigma = \sigma K_\sigma = \frac{1}{\alpha_s} = \frac{1 - S_2}{(C_0)S_2} = \sigma k \qquad \text{(Eq. 26)}$$

$$k = \frac{1 - S_2}{\sigma(C_0)S_2} \qquad \text{(Eq. 27)}$$

and β_j, according to Eqs. 25 and 27, is:

$$\beta_j = \frac{j(1 - S_2)}{(\sigma - j + 1)\,[\sigma(C_0)S_2]} \qquad \text{(Eq. 28)}$$

Osmolal and total molal concentrations can be defined and related to measurable quantities:

$$o = (A) + (A_2) + (A_3) + \ldots + (A_{j+1}) + \ldots + (A_{\sigma+1}) \qquad \text{(Eq. 29)}$$

Concentrations of various species can be expressed in terms of their corresponding equilibrium constants and free monomer concentration:

$$(A_2) = \beta_1(A)^2 \qquad \text{(Eq. 30a)}$$

$$(A_3) = \beta_1\beta_2(A)^3 \qquad \text{(Eq. 30b)}$$

$$(A_{j+1}) = \beta_1\beta_2 \ldots \beta_j(A)^{j+1} \qquad \text{(Eq. 30c)}$$

Thus:

$$o = (A) + \sum_{j=1}^{\sigma}\left(\prod_{j=1}^{j}\beta_j\right)(A)^{j+1} \qquad \text{(Eq. 31)}$$

Substituting for the product of β_j, according to Eq. 28:

$$o = (A) + \sum_{j=1}^{\sigma}\frac{j!(1 - S_2)^j}{\left[\prod_{j=1}^{j}(\sigma - j + 1)\right][\sigma(C_0)S_2]^j}(A)^{j+1} \qquad \text{(Eq. 32)}$$

By carrying similar substitutions, the total molal concentration will be:

$$m = (A) + \sum_{j=1}^{\sigma}(j + 1)\frac{j!(1 - S_2)^j}{\left[\prod_{j=1}^{j}(\sigma - j + 1)\right][\sigma(C_0)S_2]^j}(A)^{j+1} \qquad \text{(Eq. 33)}$$

The osmotic coefficient can be calculated from the definitions of o and m by the following relationship:

$$\phi = o/m \qquad \text{(Eq. 34)}$$

RESULTS AND DISCUSSION

Equations 24*a* and 24*b* indicate that the highest equilibrium constant is the first and that the experimental curves can only be generated by previous knowledge of their critical concentrations. However, a given set of K values calculated from the relationships given (in Eqs. 24*a* and 24*b*), three or four K's, failed to reproduce curves obtained experimentally when plotting their calculated osmolal *versus* total molal concentration according to Eqs. 2 and 3.

Borazan (4) hypothesized that the possible maximum number of molecules in each aggregate of the nucleosides studied is four to five (all molecules in each aggreagate are not necessarily bonded at the same time, according to the theory). Thus, one would expect the number of multiple equilibria, σ, to be between three and four.

To test the second model and the validity of the assumptions made in the derivations when osmotic coefficient, ϕ, was calculated for $\sigma = 3$, several values were assigned for the monomer concentrations and Eqs. 32–34 were applied, with data taken from Borazan and Goyan (5), and compared to experimental values; reasonable agreement was found over a wide molal range for most of the nucleosides. The data are summarized in Table II. In this way, theoretical curves can be calculated from the definitions of osmolal and molal concentrations, Eqs. 32 and 33, respectively. The overall equilibrium constants calculated according to Eqs. 25 and 27 and from data taken from Borazan and Goyan (5) (Table I) can be used to calculate concentrations of various associated forms.

It was found by trial and error that slightly lower values of S_2

for cytidine and thymidine should be used to generate curves that almost duplicate experimental curves within the limit of accuracy. Accordingly, values of 0.87 and 0.782 were used instead of 0.891 and 0.807 for cytidine and thymidine, respectively.

It was also observed that the shapes of the calculated curves were similar to those obtained experimentally and that all points fell on almost two linear slopes. The deviation of the data from the first ideal slopes is considered just about the limit of experimental error.

Ts'o and Chan (9) also based their calculations of K on multiple-equilibria processes (of the type of Eqs. 25*a*–25*d*) and on the assumption that all K's are equal. Assuming that the multiple equilibria go to infinity, they derived the following equation, which is based upon the work of Schellman (8):

$$K = \frac{1 - \phi}{M\phi^2} \qquad \text{(Eq. 35)}$$

where M = total molal concentration, and ϕ = osmotic coefficient.

Attempts to use Eq. 35 with experimental data (5) at 0.1 molal gave values for K of 0.705, 0.705, and 0.973 for uridine, cytidine, and thymidine, respectively. Ts'o *et al.* (6) calculated 0.61 and 0.87 for uridine and cytidine, respectively, while Solie (10) calculated 0.91 for thymidine at the same concentration and showed that the values held fairly well at higher concentrations. However, the low concentration values of Ts'o *et al.* (6) were somewhat influenced by curve smoothing and fitted to preselected polynomial. Attempts to calculate K values at some of the low accurately measured values (5) show that Eq. 35 fails to yield nearly constant values, even well above the critical concentration. Broom *et al.* (7) agreed that in some cases Eq. 35 fails even at higher concentrations using data taken from smoothed curves. It should be emphasized that Eq. 35 worked well at concentrations higher than 0.1 molal, while it failed to produce constant K values at concentrations lower than 0.1 molal.

Therefore, the results presented in this paper seem to be more meaningful and realistic, in that several consecutive equilibrium constants with increasing order and limited associated forms are to be considered, and theoretical values that agree with experimental data (Table II) can be generated over a far greater range than with the model previously reported (8, 9).

It should also be emphasized that generating theoretical data that agree with experimental data from a model does not mean that the model is absolutely correct. The actual situation could be different from that hypothesized, knowing that the results presented were subject to various approximations and empirical assumptions, for example, ignoring some interactions, mathematical approximations, *etc.*

CONCLUSION

Theoretical curves have been generated to reproduce experimental results within the limit of accuracy. The model in question assumes the generation of equivalent and independent binding sites. The overall equilibrium constants are increasing, and limited associated forms have to be considered, in the neighborhood of four for the nucleosides studied.

The theoretical osmotic coefficient values (Table II) agree fairly well with those reported in the literature.

Synthesis of Substituted Cinnamides: Relationship between Anticonvulsant and Monoamine Oxidase Inhibitory Properties

SURENDRA S. PARMAR*▲, P. C. JOSHI†, BASHEER ALI†, and STANLEY J. BRUMLEVE*

Abstract □ Several esters and hydrazides of substituted cinnamides were synthesized and characterized. Evaluation of their anticonvulsant activity indicated appreciable activity of hydrazides where no correlation could be observed between anticonvulsant activity possessed by these hydrazides and their ability to inhibit monoamine oxidase.

Keyphrases □ Cinnamides of substituted amino acid esters and their hydrazides—synthesis, relationship between anticonvulsant and monoamine oxidase inhibitory properties □ Monoamine oxidase inhibitors, cinnamides of amino acid esters and their hydrazides—synthesis, anticonvulsant activity □ Anticonvulsant activity—cinnamides of substituted amino acid esters and their hydrazides, relationship to monoamine oxidase inhibitory properties □ Structure-activity relationships—cinnamides, relationship between anticonvulsant and monoamine oxidase inhibitory properties

Presence of a styryl group, responsible for high π-electron density, has been postulated to account for monoamine oxidase [EC 1.4.3.4 monoamine-O_2 oxido reductase (deaminating)] inhibitory property of styrylquinoliniums (1). The ability of monoamine oxidase inhibitors to possess anticonvulsant activity (2, 3) led to the synthesis of α-benzoylamino-*N*-[*p*-(4-aryl semicarbazide/thiosemicarbazide) - benzoyl] - *p* - substituted cinnamides possessing both an ethylenic moiety and the hydrazide group in an attempt to correlate their anticonvulsant activity with *in vitro* monoamine oxidase inhibitory effectiveness (4). In the present study, substituted cinnamides of amino acid esters and their corresponding hydrazides were synthesized as possible anticonvulsants to investigate correlation between anticonvulsant activity possessed by these hydrazides with their ability to inhibit monoamine oxidase.

CHEMISTRY

The various cinnamides of substituted amino acid esters and their corresponding hydrazides (Tables I and II) were synthesized by following the methods outlined in Scheme I.

Substituted oxazolones (*Ia*) were obtained by treatment by hippuric acid with appropriate aromatic aldehydes and acetic anhydride in the presence of anhydrous sodium acetate. Compounds *Ia* were treated with ethyl esters of amino acids (*Ib*) in the presence of 2–3 drops of triethylamine to give esters (I–XII) which were converted into the corresponding hydrazides (XIII–XXIV) by refluxing with 99–100% hydrazine hydrates (1:2 molar ratio) in absolute ethanol for 6–8 hr.

EXPERIMENTAL

Ethyl Esters of Amino Acids (*Ib*)—These were prepared by following the method of Kupryszewski and Sokolowska (5). Thionyl chloride, 0.1 mole, was added at 5° to 50 ml. of an absolute ethanolic solution of the appropriate amino acid (0.1 mole) and the mixture was refluxed for 3 hr. The excess thionyl chloride was removed under reduced pressure. The free ester, which precipitated by passing a slow stream of dry ammonia into a suspension of the ester hydrochloride in chloroform, was filtered, and excess chloroform was removed by distillation under reduced pressure.

2-Phenyl-4-(substituted benzylidene)-oxazole-5-ones (*Ia*)—The various oxazolones were prepared by heating a mixture of an appropriate aromatic aldehyde (0.96 mole), powdered dry hippuric acid (1.07 moles), freshly powdered sodium acetate (0.98 mole), and acetic anhydride (2.9 moles) in a flask on an electric hot plate (6, 7). As soon as the material had liquefied completely, the flask was transferred to a steam bath and heated for 2 hr. The reaction mixture was allowed to stand overnight, and the solid mass which precipitated was filtered with suction and washed first with two 100-ml. portions of ice-cold ethanol and finally with two 100-ml. portions of boiling water. After drying, the various oxazolones were used without further purification.

α-Benzoylamino-*N*-(substituted esters)-substituted Cinnamides (I–XII)—Equimolar quantities (1 mole) of the appropriate 2-phenyl-4-(substituted benzylidene)-oxazole-5-ones and ethyl esters of amino acids were refluxed in absolute ethanol in the presence of 2–3 drops of triethylamine on a steam bath for 6–8 hr. Excess ethanol was distilled, and the cinnamides which separated on cooling were filtered and recrystallized with either ethanol or the mixture of ethanol and water. The cinnamides were characterized by their sharp melting points and elemental analyses (Table I).

α-Benzoylamino-*N*-(substituted hydrazides)-substituted Cinnamides (XIII–XXIV)—A mixture of the appropriate α-benzoylamino-*N*-(substituted esters)-substituted cinnamides (0.1 mole) and 99–100% hydrazine hydrate (0.12 mole) in absolute ethanol was refluxed on a water bath for 6–8 hr. The solid mass which separated on cooling was filtered and recrystallized from suitable solvents (Table II).

Synthesis of Substituted Cinnamides: Relationship between Anticonvulsant and Monoamine Oxidase Inhibitory Properties

SURENDRA S. PARMAR*▲, P. C. JOSHI†, BASHEER ALI†, and STANLEY J. BRUMLEVE*

Abstract □ Several esters and hydrazides of substituted cinnamides were synthesized and characterized. Evaluation of their anticonvulsant activity indicated appreciable activity of hydrazides where no correlation could be observed between anticonvulsant activity possessed by these hydrazides and their ability to inhibit monoamine oxidase.

Keyphrases □ Cinnamides of substituted amino acid esters and their hydrazides—synthesis, relationship between anticonvulsant and monoamine oxidase inhibitory properties □ Monoamine oxidase inhibitors, cinnamides of amino acid esters and their hydrazides—synthesis, anticonvulsant activity □ Anticonvulsant activity—cinnamides of substituted amino acid esters and their hydrazides, relationship to monoamine oxidase inhibitory properties □ Structure-activity relationships—cinnamides, relationship between anticonvulsant and monoamine oxidase inhibitory properties

Presence of a styryl group, responsible for high π-electron density, has been postulated to account for monoamine oxidase [EC 1.4.3.4 monoamine-O_2 oxido reductase (deaminating)] inhibitory property of styrylquinoliniums (1). The ability of monoamine oxidase inhibitors to possess anticonvulsant activity (2, 3) led to the synthesis of α-benzoylamino-*N*-[*p*-(4-aryl semicarbazide/thiosemicarbazide) - benzoyl] - *p* - substituted cinnamides possessing both an ethylenic moiety and the hydrazide group in an attempt to correlate their anticonvulsant activity with *in vitro* monoamine oxidase inhibitory effectiveness (4). In the present study, substituted cinnamides of amino acid esters and their corresponding hydrazides were synthesized as possible anticonvulsants to investigate correlation between anticonvulsant activity possessed by these hydrazides with their ability to inhibit monoamine oxidase.

CHEMISTRY

The various cinnamides of substituted amino acid esters and their corresponding hydrazides (Tables I and II) were synthesized by following the methods outlined in Scheme I.

Substituted oxazolones (*Ia*) were obtained by treatment by hippuric acid with appropriate aromatic aldehydes and acetic anhydride in the presence of anhydrous sodium acetate. Compounds *Ia* were treated with ethyl esters of amino acids (*Ib*) in the presence of 2–3 drops of triethylamine to give esters (I–XII) which were converted into the corresponding hydrazides (XIII–XXIV) by refluxing with 99–100% hydrazine hydrates (1:2 molar ratio) in absolute ethanol for 6–8 hr.

EXPERIMENTAL

Ethyl Esters of Amino Acids (*Ib*)—These were prepared by following the method of Kupryszewski and Sokolowska (5). Thionyl chloride, 0.1 mole, was added at 5° to 50 ml. of an absolute ethanolic solution of the appropriate amino acid (0.1 mole) and the mixture was refluxed for 3 hr. The excess thionyl chloride was removed under reduced pressure. The free ester, which precipitated by passing a slow stream of dry ammonia into a suspension of the ester hydrochloride in chloroform, was filtered, and excess chloroform was removed by distillation under reduced pressure.

2-Phenyl-4-(substituted benzylidene)-oxazole-5-ones (*Ia*)—The various oxazolones were prepared by heating a mixture of an appropriate aromatic aldehyde (0.96 mole), powdered dry hippuric acid (1.07 moles), freshly powdered sodium acetate (0.98 mole), and acetic anhydride (2.9 moles) in a flask on an electric hot plate (6, 7). As soon as the material had liquefied completely, the flask was transferred to a steam bath and heated for 2 hr. The reaction mixture was allowed to stand overnight, and the solid mass which precipitated was filtered with suction and washed first with two 100-ml. portions of ice-cold ethanol and finally with two 100-ml. portions of boiling water. After drying, the various oxazolones were used without further purification.

α-Benzoylamino-*N*-(substituted esters)-substituted Cinnamides (I–XII)—Equimolar quantities (1 mole) of the appropriate 2-phenyl-4-(substituted benzylidene)-oxazole-5-ones and ethyl esters of amino acids were refluxed in absolute ethanol in the presence of 2–3 drops of triethylamine on a steam bath for 6–8 hr. Excess ethanol was distilled, and the cinnamides which separated on cooling were filtered and recrystallized with either ethanol or the mixture of ethanol and water. The cinnamides were characterized by their sharp melting points and elemental analyses (Table I).

α-Benzoylamino-*N*-(substituted hydrazides)-substituted Cinnamides (XIII–XXIV)—A mixture of the appropriate α-benzoylamino-*N*-(substituted esters)-substituted cinnamides (0.1 mole) and 99–100% hydrazine hydrate (0.12 mole) in absolute ethanol was refluxed on a water bath for 6–8 hr. The solid mass which separated on cooling was filtered and recrystallized from suitable solvents (Table II).

[a] All melting points were taken in open capillary tubes and are corrected.

PHARMACOLOGY

Anticonvulsant activity was determined in mice of either sex weighing 25–30 g. The mice were divided in groups of 10, keeping the group weights as near the same as possible. Each hydrazide or its precursor ester was suspended in 5% aqueous gum acacia to give a concentration of 0.25% (w/v). The test compound was injected in a group of 10 animals at a dose of 100 mg./kg. i.p. Four hours after administration of the hydrazide or ester, the mice were injected with pentylenetetrazol (90 mg./kg. s.c.). This dose of pentylenetetrazol has been shown not only to produce convulsions in almost all untreated mice but also to exhibit 100% mortality during 24 hr. On the other hand, no mortality was observed during 24 hr. in animals treated with 100 mg./kg. of the test compounds alone. The mice were then observed 60 min. for seizures. An episode of clonic spasm that persisted at least 5 sec. was considered a threshold convulsion. Transient intermittent jerks or tremulousness was not counted. Animals devoid of threshold convulsions during the 60 min. were considered protected. The number of animals protected in each group was recorded, and the anticonvulsant activity of these α-benzoylamino-*N*-(substituted hydrazides)-substituted cinnamides and their corresponding esters was represented as percent protection. The animals were then observed for 24 hr. and their mortality was recorded.

BIOCHEMISTRY

Spectrophotofluorometric Method—A spectrophotofluorometric method was used for the determination of monoamine oxidase activity of rat brain homogenate, using kynuramine as the substrate (8). The 4-hydroxyquinoline formed during oxidative deamination of kynuramine was measured fluorometrically with a spectrophotofluorometer[1], using activating light of 315 nm. and measuring fluorescence at the maximum of 380 nm.

Male adult rats, weighing approximately 150–200 g., were killed by decapitation. Brains were quickly removed and homogenized in ice-cold 0.25 *M* sucrose with the Potter–Elvehjem homogenizer. The reaction mixture, in a final concentration, consisted of 0.5 ml. phosphate buffer (0.2 *M*, pH 7.5), 1×10^{-4} *M* kynuramine, and 0.5 ml. brain homogenate (equivalent to 10 mg. of wet weight of the tissue). The monoamine oxidase activity of the brain homogenate was determined by incubation at 37° in air for 30 min. The various α-benzoylamino-*N*-(substituted hydrazides)-substituted cinnamides were added to the brain homogenate to produce a final concentration of 5×10^{-4} *M* and incubated for 10 min. before adding kynuramine. The mixture was then incubated for an additional 30 min. The reaction was stopped by the addition of 1 ml. of 10% trichloroacetic acid (w/v), and the precipitated proteins were removed by centrifugation. Suitable 1-ml. aliquots of the supernate were taken in 2 ml. of 1 *N* NaOH solution and were assayed for 4-hydroxyquinoline. An increase in the absorbance provided a direct measurement of the 4-hydroxyquinoline formation, which was taken as an index of the enzyme activity. The percent inhibition was calculated from the decrease observed in the absorbance and this provided an index of the inhibitory property of these α-benzoylamino-*N*-(substituted hydrazides)-substituted cinnamides.

Warburg Manometric Method—The monoamine oxidase activity of rat brain homogenate was determined by the conventional Warburg manometric technique, using tyramine as the substrate (9). The decrease in the oxygen uptake for 1 hr. during oxidative deamination of tyramine in the presence of substituted cinnamides was used as an index of enzyme inhibition. The reaction mixture,

in a final concentration, consisted of 50 m*M* phosphate buffer (pH 7.4), 5 m*M* tyramine, and the homogenate (equivalent to 100 mg. of fresh tissue) in a total volume of 1.2 ml. The inhibitors, used at a final concentration of 1×10^{-3} *M*, were incubated with the enzyme preparation for 20 min. before adding the substrate. The enzyme system was then incubated an additional hour at 37° using oxygen as the gaseous phase. Readings of the oxygen uptake were taken every 10 min.

RESULTS AND DISCUSSION

In the present study, α-benzoylamino-*N*-(substituted esters)-substituted cinnamides and their corresponding hydrazides were synthesized and evaluated for anticonvulsant activity. The degree of protection afforded by these compounds against pentylenetetrazol-induced seizures and the 24-hr. mortalities are recorded in Tables III and IV. The data seem to indicate a trend of more protection from convulsions with less mortality; however, it is not sufficiently uniform to conclude that definitely (*e.g.*, Table III: 0% protection = 70% mortality, 10% protection = 90% mortality, and 30% protection = 70% mortality). Each hydrazide or its precursor ester was found to be devoid of not only the sedative or central nervous system (CNS) depressant effect but also of 24-hr. mortality in the 100-mg./kg. dose used in the present study. Thus, 24-hr. mortality in these experimental animals accounts for the toxic effects of pentylenetetrazol.

These results indicate a greater anticonvulsant activity of α-benzoylamino-*N*-(substituted hydrazides)-substituted cinnamides as compared to their corresponding esters. These esters were either devoid of activity or showed less than 30% protection. The protection afforded by these hydrazides ranged from 30 to 70%, where the greatest protection was observed when the aliphatic chain of these α-benzoylamino-*N*-(substituted hydrazides)-substituted cinnamides possessed the glycine hydrazide moiety (Compound XIII). Elongation of the aliphatic chain resulted in a decrease of anticonvulsant activity. Evaluation of monoamine oxidase inhibitory activity of these hydrazides with a view to elucidating the biochemical basis for anticonvulsant activity indicated that all α-benzoylamino-

[a] Compound numbers are those recorded in Table II. The final concentrations of the inhibitors used were 5×10^{-4} and 1×10^{-3} *M* during oxidative deamination of kynuramine and tyramine, respectively. Vessel contents and assay procedures are as indicated in the text. Each experiment was done in duplicate, and figures indicate mean values of three separate experiments with ± standard error of the mean.

N-(substituted hydrazides)-substituted cinnamides inhibited *in vitro* oxidative deamination of kynuramine and tyramine by rat brain homogenate. The results, indicating greater sensitivity of these hydrazides for monoamine oxidase when kynuramine was used as the substrate, are in agreement with other studies (1, 10) which also found greater degree of inhibition with kynuramine as compared to tyramine from the α-benzoylamino-*N*-(1-benzhydrazide)-*p*-substituted cinnamides (4).

Elongation of the aliphatic chain was found to have no significant effect on the monoamine oxidase inhibitory effectiveness of α-benzoylamino-*N*-(substituted hydrazides)-substituted cinnamides. Maximum inhibition was observed with α-benzoyl-*N*-(substituted hydrazides)-substituted cinnamides possessing the *ortho*-chloro substituent (Compound XXII) using tyramine, while substituted cinnamide possessing chloro substituents at both the 2- and 3-positions of the benzene ring (Compound XXIV) exhibited maximum inhibition of monoamine oxidase during oxidative deamination of kynuramine. CNS stimulation, a property associated with many monoamine oxidase inhibitors, was not observed with these compounds in the doses employed, presumably due to a relatively weak monoamine oxidase inhibitory activity of these compounds. These data failed to provide a relationship between anticonvulsant activity of α-benzoyl-*N*-(substituted hydrazides)-substituted cinnamides and their ability to inhibit monoamine oxidase. Further studies dealing with the detailed pharmacological and toxicological properties and the effects upon the activity of other enzymes may possibly reflect a biochemical basis for anticonvulsant activity of these substituted cinnamides.

Simultaneous Polarographic Determination of Bisulfite and Iproniazid in Gel Formulations

J. J. DONAHUE▲ and S. OLIVERI-VIGH*

Abstract □ A polarographic method is described for the simultaneous determination of sodium bisulfite and iproniazid in gel formulations. The standard deviation for the bisulfite determination was ±0.00₂% and the precision *ts* at the 95% confidence level was ±0.00₅%. The standard deviation for the iproniazid determination was ±0.03% and the precision *ts* at the 95% confidence level was ±0.07%.

Keyphrases □ Iproniazid–bisulfite—simultaneous polarographic determination □ Bisulfite–iproniazid—simultaneous polarographic determination □ Polarography—simultaneous determination of iproniazid and bisulfite in gel formulations

Due to the pharmaceutical importance of isoniazid and its derivatives, the analysis of this class of compounds has received considerable attention in the literature. The polarographic and spectrophotometric behavior of these compounds was investigated (1), and it was found that isoniazid exhibited two polarographic reduction waves in the pH 1.5–7 range. At pH >8, these waves merged to a single wave. By using the sum of both polarographic waves, isoniazid in tablets was determined with a precision of ±1.0% (1). No interference from excipients was noted. By using UV spectrophotometry, isoniazid in tablets was measured with a precision of about 1–2% (1).

A photometric procedure for the determination of iproniazid and other hydrazide derivatives, based on a reaction with molybdic acid in an acidic medium to form a red complex, also was reported (2). While the method is specific and sensitive, the concentration of acid is critical for the development of maximum color intensity.

Many methods have been reported which are based on the quantitative oxidation of the hydrazine moiety using bromine (3), iodine (4, 5), iodate (6), and nitrite (7). Recently, a titrimetric method for isoniazid and its derivatives was reported (8), which is based on the oxidation of isoniazid with excess chloramine T and back-titration. These methods all lack specificity, however, particularly when other reducing substances are present.

The most frequently used methods for the determination of bisulfite and sulfite are oxidation and subsequent determination as sulfate and direct oxidation with iodine (9). As with methods for hydrazine derivatives, these methods are also subject to interferences from other reducing substances. To avoid this problem in the determination of sulfite, a polarographic procedure was developed (10) based on the conversion of sulfite to sulfur dioxide and subsequent polarographic determination of the sulfur dioxide. The method was applied to the determination of sulfite in sewage water; however, both sulfide and thiosulfate were sources of interference.

Drug formulations containing bisulfite, as an antioxidant, and isoniazid or its derivatives do not readily lend themselves to present compendial (5) methods since simultaneous oxidation of both species occurs. The present article describes a polarographic method for the simultaneous determination of bisulfite and iproniazid which eliminates the problem of mutual interference often encountered when these species are present in the same formulation.

EXPERIMENTAL

Apparatus—A polarographic assembly[1] and a recorder[2] were used in conjunction with a dropping mercury electrode and a silver–silver chloride reference electrode (Ag/AgCl) to obtain the current voltage curves.

A digital pH meter[3] was used for all pH measurements.

The dropping mercury electrode characteristics, *m* and *t*, were determined in 0.25 *M* ammonium chloride solution at a potential of −1.0 v. *versus* Ag/AgCl and at a mercury column height of 56 cm.; *m* was 3.60 mg./sec. and *t* was 2.68 sec.

Reagents and Solutions—Triple-distilled mercury[4] was used in all polarographic experiments. Demineralized water was used to prepare all solutions. This water was prepared by passing ordinary distilled water through a demineralizer[5].

A pH 8 buffer was prepared by mixing 100 ml. of a stock solution containing phosphoric acid[6], acetic acid[7], and boric acid[7], each at a concentration of 0.04 *M*, with 62.5 ml. of 0.2 *N* sodium hydroxide[8] solution.

A 10% hydrochloric acid solution was prepared by diluting 236 ml. of concentrated hydrochloric acid[9] to 1000 ml. with demineralized water.

A stock reference standard solution of sodium metabisulfite[10] was prepared by accurately weighing approximately 40 mg. of sodium metabisulfite into a 100-ml. volumetric flask and diluting to volume with demineralized water. Ten milliliters of this solution was then diluted to 100 ml. with 40 ml. of buffer and approximately 50 ml. of demineralized water.

A stock reference standard solution of iproniazid phosphate was prepared by accurately weighing approximately 60 mg. of iproniazid phosphate into a 100-ml. volumetric flask and diluting to volume with 40.0 ml. of buffer and 60 ml. of deaerated demineralized water.

Procedure—Approximately 2 g. of the gel sample was transferred to a tared 50-ml. volumetric flask and weighed. Twenty milliliters of deaerated buffer was added, and the sample was shaken for approximately 30 min. to ensure extraction of the active substance

from the gel matrix. The sample was then diluted to volume with deaerated demineralized water. Ten milliliters of this solution was pipeted into the polarographic cell and deaerated with prepurified tank nitrogen[11] for approximately 5 min. The nitrogen flow was then reversed to the solution surface, and 1 ml. of 10% hydrochloric acid was added and mixed into the solution. The polarogram for bisulfite as sulfur dioxide was immediately recorded using a voltage span of from 0 to −1.0 v. *versus* Ag/AgCl, a mercury column height of 56.0 cm., and a current sensitivity of 0.02 μa./mm. When the polarogram was completed, the solution was vigorously deaerated with nitrogen to eliminate the sulfur dioxide formed from the bisulfite, and a residual current curve was obtained using the same polarographic conditions.

Polarograms for iproniazid were recorded using the same solution. The instrument conditions were the same, except that the current sensitivity was 0.2 μa./mm.

Polarograms were also recorded for the sodium metabisulfite and iproniazid phosphate reference standards using the same instrument conditions.

Calculations—The diffusion currents were measured by standard procedures (11). The percent bisulfite in the formulation was calculated as follows:

$$\text{percent bisulfite} = \frac{(i_s)(C_{st})(5)(1.095)}{(i_{st})(\text{weight sample, grams})} \quad \text{(Eq. 1)}$$

where:

i_s = diffusion current (microamperes) for sample
C_{st} = concentration of standard (milligrams per milliliter)
5 = dilution factor and conversion to percent
1.095 = conversion factor for metabisulfite to bisulfite
i_{st} = diffusion current (microamperes) for standard

The percent iproniazid in the formulation was calculated as follows:

$$\text{percent iproniazid} = \frac{(i_s)(C_{st})(5)(0.6465)}{(i_{st})(\text{weight sample, grams})} \quad \text{(Eq. 2)}$$

where:

i_s = diffusion current (microamperes) for sample
C_{st} = concentration of standard (milligrams per milliliter)
5 = dilution factor and conversion to percent

[11] Union Carbide Corp., Linde Division.

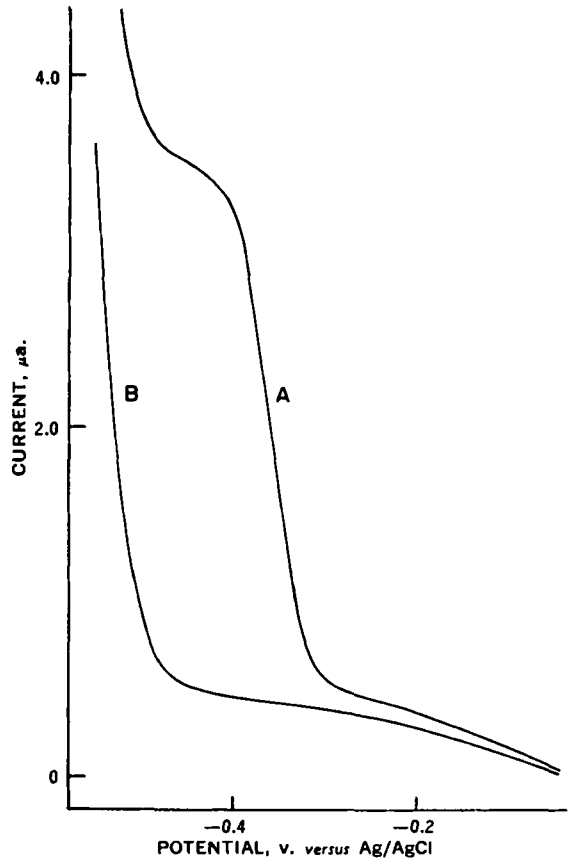

Figure 1—*Polarograms for bisulfite determination. Key: A, typical reduction wave for sulfur dioxide; and B, typical residual current curve obtained after deaeration.*

0.6465 = conversion factor for iproniazid phosphate to base
i_{st} = diffusion current (microamperes) for standard

RESULTS AND DISCUSSION

Polarographic Determination of Bisulfite—In acidic media, the gel sample exhibited three reduction waves. The first wave, which occurred at −0.38 v. *versus* Ag/AgCl (Fig. 1), may be attributed to the reduction of sulfur dioxide liberated from the bisulfite stabilizer under acidic conditions (Scheme I).

$$HSO_3^- + H^+ \rightarrow SO_2 + H_2O$$

Scheme I

According to Kolthoff and Miller (12), the resulting sulfur dioxide is reduced in a single two-electron step to sulfoxylic acid (Scheme II).

$$SO_2 + 2H^+ + 2e^- \rightarrow H_2SO_2$$

Scheme II

The metabisulfite standard, under the same solution conditions, is readily converted to bisulfite (Scheme III), which subsequently reacts as shown in Schemes I and II.

$$S_2O_5^{-2} + H_2O \rightarrow 2HSO_3^-$$

Scheme III

The polarographic results obtained for the bisulfite stabilizer are presented in Table I. The average for 18 determinations was 0.06_2% with a standard deviation of $\pm 0.00_2$% and a precision (*ts*) for 17 degrees of freedom at the 95% confidence level of $\pm 0.00_5$%.

The obvious discrepancy in bisulfite added (0.1%) and bisulfite found is most likely due to the unavoidable losses of bisulfite during formulation. While the final formulation is a neutralized gel

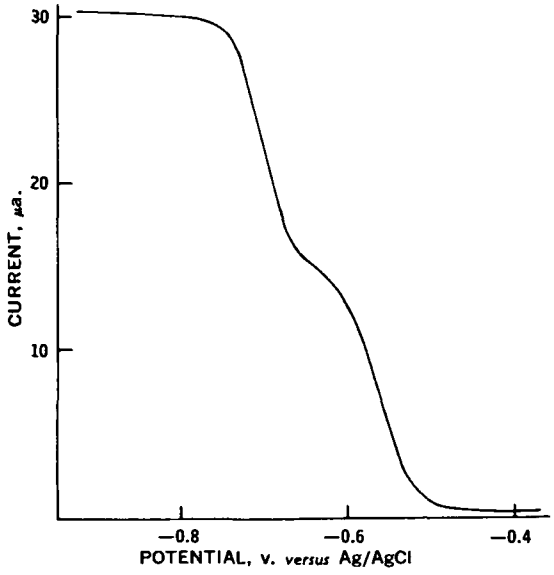

Figure 2—*Typical polarogram for iproniazid.*

medium, the pH of the formulation is acidic until the final step in the preparation due to the presence of iproniazid phosphate. This acidic pH would most likely cause losses of bisulfite as SO_2 (Scheme I).

Polarographic Determination of Iproniazid—The two additional reduction waves, observed at −0.54 and −0.72 v. *versus* Ag/AgCl in an acidic medium (Fig. 2), are due to the reduction of iproniazid (1). Although the half-wave potentials for the sulfur dioxide wave and the first reduction wave for iproniazid are separated by only 160 mv., vigorous deaeration of the solution after measurement of the sulfur dioxide wave eliminates any possible interference from sulfur dioxide in the subsequent measurement of the diffusion current for iproniazid.

Polarograms for the bulk drug at various concentrations indicated that the total current for the two reduction waves was proportional to concentration in the 0.05–0.6-mg./ml. range. A plot of diffusion current, i_d, *versus* concentration, milligrams per milliliter, was linear with a slope equal to 30 μa. ml./mg.

In contrast to the polarographic results obtained for bisulfite, the results obtained for iproniazid indicated that the determination was dependent on the extraction time used to free the hydrazide from the gel matrix. Initially, samples were extracted by shaking for approximately 5 min. prior to scanning on the polarograph. The average assay value for eight determinations was 0.95% with a standard deviation of ±0.06% and a precision (*ts*) for seven degrees of freedom at the 95% confidence level of ±0.13% (Table II). When the extraction time was increased to approximately 30 min., the average for 10 determinations was 0.98% with a standard deviation of ±0.03% and a precision (*ts*) for nine degrees of freedom at the 95% confidence level of ±0.07% (Table II).

Table II—Effect of Extraction Time on Percent Iproniazid Found

CONCLUSIONS

The advantages of the described method over procedures for bisulfite and hydrazine derivatives that are based on direct oxidation with iodine are twofold. The primary advantage is that it eliminates the mutual interference problem between bisulfite and iproniazid which may be encountered in methods based on oxidation. Secondly, the present method allows both the active hydrazine substance and the stabilizer used in the formulation to be determined in the same sample preparation. As a result, this procedure significantly reduces the overall time required for the dosage form analysis when both the active substance and the antioxidant must be determined.

Determination of Diphenhydramine Hydrochloride in Elixir

DIANE WOO[A], JOHN K. C. YEN, and KENNETH R. HEIMLICH

Abstract □ A UV spectrophotometric method for the determination of diphenhydramine hydrochloride in the presence of its postulated decomposition products and 5-(hydroxymethyl)-2-furaldehyde in elixirs was developed. The method involves simple extractions with cyclohexane and is suitable for routine and stability assays of various pharmaceutical liquid formulations. The technique is a modification of the USP XVIII method.

Keyphrases □ Diphenhydramine hydrochloride elixir—UV analysis in presence of 5-(hydroxymethyl)-2-furaldehyde □ 5-(Hydroxymethyl)-2-furaldehyde as elixir decomposition product—noninterference in UV analysis of diphenhydramine hydrochloride elixir □ UV spectrophotometry—analysis, diphenhydramine hydrochloride elixir

5-(Hydroxymethyl)-2-furaldehyde (1–3) is a well-known reaction product of the Maillard reaction. It can also be formed by the acid–base-catalyzed dehydration of hexose sugars. 5-(Hydroxymethyl)-2-furaldehyde is frequently present in pharmaceutical preparations, particularly in products containing sugar syrups. Its presence can interfere in the chemical analysis for the active ingredients.

USP XVIII (4) describes a UV assay for diphenhydramine hydrochloride elixir. This method was found to be inapplicable to certain samples undergoing stability tests. With increasing storage temperatures, consistently higher results were obtained. The separation of the base was reported (5, 6) on a cation exchanger, followed by quantitative spectrophotometric determination. A UV method was developed (7) to measure the steam-distillable compound after hydrolysis and oxidation of diphenhydramine. Colorimetric methods have also been reported. An addition compound formation between diphenhydramine and tetrabromophenolphthalein ethyl ether in 1,2-dichloroethane was used (8), as has ion-pair formation between the amine and an indicator dye (9). The reineckate was prepared in acetone (10). Nonaqueous titrimetry and salt partition was used in procedures for analysis of organic bases (11, 12). Quantitative TLC also was described (13). However, none of these methods has been suggested for stability-indicating purposes.

The present study describes a modification of the official assay procedure for the determination of the diphenhydramine content in elixirs containing postulated decomposition products and 5-(hydroxymethyl)-2-furaldehyde. The amine is separated by extraction from alkaline medium into cyclohexane, purified by washing and by filtration through anhydrous sodium sulfate before being extracted into dilute aqueous acid, and determined by UV spectrophotometry.

EXPERIMENTAL

Materials—The following were used: cyclohexane, spectrograde; 2 *N* sulfuric acid; 1% sodium hydroxide; 0.1 *N* sulfuric acid; 10% sodium hydroxide; and diphenhydramine hydrochloride USP standard reference solution, 0.5 mg./ml. in 0.1 *N* sulfuric acid. The following materials were obtained commercially[1] and used without additional purification: 5-(hydroxymethyl)-2-furaldehyde, diphenylcarbinol, and *N,N*-dimethylethanolamine.

Apparatus—A spectrophotometer[2] was employed.

Procedure—Transfer quantitatively 20 ml. of the elixir, equivalent to 50 mg. of diphenhydramine hydrochloride, into a separator. Add 30 ml. of distilled water and 1 ml. of 2 *N* sulfuric acid and extract with two 25-ml. portions of cyclohexane, discarding the cyclohexane extracts.

To the aqueous phase, add 10 ml. of 10% sodium hydroxide; then extract with three 30-ml. portions of cyclohexane and combine. Wash the combined cyclohexane extracts with two 10-ml. portions of 1% sodium hydroxide, discarding the washings. Extract the cyclohexane with three 25-ml. portions of 0.1 *N* sulfuric acid, collecting the extracts in a 100-ml. volumetric flask. Dilute to the mark with 0.1 *N* sulfuric acid and mix well.

Measure the absorbance difference between the maximum at 258 nm. and the baseline at 290 nm. in 1-cm. cells using 0.1 *N* sulfuric acid as blank. The diphenhydramine hydrochloride content of the sample is calculated from a relative absorptivity value derived by dissolving appropriate amounts of standard reference material in 0.1 *N* sulfuric acid and measuring spectrophotometrically under the same operational conditions as described for the assay procedure.

RESULTS AND DISCUSSION

The browning of the elixirs and a spectral change (Fig. 1) of

1	49.92	98.9	97.8
2	49.56	99.1	97.7
3	50.13	99.3	98.3
4	50.09	99.3	98.5
5	50.09	99.4	98.5
6	50.09	99.6	98.8
Percent recovered ± *SD*		99.3 ± 0.2	98.3 ± 0.4

Table II—Analysis of Synthetic Mixtures in the Presence of 5-(Hydroxymethyl)-2-furaldehyde

Number of Assay	Diphenhydramine, mg. Added	5-(Hydroxymethyl)-2-furaldehyde, mg. Added	Recovery, % Modified Method	Recovery, % USP Method
1	50.18	1.0	99.1	113.6
2	50.18	3.0	100.7	141.3
3	50.14	5.0	100.6	162.5
4	50.30	10.0	101.1	230.6
5	50.01	30.0	99.9	508.7
6	49.99	60.0	100.2	957.9

diphenhydramine, in which the absorption maximum shifted from 258 to 283 nm., led to an investigation of 5-(hydroxymethyl)-2-furaldehyde (I). Compound I had been isolated from the elixirs through thick-layer chromatography and identified by UV and IR absorption spectra, TLC, and the color reaction (14) with 2-thiobarbituric acid.

The postulated decomposition pathways for diphenhydramine would be hydrolysis of the ether linkage with formation of diphenylcarbinol and *N,N*-dimethylethanolamine. A study of the alkaline and acid hydrolysis of diphenhydramine was made, but only one of the postulated degradation products was isolated. The melting point, IR absorption spectrum, thin-layer chromatogram, and molar absorptivity data on this product coincide with those described for diphenylcarbinol. However, the presence of *N,N*-dimethylethanolamine was not positively confirmed.

Nevertheless, both postulated decomposition products and I have been taken into consideration as possible interferences. Diphenylcarbinol is practically insoluble in weak sulfuric acid, but it is soluble in cyclohexane and is removed by the initial cyclohexane extractions of the aqueous phase. On the other hand, I is very soluble in aqueous alkaline medium but is insoluble in cyclohexane; therefore, it remains in the aqueous phase throughout the procedure. The possible basic decomposition product, *N,N*-dimethylethanolamine, does not absorb UV radiation in the range employed.

To determine the validity of the method, a synthetic elixir was prepared by mixing a known quantity of diphenhydramine (50 mg. of pure drug) with excipients. Diphenhydramine was then assayed by the modified and USP methods. From the six determinations, the average percent recoveries were 99.3 ± 0.2 *SD* for the modified method and 98.3 ± 0.4 *SD* for the USP method. Both methods are in excellent agreement with each other, as shown in Table I.

The modified and the USP methods are both capable of eliminating the postulated decomposition products. To verify this fact, 1.7×10^{-4} mole each of diphenylcarbinol and *N,N*-dimethylethanolamine were added to the synthetic mixture and then carried through both procedures. No interfering absorbance between 300 and 235 nm. was observed. The specified amount of postulated decomposition products was used on the assumption that 100% hydrolysis of diphenhydramine would have taken place.

Synthetic mixtures in the presence of 1, 3, 5, 10, 30, and 60 mg. of I were assayed by both methods. The modified method gives results near the true values for the diphenhydramine concentration, whereas the method described by USP XVIII gives results that are far too high. The data in Table II indicate that the extraction of diphenhydramine by the USP method from an elixir containing a small amount of I results in a considerable error. This is due to the much greater absorption sensitivity of I.

Table III—Percent Recovery of Diphenhydramine Hydrochloride from Different Stability Samples

Sample	Storage Condition: Period	Storage Condition: Temperature	Recovery, % Modified Method	Recovery, % USP Method
Experimental elixir	Initial	Room temperature	100.0	98.5
	2 weeks	60°	98.7	97.9
	3 weeks	60°	99.2	101.1
	4 weeks	60°	99.6	98.7
Commercial elixir A	Initial	Room temperature	100.2	98.7
	2 weeks	60°	101.0	100.9
	3 weeks	60°	100.3	103.4
	4 weeks	60°	98.3	107.6
Commercial elixir B	Initial	Room temperature	100.6	100.8
	1 day	60°	100.3	102.0
	2 days	60°	100.0	103.1
	3 days	60°	100.3	103.8
	4 days	60°	99.9	104.6
	7 days	60°	100.1	111.6

The percent recoveries (Table III) obtained by using both the modified and USP methods for the stability samples of the experimental elixir are very similar. This similarity is expected, since the experimental elixir does not contain sucrose. The results for the stability samples of commercial Elixirs A and B (Table III) show that the percent recovery obtained by the USP method increases with storage time, while that obtained by the modified method remains constant. This could be explained simply on the basis that the commercial elixirs contained sucrose and that the I formed therefrom was removed by the modified method prior to determination. The results presented in Table III indicate the applicability and accuracy of the modified method for the assay of stability samples.

Based on our experience, the modified method provides definite improvement over the USP method. It is, therefore, suggested that the modified procedure may be considered as a stability-indicating method for the determination of diphenhydramine in various pharmaceutical liquid formulations.

Quantitative GLC Analysis of Theophylline, Ephedrine Hydrochloride, and Phenobarbital Suspension

H. WAYNE SCHULTZ▲ and CHURAIRAT PAVEENBAMPEN

Abstract □ A rapid GLC method was developed for the quantitative determination of theophylline, ephedrine hydrochloride, and phenobarbital in a suspension formulation. A simple extraction procedure was incorporated to separate ephedrine hydrochloride into one fraction (I) and theophylline and phenobarbital into a second fraction (II). An internal standard was added to each fraction, and the resulting solutions were chromatographed onto a single column. The internal standard and column temperature used were: α-naphthylamine and 150°, Fraction I; and hexobarbital and 200°, Fraction II. Quantitation was based on the sample–internal standard peak height ratio.

Keyphrases □ Theophylline, ephedrine hydrochloride, and phenobarbital suspensions—GLC analysis □ Ephedrine hydrochloride, theophylline, and phenobarbital suspensions—GLC analysis □ Phenobarbital, theophylline, and ephedrine hydrochloride suspensions—GLC analysis □ GLC—analysis, theophylline, ephedrine hydrochloride, and phenobarbital suspensions

Tablets and suspensions containing theophylline, ephedrine hydrochloride, and phenobarbital are frequently used for their actions of sedation and bronchodilation. The problem of developing a rapid and accurate assay for combinations of these components is well known (1). Although many methods are reported for the individual components, only a few reports concern the assay of mixtures of the three drugs.

A monograph for theophylline, ephedrine hydrochloride, and phenobarbital tablets is given in NF XIII (2). This represents the first recognition given by either the USP or NF to the mixture. The official assay, which also serves as the basis for identification, consists of separating the mixture into three fractions, each containing a single drug, followed by UV spectroscopy. Separation is accomplished by a laborious process involving two chromatographic columns and a liquid–liquid extraction. In addition to this time-consuming aspect, the official procedure is not directly adaptable to the mixture in suspension form.

Another assay for theophylline, ephedrine hydrochloride, and phenobarbital tablets was reported (1). This was a GLC method involving a single column and two separate sample preparations. A solution containing theophylline and phenobarbital was chromatographed directly after the solvent extraction of a tablet sample. Ephedrine was determined by treating a second tablet sample with sodium periodate to form benzaldehyde and chromatographing a solvent extract of this mixture. The oxidation step was included because ephedrine did not give a well-resolved peak. The assay was described as being rapid, specific, and precise. However, it applied only to tablets and could not be utilized directly for suspensions.

In recent years, GLC has become an increasingly important method for the analysis of theophylline, ephedrine hydrochloride, and phenobarbital, either individually or in combination with each other. This method is especially attractive because of its ability to provide both accuracy and convenience. The GLC methods used for these drugs in mixtures, such as dosage formulations and biological materials, frequently include solvent extraction (1, 3–9).

This report describes a rapid and accurate GLC method for the quantitative determination of theophylline, ephedrine hydrochloride, and phenobarbital contained in suspension. In the development of this procedure, the attainment of well-resolved peaks was sought through the use of a single column, a minimum number of sample preparations and injections, and a direct injection of the components. All of these conditions are successfully met in the described procedure.

EXPERIMENTAL

Apparatus—A gas chromatograph[1] equipped with a flame-ionization detector was used. The electrometer range was 10^2 with attenuation from 1 to 4 × 10^{-10} amp. The detector signal was fed to a 1-mv. recorder with a chart speed of 0.64 cm. (0.25 in.)/min. and a 1-sec.

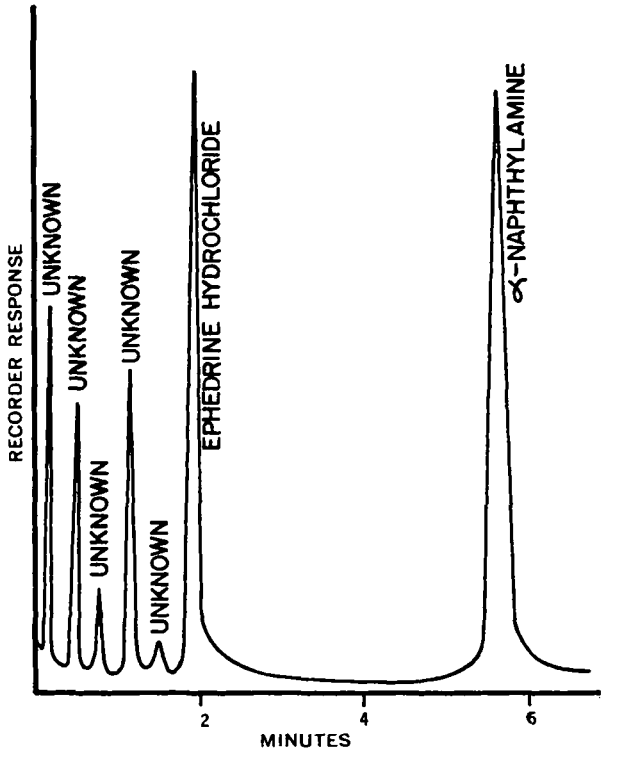

Figure 1—*Gas chromatogram of ephedrine hydrochloride in a commercial suspension. Conditions: 3% OV-17 on Gas Chrom Q; nitrogen flow rate, 75 ml./min.; column temperature, 150°; recorder chart speed, 0.64 cm./min.; and attenuation of electrometer, 2.0 × 10^{-10} amp.*

full-scale response. The gas flows were: nitrogen, 75 ml./min.; hydrogen, 35 ml./min.; and air, 280 ml./min.

GLC Column—A 1.8-m. (6-ft.) long, U-shaped, borosilicate glass tubing (4.0 mm. i.d.) was packed with 3% OV-17 on 100–120-mesh Gas Chrom Q[2]. The column was conditioned by heating at 100° for 1 hr., followed by increasing the temperature to 250° at a rate of 1°/min. and maintaining this temperature for 18 hr. with continuous carrier gas flow.

Operating Temperatures—The injection port, column, and detector temperatures for the assay of ephedrine hydrochloride were maintained at 200, 150, and 200°, respectively. For the assay of phenobarbital and theophylline, the injection port, column, and detector temperatures were maintained at 250, 200, and 250°, respectively.

Preparation of Ephedrine Hydrochloride Internal Standard Calibration Curve—*Internal Standard Solution*—A chloroform solution containing 12.5 mg. α-naphthylamine/ml. was used.

Standard Reference Solution—About 500 mg. ephedrine hydrochloride USP, accurately weighed, was dissolved in 10 ml. distilled water contained in a 125-ml. separator. The mixture was adjusted to pH 11 with 20% sodium hydroxide solution and extracted with four 25-ml. portions of chloroform. The extract was placed in a 100-ml. volumetric flask and diluted to volume with chloroform. The following quantities of this solution were pipeted into six 10-ml. volumetric flasks: 0.5, 1.0, 2.0, 3.0, 4.0, and 5.0 ml. To each flask were added 0.3 ml. of α-naphthylamine internal standard solution and sufficient chloroform to bring to volume. A 4-μl. sample of each solution was injected into the gas chromatograph. Four replicate samples of each concentration were injected, the peak heights were measured, and the average value for each concentration was determined. Upon plotting the ephedrine hydrochloride–α-naphthylamine peak height ratio to amount of ephedrine hydrochloride, a straight-line calibration curve was obtained over the 1.0–10.0-mcg. range at the corresponding range of peak height ratio values from 0.45 to 9.00.

Preparation of Phenobarbital Internal Standard Calibration Curve—*Internal Standard Solution*—Hexobarbital (0.2 mg./ml.) was dissolved in an equal volume of chloroform and methanol.

Standard Solution— Phenobarbital USP, accurately weighed, was dissolved in the hexobarbital internal standard solution to give a series of six solutions varying from about 0.2 to 3.9 mg./ml. The same GLC procedure for these solutions was followed as described for the ephedrine hydrochloride standard solution. Upon plotting the phenobarbital–hexobarbital peak height ratio to amount of phenobarbital, a straight-line calibration curve was obtained over the 0.7–15.4-mcg. range at the corresponding range of peak height ratio values from 0.40 to 8.60.

Preparation of Theophylline Internal Standard Calibration Curve—*Internal Standard Solution*—Hexobarbital internal standard solution, as described for the phenobarbital standard curve, was used.

Standard Solution—Theophylline NF, accurately weighed, was dissolved in hexobarbital internal standard solution to give a series of six solutions varying from about 0.8 to 21.0 mg./ml. The same GLC procedure was followed as described for the ephedrine hydrochloride standard solution. Upon plotting the theophylline–hexobarbital peak height ratio to amount of theophylline, a straight-line calibration curve was obtained over the 6.2–62.4-mcg. range at the corresponding range of peak height ratio values from 0.73 to 4.30.

Assay of a Synthetic Mixture—*Preparation*—A mixture containing the same quantities of theophylline, ephedrine hydrochloride, and phenobarbital as contained in a commercial suspension was formulated. Each 5 ml. contained 65.0 mg. theophylline, 12.0 mg. ephedrine hydrochloride, and 4.0 mg. phenobarbital in distilled water.

Ephedrine Hydrochloride Assay—To 5.0 ml. of the mixture was added 5 ml. distilled water, the pH was adjusted to 11 with 20% sodium hydroxide solution, and the solution was extracted two times with 12 ml. chloroform. The chloroform extract was placed into a 25-ml. volumetric flask containing 0.75 ml. of α-naphthylamine internal standard solution and diluted to volume with chloroform. Four microliters of the solution was injected into the gas chromatograph.

Phenobarbital and Theophylline Assay—To the aqueous phase remaining from the ephedrine hydrochloride assay, 4 g. of sodium chloride was added and the pH was adjusted to 4.8 with dilute hydrochloric acid. The mixture was extracted four times with 50 ml. chloroform. The chloroform extract was placed into a 200-ml. volumetric flask and diluted to volume with chloroform. With a pipet, 9.0 ml. of this solution was placed in a test tube and the solution was evaporated to dryness on a 65° water bath. One milliliter of the hexobarbital internal standard solution was pipeted into the tube to redissolve the residue. Four microliters of the solution was injected into the gas chromatograph. The results are given in Table I.

Assay of Commercial Suspension—The specific gravity of a commercial suspension[3] was determined. Approximately 6.4 g. of the suspension, accurately weighed, was mixed with 5 ml. of distilled water. This quantity, representing about 5 ml. of sample, was converted into volume using the specific gravity value. The resulting mixture was extracted and gas chromatographed by the same pro-

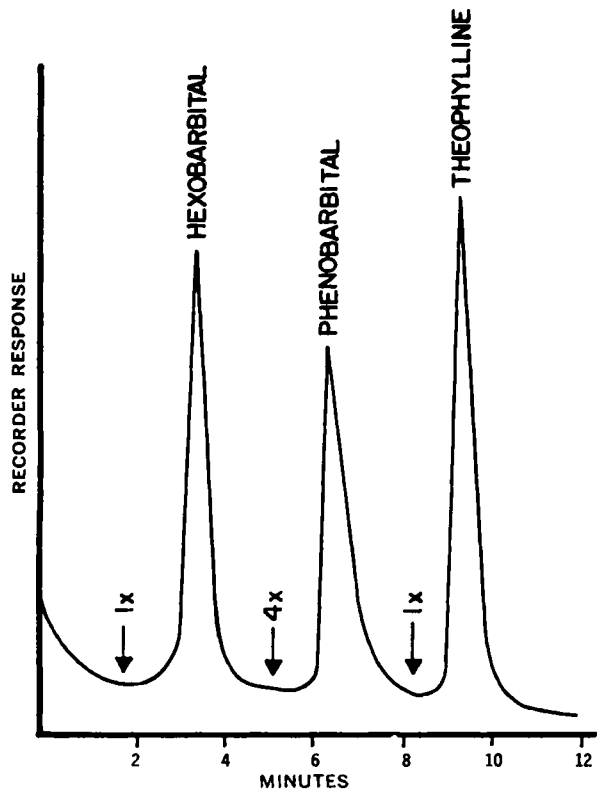

Figure 2—*Gas chromatogram of theophylline and phenobarbital in a commercial suspension. Conditions: 3% OV-17 on Gas Chrom Q; nitrogen flow, 75 ml./min.; column temperature, 200°; recorder chart speed, 0.64 cm./min.; and attenuation of electrometer, 1 × and 4 × 10^{-10} amp.*

cedure as used for the assay of a synthetic mixture. The results are given in Table II and Figs. 1 and 2.

RESULTS AND DISCUSSION

A GLC procedure for the quantitative determination of theophylline, ephedrine hydrochloride, and phenobarbital contained in a suspension formulation was presented. It was necessary to incorporate into the procedure a liquid–liquid extraction because of the varying concentration and polarity of the components. Through this process the sample was separated into two fractions, one containing ephedrine hydrochloride and the other containing theophylline and phenobarbital. Several additional substances, possible flavoring or coloring agents, were extracted by chloroform into the ephedrine extract. Complete elimination of these impurities was not attempted because they did not interfere with either the ephedrine or the internal standard peaks (Fig. 1).

The packing used in the GLC column was 3% OV-17 on Gas Chrom Q. A preliminary study showed that this packing gave the most desirable shape and resolution of peaks. In addition, it had the advantage of high thermal stability. Although peak tailing has been encountered with these drugs on various packing materials (6–8, 10), there was minimal peak tailing for all of the drugs in this investigation. The use of the silanized solid support of Gas Chrom Q probably minimized this problem.

A 4-μl. injection of each fraction was made and the resulting peak heights were measured. The peak height ratios of drug to internal standard were determined and compared to the appropriate calibration curve. Linear response was found in the calibration curves for the following ranges: ephedrine hydrochloride, 1.0–10.0 mcg.; phenobarbital, 0.7–15.4 mcg.; and theophylline, 6.2–62.4 mcg.

The procedure was used to assay a commercial suspension and a comparable synthetic mixture. Six replicate determinations were made of each preparation. Each extracted fraction was injected into the gas chromatograph four times and the average result was determined. The mean recoveries obtained (Table I) in the assay of the synthetic mixture for ephedrine hydrochloride, phenobarbital, and theophylline were 99.2 ± 0.6, 97.5 ± 1.0, and 100.3 ± 0.1%, respectively. Correspondingly, the mean recoveries for the commercial suspension (Table II) were: 95.8 ± 0.8, 110.0 ± 1.4, and 99.4 ± 0.3%, respectively. These latter values were calculated on the basis of the manufacturer's label claim. The standard deviation (Tables I and II) found for each drug in the two preparations indicated excellent precision for the procedure.

CONCLUSION

A rapid GLC method was developed for the determination of theophylline, ephedrine hydrochloride, and phenobarbital contained in a suspension formulation. A simple extraction procedure was incorporated to separate the components into two fractions. To each fraction an internal standard was added, and the resulting solutions were chromatographed onto a single column. Conditions of column packing, temperatures, internal standards, and carrier gas flow rate were selected to give well-resolved peaks. Quantitation was made on the basis of the peak height ratio of sample to internal standard. Accurate and precise values were obtained using this procedure.

Paper Chromatographic Determination of Tetracycline

M. K. YOUSSEF[A], EL. A. IBRAHIM, and I. A. ATTIA

Abstract □ A simple paper chromatographic method for separation and quantitative determination of tetracycline in pharmaceutical preparations was developed. The method is based on the complexation of the antibiotic with a mixture of urea and disodium edetate on a chromatographic paper at pH 7.4. Spots of tetracycline and its degradation products were located under UV light, and their respective R_f values were calculated. The method can be used to determine tetracycline phosphate, even in the presence of oleandomycin. The developed method proved satisfactory in monitoring the stability of the antibiotic base and its hydrochloride.

Keyphrases □ Tetracycline and tetracycline formulations—paper chromatographic analysis in presence of six degradation products □ Paper chromatography—analysis, tetracycline and tetracycline formulations □ Chromatography, paper—tetracycline and degradation products

Tetracycline antibiotics undergo rapid degradation through epimerization and/or oxidation (1–5). The ingestion of degraded tetracycline capsules was reported to cause a reversible Fanconi-type syndrome (6–10). Since the official microbiological methods suffer from many disadvantages, recent articles have been devoted to the development of simple, precise, and accurate methods for the determination of tetracycline in degraded pharmaceutical formulations.

Previous chromatographic separations of tetracycline involved paper saturated with McIlvaine's buffer at pH 3.5 (11, 12). However, epimerization of tetracycline on the chromatographic paper was reported under these conditions (13). The separation of epitetracycline from urine, using chromatographic paper[1] impregnated with edetic acid, was reported (14). Urea solution was successfully employed as an immobile phase for paper chromatographic determination of oxytetracycline (15). The formation of a slightly soluble tetracycline–urea complex also was reported (16).

Therefore, it was decided to use paper impregnated with a mixture of disodium edetate and urea for the quantitative separation and determination of tetracycline in the presence of its degradation products. This impregnating mixture resulted in better separation which led to more precise determination of tetracycline in the presence of its degradation products.

EXPERIMENTAL[2]

Separation of Tetracycline from Its Degradation Products—*Impregnating Solutions*—A 100-ml. quantity of urea solution (A) was prepared by dissolving 10 g. of urea in McIlvaine's buffer (pH 7.4) (17); 100 ml. of disodium edetate solution (B) was prepared by dissolving 5 g. of disodium edetate in McIlvaine's buffer (pH 7.4). A mixture of Solutions A and B (1:3) was used for impregnating a series of chromatographic papers[1]. The papers were then blotted between sheets of absorbent papers.

Solvents—A mixture of ethyl acetate–acetone (40:10), saturated with disodium edetate and urea, was used as a mobile phase for the papers impregnated with the mixture of Solutions A and B.

Method—A series of methanolic solutions of tetracycline base (1 mg./ml.) was prepared and stored in glass-stoppered bottles for 0, 1, 2, 3, 4, 5, 6, 7, 10, and 15 days at 26°. Other methanolic solutions of tetracycline hydrochloride (1 mg./ml.) were prepared and similarly stored for 0 and 10 days at 26°. Ten microliters from each fresh methanolic standard solution and sample solution were separately spotted on the impregnated chromatographic papers, prepared as previously described. The chromatograms were then allowed to dry partially in air; while still damp, they were transferred to the ascending chromatographic tank containing 100 ml. of the developing solvents. After the solvent front reached about 22 cm. above the starting line, the chromatograms were air dried. The separated spots were located under UV light after exposure to ammonia vapor for at least 15 sec. Mean R_f values of tetracycline and its degradation products were calculated.

Quantitative Analysis of Tetracycline Hydrochloride and Tetracycline Phosphate in Different Pharmaceutical Preparations—A starting line (10 cm.) was marked on a sheet of chromatographic paper (17.5 × 28 cm.), about 4 cm. from one end of the sheet and 2 cm. from the edges. The chromatogram was prepared as previously mentioned. Tetracycline hydrochloride solution [0.1 ml. (100 mcg.)] in methanol or a suitably diluted aliquot of another preparation was streaked on the line. The chromatogram was placed in the chromatographic tank as described previously. After the solvent front had moved about 22 cm., the chromatogram was air dried. A blank paper without antibiotic was similarly treated. The yellow fluorescent band of tetracycline was located under UV light after exposure to ammonia vapor. It was cut into 0.5-cm. squares, with equivalent areas taken from the blank paper. The bands of tetracycline and blank were separately eluted with 20 ml. of dilute hydrochloric acid (pH 1.8). The absorbance of tetracycline present in the eluate was determined spectrophotometrically at 355 nm. (17), within 1 hr., against the eluate of tetracycline standard using 2-cm. silica cells.

This procedure was used to determine the tetracycline content of capsules, injections, suspensions, pediatric drops, and ointments. Previously published methods (15) for preparing samples of oxytetracycline before application to the chromatographic papers were successfully used in the case of the tetracycline preparations. The method was also used to determine tetracycline phosphate in pharmaceutical preparations containing oleandomycin. The calculated potencies of the investigated tetracycline dosage forms are compiled in Table I.

The method was utilized to monitor the stability of tetracycline hydrochloride and tetracycline base solutions in methanol during 6 days of storage at 26°.

RESULTS AND DISCUSSION

Epimerization of tetracycline is known to proceed at a higher rate at pH 2–6 (1). Accordingly, epimerization is expected to take place on paper previously saturated with McIlvaine's buffer, pH 3.5, and this is actually the case (13). Therefore, the pH of the impregnating solution was raised to 7.4 in order to avoid such epimerization.

Separate use of either urea or disodium edetate solution in McIlvaine's buffer (pH 7.4) as an immobile phase proved to be unsatisfactory for the complete separation of tetracycline from its degradation products. The impregnation of the chromatographic papers with urea solution resulted in a marked lowering of the R_f values with the formation of intermingled zones of tetracycline and

[2] The following apparatus and reagents were used: (*a*) spectrophotometer, Carl Zeiss Jena; (*b*) UV lamp, HPW-125 W, type 57202 E/7, Philips; (*c*) ethyl acetate, acetone, methanol, disodium edetate, urea, and hydrochloric acid, all analytical grade; (*d*) tetracycline hydrochloride, tetracycline base, and troleandomycin USP or NF grade; and (*e*) tetracycline hydrochloride, international standard, provided by the World Health Organization.

Table I—Stated and Calculated Potency Values of Tetracycline in Different Dosage Forms

Dosage Form[a]	Stated Potency	Calculated Potency[b]	Standard Deviation
Tetracycline Hydrochloride Preparations			
Capsule	250 mg./capsule	252.8 mg./capsule	±4.20
Suspension	125 mg./5 ml.	93.5 mg./5 ml.	±1.15
Ointment	30 mg./g.	30.5 mg./g.	±0.99
Tetracycline Phosphate Preparations			
Suspension	125 mg./5 ml.	121.7 mg./5 ml.	±3.04
Injections:			
No. 1 (reconstituted with the provided vehicle)	100 mg./2 ml.	81.4 mg./2 ml.	±2.60
No. 2 (reconstituted with methanol)	100 mg./2 ml.	94.5 mg./2 ml.	±1.60
Pediatric drops	100 mg./ml.	97.7 mg./ml.	±1.80
Preparations Containing Tetracycline Hydrochloride and Oleandomycin			
Synthetic mixture	91 mg./136 mg.	90.8 mg./136 mg.	±2.40
Capsule	167 mg./capsule	169.3 mg./capsule	±0.94
Suspension	83.3 mg./5 ml.	84.2 mg./5 ml.	±0.95
Pediatric drops	66.7 mg./ml.	68.4 mg./ml.	±3.20
Injection	66.7 mg./2 ml.	65.2 mg./2 ml.	±1.40

[a] Commercial samples. [b] Average of four determinations.

epitetracycline; both adhered to the starting line. On the other hand, the use of a disodium edetate solution as an immobile phase produced diffuse spots with higher R_f values. The impregnation of the chromatographic papers with the mixture of Solutions A and B (1:3) gave the best results for the quantitative separation of tetracycline from its degradation products.

Figures 1 and 2 show the decomposition of tetracycline hydrochloride and tetracycline base in methanol. The acid decomposition products of tetracycline were obtained by heating tetracycline solution in 2 *N* HCl on a steam bath for 10 min., and they were then detected by spotting on the chromatogram after the appropriate dilution with methanol. Figure 2 shows that the acid-catalyzed decomposition of tetracycline proceeds mainly through the formation of anhydro derivatives of the antibiotic and its epimer. When the antibiotic was eluted from the chromatogram using ammonium chloride solution (10% w/v), it showed a shift of λ_{max} toward the lower wavelength, thus confirming the complex formation of the antibiotic on the chromatogram. The ammonium chloride solution was chosen as the eluent because tetracycline was reported to be stable in it (13). However, the use of the ammonium chloride solution gave low recoveries of the antibiotic. Dilute hydrochloric acid (pH 1.8) was found to be satisfactory as an eluting medium. The

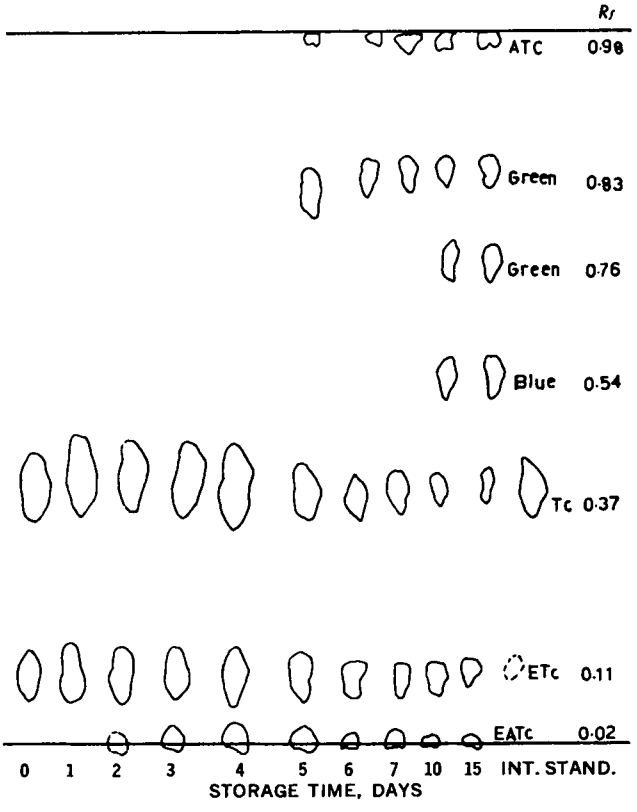

Figure 1—*Schematic chromatogram of the degradation products of tetracycline base in methanol. Key: TC, tetracycline; ETC, epitetracycline; ATC, anhydrotetracycline; and EATC, epianhydrotetracycline.*

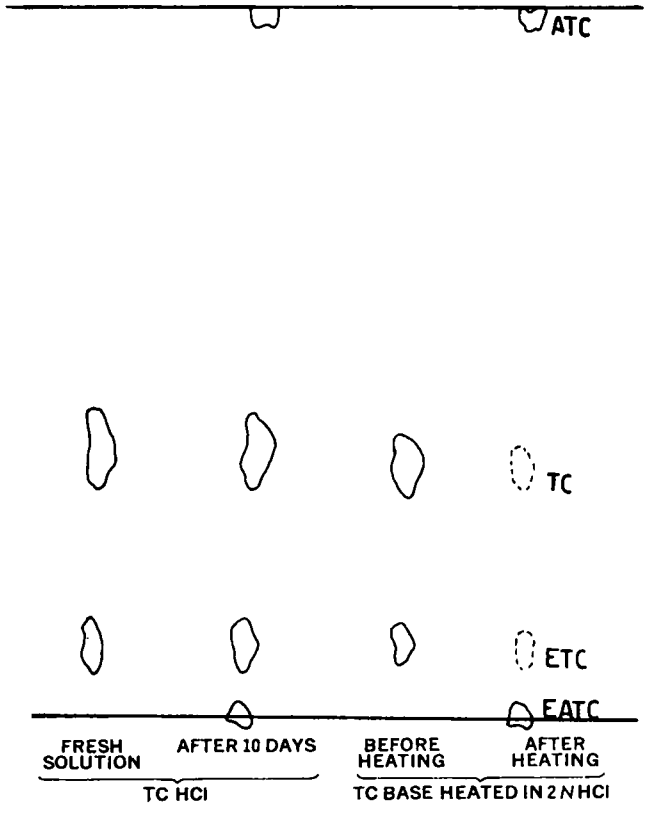

Figure 2—*Schematic chromatogram of the degradation products of tetracycline hydrochloride in methanol and the catalytic decomposition products of tetracycline base in hydrochloric acid. Key: TC, tetracycline; ETC, epitetracycline; ATC, anhydrotetracycline; and EATC, epianhydrotetracycline.*

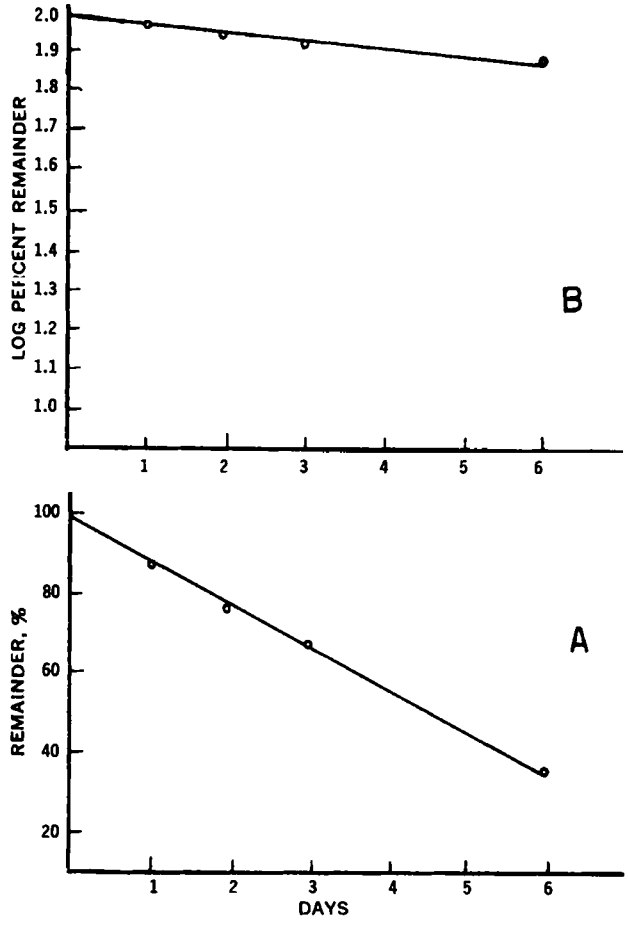

Figure 3—*Stability of tetracycline base (A) and tetracycline hydrochloride (B) solutions in methanol at 26°.*

absence of degradation spots on rechromatographing the acid eluate of tetracycline indicated that the antibiotic was not decomposed during the development and that it was stable in this solution for at least 1 hr. after elution. The absorbance of the antibiotic acid eluate at 355 nm. after 1 hr. was not changed. These results were parallel to those obtained by McCormick *et al.* (3).

The maximum load of the paper was found to be 10 mcg./spot. This necessitates the use of a horizontal line technique for applying at least 100 mcg. of the antibiotic to the chromatogram, providing a final concentration of about 5 mcg./ml. in the eluate.

Tetracycline hydrochloride, international standard, was used to study the precision and accuracy of this method. The zones representing tetracycline and 4-epitetracycline in the standard sample were combined and eluted with dilute hydrochloric acid (pH 1.8). The absorbance of the eluate at 355 nm. was compared with that of total tetracycline taken to find out the recovery of the antibiotic. Five samples gave an average recovery of 99.2 ± 1.7%.

Table I shows stated and calculated potencies of various dosage forms of tetracycline such as capsules, suspensions, injections, pediatric drops, and ointments. The data indicate that the calculated potencies of tetracycline hydrochloride capsules and ointments were close to the stated potencies. The calculated potency of tetracycline hydrochloride suspension was found to be much less than the stated potency. On observing the chromatogram of this preparation, it was found that the zone representing 4-epitetracycline was much larger than that observed in the other preparations. In addition, anhydrotetracycline was clearly detected on the chromatogram. From Table I, it is obvious that the presence of oleandomycin did not interfere with the chromatographic determination of tetracycline hydrochloride in the tested pharmaceutical preparations. The data reveal that the method is satisfactory for the determination of the antibiotic content of tetracycline phosphate in suspensions, injections, and pediatric drops. Paper chromatographic determination of tetracycline phosphate injection, after reconstitution with the provided aqueous vehicle, indicated that its potency was much less than the stated value. On the other hand, the direct measurement of the same injection, after reconstitution with methanol and immediate application on the chromatogram, gave higher results (Table I). This unexpected result might be attributed to the interference of certain additives present in the injection formulation. This suggestion is supported by the fact that the additives present in the injection are not completely dissolved in methanol. Consequently, the interference effect of these substances was greatly eliminated by the direct use of methanol as a reconstituting solvent prior to the application on the chromatogram. On the other hand, the administration of this type of tetracycline phosphate injection should be carried out promptly to avoid the degradation of the antibiotic in the reconstituting aqueous vehicle.

Table II—Microbiological and Chromatographic Estimations of Tetracycline Hydrochloride in Capsules and Suspensions

Dosage Form	Stated Potency	Calculated Potency: Microbiological Method	Calculated Potency: Chromatographic Method
Capsule	250 mg./capsule	278.8 mg./capsule	252.8 mg./capsule
Suspension	125 mg./5 ml.	97.4 mg./5 ml.	93.5 mg./5 ml.

The official microbiological method (18) was used to determine the antibiotic content of tetracycline hydrochloride capsules and suspensions. The cup-plate method was employed, and *Bacillus cereus* (var. mycoides, ATCC 9643) was the test organism used (19). The results obtained (Table II) are comparable to those obtained by the developed chromatographic procedure within 10%.

Figure 3 shows the stability of tetracycline base and hydrochloride in methanol. In the case of tetracycline base, the antibiotic decomposed through a zero-order reaction rate (K = 11.04/day), while the antibiotic decomposition of tetracycline hydrochloride followed the first-order rate (K = 0.052/day). Tetracycline hydrochloride was distinguished by its higher stability compared to the tetracycline base.

So far, the quantitative separation of tetracycline from its degradation products by chromatography has been more effectively carried out by TLC and column procedures (20, 21). The reported degradation products, which appeared as three spots on the chromatogram, were characterized as epianhydrotetracycline, epitetracycline, and anhydrotetracycline. However, previously attempted methods for the quantitative separation using paper chromatography failed to separate all of the degradation products of the antibiotic (11–14). By using the developed method, the quantitative separation of tetracycline from six degradation products was realized; three degradation products were characterized. The running time was rather short (3 hr.). Several precautions were taken to guard against degradation of tetracycline on the chromatogram, [*i.e.*, raising the pH to 7.4 to eliminate the possibility of epimerization (1) and using urea for impregnating the chromatogram and saturating the running solvents] and they contributed to the formation of a more stable complex (16). Furthermore, urea helped in the separation of the degradation products and led to the formation of well-defined spots.

In conclusion, the developed method proved adequate for the control determinations of tetracycline in different pharmaceutical preparations. It is also satisfactory as a stability-indicating assay for the selective determination of tetracycline in the presence of its decomposition and reaction products. The accuracy of the determination of tetracycline is superior to the commonly employed microbiological procedure, which has an uncertainty of about 15%, an order of magnitude less precise than the presented chromatographic method.

Analysis of Adrenocortical Steroids in Pharmaceutical Preparations by High-Pressure Liquid–Liquid Chromatography

MICHAEL C. OLSON

Abstract □ The adrenocortical steroids hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate were separated by liquid–liquid chromatography. A commercially prepared reverse-phase cyano ethyl silicone column was used in conjunction with a UV precision photometer. Linearity studies were carried out using the internal standard technique and peak height measurements. Responses of each steroid were linear over the working range when *equal* injection volumes were used. The results of a study of the controlled decomposition of hydrocortisone in basic solution indicated a good separation of drug from the degradation products. Samples of adrenocortical steroids in various dosage forms, primarily creams and ointments, were analyzed by the proposed procedure, yielding a single steroid assay value and an identification and quantitation of each foreign steroid. The sample preparation was a simple dissolution of the steroid in alcohol plus the addition of an internal standard prior to injection.

Keyphrases □ Adrenocortical steroids in pharmaceutical preparations—analyzed by high-pressure liquid–liquid chromatography □ Steroids (hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate)—analyzed by high-pressure liquid–liquid chromatography □ High-pressure liquid–liquid chromatography—analysis of adrenocortical steroids □ Chromatography, high-pressure liquid–liquid—analysis of adrenocortical steroids

Liquid–liquid chromatography is actively being investigated for drug analysis (1–9). Studies of various groups of steroids have demonstrated that both qualitative detection (10–16) and quantitative measurements (17–19) may be performed. Except for these particular works (17–19), no other reports appear to have been published dealing with the quantitative analysis of adrenocortical steroids.

The official compendial approaches (20, 21) to the assay of four adrenocortical steroids—hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate—employ well-established methods. The steroids are either extracted with alcohol for total steroid content or separated by TLC to isolate a single steroid, after which the actual measurement is carried out by blue tetrazolium colorimetry. When tablets are assayed, the foreign steroid content is determined as the difference between the results of the single steroid and the total steroid assays. The problems with the blue tetrazolium color reaction—*viz.*, its nonspecificity for individual steroids and the many compounds that interfere with it, have been thoroughly documented (22–26).

Other analytical methods for steroid analysis are available (27–31). These include spectrophotometry and colorimetry, approaches that possess the same problems in varying degrees as does the blue tetrazolium color reaction, and GLC where the problem is the labile nature of the corticosteroids. If steroid derivatives are formed to ensure thermal stability, complete and specific derivatization must be achieved.

This work describes a study of a liquid–liquid chromatographic method for the analysis of hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate and the basic aqueous decomposition of hydrocortisone. The linearity of the detector response to the concentration of the steroid was confirmed for each steroid and actual commercial products; creams, ointments, lotions, and suppositories were analyzed for the presence, identification, and quantity of foreign steroids and for the main steroid component in terms of the single steroid assay value. This method was fast, accurate, and specific for each individual steroid studied.

Analysis of Adrenocortical Steroids in Pharmaceutical Preparations by High-Pressure Liquid–Liquid Chromatography

MICHAEL C. OLSON

Abstract □ The adrenocortical steroids hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate were separated by liquid–liquid chromatography. A commercially prepared reverse-phase cyano ethyl silicone column was used in conjunction with a UV precision photometer. Linearity studies were carried out using the internal standard technique and peak height measurements. Responses of each steroid were linear over the working range when *equal* injection volumes were used. The results of a study of the controlled decomposition of hydrocortisone in basic solution indicated a good separation of drug from the degradation products. Samples of adrenocortical steroids in various dosage forms, primarily creams and ointments, were analyzed by the proposed procedure, yielding a single steroid assay value and an identification and quantitation of each foreign steroid. The sample preparation was a simple dissolution of the steroid in alcohol plus the addition of an internal standard prior to injection.

Keyphrases □ Adrenocortical steroids in pharmaceutical preparations—analyzed by high-pressure liquid–liquid chromatography □ Steroids (hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate)—analyzed by high-pressure liquid–liquid chromatography □ High-pressure liquid–liquid chromatography—analysis of adrenocortical steroids □ Chromatography, high-pressure liquid–liquid—analysis of adrenocortical steroids

Liquid–liquid chromatography is actively being investigated for drug analysis (1–9). Studies of various groups of steroids have demonstrated that both qualitative detection (10–16) and quantitative measurements (17–19) may be performed. Except for these particular works (17–19), no other reports appear to have been published dealing with the quantitative analysis of adrenocortical steroids.

The official compendial approaches (20, 21) to the assay of four adrenocortical steroids—hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate—employ well-established methods. The steroids are either extracted with alcohol for total steroid content or separated by TLC to isolate a single steroid, after which the actual measurement is carried out by blue tetrazolium colorimetry. When tablets are assayed, the foreign steroid content is determined as the difference between the results of the single steroid and the total steroid assays. The problems with the blue tetrazolium color reaction—*viz.*, its nonspecificity for individual steroids and the many compounds that interfere with it, have been thoroughly documented (22–26).

Other analytical methods for steroid analysis are available (27–31). These include spectrophotometry and colorimetry, approaches that possess the same problems in varying degrees as does the blue tetrazolium color reaction, and GLC where the problem is the labile nature of the corticosteroids. If steroid derivatives are formed to ensure thermal stability, complete and specific derivatization must be achieved.

This work describes a study of a liquid–liquid chromatographic method for the analysis of hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate and the basic aqueous decomposition of hydrocortisone. The linearity of the detector response to the concentration of the steroid was confirmed for each steroid and actual commercial products; creams, ointments, lotions, and suppositories were analyzed for the presence, identification, and quantity of foreign steroids and for the main steroid component in terms of the single steroid assay value. This method was fast, accurate, and specific for each individual steroid studied.

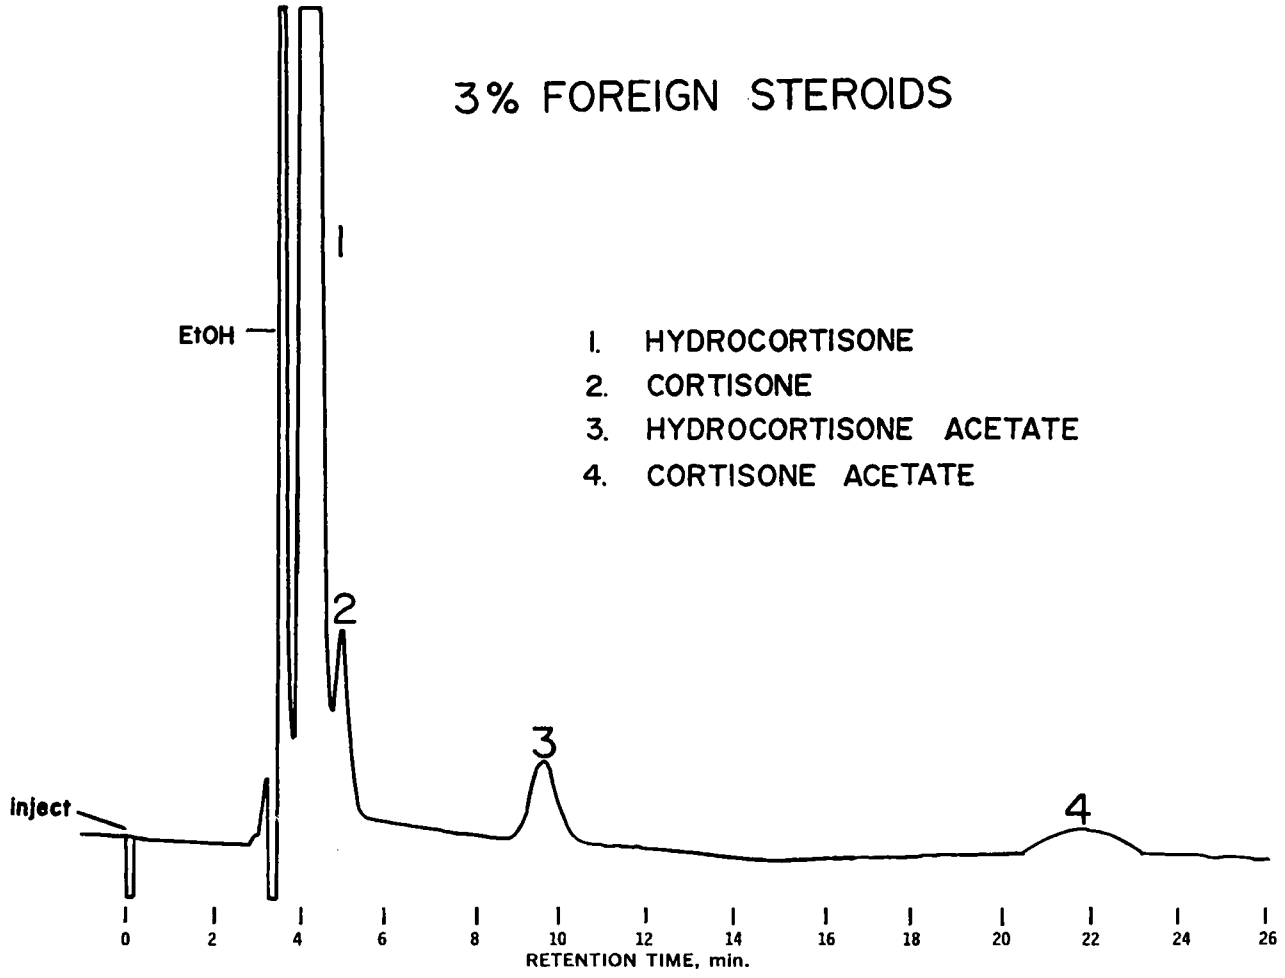

Figure 1—*Chromatogram of standards, 3% (w/w) cortisone, hydrocortisone acetate, and cortisone acetate, based on 6 mg. of hydrocortisone on the cyano ethyl silicone column illustrating foreign steroids test. Mobile phase = 1% methanol in water, attenuation = 0.02 aufs., pressure = 500 psig., flow rate = approximately 0.5 ml./min., and temperature = ambient.*

EXPERIMENTAL

Chemicals, Apparatus, and Instrumentation—Solvents were at least reagent grade and the steroid standards were either official grade (USP or NF) or working grade with a purity greater than 99.0%. Ethanol refers to 95% ethanol (USP grade).

All injections were made with either a 5-μl. high-pressure syringe[1] or a 10-μl. syringe[1] equipped with a Kel-F guide[1].

A liquid–liquid chromatograph[2] equipped with a precision UV photometer set at 254 nm. was used. The columns were precision-bore stainless steel, 1 m. × 2.1 mm. i.d., commercially[3] packed with either a cyano ethyl silicone[4] coated 1% on Zipax or an octadecyl silane[5] permanently bonded to Zipax.

Unless otherwise noted, the instrument parameters for the cyano ethyl silicone column were as follows: pressure, 500 psig. (flow rate approximately 0.5 ml./min.); temperature, ambient (approximately 25°); and mobile phase, water containing about 1% methanol.

Method for Linearity Study—The four steroids were studied on the cyano ethyl silicone column. It was convenient to prepare only two solutions (I and II), both in ethanol, containing all of the steroids in combination with the chosen internal standard; the latter, for convenience, was one of the steroids itself. The concentration range (in micrograms per milliliter) over which each steroid was studied was: Solution I—hydrocortisone, 500–15.6; cortisone 500–15.6; and hydrocortisone acetate, 1500–46.9; and Solution II—hydrocortisone acetate, 1000–31.2; and cortisone acetate, 2000–62.5.

Solution II was injected at a higher pressure, 1200 psig., to shorten the retention time of the latest eluting compound, cortisone acetate. Varied amounts of each dilution of the two solutions were injected into the liquid chromatograph in a pattern such that the concentration level of each solution was half of the concentration of its predecessor. As a result, to maintain a relatively constant detector response, a reciprocal attenuator setting was chosen for the recorder. The actual injection scheme for each solution is presented in Table I. The peak heights were measured for each compound.

Decomposition of Hydrocortisone—A 1.00-ml. volume of a 1-mg./ml. solution of hydrocortisone standard in ethanol was pipeted into 11 10-ml. volumetric flasks. Then 1.00 ml. of a 0.05 *N* aqueous sodium hydroxide solution was added. After sitting at room temperature for specific periods, 1.00 ml. of 0.05 *N* aqueous hydrochloric acid was added to quench the reaction. The solutions were diluted to volume with ethanol, and multiple injections of each solution were made on the cyano ethyl silicone column. As an index of steroid remaining, the hydrocortisone peak height was measured for each injection and the average peak height for each decomposition time was calculated.

Sample Analysis: Foreign Steroids and Assay—Random samples of creams, ointments, suppositories, and lotions containing hydrocortisone, hydrocortisone acetate, and cortisone acetate were obtained. The sample preparation was identical for each dosage form, with the only differences being the sample size for each different steroid and their respective internal standards. The following was the generalized sample preparation procedure used.

A sample equivalent to 6 mg. of hydrocortisone or cortisone, 12 mg. of hydrocortisone acetate, and 25 mg. of cortisone acetate

[1] Hamilton Co., Whittier, CA 90608

[5] ODS.

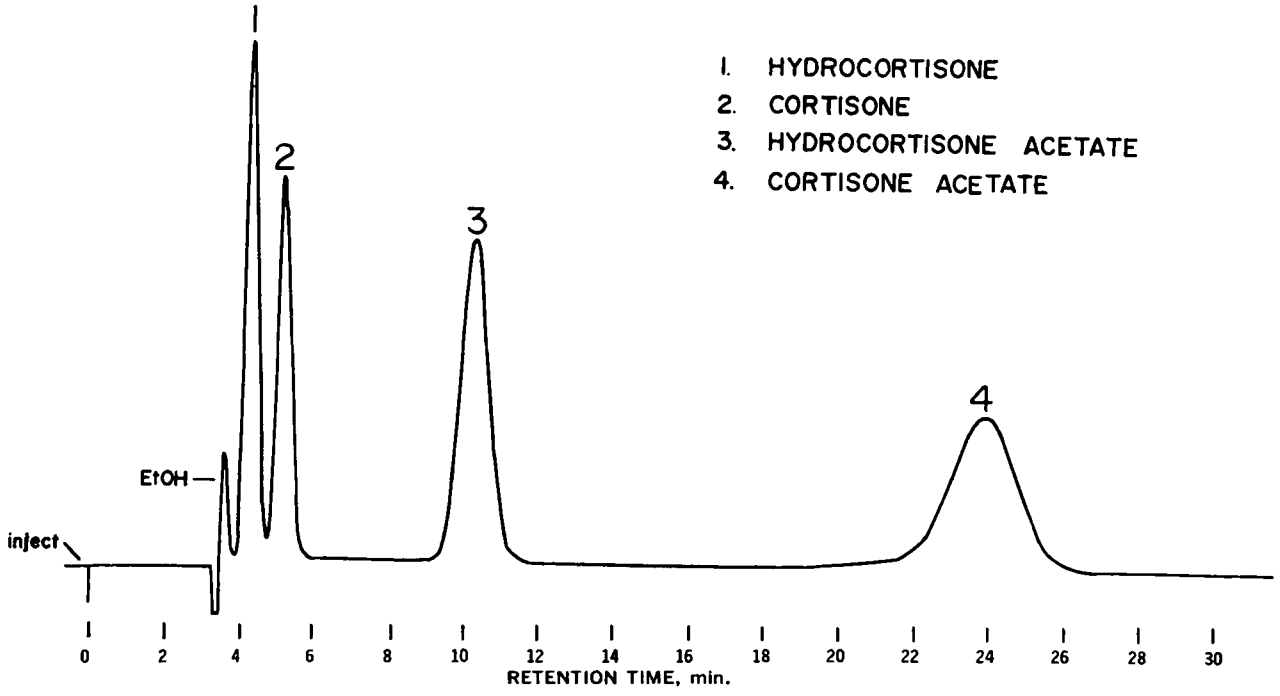

Figure 2—*Chromatogram of standards, hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate, on the cyano ethyl silicone column. Mobile phase = 1% methanol in water, pressure = 500 psig., flow rate = approximately 0.5 ml./min., and temperature = ambient.*

was accurately weighed into a 50-ml. glass-stoppered centrifuge tube. A 30-ml. volume of hot ethanol was added and the tube was shaken by hand or held on a mixer[6] for a few minutes, heated on a steam bath, and mixed again. If the sample dissolved totally or formed a cloudy suspension without any solid material remaining on the bottom of the tube, it was ready for the next step of the procedure. Further treatment was required if the ethanol was not dispersed into the semisolid base. This additional treatment included reheating, additional shaking, or ultrasonic agitation. After the solubilization step, the sample was allowed to cool, overnight if convenient, to allow the excipient materials to settle out; the tube was then centrifuged at about 1500 r.p.m. for 20 min.

To determine the foreign steroids content, this solution was injected onto the cyano ethyl silicone column at a recorder attenuation of 0.02 absorbance unit full scale (0.02 aufs.), a value four times as sensitive as the one used for the assay procedure (0.08 aufs.). A foreign steroid standard was prepared, which in the case of hydrocortisone was based on a sample size equivalent to 6 mg. of this steroid, containing each contaminant 3% by weight of the subject steroid. The chromatogram of this standard is shown in Fig. 1. In preparing the standards for the other three steroids, it was just a matter of varying the amounts of each of the four steroids, since they are cross-contaminants for each other. By using the standard chromatogram as a guide, the approximate level of each contaminant was determined.

If it appeared that the foreign steroids level was excessive, a more accurate quantitative determination could be made by increasing the sample size or by injecting the sample at a higher sensitivity. (The maximum sensitivity for the instrument used in these studies was 0.005 aufs.).

To carry out the assay, equal amounts of the appropriate internal standard were added to both the sample and a standard preparation and equal volumes of both solutions were injected. If the steroid to be used as an internal standard is found to be a foreign steroid contaminant, another steroid may be chosen as an internal standard. The assay value was calculated using peak height measurements and Eq. 1:

$$\text{percent steroid in sample} = \frac{PH_{spl}}{PH_{std}} \times \frac{PH^{I.S.}_{std}}{PH^{I.S.}_{spl}} \times \frac{wt_{std}}{wt_{spl}} \times 100 \quad \text{(Eq. 1)}$$

where:

PH_{spl} = peak height of sample
PH_{std} = peak height of reference standard
$PH^{I.S.}_{std}$ = peak height of internal standard in the standard
$PH^{I.S.}_{spl}$ = peak height of internal standard in the sample
wt_{std} = weight of standard
wt_{spl} = weight of sample

RESULTS AND DISCUSSION

Column Selection—The principal task was to find a column that would yield the best separation of the four corticosteroids in the shortest time. The first column examined, a cyano ethyl silicone column, satisfied these criteria (Fig. 2). The numbers of theoretical plates calculated for each compound were: hydrocortisone, 1254; cortisone, 1002; hydrocortisone acetate, 907; and cortisone acetate, 741. Of the four compounds, hydrocortisone had the lowest affinity for the column, which functions on the reverse-phase principle (10, 32); the most polar mobile phase, water, was required for retention of this compound. Lowering the polarity of the mobile phase by adding alcohol produced shorter retention times for all four compounds, indicating that the optimum mobile phase was water. However, the addition of a small amount of methanol (about 1%) was necessary for column stability.

[a] x denotes an injection.

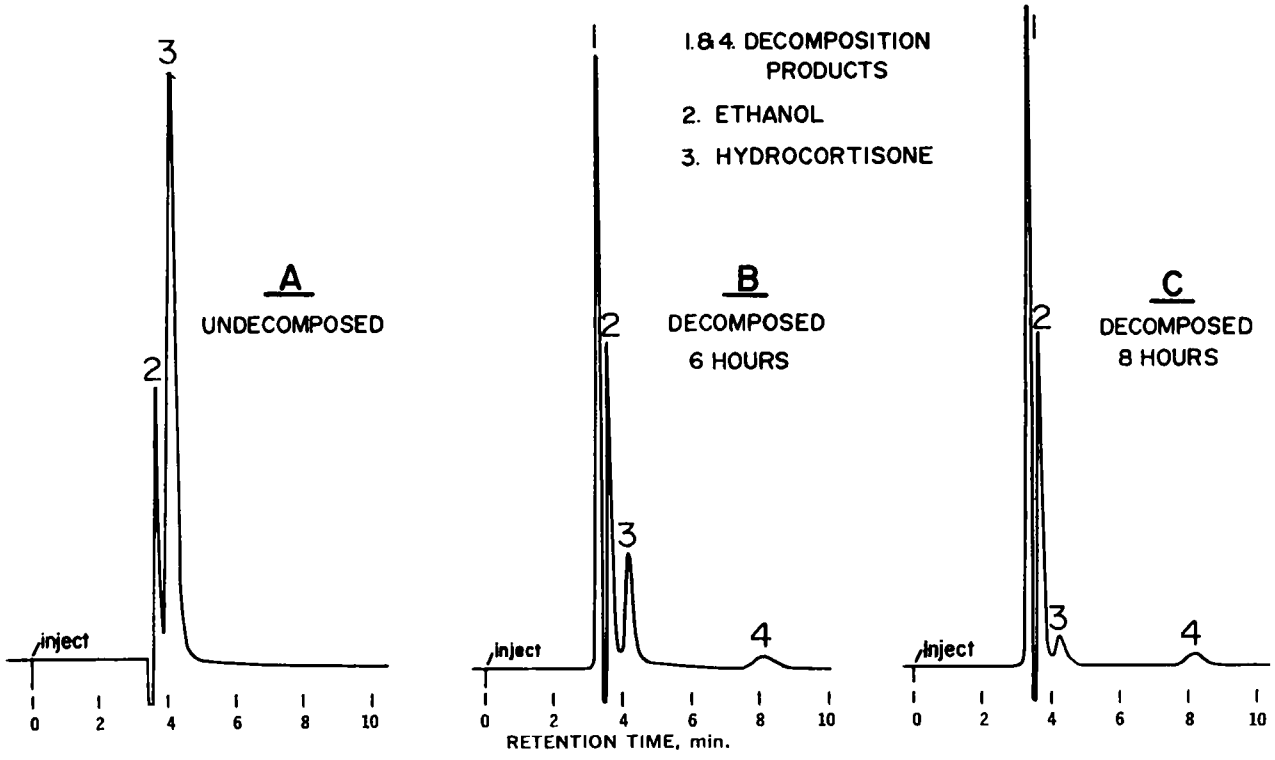

Figure 3—*Decomposed standards on the cyano ethyl silicone column. Conditions were the same as in Fig. 2, and attenuation = 0.08 aufs.*

The second column material evaluated was octadecyl silane[7]. This material, which also functions by reverse-phase chromatography, yielded the same elution order as the cyano ethyl silicone column with one exception; hydrocortisone and cortisone were not resolved. As before, water was the best mobile phase, in conjunction with a column temperature of 60° as recommended (33) and a pressure of 700 psig. Due to the need for elevated temperatures, a capability that not all instruments possess, and its inability to separate two steroids, this column was considered as second choice to the cyano ethyl silicone column for this study.

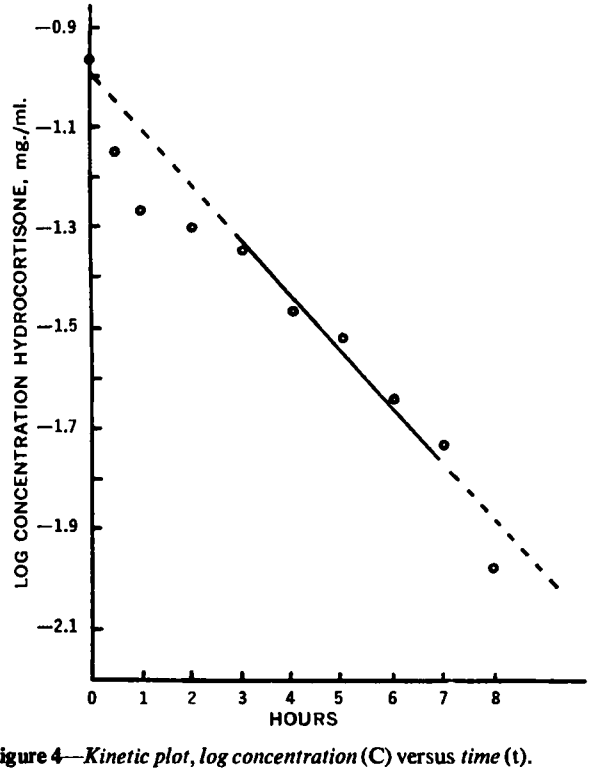

Figure 4—*Kinetic plot, log concentration* (C) versus *time* (t).

Peak Height Measurement and Linearity of Response—In all of the work presented, the quantity of active ingredient and foreign steroids was determined by using peak height measurement. While this property is most frequently used, it is recognized that a better measurement of material eluted is represented by the area under the peak. The use of peak heights is made assuming that the peak widths at half-height are equal for the same compound under the same instrumental conditions, thereby establishing the proportionality of the area to peak height. The peak height measurement was used for convenience and because the early eluting peaks have very narrow widths at half-height, making measurement of this band difficult and susceptible to large relative errors.

The relationship of detector response to the quantity of steroid was determined. This task was made more complex since the use of an internal standard in the assay procedure requires that linearity of detector response be established both for the test compound and the internal standard. To simplify the problem, the steroids were used as the internal standards for each other in the following arrangement: for hydrocortisone, cortisone, and cortisone acetate, the internal standard was hydrocortisone acetate; for hydrocortisone acetate, the internal standard was cortisone. By examining the chromatograms of Solutions I and II, it was simply a matter of measuring the peak heights for each compound and calculating the ratios of the subject steroid to the internal standard for the different pairs at each injection.

To simplify the experimental manipulations, serial dilutions of Solutions I and II were made according to the scheme summarized in Table I. The subsequent dilutions of the parent solution should have produced the same ratios for each pair if Beer's law is followed at 254 nm. over the concentration range studied. The calculated ratios are presented in Table II, columns A–F. It is apparent from columns C and E that different injection volumes of the same solution produce varying peak height ratios. When the injection volume (column C) was kept constant and the concentration was varied (column D), a relatively constant value was obtained (column E); the relative average deviation of the ratios for the different concentrations at a constant injection volume are shown in column F. From the data in

[7] Permaphase.

Table II—Results of Linearity Study

	A Subject / Internal Standard	B Retention	C Injection Volume, μl.	D Number of Different Concentrations Studied	E Average of Ratios of Peak Heights	F Reproducibility of Ratios for a Single Injection Volume in Relative Average Deviation Units, %[c]
1[a]	Hydrocortisone / Hydrocortisone acetate	55 mm. / 122 mm.	5	3	0.80	0.6
			3	6	0.92	1.2
			1	1	1.02	
2[a]	Cortisone / Hydrocortisone acetate	64 mm. / 122 mm.	5	3	0.64	1.6
			3	6	0.67	0.9
			1	1	0.69	
3[b]	Cortisone acetate / Hydrocortisone acetate	112 mm. / 50 mm.	10	3	0.82	
			8	3	0.82	
			6	6	0.82	
			4	6	0.81	
			2	6	0.80	
4[b]	Hydrocortisone acetate / Cortisone acetate	50 mm. / 112 mm.	10	3	1.21	0.9
			8	3	1.22	0.4
			6	6	1.22	0.5
			4	6	1.23	0.2
			2	6	1.25	0.3

[a] Ratios 1 and 2 were calculated from the injections of Solution I. [b] Ratios 3 and 4 were taken from the same chromatogram and are reciprocals of each other. Solution II was used in this case and the chromatogram was recorded at 1200 psig. pressure. [c] Relative average deviation =

$$\sum_{i=1}^{n} \frac{[\bar{x} - x_i]}{(n)(\bar{x})} \times 100$$

where $\bar{x}$ = mean, n = number of data, and x_i = datum.

column F, it is apparent that for identical injection volumes the compounds consistently exhibit a linear detector response for the quantity of material being measured over the range examined (35).

Decomposition of Hydrocortisone, Product Separation, and Kinetics—The decomposition of hydrocortisone in basic aqueous medium was studied to ensure the specificity of the column for this compound and its decomposition products. A study was reported (17) on flumethasone pivalate utilizing liquid–liquid chromatography. The decomposition of prednisolone was studied (34) in alkaline solution using chloroform extraction followed by UV spectroscopy. This study is cited because of the structural similarities between prednisolone and hydrocortisone, differing as they do only by a double bond in the A ring.

While the decomposition reaction for hydrocortisone is complex, the major site of reaction is at the C_{17} side chain; reaction rates and decomposition products similar to those found in prednisolone would be expected. The chromatograms obtained by injecting samples of the degraded solutions onto the cyano ethyl silicone column are shown in Fig. 3. Guttman and Meister (34) reported two classes of decomposition products in their study: a small amount of neutral material and a larger amount of acidic material. Chromatograms B and C in Fig. 3 show two additional peaks; peak 1, unretained by the column, is probably the large quantity of acidic material, and peak 4 may correspond to the smaller amount of neutral material. A hydrocortisone standard that was degraded for 72 hr. yielded no peaks at the hydrocortisone retention time using the cyano ethyl silicone column, proving that the decomposition products are separated from the parent steroid. Identification of decomposition peaks was not attempted.

The quantitative data available from the chromatograms (Fig. 3) were interpreted using familiar kinetic concepts. The average peak height for each time was used to calculate concentration (C). Since the molar ratio of sodium hydroxide to hydrocortisone is 1.81×10^4 and since previous work (34) showed the decomposition of prednisolone to be pseudo-first order, a plot of the data was made in terms of log C *versus* time (Fig. 4). A straight line is drawn in the region where five points appear to be linear. When this line is extrapolated back to the axis, the intersection is very close to the experimental value for an undecomposed solution. Similarly, the slope of the straight-line segment yields a rate constant of 0.252 $hr.^{-1}$ at room temperature. This is compared to prednisolone, at the same concentration and in a solution of the same pH as in this work, for which a rate constant of 0.293 $hr.^{-1}$ was reported (34) at 35°, a comparable but higher value than that for hydrocortisone, to be expected for a higher temperature.

The scatter of points in Fig. 4 introduces some doubt as to the reaction order. The main scatter is at the initial times where the concentrations are changing most rapidly; these points are not considered in the construction of the straight line. On the other hand, the extrapolated value (−0.99) resulting from the straight line agrees well with the experimental result (−0.97), and the agreement of the slope with that reported (34) indicates that the line is not of fortuitous origin. It may be that additional work could result in a more linear overall response, but, in any case, the method separates the decomposition products from the parent molecule effectively, a desirable attribute for any analytical approach.

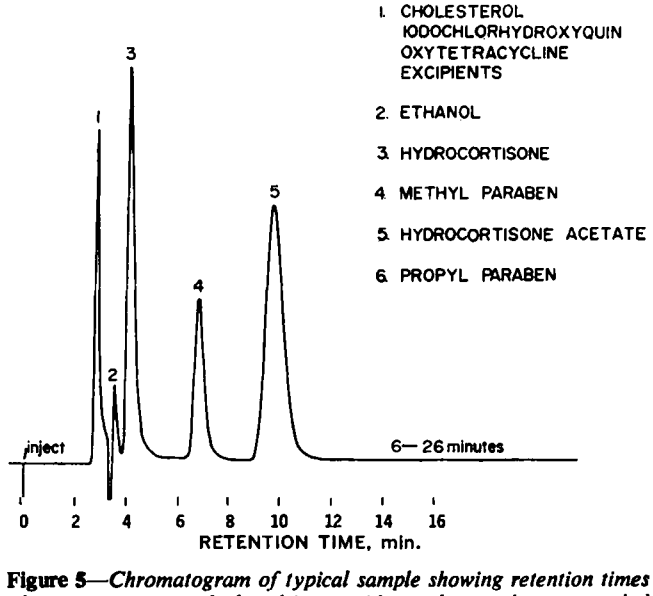

Figure 5—*Chromatogram of typical sample showing retention times of common compounds found in steroid samples on the cyano ethyl silicone column under same conditions as in Fig. 3.*

Table III—Assay Results of Commercial Samples

Number	Active Ingredient, Hydrocortisone, %	Product Type	Other Active Ingredients	Assay, % of Declared: Liquid–Liquid Chromatography	Assay, % of Declared: Other Methodology

Procedural Format—The procedure for foreign steroids and assay covers situations where both detection of undesirable steroids and measurement of the major component are accomplished. Because of the nature of the assay and its use of internal standards, the procedure should be followed as written. The determination of foreign steroids not only accomplishes the accurate detection of the related but undesirable steroidal impurity, but it assures the analyst that the elution region in which the internal standard is to emerge is vacant and not occupied by some unanticipated compound. Clearly, the foreign steroids procedure provides for the validity of the assay which follows.

Analysis of Dosage Forms—A number of pharmaceutical dosage forms were analyzed by the proposed method. This procedure is capable of identifying and quantitatively measuring the main component and each foreign steroid, if present. By using the cyano ethyl silicone column, it was confirmed that none of the products in Table III had excessive foreign steroid levels based on the tolerances in the official compendia for tablet formulations. In most cases, however, some foreign steroids were found at the 1% level. When samples were analyzed which were manufactured by the same company and differed only in the strength of the active ingredient, it was observed that the same foreign steroids were present in each product at identical levels, indicating that the steroid raw material for the products probably came from the same lot or process. This procedure would be most effective for certifying the purity of raw material steroids.

The internal standards were used to monitor and determine the sample preparation content. In determining the ratio of internal standard to steroid needed for equivalent responses, the approximate peak height response ratio used was 1:1:3:6 for hydrocortisone, cortisone, hydrocortisone acetate, and cortisone acetate, respectively. If internal standards are not available, the assay procedure may be altered to require dilution to a definite volume and multiple injections. The average peak heights would then be used to determine the assay value. This procedure would probably be less accurate but would suffice in most cases.

Assay results for the products analyzed on the cyano ethyl silicone column are given in Table III. Results achieved by other analytical methods for some samples are included for comparison. Only Sample 2 fell outside of the official limits; it was assayed by two other procedures that showed very good correlation with the proposed procedure. Sample 6 was analyzed by two different chemists using the blue and red tetrazolium procedures which yielded erratic results. This sample was assayed five times by liquid–liquid chromatography using five different sample weights from three tubes of the same code, with the results of 92.6, 96.6, 91.6, 95.6, and 97.2% of declared. The average deviation of these five results is 2.1%, which can be attributed in part to slight sample inhomogeneity but proves that it is not at the high level indicated by the tetrazolium results. One sample of hydrocortisone tablets was assayed on the octadecyl silane column and yielded no extraneous peaks other than the product peak. Due to the similarity of this and the cyano ethyl silicone columns, *i.e.*, they are both nonpolar and operate on the reverse-phase principle, it would be safe to assume that tablet formulations would provide no interferences on the latter column.

Interferences—The main problem in any chromatographic procedure is interfering compounds. In analyzing all of the products presented in Table III, none of the active ingredients in combination with the steroids interferes with the steroid peak but a problem may be encountered because of the peak ascribable to the cream, ointment, suppository, and lotion *base* or other formulation components. Most of this material is unretained by the column. In some cases where a large amount of excipient material comes through the extraction procedure, a broad peak is obtained. This results in a subsequent loss of resolution between the hydrocortisone and excipient peak. When this situation arises, care must be taken in constructing the baseline for the hydrocortisone. Products containing the other steroids do not present this problem owing to the longer retention time. Figure 5 presents a general chromatogram indicating the elution behavior of various compounds found in combination with the steroid.

This procedure appears to be applicable to other steroids that are accompanied by foreign steroid contamination. With this type of procedure, not only may the main steroid be quantitatively measured but each individual contaminant can be identified and quantitatively analyzed.

PHARMACEUTICAL TECHNOLOGY

Tooling as a Factor in Tablet Weight Variation and Control

WILFRED C. LING

Abstract □ The importance of punch length uniformity to the control of tablet weight variation was demonstrated in a rotary tablet press. An assessment of the weight variation of single-station compression on the multiple-station tablet press was obtained by means of a special isolation technique involving a force-actuated weight control device. Analysis of the relation between punch length and compression force pointed to the uncertainty of the relationship between tablet weight and compression force when variations of upper and lower punch lengths are considered. Control of tablet weight based on compression force signal suffers from this uncertainty, as demonstrated by experimental data.

Keyphrases □ Tablet weight variation—statistical contribution of individual tool parameters of rotary press □ Weight variation, tablets—statistical contribution of individual tool parameters of rotary press □ Tool parameters of rotary press—effect on tablet weight variation □ Punch length uniformity, rotary tablet press—effect on tablet weight variation

A foremost concern in the manufacture of tablets is the assurance of tablet weight uniformity. Studies of tablet weight variation on single-punch tablet machines (1, 2) have generally attributed the weight variation to nonuniform filling of the dies caused by variations in such parameters as granule size and distribution, bulk density, and flow properties of the granulations. In the case of the multiple-station rotary press, however, an

[a] Length is the working length from the face of the punch tip to the flat of the punch head. [b] All dimensions are converted from the original measurements in inches. Measurements were made to the nearest 0.0254 mm. (0.001 in.). [c] ΔL = deviation of length dimension from a reference punch in millimeters. [d] C = cup depth in millimeters.

additional source of weight variation is introduced due to dimensional variations inherent in the use of a multiplicity of punches and dies. A purpose of this study was to determine, through compression study of a single product, how dimensional variation in punch length affects weight variation and what portion of the variation is contributed by each tool parameter. A comprehensive program in tool maintenance and record keeping was described previously (3, 4). Recent establishment of standard specifications (5) of tableting tools within the pharmaceutical industry provides a sound and uniform basis for pursuing a tool control program.

Progress made in recent years on strain gauge instrumentation of the rotary tablet press allows continuous monitoring of the tablet compression process in a production situation. The relationship between tablet weight and compression force is almost linear for a significant portion of the curve (6). The use of this relation to control tablet weight automatically was reported (7, 8). However, the value of such instrumentation is contingent upon the user's awareness that the weight control is of an indirect nature and subject to restraints of dimensional tolerance of the tableting tools. Part of the data gathered in this study shows the possibility of erroneous control if tablet punch dimensions are not adequately maintained.

EXPERIMENTAL

Materials—The material used was a granulation consisting of about 94% lactose with acacia and starch binders. It is a regular production lot for producing a specially shaped ovaloid tablet with a specified average weight range of 195–205 mg. based on the weighing of 10 tablets.

Equipment—A rotary tablet press[1] with 16 stations was used. The machine was equipped with strain gauges for use with a weight checking device[2].

The punches were standard 19-mm. (0.75-in.) diameter with a flat face beveled edge tip. The tip configuration was a 12.7 × 4.8-mm. (0.5 × 0.19-in.) ovaloid with center bisection. Both the tablet press and the tooling were regular production equipment[3]. A machine speed of approximately 60 r.p.m. was used.

Method—The tablet press was set up and operated by production personnel according to standard procedures. Weight checks and hardness tests were performed prior to production runs. After about 0.5 hr. of run time, a sample of tablets was taken and bottled. These tablets were then weighed individually on an analytical balance[4] to the nearest 0.1 mg. The length of each punch was measured, using a dial comparator and a V-block, to the nearest 0.02 mm. (0.001 in.).

During this study, changes were made in the upper and lower punches as well as in the dies to evaluate their effects on tablet weight variations. In addition, the weight controller[2] was put into operation for a portion of the test run during which off-weight tablets were rejected by the control device. These rejects were individually weighed. The upper and lower weight limits were set in terms of their compression force readings according to a regression line established prior to the run. Repeated test runs established the reliability and stability of the electromechanical systems of the weight control instrument.

Table I summarizes the different parameters used in the five runs as well as the number and description of tablet samples taken in these runs.

RESULTS AND DISCUSSION

Variation of Tablet Weight—The weight data gathered from each run were treated statistically to obtain mean tablet weight, standard deviation, and frequency distribution. Figure 1 shows the frequency distribution of tablet weight for Run 1 where old punches and dies were used. The length measurement of the upper and lower punches used is shown in Table II. Figure 2 shows the frequency distribution of tablet weight when new punches with ±0.02-mm. tolerance were used. Figure 3 shows a corresponding distribution when both punches and dies were new (Run 5). The bore of the old dies, under microscopic examination, showed signs of wear. Although no attempt was made to measure the amount of wear, it was sufficient to cause frequent capping problems during all runs except Run 5, when a new set of dies was installed.

Since the purpose of this study was to determine the tooling effect on weight variation and since these effects were not time variant, all samples were collected over a period just long enough for producing a specified number of tablets. Chi-square analysis

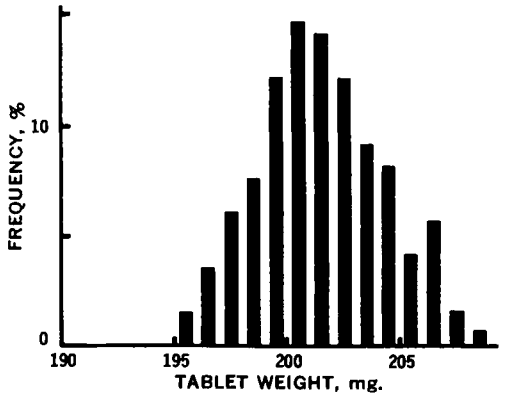

Figure 1—*Frequency distribution of tablet weight, Run 1, old punches and old dies. Mean sample weight = 201.4 mg., SD = 2.8 mg.*

of the tablet weight distribution showed that all samples gave normal distribution at the 95% probability level.

Table III lists the mean sample weight and the variances for Runs 1, 2, 3A, 4, and 5, where different tool parameters were used. No significance should be attached to the different values of mean weight as many weight adjustments were made throughout this study spanning several days. The tablets of Run 3A were made extra heavy by the use of an extra-short lower punch so that tablets produced at this station could be automatically rejected by the weight controller. The purpose was to isolate tablets made from a single-punch station and study the weight variation.

Effect of Tool Parameters on Weight Variation—Table III indicates that variance information may be derived from the available data to show what each parameter contributes toward the total variability of tablet weight. This follows from the statistical principle that the total variance of a system is equal to the sum of its components. The variances of Samples 1, 2, 3A, and 5 in Table III were tested and found to be significantly different at the 0.05 level or less.

In this study, the total weight variance was associated with the use of old punches and dies. The next level of variability occurred when the old punches were substituted with new punches, keeping all other parameters constant. The variability was still lowered by using new dies. The final level of variability was exhibited when only a single-punch station was involved. This "single-station" effect was achieved, as indicated earlier, by producing extra-heavy tablets through the use of an extra-short lower punch and rejecting (isolating) the tablets automatically through the tablet weight controller. The residual variability of the single-station compression stemmed primarily from variations due to granulations and the nontool part of the tablet press.

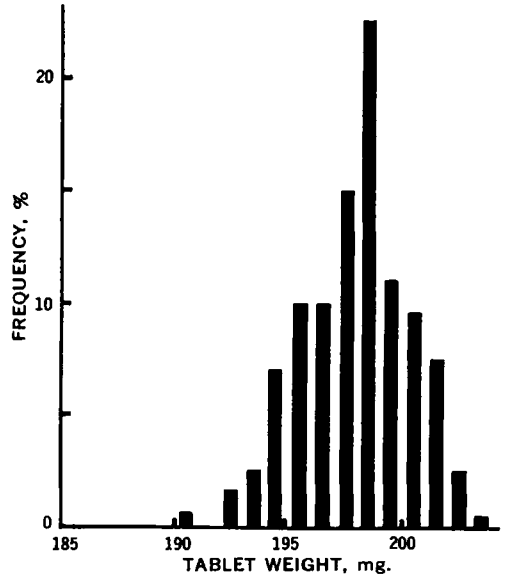

Figure 2—*Frequency distribution of tablet weight, Run 2, new punches and old dies. Mean sample weight = 197.9 mg., SD = 2.3 mg.*

Table III—Summary of Statistical Data

Run Number	Mean Tablet Weight, $\bar{x}$, mg.	Variance, S^2	Source of Variance
1	201.4	7.97	Old punches plus old dies plus single-station variability
2	197.9	5.51	New punches plus old dies plus single-station variability
3A	205.8	1.73	Single-station variability
4	204.7	5.20	Old punches plus old dies plus single-station variability plus regression error in force-weight correlation
5	201.1	4.35	New punches plus new dies plus single-station variability

Table IV shows the variance associated with each parameter. These variance components were calculated from the data of Table III in a manner shown under the column "Reference to Variance of Table III." The subscripts for the different variances, S^2, refer to the run number. Obviously, the variance component and percentages are specific to the particular system under study and cannot be generalized to other situations. For instance, a granulation with difficult flow characteristics would have a higher proportion of the total variance associated to single-station compression. Similarly, a different set of punches with a marginal maintenance record may show a large variance and, therefore, a higher percentage of the total variance due to nonuniformity of the punches. While the comparison of variances in Table IV is not intended for generalization, such analysis is useful in pointing to the significance of good tooling as reflected in tablet weight uniformity. In the present case, as much as 45% of the weight variance was eliminated by substituting old punches and dies with new tools and a 30% reduction in variance was achieved with use of close tolerance punches (±0.02 mm.) alone.

Effect of Punch Length on Automatic Weight Control Based on Punch Force—The discussions so far have been on weight variation caused by nonuniform die fill due to variations in lower punch and die dimensions. With the availability of tablet weight control devices based on compression force, the length uniformity of the upper punches assumes added importance. The following analysis considers what happens to the compression force when the length of one or both punches is changed by a fixed amount.

The density of sulfathiazole tablets was found to be (9) linearly proportional to the logarithm of compression force for all but the

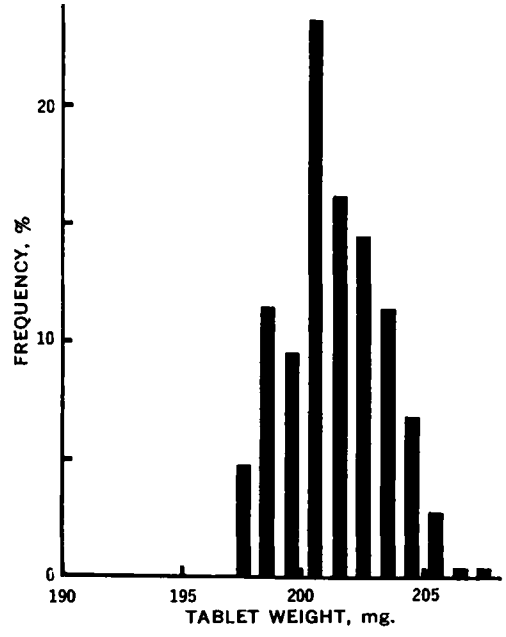

Figure 3—*Frequency distribution of tablet weight, Run 5, new punches and new dies. Mean tablet weight = 201.1 mg., SD = 2.1 mg.*

Table IV—Variance Components of a Tablet Compression System Using Old Punches and Dies

Source of Variance	Reference to Variance of Table III	Variance Component, S^2	Percent of Total Variance, %
Single-station compression	S_3^2	1.73	22
Multiple-station compression with new punches and dies	$S_5^2 - S_3^2$	2.62	33
Old punches	$S_1^2 - S_2^2$	2.46	31
Old dies	$S_2^2 - S_5^2$	1.16	14
	Total variance =	7.97	100%

highest level of force. Similar relationships have been reported for *p*-acetanisidine (methacetin) (10) and for several alkaline halides (11). This empirical relation may be expressed as follows:

$$\ln F = \ln A + B\rho_2 \qquad \text{(Eq. 1)}$$

or:

$$F = Ae^{B\rho_2} = Ae^{B\rho_1 V_1/V_2} \qquad \text{(Eq. 2)}$$

Differentiating gives:

$$dF = \frac{AB\rho_1 e^{B\rho_1 V_1/V_2}}{V_2^2}(V_2\,dV_1 - V_1\,dV_2) \qquad \text{(Eq. 3)}$$

where F = compression force, ρ_1 = bulk density of granulation, ρ_2 = density of finished tablet, V_1 = volume of die fill, V_2 = volume of tablet, A = proportionality constant, and B = proportionality constant.

For very small changes in volume, Eq. 3 may be written as follows:

$$\Delta F = \frac{AB\rho_1 e^{B\rho_1 V_1/V_2}}{V_2^2}(V_2\,\Delta V_1 - V_1\,\Delta V_2) \qquad \text{(Eq. 4)}$$

where $V_1 > V_2$, ΔF = change in compression force, ΔV_1 = change in die fill volume, and ΔV_2 = change in tablet volume.

Although data were not available to quantify the dependence of force on punch length variation according to Eq. 4, the equation does allow estimation of the direction of change in force as a result

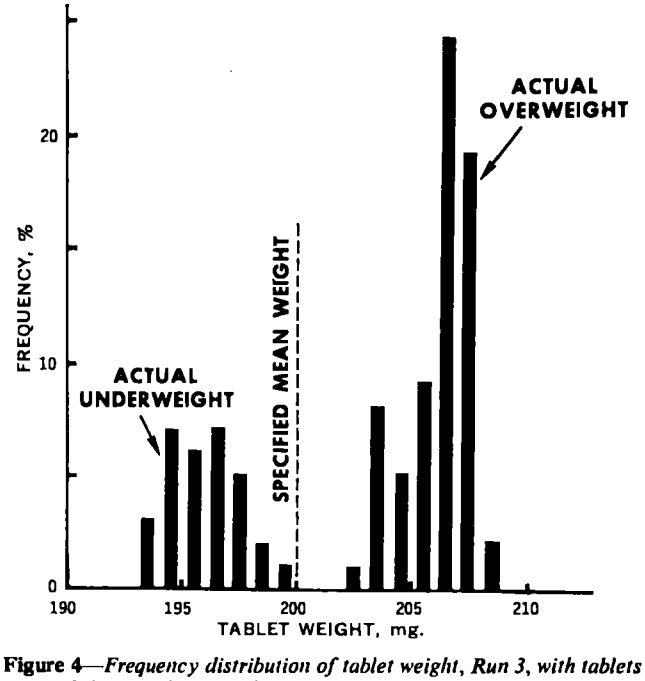

Figure 4—*Frequency distribution of tablet weight, Run 3, with tablets rejected by weight controller as underweight. One lower punch is 0.25 mm. short.*

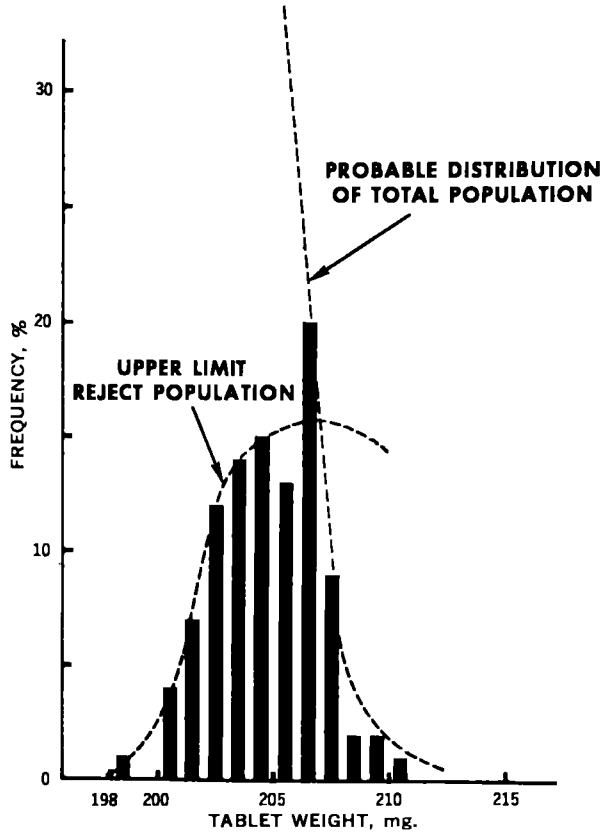

Figure 5—*Frequency distribution of tablet weight, Run 4, with tablets rejected by weight controller at upper weight limit. Mean sample weight = 205 mg., SD = 2.3 mg.*

of a fixed change in punch lengths in a selected combination. Table V illustrates the use of this method of estimation whereby punch length deviations of 0, +d, and −d were assumed for nine combinations. Depending upon these combinations, the punch length deviations can be translated as an increase (+) or a decrease (−) of the die fill and tablet volumes, ΔV_1 and ΔV_2. The tablet weight control device, receiving inputs of compression force, indicates deviation of the specified tablet weight in relation to the deviation of compression force, ΔF, from the set point. Thus, there is no weight deviation if $\Delta F = 0$, there is overweight if ΔF is positive, and there is underweight if ΔF is negative.

Examination of Table V reveals that it is possible to have the weight controller output contradicting the actual tablet weight. In fact, in the simplified analysis of Table V, only Cases 1, 5, and 9 give indicated weight (instrument output) in agreement with the actual tablet weight. The magnitude of the discrepancy between the indicated weight and actual weight would depend upon the extent of the punch length deviation, upper and lower punch combinations, tablet thickness, compression ratio, granulation density, and compressibility. Published data (9) were used in conjunction with Eq. 4 to gain an approximate estimate of indicated weight deviation based on deviations in punch length. Such a calculation showed that if one of the lower punches is short by 0.05 mm. (0.002 in.), the weight deviation as indicated by the weight control instrument would be about 0.7% overweight whereas the actual tablet is about 0.4% overweight. If both upper and lower punches of a station were 0.05 mm. (0.002 in.) short, then the indicated weight deviation would be about 2.5% *underweight* with the actual tablet weight still 0.4% overweight.

Tablet punches of wide dimensional variations are likely to produce tablets with a wide distribution of tablet weight. Under such circumstance, use of a tablet weight controller may not always assure uniformity of weight. On the contrary, erroneous control is likely, including the acceptance of rejectable tablets and rejection of acceptable tablets.

Figure 4 is a frequency distribution of tablet weight of Run 3 where an extra-short lower punch (0.25 mm. shorter than standard)

Table V—Effect of Punch Length Variation on Output Signal of Tablet Weight Controller

Case Number	Lower Punch Length[a]	Upper Punch Length[a]	ΔV_1[b]	ΔV_2[c]	ΔF[d]	Indicated Weight (from Instruments)	Actual Weight (Determined by Lower Punch)
1	Standard	Standard	0	0	0	Standard	Standard
2	Standard	+d	0	−	+	Overweight	Standard
3	Standard	−d	0	+	−	Underweight	Standard
4	−d	Standard	+	+	−	Underweight	Overweight
5	−d	+d	+	0	+	Overweight	Overweight
6	−d	−d	+	+	−	Underweight	Overweight
7	+d	Standard	−	−	+	Overweight	Underweight
8	+d	+d	−	−	+	Overweight	Underweight
9	+d	−d	−	0	−	Underweight	Underweight

[a] In this analysis, deviation from standard punch length is either +d (longer by d mm.) or −d (shorter by d mm.). [b] ΔV_1 = change in die fill volume. [c] ΔV_2 = change in tablet volume. [d] ΔF = change in compression force.

was used. The strongly bimodal distribution indicates the presence of two distinct populations within the sample. The tablets with mean weight of 195 mg. were actually underweight tablets produced at the same time as those made by the short punch station with a mean weight of 206 mg. Both groups exhibited low compression force and were rejected as underweight, although one group was actually overweight. This illustration is similar to Case 4 or 6 of Table V.

Figure 5 is a frequency distribution of tablet weight from a sample of overweight rejects. A sharp cutoff is absent at the overweight reject point. Rather, the weights are normally distributed with a standard deviation as large as that of the tablet population (Fig. 3). Underweight rejects, although not analyzed, are believed to have similar frequency distributions. Although there are other factors, tool uniformity is probably a significant factor in causing a weight distribution rather than a sharp cutoff at the rejection point. The same factor is probably also responsible for a lack of precise correlation between compression force and tablet weight. Ridgway *et al.* (8), in analyzing the performance of their closed-loop weight controller, experienced similar frequency distribution in the underweight and overweight rejects as well as scattering of data in the correlation between compression pressure and tablet weight.

SUMMARY

The weight variations of tablets produced on a rotary tablet press were analyzed. Estimates were made from the statistical data as to the contribution of each tool parameter to the total variance in tablet weight.

The effect of punch length variation was also explored for its interaction with tablet weight controllers which derive their input signal from compression force. Possible erroneous control is cautioned if critical tool dimensions are not adequately maintained.

Nitroglycerin Sublingual Tablets II: Preparation and Stability of a New, Stabilized, Sublingual, Molded Nitroglycerin Tablet

SALVATORE A. FUSARI

Abstract □ A new, molded, stabilized, sublingual nitroglycerin tablet was prepared. This tablet shows the same bioavailability as conventional tablets but has the advantage of markedly improved stability. In contrast to conventional tablets, which often develop marked intertablet dose variation within 1 month, the stabilized tablet maintains its content uniformity for long periods, even at 37 and 45°, thus assuring a more uniform and predictable dose to the patient.

Keyphrases □ Nitroglycerin sublingual tablets—preparation, stability analysis of molded tablets containing polyethylene glycol as a fixative □ Sublingual nitroglycerin tablets—preparation, stability analysis of molded tablets containing polyethylene glycol as a fixative

Many papers have reported the instability of conventional molded sublingual tablets (1–7), and all have noted that the volatilization of nitroglycerin plays a part in this instability. However, it has only recently been recognized that one fundamental change accompanying volatilization is intertablet migration of nitroglycerin, leading to large intertablet dose variation. A report (8) showed that conventional nitroglycerin tablets are unstable, not in the usual sense of chemical breakdown but with respect to (*a*) slow loss of potency due to volatilization of nitroglycerin, and (*b*) maintenance of content uniformity.

Since this instability could not be controlled by manipulating the container and cap liner, it was decided that the best solution involved reformulation of the tablet to minimize volatilization and subsequent intertablet migration of nitroglycerin.

As shown in the first paper of this series (8), all results indicated that the problem with conventional sublingual nitroglycerin tablets starts with the manufacturing process[1]. During this procedure, a mixture of alcohol and water is added to a blended mixture of nitroglycerin, lactose, and sucrose. After molding, the tablets are air dried. It is postulated that nitroglycerin can be brought to the tablet surface during the drying process by the evaporation of alcohol and water, where it becomes available for loss and/or migration by slow volatilization, depending on the character of the immediate environment. If this hypothesis is correct, the addition of a "fixing" agent to the tablets should inhibit the volatilization of nitroglycerin and help solve the problems of potency loss and intertablet dose variation caused by the migration of nitroglycerin.

This paper describes the preparation of a stabilized tablet and its properties, followed by a description of the experiments that confirmed its superior stability.

[1] This possibility was also suggested by M. D. Richman *et al.* (1).

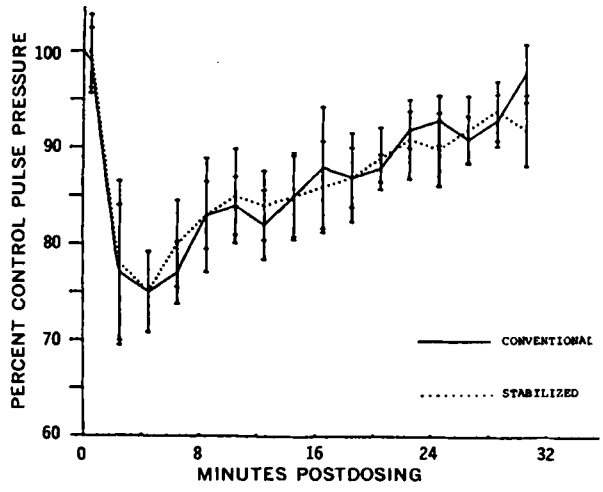

Figure 1—*Comparative bioavailability of conventional and stabilized nitroglycerin tablets in dogs.*

Both short-term stress experiments and long-term stability studies were included. While some short-term stress experiments have no necessary parallel in a real life situation, they illustrate the regulated or controlled behavior of the stabilized tablet, which is in marked contrast to the irregular behavior exhibited by the conventional tablet. The long-term stability studies are still in progress; data up to 25 months will be given.

EXPERIMENTAL

Tablet Manufacture

Molded, stabilized, sublingual tablets[2] were made in exactly the same way as conventional sublingual tablets, except that a water-soluble, nonvolatile fixing agent[3] was added to the formulation. The fixative was added as a constant percentage of the nitroglycerin present in our three different formulations (0.3, 0.4, and 0.6 mg. nitroglycerin per tablet). The lactose, sucrose, and 10% nitroglycerin tablet mixture[4] was blended in a 142-l. blender (PK), equipped with a liquid feed bar (intensifier bar), for 10 min. The granulating fluid, consisting of water, alcohol, and fixative, was added through the intensifier bar over 3 min., after which the mixture was blended for another 12 min. The intensifier bar operated continuously throughout the entire 25-min. blending period. The blended mixture was then stored overnight in a refrigerator. The molded[5] tablets were then air dried for about 20–48 hr. before bottling and packaging.

[2] Nitrostat; Parke, Davis brand of stabilized, molded, sublingual nitroglycerin tablets.

[3] Polyethylene glycol 400 was used for the tablets described in this paper, but polyethylene glycol 4000 has also been used successfully. The amount used was 85% (w/w) of the nitroglycerin in the tablet formula.

[4] E. I. duPont de Nemours supplies this as a 10% nitroglycerin–90% β-lactose (w/w) mixture.

[5] Molding was accomplished using a Colton tablet molding machine, model 720.

Biopharmaceutical Equivalence

An experimental model using dogs was developed to compare bioavailability of stabilized and conventional tablets. Six nonanesthetized adult beagle dogs, weighing 12 kg., were used. Tablets were given sublingually, and peripheral pulse pressure was monitored using an on-line computer[6] (9).

Short-Term Experiments—*Exposure to High Vacuum from Open Dishes*—Stabilized and conventional tablets were placed close to each other in open 7.62-cm. (3-in.) watch glasses or 5.3-cm. petri dishes in glass vacuum desiccators and were exposed to pump vacuum for 24 hr. This procedure was repeated three times.

Exposure to High Vacuum in Opened Commercial Containers—The caps and stuffing were removed from stabilized and conventional tablets in their commercial containers, and the bottles were placed as far away from each other as possible in *glass* vacuum desiccators. Vacuum, from a vacuum pump, was continuously applied for 24 hr., after which the vacuum (about 1 torr) was released and 30 tablets from each bottle were assayed. Four separate experiments were run.

Exposure to High Vacuum on Open Dishes in Plastic Desiccator—Two 7.62-cm. (3-in.) petri dishes were placed in a 25.40-cm. (10-in.) plastic desiccator. One dish contained stabilized tablets and the other contained conventional tablets. Pump vacuum (about 1 Torr) was applied for 23 hr., after which the vacuum was disconnected and 30 tablets from each dish were assayed. The experiment was repeated.

Storage in Polystyrene Boxes (Patient-Type Containers) for 1 Month at 37°—One hundred stabilized and conventional tablets were placed in separate polystyrene boxes, 3.81 × 5.71 × 1.58 cm. (1.5 × 2.25 × 0.625 in.), with hinged lids; two sets of boxes were used for each type of tablet. In addition, tablets of each type were stored in closed, regular amber-glass containers as controls. After obtaining an "initial time" assay, all samples were stored at 37°. One box of each set was opened twice a day for 2 min. and the other was kept closed. After 1 month, 30 individual tablets were assayed.

[6] EMR.

Table III—Effect of Storage of Stabilized Tablets and Conventional Tablets in Open Commercial Containers under Vacuum in Glass Desiccators for 24 hr.

Tablet	Diameter of Desiccator (in.)	Before Vacuum: Average Assay, % of L.C.[a]	Before Vacuum: Range of Assays, % of L.C.[a]	Before Vacuum: Percent Relative Standard Deviation	After Vacuum: Average Assay, % of L.C.[a]	After Vacuum: Range of Assays, % of L.C.[a]	After Vacuum: Percent Relative Standard Deviation
Stabilized tablet, 432 mcg. (1/150th gr.)[b]	25.40 cm. (10)	102.8	92.6–109.9	3.3	101.6	92.2–112.2	5.1

Polystyrene "closed," after 1 month	92.7	82.6–101.8	5.1	94.4	64.6–119.5	13.1

[a] Label claim.

Storage in Cardboard Boxes (Patient-Type Containers) at 37° for 1 Month—Cardboard boxes are easily available to patients. The box[7] selected measures 6.98 × 8.25 × 0.15 cm. (2.75 × 3.25 × 0.06 in.) and has an inner compartment which is completely covered over by a sliding outer shell in the manner of a safety match box. Since these boxes are not as tight as polystyrene boxes, three sets of boxes, plus a glass bottle control, were used. One box was opened two times a day for 1 month, another was kept closed, and the third box was sealed with wax. The glass bottle controls for stabilized and conventional tablets served to give the initial time assay for each set. Boxes and bottles, each containing 100 tablets, were stored at 37°. After 1 week and again after 1 month, 30 individual tablets were assayed from each box and the glass bottle.

Effect of Storage with Different Liners, Rayon Stuffing, and Periodic Bottle Opening (Closed Environment)—One lot of stabilized tablets was compared to a lot of conventional tablets. Tablets were

[7] Parke, Davis "Medicated Throat Disc" package.

[a] These results are not as dramatic as those described earlier (8) using the 648-mcg. (1/100th-gr.) tablet; however, since this was a side-by-side comparison, the results are indicative of the differences in the tablets. [b] Label claim.

placed in amber-glass bottle containers; half of the bottles had a small pledget of rayon stuffing inserted and the other half had no stuffing. One liner[8] was used for the conventional tablets, and several liners[9] were used for the stabilized tablets. After capping, all bottles were stored at 37° for 1 month. Half of the bottles of each type were used as closed bottle controls, while the remaining bottles were opened once a day, except weekends, for 2 min. for a total of 21 openings.

Effect of Storing in Presence of Placebo Tablets (Closed Environment)—This experiment was performed to compare the behavior of two types of tablets when stored with placebos. The tablets used were 432 mcg. (1/150th gr.). Three separate runs were made, two involving conventional tablets and one involving the stabilized tablet. After initial assays were run, 69 nitroglycerin-containing

[8] Excelloseal (Kerr and Owens Illinois).
[9] Excelloseal, tinfoil, Esterfoil, and polyethylene terephthalate (Mylar).

Table IX—Comparison of Retention of Original Potency for Stabilized Tablets and Conventional Tablets Exposed on Open Dishes at Room Temperature

Conventional tablet, 432 mcg. ($^1/_{150}$th gr.)	0	101.3	85.9–122.8	8.0
	28	97.9	78.6–137.4	12.0

[a] Label claim.

tablets were mixed with 30 placebo tablets in amber-glass or high density polyethylene containers and stored at 37° for 1 month. At the end of 8 days, five placebo tablets were removed from the container and assayed. At the end of 1 month, 10 placebos were removed for assay.

Complete Exposure of Tablets to Surrounding Air on Watch Glasses (Open Environment)—Stabilized and conventional tablets were applied to watch glasses, which were stored side-by-side without covering at room temperature for 5–7 days. At given intervals, 30 individual tablets were assayed.

Effect of Storage in Open Commercial Containers (Open Environment)—Stabilized and conventional tablets in bottles of 100 were obtained in-house or commercially; the caps, liners, and stuffing were removed and the containers were stored at room temperature without caps in an area free from drafts. There was a 3–4-cm. distance between the top of the tablets and the lip of the container. At given intervals, 30 tablets from a bottle were assayed; a different bottle was used at each assay period.

Long-Term Stability[10] of Conventional and Stabilized Tablets in Glass Bottles with Polyethylene Terephthalate Liners at 25, 37, and 45°—Two lots of conventional tablets were packaged exactly as were the stabilized tablets, *i.e.*, amber-glass bottle with rayon stuffing and a polyethylene terephthalate cap liner. These lots were stored under the same conditions as the stabilized tablets to obtain comparable stability data.

RESULTS AND DISCUSSION

Tablet Manufacture and Bioavailability—The stabilized tablet was designed to keep the good physical characteristics of the ordinary sublingual tablet such as ready disintegration, dissolution, and "wickability"[11], while at the same time reduce the intertablet migration of nitroglycerin by volatilization. Easy disintegration and wickability are related to the release rate of nitroglycerin and were desirable in the stabilized tablet (Table I). The stabilized and conventional tablets were required to meet the same specifications for disintegration and wickability. In actual practice, the disintegration time generally falls between 10 and 30 sec.

The average assay for stabilized tablets was 99.7% of label claim, with a range of 92.1–108.1% and a standard deviation of 4.0%;

[10] Long-term stability studies on stabilized tablets are still in progress on many lots of tablets and include storage at 4°, room temperature, 37°, and 45°.

[11] Defined as the time in seconds required for water to wet the tablet completely by capillary action under controlled conditions.

[a] Label claim. [b] A lot better than normal; 3–4 is more normal; the jump to 5.2 in 1 month probably indicates this was an exceptional bottle.

when the assays were corrected for the weight of the tablets, the standard deviation of the assays fell to 1.3%. This indicates a satisfactory blending operation and shows that the initial variability in the tablet assays is largely due to tablet weight differences. The latter are more difficult to control in a molded tablet than in a compressed tablet.

The chief virtue of molded sublingual nitroglycerin tablets has been their ability to release nitroglycerin readily. Figure 1 shows a comparison of the bioavailability of nitroglycerin from conventional and stabilized tablets in dogs. The stabilized and conventional tablets were comparable in pharmacological effect; both caused a marked fall in pulse pressure within 3 min. of sublingual administration. There was a partial return to normal over the next 10 min., but lesser effects could be seen for up to 30 min. Although not shown in Fig. 1, it was observed that the pulse pressure returned to pretest levels within 50 min. Human clinical trial followed the dog experiments and confirmed that the stabilized tablet gives the same pharmacological effect as the conventional tablet.

Effects of High Vacuum—Many different experiments were carried out under pump vacuum for 20–24 hr. at about 1 Torr to compare the behavior of the stabilized and conventional tablets. These experiments involved exposure of the different tablets either in their opened, commercial containers or in uncovered petri dishes. Both glass and plastic vacuum desiccators were used without internal drying agents[12]. In general, these experiments showed that the stabilized tablet is more retentive of its nitroglycerin than is the

[12] No phosphorus pentoxide was used in these desiccators. Two separate experiments, using phosphorus pentoxide in the bottom of glass desiccators, showed that both stabilized and conventional tablets lost large amounts of nitroglycerin. The stabilized tablets retained 70–80% of their original potency, while the conventional tablets retained only 16–30%. Moreover, the loss from the stabilized tablets was in a much more even or controlled manner than from the conventional tablets.

conventional tablet and that plastic desiccators cause a much greater loss of nitroglycerin than do glass desiccators.

The most interesting results, however, were obtained when stabilized and conventional tablets were placed in the same glass vacuum desiccator and then exposed to vacuum. The results always showed a substantial transfer of nitroglycerin from the conventional tablets to the stabilized tablets when the vacuum exposure was from open petri dishes (Table II). The results were slightly more variable in the case of the commercial containers. In one experiment, both the stabilized and conventional tablets showed a small net loss of nitroglycerin; in three other experiments there was a large transfer of nitroglycerin from the conventional to the stabilized tablets (Table III). These observations further substantiate the fact that nitroglycerin can and does migrate; they also demonstrate the high affinity of fixative for nitroglycerin. In practice, this is demonstrated by the better stability profile shown by stabilized tablets. The stabilized tablets absorbed the nitroglycerin in a controlled manner (Tables II and III); that is, there was little change in the percent relative standard deviation of the tablets after the absorption of nitroglycerin. The conventional tablets, by contrast, lost nitroglycerin very irregularly.

The experiment using plastic desiccators was prompted by an article (6) reporting FDA removal of plastic pen containers from the market because of the very high loss of nitroglycerin from these containers. The losses described were so severe, *i.e.*, 50% in 1 day, 80% in 3 days, and 93% in 30 days, as to be unexplainable on the basis of volatilization alone. It appeared that some active transport had to be involved. Observations in Table IV are in keeping with the results observed by the FDA. The results showed *severe* losses of nitroglycerin from the conventional tablets and much smaller losses of nitroglycerin from the stabilized tablets. These losses were far greater than those experienced in glass desiccators. Although the stabilized tablet lost nitroglycerin, it did so in a well-regulated manner as opposed to the large, irregular loss shown by the conventional tablets.

Effects of Patient-Type Container Storage—To duplicate actual patient use, nitroglycerin tablets were stored in hinged polystyrene and cardboard boxes (Tables V and VI). Table V indicates the sharp difference in behavior between the stabilized and conventional tablets stored in the hinged polystyrene boxes. Stabilized tablets lose considerably less potency from the open box; moreover, the potency loss occurred with much less spreading in the range of assays, *i.e.*, the content uniformity was maintained. The unopened glass bottle controls illustrate a point made previously; *i.e.*, there is considerable spreading in the range of assays for conventional tablets stored even in closed bottles (8).

Table V shows that cardboard boxes are extremely poor containers for nitroglycerin tablets. Nevertheless, the data point out that stabilized tablets lose less of their original potency than conventional tablets in the same period. The conventional tablets retained only 5–8% of their original potency, whereas the stabilized tablets retained 28–41%.

Effects of Immediate Closed Environment—The first paper of this series (8) reported that conventional nitroglycerin tablets were affected by their immediate environment and that they behaved differently in the presence of different cap liners[13].

Two experiments were performed to illustrate that stabilized tablets are more independent of their immediate closed environment than are conventional tablets. To some extent, this was al-

[13] Excelloseal retained the average potency but was unsuitable for maintenance of content uniformity. Polyethylene terephthalate (Mylar), tinfoil, fluorohalocarbon film (Aclar), and Esterfoil (supplied by Owens Illinois) liners were better than Excelloseal for conventional nitroglycerin tablets, but even they did not hold much promise for long-term maintenance of content uniformity.

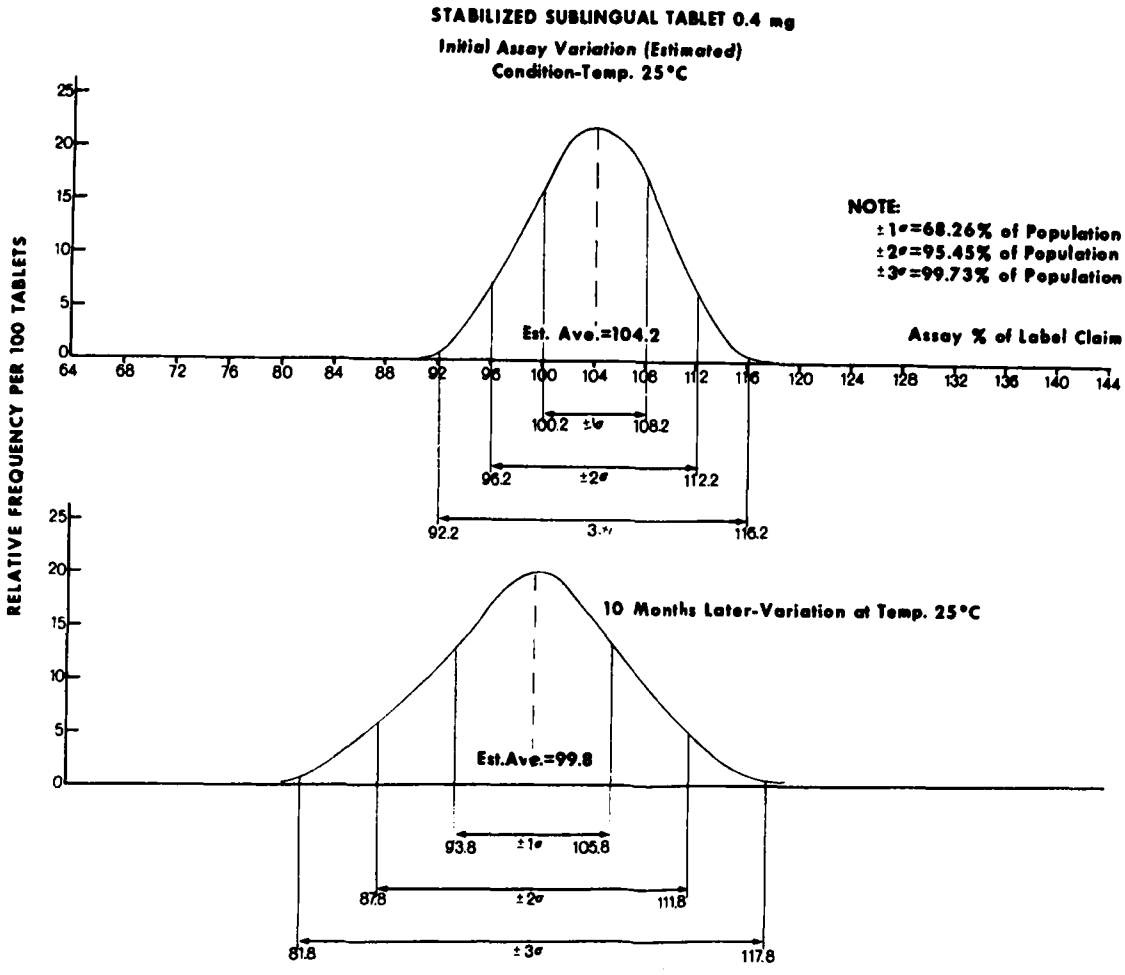

Figure 2—*Distribution curves for stabilized sublingual nitroglycerin tablets at the time of manufacture and after being packaged for 10 months.*

ready demonstrated by the polystyrene and cardboard box experiments. The two experiments were carried out in screw-capped glass bottles, which are a much preferred container to hinged polystyrene boxes. The results (Table VII) show that stabilized tablets, in contrast to conventional tablets, are little affected by their immediate container and/or the presence of rayon stuffing material, as shown by the values for average potency and standard deviation. Furthermore, daily bottle openings had little to no effect on the stabilized tablets; the latter fact is considerably important to a patient.

Table VIII shows the effect of storing stabilized and conventional tablets in the presence of placebo tablets. This experiment used different nitroglycerin-containing tablets and compressed lactose placebo tablets than were used previously (8). The results show that the stabilized tablet is more retentive of its nitroglycerin than is the conventional tablet; consequently, it maintains its content uniformity better than the conventional tablet. Recently, this same effect was also demonstrated by Shangraw and Contractor (7).

Effects of Immediate Open Environment—Two experiments were done to check the effects of an immediate open environment (Tables IX and X). Both types of tablets lost substantial amounts of nitroglycerin from open dishes (Table IX), but the stabilized tablets lost activity more slowly than the conventional tablets. After 5 days, the stabilized tablet lost the same amount or less nitroglycerin than the conventional tablets lost in 3 days. These results are, in essence, an extension of similar results obtained using cardboard boxes for storage. In the latter case, the boxes offered some protection so that the rate of loss was slower, but the results parallel each other.

The results using open commercial bottles stored in a draft-free area are in marked contrast to the results obtained on open dishes exposed to room temperature air. Very little potency was lost from either type of tablet under these circumstances. This is probably due to two factors:

1. The 3–4-cm. "dead space" above the tablets which acts as insulation from the surrounding air. In essence, the tablets are surrounded by a relatively quiescent, stagnant atmosphere instead of being swept by air currents.

2. The small surface area exposed from commercial containers compared to the larger area exposed from dishes.

Long-Term Stability—Long-term stability studies on stabilized tablets are still in progress, but some of the long-term data are summarized in Tables XI and XII. The stabilized tablets maintain both average potency and content uniformity even at 37 and 45°, thus assuring a more uniform and predictable dose to the patient.

Table XIII shows a comparison of the stability of both conventional and stabilized tablets when both types of tablets were stored under identical conditions using the same bottle and liner used for stabilized tablets. The conventional tablets develop marked intertablet dose variation within 1 month, whereas the stabilized tablets maintain their content uniformity at all temperatures tested. The stability exhibited by the stabilized tablets is a marked improvement over the stability shown by conventional sublingual nitroglycerin tablets.

Figures 2–4 give a graphical summary of the stability profiles of both stabilized and conventional tablets at room temperature. These figures show that the stabilized tablets maintain their content uniformity (Fig. 2) while the conventional tablets develop considerable intertablet dose variation (Figs. 3 and 4).

Disintegration times and wickability were also monitored during all stability studies. Although not shown in any of the tables, the values obtained were within the specification limits shown in Table I.

SUMMARY

A new, molded, stabilized, sublingual nitroglycerin tablet was prepared. This tablet shows the same bioavailability as conventional

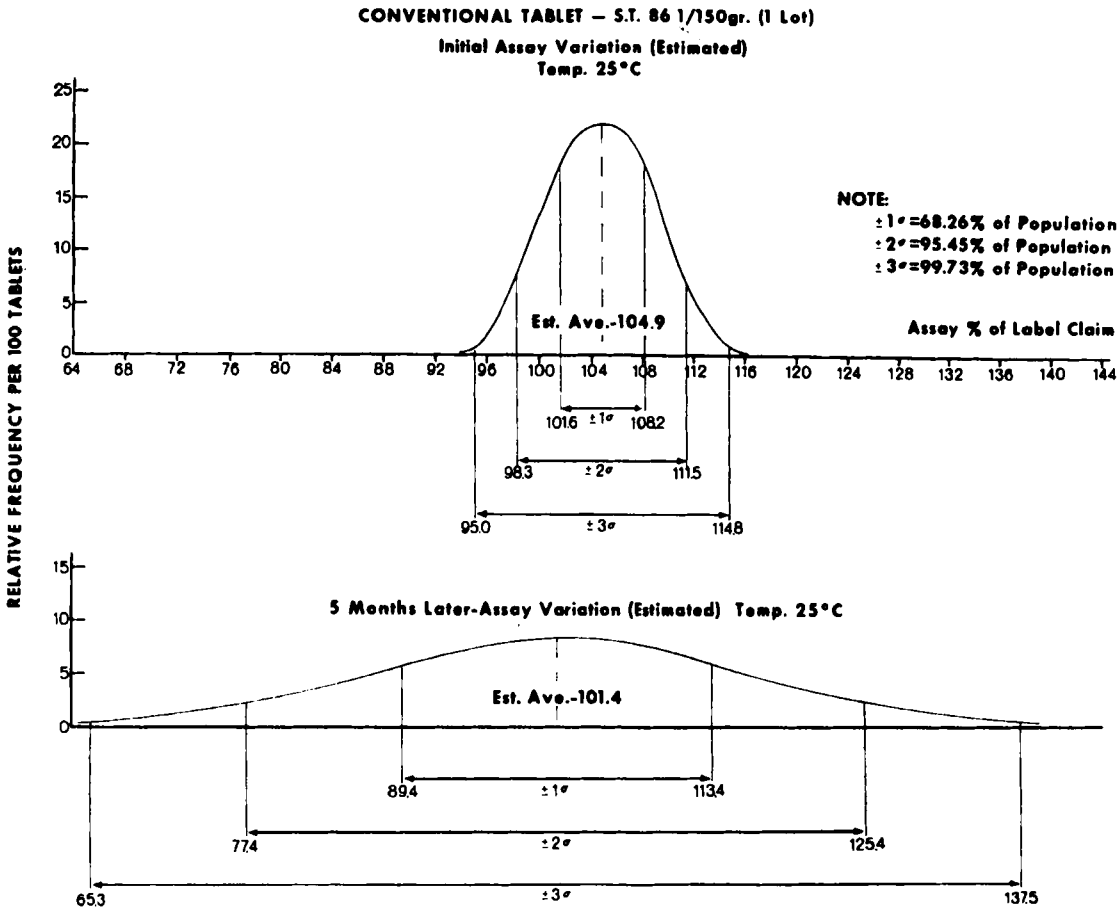

Figure 3—*Distribution curves for conventional sublingual tablets at the time of manufacture and after being packaged for 5 months.*

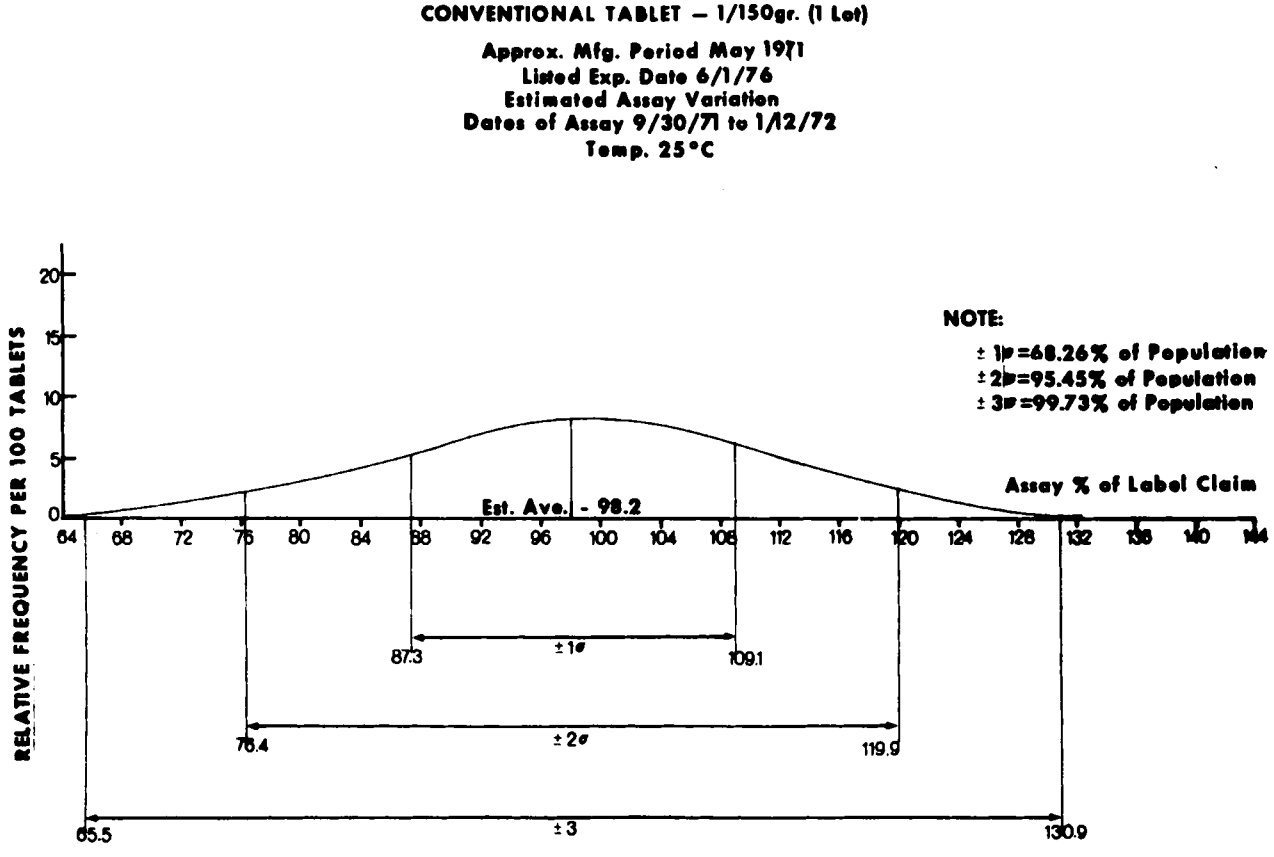

Figure 4—*Distribution curve for conventional sublingual nitroglycerin tablets after being packaged for about 7 months.*

tablets but has the advantage of markedly improved stability. In contrast to conventional tablets, which often develop marked intertablet dose variation within 1 month, the stabilized tablet maintains its content uniformity for long periods, even at 37 and 45°, thus assuring a more uniform and predictable dose to the patient.

NOTES

Synthesis of Analogs Related to Pilocarpine

ROBERT T. KODA[▲], FRANK J. DEA, KOCHY FUNG, CHRISTIAN ELISON, and JOHN A. BILES

Abstract □ Pilocarpine analogs with modification of the lactone ring were synthesized, and preliminary pharmacological evaluations indicate that several of the synthesized compounds possess interesting cholinergic activity.

Keyphrases □ Pilocarpine analogs—synthesized and screened for cholinergic activity □ Cholinergic activity—pilocarpine analogs with modified lactone rings synthesized and screened □ Structure–activity relationships—pilocarpine analogs synthesized and screened

Several naturally occurring alkaloids, *e.g.*, pilocarpine and muscarine, have been shown to possess potent cholinergic activity. This activity has been associated with the direct action of these substances on cholinergic receptors at synaptic junctions in target organs.

The nature of the cholinergic receptor is still not well understood. Presumably, acetylcholine must geometrically orient itself in such a manner that it binds to the receptor group at two points—the cationic and esteratic sites. Waser (1) postulated that the attachment of muscarinic agents to cholinergic receptors in smooth muscle involved two oxygen atoms and a quaternary nitrogen, having an optimum distance of approximately 4 Å separating the quaternary nitrogen from the ether or carbonyl oxygen. Jones (2) proposed that pilocarpine could assume a conformation similar to that of the active group postulated for the muscarinic receptor in ganglia.

A review of the literature indicates that structural requirements for cholinergic activity in pilocarpine analogs have not been studied adequately. It has been reported that an intact lactone ring is essential for activity. Moreover, the C-2 ethyl substitution on the lactone ring also has been reported as necessary for activity. Demethylation of pilocarpine on the imidazole moiety (pilocarpidine) showed reduced physiological activity (3). Brochmann-Hanssen *et al.* (4) found that various amine analogs, substituted for the imidazole moiety of pilocarpine, produced compounds with reduced activity. Quaternization of the imidazole ring giving the methyl iodides of both pilocarpine and isopilocarpine were synthesized (5) but their biological activity has not been reported. Ben Bassat *et al.* (6) presented data indicating that quaternization of pilocarpine derivatives on the imidazole moiety with a benzyl group possessed anticholinergic activity. This activity was augmented by the addition of *para*-substituents such as bromo, chloro, and methyl groups.

It appears that compounds possessing parasympathomimetic activity must contain a cationic site in the form of either a protonated tertiary or quaternary nitrogen separated from a region of high electron density approximately 4 Å away. Whether this site of high electron density in pilocarpine analogs is located about the carbonyl oxygen or the ether oxygen has not been determined. It appeared that minor alterations in the

tablets but has the advantage of markedly improved stability. In contrast to conventional tablets, which often develop marked intertablet dose variation within 1 month, the stabilized tablet maintains its content uniformity for long periods, even at 37 and 45°, thus assuring a more uniform and predictable dose to the patient.

NOTES

Synthesis of Analogs Related to Pilocarpine

ROBERT T. KODA[▲], FRANK J. DEA, KOCHY FUNG, CHRISTIAN ELISON, and JOHN A. BILES

Abstract □ Pilocarpine analogs with modification of the lactone ring were synthesized, and preliminary pharmacological evaluations indicate that several of the synthesized compounds possess interesting cholinergic activity.

Keyphrases □ Pilocarpine analogs—synthesized and screened for cholinergic activity □ Cholinergic activity—pilocarpine analogs with modified lactone rings synthesized and screened □ Structure–activity relationships—pilocarpine analogs synthesized and screened

Several naturally occurring alkaloids, *e.g.*, pilocarpine and muscarine, have been shown to possess potent cholinergic activity. This activity has been associated with the direct action of these substances on cholinergic receptors at synaptic junctions in target organs.

The nature of the cholinergic receptor is still not well understood. Presumably, acetylcholine must geometrically orient itself in such a manner that it binds to the receptor group at two points—the cationic and esteratic sites. Waser (1) postulated that the attachment of muscarinic agents to cholinergic receptors in smooth muscle involved two oxygen atoms and a quaternary nitrogen, having an optimum distance of approximately 4 Å separating the quaternary nitrogen from the ether or carbonyl oxygen. Jones (2) proposed that pilocarpine could assume a conformation similar to that of the active group postulated for the muscarinic receptor in ganglia.

A review of the literature indicates that structural requirements for cholinergic activity in pilocarpine analogs have not been studied adequately. It has been reported that an intact lactone ring is essential for activity. Moreover, the C-2 ethyl substitution on the lactone ring also has been reported as necessary for activity. Demethylation of pilocarpine on the imidazole moiety (pilocarpidine) showed reduced physiological activity (3). Brochmann-Hanssen *et al.* (4) found that various amine analogs, substituted for the imidazole moiety of pilocarpine, produced compounds with reduced activity. Quaternization of the imidazole ring giving the methyl iodides of both pilocarpine and isopilocarpine were synthesized (5) but their biological activity has not been reported. Ben Bassat *et al.* (6) presented data indicating that quaternization of pilocarpine derivatives on the imidazole moiety with a benzyl group possessed anticholinergic activity. This activity was augmented by the addition of *para*-substituents such as bromo, chloro, and methyl groups.

It appears that compounds possessing parasympathomimetic activity must contain a cationic site in the form of either a protonated tertiary or quaternary nitrogen separated from a region of high electron density approximately 4 Å away. Whether this site of high electron density in pilocarpine analogs is located about the carbonyl oxygen or the ether oxygen has not been determined. It appeared that minor alterations in the

lactone ring would provide useful information regarding the nature of the cholinergic receptor. It was proposed that the removal of the carbonyl function would further serve to provide information regarding the importance of that group without significantly altering the geometry of the pilocarpine molecule. In addition, it was felt that the lactam and *N*-methyllactam analogs should be prepared to determine whether the nitrogen in the lactam ring could be involved in an interaction with the receptor group.

RESULTS AND DISCUSSION

The methods used in the conversion of lactones to lactams generally involved the reaction of a lactone with ammonia in various polar solvents (7–9). It is possible that in the aminolysis of pilocarpine, either a hydroxyamide or a lactam derivative could occur. Gresham *et al.* (10) found that the reaction of methylamine with β-lactones in acetonitrile favored the formation of the β-amino acid, which subsequently could be cyclized to the lactam. In this study, however, when pilocarpine was reacted with anhydrous ammonia in acetonitrile at 0°, only the hydroxyamide derivative (I) was obtained. The hydroxyamide derivative was also obtained using anhydrous ammonia in absolute methanol, 95% ethanol, or aqueous ammonia. Reactions of pilocarpine with aqueous solutions of methylamine or isopropylamine gave similar results, yielding the respective *N*-methylhydroxyamide (II) or *N*-isopropylhydroxyamide (III) derivatives (Scheme I).

The lactam analog (IV) was successfully prepared by a reaction of pilocarpine (VII) with liquid ammonia at 200–210° according to the method of Späth and Lintner (11) (Scheme I). Similarly, the *N*-methyllactam analog (V) was prepared by the reaction of liquid methylamine and pilocarpine (VII) at 225° for 2 hr.

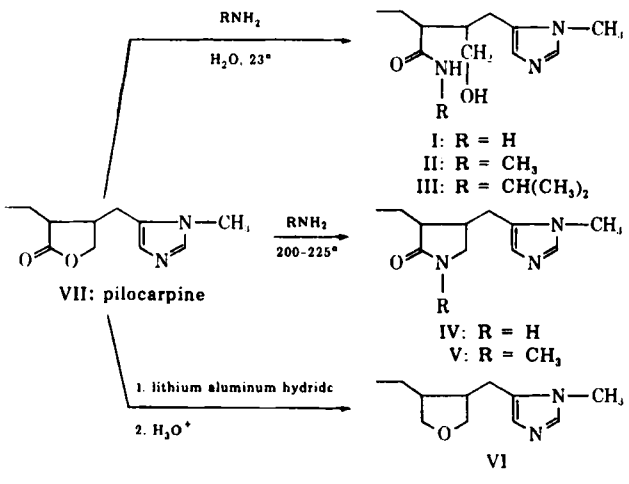
Pilocarpine reduction was accomplished using lithium aluminum hydride in anhydrous tetrahydrofuran (Scheme I). The IR spectra indicated a disappearance of the normal carbonyl peak. Elemental analysis was consistent with the calculated values for the tetrahydrofuran analog (VI).

The NMR spectrum of I indicated a two-proton doublet at δ 3.35 (—CH_2OH), whereas the spectrum of pilocarpine (VII) indicated a two-proton multiplet at δ 4.12 (—CH_2O—). In addition, the NMR spectrum of II indicated an absorption at δ 2.60 (N—CH_3, amide).

The NMR of IV gave a two-proton multiplet at δ 3.10–3.51. These data are consistent with the C-5 (N—CH_2—) protons reported for 2-pyrrolidone. Compound V gave a three-proton singlet at δ 2.90 (N—CH_3 lactam).

The appearance of two doublets at δ 3.48–3.61 and 3.98–4.12 (4H) for VI is consistent for the C-2 and C-4 protons on the tetrahydrofuran moiety.

Specific rotations (Table I) and NMR evidence do not clearly establish whether isomerization occurred during the synthesis of Compounds IV and V. The C-3 and C-4 protons on the 2-pyrrolidone ring of IV and V were assigned δ 2.19 (m, 1H, CH) and 2.52 (m, 1H, CH) and δ 2.28 (m, 1H, CH) and 2.50 (m, 1H, CH), respectively. The C-3 and C-4 protons on the tetrahydro-2-furanone ring of pilocarpine were assigned δ 2.33 (m, 1H, CH) and 2.83 (m, 1H, CH). The NMR peaks for the C-3 and C-4 protons in isopilocarpine were not clearly shown. Thus, these data are not sufficiently definitive to indicate whether isomerization had occurred during the synthetic procedure.



Scheme I

PHARMACOLOGY

Results of the pharmacological studies indicate that there is no significant parasympathomimetic activity for Compounds I, II, and III. However, the administration of IV and V in comparable doses to the pilocarpine control resulted in a sialogogue activity greater than pilocarpine itself. This activity could be antagonized by the administration of 0.4 mg./kg. i.v. of atropine. The administration of IV and V did not induce vomiting and defecation, with only a few drops of urine being discharged. However, unlike pilocarpine, IV and V produce hypertension which is not modified by the administration of atropine during the hypertensive phase.

The intravenous administration of VI resulted in sialogogue activity which could be antagonized by the administration of 0.4 mg./kg. i.v. atropine. When 3.0 mg./kg. VI was administered, a transient hypotension was produced, followed by a hypertensive phase with an attendant bradycardia. The cardiac rate became erratic with a fall in blood pressure. Atropine (0.4 mg./kg. i.v.) did not reverse the cardiovascular effects and the animal died in cardiac arrest. Compound VI exerts a more potent effect on the cardiovascular system than equal doses of pilocarpine.

The preliminary pharmacological evaluation of pilocarpine analogs in which the lactone ring was modified further substantiates the observation that an intact ring structure (lactone or its equivalent) is necessary for biological activity.

EXPERIMENTAL[1]

The pharmacological activity of pilocarpine analogs was determined in male dogs weighing between 13 and 20 kg.; the dogs were previously anesthetized with 30 mg./kg. sodium pentobarbital. Three experiments were run on each compound tested. The anesthetized animal was secured to a dog board; the electroencephalogram (EEG), through fronto-temporal leads, and the electrocardiogram (ECG), through lead I, were recorded using a physiograph. Blood pressure measurements were made through a cannulated left femoral artery, and the right femoral vein was exposed for injection of drug. Estimations of salivary flow were determined by tilting the head of the animal in such a manner that all salivary secretions would drain into a container.

All compounds to be tested were prepared in isotonic saline in concentrations expressed as the free base. The primary objective of the pharmacological study was to compare cholinergic activity of the analogs with the parent compound pilocarpine. A single dose of 3 mg./kg. was used for each compound tested.

Aminolysis of Pilocarpine by Ammonia, Methylamine, and Isopropylamine—Three grams (12.25 mmoles) of pilocarpine hydrochloride (VII) was suspended in 25 ml. of ammonium hydroxide (28%), and the mixture was stirred at room temperature. The crystals of VII slowly dissolved in the mixture. After 30 min., precipitation occurred in the form of a white crystalline suspension. Stirring was continued for an additional 2 hr., at which time a heavy white suspension was obtained. The suspension was filtered and the product was recrystallized from a minimum amount of 28% ammonium hydroxide, yielding 2.05 g. (74%) of 2-ethyl-3-hydroxymethyl-4-

[1] Melting points were determined on a Fisher-Johns melting-point apparatus and are uncorrected. Elemental microanalyses were performed by Elek Microanalytical Laboratory, Torrance, Calif., and C. F. Geiger, Ontario, Calif. All compounds were dried over phosphorus pentoxide under vacuum at 100° for at least 4 hr. IR spectra were run as mineral oil mulls between sodium chloride windows or as potassium bromide pellets on a Perkin-Elmer Infracord, model 137, and were consistent with proposed structures. Thin-layer chromatograms were run on Gelman ITLC (sg) in a solvent system composed of *n*-butanol–*n*-butyl ether–acetic acid (58:40:10) and were detected by spraying with Dragendorf's reagent. NMR spectra were run on a Hitachi Perkin-Elmer spectrometer, model R-24, and were consistent with assigned structures. Optical rotations were determined in a Cenco-Kern Polarmeter using water as a solvent at 23°.

Table I—Specific Rotations of Pilocarpine and Its Derivatives

Compound	$[\alpha]_D^{23}$
Pilocarpine nitrate (VII)	79.0° (c 1.0)
Isopilocarpine nitrate	36.9° (c 1.0)
Amide derivative (I)	47.4° (c 1.0)
Lactam nitrate (IV)	42.2° (c 1.0)
N-Methyllactam (V)	47.4° (c 1.0)
Tetrahydrofuran analog (VI)	26.3° (c 1.0)

(3-methyl-4-imidazolyl)-*n*-butyramide (I), m.p. 195–196°; IR_{max}: 1650 (C=O, amide) and 3200 (NH) cm.$^{-1}$; NMR (dimethyl sulfoxide-d_5): δ 3.35 (d, 2H, CH_2OH).

Anal.—Calc. for $C_{11}H_{19}N_3O_2$: C, 58.64; H, 8.50; N, 18.65. Found: C, 58.85; H, 8.66; N, 18.50.

Similarly, the *N*-methylamide derivative (II) was synthesized using a 30% aqueous solution of methylamine. The product was recrystallized from absolute ethanol, giving 2.25 g. (77%) of 2-ethyl-3-hydroxymethyl-4-(3-methyl-4-imidazolyl)-*N*-methyl-*n*-butyramide (II), m.p. 215–216°; IR_{max}: 1620 (C=O, amide) and 3200 (NH) cm.$^{-1}$; NMR (D_2O): δ 2.60 (s, 3H, N—CH_3, amide).

Anal.—Calc. for $C_{12}H_{21}N_3O_2$: C, 60.22; H, 8.84. Found: C, 60.34; H, 8.88.

The isopropylamide derivative (III) was prepared by stirring 3.0 g. of VII with a mixture of 25 ml. of isopropylamine and 10 ml. of water at room temperature until VII dissolved. The solution was placed in the refrigerator overnight at 4°. The solution was heated on a steam bath to remove the excess isopropylamine. Ten milliliters of water and decolorizing charcoal were added, and the mixture was filtered while hot. Upon cooling, fine white needles of 2-ethyl-3-hydroxymethyl-4-(3-methyl-4-imidazolyl)-*N*-(2-methylethyl)-*n*-butyramide (III) were obtained. The yield was 1.78 g. (55%), m.p. 224°; IR_{max}: 1640 (C=O, amide) and 3330 (NH) cm.$^{-1}$.

Anal.—Calc. for $C_{14}H_{25}N_3O_2$: C, 62.89; H, 9.42. Found: C, 62.74; H, 9.27.

3-Ethyl-4-(3-methyl-4-imidazolyl)methyl-2-pyrrolidone Nitrate (IV)—Crystals of VII were dried in a desiccator over calcium chloride under vacuum. To 2.0 g. (12.25 mmoles) of dried VII in a Parr high pressure reaction bomb was added an excess of liquid ammonia (approximately 10 ml.). The reaction bomb was sealed and heated in an oil bath at 200–210° for 2 hr. The reaction bomb was cooled to −5° and then vented, allowing the excess ammonia to escape. The reaction mixture was evaporated under vacuum, leaving an oily residue. To this residue was added 25 ml. of chloroform. The solution was dried with anhydrous calcium chloride and filtered. The chloroform filtrate was evaporated, leaving an oily residue which was dissolved in absolute ethanol and acidified with nitric acid. Upon acidification, IV precipitated. The product was recrystallized twice from absolute ethanol, giving 1.67 g. (53%) of 3-ethyl-4-(3-methyl-4-imidazolyl)methyl-2-pyrrolidone nitrate (IV), m.p. 160.5–161.5°; IR_{max}: 1675 (C=O, lactam) cm.$^{-1}$; NMR ($CDCl_3$): δ 2.72 (d, 2H, CH_2) and 6.70 (s, 1H, NH, lactam).

Anal.—Calc. for $C_{11}H_{18}N_4O_4$: C, 48.88; H, 6.71; N, 20.73. Found: C, 49.04; H, 6.87; N, 21.25.

The procedure for the preparation of 1-methyl-3-ethyl-4-(3-methyl-4-imidazolyl)methyl-2-pyrrolidone nitrate (V) is similar to that presented for the preparation of IV, substituting anhydrous liquid methylamine for ammonia with the reaction being carried out at 225° for 2 hr. The product was worked up in the usual way and recrystallized twice from absolute ethanol, yielding 1.85 g. (53%) of V, m.p. 174.5–175° dec.; IR_{max}: 1670 (C=O, lactam) cm.$^{-1}$; NMR ($CDCl_3$): δ 2.90 (s, 3H, CH_3 lactam) and 3.12–3.52 (m, 2H, C-5 N—CH_2).

Anal.—Calc. for $C_{12}H_{20}N_4O_4$: C, 50.69; H, 7.09; N, 19.71. Found: C, 50.41; H, 7.32; N, 20.21.

3-Ethyl-4-(3-methyl-4-imidazolyl)methyl Tetrahydrofuran Nitrate (VI)—Anhydrous ammonia was passed into a suspension of 5.0 g. (20.4 mmoles) of VII in 50 ml. of chloroform at 0°. The precipitate of ammonium chloride was filtered, and the chloroform solution evaporated to dryness under reduced pressure, leaving an oily residue of pilocarpine free base.

One gram (26.40 mmoles) of lithium aluminum hydride[2] was added with stirring to 50 ml. of dry tetrahydrofuran in a three-necked flask fitted with a condenser and dropping funnel. The reaction mixture was protected from moisture with drying tubes on all openings. The previously prepared pilocarpine base dissolved in dry tetrahydrofuran was added to the solution of lithium aluminum hydride over 3 hr. at 0°. After the reaction period, water was carefully added to the mixture. The resultant suspension was filtered and the tetrahydrofuran was evaporated under reduced pressure. The oily residue was refluxed with 25 ml. of 10% sulfuric acid for 2 hr. The reaction mixture was cooled to room temperature, adjusted to pH 9 with ammonium hydroxide, and then extracted with four 25-ml. portions of chloroform. The combined chloroform extracts were dried with calcium sulfate, filtered, and evaporated to near dryness, giving an oily residue. The residue was dissolved in 20 ml. of absolute ethanol and acidified with nitric acid. The alcoholic solution was gently heated to boiling, decolorized with charcoal, and filtered. Upon cooling, 2.0 g. (38% based on pilocarpine hydrochloride) of VI was obtained, m.p. 144–146°; IR_{max}: 1550, 1600 (C=C, C=N) cm.$^{-1}$; NMR (D_2O): δ 3.48–3.61 and 3.98–4 12 (2d, 4H, C-2 and C-5 CH_2).

Anal.—Calc. for $C_{11}H_{18}N_3O_4$: C, 51.35; H, 7.44. Found: C, 51.33; H, 7.59.

Human Urinary Excretion of Piperazine Citrate from Syrup Formulations

S. HANNA[▲] and A. TANG

Abstract □ A modified colorimetric method using Folin's amino acid reagent was used for the quantitative determination of piperazine in human urine. Comparative urinary excretion trials were carried out on five subjects using two different piperazine citrate syrup formulas. Within each individual, the percentage and pattern of excretion of piperazine citrate after oral administration of a newly developed syrup formula, equivalent to 3.5 g. piperazine hexahydrate, compared favorably with a commercial syrup sample taken in this investigation as a standard.

Keyphrases □ Piperazine citrate (syrup formulations)—determination in human urine, excretion profiles □ Excretion profiles—piperazine citrate syrup formulations, comparison of formulations, colorimetric method developed □ Colorimetry—analysis of piperazine citrate syrup formulations, human urine

Piperazine is the agent of choice in ascariasis, and its preparations are always given orally. Piperazine is readily absorbed from the GI tract (1). A portion of the absorbed drug is degraded in the body, and the remainder is excreted in the urine (2). Quantitative determination of piperazine in urine has not been widely studied. Titration of the monoperiodate piperazine derivative has been employed (3); however, this was not sufficiently accurate for the present study. A potentiometric method was described (4), which required long preliminary treatment of the urine. A lengthy quantitative color reaction of piperazine with acidified benzoquinone also was published (5).

In this paper, a modified colorimetric method of Rogers (6) was used to achieve higher sensitivity and more accurate results. In Rogers' method, readings were taken at 480 nm. after standing for 10 min. The present work has shown that this length of time would allow neither for the optimum stability and intensity of the color derivative nor for the reading at its maximum wavelength.

The aim of this study was to compare the amount of piperazine excreted in the urine over 24 hr. after oral administration of a newly developed syrup formula, equivalent to 3.5 g. piperazine hexahydrate, against a commercial syrup sample. This dose was chosen according to the normal adult dose range for the treatment of ascariasis.

1	1.0278	±0.061

[a] Average of five determinations using the modified method.

EXPERIMENTAL

Determination of Piperazine in Urine—Piperazine was determined quantitatively in urine by its color reaction with Folin's amino acid reagent[1]. The color intensity increased rapidly from 0 to 18 min. and was stable for 10 min. (Fig. 1). The maximum absorbance of the color was determined by scanning the developed color under visible light at a range of from 800 to 320 nm. and was found to be at 490 nm. The color obeyed Beer's law in concentrations between 0 and 200 mcg./ml. Each urine sample was measured for the exact volume, and a dilution of 1:25 with water was made for each sample including the control urine. This dilution was used for testing according to Table I using the various reagents in the tabulating order. After standing for 20 min., readings[2] were carried out within 5 min. at 490 nm. The value of the unknown sample was then compared with the standard sample reading.

The validity of this method was verified by adding various known amounts of piperazine citrate to the urine. This urine was tested and assayed for the amount of piperazine present according to the described method. Each experiment was repeated five times, and the standard deviation was found to be ±0.42 (Table II).

Urinary Excretion of Piperazine—Five Caucasian subjects, three men and two women ranging from 23 to 38 years of age, in normal state of health as determined by prior physical and laboratory medical examination, were used in this trial. Each was administered an oral dosage of 35 ml. of piperazine citrate syrup equivalent to 3.5 g. piperazine hexahydrate. At least 48 hr. elapsed between the administration of the new formula and the commercial sample[3]. Prior to the oral administration of either syrup sample, a urine sample was collected from each individual to be used as an internal control. The amino acids and other naturally occurring chromogens

[a] The first number is for age (years) and the second number is for body weight (kilograms). [b] I = new syrup formula, 3.5 g. piperazine hexahydrate. II = commercial syrup sample, 3.5 g. piperazine hexahydrate. [c] The t test of significance, where $t = \bar{x}_1 - \bar{x}_2/s\sqrt{n_1n_2/n_1 + n_2}$, $p = 0.05$, and $df = 8$ (7). The t value was calculated with the pooled variance of the two syrup samples. [d] Zero excretion.

present in normal urine had been found to give colored derivatives with the reagent used. Urine samples were collected, whenever possible, at 1, 2.5, 4.5, 6.5, 9, 13, 20, and 24 hr. after oral administration. The values obtained for the samples were corrected by subtracting the value of the normal urine reading for each individual. Piperazine concentration in the diluted urine sample was then calculated by comparing these corrected values with the standard reading carried out simultaneously. The total piperazine concentration in the urine sample was calculated by multiplying its dilution factor and urine volume. The total amount of piperazine excreted and the percentage of excretion of each individual was then ascertained as piperazine hexahydrate.

RESULTS AND DISCUSSION

The results of the total urinary excretion of piperazine calculated as hexahydrate after the oral administration of an amount equivalent to 3.5 g. of piperazine hexahydrate are shown in Table III and Fig. 2.

The percentage and pattern of urinary excretion of piperazine calculated as hexahydrate varied from individual to individual, as seen in the five subjects. The total urinary recovery varied from 15 to 75%. However, the results and pattern of urinary excretion for both syrup formulas compared favorably within each individual.

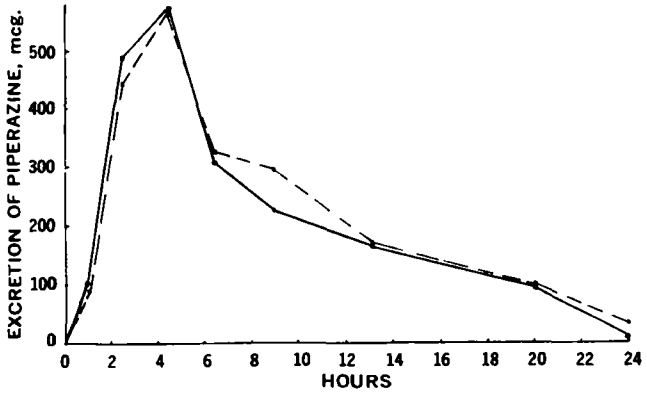

Figure 2—*Urinary excretion of piperazine after oral administration of the syrup formulas (average data for five individuals). Key:* —○—, *piperazine syrup, new formula; and* --●--, *piperazine syrup, commercial sample.*

Urinary excretion began 1 hr. after the oral administration, and the rate was maximal between 2 and 6 hr. Excretion was nearly completed in 24 hr.

CONCLUSION

1. The modified colorimetric method of analysis of piperazine in urine is accurate and simple to perform.
2. The percentage and pattern of urinary excretion of piperazine varied from individual to individual.
3. The percentage and pattern of urinary excretion after oral administration of the newly developed syrup formula, equivalent to 3.5 g. piperazine hexahydrate, compared favorably with that of the commercial syrup sample with each individual.
4. The maximum urinary excretion occurred 2–6 hr. after oral administration and was nearly completed at 24 hr. for both syrup formulas under investigation.
5. The t test of significance, where the t-value was calculated with the pooled variance of the two syrup samples, showed no significant difference.

Polymer-Induced Flocculation of Pharmaceutical Suspensions

ALVIN FELMEISTER▲, GALE M. KUCHTYAK, SUSAN KOZIOL, and CHARLES J. FELMEISTER

Abstract □ The effect of concentration of an anionic heteropolysaccharide on the sedimentation volume of sulfaguanidine, zinc oxide, talc, bismuth subcarbonate, and bismuth subnitrate aqueous suspensions was determined. All materials with the exception of sulfaguanidine showed a steady increase in sedimentation volume with increasing polymer concentration. Sulfaguanidine exhibited a maximum in the sedimentation volume–polymer concentration curve. All suspensions appeared uniform except for the bismuth subnitrate, which exhibited coarse, unsightly floccules. This effect was attributed to an interaction between the anionic polymer and the cationic bismuth subnitrate particles. Polymer bridging was postulated as the mechanism of flocculation in the other systems.

Keyphrases □ Flocculation, polymer induced—effect of polymer concentration on sedimentation volume of five pharmaceutical suspensions □ Polymers, anionic heteropolysaccharide—effect of concentration on induction of flocculation in pharmaceutical suspensions □ Suspensions—effect of polymer concentration on polymer-induced flocculation

Flocculation is recognized as an effective way of reducing the settling and subsequent caking of relatively coarse suspensions. Reduction of charge, chemical interaction, and polymer bridging have all been used to achieve this effect. Of these, polymer bridging appears to be the most efficient approach. The purpose of this study was to investigate the ability of an anionic heteropolysaccharide[1] to flocculate various pharmaceutical suspensions *via* polymer bridging.

EXPERIMENTAL

Materials—The polymer used was an anionic heteropolysaccharide[1] produced by the action of the bacterium *Xanthomonas campestris* on carbohydrate. The other materials were sulfaguanidine NF XI[2], talc USP[3], zinc oxide USP[3], bismuth subcarbonate USP[3], bismuth subnitrate NF[3], and propylparaben USP[4]. Deionized water was used throughout this study.

Procedure—Five grams of drug was suspended in water, and the appropriate amount of a 5% aqueous dispersion of the polymer (preserved by 0.05% propylparaben) was added. The sedimentation volume was determined (1) in a 100-ml. glass-stoppered cylinder after 48 hr. Viscosity was determined using a rotational viscometer[5].

RESULTS AND DISCUSSION

The viscosity of the suspending media at a relatively low shear rate (30 r.p.m.) ranged from 225 cps. for the maximum polymer concentration of 0.2% to 55 cps. for the 0.1% concentration.

Sulfaguanidine Suspensions—The sedimentation volume, H_u/H_0, increased with increasing polymer concentration up to 0.1% (Fig. 1). Beyond that level, the sedimentation volume decreased and appeared to level off only slightly above that observed in the absence of polymer. This effect is indicative of polymer adsorption and bridging, as postulated by LaMer and Healy (2); *i.e.*, maximum bridging occurs at some optimal polymer concentration and, consequently, a maximum in the sedimentation volume–polymer concentration is anticipated. Furthermore, the higher sedimentation volumes observed in this study, compared to those that resulted when sulfaguanidine was flocculated by a reduction in ζ-potential (3), are a further indication of polymer bridging.

Zinc Oxide and Talc Suspensions—As with sulfaguanidine, increasing the concentration of the polymer resulted in an increase in the sedimentation volume (Fig. 2). In the case of these two materials, however, the maximum sedimentation volume was much higher than with sulfaguanidine, reaching a value of 1 at a polymer concentration of 0.2%. At all sedimentation volumes, the suspension appeared to be uniform with no evidence of large separate floccules. This suggests that the suspension exists as a "single floc" extending throughout the vehicle as previously described (4).

Unfortunately, the effect of higher polymer concentrations on polymer–particle bridging and sedimentation volume could not be determined because of the polymer concentration required to achieve the maximum effect. Above this polymer concentration, the viscosity of the solution increased rapidly and there was evidence of a yield value, both of which tended to inhibit the settling almost completely over the observation period.

Bismuth Suspensions—The suspension of bismuth subcarbonate (Fig. 3) behaved essentially like the suspensions of zinc oxide and talc. However, the bismuth subnitrate formed very coarse, granular-appearing floccules which tended to settle rapidly to sedimentation volumes lower than those observed for the other materials at similar polymer concentrations. This effect apparently is the result of a chemical interaction between the negatively charged polymer and the positively charged bismuth subnitrate (5).

No attempt was made to quantify the redispersibility of the flocculated suspensions. However, qualitatively, it could be seen by gently inverting the cylinders containing the suspensions that all

the flocculated systems, with the exception of the bismuth subnitrate system, redispersed more easily than the deflocculated systems. Furthermore, with the same exception, all suspensions appeared smooth and could be readily poured from the cylinder after redispersion.

CONCLUSIONS

The anionic polysaccharide polymer used in this study is an effective flocculating agent at relatively low concentrations for a wide variety of insoluble pharmaceutical materials. The high sedimentation volumes observed, in some instances apparently reaching the single floc condition (4), are indicative of polymer–particle bridging. The anionic charge on the polymer, however, interacts with the positive charge on the surface of bismuth subnitrate particles (and, probably, other positively charged particles) to yield an inelegant, and generally unacceptable, pharmaceutical suspension.

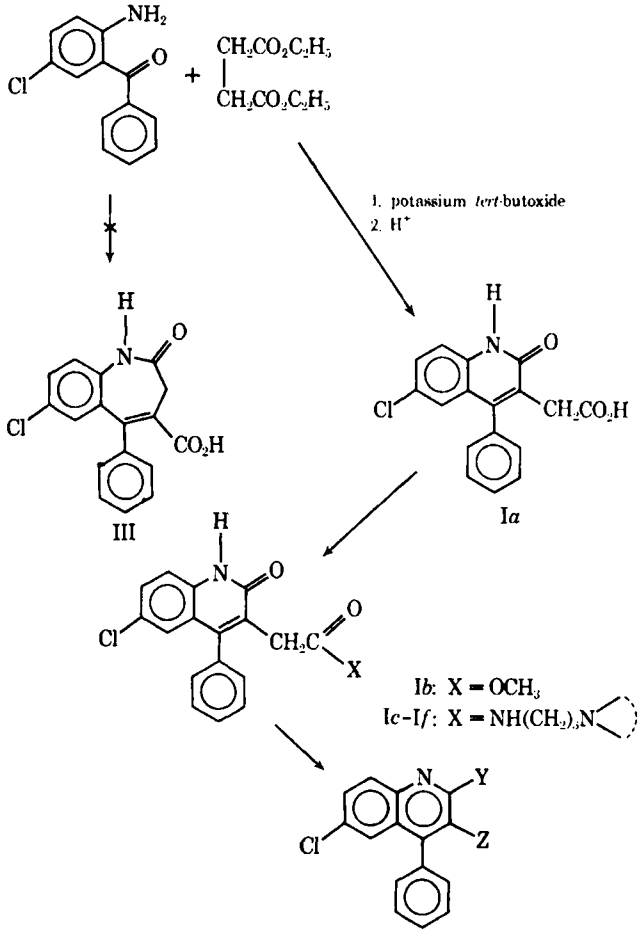
Synthesis and Biological Activity of Quinolyl Acetic Acid Derivatives

H. KOHL▲, N. J. de SOUZA, and P. D. DESAI

Abstract □ Derivatives of 6-chloro-4-phenyl-3-carboxymethyl-2-quinolone and 6-chloro-4-phenyl-2,3-substituted quinolines were prepared and evaluated as CNS depressants and as antibacterial agents. The compounds had no CNS activity. The quinolyl acetamides exhibited antibacterial activity against Gram-positive bacteria.

Keyphrases □ Quinolyl acetic acid derivatives—synthesis and pharmacological screening □ Quinoline derivatives—synthesis and pharmacological screening □ Antibacterial agents, potential—synthesis and screening of quinolyl acetic acid derivatives □ CNS activity—synthesis and screening of quinolyl acetic acid derivatives

The 5-chloro-2-aminobenzophenone moiety is a structural feature of several drugs affecting the central nervous system (CNS) (1–3). In addition, heterocyclic compounds containing a carbamoyl group have been reported to possess various biological activities (4–7). Consequently, as part of a program using 5-chloro-2-aminobenzophenone as a starting material for the synthesis of new nitrogen heterocyclic compounds, it was of interest to synthesize some quinolyl acetic acid derivatives (I and II), including a few quinolyl acetamides (Ic–I*f*), and to test them as CNS depressant and antibacterial agents.



IIa: Y = Cl, Z = $CH_2CO_2CH_3$
IIb: Y = OCH_3, Z = $CH_2CO_2CH_3$
IIc: Y = OCH_3, Z = CH_2CO_2H
IId: Y = OCH_3, Z = CH_3

Scheme I

5-Chloro-2-aminobenzophenone was condensed with diethyl succinate in the presence of potassium *tert*-butoxide to give 6-chloro-4-phenyl-3-carboxymethyl-2-quinolone (I*a*) in a yield of 75%. No formation was observed of a theoretically possible alternative product, the benzazepine III.

The structure of I*a* was assigned on the basis of its spectral similarity to carbostyrils and was confirmed by its facile conversion (Scheme I) to a 3-carboxymethylquinoline derivative, II*c*, which was readily decarboxylated to the corresponding 3-methylquinoline, II*d*. Loev *et al.* (8) carried out a similar condensation of 5-chloro-2-aminobenzophenone and diethyl succinate, using conditions different from those reported here. The product they obtained was also a six-membered carbostyril rather than a benzazepine, although it is unclear from their report whether they obtained a 4-phenyl-3-carboxymethyl-2-quinolone or a compound identical to I*a*. Compounds I*b*–I*f* (Table I) and II*a*–II*d* (Table II) were newly synthesized by literature methods (9–12).

PHARMACOLOGY

The compounds described in this paper were evaluated as CNS depressants by submitting them to a battery of behavioral and drug interaction tests in mice (13–21). No compound exhibited any significant CNS activity. The compounds were also tested[1] for antibacterial activity in a serial dilution test using a liquid medium[2]. The bacteriostatic values were determined after incubation for 24 hr. at 37°. Only the quinolyl acetamides, I*c*–I*f*, showed some antibacterial activity against Gram-positive bacteria. The three best results are shown in Table III.

EXPERIMENTAL[3]

6-Chloro-4-phenyl-3-carboxymethyl-2-quinolone (I*a*)—Potassium (66.3 g., 1.7 g. atom) was dissolved in *tert*-butanol (1000 ml.) at 50°, and subsequently diethyl succinate (348 g., 2 moles) and 5-chloro-2-aminobenzophenone (324 g., 1.4 moles) were added. After refluxing for 8 hr., the solvent was evaporated *in vacuo* and the residue was diluted with water, acidified with 2 *N* hydrochloric acid, and extracted with isopropyl ether. The solid material remaining in the

[1] For testing methods, refer to Table III.
[2] Merck Standard Bouillon I.
[3] Melting points were taken on a Kofler heating bench, type 7841, and are uncorrected. UV spectra were obtained on a Pye-Unicam spectrophotometer, model SP500, and the IR spectra were recorded on a Perkin-Elmer spectrophotometer, model 521, using KBr pellets. NMR spectra were obtained on Varian A-60 and T-60 spectrometers using tetramethylsilane as the internal standard and dimethyl sulfoxide as solvent. The mass spectra were recorded on a MS9 (AEI).

aqueous phase was separated by filtration and washed with water and isopropyl ether. After dissolving the solid in warm 4 *N* potassium hydroxide, the solution was treated with charcoal and filtered. The filtrate was acidified with 2 *N* hydrochloric acid to give a colorless precipitate, which was collected by filtration, washed with water, and crystallized from acetic acid, yielding 329 g. (Table I); UV: $\lambda_{max}^{CH_3OH}$ 235 nm., ϵ_{molar} 4.88 × 10^4; IR: ν_{max} 1720, 1665 (CO), 1630 (C=C), 3400, 3200, and 3050 (OH, NH) $cm.^{-1}$; NMR: δ 3.17 (s, 2H, CH_2), 7.4 (m, 8 aromatic protons), and 12.1 (broad s, 1H, COOH); mass spectroscopy (200°/70 ev.): M^+ = 313.

6-Chloro-4-phenyl-3-methylcarboxymethyl-2-quinolone (I*b*)—Phosphorus oxychloride (7 ml.) was added to the solution of I*a* (84.6 g., 0.27 mole) in methanol (1000 ml.). The mixture was refluxed with stirring for 8 hr. On cooling, the solid material obtained was separated by filtration, washed with methanol, and ether (ethyl), and dried. Recrystallization from methanol afforded 66.5 g. of colorless crystals (Table I); IR: ν_{max} 1730, 1665 (CO), 1630 (C=C), 3400, and 3200 (NH) $cm.^{-1}$; NMR: δ 3.18 (s, 2H, CH_2), 3.99 (s, 3H, OCH_3), and 7.5 (m, 8 aromatic protons); mass spectroscopy (180°/70 ev.): M^+ = 327.

***N*-Substituted Basic Amides of 6-Chloro-4-phenyl-3-carboxymethyl-2-quinolone (I*c*–I*f*)**—A mixture of I*b* (163.9 g., 0.5 mole) and the corresponding amine (0.2 mole) was refluxed for 4 hr. After dilution with ligroin, the separated solid was collected and crystallized from dilute ethanol. The characteristics of I*c*–I*f* are listed in Table I.

2,6-Dichloro-4-phenyl-3-methylcarboxymethylquinoline (II*a*)—A mixture of I*b* (98.3 g., 0.3 mole), phosphorus trichloride (0.5 mole), and phosphorus oxychloride (350 ml.) was refluxed for 4 hr. The reaction mixture was cooled and poured on ice. The separated solid material was filtered, dried, and crystallized from toluene–ligroin, yielding 83 g. (Table II); IR: ν_{max} 1728 (CO) and 1632 (C=C) $cm.^{-1}$; NMR: δ 3.19 (s, 2H, CH_2), 4.0 (s, 3H, OCH_3), and 7.4 (m, 8 aromatic protons); mass spectroscopy (170°/70 ev.): M^+ = 345.

2-Methoxy-4-phenyl-6-chloro-3-methylcarboxymethylquinoline (II*b*)—A solution of II*a* (69.2 g., 0.2 mole) in benzene (500 ml.) was added to a methanol solution of sodium methoxide (8 g. sodium in 200 ml. methanol). After refluxing for 8 hr., the solvents were partially evaporated and cold water was added. The mixture was extracted with ethyl acetate. The extract was dried over anhydrous sodium sulfate, filtered, and evaporated *in vacuo* to give a residue which was crystallized from toluene–ligroin, yielding 54 g. (Table II); IR: ν_{max} 1730 (CO), 1632 (C=C), and 2830 (OCH_3) $cm.^{-1}$; NMR: δ 3.19 (s, 2H, CH_2), 3.99 (6H, $2OCH_3$), and 7.5 (8 aromatic protons); mass spectroscopy (180°/70 ev.): M^+ = 341.

Determination of 6-Demethylgriseofulvin in Urine

MALCOLM ROWLAND▲ and SIDNEY RIEGELMAN

Abstract □ A simple UV assay is reported that is capable of measuring 1 mcg. 6-demethylgriseofulvin/ml. urine. The method utilizes the difference in the absorbance of the ionized and unionized forms of this molecule at 327 nm.

Keyphrases □ Griseofulvin metabolites—UV spectrophotometric determination of 6-demethylgriseofulvin in urine □ 6-Demethylgriseofulvin—UV spectrophotometric determination in urine □ UV spectrophotometry—determination of 6-demethylgriseofulvin

In man (1) as well as rabbit (2) and dog (3), *O*-demethylation of the antifungal agent, griseofulvin, to 6-demethylgriseofulvin is a significant route of elimination. Griseofulvin, ingested as a solution in polyethylene glycol 300, was almost quantitatively recovered (4) in the urine as 6-demethylgriseofulvin in man. While griseofulvin was readily seen in the plasma following oral administration of standard 250- and 500-mg. doses,

less than 0.1% of the dose appeared unchanged in the urine (1, 5). Urinary excretion measurement of 6-demethylgriseofulvin therefore offers convenient and supplemental information when studying bioavailability profiles of griseofulvin under various conditions. This report describes a simple method for measuring this metabolite in urine, utilizing the difference in the spectrum between the ionized and unionized forms of 6-demethylgriseofulvin at 327 nm.

EXPERIMENTAL[1]

Citrate Buffer—Citric acid, 1 *M*, is adjusted to pH 3.9 with 1 *M* sodium citrate.

Organic Solvent—Cyclohexane–ethylene dichloride (50:50) is prepared by successively washing each solvent with 1 vol. 1 *N* NaOH, 1 vol. 1 *N* HCl, and 2 vol. distilled water.

Phosphate Buffer (McIlvaine's Buffer)—Citric acid (0.2 *M*, 27.5 ml.) is diluted to 1000 ml. with 0.2 *M* Na_2HPO_4, final pH 7.9.

Procedure—To 2 ml. of urine (containing 0–10 mcg. 6-demethylgriseofulvin/ml.) are added 1 ml. citrate buffer and 10 ml. organic solvent; the mixture is shaken for 2 min. and centrifuged. Six milliliters of the organic layer is pipeted into another tube containing 6 ml. pH 7.9 phosphate buffer, shaken for 2 min., and centrifuged; then the upper organic layer is aspirated off. Two milliliters of the remaining aqueous layer is pipeted into each of two tubes, one containing 0.2 ml. 5 *N* HCl and the other containing 0.2 ml. McIlvaine's buffer (pH 7.9). The absorbance of the basic solution is read against the acidic solution at 327 nm. The concentration of 6-demethylgriseofulvin in the urine is calculated by reference to a standard curve prepared by taking known concentrations of 6-demethylgriseofulvin (0–10 mcg./ml.) through the same procedure.

The concentration of the glucuronide of 6-demethylgriseofulvin is determined as the difference between the concentration of 6-demethylgriseofulvin before and after incubation of the urine sample overnight at 37° with 100 units of β-glucuronidase in 1 ml. of phosphate buffer (pH 6.8).

RESULTS AND DISCUSSION

Most plasma assays for griseofulvin utilize its native fluorescence in aqueous and hydroalcoholic solutions. It was reasoned and subsequently verified that unionized 6-demethylgriseofulvin also fluoresces with the same activation (315 nm.) and fluorescence (450 nm.) maxima as griseofulvin and, thereby, an avenue should exist for the establishment of a sensitive assay for this metabolite. Surprisingly, a pH fluorescence profile indicated a maximum fluorescent intensity at pH 2.4 equal to 30% of griseofulvin on a molar basis. The decreasing fluorescence, seen with increasing pH beyond 2.4 and virtually absent above pH 7.0, suggests that only the unionized molecule fluoresces. A half-maximal fluorescence at pH 4.5, very similar to the pKa (4.27) of 6-demethylgriseofulvin (6), supports this hypothesis. Below pH 2.4, the fluorescence also declines and it is negligible at pH < 0.5, presumably caused by protonation of 6-demethylgriseofulvin. While subsequent attempts to develop a fluorometric assay for urinary 6-demethygriseofulvin proved unsuccessful because of excessive fluorescent species in urine, fluorescent measurements were used to determine pH partition profiles of this metabolite with various organic solvents. Furthermore, while griseofulvin fluorescence is pH insensitive above pH 2.2, like 6-demethylgriseofulvin it diminishes markedly in a more acidic environment. This last observation provided a useful modification to the usual fluorometric assay for griseofulvin in plasma (7).

By using a 5:1 volume ratio of organic solvent to aqueous buffer, 6-demethylgriseofulvin is extracted quantitatively into ethylene dichloride or ether below pH 3.5. Above pH 3.5, extraction progressively diminishes. Partitioning occurs more favorably into the former solvent, 50% 6-demethylgriseofulvin being extracted into ethylene dichloride at pH 6.9 and 6.0 with ether. Both solvents were investigated in a potential assay in which the urine was adjusted to pH 4.0 (range 3.92–4.30) with strong citrate buffer (pH 3.9) prior to extraction. This pH allows quantitative 6-demethylgriseofulvin extraction while reducing interference from urinary constituents that are extracted in higher proportions from a more acidic urine. 6-Demethylgriseofulvin was determined by differential spectrophotometry, taking advantage of the low absorbance of the unionized phenol at the λ_{max} (327 nm.) for the phenolate ion ($\Delta\epsilon$ = 26,900) (8). One microgram 6-demethylgriseofulvin/ml. aqueous solutions could readily be measured.

Unfortunately, both ether and ethylene dichloride extracted too many absorbing materials from blank urine. Various combinations of cyclohexane with ether, ethylene dichloride, and chloroform were examined to reduce the urine blank. An equal volume of cyclohexane and ethylene dichloride proved the most suitable solvent. This mixture has a lower specific gravity than water, allowing facile transfer from one tube to another; it also does not form emulsions with urine and quantitatively extracts 6-demethylgriseofulvin at and below pH 4.5. Furthermore, extraction of 6-demethylgriseofulvin into this solvent mixture is negligible at pH 7.5 or greater, so a pH 7.9 buffer was chosen to back-extract this metabolite. The absorbance of the pH 7.9 buffer extract was then measured at 327 nm. against the same solution made acidic with 5 *N* HCl. When using this procedure, blank values were always less than 0.35 mcg. 6-demethylgriseofulvin equivalents/ml. urine. Also, a linear regression was observed between absorbance and concentration in the range of 0–10 mcg./ml. urine. Comparison of the slope of a calibration curve taken through the procedure with an aqueous standard curve indicates an overall recovery of 97.7%.

The presence of 6-demethylgriseofulvin in an ethereal extract of acidic urine was confirmed by TLC on silica gel plates containing a green fluorophore, using chloroform–acetic acid–water (4:1:1) as the developing solvent. A spot at the same R_f value as authentic 6-demethylgriseofulvin (R_f 0.34) was absent in blank urine but present in urine of subjects ingesting griseofulvin. Like 6-demethylgriseofulvin, the native fluorescence of this spot in the acidic environment of the developing solvent was quenched by exposure to ammonia fumes. The presence of another metabolite, 4-demethylgriseofulvin, formed in the rat and rabbit (9), was also sought. This metabolite, synthesized by a literature method (10), gave a different R_f value (0.55) in this thin-layer system. No spot corresponding to 4-demethylgriseofulvin was detected in the urine of subjects receiving griseofulvin before or after incubation with β-glucuronidase. The presence of 6-demethylgriseofulvin glucuronide was assessed by exhaustively extracting 6-demethylgriseofulvin from acidic urine with ether, adjusting to pH 6.8, and incubating with β-glucuronidase in phosphate buffer (pH 6.8) at 37° overnight. The appearance of a spot, absent in control urine, at the same R_f value as 6-demethylgriseofulvin and with identical fluorescent properties was taken as evidence of 6-demethylgriseofulvin glucuronide. Incubation studies under the assay conditions indicated that the glucuronide was hydrolyzed within 4 hr. (11). A GLC assay has been used (11) for the determination of urinary 6-demethylgriseofulvin. The reported (11) failure to find conjugated metabolites conflicts with the present findings. These differences may have arisen from different conditions used in the hydrolysis.

By utilizing the described assay, between 70 and 100% of an intravenous dose of griseofulvin was recovered as the sum of 6-demethylgriseofulvin and 6-demethylgriseofulvin glucuronide in man (12). Also, in man (13), unlike dogs (3, 14), excretion of 6-demethylgriseofulvin is rate limited by the elimination of griseofulvin. Furthermore, the proportionality between the amount of 6-demethylgriseofulvin excreted and the area under the griseofulvin plasma time curve (10) indicates that urinary 6-demethylgriseofulvin may be used to assess the availability of oral griseofulvin.

[1] A Beckman DU spectrophotometer and Beckman pH meter were used. 6-Demethylgriseofulvin was supplied by McNeil Laboratories, Fort Washington, Pa.; β-glucuronidase was purchased from Sigma Chemical, Chicago, Ill. All chemicals and solvents were Baker analyzed grade.

Quantitative TLC Determination of Primidone, Phenylethylmalonediamide, and Phenobarbital in Biological Fluids

Y. GARCEAU, Y. PHILOPOULOS*, and J. HASEGAWA▲

Abstract □ A rapid and reproducible TLC determination of primidone and its metabolites in plasma and urine is described. The method consists of extracting the drugs into chloroform, evaporating the organic phase to dryness, dissolving the residue in an accurately measured volume of chloroform–acetic acid (9:1), and spotting this solution on a thin layer of silica gel. Quantitation is achieved by comparing the areas under the peaks obtained from scanning the TLC plates in a spectrodensitometer. The limit of detection is 1 mcg./ml. plasma for primidone and phenobarbital and 2 mcg./ml. plasma for phenylethylmalonediamide. Mean recoveries obtained from spiked plasma samples were: primidone, 93%; phenylethylmalonediamide, 97%; and phenobarbital, 102%.

Keyphrases □ Primidone—TLC separation and quantitation with phenylethylmalonediamide and phenobarbital in biological fluids □ Phenylethylmalonediamide—TLC separation and quantitation with primidone and phenobarbital in biological fluids □ Phenobarbital—TLC separation and quantitation with primidone and phenylethylmalonediamide in biological fluids □ TLC—separation and quantitation of primidone, phenylethylmalonediamide, and phenobarbital in biological fluids

Several procedures have been published on the quantitation of primidone and two of its metabolites, phenylethylmalonediamide and phenobarbital, in biological fluids. One chemical method used oxidation of primidone to phenobarbital (1). The other procedures used either TLC (2–4) or GLC (5–11). The TLC procedures were semiquantitative, since they relied on measuring spot size and intensity or colorimetric estimation after elution of compounds from the plates. The GLC methods were generally reproducible, accurate, specific, and sensitive but were relatively time consuming. This disadvantage cannot be neglected when analysis time is important as in a bioavailability study involving several hundred assay samples. This paper describes a fast and quantitative TLC procedure for estimating primidone, phenylethylmalonediamide, and phenobarbital in plasma and urine.

EXPERIMENTAL

Apparatus—A spectrodensitometer[1] equipped with a density computer[2] was used. The light source consisted of a xenon–mercury 200-w. lamp[3]. The instrument was operated in the reflection mode, using the dual-beam system. Samples were scanned at 220 nm. (density computer set at 0.2 o.d.). Scanning and chart speeds were set at 10.2 cm. (4 in.)/min.

Materials and Chemicals—Silica gel TLC plates[4] (20 × 20 cm.) were employed. The plates were divided into 20 equal channels, each 1 cm. wide, with a scoring device[5]. The plates were heated at 100° for 1 hr. before use. Stock solutions of primidone[6], phenylethylmalonediamide[6], and phenobarbital[7] were prepared by dissolving accurately weighed amounts in methanol. Working standards were made by appropriate dilutions of the stock standards. All solvents used were reagent grade. Samples were applied to the plates with 10-, 25-, or 50-μl. syringes[8].

Developing Systems—For primidone and phenylethylmalonediamide analysis, the following developing system was used: ethyl acetate–benzene–acetic acid (90:20:10) (System A). For phenobarbital analysis, the system consisted of benzene–ethyl acetate–acetone–acetic acid (100:25:15:10) (System B). These systems require saturated tanks and an environment where the relative humidity is maintained at less than 25%.

Procedure for Determining Drugs in Plasma—Two-milliliter plasma samples spiked with appropriate amounts of all three drugs were extracted with 30 ml. chloroform in 50-ml. conical tubes. The tubes were shaken on a mechanical device[9] for 15 min. Unspiked plasma samples served as blanks. After extraction, the tubes were centrifuged and 25 ml. of the extracts were transferred to a clean 50-ml. conical tube and evaporated under nitrogen[10]. The sides of the tubes were washed with 1-ml. portions of chloroform, and the solutions were evaporated to dryness. The residues were dissolved in 100 μl. of a solution of chloroform–acetic acid (9:1).

Appropriate aliquots (25–50 μl.) were spotted on scored TLC

plates, generally in duplicate. Each channel on which a sample was spotted had to its immediate left a nonspotted reference channel. Standards of at least two different concentrations were also spotted so that a calibration line was included on each plate. The plates were then developed, dried, and read as described. Drug concentration was determined by comparing the areas under the peaks obtained from the standards to those obtained from the spiked samples. The procedure is also applicable to the determination of primidone, phenylethylmalonediamide, and phenobarbital in urine. Specimens are adjusted to pH 7.0 before extraction.

***In Vivo* Experiment**—To assess the applicability of the method, six beagle dogs were given 192 mg. of primidone intravenously (drug dissolved in 4 ml. dimethylformamide). Heparinized blood samples were collected prior to injection and at 0.25, 0.50, 0.75, 1, 2, 3, 4, 6, and 8 hr. after injection. The blood samples were centrifuged immediately, and the plasma was frozen until analyzed.

RESULTS AND DISCUSSION

With developing System A, primidone (R_f 0.42) can be separated from its metabolites phenylethylmalonediamide (R_f 0.53) and phenobarbital (R_f 0.67) and from extractable plasma impurities (Fig. 1). Both primidone and phenylethylmalonediamide can be quantitated when System A is used, but phenobarbital cannot be estimated due to interfering plasma components. However, the system can be used for the determination of all three drugs in urine, because interfering impurities are absent. To quantitate phenobarbital in plasma, developing System B must be used (Fig. 2). The use of two developing systems may make the method less appealing, but they are necessary only when phenobarbital needs to be determined in plasma. This method was developed for application in bioavailability studies. When a single dose of primidone is administered, phenobarbital determination is not required since it is not detectable in plasma following such a dose (12). However, phenobarbital determination is indicated in studies involving multiple dosing of primidone.

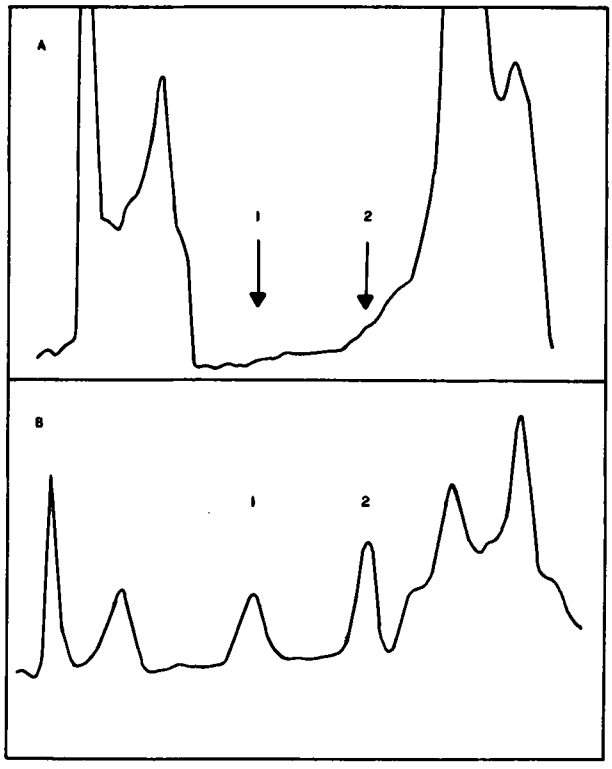

Figure 2—*(A) Chromatogram of a blank plasma extract showing* R_f *values for primidone (1,* R_f *0.34) and phenobarbital (2,* R_f *0.58). Phenylethylmalonediamide has same* R_f *as primidone in this system. (B) Chromatogram of an extract from a plasma sample spiked with primidone (1) and phenobarbital (2) at 5-mcg./ml. concentration. Extra peaks represent extractable plasma impurities.*

Typical calibration lines are shown in Fig. 3. Correlation coefficients are: primidone, 0.996; phenylethylmalonediamide, 0.993; and phenobarbital, 0.990 (n = 5). Although the range of linearity is rather narrow for phenobarbital (about 1–6 mcg.), it is not a problem as long as a calibration line covering the concentration range of the unknowns is included on every plate.

A summary of the recovery studies performed in plasma is given in Table I. Mean recoveries were: primidone, 93% (n = 21); phenylethylmalonediamide, 97% (n = 18); and phenobarbital, 102% (n = 21). Mean recoveries from spiked urine samples were: primi-

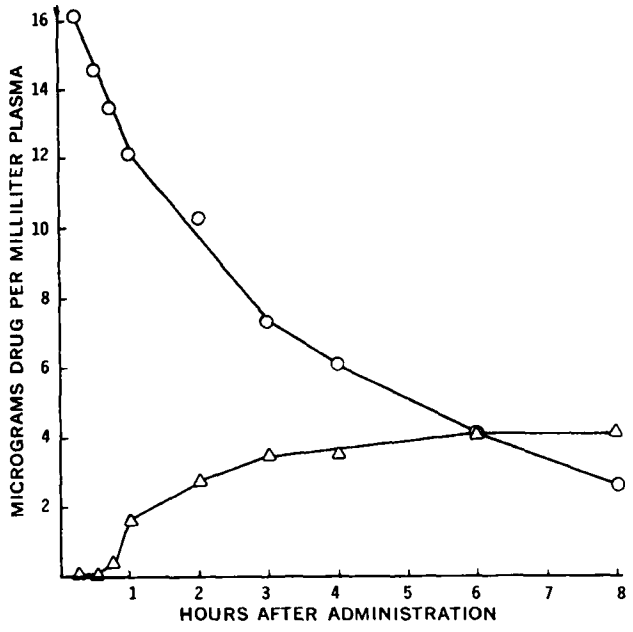

Figure 4—*Mean plasma levels of primidone* (○) *and phenylethylmalonediamide* (△) *following intravenous injection of primidone in dogs.*

done, 85%; phenylethylmalonediamide, 92%; and phenobarbital, 93%. The procedure is simple and rapid. One chemist can easily analyze 20–25 samples in a working day.

An *in vivo* study was performed to verify the applicability of the method. Plasma levels of primidone and phenylethylmalonediamide obtained following a single intravenous injection of primidone to dogs are shown in Fig. 4. Phenobarbital was not detected.

In summary, a quick, reproducible, and specific quantitative TLC method for the determination of primidone and its metabolites in plasma and urine was described. The method is especially useful when a large number of samples must be assayed.

Enhancement of Benzalkonium Chloride and Chlorhexidine Acetate Activity against *Pseudomonas aeruginosa* by Aromatic Alcohols

R. M. E. RICHARDS* and R. J. McBRIDE▲

Abstract □ The actions of benzalkonium chloride and chlorhexidine acetate in combination with benzyl alcohol, 2-phenylethanol, or 3-phenylpropanol were evaluated at subinhibitory concentrations by measuring the growth rates of *Pseudomonas aeruginosa* NCTC 6750. When tested separately, all three alcohols had an effect on both benzalkonium chloride and chlorhexidine acetate that was more than additive. Phenylpropanol showed the greatest enhancement and benzyl alcohol showed the least enhancement.

Keyphrases □ Benzalkonium chloride—enhanced activity by aromatic alcohols against *Pseudomonas aeruginosa* □ Chlorhexidine acetate—enhanced activity by aromatic alcohols against *Pseudomonas aeruginosa* □ Interactions—enhancement of antibacterial action of benzalkonium chloride and chlorhexidine acetate by aromatic alcohols against *Pseudomonas aeruginosa* □ Preservatives—enhanced activity of benzalkonium chloride and chlorhexidine acetate by aromatic alcohols, tested against *Pseudomonas aeruginosa*

Formulations containing two or more preservatives are increasing in number; 50% of commercial ophthalmic preparations contain such combinations (1), but reports on their evaluation have not appeared. In the past, medicinal antibiotic combinations were evaluated by different *in vitro* techniques which resulted in different definitions to describe the synergistic, additive, antagonistic, or indifferent effects observed between the drugs. The disappointing lack of correlation between such *in vitro* results and *in vivo* effects has been reflected by a lack of reports on *in vitro* evaluation of such combinations. However, pharmaceutical preparations preserved with combinations of bactericides differ from medicinal antibiotic combinations because the preservative capacity of the preparations can be assessed by *in vitro* techniques.

Garrett (2) reviewed the various definitions of antibiotic combination effects and suggested that antibiotic combinations should be evaluated on the basis of: (*a*) additivity, where the combined effect or response is additive with respect to the separate responses of the components; and (*b*) equivalence, in which the antibiotics act in the same manner with the same dose–response curve, separately or in combination, except for a difference in the weight of an arbitrarily defined "unit dose." Garrett (2) also stated that the definition of additivity by Bliss *et al.* (3)—that when one antibiotic is added to another, the effect is improved only to the extent that would occur had an equivalent portion of the same antibiotic been added—was the most restrictive. Thus, the quantity of antibiotic having the same effect or response as the other component of the combination is added to the quantity of the same antibiotic present in the combination, giving the total amount of one antibiotic having the same response as an additive combination. Garrett and coworkers (4, 5) evaluated the additive interaction between chloramphenicol and tetracycline and between erythromycin and lincomycin by measuring the growth rates of *Escherichia coli* in media containing subinhibitory concentrations of the different antibiotics, alone and in combination.

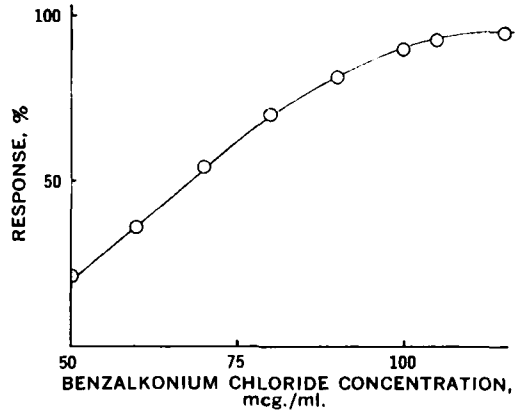

Figure 1—*Dose–response correlation for benzalkonium chloride against* P. aeruginosa.

It was recommended (6) that quick-acting preservatives should be used in ophthalmic preparations and that the final preparation should sterilize a large inoculum of *Pseudomonas aeruginosa* in less than 1 hr. A number of ophthalmic formulations inoculated with 10^6 *P. aeruginosa*/ml. did not pass this test; but when phenylethanol was present as well as the preservative, the preparations sterilized such inocula within 1 hr. (7, 8). Benzyl alcohol and phenylpropanol also enhanced the bactericidal action of benzalkonium chloride (9).

The present investigation was undertaken to determine whether the enhancement of the antibacterial action of benzalkonium chloride and chlorhexidine acetate by aromatic alcohols was greater or less than additive, using growth rate studies of log phase cultures of *P. aeruginosa* in subinhibitory concentrations of the preservatives.

EXPERIMENTAL

Materials—Benzyl alcohol[1] (reagent grade), phenethyl alcohol[1] (phenylethanol or 2-phenylethanol) (reagent grade), phenylpropanol[1] (3-phenylpropanol) (reagent grade), benzalkonium chloride BP[2], and chlorhexidine acetate BPC[3] were used. *P. aeruginosa* NCTC[4] 6750 was the test organism, Oxoid nutrient broth No. 2 was the growth medium, and incubation was at 37°. Maintenance of stock cultures and experimental details were as previously described (9).

Table I—Effect of Benzalkonium Chloride and Chlorhexidine Acetate, Alone and in Combination with Benzyl Alcohol, Phenethyl Alcohol, or Phenylpropanol on the Growth Rate of *P. aeruginosa*

Bactericide, Percentage Concentration	Percentage Response	Percentage Antibacterial Equivalent to Alcohol	Antibacterial Estimated to be Equivalent to Combination: Percentage Concentration	Antibacterial Estimated to be Equivalent to Combination: Percentage Response		Experimental Percentage Response for Combination
Benzalkonium chloride, 0.003	18.5					
Benzyl alcohol, 0.175	41.9	0.0041	0.0071	53.7		76.7
Phenethyl alcohol, 0.175	51.5	0.0046	0.0076	62.0		91.5
Phenylpropanol, 0.175	45.8	0.0043	0.0073	52.0		Lysis
				Mode of Action: First	Second	
Chlorhexidine acetate, 0.0002	18.5					
Benzyl alcohol, 0.175	41.9	0.0031	0.0051	32.0	Lysis	65.9
Phenethyl alcohol, 0.175	47.6	0.0033	0.0053	32.5	Lysis	86.7
Phenylpropanol, 0.175	44.7	0.0032	0.0052	32.3	Lysis	Lysis

Effect of Single Bactericide—The growth of *P. aeruginosa* in media containing different concentrations of a bactericide was followed by measuring the extinctions at 420 nm. The effect or response of a particular concentration is the difference between the growth rate of the control containing no bactericide and that of the bactericide; the percentage response is the difference expressed as a percentage of the control growth rate. The results for benzalkonium chloride and chlorhexidine acetate are illustrated in Figs. 1 and 2, where the percentage response is plotted against bactericide concentration.

Effect of Alcohol–Bactericide Combinations—The procedure with benzalkonium chloride was described previously (9), and a similar procedure was used with chlorhexidine acetate (Fig. 3). The results for both chemicals are given in Table I.

DISCUSSION

Simple addition of the individual response for each component of a combination assumes that the concentration–response correlation for the antibiotic is rectilinear, when often it is not (10). Figure 4 illustrates the influence of the concentration–response correlation upon the theoretical additive response of a combination. If the percentage response of one component, *M*, is 27%, this response is similar to that of 4 units of Component *N*. In a combination of *M* and 4.5 units of *N* (response of 30%), the theoretical additive response would be the same as that of 8.5 units of *N*. But only when the concentration response correlation is rectilinear, as in Type A, does the percentage response (57%) for the 8.5 units of *N* equal the sum of the individual responses. When the concentration response is of Type B, 8.5 units of *N* has a percentage response of 81%; Type C would indicate a response of 39%. Thus, in measuring concentration–response correlations, the concentration of a single preservative equivalent to that of the combination should be included to avoid extrapolation.

The dose–response correlation for each aromatic alcohol was rectilinear (9) and is similar to Type A in Fig. 4. Thus, in determining the theoretical additive response based on the quantity of alcohol having the same effect as the combination, the percentage responses for the components of the combination as single substances were added. The sum of either bactericide with any of the three alcohols was always less than the experimental value obtained, indicating that the response was greater than additive and increased with the molecular weight of the alcohol.

The dose–response correlation for the benzalkonium chloride (Fig. 1) was similar to Type C in Fig. 4, *i.e.*, linear at low concentrations and becoming asymptotic at higher concentrations. The concentrations of benzalkonium chloride that have the same response as each alcohol were determined, and the theoretical response based on the quantity of benzalkonium chloride having the same effect as the combination was also determined. The tabulated results again show that the combination has an effect greater than additive, with phenylpropanol having the largest increase and benzyl alcohol having the smallest.

The dose–response for chlorhexidine acetate (Fig. 2) has a bilinear correlation, showing a slow increase in response with increasing concentration to between 2.75 and 3.0 mcg./ml. and higher concentrations having a very rapid response. In all media containing more than 3.75 mcg./ml. chlorhexidine acetate, lysis occurred. A similar result was observed (11) when the growth rate of *Klebsiella cloaca* was measured in media containing different con-

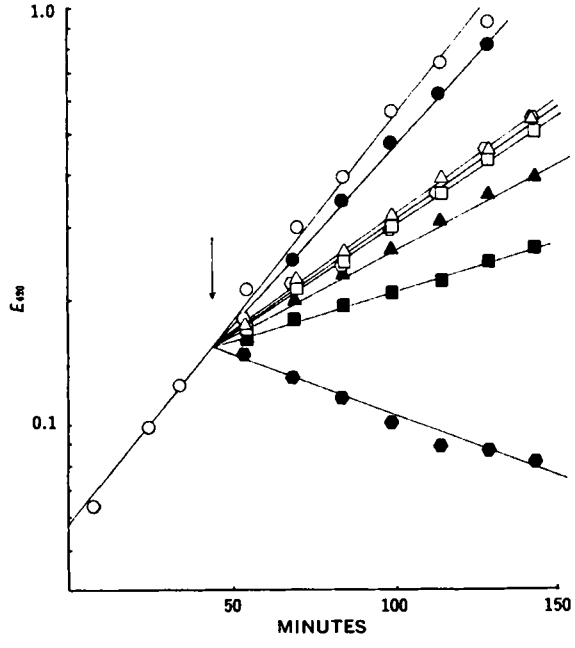

Figure 3—*Effect of 0.175% benzyl alcohol* (△), *0.175% phenethyl alcohol* (□), *and 0.175% phenylpropanol* (○), *alone (open symbols) and in combination with 0.0002% chlorhexidine acetate (closed symbols) on* P. aeruginosa. *The circles indicate alcohol-free control cultures, and additions were made at the time indicated by the arrow.*

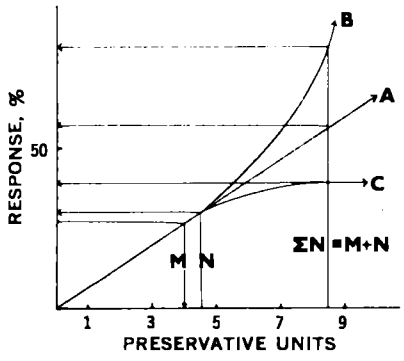

Figure 4—*Effect of the concentration–response correlation on the theoretical additive response of a combination.*

centrations of phenol. It was postulated that if an inhibitor combined with cellular enzymes, the velocity of the enzyme-catalyzed reaction will depend on the concentration of uncombined enzyme, and where an inhibitor affects more than one enzyme in different concentration ranges of inhibitor, each range will display different concentration effects or modes of action. The dose–response correlation indicates that chlorhexidine acetate has two modes of action according to the enzyme model of Harris and Morrison (11). The quantities of chlorhexidine acetate having the same responses as the alcohols would affect the growth of *P. aeruginosa* by the second mode of action; calculation of the theoretical additive response based on the equivalent quantity of chlorhexidine acetate indicates that lysis would occur (Table I). Since the alcohol has a different mode of action from chlorhexidine acetate, sufficient chlorhexidine may not be present to enable the second mode of action to occur, even though the quantity of chlorhexidine acetate in the biophase may increase due to the permeability effect of the alcohol. The amount of chlorhexidine acetate in the combination only affects the initial mode of action when used as a single substance; if this controls the growth rate, the theoretical additive response can be obtained by extrapolation of the initial dose–response correlation (Fig. 2). As shown in Table I, the theoretical percentage response was approximately 32%, which is less than that with the alcohol alone. The experimental results indicate a response greater than additive for chlorhexidine acetate in combination with the aromatic alcohols, with phenylpropanol showing the greatest enhancement and benzyl alcohol showing the least.

In a description of the desirable properties for a combination of preservatives, it has been stated that the combination should act more rapidly against the test organism than do the same concentrations of each agent used separately (12). This does not differentiate between agents that combine to give a response greater or less than additive while still exceeding that of any one member of a combination. While such differentiation may not be important, there are obvious advantages in using combinations whose response is greater than additive.

Determination of Equilibrium Constants and Binding Capacities Using a Modified Scatchard Method in Drug–Protein Binding Studies

JOSEPH K. H. MA, H. W. JUN, and L. A. LUZZI▲

Abstract □ The equilibrium constants and the number of binding sites for the binding of 1-anilinonaphthalene-8-sulfonate to human and bovine serum albumin, studied by a fluorescent method, were determined by an equation derived from the Scatchard multiple-equilibrium treatment. The results and the equation are discussed and compared with other equations used in drug–protein binding studies. Treatment of data by the modified method allows a clear determination of the number of binding sites.

Keyphrases □ Drug–protein binding—equilibrium constants and binding capacities using modified Scatchard method, equations □ Equilibrium constants—determined using a modified Scatchard method, drug–protein binding studies, equations □ Binding capacities—determined using a modified Scatchard method, drug–protein binding studies, equations □ Scatchard multiple-equilibrium treatment, modified—equation derived to determine equilibrium constants and binding capacities, drug–protein binding studies

In drug–protein binding studies, several equations have been used for binding constant calculation (1–3). One frequently used equation is the Langmuir-type equation:

$$\bar{\nu}/(D) = nK - \bar{\nu}K \qquad \text{(Eq. 1)}$$

where $\bar{\nu}$ represents the ratio of moles of bound drug per mole of total protein, (D) is the concentration of unbound drug, K is the binding constant, and n is the number of binding sites on a single protein molecule, assuming that all sites are of equal binding strength. However, the plot of $\bar{\nu}/(D)$ *versus* $\bar{\nu}$ frequently gives a downward curve rather than a convincing straight line. Such curvature may be indicative of binding to more than one class of sites (4). Mathematical treatments for the determination of binding parameters along this line were also reported (5, 6).

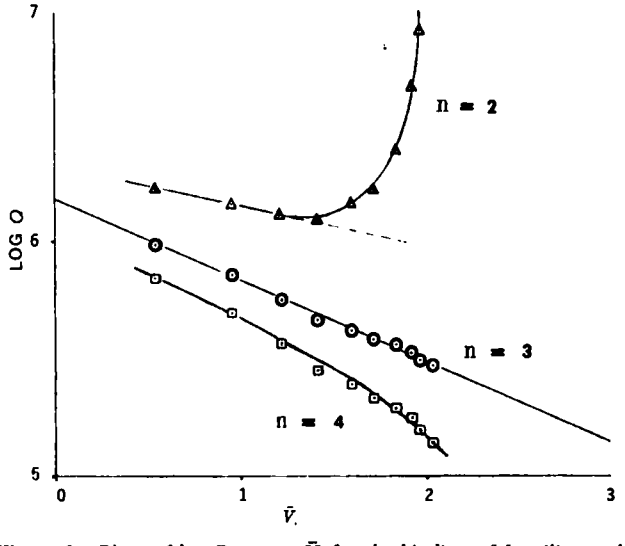

Figure 1—*Plots of log* Q versus $\bar{\nu}$ *for the binding of 1-anilinonaphthalene-8-sulfonate to human serum albumin.*

Recently, Eq. 1 was modified (7, 8) by the introduction of an empirical parameter:

$$\log [\bar{\nu}/(n - \bar{\nu})] = m \log (D) + m \log K \qquad \text{(Eq. 2)}$$

By this method, the value of n is estimated by trial and error so that the plot of $\log [\bar{\nu}/(n - \bar{\nu})]$ *versus* $\log (D)$ might be linear, and m and $\log K$ are evaluated from the slope and the intercept of the graph. When $m = 1$, Eq. 2 may be reduced to Eq. 1. For the binding of 2-(4′-hydroxyphenylazo)benzoic acid to bovine serum albumin, it was shown (7, 8) that m is not equal to 1 and that it varies with factors such as the concentrations of albumin and buffering agent and temperature.

In the present study, the binding of 1-anilinonaphthalene-8-sulfonate to human and bovine serum albumins was studied by a fluorescent method (9). The data were treated using a modified Scatchard equation for multiple equilibria.

EXPERIMENTAL

Materials—1-Anilinonaphthalene-8-sulfonate[1], crystalline human serum albumin[2], bovine serum albumin[3], and spectroscopic grade methanol (as a solvent) were used. All other chemicals were of reagent grade.

Instruments and Methods—All fluorescence measurements were made on a spectrophotofluorometer[4] equipped with a 150-w. xenon lamp and 1P21 photomultiplier tube. Fluorescence titrations over a range of protein concentrations were carried out at the emission maxima of 474 and 467 nm. for human and bovine serum albumins, respectively, with the excitation for both systems at 375 nm. Two milliliters of each protein solution in pH 7.4 phosphate buffer was titrated with successive additions of 2 μl. of 1×10^{-3} *M* 1-anilinonaphthalene-8-sulfonate. The probe was dissolved in methanol and delivered with microsyringes[5]. The temperature of all samples was 25 ± 0.5°.

RESULTS AND DISCUSSION

The relative fluorescence intensities of solutions containing various amounts of 1-anilinonaphthalene-8-sulfonate in the absence and presence of human and bovine serum albumins are shown in Table I. During the titration, above the critical protein concentrations of 29.10×10^{-6} *M* for human serum albumin and 61.41×10^{-6} *M* for bovine serum albumin, there was no further enhancement of the fluorescence upon increases in protein concentration. It was then assumed that all of the drug was bound to protein. The fractions of bound and unbound drug and the molar ratio of the drug bound to protein were calculated by a method previously used in these laboratories (10). Determinations of binding constants were made for solutions containing 1.45×10^{-6} *M* human serum

[a] The total 1-anilinonaphthalene-8-sulfonate concentration.

albumin and 1.23×10^{-6} M bovine serum albumin with varying concentrations of 1-anilinonaphthalene-8-sulfonate.

To calculate the equilibrium constants, a function, Q, is defined by the relation:

$$Q = \bar{V}/(n - \bar{V})(D) \qquad \text{(Eq. 3)}$$

or:

$$\log Q = \log [\bar{V}/(n - \bar{V})] + pD \qquad \text{(Eq. 4)}$$

Equation 3 was developed by Scatchard and first employed by Edsall *et al.* (11). The method of Edsall *et al.* was used for the present study to determine the binding parameters. The value of n was not obtained experimentally, however, since it was previously reported (12) that each mole of bovine serum albumin was bound by 3 moles of 1-anilinonaphthalene-8-sulfonate; it was decided to introduce this number first as the probable value for n. The following equilibrium processes ($n = 3$) were chosen for the determination of the equilibrium constants:

$$P + D = PD \qquad k_1 = (PD)/(P)(D) \qquad \text{(Eq. 5)}$$

$$PD + D = PD_2 \qquad k_2 = (PD_2)/(PD)(D) \qquad \text{(Eq. 6)}$$

$$PD_2 + D = PD_3 \qquad k_3 = (PD_3)/(PD_2)(D) \qquad \text{(Eq. 7)}$$

where P represents protein and k_1, k_2, and k_3 are the successive equilibrium constants.

A plot of calculated values for log Q *versus* $\bar{V}$ will give a straight line (13, 14), although the points as $\bar{V}$ approaches zero or the maximum number of binding sites may show some curvature due to experimental error. For $n = 3$, the extrapolated log Q values at

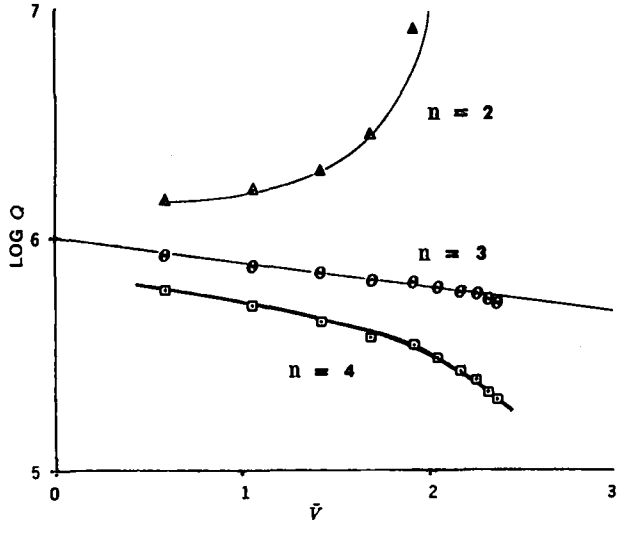

Figure 2—*Plots of log* Q versus $\bar{V}$ *for the binding of 1-anilinonaphthalene-8-sulfonate to bovine serum albumin.*

Table II—Successive Logarithmic Equilibrium Constants of the Binding of 1-Anilinonaphthalene-8-sulfonate to Human and Bovine Serum Albumins

Protein	Concentration	n	log k_1	log k_2	log k_3
Human serum albumin	1.45×10^{-6}	3	6.66	5.66	4.66
Bovine serum albumin	1.23×10^{-6}	3	6.48	5.84	5.20

$\bar{V} = 0$ and $\bar{V} = 3$ are essentially equal to log K_1 and log K_3, respectively. K_1 and K_3 are the intrinsic association constants, which are related to the equilibrium constants by the following equations:

$$K_1 = k_1/3 \qquad \text{(Eq. 8)}$$

$$K_2 = 2k_2/2 \qquad \text{(Eq. 9)}$$

$$K_3 = 3k_3 \qquad \text{(Eq. 10)}$$

To obtain k_2, the following procedure (13) can be used. From the plot of log Q *versus* $\bar{V}$, one can determine log Q at $\bar{V} = 1.5$ as:

$$\log Q = \log [1.5/(3 - 1.5)] + pD \qquad \text{(Eq. 11)}$$

The value of pD can be easily calculated and is taken to be the value of log k_2.

In the present study, three sets of log Q values were calculated using Eq. 4 by letting $n = 2$, 3, and 4, respectively. These values for log Q were then plotted as a function of $\bar{V}$. The results seen in Fig. 1 represent the plots for $n = 2$, 3, and 4 when human serum albumin is the protein. Figure 2 is a similar representation of data when bovine serum albumin is the protein. The plots are linear for both systems at $n = 3$. For $n = 2$ and 4, however, two opposing curves, above and below the straight line, were obtained. These results indicate that both human and serum albumins probably have three binding sites for 1-anilinonaphthalene-8-sulfonate. This is reinforced when one considers previously reported values for n in similar systems.

The successive equilibrium constants determined from Figs. 1 and 2 are listed in Table II. Human serum albumin has a larger log k_1 value but smaller values of log k_2 and log k_3 than those of bovine

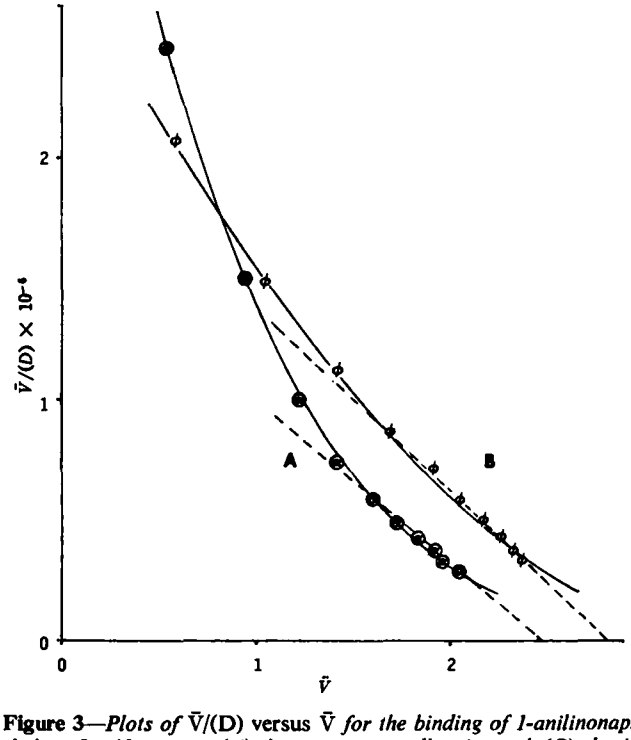

Figure 3—*Plots of* $\bar{V}$/(D) versus $\bar{V}$ *for the binding of 1-anilinonaphthalene-8-sulfonate to (A) human serum albumin and (B) bovine serum albumin.*

serum albumin. This suggests that the binding of one 1-anilinonaphthalene-8-sulfonate molecule to human serum albumin discourages other 1-anilinonaphthalene-8-sulfonate molecules from combining in a greater extent than the binding of 1-anilinonaphthalene-8-sulfonate to bovine serum albumin.

Equation 1 was suggested by Scatchard (3) for the special case when the intrinsic association constants are all equal. He also pointed out that, if the plot of $\bar{V}/(D)$ *versus* $\bar{V}$ does not give a straight line, it may be inferred that the intrinsic constants are not equal and/or there is interaction among the bound ions. The former effect is well demonstrated by the results of this study. For comparison, the plots of $\bar{V}/(D)$ *versus* $\bar{V}$ for both protein systems are shown in Fig. 3; these plots are not quite linear. If one were to discount the low values of $\bar{V}$, one could plot a straight line with a high significance factor. The n values for the human and bovine serum albumin systems obtained from the straight-line portion of the Scatchard plots are 2.5 and 2.8, respectively. When using Eq. 3, the results seem to be much more satisfactory. It is possible to detect the number of sites with greatest affinity as well as to detect dramatically the total number of binding sites over a range of small molecule concentrations.

Equation 2 is an empirical equation in which a parameter, m, is introduced into Eq. 1 to obtain a straight-line plot. The fact that m is varied by the protein concentration, buffer agent, and temperature (7) may indicate the effect of these factors on the binding. However, the physicochemical meaning of m is still not clear.

The determination of the binding parameters may also depend on the experimental methods used. The results obtained from the fluorescence technique are different from those of other methods, probably in the manner that only the primary (strong) binding sites are detected, whereas the results obtained from other methods such as dialysis (15, 16) often show larger numbers of binding sites. The curvature of the Scatchard plot has been interpreted (4) as the binding of the small molecule to more than one class of sites on the protein. However, it is possible that the intrinsic association constants of the binding of these sites are not equal even in the same class.

Low Temperature Maintenance of Test Organism Suspensions for Antibiotic Assays

DONALD T. SALT▲, BERNARD ARRET, and JEROME WILNER

Abstract □ The survival rates of 14 test organisms that had been suspended in saline, distilled water, peptone water, or nutrient broth were compared after storage at −70°. Viable cell counts and dose–responses to various antibiotics were determined prior to freezing and at 3-month intervals for 2 years after freezing. Most test organisms were successfully maintained in this manner using water, peptone water, or broth with little or insignificant losses in viable cells or change in dose–response in antibiotic assay systems.

Keyphrases □ Microorganisms—low temperature maintenance for use in antibiotic assays □ Antibiotic assays—low temperature maintenance of test organism suspensions □ Test organisms—low temperature maintenance for use in antibiotic assays

This laboratory maintains a number of test organism suspensions for daily use in turbidimetric and agar diffusion assays of antibiotics (1). Detailed procedures for the preparation of these suspensions are described in the *Code of Federal Regulations* (2). Because of the variety of antibiotics tested and the volume of samples to be assayed, preparing fresh suspensions on a weekly or biweekly basis is a time-consuming task attended by a number of laboratory problems. Ideally, the growth characteristics and specific antibiotic dose–response of any given suspension are reproducible if the suspension has been prepared according to the official method and stored under refrigeration at temperatures just above freezing. In actual practice, even the most exacting

serum albumin. This suggests that the binding of one 1-anilinonaphthalene-8-sulfonate molecule to human serum albumin discourages other 1-anilinonaphthalene-8-sulfonate molecules from combining in a greater extent than the binding of 1-anilinonaphthalene-8-sulfonate to bovine serum albumin.

Equation 1 was suggested by Scatchard (3) for the special case when the intrinsic association constants are all equal. He also pointed out that, if the plot of $\bar{V}/(D)$ *versus* $\bar{V}$ does not give a straight line, it may be inferred that the intrinsic constants are not equal and/or there is interaction among the bound ions. The former effect is well demonstrated by the results of this study. For comparison, the plots of $\bar{V}/(D)$ *versus* $\bar{V}$ for both protein systems are shown in Fig. 3; these plots are not quite linear. If one were to discount the low values of $\bar{V}$, one could plot a straight line with a high significance factor. The n values for the human and bovine serum albumin systems obtained from the straight-line portion of the Scatchard plots are 2.5 and 2.8, respectively. When using Eq. 3, the results seem to be much more satisfactory. It is possible to detect the number of sites with greatest affinity as well as to detect dramatically the total number of binding sites over a range of small molecule concentrations.

Equation 2 is an empirical equation in which a parameter, m, is introduced into Eq. 1 to obtain a straight-line plot. The fact that m is varied by the protein concentration, buffer agent, and temperature (7) may indicate the effect of these factors on the binding. However, the physicochemical meaning of m is still not clear.

The determination of the binding parameters may also depend on the experimental methods used. The results obtained from the fluorescence technique are different from those of other methods, probably in the manner that only the primary (strong) binding sites are detected, whereas the results obtained from other methods such as dialysis (15, 16) often show larger numbers of binding sites. The curvature of the Scatchard plot has been interpreted (4) as the binding of the small molecule to more than one class of sites on the protein. However, it is possible that the intrinsic association constants of the binding of these sites are not equal even in the same class.

Low Temperature Maintenance of Test Organism Suspensions for Antibiotic Assays

DONALD T. SALT▲, BERNARD ARRET, and JEROME WILNER

Abstract □ The survival rates of 14 test organisms that had been suspended in saline, distilled water, peptone water, or nutrient broth were compared after storage at −70°. Viable cell counts and dose–responses to various antibiotics were determined prior to freezing and at 3-month intervals for 2 years after freezing. Most test organisms were successfully maintained in this manner using water, peptone water, or broth with little or insignificant losses in viable cells or change in dose–response in antibiotic assay systems.

Keyphrases □ Microorganisms—low temperature maintenance for use in antibiotic assays □ Antibiotic assays—low temperature maintenance of test organism suspensions □ Test organisms—low temperature maintenance for use in antibiotic assays

This laboratory maintains a number of test organism suspensions for daily use in turbidimetric and agar diffusion assays of antibiotics (1). Detailed procedures for the preparation of these suspensions are described in the *Code of Federal Regulations* (2). Because of the variety of antibiotics tested and the volume of samples to be assayed, preparing fresh suspensions on a weekly or biweekly basis is a time-consuming task attended by a number of laboratory problems. Ideally, the growth characteristics and specific antibiotic dose–response of any given suspension are reproducible if the suspension has been prepared according to the official method and stored under refrigeration at temperatures just above freezing. In actual practice, even the most exacting

quality controls do not exclude occasional contamination or prevent batch-to-batch variations in the composition of dehydrated media and related problems. Preparing large quantities of test organism suspension for use over an extended period makes it possible to decrease the occurrence of such aberrations and has the further advantage that once an acceptable suspension has been prepared there is a continuity of reproducible assay response.

Conditions for the preservation and maintenance of test organism suspensions have been reported by numerous investigators. Sokolski *et al.* (3) reported the preparation of frozen suspensions for vitamin B_{12} assays. Complete recovery of viable cells was obtained when the suspensions in basal medium were rapidly frozen by direct immersion into liquid nitrogen and rapidly thawed by agitating in a water bath at 40°. McDaniel and Bailey (4) found that liquid nitrogen storage was the most satisfactory method for supplying standard *Streptomyces viridoflavus* inoculum for laboratory and pilot plant experimentation. There were no detectable changes in viability over 12 months when cotton-plugged ampuls were stored in the gas phase of a liquid nitrogen refrigerator. Tanguay (5) reported on the direct freezing of test organisms either in tryptose–saline containing 15% glycerol or in 0.067 *M* phosphate buffer, pH 7.0, containing 15% glycerol. When frozen and stored at −40°, these organisms maintained a satisfactory growth response from 6 months to 1 year or more. The main advantages claimed for this technique are that assays can be done at any time without the necessity of preparing daily inocula or maintaining the sensitivity of test organisms and that assay responses are standardized. Day-to-day fluctuations in growth responses and invalid assays due to inoculum failure are largely eliminated (5). These qualities are essential to the success of the certification program at the National Center for Antibiotic Analysis. This report describes the results of direct freezing of various test organisms used at the National Center.

EXPERIMENTAL

The 14 official antibiotic assay organisms listed in Table I were tested at 3-month intervals for periods ranging from 6 months to up

[a] AD = agar diffusion assay, and T = turbidimetric assay. [b] Defined in terms of slope where b = slope = range over 1 log cycle (expressed in millimeters of zone diameter for agar diffusion assay and absorbance values for turbidimetric assay). [c] Discontinued after the time indicated because of loss of viable cells. [d] Discontinued after the time indicated because of significant change in dose-response.

to 2 years. Some tests were terminated earlier than 2 years, *e.g.*, at 6, 12, or 15 months, depending on the number of viable cells present and/or the dose-response at that time. The suspending agents and their compositions were: (*a*) sterile normal saline, (*b*) sterile distilled water, (*c*) sterile 0.5% peptone water, and (*d*) nutrient broth (Medium 3) (2).

The test organisms were maintained on agar slants containing 10 ml. of appropriate medium, and the suspensions were prepared as described in the *Code of Federal Regulations* (2). Growth was washed from the agar surface of the Roux bottles with 50 ml. of the appropriate suspending agent. Washings from three Roux bottles were pooled for each diluent to give a total of 150 ml. of suspension. From each pooled suspension, 12-ml. portions were placed in 30-ml. polycarbonate centrifuge tubes [1.27-cm. (0.5-in.) mouth] and closed with polypropylene screw caps. The tubes of suspension were quick frozen by a mixture of equal parts of dry ice and 95% ethanol (6) and then placed in a low temperature freezer (one capable of temperature to −90°) at −70°.

Viable cell counts and dose-responses (7) to the appropriate antibiotics were determined prior to freezing and at 3-month intervals up to 2 years. At each interval, a tube of frozen suspension was thawed by placing in a refrigerator for 2 hr. Each thawed suspension was tested initially upon thawing and then was stored for 2 weeks under refrigeration and tested each week for viable cell count and dose-response. The percent inoculum varied with the organism being tested; the incubation time also varied, depending on whether the agar diffusion or turbidimetric assay method was used to determine the dose-response to a particular antibiotic.

RESULTS AND DISCUSSION

As shown in Table I, most test organisms can be maintained satisfactorily for up to 2 years without any significant loss in viability and, as shown in Table II, such a procedure maintains an acceptable dose-response to the various antibiotics. Outstanding success was obtained with *Staphylococcus aureus* (resistant to novobiocin), *Sarcina subflava*, and *Sarcina lutea* (resistant to erythromycin) with no loss of viable cells in saline, water, or peptone water (Table I). In these instances, peptone water was selected as the vehicle of choice because of the stability of most organisms under refrigeration after they are thawed. Table I also shows that, of the organisms tested, the least success was obtained with *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas pyocyanea;* tests were discontinued early in the study because of losses in viable cells ranging from 70 to 100% after only 3 months.

Table III—Recommended Procedures for Storage at −70°

Test Organism	Suspending Vehicle	Maximum Storage Time, Months Frozen	Stability (Weeks Unfrozen) under Refrigeration
Staphylococcus aureus, resistant to novobiocin (ATCC 12692)	Peptone water	12	1
Saccharomyces cerevisiae (ATCC 9763)	Peptone water	12	2
Saccharomyces cerevisiae (ATCC 2601)	—	Not recommended	4
Staphylococcus epidermidis (ATCC 12228)	Peptone water	12	1
Staphylococcus aureus (ATCC 6538P)	Broth	12–18 (Agar diffusion assay) 6 (Turbidimetric assay)	1 1
Bordetella bronchiseptica (ATCC 4617)	Water	6	1
Sarcina lutea (ATCC 9341)	Peptone water	12	2
Sarcina subflava (ATCC 7468)	Peptone water	12	2
Pseudomonas pyocyanea (ATCC 23389)	—	Not recommended	2
Klebsiella pneumoniae (ATCC 10031)	—	Not recommended	1
Escherichia coli (ATCC 10536)	—	Not recommended	2
Sarcina lutea, resistant to erythromycin (ATCC 15957)	Peptone water	12	2
Sarcina subflava, resistant to dihydrostreptomycin (ATCC 7468/d)	Peptone water	12	2
Streptococcus faecalis (ATCC 10541)	—	Not recommended	24 hr.

Table III indicates that the recommended maximum storage time for most tested organisms is 1 year in peptone water. The 1-year time limit was selected to allow for some margin of error, even though excellent results were obtained for up to 2 years for most organisms.

In conclusion, most tested organisms can be frozen for 6 months to 2 years in water, peptone water, or broth with little or no loss in viable cells or change in dose-response. The method is simple and requires no elaborate equipment other than a low temperature freezer capable of maintaining temperatures of −70°. Frozen suspensions, although not specifically mentioned in the *Code of Federal Regulations*, are implicit in the directions to maintain the suspensions under "refrigeration." The findings show that subfreezing refrigeration temperatures offer a suitable and reliable method for maintaining suspensions of antibiotic test organisms.

Cannabis sativa L. (Marijuana) IV: Chemical Basis for Increased Potency Related to Novel Method of Preparation

ALVIN B. SEGELMAN▲ and R. DUANE SOFIA*

Abstract □ Recent reports from the drug subculture in this country indicate that the simultaneous use of marijuana teas together with smoking previously boiled marijuana plant material results in more profoundly experienced psychotropic effects. It was found that the boiling water treatment of marijuana removes water-soluble materials equivalent to 30% of the weight of the plant material, thus leading to marijuana correspondingly enriched in cannabinoids, including (−)-*trans*-Δ⁹-tetrahydrocannabinol, one of the major psychoactive compounds present in the plant. This finding explains, in part, the reputed increased pharmacological effects resulting from this newly described method of marijuana use. Moreover, the potential dangers inherent in the described method are discussed.

Keyphrases □ *Cannabis sativa*—new method of street use, chemical basis of increased potency, GLC □ Marijuana—new method of street use, chemical basis of increased potency, GLC □ Cannabinoids—stability following boiling water treatment, related to new street use to increase potency, GLC

Various preparations derived from the plant *Cannabis sativa* L. have long been used for their intoxicating properties (1). In the United States, the plant is usually employed as a euphoriant by means of smoking cigarettes or pipes containing marijuana[1] or marijuana admixed with other substances (2). It is generally accepted that (−)-*trans*-Δ⁹-tetrahydrocannabinol (I) is the major psychoactive constituent of marijuana (3). Marijuana is considered to be of high potency when the content of I is approximately 1% (w/w) (4). This report concerns a novel method of marijuana preparation and use among certain fringe groups of the drug subculture in this country[2].

The marijuana is first slurried with sufficient water to cover the plant material, and this mixture is subsequently boiled in a suitable container for 1 to several hours. Additional portions of fresh water are sometimes added periodically to maintain the level of the liquid and thus prevent possible charring of the marijuana. Upon termination of the boiling process, the hot mixture is allowed to cool to room temperature and is then strained through several layers of cheesecloth.

The resulting filtrate ("marijuana tea") is reserved and stored in a refrigerator because it has been found that the tea is prone to mold growth. The marijuana remaining on the filter is removed, manually expressed free of excess liquid, which is added to the reserved tea, and finally spread out and allowed to air dry. In some reported cases, the damp marijuana is dried using an ordinary baking oven set at moderate heat. The resulting dried marijuana plant material is subsequently formed into cigarettes in the usual manner, with no adjustment being made in the approximate weight of plant material used to prepare individual cigarettes. These cigarettes are smoked normally except for the following major variation. Just prior to smoking, the reserved marijuana tea is consumed at once. Those persons employing marijuana in this fashion claim that the subsequent effects of the drug are perceived to be significantly more profound, both in terms of intensity and duration, than are the effects experienced by smoking marijuana prepared by more conventional means.

The results of studies designed to assess the possible chemical consequences from this previously unreported utilization of marijuana are reported.

[1] The term marijuana as used here refers to the crushed leaves, stems, and flowering tops of *C. sativa*.

[2] It is presently not possible to determine accurately the extent of this practice. However, essentially similar practices have been related by particularly reliable sources from various areas of the eastern United states, including Massachusetts, Pennsylvania, New Jersey, and Delaware.

Table I—Effect of Prolonged Boiling Water Treatment on the I Content of Marijuana

Marijuana Material	I, % Calculated	I, % Found[a]
Untreated marijuana	1.86[b]	1.90
Boiling water-treated marijuana	2.65[c]	2.56

[a] The GLC peaks identified with I were further confirmed in separate experiments using combined GLC–mass spectrometry according to procedures described earlier (9). [b] From the supplier's assay results. [c] Calculated by assuming that a total of 1.86 g. of I remained unchanged in the 70 g. of dried, boiling water-treated marijuana derived from 100 g. of starting untreated marijuana material, as described under *Preparation of Boiling Water-Treated Marijuana and Marijuana Tea.*

EXPERIMENTAL

Plant Material and Preparation of Standard Solutions—Marijuana plant material and all authentic cannabinoids[3] were obtained from the National Institute of Mental Health. The coarsely milled and air-dried marijuana represented female plant material, designated as Campus Mexican Female, which had been grown for 14 weeks and subsequently harvested at the University of Mississippi during the 1971 season. The GLC tracings and other data accompanying this material indicated the following cannabinoid content: I, 1.86% [84% as the acid (V), which acid (A or B) not specified]; II, 0.03%; III, 0.19%; and IV, not quantitatable. Separate standard solutions of each authentic cannabinoid were prepared in 95% ethanol to furnish a final concentration of 0.5 mcg./μl. in each case. These solutions were used to obtain the standard tracings for the GLC analyses and were stored at −5° in the dark prior to use.

GLC—All analyses were carried out on a modified gas chromatograph[4] equipped with a hydrogen flame-ionization detector and a 6-mm. o.d. × 2-mm. i.d. × 1.83-m. glass column packed with 80–100 mesh Supelcoport, AW, DMCS coated with 3% OV-17[5]. The instrument was modified such that the exit end of the column led directly to the base of the flame tip while the other end of the column

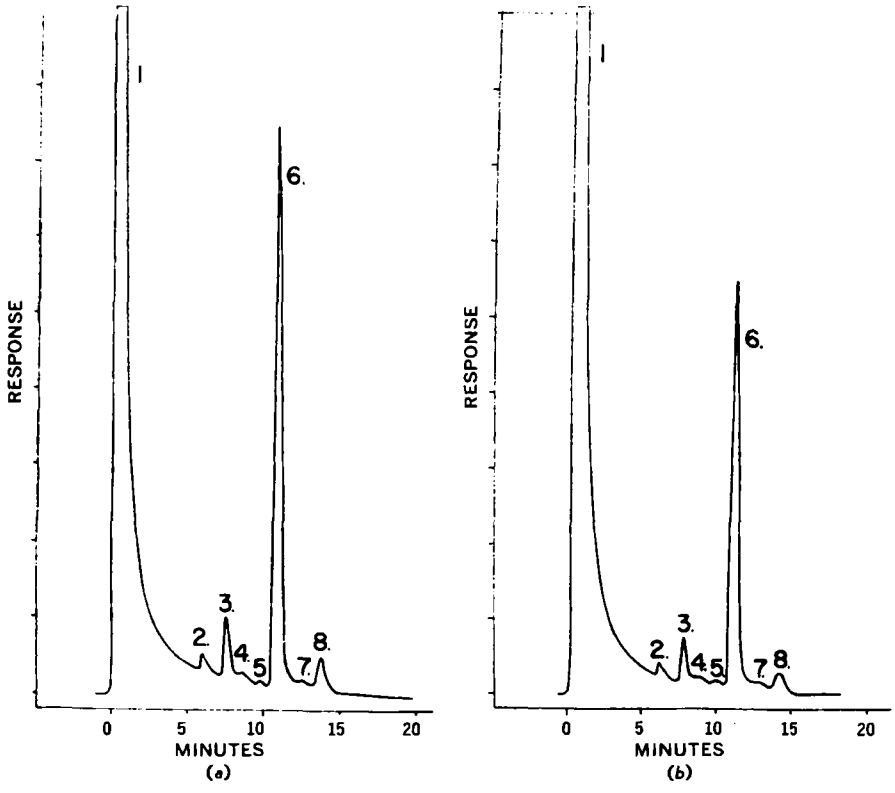

Figure 1—*Gas–liquid chromatograms of marijuana extracts (see text for method of preparation).* (a) *Extract A (boiling water-treated marijuana).* (b) *Extract B (untreated marijuana). Comparison of* a *and* b *reveals only quantitative differences. The analogous peaks (boiling water-treated marijuana* versus *untreated marijuana) are in the approximate ratio of 1.4:1, thus showing enrichment of the cannabinoids in the boiling water-treated marijuana. Key: 1, solvent; 2, unknown; 3,* (—)-trans-*cannabidiol; 4, unknown; 5,* (−)-trans-Δ^8-*tetrahydrocannabinol; 6,* (−)-trans-Δ^9-*tetrahydrocannabinol; 7, unknown; and 8,* (−)-*cannabinol.*

extended nearly to the injector port septum, thus resulting in an essentially all-glass system and allowing for on-column injection of the samples. The injector port and detector block temperatures were maintained at 263° while the column was operated isothermally at 203°. Attenuation was 7×10^{-11} amperes full scale for all analyses. Helium was used as the carrier gas at a flow rate of 10 ml./min.; hydrogen and dry air flow rates were 20 and 250 ml./min., respectively.

A strip chart recorder[6] with a chart speed of 0.508 cm./min. was employed. The peak areas recorded for all analyzed samples were calculated by the triangulation method (area = height × width at half-height) and compared with standard curves prepared by plotting the areas against known concentrations of standards analyzed in a similar manner. The results were found to be linear over the concentration ranges used. In those cases requiring derivatization (silylation), 0.5 ml. of the particular sample was evaporated using flowing nitrogen. The resulting dry residue (in a Teflon-lined screw-capped vial)[7] was treated with 0.5 ml. of a silylating reagent[8] and warmed (50°) for 3 min. It was found that derivatization was quantitative under these conditions, and subsequently an aliquot (usually 0.5–1.5 μl.) of the reaction mixture could be injected into the column.

Preparation of Boiling Water-Treated Marijuana and Marijuana Tea—A total of 100 g. of marijuana previously slurried with 1500 ml. of distilled water was continuously refluxed for 5 hr. using a Clevenger apparatus (for oils lighter than water) (5). No precautions were taken to exclude air or light from the boiling mixture. Following refluxing, the slurry less the volatile oil (0.2 ml.) was cooled to room temperature and suction filtered. The volume of the dark-brown filtrate was approximately 1300 ml. Finally, the plant material remaining on the filter was alternately washed and expressed, using small portions of hot water until the last wash filtrates were nearly colorless. These washings were combined with the initial filtrate until the total volume was adjusted to 1500 ml. This solution (marijuana tea) was frozen and lyophilized to give 30 g. of a dark-brown residue, which was stored under nitrogen at 4° for future chemical and pharmacological study. The remaining damp marijuana was allowed to air dry at ambient (23–25°) temperature for 5 days. This air-dried material was found to weigh 70 g. and was designated as boiling water-treated marijuana.

GLC of Boiling Water-Treated Marijuana and Untreated Marijuana—Fifty grams of boiling water-treated marijuana was percolated at a slow rate, using a total of 2000 ml. of 95% ethanol. The combined percolates were evaporated *in vacuo* to give a green syrup (about 25 ml.), which was brought to a volume of exactly 50 ml. with 95% ethanol. An aliquot (0.5 ml.) of this ethanolic solution was diluted using 95% ethanol to furnish 10 ml. of Extract A. Similarly, 50 g. of untreated marijuana was processed to furnish 10 ml. of Extract B. Aliquots (0.5–1.5 μl.) of Extracts A and B were analyzed by GLC to determine the cannabinoid profiles of the boiling water-treated marijuana and the untreated marijuana, respectively (Figs. 1*a* and 1*b*).

RESULTS AND DISCUSSION

It was found that 30% of the dry weight of the marijuana studied was removed by treatment with boiling water under conditions simulating those employed by certain members of the drug subculture. Thus, the loss of substantial quantities of water-soluble substances leads to marijuana (*viz.*, boiling water-treated marijuana) enriched in water-insoluble components, including cannabinoids such as I, a major psychoactive component of marijuana (Figs. 1*a* and 1*b*). For example, the boiling water-treated marijuana contained 1.4 times more I than was found in the untreated marijuana (Table I).

Under the conditions of these experiments, V was quantitatively decarboxylated to furnish the psychoactive I (Figs. 2*a* and 2*b*). This was not unexpected since it had earlier been pointed out that the cannabinoid acids rapidly decarboxylate at temperatures approaching 103° (6). What was surprising, but not totally unexpected, was that the cannabinoids present in the original untreated marijuana were stable when subjected to the relatively drastic conditions of prolonged boiling. Indeed, when the GLC analyses of the boiling water-treated marijuana and the untreated marijuana are compared (Figs. 1*a* and 1*b*), it is clear that the differences noted are quantitative and not qualitative. It was recently shown (7, 8) that certain cannabinoids are especially stable when they are present in crude preparations derived from *C. sativa*. In these cases, the complex

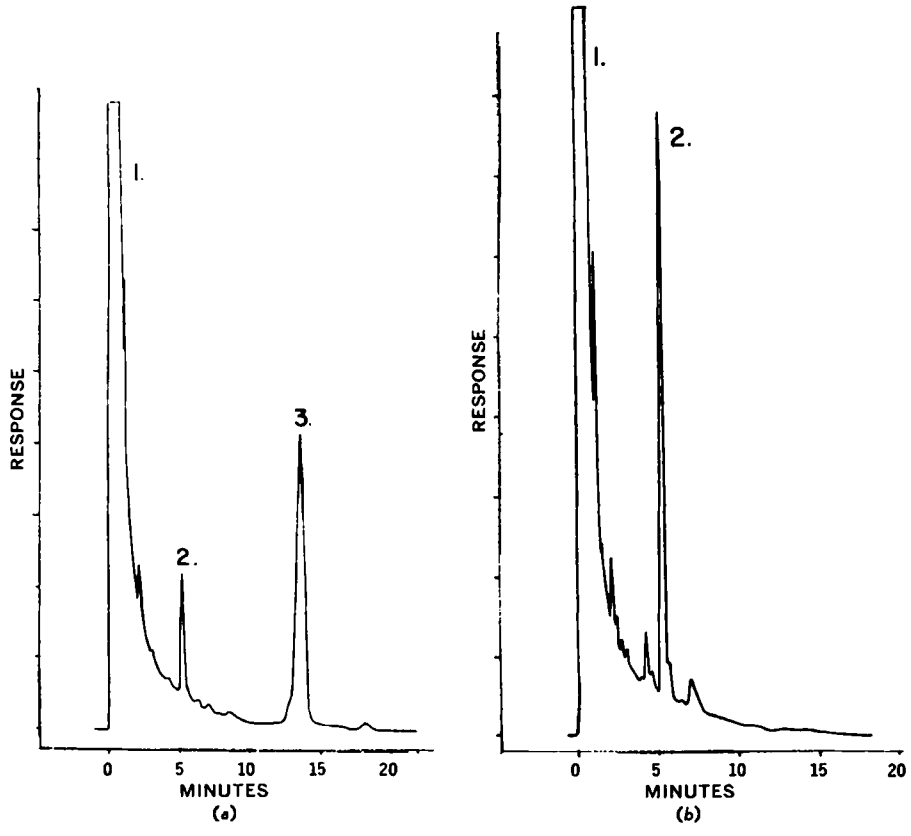

Figure 2—*Gas–liquid chromatograms of silylated marijuana extracts (see text for method of preparation). (a) Extract B (untreated marijuana) showing total (−)-trans-Δ⁹-tetrahydrocannabinol content was 84% (−)-trans-Δ⁹-tetrahydrocannabinol acid and 16% (−)-trans-Δ⁹-tetrahydrocannabinol. (b) Extract A (boiling water-treated marijuana). The absence of the (−)-trans-Δ⁹-tetrahydrocannabinol acid – trimethylsilyl derivative peak and the presence of the (−)-trans-Δ⁹-tetrahydrocannabinol–trimethylsilyl derivative peak indicate that the (−)-trans-Δ⁹-tetrahydrocannabinol acid was quantitatively decarboxylated to furnish (−)-trans-Δ⁹-tetrahydrocannabinol as a result of the boiling water treatment. Key: 1, solvent; 2, (−)-trans-Δ⁹-tetrahydrocannabinol–trimethylsilyl derivative; and 3, (−) - trans - Δ⁹ - tetrahydrocannabinol acid–trimethylsilyl derivative.*

mixture of phytoconstituents apparently retards the decomposition of the cannabinoids. This phenomenon may also explain the stability of the cannabinoids remaining in the boiled crude marijuana plant material[9].

Hence, the reputed claims made for the increased biological potency of boiling water-treated marijuana appear to be related, at least in part, to increased concentrations of presently known psychoactive components. Obviously, individuals who smoke the same weight of this material as the untreated marijuana (as indeed they do, as mentioned earlier) would experience increased drug effects.

The biological activity of the aqueous extract (marijuana tea) taken concomitantly with the boiling water-treated marijuana has not yet been fully evaluated. Both chemical and pharmacological studies of the marijuana tea are currently underway in these laboratories and results will be reported subsequently.

Nevertheless, immediate attention is called to the possible serious consequences that may result from the oral self-administration of marijuana teas for the following reasons. Since drugs are commonly misrepresented in the illicit market, it is not unusual to find contraband marijuana admixed with various noncannabis substances (2). Consider, for example, a street sample of marijuana containing equal amounts of tobacco and marijuana. In this particular case, a tea prepared from this material would probably contain relatively large amounts of the poisonous alkaloid nicotine; under normal smoking conditions most of the nicotine content of tobacco is destroyed. Similarly, analysis of confiscated marijuana (10) showed it to be impregnated with significant amounts of lysergic acid diethylamide (VI). Although VI is not biologically active when smoked, dangerous effects could result from ingesting teas prepared from VI-containing marijuana. Moreover, it may not be unreasonable to assume that marijuana may be adulterated with other drugs which are not biologically active when smoked but which may induce a variety of undesirable physiological effects when ingested in teas.

[9] Moreover, in separate experiments, the boiling water-treated marijuana was shown to be biologically active (dog ataxia test) according to procedures described elsewhere (7).

Identification of Barbiturates in Urine

RICHARD I. H. WANG▲ and MARILYN A. MUELLER

Abstract □ A TLC method was developed which employs a resin column for the extraction and identification of barbiturates in urine. The method is sensitive to less than 1 mcg./ml. for all of the barbiturates tested. Certain tranquilizers and sedatives appear on the chromatogram with the barbiturates, but they do not interfere with barbiturate detection. The efficacy of this method was demonstrated using urine samples obtained from both inpatients and outpatients under supervised conditions.

Keyphrases □ Barbiturates—TLC method of identification in urine, designed for drug abuse screening programs, elimination of interference from tranquilizers and sedatives □ Drug abuse screening programs—TLC method of identifying barbiturates in urine □ TLC—method of identifying barbiturates in urine, application to drug abuse screening programs

In the general area of drug abuse, much recent effort has been concentrated on the detection and treatment of narcotic addiction. However, probably due to the high price of heroin, there has been a steady increase in barbiturate abuse. For this reason, urine surveillance that includes the detection of barbiturates is important. Because of shortcomings in present methods, this laboratory has investigated and developed a new procedure for identifying barbiturates in urine.

In the last year, many different TLC procedures, solvent systems, and sprays were studied in this laboratory to detect and separate barbiturate metabolites in urine from the metabolites of other drugs such as chloral hydrate, tybamate, methyprylon, and glutethimide. These drugs, when given to drug abuse patients as part of their daily medications, were found to interfere consistently with the detection of barbiturates by existing methods. Several TLC methods were reported (1–5) but it was difficult for the present authors to distinguish barbiturates from certain sedatives and tranquilizers when following these reported procedures. Similar interference was noted using the ion-exchange paper methods of Dole *et al.* (6) and Kaistha and Jaffe (7). GLC (8), spectrophotometry (9, 10), and radioimmunoassay (11) are more sensitive than TLC for barbiturates. However, these methods indicate only one class of drugs at a time and are suitable mainly for confirmatory tests—not for routine urine surveillance performed in an average laboratory.

To avoid false-positive and false-negative results during urine surveillance of drug abuse patients who might be taking one or more interfering drugs, a reliable but simple method of identifying barbiturates was needed. This paper describes the procedure developed for detecting barbiturates in the presence of other drugs.

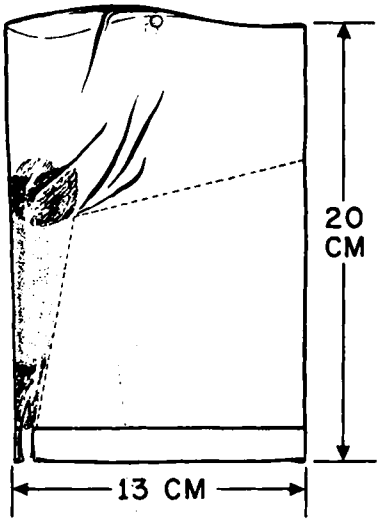

Figure 1—*A polyethylene bag is prepared and labeled for each sample. Urine (50 ml.) is poured into the upper channel of the bag, flows through the resin column, and drains out through the glass wool stopper at the bottom of the column.*

EXPERIMENTAL

Materials—Drugs were extracted from the urine using a resin column[1]. The resin is a styrene divinylbenzene copolymer which has a nonionic, macroreticular structure with high surface area capable of adsorbing many water-soluble organic compounds (12). The resin was first rinsed with 5% sodium chloride and 1% sodium bicarbonate to control bacteria and mold growth during storage. Several bed volumes of distilled water were washed over the surface of the resin until the decant became clear (13).

Columns were fabricated by heat sealing a 1.5 × 10-cm. channel on one side of a 12 × 20-cm. polyethylene bag and plugging both ends of the channel with glass wool stoppers. The columns were filled to a height of 7 cm. by gravity packing an aqueous slurry of the resin into the channel (Fig. 1). The colored portion of the eluate collected from the column was concentrated and spotted on silica gel-impregnated microfiber sheets[2].

All chemicals were of reagent grade. The solvent system consisted of chloroform–acetic acid (50:0.1) prepared fresh daily. One of the colored sprays used was diphenylcarbazone, prepared as a 0.1% solution in 95% ethanol. This reagent was stable for 2 or 3 weeks but should be refrigerated in an amber bottle. The second spray, prepared by dissolving 20 g. mercurous nitrate in 500 ml. of 0.15 *M* nitric acid, was also stable for several weeks.

Procedure—Fifty milliliters of urine was poured through the resin column. The column was compressed to force all of the urine to pass through it, and then the compounds adsorbed by the resin were eluted with 15 ml. of methanol. The colored portion of the eluate was collected, and 10 ml. of this eluate was concentrated to about 1 ml. Forty microliters of the concentrated eluate was spotted on precoated thin-layer sheets[2] and developed in a chloroform–acetic acid solvent system for 10 min. The chromatograms were air dried and sprayed with diphenylcarbazone until a pink color became visible. The dried chromatograms were then sprayed with mercurous nitrate solution, and a blue color developed. Within 5 min., white spots appeared at approximate R_f 0.7, indicating the presence of a barbiturate.

Since R_f values may vary slightly, at least one known barbiturate urine standard must be spotted on each chromatogram. Phenobarbital produced a V-shaped spot which may be distinguished from the rectangular-shaped spot shown by the other barbiturates. The appearance and position of the white spots should be recorded immediately since they fade to a blue color, indistinguishable from

Table I—Color Imprint and R_f Value of Drugs on Chromatogram

Generic Name	White Spot, R_f 0.7	Blue Spot, R_f 0.7	Faint Blue Spot, R_f 0.7 (or Lower)
Amobarbital	+	+	−
Pentobarbital	+	+	−
Phenobarbital	+	+	−
Secobarbital	+	+	−
Chloral hydrate	−	+	−
Chlordiazepoxide	−	−	+
Diazepam	−	−	+
Ethchlorvynol	−	−	+
Glutethimide	−	−	+
Meprobamate	−	−	+
Methyprylon	−	+	−
Tybamate	−	+	−

the background, within 15 min. Following the disappearance of the white spot, the blue background began to fade, revealing a blue spot with the same or slightly lower R_f value than the white barbiturate spot. This blue spot was characteristic of barbiturates and certain other drugs.

RESULTS AND DISCUSSION

The reliability, specificity, and sensitivity of this method were tested using urine samples from both inpatients and outpatients[3].

Reliability—To test the reliability of this method, 550 urine samples from drug abuse patients were analyzed for barbiturates and other drugs. Forty-one of these patients were taking prescribed barbiturates, and the white spot on the chromatogram revealed the presence of barbiturate in the urine of each of these. Barbiturate was also found in the urine of 15 additional patients. Since some patients admitted taking illicit barbiturates, a maximum false-positive error of <2.7% was indicated.

Specificity—Table I summarizes the color imprint and R_f value of the drugs which appeared on a chromatogram used in the present barbiturate identification system. Figure 2 illustrates the appearance of some of these drugs on the chromatogram immediately after spraying with mercurous nitrate solution and later after the background had faded. The white spot at R_f 0.7 was specific for the presence of barbiturates, and no drug listed in Table I interfered with barbiturate detection. The appearance of the blue spot at R_f 0.7 after the background faded indicated the presence of barbiturates and other drugs listed in Table I. Because of the interference of these other drugs, the blue spot obtained by using diphenylcarbazone and mercurous nitrate sprays cannot be considered as evidence specific for either barbiturates or any one of the drugs listed in Table I. However, the presence of chloral hydrate, tybamate, or methyprylon can be verified, since these drugs showed characteristic R_f values in the previously published system for the detection of opiates (12).

Sensitivity—The sensitivity of this method was determined by measuring the barbiturate concentration in the column eluate, using a modification of Broughton's procedure (14). Fifty milliliters of known barbiturate urine was poured through the resin column and eluted with 15 ml. methanol. Before concentrating 10 ml. of the colored portion of the eluate to dryness, the eluate was treated with decolorizing charcoal, which removed the pigment. Reference standards of 0.45 *N* sodium hydroxide and a combination of 0.45 *N* sodium hydroxide and boric acid solution were prepared. Each standard was compared to a solution containing 1 ml. of the standard plus 1 ml. of the decolorized eluate redissolved in 0.45 *N* sodium hydroxide. Barbiturate concentration was determined by measuring the difference in absorbance at 260 nm. The difference in the absorbance of the two test solutions when compared with the absorbance of the two standards at the same wavelength indicated the amount of barbiturate present in the urine.

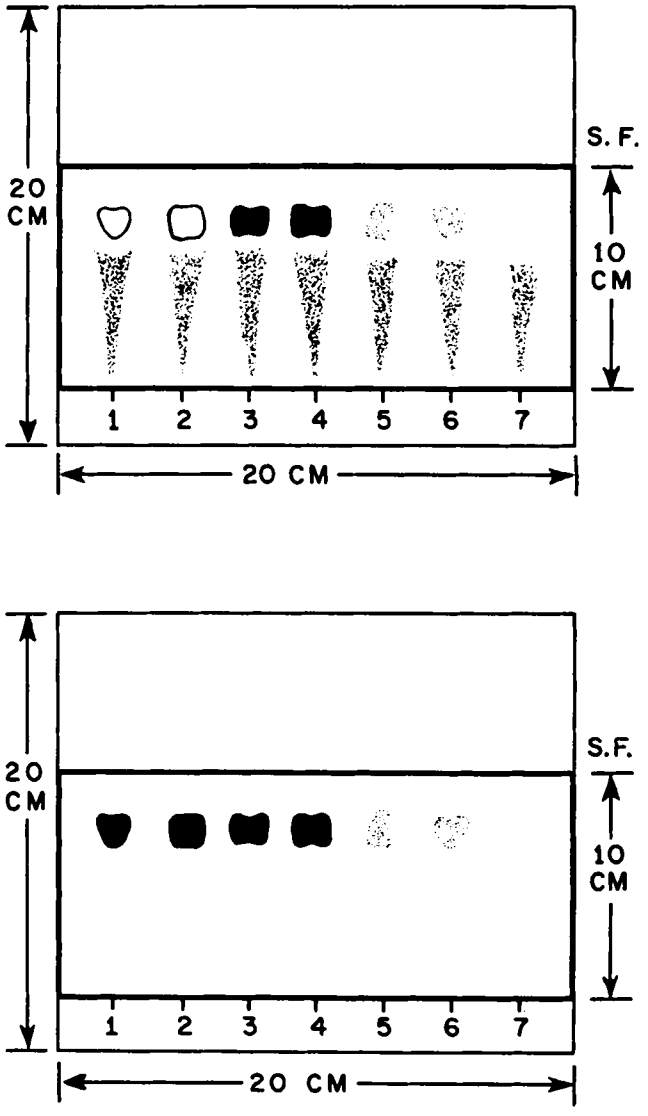

Figure 2—*(Top) Appearance of drugs on chromatogram immediately after mercurous nitrate spray. Key: 1, phenobarbital; 2, other barbiturates; 3, chloral hydrate, tybamate, and methyprylon; 4, ethinamate; 5, chlordiazepoxide, diazepam, ethchlorvynol, and glutethimide; 6, meprobamate; and 7, drug-free urine. (Bottom) Appearance of drugs on chromatogram after background has faded.*

This procedure was followed with separate urine samples containing pentobarbital, phenobarbital, and secobarbital. After the amount of barbiturate in each of the three urine samples was determined, each urine sample was diluted into smaller aliquots with normal urine to decrease the barbiturate concentration in the urine. Each diluted urine sample was assayed through the chromatographic method. The last diluted urine sample that revealed a white spot on the chromatogram represented the degree of sensitivity of the method for the detection of that barbiturate. The minimum sensitivity of the method was 0.7 mcg./ml. for patients receiving secobarbital, 0.4 mcg./ml. for patients receiving pentobarbital, and 0.02 mcg./ml. for patients receiving phenobarbital. It was also noted that barbiturate could be detected in the urine of drug abuse patients for at least 36 hr. after ingestion of 100 mg. of barbiturate. Longer periods were not checked due to the faintness of the white spots after 36 hr.

Confirmation—The identity of the white spot as barbiturate was confirmed using ^{14}C-labeled phenobarbital. A 48-hr. urine sample was collected from a rat given one injection of phenobarbital (25 mg./kg.) containing 2 mcg. of ^{14}C-phenobarbital labeled in the 2-

[3] At the Drug Abuse Treatment and Rehabilitation wards and clinics, Wood Veterans Administration Center. There were approximately 30 drug abuse patients in the wards and about 80 outpatients at any given time. Periodically, the staff also participated in studies to provide control and standard barbiturate urine samples.

position. The urine was processed by the described method, and the developed chromatogram was placed on X-ray film for 48 hr. The resulting radioactive spot on the X-ray film had the same shape and position as the white spot on the chromatogram.

CONCLUSIONS

Urine surveillance is an integral part of every successful drug abuse treatment and rehabilitation program. For urine surveillance to be effective, samples must be collected, labeled, and transported under controlled conditions. Urine must be analyzed accurately, and results must be reported promptly. A reliable laboratory method, specific for abuse drugs, is required to avoid both false-positive results, which would damage a patient's confidence and morale, and false-negative data, which could permit the undetected use of abuse drugs to continue.The laboratory method must also be inexpensive and efficient enough to evaluate a high volume of samples rapidly on a continuing basis.

The barbiturate identification procedure developed by the present investigators satisfies these requirements. It is particularly significant that interference from sedatives and tranquilizers has been eliminated. The method described in this paper avoids false-positive results and provides reliable identification of barbiturate metabolites in the urine of patients taking various drugs.

Precursor-Type Insect Repellents: Kinetics of Hydrolysis

DANIEL D. GARNER and LORRIN R. GARSON▲

Abstract □ The rates of ester hydrolysis of representative dihydroxyacetone monoesters were determined by titrimetric analysis. The esters were designed to elicit prolonged insect repellency by gradual hydrolysis in dermal tissue. No correlation was found between the agents' repellent activity and their susceptibility to hydrolysis. The repellency elicited by the esters appears to be due to the intact molecules rather than a hydrolytic product.

Keyphrases □ Dihydroxyacetone monoesters—rates of hydrolysis, effect on insect repellency □ Insect repellents, dihydroxyacetone monoesters—rates of hydrolysis, compared to repellent activity □ Hydrolysis kinetics—dihydroxyacetone monoesters, attempted correlation of hydrolysis rates and repellent activity

In previous articles from these laboratories, the syntheses and insect repellent data of 1,3-dihydroxy-2-propanone (dihydroxyacetone) monoesters were reported (1–4). The activity of these precursor-type repellents was explained, in part, by their ability to hydrolyze, subsequent to topical application, and thereby release the insectifugal acids. The rationale of this approach was previously discussed in detail (2, 5). Compounds I, III, IV, VI, XI, and XIII (Table I) were studied because of their similarities in structure and physical properties and also because of their wide range in repellent activity. Due to the many physical parameters which reportedly play a role in the insect repellency of a compound (6), the objective was to ascertain if the hydrolysis of the dihydroxyacetone esters was responsible for their activity or if some other factors were involved.

EXPERIMENTAL

Materials—Compounds I, III, IV, VI, XI, and XIII were previously prepared in these labotatories (1–4). However, since these agents can exist in both monomer and dimer (a cyclic hemiketal) forms, the structure and purity of these moieties had to be confirmed. Heating the dimeric dihydroxyacetone monoesters in ethanol converts the dimer to the corresponding monomeric form (7). Solutions of the esters in either acetone or ethanol (the ethanol solution had been previously heated) elicited identical chromatographic behavior, that is, a single spot with the same R_f values[1]. Therefore, in an acetone–water (3:1) solution, the medium selected to conduct the hydrolysis studies, the esters would appear to be exclusively in the monomeric state. IR spectra of the samples were equivalent to those of analytically pure compounds; NMR spectra were consistent with their respective structures[2].

[1] The TLC procedure utilized Mallinckrodt SilicAR TLC-7GF as the sorbent and acetone–water (3:1) as the solvent system. The compounds were applied to the plates and, after development, the spots were visualized with iodine vapor.

[2] Spectra (IR and NMR) were obtained with the Beckman model IR-33 and the Hitachi Perkin-Elmer model R-24 spectrophotometers, respectively.

position. The urine was processed by the described method, and the developed chromatogram was placed on X-ray film for 48 hr. The resulting radioactive spot on the X-ray film had the same shape and position as the white spot on the chromatogram.

CONCLUSIONS

Urine surveillance is an integral part of every successful drug abuse treatment and rehabilitation program. For urine surveillance to be effective, samples must be collected, labeled, and transported under controlled conditions. Urine must be analyzed accurately, and results must be reported promptly. A reliable laboratory method, specific for abuse drugs, is required to avoid both false-positive results, which would damage a patient's confidence and morale, and false-negative data, which could permit the undetected use of abuse drugs to continue.The laboratory method must also be inexpensive and efficient enough to evaluate a high volume of samples rapidly on a continuing basis.

The barbiturate identification procedure developed by the present investigators satisfies these requirements. It is particularly significant that interference from sedatives and tranquilizers has been eliminated. The method described in this paper avoids false-positive results and provides reliable identification of barbiturate metabolites in the urine of patients taking various drugs.

XIII		0.08	2.11 (0.04)	237

[a] The repellency index is the average protection time effected by the dihydroxyacetone monoester divided by the average protection time effected by the standard, diethyltoluamide. Repellency tests were conducted on the forearms of human volunteers as previously described (1–4). [b] Units of k_2 are liters mole^{-1} minute^{-1}. [c] The reproducibility of the technique was evaluated using Compound XI and found to be ±4.59%.

The two aqueous potassium hydroxide solutions[3] employed were standardized against potassium acid phthalate and found to be 0.3905 and 0.004684 *N*. These solutions are designated Solutions 1 and 2, respectively.

Kinetic Measurements—The kinetics of the base-catalyzed reaction were recorded[4] at constant pH (pH 12). The procedure employed for Compounds I, III, IV, VI, XI, and XIII is illustrated by the following example for Compound I.

A 5.00×10^{-2}-mmole sample of I [25 ml. of a 2.00×10^{-3} *M* solution in acetone–water (3:1)] was pipeted into the reaction vessel. After equilibration at 25 ± 0.2°, 0.128 ml. (5.00×10^{-2} mmole) of Solution 1 was pipeted[5] into the solution. The disappearance of base was then followed as a function of time by the continual addition of Solution 2 so that a pH of 12 was maintained[6].

To confirm that the reaction rate being studied was indeed ester hydrolysis, 1.30 g. (6.00 mmoles) of XI was subjected to conditions identical to those already described [3000 ml. acetone–water (3:1), 15 ml. (6.00 mmoles) of Solution 1]. After 30.5 hr., the acetone was removed from the mixture by distillation *in vacuo*, affording a

[4] The components consisted of a pH meter (PHM28), an automatic titrator (TTT11), a titrigraph (SBR2c), and a syringe buret assembly (SBU1). A saturated calomel electrode (Radiometer type K401) and a glass electrode (Radiometer type G202C) were employed, and stirring was accomplished by means of a mechanical electrically driven motor, as provided by the Radiometer Co. The jacketed glass reaction cell was thermostated at 25 ± 0.2° by circulating water from a Heto (Denmark) Ultrathermostat.

[5] This was accomplished with a 250-μl. syringe with a 10.16-cm. (4-in.) needle (Hamilton Co., Inc.).

[6] A more detailed description of the instrumental procedure was given by Stanley (8).

residual aqueous solution which was brought to pH > 12 with Solution 1 and extracted with chloroform (6 × 50 ml.). The aqueous phase was acidified with dilute hydrochloric acid and extracted with chloroform (8 × 50 ml.). The chloroform extracts of the acidic aqueous solution were combined, dried, and distilled *in vacuo*, affording a residual liquid. Distillation *in vacuo* of the oily residue yielded pure octanoic acid (0.39 g., 45%), b.p. 63–64° (0.05 mm.); IR (carbon tetrachloride): 3400–2500 (—OH) and 1705 (C=O) $cm.^{-1}$; NMR ($CDCl_3$): δ 11.82 (s, 1, —COOH), 2.36 (m, 2, $—CH_2CO—$), 1.33 [m, 10, $CH_3(CH_2)_5CH_2—$], and 0.88 (m, 3, $CH_3—$) p.p.m.

RESULTS AND DISCUSSION

The rates of hydrolysis of the compounds followed second-order kinetics, as determined by obedience of the data to the criteria established for second-order reactions. The mean and standard deviation of the rates were computed for each compound and are tabulated in Table I along with the calculated half-lives. The kinetic rates were calculated employing Eq. 1, which requires the concentration of the ester and base to be equivalent:

$$k_2 = \frac{1}{at}\left[\frac{x}{(a-x)}\right] \qquad \text{(Eq. 1)}$$

where k_2 is the second-order rate constant, a is the initial concentration of the ester or base, t is time, and x is the concentration of the ester that has been hydrolyzed at time t.

Under the experimental conditions, the concentration of base present in the reaction mixture is slowly increased, relative to the ester, as the standard base is titrimetrically added. However, the expected increase in kinetic rate was not observed until approximately 10% of the initial ester had been hydrolyzed; that is, the data fit Eq. 1 prior to reaching this point. In calculating the reported rates, only values obtained prior to less than 8% ester hydrolysis were employed.

The order of the rates follow what would be expected from consideration of steric factors (9). For example, introduction of alkyl substituents at the α- or β-carbon atoms markedly diminishes the rate of hydrolysis (compare I and XI with III, IV, and VI). As expected, XIII is more susceptible to hydrolysis than III, XIII being less sterically hindered about the ester carbonyl.

The stability of these agents to *in vitro* acid-catalyzed hydrolysis prompted an examination of the relationship between hydrolysis and biological response. Although the dermal environment is slightly acidic and, therefore, an *in vitro* acid-catalyzed study would be expected to approximate more closely *in vivo* conditions, the determination of acid-catalyzed rates was not experimentally feasible. In a preliminary experiment employing XI (0.02 *N*) in 0.05 *N* sulfuric acid [in acetone–water (3:1)], no detectable hydrolysis was observed within 48 hr. However, according to Newman (9) regarding the structure of the acyl component, the *ranking* of the rates of hydrolysis is probably the same whether carried out under acidic or basic conditions—even though the rate for a specific ester is generally faster in saponification (10).

CONCLUSIONS

It is possible to ascertain whether hydrolysis (acid or base catalyzed) is the major factor regulating repellency of the dihydroxyacetone monoesters. From the data given in Table I, it is readily apparent that there is no correlation between insectifugal activity of the compounds and their ease of hydrolysis. The order of repellent activity of the compounds studied is I > III > IV > VI > XI > XIII, whereas the order of their hydrolytic rates is I > XI > XIII > III > VI > IV. The difference in insect repellency of the corresponding free acids does not account for the lack of correlation; whereas Compounds I (repellency index 0.62) and XI (repellency index 0.11) have similar rate constants, their corresponding acids (hexanoic acid and octanoic acid, respectively) have widely different repellent activity, with octanoic acid being a much better repellent than hexanoic acid[7]. Accordingly, if chemical hydrolysis were a controlling factor, XI would be expected to elicit the greater biological response.

These kinetic studies do not preclude the possibility of hydrolysis of the esters by enzymes in the skin; cholinesterase, the lipases, and probably other esterases are known to be present in dermal tissue (12). Enzymes catalyzing the hydrolysis of esters are generally nonspecific; for example, it has been shown that ethyl hexanoate and ethyl octanoate are hydrolyzed by horse liver carboxylesterase at relative rates of 0.6 and 0.8, respectively, with ethyl butyrate taken as unity (13). Again comparing I and XI, enzymatic cleavage of I would only diminish insect repellent activity whereas scission of XI could be expected to increase repellency. One can only conclude that the insect repellency observed for these esters is due to the intact molecule.

GLC Analysis of Methapyrilene in Plasma and Urine Using a Sulfur-Specific Flame-Photometric Detector

R. E. SCHIRMER▲ and R. J. PIERSON

Abstract □ A GLC procedure was developed for analysis of methapyrilene in blood and urine. Samples are extracted with chloroform, dried, dissolved in methanol, and injected on a 1.22-m. (4-ft.) glass column packed with 1% cyclohexanedimethanol succinate and 10% of a 5%-substituted phenyl methyl silicone on acid-washed, silylated diatomaceous earth and operated at 220°. A sulfur-specific flame-photometric detector is used, which allows concentrations as low as 50 ng./ml. to be measured. Methapyrilene was not detected in plasma or urine of human subjects receiving normal clinical doses of methapyrilene hydrochloride, but a methapyrilene metabolite was found in the urine samples. The absence of detectable levels of methapyrilene is probably due to rapid conversion of this compound to a metabolite that is not detected by the GLC procedure.

Keyphrases □ Methapyrilene—GLC analysis in plasma and urine using sulfur-specific flame-photometric detector □ GLC—analysis of methapyrilene in plasma and urine, sulfur-specific flame-photometric detector □ Sulfur-specific flame-photometric detector—GLC analysis of methapyrilene in plasma and urine

Many analytical methods for methapyrilene have been reported in the literature, including spectrophotometric (1–6), fluorometric (7, 8), and GLC (9–14) procedures. Three reported methods are concerned with methapyrilene in blood and urine (3, 5, 7), but the methods are neither specific enough nor sensitive enough for measuring methapyrilene blood levels in human subjects following normal doses of drug (25–50 mg.). This paper reports an attempt to develop a GLC assay for methapyrilene in plasma and urine utilizing a sulfur-specific flame-photometric detector. Although the method allows detection of as little as 10 ng. of methapyrilene on-column, no methapyrilene was found in plasma or urine samples from subjects receiving the drug, presumably due to rapid metabolism of this drug substance. Some special features of the flame photometric detector also are discussed.

EXPERIMENTAL

A gas chromatograph[1] equipped with a sulfur-specific flame-photometric detector[2] was used for the analysis. The column was a 1.22-m. (4-ft.) glass U-tube (3 mm. i.d.) packed with 1% Hi-Eff 8BP and 10% SE-52 on 80–100-mesh Gas Chrom Q. The column was operated isothermally at 220° with the injection port at 250°, the detector at 225°, and helium as the carrier gas. The hydrogen–oxygen–air ratio was 100:60:20. Under these conditions, the retention times of methapyrilene and phenothiazine (internal standard) were approximately 3.5 and 6.8 min., respectively.

Several column packings were screened before selecting the mixture of 8BP and SE-52. These packings included: 0.5 and 2% OV-17 on 80–100-mesh Chromosorb G, 5% SE-52 on 80–100-mesh Chromosorb G, 1.5% Versamid 900 on 60–80-mesh acid-washed Chromosorb W, and 11% QF-1 on 80–100-mesh Gas Chrom Q. These columns were rejected because of poor peak shape when 10–50 ng. of methapyrilene was injected onto the column or because methapyrilene was not sufficiently separated from the compounds considered for use as internal standards.

Table I—Efficiency of Extraction of Methapyrilene by Chloroform and Ethyl Acetate as a Function of pH

pH	Buffer Composition	Percent Methapyrilene Extracted by[a]: Chloroform	Ethyl Acetate
1.0	0.1 *M* HCl	0.2	0.4
3.0	0.2 *M* acetate buffer	2.7	0.3
5.0	0.2 *M* acetate buffer	89.7	37.0
7.0	0.2 *M* phosphate buffer	100.0	100.0
10.0	0.2 *M* borate buffer	100.0	100.0

[a] Percent methapyrilene in the organic phase after partitioning against an equal volume of the aqueous buffer solution.

Table II—Calibration Curve for the Flame-Photometric Sulfur Detector[a]

Concentration, mcg./ml.	Response Ratio[b]
50	1.58
100	8.16
150	15.3
200	33.5
250	51.1

[a] See text for operating conditions of the detector. [b] The response ratio is calculated as the height of the methapyrilene peak divided by the height of the phenothiazine peak. All samples contained 30 mcg./ml. phenothiazine.

Plasma samples were analyzed by extracting 1 ml. of the sample three times with 5-ml. portions of chloroform. Fifty microliters of a 30-mcg./ml. solution of phenothiazine in chloroform was added to the combined chloroform extracts, and the sample was then evaporated to dryness under a stream of nitrogen. The residue was dissolved in 10.0 μl. of methanol, and 2 μl. of the methanol solution was injected into the chromatograph for analysis. A calibration curve was prepared by injecting 1.0 μl. each of solutions containing 30 mcg./ml. phenothiazine and 25, 50, or 100 mcg./ml. methapyrilene in methanol. A typical chromatogram is presented in Fig. 1. The sample is injected in a methanol solution rather than in chloroform, because chloroform causes an undesirable background response in the flame-photometric detector.

Urine samples were analyzed by adjusting the pH of a 10-ml. aliquot to 10.0 with sodium hydroxide and extracting it three times with 10-ml. aliquots of chloroform. One milliliter of a 250-mcg./ml. solution of phenothiazine in methanol was added to the combined chloroform extracts, and the sample was then evaporated to dryness under a stream of nitrogen. The residue was dissolved in 100 μl. of methanol, and 2 μl. of this solution was injected into the

Table III—Precision and Accuracy of the Analytical Method

Concentration, mcg./ml.	Number of Replicates	Mean Result	Relative Error, %	Standard Deviation of the Mean
0.250	4	0.254	+1.6	0.008
0.500	7	0.524	+4.8	0.094
0.750	11	0.702	−6.3	0.118
1.000	5	1.020	+2.0	0.120
1.250	7	1.250	0.0	0.127

chromatograph. The calibration curve was prepared using the procedure described for plasma samples.

The efficiency of extraction of methapyrilene by chloroform and ethyl acetate was studied as a function of pH to establish conditions for the extraction in the assay. The extraction was studied by partitioning 10-ml. aliquots of 0.5 mg./ml. methapyrilene in either chloroform or ethyl acetate against 10-ml. aliquots of aqueous buffers of pH 1.0, 3.0, 5.0, 7.0, and 10.0. The percent methapyrilene remaining in the organic phase was determined by measuring the absorbance of the organic phase at 310 nm. and comparing it with the absorbance of the original 0.5-mg./ml. solution in the same solvent. The results are summarized in Table I. The extraction efficiencies from plasma and urine under the conditions outlined previously were checked and found to be identical to the corresponding values in Table I.

Studies of the response characteristics of the flame-photometric detector were reported in the literature (15, 16). In the sulfur-specific mode, the response varies linearly with the mass of the sample injected on-column under some gas flow conditions and with the square of the mass under other conditions (16). Therefore, it was considered desirable to establish the response characteristics of the detector under the flow conditions used in this procedure before using the method quantitatively. The response, R, can be written as:

$$R = k(mv)^n \qquad \text{(Eq. 1)}$$

where k is the response factor, m is the concentration of the methapyrilene solution, and v is the volume injected. By using primes to denote the analogous quantities for phenothiazine, the ratio of the response from methapyrilene to that from phenothiazine may be written as:

$$r = \frac{R}{R'} = \frac{k}{k'}\left(\frac{m}{m'}\right)^n \qquad \text{(Eq. 2)}$$

Thus, n may be evaluated by regressing log r against log m for a series of standard solutions containing a fixed concentration of phenothiazine. Methanol solutions containing 30 mcg./ml. of phenothiazine and from 50 to 250 mcg./ml. of methapyrilene in 50-mcg./ml. increments were prepared, and injections of 1.0-μl. portions of each of these solutions were made. The results are recorded in Table II. Analysis of these data gave $n = 2.10$, with 95% confidence limits of ± 0.08 and a correlation coefficient of 0.9916. A value of $n = 2.0$ was used throughout the remainder of this work.

The precision and accuracy of the method were determined by analyzing replicate samples of plasma spiked at several different methapyrilene levels. These samples were analyzed against the calibration curve presented in Table II, and the results are presented in Table III.

DISCUSSION

The standard deviations presented in Table III are quite large and are essentially constant over the upper end of the concentration range. The primary contribution to this variability is within the detector itself under the conditions of operation used in this study. It is possible that this variability could be reduced by better control of the gas flow rates or of the detector temperature. The flame is generally extinguished by each shot and must be relit before the sample peaks elute, so the effective detector temperature is probably quite variable.

In spite of the poor reproducibility, the sulfur-specific flame-photometric detector offers several significant advantages over a flame-ionization detector in the GLC assay for methapyrilene. The first advantage is greater sensitivity; the reported method can be used to measure concentrations as low as 50 ng./ml. in plasma or urine, and this limit could be reduced even further by using larger samples and injecting larger aliquots onto the GLC column. Another advantage is the very low background observed with extracts of plasma and urine. Under similar conditions, a flame-ionization detector would register many other peaks and the extraneous peaks would make it very difficult to measure methapyrilene at low levels.

Following development of the method on spiked plasma and urine samples, plasma and urine samples from human subjects who had received methapyrilene hydrochloride were analyzed. The subjects received 20 mg. by intramuscular or subcutaneous injection or 50 mg. orally. Plasma samples were obtained at 15 and 30 min. and at 1, 2, and 4 hr. An 8-hr. urine sample was also collected. The analysis revealed no methapyrilene in any plasma samples. The urine samples contained small amounts of a component whose retention time was identical to that of methapyrilene. Preliminary structural data indicate, however, that the component measured in urine is a hydroxylated metabolite of methapyrilene rather than methapyrilene itself. Work on identification of this metabolite is in progress. The presence of this metabolite in the urine, the drowsiness reported by the subjects, and the absence of detectable levels of parent compound in plasma together suggest that the absence of detectable levels of parent compound in plasma is not due to poor absorption of the drug from the gut or from the site of injection but rather to rapid conversion of methapyrilene to metabolites that are not detected by the GLC procedure.

N-Dimethylation of β-Phenylethylamine Derivatives

GEORGE D. CHERAYIL

Abstract □ Direct *N*-methylation of 3,4-dimethoxyphenethylamine, 4-methoxyphenethylamine, tyramine, and 3-methoxytryamine, by refluxing each compound with a mixture of formaldehyde and formic acid in the presence of dimethylformamide, to the corresponding *N*-dimethyl derivative in 45–86% yield is reported. The synthesis of macromerine from normetanephrine by a two-step methylation, using diazomethane and formaldehyde–formic acid mixture, is also reported.

Keyphrases □ *N*-Dimethylation—aromatic primary amines in dimethylformamide using formaldehyde–formic acid □ β-Phenylethylamines and β-phenylethanolamines, *N,N*-dimethyl derivatives—as potential metabolites of levodopa □ Macromerine—synthesis, two-step methylation using diazomethane and formaldehyde–formic acid

Levodopa (L-3,4-dihydroxyphenylalanine) is used extensively in the treatment of Parkinson's disease. In spite of marked improvements in many patients, some adverse reactions, including psychotic symptoms such as confusion, hallucination, and agitation, have been noted (1, 2). *N,N*-Dimethyl-3,4-dimethoxy-β-hydroxy-β-phenethylamine (macromerine), a possible metabolite of levodopa, was reported to be hallucinogenic when tested in squirrel monkeys (3). A number of alkaloids, including *N,N*-dimethyl-3,4-dimethoxyphenethylamine, *N,N* - dimethyl - 3 - methoxytyramine, *N,N* - dimethyltyramine (hordenine), *N*-methyl-3,4-dimethoxy-β-hydroxy-β-phenethylamine (normacromerine), and macromerine have been isolated from cactus plants (4–7).

The possibility that such compounds may be formed in the human or animal body as metabolites of levodopa or 3,4-dihydroxyphenethylamine (dopamine) prompted the search for a relatively simple method of *N*-methylation of β-phenylethylamine and β-phenylethanolamine derivatives. The preparation of *N*-methylated derivatives of β-phenylethylamine and the ring-substituted compounds was reported previously (8). This method involves several steps, starting with the corresponding aldehyde, and is very time consuming. Methods for methylating aliphatic amino alcohols and amino mercaptans using formaldehyde and formic acid were described (9, 10), and a modified method for preparing *N,N*-dimethyl derivatives of other amino alcohols or amino mercaptans in 90–100% yield was published (11). This method has been modified to include a reaction medium, dimethylformamide, and extended to the *N*-methylation of β-phenylethylamine derivatives.

An attempt to identify these compounds as metabolites of levodopa in Parkinson's disease is in progress.

EXPERIMENTAL[1]

Materials—3,4-Dimethoxyphenethylamine (I) and its hydrochloride (I*a*), 4-methoxyphenethylamine (II), tyramine (III), 3-methoxytyramine (IV), normetanephrine hydrochloride (V), octopamine hydrochloride (VI), dimethylformamide[2], formaldehyde (35%)[3], formic acid (88%), ethyl acetate, ether, and methanol[4] were used.

Methylations—N,N-*Dimethyl-3,4-dimethoxyphenethylamine* (*VII*) —To 220 mg. (1 mmole) of I*a* taken in a 10-ml. round-bottom flask,

[1] All melting points were taken on a Fisher-Johns hot-stage melting-point apparatus and are uncorrected. Microanalyses were performed by PCR, Inc., Gainesville, Fla. TLC was done on silica gel G (E. Merck, Darmstadt, Germany) in two solvent systems: Solvent A, *n*-butanol–acetic acid–water (4:1:1); and Solvent B, isopropanol–10% ammonia–water (8:1:1) (12). GLC was performed in a Barber-Colman model 15 gas chromatograph provided with an ionization detector system (radium source). A glass U-tube (1.83 m. × 4 cm.) containing 12% C_6-diethylene glycol succinate on Anakrom ABS 60–70 mesh (Analabs, Inc., North Haven, Conn.), preconditioned at 200° for 72 hr. with nitrogen flowing at the rate of 100 ml./min. and maintained at 200° with an external argon pressure of 20 p.s.i. (flow rate at exit 98 ml./min.), was used as a polar column. A nonpolar column of 15% Apiezon L on 100–120-mesh Gas Chrom Q (Applied Science Laboratories, State College, Pa.), preconditioned at 255° for 144 hr. with nitrogen flowing at the rate of 66 ml./min. and maintained at 255° with an external argon pressure of 30 p.s.i. (flow rate 50 ml./min.) was also used for analyses.

Keyphrases □ *N*-Dimethylation—aromatic primary amines in dimethylformamide using formaldehyde–formic acid □ β-Phenylethylamines and β-phenylethanolamines, *N,N*-dimethyl derivatives—as potential metabolites of levodopa □ Macromerine—synthesis, two-step methylation using diazomethane and formaldehyde–formic acid

Levodopa (L-3,4-dihydroxyphenylalanine) is used extensively in the treatment of Parkinson's disease. In spite of marked improvements in many patients, some adverse reactions, including psychotic symptoms such as confusion, hallucination, and agitation, have been noted (1, 2). *N,N*-Dimethyl-3,4-dimethoxy-β-hydroxy-β-phenethylamine (macromerine), a possible metabolite of levodopa, was reported to be hallucinogenic when tested in squirrel monkeys (3). A number of alkaloids, including *N,N*-dimethyl-3,4-dimethoxyphenethylamine, *N,N* - dimethyl - 3 - methoxytyramine, *N,N* - dimethyltyramine (hordenine), *N*-methyl-3,4-dimethoxy-β-hydroxy-β-phenethylamine (normacromerine), and macromerine have been isolated from cactus plants (4–7).

The possibility that such compounds may be formed in the human or animal body as metabolites of levodopa or 3,4-dihydroxyphenethylamine (dopamine) prompted the search for a relatively simple method of *N*-methylation of β-phenylethylamine and β-phenylethanolamine derivatives. The preparation of *N*-methylated derivatives of β-phenylethylamine and the ring-substituted compounds was reported previously (8). This method involves several steps, starting with the corresponding aldehyde, and is very time consuming. Methods for methylating aliphatic amino alcohols and amino mercaptans using formaldehyde and formic acid were described (9, 10), and a modified method for preparing *N,N*-dimethyl derivatives of other amino alcohols or amino mercaptans in 90–100% yield was published (11). This method has been modified to include a reaction medium, dimethylformamide, and extended to the *N*-methylation of β-phenylethylamine derivatives.

An attempt to identify these compounds as metabolites of levodopa in Parkinson's disease is in progress.

EXPERIMENTAL[1]

Materials—3,4-Dimethoxyphenethylamine (I) and its hydrochloride (I*a*), 4-methoxyphenethylamine (II), tyramine (III), 3-methoxytyramine (IV), normetanephrine hydrochloride (V), octopamine hydrochloride (VI), dimethylformamide[2], formaldehyde (35%)[3], formic acid (88%), ethyl acetate, ether, and methanol[4] were used.

Methylations—N,N-*Dimethyl-3,4-dimethoxyphenethylamine* (*VII*) —To 220 mg. (1 mmole) of I*a* taken in a 10-ml. round-bottom flask,

[1] All melting points were taken on a Fisher-Johns hot-stage melting-point apparatus and are uncorrected. Microanalyses were performed by PCR, Inc., Gainesville, Fla. TLC was done on silica gel G (E. Merck, Darmstadt, Germany) in two solvent systems: Solvent A, *n*-butanol–acetic acid–water (4:1:1); and Solvent B, isopropanol–10% ammonia–water (8:1:1) (12). GLC was performed in a Barber-Colman model 15 gas chromatograph provided with an ionization detector system (radium source). A glass U-tube (1.83 m. × 4 cm.) containing 12% C_6-diethylene glycol succinate on Anakrom ABS 60–70 mesh (Analabs, Inc., North Haven, Conn.), preconditioned at 200° for 72 hr. with nitrogen flowing at the rate of 100 ml./min. and maintained at 200° with an external argon pressure of 20 p.s.i. (flow rate at exit 98 ml./min.), was used as a polar column. A nonpolar column of 15% Apiezon L on 100–120-mesh Gas Chrom Q (Applied Science Laboratories, State College, Pa.), preconditioned at 255° for 144 hr. with nitrogen flowing at the rate of 66 ml./min. and maintained at 255° with an external argon pressure of 30 p.s.i. (flow rate 50 ml./min.) was also used for analyses.

[3] E. Merck & Co., Rahway, N. J.

[4] Mallinckrodt Chemical Works, St. Louis, Mo.

84 mg. (1 mmole) of sodium bicarbonate and 5 ml. of dimethylformamide were added; while the flask was kept cooled in ice, a mixture of 0.22 ml. of 88% formic acid (5 mmoles) and 0.42 ml. of 35% formaldehyde (5 mmoles) was added slowly. The mixture was heated gently on a heating mantle until the vigorous evolution of carbon dioxide subsided and then was refluxed with a water condenser for 5 hr. The solution was cooled and added to 15 ml. of cold water, made alkaline with solid sodium hydroxide (pH ~ 8), and extracted three times with 25-ml. portions of ethyl acetate. The combined ethyl acetate layer was washed twice with 30 and 25 ml. each of water, and the organic phase was dried (sodium sulfate) and filtered through glass wool. Finally, the ethyl acetate was evaporated in a flash evaporator. A light-yellow oil (184 mg., 92%) was obtained.

This oil (69.5 mg.) was converted to the hydrochloride by adding a solution of 10% concentrated hydrochloric acid in methanol and evaporating the solution to dryness when tiny chalk-white crystals were formed. The crystals were recrystallized from methanol–ether to yield 65.5 mg. (80%) of VII-hydrochloride (overall yield 72%), m.p. 196–198° [lit. (8) m.p. 197°]. GLC of this compound as the free amine on diethylene glycol succinate and Apiezon L showed only one peak in each case with retention times of 4.5 and 6.3 min., respectively. When I was used as the starting material, the sodium bicarbonate was excluded from the reaction mixture and the proportions of formic acid and formaldehyde were reduced by one-half. A similar yield was obtained.

N,N-*Dimethyl-4-methoxyphenethylamine* (*VIII*)—To 1.52 g. (10 mmoles) of II, 30 ml. of dimethylformamide, 1.1 ml. of 88% formic acid (25 mmoles), and 2.1 ml. of 35% formaldehyde (25 mmoles) were added and refluxed for 5 hr. The solution was added to water containing sodium hydroxide (pH ~ 10) and extracted three times with ethyl acetate; on evaporation of the ethyl acetate, 1.87 g. of a colorless oil (104%) was obtained. A portion of this dimethylamine (98.0 mg.) was converted to the hydrochloride, as already described, to yield 101.6 mg. (overall yield 86%) of white crystals, m.p. 175–176° [lit. (8) m.p. 176.5°].

N,N-*Dimethyl-3-methoxytyramine* (*IX*)—The hydrochloride of IV (95.6 mg., 0.5 mmole), 0.5 mmole sodium bicarbonate, and 2.5 mmoles each of formaldehyde and formic acid were mixed with 5 ml. of dimethylformamide. The mixture was refluxed for 5 hr., cooled, added to 15 ml. of water containing 20 ml. of 0.5 *M* sodium borate buffer (pH 10), and extracted three times with 25-ml. portions of ethyl acetate. After drying (sodium sulfate) and evaporating the solvent, 84.0 mg. (92%) of a light-yellow oil was obtained. This oil was partially purified by chromatography on 10 g. of magnesium silicate[5] by eluting with 125 ml. of ethyl acetate and 50 ml. of chloroform–methanol (2:1) when 71.8 mg. of colorless oil was obtained. A portion of the oil (33.0 mg.) was dissolved in ethyl acetate and kept at −18° for several days when 27.5 mg. of shining flat white crystals, m.p. 94–96°, was obtained. This compound gave a green color with ferric chloride, indicating the presence of a phenolic group, and no pink color with ninhydrin, indicating the absence of a primary amino group. TLC of this compound (IX) gave spots with an R_f value lower than IV (0.22 *versus* 0.44) in Solvent A and higher than IV (0.50 *versus* 0.33) in Solvent B. GLC on diethylene glycol succinate and Apiezon L gave only a single peak in each case with retention times of 7.5 and 6.75 min., respectively.

Anal.—Calc. for $C_{11}H_{17}NO_2$: C, 67.66; H, 8.78; N, 7.17. Found: C, 67.74; H, 8.76; N, 7.11.

The remaining oil (free base, 38.0 mg.) was converted to the hydrochloride and recrystallized from methanol–ether to yield 45.5 mg. (100%) of crystals, m.p. 191–192° [lit. (5) m.p. 190–191°]. The overall yield of the *N,N*-dimethyl hydrochloride derivative was 70%.

Anal.—Calc. for $C_{11}H_{18}ClNO_2$: C, 57.02; H, 7.83; N, 6.04. Found: C, 56.77; H, 7.75; N, 6.14.

N,N-*Dimethyltyramine* (*Hordenine*) (*X*)—Compound III (5.488 g.) was similarly converted to the *N,N*-dimethyl derivative and extracted from borate buffer with ethyl acetate to give 4.142 g. (63%) of oil, part of which (1.116 g.) was crystallized from benzene–petroleum ether to yield 0.648 g. (58%) of white flaky crystals, m.p. 116–117° [lit. (13) m.p. 117–118°]. The mother liquor and the rest of the free amine (3.494 g.) were converted to the hydrochloride, decolorized with activated charcoal, and crystallized from methanol–ether. Fine needle-shaped crystals (1.914 g., 55%; overall yield, 45%), m.p. 181–183° [lit. (8) m.p. 181°], were obtained.

Macromerine Hydrochloride (*XI*)—One hundred milligrams of V dissolved in methanol was treated with an ethereal solution of diazomethane until the solution was yellow. The solvent and excess diazomethane were evaporated under nitrogen and the free amine was extracted from borate buffer with ethyl acetate. The residue (80 mg.) was *N*-methylated as before with formaldehyde–formic acid. The dimethylamine was converted to the hydrochloride, decolorized with charcoal, and crystallized from methanol–ether to yield 58 mg. (overall yield 52%) of needle-shaped crystals, m.p. 162–163° [lit. (14) m.p. 163–164°]. Compound XI had the same R_f value as authentic macromerine in both Solvents A and B.

Attempts to N-Methylate V and VI—Methylation of 440.7 mg. of V analogously yielded 403.0 mg. of yellow oil, which had an R_f value lower than V (0.23 *versus* 0.43) on TLC in Solvent A and higher than V in Solvent B (0.45 *versus* 0.40). It gave a green color with ferric chloride and no pink color with ninhydrin. The *N*-methylated free amine or its hydrochloride was not obtained in crystalline form, so the product is only tentatively identified as the *N,N*-dimethyl derivative of V.

Compound VI (81.5 mg.) was methylated similarly to yield 67.6 mg. of yellow oil, which had an R_f value lower than VI in Solvent A (0.33 *versus* 0.63) and higher than VI in Solvent B (0.50 *versus* 0.45). The methylated product gave a brown color with ferric chloride and no color with ninhydrin. Attempts to crystallize the *N*-methylated free base or the hydrochloride were unsuccessful, so the identification of the derivative as *N,N*-dimethyloctopamine is only tentative.

Separation of Methotrexate and Nonmethotrexate Components in Rat Plasma

Keyphrases □ ^{3}H-Methotrexate—separation from labeled metabolites in rat plasma □ Plasma levels, ^{3}H-methotrexate—separation from labeled metabolites, rats

Sir:

Methotrexate (4-amino-N^{10}-methylpteroylglutamic acid) has been reported to be extensively metabolized by intestinal bacteria of mice and rats (1, 2) and to a lesser degree in man (3). Valerino (4) reported the separation of four different metabolites in the urine and feces of rats receiving tritiated methotrexate by gastric intubation and tentatively identified two as 2,4-diamino-6-carboxylpteridine and 2,4-diamino-6-methylpteridine. Although metabolites of methotrexate have been demonstrated in the urine and feces of animals, no reports of the separation of methotrexate from its metabolites in the plasma have appeared. A method for separation of methotrexate from its metabolites in plasma is essential for the necessary refinement of recently reported models of methotrexate pharmacokinetics (3, 5). These models have been derived from measurements of plasma concentrations of total radioactivity following administration of ^{3}H-methotrexate. This communication reports a simple method for the separation of ^{3}H-methotrexate from other labeled components in rat plasma.

Male Sprague–Dawley rats (450–500 g.) were injected with 25 mg./kg. of purified (6) ^{3}H-methotrexate *via* a cannula in the right external jugular. At specified times, 4 ml. of blood was drawn into a heparinized syringe and then centrifuged. Because of the volume of blood removed, no more than three samples were taken from any rat. Following centrifugation, the plasma was removed and the blood cells were washed with 2 ml. of normal saline and centrifuged. The saline supernate and plasma were combined and placed in a membrane filter cone[1]. The plasma water filtrate was obtained by centrifugation. The protein residue was washed with 2 ml. of water and again centrifuged. The combined filtrate was then frozen and lyophilized. The lyophilate, which contained ^{3}H-methotrexate, other labeled species, and plasma salts, was dissolved in a few drops of 95% ethanol and spotted on chromatography paper[2]. The chromatogram was developed using 0.1 *M* phosphate buffer (pH 7.0) as solvent. In control studies, methotrexate migrated as a single peak, R_f 0.50. The chromatographic strips were cut into sections, oxidized[3], and counted on a liquid scintillation spectrometer[4]. Following appropriate quench corrections, concentrations of ^{3}H-methotrexate and other labeled components in plasma were determined.

Table I—Percent of Total Label in Plasma Associated with Methotrexate and Nonmethotrexate Paper Chromatographic Peaks at Various Plasma Sampling Times[a]

Compound	Percent at 1 hr.	2 hr.	4 hr.	6 hr.
Methotrexate (R_f 0.5)	95	87	72	49
Nonmethotrexate (R_f 0.23)	2	5	25	50
Total	97	92	97	99

[a] Following a 25-mg./kg. i.v. dose.

Only one peak was found in the chromatogram of plasma samples taken from rats within the 1st hr. after injection. In samples taken from 1 to 6 hr. after injection of ^{3}H-methotrexate, two peaks were observed. The nonmethotrexate peak migrated with an R_f value of 0.23. Using this chromatographic system, Valerino (4) found all four metabolites in urine and feces to migrate with an R_f of 0.26–0.27. The proportion of label represented by this nonmethotrexate peak increased with time (Table I).

The total plasma levels of tritium label were corrected according to the percentage of total label under the

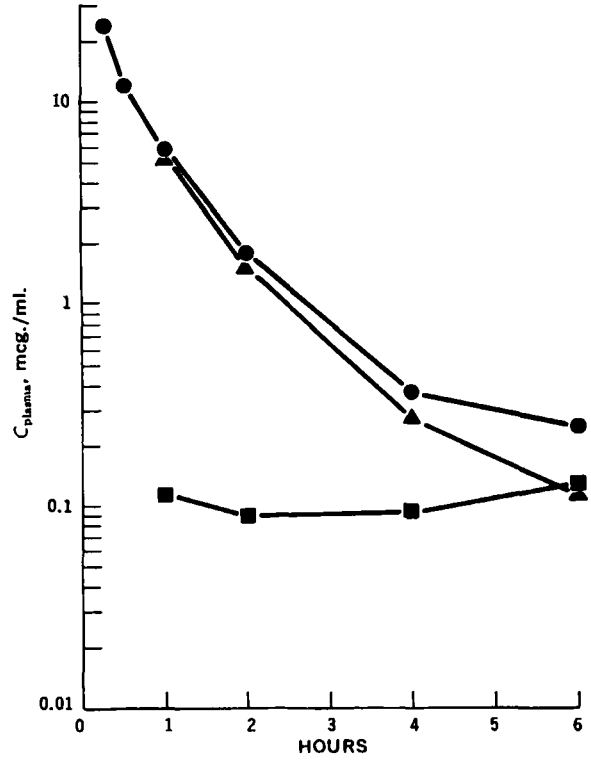

Figure 1—*Plasma concentration of ^{3}H-methotrexate equivalents with time. Key:* ●, *total;* ▲, *methotrexate; and* ■, *nonmethotrexate.*

[4] Packard Tri-Carb.

methotrexate peak to give levels of actual methotrexate. As can be seen in Fig. 1, by 4 hr. the contribution of the nonmethotrexate component was very significant. Although the percentage of total label represented by the nonmethotrexate component increased with time, the actual concentration appeared to remain relatively constant.

Whether the nonmethotrexate component originates from metabolism of methotrexate by intestinal bacteria, by metabolism within the rat, from a trace contaminant in the purified ^{3}H-methotrexate solution for injection, or from a combination of these factors is unknown at this time.

Inconsistencies in Rationale Underlying Official USP Dissolution Rate Specifications for Nitrofurantoin

Keyphrases ☐ Nitrofurantoin tablets and oral suspension—dissolution rate specifications with respect to compendial requirements ☐ Oral suspension, nitrofurantoin—dissolution rate specifications with respect to compendial requirements ☐ Dissolution rates, nitrofurantoin tablets and oral suspension—considerations with respect to compendial requirements

Sir:

Nitrofurantoin, 1-[(5-nitrofurfurylidene)amino] hydantoin, is an antibacterial agent used clinically to treat specific urinary tract infections. Physiocochemically, the drug is a weak acid (pKa 7.2) possessing relatively low aqueous solubility characteristics at pH values normally encountered in the various segments of the GI tract of man. As a result, it is not surprising that the drug displays a particle-size dependence in its dissolution rate (1) and rate and extent of absorption (bioavailability) in man (1–4).

USP XVIII (5) recognizes aqueous suspension and compressed tablet dosage forms of the drug, but only the monograph for nitrofurantoin tablets contains specifications for dissolution rate determinations. The requirement, contrary to that for other official drug tablet dosage forms, states that: "The time required for 60 percent of the labeled amount [50 or 100 mg.] of $C_8H_6N_4O_5$ in the Tablets to dissolve is not less than 1 hour, pH 7.2 phosphate buffer [900 ml.] being used as the *Dissolution Medium* and the basket being rotated at 100 r.p.m., and ...." Apparently, it is the intent of this unusual specification to ensure a *slow* rate of dissolution of nitrofurantoin from commercial tablet dosage forms in the GI fluids and thereby reduce both the maximum concentration of drug bathing the GI mucosa and present in the systemic circulation at any time. This, in turn, would presumably minimize the incidence of the major side effects of nitrofurantoin therapy in man, namely, locally (mucosal irritation) and/or systemically induced nausea and emesis (2, 6). Based on clinical observations of increased tolerance to capsules containing *macrosize* drug (80–200 mesh) as compared to tablets containing *microsize* (about 10 μ) drug (6), the rationale underlying the official dissolution rate specification for nitrofurantoin tablets appears, at first glance, to be sound, albeit totally arbitrary from a quantitative point of view. However, the requirement does not impose an upper dissolution rate limit and thus fails to ensure optimal bioavailability of nitrofurantoin from various brands of commercial tablets. Hence, the test does not reflect differences encountered in the *in vivo* absorption characteristics of nitrofurantoin from several different tablet formulations (7).

In addition, it appears quite inconsistent for the compendia, on the one hand, to be cognizant of the potential side effects of nitrofurantoin from tablet dosage forms but, on the other, not to provide for a dissolution rate specification for nitrofurantoin oral suspension USP. Apparently, it failed to recognize that the possible occurrence of adverse drug reactions from a suspension dosage form may be equal to, or even significantly greater than, that from a tablet dosage form. This conclusion can be readily appreciated from a consideration of basic biopharmaceutical principles (8)—*viz.*, that a relatively water-insoluble drug, administered orally in an aqueous suspension dosage form, generally dissolves, is absorbed, and, therefore, appears in the systemic circulation at a faster rate than can be normally achieved *via* administration of a compressed tablet dosage form.

While studying the rate of absorption and bioavailability of nitrofurantoin in man from different pharmaceutical dosage forms, the need arose to develop a *single* dissolution rate methodology applicable to both the official aqueous suspension and tablet dosage

Table I—*In Vitro* Dissolution Rates of Nitrofurantoin from Commercial Aqueous Suspension and Tablet Dosage Forms at 37°

Commercial Dosage Form	Mean Dissolution Half-Life, min.[a], at pH 7.20

Compressed tablet	167 (±35.8)

[a] Determined from log-normal probability plots of dissolution rate data. Mean of five determinations. [b] Standard deviation in parenthesis.

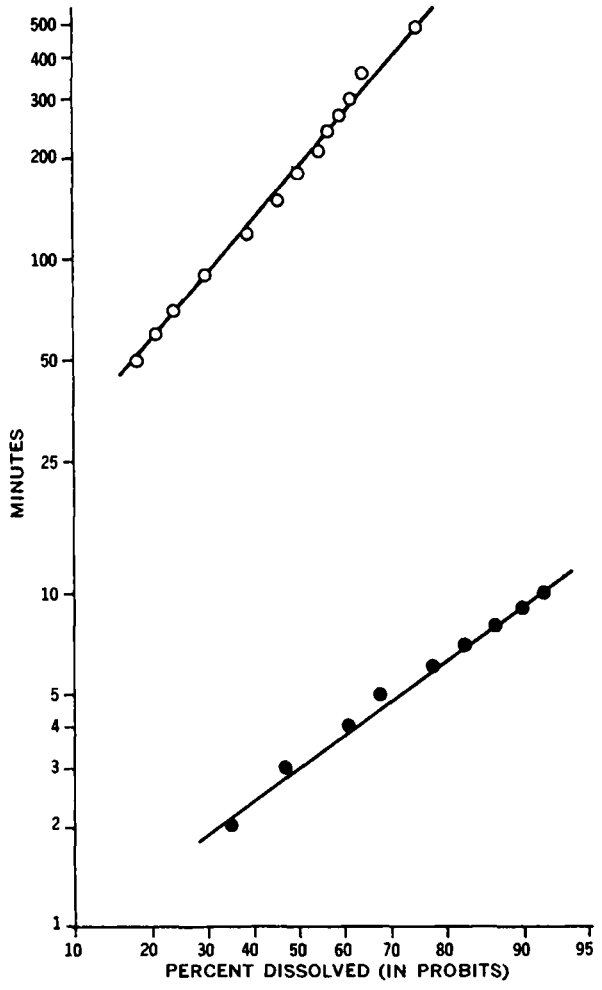

Figure 1—*Representative log-normal probability plots of dissolution rate data for nitrofurantoin from commercial dosage forms at 37° (pH 7.20). Key: —●—, aqueous suspension; and —○—, compressed tablet.*

forms. This precluded the use of the USP rotating-basket apparatus, since it was found to be inappropriate for dissolution rate studies performed with the official suspension dosage form. This preliminary communication presents some of our *in vitro* research experiences with the *stirrer-flask method*, which was demonstrated previously in our laboratories to be quite appropriate for suspension and tablet dosage forms of salicylamide (9) and provides correlation with *in vivo* absorption parameters in man (1, 9) and lower animals (10).

The apparatus employed to evaluate the dissolution behavior of nitrofurantoin from commercial aqueous suspension[1] (25 mg. microsize drug/5 ml.) and tablet[2] (100 mg. microsize drug/tablet) dosage forms was described elsewhere (9). At time zero, one tablet or a weight of suspension equivalent to 100 mg. of nitrofurantoin was added to 900 or 880 ml. of pH 7.20 phosphate buffer, which had been previously equilibrated to 37° under an agitation intensity of 200 r.p.m. Both the aqueous, gel-like suspension and tablet dosage forms were dense enough to sink immediately to the bottom of the 1-l., three-necked, round-bottom flask and occupy a central position, 5 cm. below the 70-mm. diameter Teflon stirring propeller. Periodically, 5-ml. samples were withdrawn from the flask, filtered, and assayed spectrophotometrically (1) for drug content. Following the removal of each sample, a 5-ml. quantity of fresh dissolution medium was added to the flask. All dissolution rate data were corrected appropriately for this dilution effect (11). The equilibrium solubility of nitrofurantoin at 37° was determined to be 272 mg./l. of pH 7.20 phosphate buffer. Five dissolution rate determinations were made with each dosage form.

Representative dissolution rate profiles of nitrofurantoin from the two different pharmaceutical dosage forms at pH 7.20 are depicted in Fig. 1 as log-normal probability plots of the dissolution data. The dissolution half-life (T_{50}) for each run was determined from such linear plots. An examination of the mean half-life data (Table I) reveals that the dissolution rate of nitrofurantoin from the commercial aqueous suspension is markedly faster (approximately 60-fold) than from the commercial tablet. These differences are consistent with the physical observation that unlike the aqueous suspension dosage form, which rapidly dispersed throughout the dissolution medium, the tablet dosage form displayed poor disintegration characteristics, produced relatively large granules, and maintained most of its shape during most of the dissolution run.

In light of the present findings, the rationale underlying the official dissolution rate specification for nitrofurantoin tablets appears quite arbitrary and inconsistent with the dissolution profile and potential toxicity of the official suspension dosage form.

Occurrence of Negative Time Lags in Permeability Studies of Solutes through Polyethylene

Keyphrases ☐ Permeability of solutes through polyethylene—occurrence of lag times ☐ Polyethylene films—permeability, occurrence of lag times

Sir:

Recently, Serota *et al.* (1) reported their study on the permeability of substituted anilines from aqueous solutions through polyethylene and noted the occurrence of negative time lags. They used the permeation cell according to Rodell *et al.* (2) and determined the permeation rate spectrophotometrically.

Treating the time lag method mathematically, Siegel and Coughlin (3) found that considerable errors could result if the straight line were drawn through data taken after times less than 2θ. By neglecting this fact, smaller values will be obtained, but negative time lags can never result.

In our investigation of the permeability of some phenols and aromatic amines through low density polyethylene, we obtained diffusion coefficients in the 10^{-9}–10^{-10}-cm.^{2} sec.$^{-1}$ range. For example, in the case of *o*-phenylenediamine, we found a time lag of 130 min., corresponding to a diffusion coefficient of 2.0×10^{-10} cm.^{2} sec.$^{-1}$ (temperature 35°; film thickness 30.6 μm.). Therefore, we drew a straight line through data taken after 5 hr. These data are in good agreement with literature values (4).

Using aqueous solutions in a slightly modified cell, we obtained negative time lags if quantitation was done spectrophotometrically in the UV region. Since it is impossible that a considerable amount of substance has permeated at time zero, these data can only be explained by an anomalous behavior at the beginning of the permeation process. Using a colorimetric procedure (5), however, we obtained the reported results.

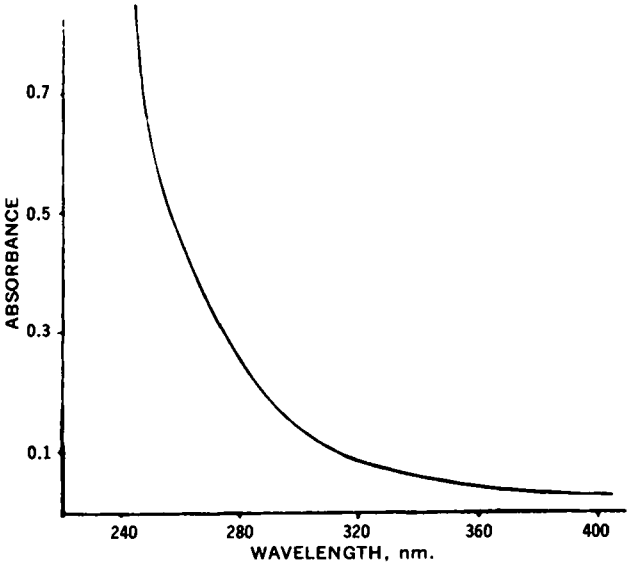

Figure 1—*UV absorption spectrum of the unknown substance eluted from polyethylene films.*

We suggest, therefore, that some substance could be eluted from the polyethylene film which shows strong UV absorption. In our experiments, we used polyethylene films[1] without pretreatment. They did not contain additives. To confirm our suggestions concerning the presence of an interfering substance, we extracted the solution in which quantitation was done with chloroform. After evaporation of the organic solvent, we examined the extract by TLC on silica gel [solvent of benzene–petroleum ether (7:3)] by comparison with blank tests. Because of the decomposition of *o*-phenylenediamine during evaporation, the chromatogram could not be evaluated exactly. With phenol as the permeant, however, the starting point of the chloroform extract only gave a green fluorescence. After spraying with 2,6-dichlorquinonchlorimide, only phenol appeared as a colored spot. The green fluorescing spot did not react. Phenol and all other substances were tested for purity by TLC.

After elution from the thin-layer plate, we recorded the UV spectrum of this substance (Fig. 1). It showed considerable absorption and, thus, interfered with the spectrophotometric determination of aromatic compounds. We have not been able to characterize this substance further because of the minute amounts.

If one wishes to interpret this effect, one must assume that elution of this substance occurs at the beginning of the permeation process within a relatively short time. It is due to the interaction between permeant and polymer membrane. Treating the membrane only with water, alcohol, and alcohol–water (1:1), we could not find this substance.

These findings explain the occurrence of negative lag times in the case of compounds with low permeability coefficients if the permeation rate is determined spectrophotometrically. In the investigation of substances with higher permeabilities, experimental lag times may still be slightly positive. The detailed results of our investigations will be published later.

Density Changes in Lactose Tablets

Keyphrases ☐ Tableting, lactose—effect of particle size and speed of compaction on density ☐ Compaction—effect of particle size and speed of compaction on lactose tablet density ☐ Density, lactose tablets—effect of particle size and speed of compaction ☐ Lactose, crystalline and spray dried—tablet density changes related to particle size and compaction speed

Sir:

Fell and Newton (1) considered the density changes during compaction at two different speeds of several particle-size fractions of crystalline and spray-dried lactose. They referred to earlier work in which we (2) reported that application of the Heckel (3) treatment allowed an interpretation of the mechanism of consolidation. Our work showed that while lactose consolidated by particle rearrangement, particle-size reduction, and plastic deformation, sodium chloride consolidated by particle rearrangement and plastic deformation. These findings supported earlier work showing that tablet strength was dependent upon original particle size for sodium chloride but not for lactose (4, 5).

This concept of two principle mechanisms of consolidation, *i.e.*, with or without fragmentation, was supported by the results of Hardman and Lilley (6), and it appeared that the Heckel equation could be used to distinguish between these mechanisms (7). We have subsequently repeated much of this work using equal volumes (measured at zero applied pressure) of different particle-size fractions of both lactose and sodium chloride. Under these circumstances, use of the Heckel treatment did not produce an identical trace for the different particle-size fractions of lactose. Measurements of the slope of the individual traces showed considerable variation for the mean yield pressure[1] of lactose varying between 85 MPa for the 250–420-μm. fraction and 175 MPa for the fraction smaller than 125 μm. Variation may be caused by a number of factors such as the presence of trace quantities of moisture or other contaminant materials; the method of measurement of the volume, either under pressure or after ejection from the die; the dimensions of the compact; the presence or absence of lubricant; and a particle-size effect *per se* as indicated by the work of Griffith (8).

In the current work, the materials were classified using a sonic-sifter[2] and stored in a desiccator after oven drying to remove free moisture. The previously reported value for the mean yield pressure of lactose of 401 MPa (2) resulted from an omission of the value of e in calculation and should read 174 MPa, which is in close agreement with the values reported by Fell and Newton (1) and supported by the present results. For lactose, we found a tendency for the mean yield pressure to increase with a decrease in particle size, as would be expected from the Griffith theory. This theory states that as the size of crystals decreases, there is an increase in the stress necessary to cause extension of any crystal cracks.

The Heckel (3) graph for lactose showed a straight line in all cases except at low pressures. However, for sodium chloride, a linear relationship is observed even at low pressures, indicating that, while lactose deforms by fragmentation in the early stages of compaction, sodium chloride apparently deforms only by plastic deformation.

If particle rearrangement takes place, it would be expected to occur at extremely low pressures as indicated by Fell and Newton (1). However, for both lactose and sodium chloride, the volume at zero applied pressure coincides with the Heckel plot. This would indicate that in the present case such rearrangement is not an important mechanism of consolidation, possibly because the use of a large diameter die permitted optimal packing of the particles during initial filling of the die.

ERRATA

In the article titled "Dissolution Rate Patterns of Log-Normally Distributed Powders" (1), the following corrections should be made:

On page 225, column 2, Eq. 6 and the sentence following it should read:

$$\frac{w(\tau)}{w_0} = \frac{\pi \cdot \rho}{6 w_0} \cdot \int_{\tau_c - \tau}^{Q-\tau} a^3 \cdot \phi(a + \tau)\, da$$

where $\phi(a)\, da$ is the number of particles initially between diameters a and $a + da$.

On page 226, column 2, Eq. 7 should read:

$$\frac{w(\tau)}{w(\tau_c)} = \int_0^{Q-\tau} a^3 \cdot \phi(a + \tau)\, da \Big/ \int_0^{Q-\tau_c} a^3 \cdot \phi(a + \tau_c)\, da$$
