The crystal forms of sulfameter were studied and identified as three polymorphs, two solvates, and an amorphous phase (48, 49). The GI absorption of Forms II and III was studied in humans. One gram of either crystal phase was suspended in a mixture of 25 ml each of 20% mucilage of acacia and simple syrup. The mean blood concentration curves are shown in Fig. 8. The energetic crystal Form II had an absorption rate about 1.4 times as great as that of the water-stable Form III. Marketed pharmaceutical preparations of sulfameter were also studied and contained mainly Form III. As a result of the absorption study, the use of Form II, the more biologically available crystal form, was recommended, provided adequate measures are taken to prevent its transformation.

Borka (50, 51), using both differential thermal analysis and IR spectrophotometry, identified the different polymorphs of chloramphenicol palmitate and studied their solid and solution phase transformations. He found that Form B, although metastable, has unusual stability, which, combined with its low solubility in water, assures very reliable drug preparations not only in the dry form as capsules but also when suspended in water.

Aguiar (52) continued his work on the different polymorphs of chloramphenicol palmitate and determined their dilatometric behavior. Aguiar and Zelmer (53) also studied the relative dissolution and solubility of the three polymorphs of chloramphenicol palmitate. From a comparison of the *in vivo* absorption data in humans and thermodynamic parameters, they postulated that when the free energy differences between the polymorphs are high, they might affect the absorption profiles. However, if the free energy differences are not high, as in mefenamic acid, there are no significant differences in their absorptions as measured by blood levels.

Banerjee *et al.* (54) followed the absorption of amorphous and polymorph A chloramphenicol palmitate suspensions and found that the absorption of the amorphous form was "definitely superior" in children. Miyamoto *et al.* (55) also studied the differential scanning calorimetry of chloramphenicol palmitate and its phase transitional behavior during the preparation of its oral suspension.

Finally, after billions of aspirin tablets have been produced and consumed, Tawashi (56) reported that aspirin is dimorphic. He also studied the GI absorption of these two forms in humans; 600 mg of each phase dispersed in water was ingested by each volun-

teer and the total serum salicylates were measured. The salicylate concentration–time curve is given in Fig. 9 (57). The disclosure by Tawashi generated one of the most concentrated efforts in the field of polymorphism, and the outcome is yet far from the fate of Derjaguin's "polywater."

Summers *et al.* (58) agreed that aspirin is polymorphic and proposed six different forms; Borka (59), using data obtained from solution phase transformations, agreed that aspirin is at least dimorphic. The major opponents to the polymorphism of aspirin have been Mitchell and coworkers (60, 61), who suggested that differences seen in different aspirins crystallized from different solvents are due to crystal defects (60), aging and ripening of the crystals, or poisoning by impurities other than salicylic acid (61).

Questions (62–64) raised on crystal habits, crystal size, or salicylic acid impurities, coupled with the mentioned controversies, will surely generate more work on the crystal chemistry of aspirin until a final agreement is reached. This author believes that the best way to solve the questions will be by doing a total structure determination using single-crystal X-ray crystallography, which has already been successfully used with other polymorphic substances.

Other compounds reported to exhibit polymorphism are water with nine polymorphs (65), sulfur with 12 crystalline phases (66), chlordiazepoxide hydrochloride (6), methylchloromethane (67), cholesteryl palmitate (68), adiphenine hydrochloride (69); benzocaine picrate (70), phenobarbital (71), meprobamate (72), and erythromycin free base (73). The polymorphism of 3-(3-hydroxy-3-methylbutylamino)-5-methyl-*as*-triazino[5,6-*b*]indole (74) and 1-(2,3-dihydro-5-methoxybenzo[*b*]furan-2-ylmethyl)-4-(*o*-methoxyphenyl)piperazine hydrochloride (75) also was reported.

Dissolution Kinetics of Polymorphs—Kuhnert-Brandstätter and Burger (76–78) developed mathematical derivations on dissolution kinetics of both crystalline and amorphous phases of drugs and applied them to crystalline sulfathiourea and pyrithyldione and to crystalline and amorphous phases of calcium D-pantothenate. Dissolution studies were also carried on with different polymorphs of phenobarbital (79). Phase transitions between different crystalline forms were followed for methylprednisolone in the solid form (80), barbital (81), and sulfameter (sulfamethoxydiazine) (82) suspended in water.

Dissolution studies were taken one step further with the development of a mathematical derivation to determine the transition temperature of sulfathiazole polymorphs and the transition temperature between hydrate and anhydrous forms of phenobarbital by measuring their initial dissolution rates (83, 84). This method was in good agreement with values obtained by the conventional solubility equilibrium method.

Pharmaceutical Application of Polymorphism—*Polymorphism and Tableting Behavior of Powders*—Simmons *et al.* (85) reported that tolbutamide exists as Forms A and B, and they evaluated their respective tableting behavior. A preliminary evaluation on a rotary press revealed that Form B was responsible for both powder bridging in the hopper and extensive capping problems during tableting. This behavior was due to the platy habit of Form B and could be corrected by using nonplaty Form A raw material.

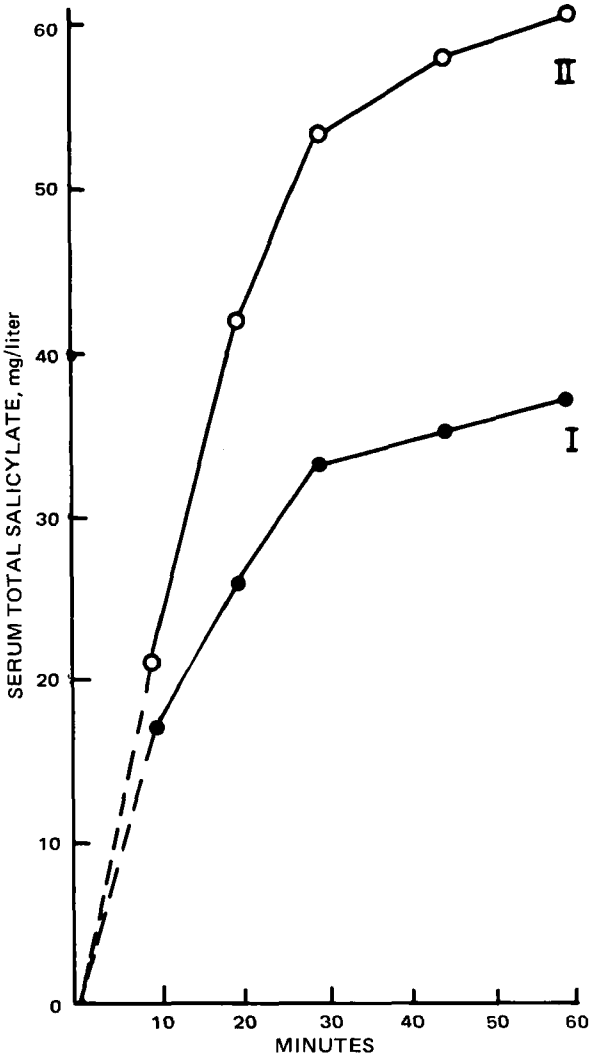

Figure 9—*Serum total salicylate concentration after oral ingestion of aspirin Forms I and II. (Reproduced, with permission, from Ref. 57.)*

Polymorphism and Physically Stable Dosage Forms—Pearson and Varney (86) followed the growth of oxyclozanide crystals in quiescent suspensions with the use of a particle counter[1]. They found that there was an increase in the particle size as a result of an isothermal, solvent-mediated phase transition between two polymorphs. The rearrangement of molecules in the crystal occurs through selective dissolution and redeposition between crystals of different chemical potential. By this mechanism, the less soluble phase grows at the expense of the more soluble phase. To form a stable suspension, the initial use of a less soluble polymorph is mandatory. However, as Ebian *et al.* (87) reported in their work with sulfameter (sulfamethoxydiazine), the addition of transformation-retardation agents, *e.g.*, polyvinylpyrrolidone, might be useful.

[1] Coulter.

Polymorphism and Chemical Stability—Munshi and Simonelli (88), working with two polymorphs of methylprednisolone, found that Phase II degraded when exposed to various temperatures and relative humidity while Phase I was stable. They also found that this surface reaction was catalyzed by heat, UV light, and humidity.

As a result of the scientific evaluation of different polymorphs of drugs, there is a totally new awareness in this field. This awareness was demonstrated with the introduction of a new section on X-ray diffraction in NF XIII (89) and special X-ray diffraction patterns for different polymorphs of some drugs being included in the compendia. It is encouraging that this awareness of different polymorphs of different chemicals is now reflected in drug catalogs (90). This author's hope is that this kind of information will be available for any marketed chemical.

Molecular adducts of chemicals and the solvent of crystallization can be in either a stoichiometric proportion, as in the case of solvates, or a nonstoichiometric proportion, as in the case of inclusion compounds.

STOICHIOMETRIC ADDUCTS-SOLVATES

Definition—During crystallization from a solution, crystals separating may consist of a pure component or be a molecular compound. Molecular compounds may contain two or more constituents that have completely satisfied classical "valence forces" and are crystallized together as a new single crystalline entity. Solvates are molecular complexes that have incorporated the crystallizing solvent molecule in their lattice. When the solvent incorporated in the solvate is water, it is called a hydrate.

To distinguish solvates from polymorphs, which are not molecular compounds, the term pseudopolymorph is used (91). All solvates are formed with stoichiometric proportions between the compound and solvent of crystallization (92). Just as different chemical compounds can have different polymorphs, solvates of different compounds can exhibit polymorphism too. Kuhnert-Brandstätter and Gasser (91), in their work with fluocortolone, found dimorphism of the ethanolic solvates. Similarly, polymorphism was also reported for hydrates of fluprednisolone (29) and succinylsulfathiazole (93).

Examples of Solvates—The pharmaceutical literature on examples of solvates is relatively new, but an extensive amount has been published in the last 20 years. Kuhnert-Brandstätter and coworkers (91, 92, 94–96) worked extensively on solvates of steroids and found that solvate formation is independent of polymorphism. Of all the steroids examined, they found that estradiol formed solvates with all 30 solvents tested, the highest number of solvates so far recorded (92). Other steroids that have been observed to form solvates include hydrocortisone acetate (97), cortisone acetate (98), fluprednisolone (29), the *tert*-butylacetates of prednisolone and hydrocortisone (99), and fludrocortisone (fluorohydrocortisone) acetate and cholesterol (93).

Many antibiotic–antibacterials can also form solvates, *e.g.*, erythromycin (100), gramicidin (101), furaltadone (nitrofurmethone) (102), ampicillin (103, 104), cephaloridine (105), chloramphenicol (106), griseofulvin (107), sulfanilamide (108), sulfabenzamide (43), sulfaguanidine (43), succinylsulfathiazole (93), sulfameter (sulfamethoxydiazine and sulfamonomethoxine) (48, 109). Other miscellaneous compounds also forming solvates include caffeine, theophylline, glutethimide (93), ouabain (110), phenobarbital (111), triazinoindoles (74, 112), and at least 90 other hydrates included in USP XVIII (32) and NF XIII (89).

Preparation of Solvates—Most solvates are prepared by crystallization of the solvated compound from the respective solvent of solvation. In some cases where mixed solvents are used, solvates might be formed from either or both solvents. Holden and Singer (113), in their book on crystal growing, discussed salt hydrate formation where a salt is added to water which weakens the electric forces between the ions and also attracts the ions away from the solid. Once ions are free, they gather water molecules around them. Positive ions gather water molecules to them more readily than negative ions. When these hydrated ions arrive at the surface of a growing crystal, they crystallize into a salt hydrate, carrying some or all of their attached water molecules into the solid composition (Fig. 10).

Even when the number of water molecules is definite and the hydrated ions are combined into a crystalline solid (an orderly arrangement of ions and water molecules), they may, nonetheless, be able to combine in several ways to form different solids. For each hydrate, the number of water molecules per ion

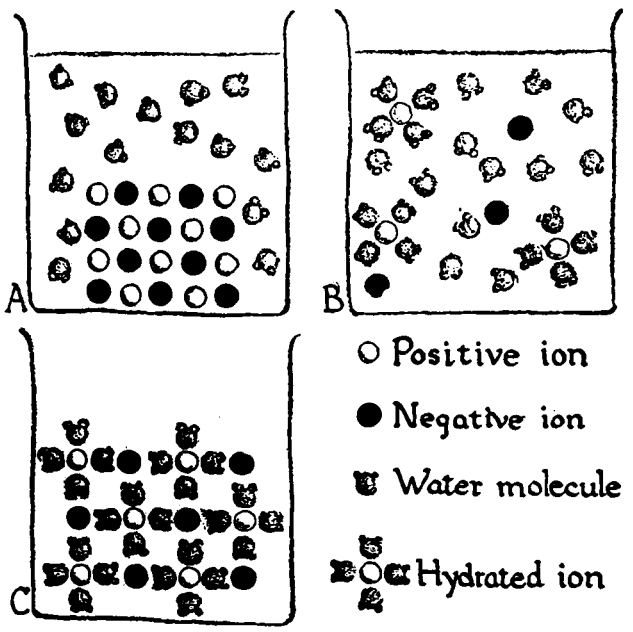

Figure 10—*Formation of a salt hydrate. When the anhydrous salt comes in the presence of water (A), it dissolves and the positive ions become hydrated (B). When crystallizing from solution again, the ions may remain hydrated and then the water molecules play an orderly role in the crystalline salt hydrate (C). (Reproduced, with permission, from Ref. 113.)*

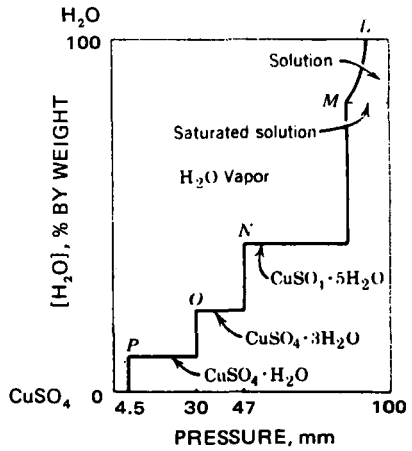

Figure 11—*Pressure–concentration curve for the cupric sulfate–water system at 50°. (Reproduced, with permission, from Ref. 114.)*

has a definite value. Solvates of a compound with different moles of solvent can be prepared in different ways, either by holding the temperature constant or by maintaining the pressure constant in the concentration–temperature–pressure systems.

Figure 11 represents the concentration–pressure curve at 50° for the cupric sulfate–water system (114). If a dilute solution of cupric sulfate is placed in an evacuated desiccator at 50° and water vapor is removed so slowly that an equilibrium is maintained, the water vapor pressure changes along the *LMNOP* line. As water is removed, the cupric sulfate concentration increases; the vapor pressure of the solution then decreases along line *LM*. When the solution becomes saturated, the pressure remains constant (vertical line at *M*), while the water is removed.

The gross composition of the system changes as the water is removed, and the relative amounts of saturated solution and $CuSO_4 \cdot 5H_2O$ change. However, since the compositions of the two phases do not change, the vapor pressure remains constant. When all of the solution has disappeared, the pressure drops abruptly to 47 mm at *N*. The pressure over a $CuSO_4 \cdot 5H_2O$ and $CuSO_4 \cdot 3H_2O$ mixture remains constant at 47 mm. When all the $CuSO_4 \cdot 5H_2O$ has been dehydrated to $CuSO_4 \cdot 3H_2O$, the partial pressure of water drops abruptly to 30 mm at *O*. It remains constant until 2 more moles of water/mole of cupric sulfate is lost at *P*. Then the water vapor pressure drops to 4.5 mm and remains constant until dehydration is complete (114).

Table II—Water Content and Temperature of Isolation of Ouabain Hydrates

Hydrate	Temperature of Isolation
Ouabain·$9H_2O$	0–15°
Ouabain·$8H_2O$	15–28°
Ouabain·$4\frac{1}{2}H_2O$	20–30°[a]
Ouabain·$4H_2O$	20–30°[b]
Ouabain·$3H_2O$	20–30°[c]
Ouabain·$2H_2O$	28–90°
Ouabain	150°[d]

[a] From 95% ethanol. [b] From 97% methanol. [c] From dioxane containing 6% water. [d] Obtained by heating ouabain recrystallized from ethanol in abderhalden apparatus at 150°.

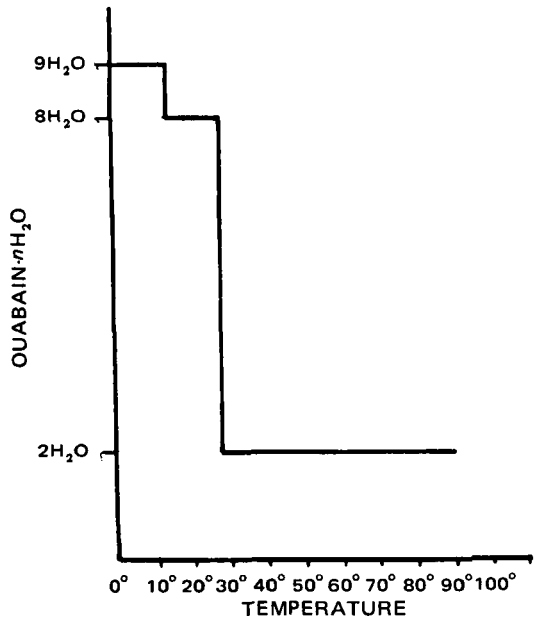

Figure 12—*Temperature–water composition phase diagram for ouabain hydrates. (Reproduced, with permission, from Ref. 110.)*

Trivedi *et al.* (110), using the alternative method of holding pressure constant, obtained hydrates of ouabain with different molecules of water by adding excess amounts of ouabain to the solvent for recrystallization and heating it above the crystallization temperature. The solutions were then allowed to cool to the temperature desired for crystallization. After a sufficient amount of ouabain had crystallized, the containers were closed to help equilibrate the system without evaporation. In this manner, ouabain was crystallized at 0° and at intervals of 10° from 20 through 90°. Six different ouabain hydrates were obtained, depending on the temperature of crystallization. Table II shows the water content and tempera-

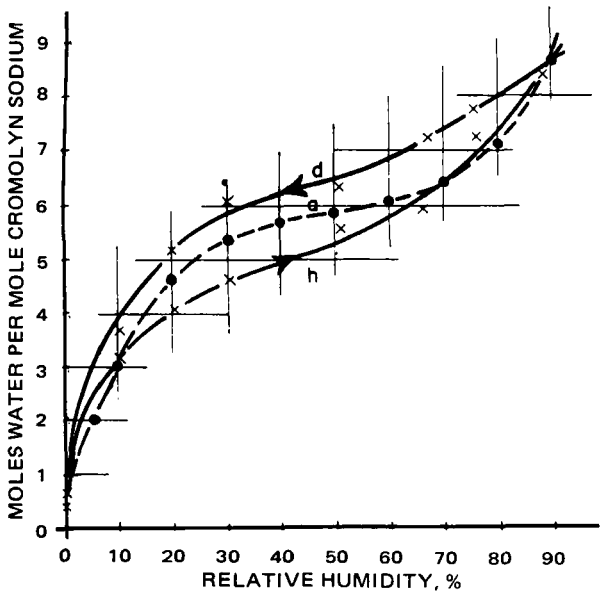

Figure 13—*Water content as a function of relative humidity during hydration (h) and dehydration (d), and an average curve for all data determined (a). (Reproduced, with permission, from Ref. 115.)*

ture of isolation. The temperature–water composition phase diagram for the hydrates isolated from water is illustrated in Fig. 12.

Cox *et al.* (115), in their work on solid-state chemistry of cromolyn sodium, obtained a continuous series of interstitial solid solutions or lyotropic mesophases with water by changing the relative humidity. Figure 13 represents the change of water content as a function of relative humidity. The hydration curve shows that, although there is a region of slow increase of moisture content with increasing humidity, there are no sharp plateaus corresponding to fixed hydrates. This absorbed water, amounting to as much as 24 wt. % at about 90% relative humidity, resulted in reversible expansion of the lattice, especially along

the *b* crystallographic direction. This, in turn, caused changes in X-ray diffraction patterns, density, and other physical properties.

Characterization of Solvates—Different analytical methods have been used for identification of either the solvates or the solvent of the molecular complex.

Methods Used to Identify Solvates—Hirtz *et al.* (116), using thermogravimetric analysis, studied the solvation of organic compounds with pharmaceutical interest. Thermograms of different solvates show different steps of desolvation, which correspond, at a certain interval of temperature and pressure, to the stable solvate. The distinction of the steps on the thermogram could be due to real solvation or to pseudosolvation, which is due to the special setup of the experiment.

Real solvation for tetracycline base is illustrated in Fig. 14. A linear increase of temperature produces a loss of initial weight, which varies from sample to sample and is due to volatilization of "free water." This loss is followed with a second loss of weight, in this case equivalent to 6 moles of water and independent of sample analyzed, indicating that the original sample was a hexahydrate. In the case of thermograms that are the results of special sets of experimental conditions, one can see, as in Fig. 15, that when the temperature increase is not linear, a false step develops on the thermogram which disappears during a linear temperature increase.

Using differential thermal analysis, Brancone and Ferrari (109) were able to demonstrate that sulfameter is a solvate. Similarly, Sekiguchi *et al.* (107) used differential thermal analysis to identify different hydrates of phenobarbital, theophylline, and other organic pharmaceuticals.

Differential scanning calorimetry, a method similar to differential thermal analysis, was also used by Sekiguchi *et al.* (107) to identify the chloroform solvate of griseofulvin.

Gas evolution analysis can be done simultaneously with differential scanning calorimetry. Himuro *et al.* (106), in their work on pyridine solvate of chloramphenicol, plotted differential scanning calorimetry–

gas evolution analysis and thermogravimetric analysis thermograms (Fig. 16). There is a very close correlation of the three different methods used in identifying the solvate.

Trivedi *et al.* (110), using the petrographic microscope, determined optical crystallographic data for ouabain hydrate. These data included the crystal system, optic orientation, optic sign, axial angle, dispersion, common orientation, and refractive indexes. Kuhnert-Brandstätter and Grimm (95) used thermomicroscopy to identify different solvates and polymorphic modifications of different steroids.

Most X-ray diffraction work reported employed powder diffraction. This method was used to differentiate fluprednisolone polymorphs from fluprednisolone solvates (29), to study pseudopolymorphism of furaltadone (102), and to differentiate chloramphenicol from its pyridinate solvate (106). Moustafa *et al.* (48) used powder diffraction to differentiate polymorphs and solvates of sulfameter. If the purity of a sample is established, powder X-ray diffraction is one of the best methods available to differentiate any crystalline modification, be it polymorphs, solvates, or clathrates. Busetta *et al.* (117), continuing their work on single-crystal X-ray crystallography of pharmaceuticals, determined the crystal structure of methanol plus water, of ethanol, and of dimethyl sulfoxide solvates of diethylstilbestrol. They found that all three phases are triclinic crystals. Single-crystal X-ray diffraction also was used to determine the structure of different pharmaceutical hydrates (118, 119).

IR spectrophotometry is much more useful for distinguishing between solvates and anhydrous forms than for identifying polymorphs because of the addition of new stretching frequencies resulting from solvation. Biles (99) used IR spectrophotometry to differentiate crystalline modifications of the *tert*-butylacetates of prednisolone and hydrocortisone. Haleblian *et al.* (29) used IR spectrophotometry in their work on characterization of different solid phases of fluprednisolone. Kuhnert-Brandstätter and Grimm (94, 95) also used this method for identification of solvates of some of the different steroids studied, although they felt that it was difficult and often impossible to distinguish crystal forms containing solvent from polymorphic modifications (94).

Methods Used to Identify Solvent of Solvation—Most solvents of solvation are determined by using some method that produces the release of the solvent, which, in turn, is trapped and identified. If the solvent of solvation is water, *e.g.*, hydrates, some of the USP XVIII (120) methods for water determination can be used. Of these, the most important is the Karl Fischer titrimetric method. This method was used to identify the hydrates of fluprednisolone (29) and ouabain (110).

IR spectrophotometry was used to identify the solvents of solvation that are readily vaporized and give satisfactory spectra at low concentrations in conventional gas cells (121). The sample was heated in polyethylene glycol 300, a liquid of high boiling point, which dissolves the sample, and the vapor was examined in an evacuated gas cell for the presence of absorption spectra characteristic of a particular solvent.

The GC method described in the British Pharmacopoeia 1968 was also used to identify solvents (121).

Investigation of hydrated crystals using proton magnetic resonance was pioneered by Pake (122) and advanced by McGrath and Silvidi (123) and Pedersen (124). Chapman *et al.* (105), in their work on cephaloridine, obtained quantitative information on the different solvated solvents by using proton magnetic resonance.

Differential scanning calorimetry has also been used. Different amounts of water in cortisone acetate hydrates were measured by calibrating the effluent analyzer, using $CuSO_4 \cdot 5H_2O$ as the standard (98).

Properties of Solvates—*Dissolution Rate of Solvates*—Shefter and Higuchi (93), in their work on the dissolution behavior of crystalline solvated and nonsolvated forms of some pharmaceuticals, were the first to treat mathematically the dissolution rate of solvates. The dissolution of a solvate can be expressed in water as in Scheme II:

$$A{:}\,nB_{\text{solid}} \rightleftharpoons A_{\text{aqueous}} + nB_{\text{aqueous}}$$

Scheme II

where A is the drug component and B is the solvent that is solvated. The rate of dissolution can be given by:

$$G = \frac{dC_A^*}{dt} = kD_A(C_A - C_A^*) = \frac{1}{n}\frac{dC_B^*}{dt} = \frac{kD_B}{n}(C_B - C_B^*) \quad \text{(Eq. 2)}$$

where C_A^* and C_B^* are the concentrations of the two species in the bulk of the solution, C_A and C_B are their respective concentrations at the crystal surface, D_A and D_B are the respective diffusivities, and k is a combined geometric and agitation factor.

For the case where $n = 1$ and $D_A = D_B$, Eq. 2 can be simplied to:

$$G = \frac{dC_A^*}{dt} = kD_A(\sqrt{Ksp} - C_A^*) \quad \text{(Eq. 3)}$$

where $[C_A][C_B]^n = Ksp$.

From Eq. 3, it can be seen that C_A^* may be able to build above the solubility of A itself in water. If the concentration of C_B^* is increased much more than C_A^* by the addition of the solvating solvent in the dissolution medium, then:

$$G = \frac{KD_A Ksp - kD_A C_A^*}{C_B^*} \quad \text{(Eq. 4)}$$

which indicates that the dissolution rate for the solvate will decrease with an increase of B in solution.

Nogami *et al.* (111), in their work on the dissolution of organic medicinals involving simultaneous phase changes, defined dissolution rate as:

$$\frac{dC}{dt} = k_t\{C_{SA}e^{-k_t t} + C_{SH}[1 - e^{-k_t t}] - C\} \quad \text{(Eq. 5)}$$

where C is the concentration in the bulk liquid, C_{SA}

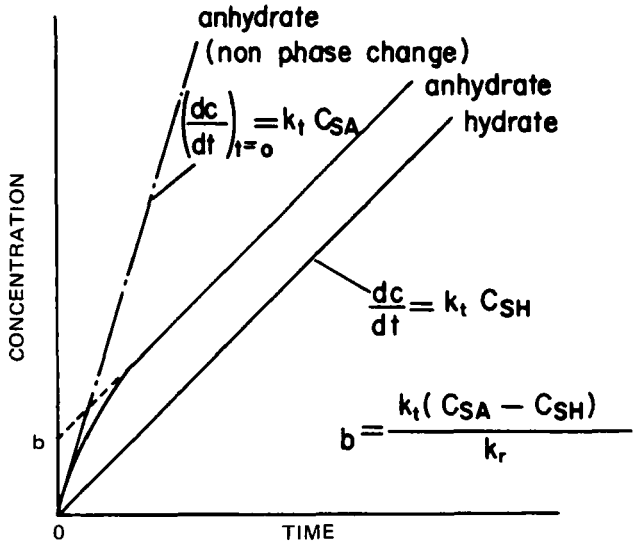

Figure 17—*Schematic illustration for relationship between concentration and time in initial time of dissolution according to Eqs. 8 and 10. (Reproduced, with permission, from Ref. 111.)*

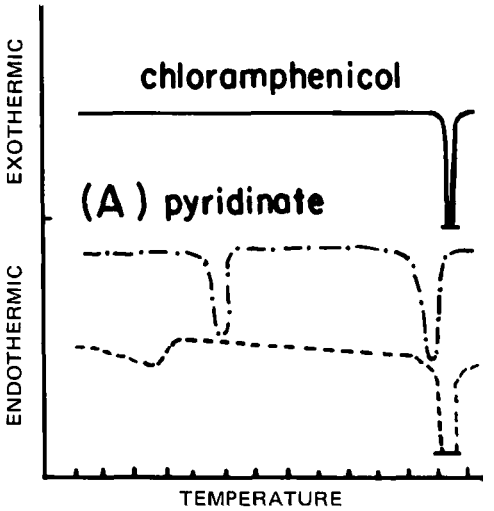

Figure 18—*Differential scanning calorimetry thermogram of chloramphenicol pyridinate solvate. (Reproduced, with permission, from Ref. 106.)*

is the saturated concentration of the anhydrous phase, C_{SH} is the saturated concentration of the hydrate, and k_r and k_t are the rate constants of crystallization and transport processes, respectively. Since $C = 0$ and $t = 0$, Eq. 5 is integrated to:

$$C = \frac{k_t(C_{SA} - C_{SH})}{k_t - k_r}(e^{-k_r t} - e^{-k_t t}) + C_{SH}(1 - e^{-k_t t}) \quad \text{(Eq. 6)}$$

This equation expresses the general dissolution curve involving the phase change caused by hydration. Since C_i, the effective concentration on the solid surface, is initially greater than C, Eq. 5 is modified to:

$$\frac{dC}{dt} = k_t(C_{SA}e^{-k_r t} + C_{SH}[1 - e^{-k_r t}]) \quad \text{(Eq. 7)}$$

Under the initial condition $C = 0$ at $t = 0$, Eq. 7 is integrated to yield:

$$C = \frac{k_t(C_{SA} - C_{SH})}{k_r}[1 - e^{-k_r t}] + k_t C_{SH} t \quad \text{(Eq. 8)}$$

Since t may be sufficiently long, even in the initial stage, Eq. 8 gives a linear relationship with the gradient of $k_t C_{SA}$. Then, when the linear portion of Eq. 8 is extrapolated, the intercept, b, is given by:

$$b = \frac{k_t(C_{SA} - C_{SH})}{k_r} \quad \text{(Eq. 9)}$$

Equation 9 predicts how much the dissolution data of the anhydrous phase undergoing phase transition deviate from the dissolution curve expected from the hydrate alone.

The initial dissolution rate, $(dC/dt)_t = 0$, is derived from Eq. 7 with:

$$\left(\frac{dC}{dt}\right)_{t=0} = k_t C_{SA} \quad \text{(Eq. 10)}$$

which corresponds to the dissolution rate of the anhydrous phase undergoing no phase transition. The general patterns of dissolution behavior according to Eqs. 8 and 10 are illustrated in Fig. 17 (111).

The rate of dissolution of fluprednisolone above a certain temperature may be faster than the rate of transition (anhydrous → hydrous) and not noticeable in the concentration *versus* time plots (125). Ways of calculating different thermodynamic parameters were derived for the anhydrous–hydrated systems, *e.g.*, enthalpy of hydration, free energy of hydration, entropy change, and transition temperatures (93).

Melting Behavior of Solvates—Clear solvate crystals, when observed by transmitted light under a hot stage microscope, lose their solvent of crystallization and become either cloudy or opaque crystals, a process known as pseudomorphosis. Sometimes a solvate first melts and then resolidifies as the temperature rises to give the solvate-free form, which finally again melts. This phenomenon is illustrated by the differential scanning calorimetry curves of chloramphenicol pyridinate (Fig. 18) (106). The differential scanning calorimetry curve consists of three peaks (Fig. 18) (106):

1. The first endothermic peak is due to the desolvation of pyridine, because the shape and the temperature of peak decline are strongly influenced by experimental conditions.
2. The small exothermic rise is due to crystallization of amorphous solid or a metastable melt.
3. The second sharp endothermic peak represents melting of desolvated chloramphenicol.

Brancone and Ferrari (109) found, using differential thermal analysis, that the shallow endotherm of sulfameter at 120° is due to a solvent. They confirmed this observation by running another thermogram under reduced pressure where the endotherm, due to the solvent, had shifted to 66°.

A classical method for distinguishing solvates from polymorphs involves observation of the melting behavior of crystals embedded in silicone oil, where, upon heating, bubbles of solvent are generated by solvates. In the case of polymorphs, no such generation occurs.

This reviewer's opinion is that during heating of crystals embedded in silicone oil, the temperature at

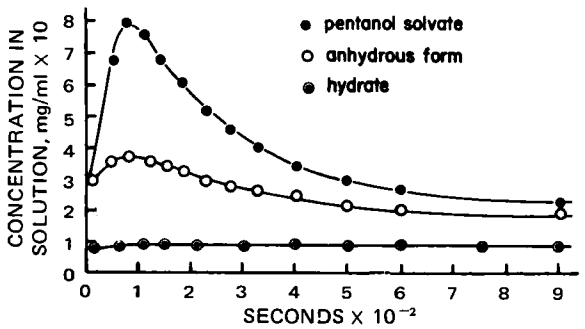

Figure 19—*Dissolution behavior of different forms of succinylsulfathiazole in ~0.001 N sulfuric acid solution at 20°. (Reproduced, with permission, from Ref. 93.)*

which gas bubbles generate is in the vicinity of the boiling point of the solvating solvent. In the case of clathrates (discussed later), this temperature is much higher than the boiling point of the clathrated solvent and very near the melting point of the clathrate.

Pharmaceutical Application of Solvates—*Dissolution*—As anticipated from the theoretical properties of solvates, the dissolution behavior of crystalline solvated and nonsolvated forms of some pharmaceuticals agreed with the theory (93). Figure 19 shows the dissolution behavior of anhydrous, hydrated, and pentanol-solvated forms of succinylsulfathiazole. These curves confirm the theoretical prediction that the dissolution rate of a solvate may be many times greater than the anhydrous form. On the other hand, the dissolution rate of the hydrate is less than the anhydrous form.

Another interesting confirmation of theory (93) is the effect of the concentration of the solvating solvent in the dissolution medium. When measuring the dissolution of the pentanol solvate of fludrocortisone acetate, the dissolution rate was retarded by the addition of pentanol in the dissolution medium. According to this study, it is conceivable that solvates will find broad use in dosage form development "due to their higher temporary solution concentrations and rates of solution which can be obtained by their use instead of the anhydrous form. This is because the system utilizes the free energy of dilution of the complexing agent to raise the solubility of the drug." (93).

Bioavailability—The physicochemical factors influencing the absorption of the anhydrous and trihydrate forms of ampicillin were studied (103). The aqueous solubility of the anhydrous form was 20% greater than the trihydrate at 37° (10 and 8 mg/ml, respectively). The effect of the observed solubility differences on the *in vitro* availability of the drug was also studied. The T_{50} (time required for 50% of the labeled amount to appear in solution) was 7.5 and 45 min for the anhydrous and trihydrate forms, respectively.

In vivo experiments were also done with dogs and humans, where the anhydrous and the trihydrate forms of the drug were given as oral suspensions or capsules. The anhydrous form produced higher and earlier peaks in the blood serum than the trihydrate form. This result was more pronounced in the suspension formulations. Figure 20 shows the mean blood serum concentration in human subjects after oral administration of a 250-mg dose of the suspension. With both formulations, the area under the blood serum level *versus* time curve was greater with the anhydrous form, indicating that the anhydrous form is more efficiently absorbed.

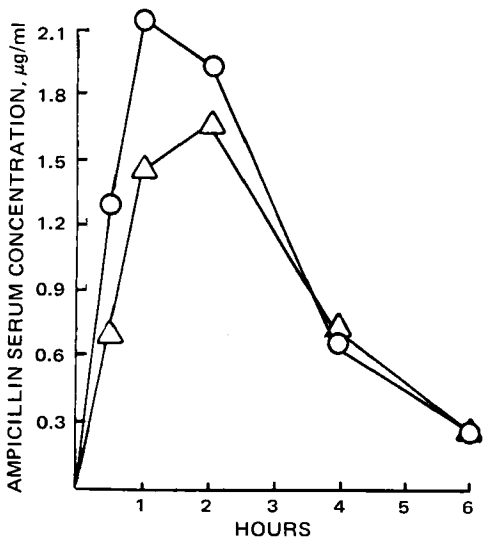

Figure 20—*Mean blood serum concentrations of ampicillin in human subjects after oral administration of 250-mg doses of oral suspension. Key: ○, anhydrous; and △, trihydrate. (Reproduced, with permission, from Ref. 103.)*

Hill *et al.* (126) questioned the conclusion (103) that the differences seen in ampicillin bioavailability were due to the hydration of ampicillin, since they found that the solubilities of the two phases in dilute hydrochloric acid at 37° were very similar. As a result of their data, they suggested that differences in the bioavailability are related to formulation factors rather than the hydration state of the raw material.

Ballard and Biles (127) studied the *in vitro* absorption rates of the *tert*-butylacetates of hydrocortisone and prednisolone and their solvates by the pellet implantation technique. They found that solvates affect the absorption rate from solid drug implants (Table III). With prednisolone tebutate pellets, for example, the monoethanol solvate (Phase II) had an absorption rate 4.7 times greater than that of the anhydrous phase (Phase I). The hemiacetone solvate (Phase IV) had practically the same mean absorption rate as the

Table III—Absorption Rate of the *tert*-Butylacetates of Hydrocortisone and Prednisolone

Crystal Modification		Absorption Rate per Unit Area, mg/hr/cm²
	Prednisolone *tert*-Butylacetates	
Phase I	Anhydrous phase	1.84×10^{-3}
Phase II	Monoethanol solvate	8.70×10^{-3}
Phase III	Hemiacetone solvate	2.20×10^{-3}
	Hydrocortisone *tert*-Butylacetates	
Phase I	Monoethanol solvate	1.83×10^{-3}
Phase II	Monoethanol solvate	7.32×10^{-3}
Phase III	Hemichloroform solvate	7.40×10^{-3}
Phase IV	Anhydrous	4.74×10^{-3}

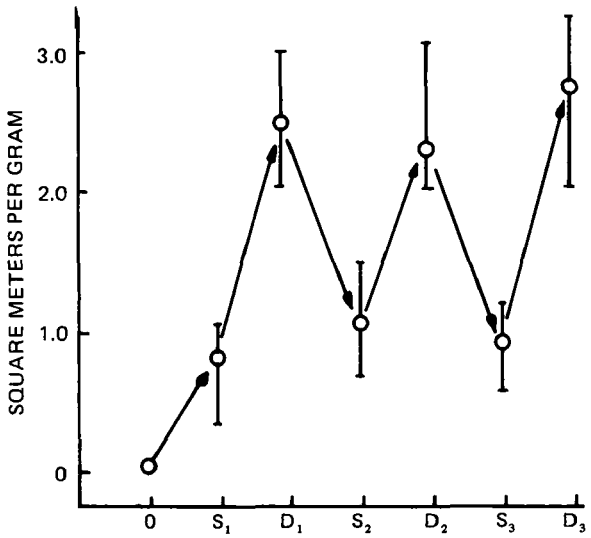

Figure 21—*Effect of repeated solvation and desolvation upon specific surface area of griseofulvin and its chloroformate. Key: O, ordinary crystal; S_1, solvated crystal; and D_1, desolvated crystal. (Reproduced, with permission, from Ref. 107.)*

anhydrous phase. With hydrocortisone *tert*-butylacetate pellets, the mean absorption rate for the solvates were all significantly different from the mean rate of the anhydrous phase (Phase IV). Also one monoethanol solvate (Phase II) had 4.0 times the mean absorption rate of the other monoethanol solvates (Phase I). These results indicate that drug solvates may exhibit dimorphism and each form may exhibit different *in vitro* absorption rates.

In a comparison of the physical properties and biological activities of some crystalline phases of fluprednisolone, Haleblian *et al.* (125) isolated one amorphous and six crystalline phases. Two phases were dimorphic solvates containing 1 mole of water. One existed as the *tert*-butylamine disolvate and three were anhydrous trimorphs. Using the Wruble apparatus, they determined the *in vitro* aqueous dissolution rates (6 rpm and 23°) of the anhydrous and hydrated forms. The dissolution rate ratio for the highest and lowest energetic phases was 2.24, where Form I was the most energetic phase and the α-monohydrate was the least energetic phase.

Similar results were obtained by comparing the *in vivo* dissolution rates of pellets of each crystalline phase, implanted subcutaneously by the method of Ballard and Nelson (128) into males rats. The *in vivo* dissolution rate ratio between the highest and lowest energetic phases was 1.61. Thus, the biological uptake of Form I of fluprednisolone in pellet form was 1.61 times that of the α-monohydrate phase. This value illustrates the effect that crystalline phases may have on biological activity. The *in vivo* and *in vitro* dissolution rates were also correlated with a pharmacological response–adrenal cortex atrophy of the rats. The adrenal cortex atrophy resulting from the uptake of Form I from pellet implants was 1.46 times that of the α-monohydrate.

Physically Stable Suspensions—When aqueous topical suspensions of two anhydrous forms of two different triazinoindoles were formulated, both produced large crystals upon aging. When these crystals were isolated, both were found to be monohydrates of the respective compounds. When the air-milled monohydrate of triazinoindole I, which is labile but does not lose water during milling, was used, suspensions resulted which were physically stable for 2 years.

Table IV—Effect of 3 hr of Exposure to Direct Sunlight or 1 hr of Exposure to 85° of Different Crystals of Coenzyme Form Vitamin B_{12} (Average of Two Runs)

	Percent Remaining	
	After 3 hr of Exposure to Direct Sunlight	After 1 hr of Exposure to 85°
Conventional crystals	74.85	23.70
Hydrated Form A	98.75	72.70
Hydrated Form B	73.75	37.25

Particle-Size Reduction of Medicinal Compounds—Sekiguchi and coworkers (106, 107, 129, 130), working with griseofulvin and chloramphenicol, developed a method of crystal-size reduction involving phase conversion. The technique required use of a proper solvent which forms a solvate with a medicinal compound and which also can be easily desolvated. The effects of repeated solvation and desolvation on the specific surface area of griseofulvin and its chloroformate particles were examined using the Brunauer, Emmett, and Teller (131) method with nitrogen as the adsorbing gas. When ordinary crystals were sorbed with chloroform vapor under vacuum, the apparent volume of the crystal mass was increased by about 50%. But continued desorption and sorption did not change the volume.

A zigzag curve was obtained, and the size reduction was practically finished by one cycle of solvation and desolvation (Fig. 21) (107).

The specific surface area after each desolvation exceeded 2 m^2/g; that of the solvated crystals was about 1 m^2/g after the second solvation. Although no liquid was observed visually at the end of sorption of vaporous chloroform, a minute amount of liquid probably was formed between particles by such a capillary condensation. Therefore, the primary particles are bridged, so surface area is decreased considerably. It was concluded that repeated applications of the method influence the specific surface area only slightly. However, when a solid substance forms a molecular compound with a gas, its surface area increases continuously by repetition of sorption and desorption of the gas (107).

Solvates and Chemical Stability—A patent was granted (132) for light- and heat-stable hydrate crystals of the coenzyme form of vitamin B_{12}. The coenzyme form of vitamin B_{12} can exist as conventional crystals (not specified if anhydrous or not) and as two hydrates, A and B, containing 15% weight of water. Table IV shows the effect of 3 hr of exposure to direct sunlight and also of 1 hr of exposure to 85°. From these data, it can be seen that the hydrate form A is chemically more stable than the other two forms.

Hydrocortisone 21-*tert*-butylacetate can spontaneously oxidize in air and change from 11β-ols to 11-

ones (133). This reaction requires molecular oxygen and produces water. The reaction is accelerated by heat and greatly accelerated by free-radical initiators or UV light. Three crystalline phases of the compound were studied. Phase A is a form in which the crystallizing solvent is held within the crystal in nonstoichiometric proportion; it can be completely desolvated in a vacuum without changes in the X-ray diffraction pattern. Phase B is a stoichiometric solvate. Desolvation is accomplished only at elevated temperature and is accompanied by changes in the X-ray diffraction pattern. Phase C is a nonsolvated form. Esters subject to air oxidation are Phase A, while Phases B and C are resistant to oxidation. Prednisolone tebutate behaved similarly to a lesser degree.

Inclusion compounds are a specialized form of molecular compounds; they do not exhibit stoichiometry. The title "inclusion compounds" for this class of complexes was first used by Schlenk (134, 135). Inclusion compounds vary from the other molecular compounds in that hydrogen bonding plays a minor role or is even nonexistent (136). In all three general types of inclusion compounds, a guest molecule is physically entrapped in a host molecule. The constituents are usually present in constant, but not necessarily stoichiometric, proportions.

The formation of these inclusion compounds[2] or adducts are dependent on the respective molecular size and shape of the constituents. The hollow space in which the guest molecule is enclosed may be a channel, a layer, or a cage.

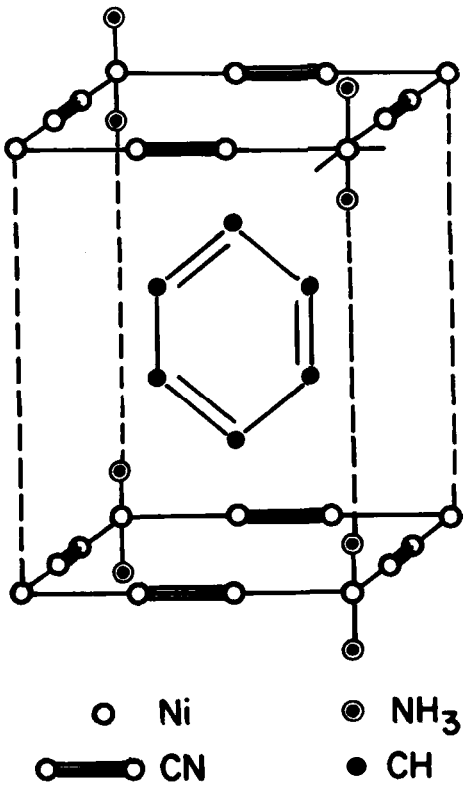

Figure 22—*Schematic representation of the clathrate of benzene with an ammonia–nickel cyanide complex* $[Ni(CN)_2NH_3—C_6H_6]$. *[Reproduced, with permission, from* Nature, ***163,*** *566(1949).]*

NONSTOICHIOMETRIC ADDUCTS-CLATHRATES

Definition—Clathrates are inclusion compounds. They were given this name by Powell (138) since the guest is enclosed or protected by crossbars of a grating. According to one source (139), a clathrate is a single-phased solid with two distinct components: the host and the guest. The guest is retained in closed cavities provided by the crystalline structure of the host. Generally, a cage and its enclosed molecule(s) are taken as a unit cell.

Figure 22 illustrates a typical clathrate where the guest, benzene, is clathrated in the host, ammonia–nickel cyanide. Since a crystalline structure cannot be easily deformed, a particular cage retains only molecules or atoms within a definite size and shape range. The lower limit of size is determined by the openings in the cage walls through which the guest components could escape. Two series of clathrates may have a common host component, but different cage structures, and contain physically different guest components. Moreover, the unit cells of some clathrates contain cages of two different sizes. A single clathrate of this type may have two different guest components.

The two components of a clathrate do not react chemically with each other, and a chemical equation implying bonds and chemical stoichiometry is inapplicable. Instead, a simple clathrate may be designated by a maximum-composition formula of $(nC)(mM)$, where C and M are the host and guest components, respectively; n is the number of C molecules per unit cage cell; and m is the maximum number of M molecules that can be accommodated in a single cage. The formula $(n/m)(CM)$ may also be used (139).

A special case of clathrate is a self-clathrate, built by incorporation of two identical but independent frameworks of the same compound. The polymorph VI of ice is built this way, where two independent tetrahedral frameworks interpenetrate but are not interconnected by hydrogen bonds. Each framework fills the void space in the other and, in reality, forms a self-clathrate (65).

Crystal Structures and Examples of Clathrates—Crystal structures of different clathrates have one thing in common; that is, they have enclosed spaces, which may be empty, partially occupied, or totally occupied with one or more kinds of guest molecules. On the other hand, there is no common structural characteristic of the enclosing part. The guest molecules, which have nonbonded distances with the host, have a nonstoichiometric relationship with each other. These guest molecules also have some interaction with their cage but cannot be firmly trapped in a cage that is not itself firmly constructed. This implies that the component parts of a host cage should be strongly bound together. The binding between the host atoms may be classified as covalent bonds, ionic bonds, metallic bonds, hydrogen bonds, or van der

[2] The general subject of inclusion compounds will be reviewed later (137).

Waals bonds. In any cage structure, more than one of these types may be involved.

The major classes of clathrates are hydroquinone clathrates, water clathrates[3], phenol clathrates, and clathrates of Dianin's compound. The only official monograph of a pharmaceutical clathrate is that of sodium warfarin clathrate in USP XVIII (140). This clathrate consists principally of sodium warfarin, isopropyl alcohol, and water, where the molecular proportions vary between 8:4:0 and 8:2:2. The expenditure of more time and effort will surely result in the discovery of more pharmaceutical clathrates as has happened with pharmaceutical polymorphs and solvates during the last 15 years.

Preparation of Clathrates—Preparation of most clathrates can be done easily under ordinary laboratory conditions. Most clathrates are generally prepared by recrystallization from solution, where the composition of the clathrate depends on the availability of the guest component at the site of crystal growth. Whenever a host is soluble in the guest, the preparation of the clathrate proceeds without difficulty, and a maximum clathrate composition is realized. Some problems may arise where a common solvent for both host and guest must be used. For example, when the guest concentration is low, slow crystallization with stirring is advised to ensure adequate concentration of the guest at the site of crystallization. Another problem is the choice of the common solvent, which should be inert as far as clathrate formation with the host.

In the case of clathrates formed with gases, high pressure is used to increase the concentration of the second component; at ordinary pressures, the solubility of the gas in the crystallization medium is not sufficient. This method was used to prepare hydroquinone clathrates of the inert gases argon (141), krypton (142), and xenon (143). A most unusual way of obtaining clathrates of substances that might not enclathrate has been suggested (138). This method involves the enclathration of molecules which will decompose within the host cage. Two factors must be satisfied: (*a*) the enclathrated compound must be capable of decomposition by the action of heat, UV light, or X-rays; and (*b*) the cage component must be stable under the decomposition conditions. For more details of the formation of clathrates, the reader is directed to the excellent review by Hagan (144).

Characterization of Clathrates—*Methods Used to Identify Clathrates*—X-Ray diffraction studies on a single crystal is the only sure way to construct the structure of clathrates totally. This is true for any crystalline modification of pharmaceuticals, be it polymorphs, solvates, or clathrates. Rayner and Powell (145, 146), using single crystals, found the crystal structure of the clathrate of benzene with an ammonia–nickel cyanide complex (Fig. 22) and also the crystal structure of hydrated nickel cyanide ammoniate.

X-Ray powder diffraction, although not as powerful a tool as the single-crystal X-ray studies, is a very potent tool for identification purposes. McAdie (147), in his work on urea–*n*-paraffin inclusion compounds, used this technique to differentiate urea from the urea–*n*-paraffin inclusion compound. This technique was not sensitive enough to differentiate the different chain-length paraffins. This finding might mean that once the host cage of an inclusion compound is formed, be it channel, cage, or layer type, X-ray powder diffraction does not vary with the change of the guest molecule. Another interesting observation was made by Mesley (148), who found that the X-ray powder diffraction of clathrates formed by chloroform with hydrocortisone, dexamethasone acetate, and prednisone did not change with various chloroform contents and only reverted to the pure steroid diffraction pattern when all chloroform was removed by heating.

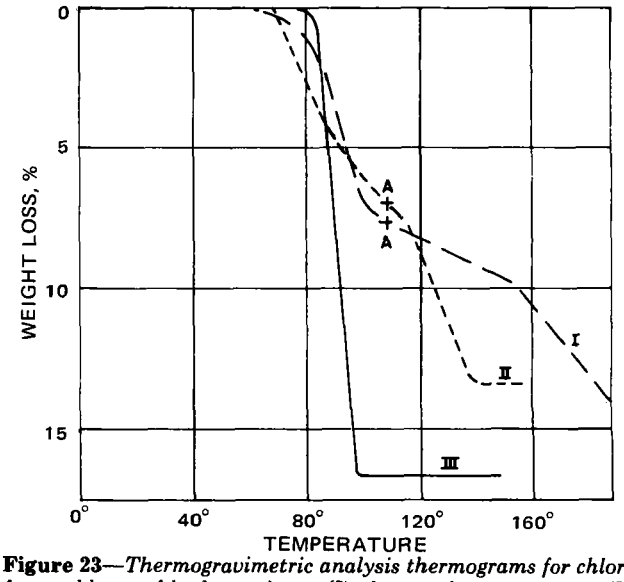

Figure 23—*Thermogravimetric analysis thermograms for chloroform adducts of hydrocortisone (I), dexamethasone acetate (II), and prednisolone (III). (Reproduced, with permission, from Ref. 148.)*

Due to the change of habits of different clathrates, microscopy, both plain and polarized, can be used to identify clathrates. Powell (141), in his work with clathrates of hydroxyquinone with argon, differentiated the large rhombohedra crystals of the clathrate from needle-shaped crystals of α-hydroxyquinone.

Using thermogravimetric analysis, Mesley (148), showed the thermogravimetric curves of hydrocortisone, dexamethasone acetate, and prednisone clathrates with chloroform (Fig. 23). According to this investigator, the chloroform adducts of hydrocortisone and dexamethasone acetate differed from that of prednisone in two respects. The thermogravimetric curves showed two distinct stages of weight loss compared with the rapid and complete decomposition of the prednisone compound. If the thermal decomposition of hydrocortisone and dexamethasone acetate is interrupted at points A in Fig. 23, the materials are still in the crystal form of the clathrate but contain relatively little chloroform. Thus, the initial weight loss is due to removal of chloroform from the lattice, while the second stage corresponds to the

[3] This group should not be confused with crystalline hydrates, as discussed in the solvate section. Here the water is the host of a clathrate host–guest system; in hydrates, water is the solvent of solvation.

breaking up of the lattice. In the case of hydrocortisone, this is followed immediately by steroid decomposition (148).

McAdie (147), working with urea–*n*-paraffin inclusion compounds, used differential thermal analysis. Although these were not clathrates as such, he differentiated the different chain lengths of the *n*-paraffins in the inclusion compounds. This result was just the opposite of that from X-ray powder diffraction, where he was unable to differentiate the inclusion compounds.

One common method used to identify clathrates has been IR spectrophotometry. Using IR, Mesley (148) was able to distinguish the chloroform both in the lattice and on the surface of hydrocortisone and dexamethasone acetate clathrates. Staveley (149) reviewed all of the different spectroscopic studies used in identifying clathrates including IR spectra, nuclear quadrupole resonance spectra, paramagnetic resonance studies, and NMR studies.

Methods Used to Identify the Guest Molecule—Most methods involve breaking the cage structure of the host to liberate the guest molecule for identification purposes.

Lowther and Williams (121) used a grating IR spectrophotometer with a conventional gas cell for identification of the inclusion compound in several clathrated pharmaceuticals found in the British Pharmacopoeia of 1968. This was done by liberating the guest by heat, trapping in a gas cell, and recording the absorption spectrum of the vapor. They were also able to calculate the percentage of solvent found in the clathrate.

Lowther and Williams (121) also used the GC method described in the British Pharmacopoeia of 1968 to identify the guest solvent in several pharmaceuticals.

Using mass spectrometry, Mandelcorn *et al.* (150), while working with the sulfur hexafluoride clathrate of Dianin's compound, calculated the amount of sulfur hexafluoride by melting the clathrate and determining the amount of gas released with a mass spectrometer.

Baker *et al.* (151) were able to use elemental analysis of the adduct when it contained a high proportion of nitrogen, sulfur, and halogen.

Titration can also be used to identify the guest molecule. If the adduct is an acid, the clathrate is dissolved in a suitable solvent and titrated with a suitable alkali (151).

Methods Used to Analyze Host–Guest Physical–Chemical Relationships—There is no doubt that a total X-ray diffraction analysis using single crystals is the only way to identify the host–guest physical–chemical relationships. This is illustrated by work on the crystal structure of the clathrate of benzene with an ammonia–nickel cyanide complex (145) and by work on the chlorine clathrate of water (152).

Other than X-ray diffraction, IR spectrophotometry is also used to check the host–guest physical–chemical relationships. Mandelcorn *et al.* (150), using this technique, were able to find that the interaction between sulfur hexafluoride and its enclosing Dianin's compound cage is very weak.

Properties of Clathrates—Clathrate compounds exhibit the general behavior of molecular compounds. They might have some properties that are those of the host, while others might indicate the presence of the guest. Also, some properties may be seen that are variations resulting from the mutual effect of the host and guest in close proximity.

Molecular Properties—According to Mandelcorn, the host of a clathrate is characterized by one or more permanent dipoles and/or an awkward molecular shape. Molecules not possessing such characteristics are usually arranged, in the crystalline state, as closely packed aggregates; the intermolecular distances are so small that the empty crystalline spaces cannot accommodate molecules larger than those of hydrogen. These molecular properties of the host cause intermolecular interactions and orientations in the crystalline state that lead to the open molecular arrangements essential for a clathrate structure (139). The clathrate structure of Dianin's compound is an example of the effects of both a permanent dipole and an awkward molecular shape (153).

Some weak interactions between a guest molecule and its surrounding cage are similar to those found in physical adsorption. These interactions range from very weak van der Waals intermolecular attractions to highly oriented dipole contacts. The resultant forces contribute to the stability of a clathrate. However, molecules whose interactions with the host are great enough to create new molecular species cannot form clathrates. Hydrogen sulfide interacts very weakly with water; it therefore forms a clathrate with water because of its appropriate molecular size. However, hydrogen chloride reacts chemically with water to form hydronium and chloride ions rather than remain undissociated in a water clathrate structure which accommodates molecules of that size (139).

Thermodynamics—Van der Waals (154) gave a statistical mechanical description of clathrate compounds of nonpolar gases. He first derived the general form of the partition function for a clathrate crystal, while leaving the potential field within a cavity unspecified, and then discussed the thermodynamic consequences of the general formulation. He calculated the potential field within the cavities using the Lennard-Jones and Devonshire method. This method permits the expression of thermodynamic properties of clathrates in terms of a few simple parameters.

Thermal Decomposition—According to Mandelcorn (139), the thermal decomposition of a clathrate into its host and guest at temperatures below its melting point may involve one or more of the following:

1. Sublimation of the host.
2. Change of the clathrate structure to the nonclathrate form of the host.
3. Diffusion of guest molecules through the lattice structure of the clathrate.
4. Desorption of the guest from the surface of the solid clathrate.

All of these processes, except Process 2, are characterized by kinetic expressions that include the geom-

etry of the decomposing clathrate particles. The activation energies of Processes 1 and 2 are determined by the crystalline lattice energies of the clathrate. The activation energy of Process 3 is determined by the lattice energy and guest molecule–cage interaction energy, and the activation energy of Process 4 is determined by the forces of attraction of the guest molecule to the surface of the solid clathrate. A kinetic interpretation of decomposition data can be extremely difficult when more than one of these processes is occurring (139).

Pharmaceutical Application of Clathrates—Although most applications of clathrates are not useful pharmaceutically, a brief review will be given of uses with potential application.

Purification—Evans *et al.* (155) purified benzene of one of its usual contaminants (thiophene) by clathrate formation. Although both thiophene and benzene form clathrates with monoamminenickel cyanide, benzene is more firmly held in the cage structure, so it is preferentially clathrated. The solid clathrate formed between benzene and monoamminenickel cyanide is separated from the solution by filtration. On dry distillation of the clathrate, the thiophene-free benzene is readily recovered.

Separation of Rare Gases—Rare gases were separated by selective clathration (156). Argon is separated from neon by adjusting the pressure conditions under which the hydroquinone–argon clathrate is formed; under the same pressure condition, neon does not form a clathrate with hydroquinone.

Separation of Optical Isomers—Another inclusion complexing substance that will separate optical isomers is tri-*o*-thymotide. This molecule is nonplanar and lacks both a mirror plane and a center of symmetry. It forms two stereochemical configurations, which resemble a three-bladed propeller and are optically active and interconvertible by heating. Slow crystallization provides the chance formation of either the *l*- or *d*-form. These forms have inclusion cavities that are mirror images. Thus, crystallization of trithymotide from a reactive solvent that is also a racemic mixture results in the preferential inclusion of either the *l*- or *d*-form of the solvent. This agent has been used to achieve the optical resolution of *sec*-butyl bromide (157).

Storage of Inert Gases—Hydroquinone–inert gas clathrates are granular materials whose gaseous constituents may be about 10% of the total weight. When the solid volume is taken into account, this gas concentration would exert a pressure of 90 atm in a similar free volume space. The gas can be released by heating or dissolving the clathrate. Therefore, these clathrates may be used for convenient storage of inert gases or to introduce such gases into fairly inaccessible locations. A predetermined amount of clathrate may be sealed into a container. Then, when heat is applied, the container is filled with a desired amount of gas (139, 141). This concept of storage of gases on a commercial basis was patented by Mandelcorn *et al.* (158).

Handling of Dangerous Materials—Cross *et al.* (159) found that dimethylmercury, which is a volatile and extremely toxic compound, can form a stable clathrate with 4-*p*-hydroxyphenyl-2,2,4-trimethylthiochroman as a host. This clathrate is very convenient for preparing solutions of known concentration of dimethylmercury; the preweighed quantity of the adduct is just dissolved in the appropriate solvent. Controlled release of guests that are difficult or hazardous to handle in the free state can be of considerable value in, for example, organic synthesis.

Mode of Action of Anesthetics—Pauling (160, 161), in his hydrate–microcrystal theory of anesthesia, proposed that nonhydrogen-bonding anesthetics work primarily due to the clathrate formation of the molecules of the anesthetic agent with the water contained in the neurons and around the neural network, both in the cells of the neurons and the synaptic regions between the neurons. These water molecules may trap some electrically charged side chains of neuronal proteins and interfere with the movement of ions in the synapses and neurons in such a way as to increase the impedance to the reverberating electric oscillations, thus reducing electrical activity to the point at which consciousness is lost (162).

CONCLUSIONS

Different techniques of identifying habits and characterization of amorphous or crystalline solids, along with their pharmaceutical application, have been discussed. Special emphasis has been given to differentiate polymorphs from molecular adducts, which can occur both stoichiometrically as solvates or nonstoichiometrically as clathrates. The rewards to formulators who characterize the habits and crystalline modification of active drugs and study their cause–effect relationships as part of preformulation studies include: *(a)* fewer processing and shelflife problems, along with rapid solution to problems that do arise; *(b)* the best bioavailable formulations; and *(c)* controlled production of the most efficacious dosage forms.

With all of these examples of the effects of habits, polymorphs, solvates, and clathrates on optimizing pharmaceutical formulations, this reviewer's hope is that crystal chemistry will become a routine part of every pharmaceutical company's preformulation program.

Linear Drug Release from Laminated Hydroxypropyl Cellulose–Polyvinyl Acetate Films

SAUL BORODKIN ˣ and FLORENCE E. TUCKER

Abstract □ Release of drug from a single-layer film containing dispersed drug follows a diffusion-controlled matrix model, where the quantity released per unit area is proportional to the square root of time. The kinetics may be made linear with time (zero order) by laminating a second film without drug to the releasing side of the film with dispersed drug. In this manner, the drug layer serves as a reservoir and controls the duration of drug release, while the nondrug layer functions as a rate-controlling membrane. Zero-order drug release was demonstrated in such laminated films using 18–45% pentobarbital, methapyrilene, or salicylic acid contained in hydroxypropyl cellulose as the reservoir layer and mixtures of hydroxypropyl cellulose and polyvinyl acetate as the membrane layer. Inverse relationships between the release rate and membrane thickness and between the logarithm of the rate and the percentage of polyvinyl acetate in the membrane layer were observed. Of the three drugs tested, salicylic acid gave the fastest release rates while pentobarbital gave the slowest.

Keyphrases □ Drug release (methapyrilene, pentobarbital, salicylic acid) from laminated hydroxypropyl cellulose–polyvinyl acetate films—linear drug release, effects of membrane thickness and polyvinyl acetate content □ Polymer films, laminated hydroxypropyl cellulose–polyvinyl acetate—linear drug release (methapyrilene, pentobarbital, salicylic acid) □ Laminated hydroxypropyl cellulose–polyvinyl acetate films—linear drug release □ Hydroxypropyl cellulose–polyvinyl acetate films, laminated—linear drug release

The release kinetics of drugs dispersed in films composed of different ratios of hydroxypropyl cellulose and polyvinyl acetate were recently described (1). Drug release followed a diffusion-controlled matrix model, originally suggested by Higuchi (2, 3), where the quantity released per unit exposed area, Q, is proportional to the square root of time, t:

$$Q = \left[\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s\right]^{1/2} t^{1/2} \qquad \text{(Eq. 1)}$$

where D and C_s refer to the diffusivity and solubility of the drug in the permeating fluid, respectively; A is the initial drug concentration; and τ and ϵ describe the tortuosity and porosity of the matrix, respectively. Although the release rates could be drastically altered by changing the polymer ratio and drug concentration, the Q *versus* $t^{1/2}$ linear relationship was inviolate.

For many dosage applications, linearity with time (zero-order release) would be desirable. Capsules (4), bandages (5), and tapes (6) that provide long-term uniform availability of drugs and pesticides have been described. Zero-order release from these devices appears to be obtained by maintenance of a constant concentration gradient through a membrane from a controlled concentration at the inner surface to zero concentration at the outer surface. This mechanism was recently reviewed (7), and it may be described by the following equation after an initial lag time:

$$\frac{dQ}{dt} = \frac{DC_0}{h} \qquad \text{(Eq. 2)}$$

where D is the diffusion constant through the membrane, C_0 is the concentration at the internal membrane surface, usually at saturation, and h is the membrane thickness. Analogously, zero-order release from a film should be attainable by laminating a polymer layer without drug to the releasing face of a film containing dispersed drug. In this way, the nondrug layer can serve as the rate-controlling membrane, while the drug-containing layer serves as a reservoir to maintain C_0 and the constant gradient.

This paper describes studies of drug release from such laminated films. Pentobarbital, methapyrilene, and salicylic acid contained in hydroxypropyl cellulose were used as the reservoir layers; the membrane layers were composed of different ratios of hydroxypropyl cellulose and polyvinyl acetate.

EXPERIMENTAL

Chemicals—Hydroxypropyl cellulose[1] was a food or pharmaceutical grade with an average molecular weight of 100,000, which gives a viscosity of 75–150 cps as a 5% solution in water. Polyvinyl acetate[2] had an average molecular weight of 500,000 and a viscosity of 90–110 cps as an 8.6% solution in benzene. Pentobarbital sodium and salicylic acid were USP grade, while methapyrilene hydrochloride was NF grade.

The pH 7.0 buffer used in all release rate studies was prepared by dissolving 28.9 g of $Na_2HPO_4 \cdot 7H_2O$ and 8.05 g of $NaH_2PO_4 \cdot H_2O$ in enough water to give 1 liter of solution.

Film Preparation—The reservoir layer films were cast from solutions containing 10% solute (drug plus hydroxypropyl cellulose), with a methylene chloride–methanol mixture (9:1) as the solvent. Hydroxypropyl cellulose was added as a dry powder by slow addition to the vigorously stirring solution. Salicylic acid was added as the dry powder, while pentobarbital and methapyrilene were incorporated from stock methylene chloride solutions prepared from the drug salts.

The pentobarbital stock solution, containing 60.8 mg/ml, was prepared by dissolving 12.0 g of pentobarbital sodium in 50 ml of water, adding 5 ml of concentrated hydrochloric acid, extracting three times with 50-ml portions of methylene chloride, and adjusting the volume of the combined extract to 180 ml. The methapyrilene base solution, containing 58.5 mg/ml, was prepared by dissolving 12.0 g of methapyrilene hydrochloride in 60 ml of water, adding 10 ml of 5 N NaOH, extracting three times with methylene chloride, and adjusting the volume of the combined extract to 180 ml. Films were cast from the solutions at various wet thicknesses

[1] Klucel LF, Hercules, Inc., Wilmington, DE 19899
[2] Gelva V-100, Monsanto Co., St. Louis, MO 63166

(0.64–2.54 mm) by spreading with a knife[3] on Teflon-coated plate glass and allowing the films to air dry at least 24 hr before combining with the membrane layer.

The membrane layers were prepared separately by slowly adding hydroxypropyl cellulose and polyvinyl acetate to a methylene chloride–methanol mixture (9:1) with vigorous stirring to give a solution containing 10% solutes. The solutions were spread on Teflon-coated plate glass with a knife[3], and the films were allowed to air dry at least 24 hr before lamination to the reservoir layer.

The laminated films were prepared by cutting a section (approximately 5 × 5 cm) of the drug reservoir film, measuring its thickness in five places with a micrometer[4], placing it on Teflon-coated plate glass, and spraying one side with methylene chloride. A slightly larger section of the membrane layer, of which the thickness had been previously measured in five places with a micrometer, was immediately pressed on the tacky side of the drug film. The laminated film was allowed to air dry for 24 hr and inspected to assure adhesion between the two layers before use in release rate testing.

Release Rate Determinations—Rectangular films, 2.2 × 4.0 cm (8.8 cm^2), were obtained by cutting a section of the laminated film with a razor blade; a microscope cover glass was used as a template. A thin coating of high vacuum silicone lubricant[5] was applied to a 2.54 × 7.62-cm microscope slide and the exposed face of the drug reservoir layer. The film was then carefully pressed onto the slide with the membrane layer exposed, making sure that all edges adhered and were below the silicone lubricant level but that no lubricant touched the exposed surface. The water repellency of the silicone lubricant covering the film edges prevented any drug release from the edges of the reservoir layer. Studies in which the reservoir layer surface was coated with silicone lubricant and exposed to release conditions showed only insignificant drug dissolution after 7 hr.

The slide was placed film side up at about a 45° angle into a 250-ml beaker in a 37° water bath containing 200 ml of pH 7.0 buffer preheated to 37°. A nonagitated system was selected to eliminate any effect of turbulence on the release rate as well as to prevent any disruption of the film. Periodic assay samples (generally hourly for 8 hr) were obtained by removing the slide, stirring the solution, and pipetting a 5-ml sample. The slide was quickly reinserted, making sure that the film remained completely immersed throughout the release study. The beaker was kept covered[6] except during sampling to prevent evaporation. After 24 hr, the run was terminated and the solution was assayed.

All samples were assayed by UV spectrophotometry[7] after the required dilution in the specific solvent used for each drug. Pentobarbital was assayed at 240 nm in 0.1 *N* NH_4OH, methapyrilene was assayed at 312 nm in 0.1 *N* HCl, and salicylic acid was assayed at 297 nm in 0.1 *N* NaOH.

RESULTS AND DISCUSSION

Drug Release Kinetics—Drug release kinetics from films containing dispersed drug could be changed from linearity with the square root of time to linearity with time (zero order) by laminating a membrane layer to the releasing surface. This effect was demonstrated in many such laminated films using a hydroxypropyl cellulose matrix in the reservoir layer and hydroxypropyl cellulose–polyvinyl acetate composite mixtures in the membrane layer. Figures 1–3 compare drug release from films containing dispersed drug with and without membrane layers. The results of all release rate studies from the laminated films are summarized in Tables I–III. The high correlation coefficients obtained from linear regression analysis (9) of the *Q versus t* treatment attest to the zero-order release kinetics.

The slopes obtained by plotting the amount released per area *versus* time are designated in the tables by an apparent zero-order rate constant, k_0, with the units of milligrams centimeters^{-2} hours^{-1}. Integration of Eq. 2 and evaluation of the integration constant in terms of the lag time (intercept on the time axis obtained when steady-state rate is extrapolated), t_{lag}, yield:

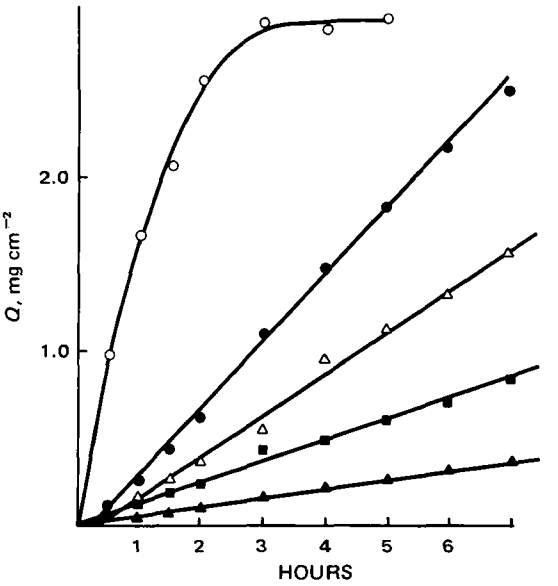

Figure 1—*Drug release from films containing 18.2% pentobarbital in hydroxypropyl cellulose as the reservoir layer. Key:* ○, *no membrane layer;* ●, *0.091-mm hydroxypropyl cellulose–polyvinyl acetate (9:1) membrane;* △, *0.137-mm hydroxypropyl cellulose–polyvinyl acetate (8:2) membrane;* ■, *0.128-mm hydroxypropyl cellulose–polyvinyl acetate (6:4) membrane; and* ▲, *0.093-mm hydroxypropyl cellulose–polyvinyl acetate (4:6) membrane.*

$$Q = \frac{DC_0}{h}t - \frac{DC_0}{h}t_{lag} \qquad \text{(Eq. 3)}$$

For a given film in which the membrane remains intact, D, C_0, and h are constant through most of the release, and the apparent zero-order rate constant may be defined as:

$$k_0 = \frac{DC_0}{h} \qquad \text{(Eq. 4)}$$

and:

$$Q = k_0 t - k_0 t_{lag} \qquad \text{(Eq. 5)}$$

Generally, the lag times were less than 15 min. However, in some cases, especially with methapyrilene as the drug, lag times of greater than 30 min were observed before attainment of steady-state release.

No correlation could be seen between the membrane thickness and lag time, as might be expected from the theoretically developed equation (7):

$$t_{lag} = \frac{h^2}{6D} \qquad \text{(Eq. 6)}$$

It appears likely that other factors, such as hydration of the film or attainment of saturation conditions within the reservoir layer, were more dominant in establishing steady-state conditions and the lag time.

The zero-order relationship would be expected to break down before total drug release when the reservoir layer is no longer able to sustain C_0 at the interface of the two layers. As reflected by the half-lives shown in Tables I–III, none of the laminated films gave complete release in the 7–8-hr release times generally studied. However, in a number of films, the release went well beyond the half-life with no observed deviation from zero-order linearity. In all cases where release was calculated to be incomplete at 24 hr ($t_{1/2} > 12$ hr), the 24-hr assays were in line with those projected by k_0.

Lamination of a membrane layer to a film containing dispersed drug results in slower drug release, as well as a change in kinetics, due to the barrier nature of the membrane layer. This does not mean that all laminated films must release drug at slower rates than nonlaminated films and single- and double-layer films with comparable rates, but different release patterns can be fabricated. Figure 4 compares the release obtained from two salicylic acid films: one a single-layer film following the Q *versus* $t^{1/2}$ linear rela-

Key: ○, no membrane layer; ●, 0.171-mm hydroxypropyl cellulose–polyvinyl acetate (9:1) membrane; □, 0.160-mm hydroxypropyl cellulose–polyvinyl acetate (7:3) membrane; and △, 0.210-mm hydroxypropyl cellulose–polyvinyl acetate (5:5) membrane.*

tionship and the other a laminated type following zero-order kinetics. Although both gave approximately 60% release in 6 hr, the release kinetics were quite different.

Effect of Membrane Thickness—Equation 4 indicates that the apparent zero-order rate constant, k_0, should be inversely proportional to the membrane layer thickness. Figure 5 shows this relationship using three different thicknesses of pure hydroxypropyl cellulose as the membrane layers; Fig. 6 shows similar results with the much slower releasing hydroxypropyl cellulose–polyvinyl acetate (5:5) membranes.

The linearity of the observed rate constant with the reciprocal of the measured membrane thickness allows calculation of a thickness-independent zero-order constant, k_0', with the dimensions milligrams centimeters^{-1} hours^{-1}, where:

$$k_0' = k_0 h \qquad \text{(Eq. 7)}$$

These values, which should approximate DC_0, are also included in Tables I–III. Their independence of membrane thickness makes them more useful in comparing films of different composition.

The hydrophilic nature of the membrane layer would indicate that the fully hydrated swelled membrane would be the true barrier layer. This would still be consistent with the zero-order release model, although the rate of attaining full hydration might affect the lag time.

During dosage development, it may be beneficial or desirable to increase the initial release of drug. This approach may be necessary to overcome a lag time or to establish a useful therapeutic level which might be followed by a maintenance rate. This can con-

ceivably be accomplished by including a low level of drug in the membrane layer.

Reservoir Layer—To achieve the constant concentration gradient in the membrane layer required for zero-order release, the drug layer must continually provide sufficient drug to maintain a constant concentration, C_0, at the inner membrane surface. This condition may be achieved if C_0 is equivalent to saturation and the transfer rate from the reservoir is rapid enough to maintain saturation. Alternatively, C_0 may remain constant through partitioning from a constantly maintained saturated solution phase in the reservoir layer. Such a condition can exist if the reservoir layer contains a high dispersed drug concentration relative to the solution phase level ($A \gg \epsilon C_s$ in terms of Eq. 1) and transfer of drug through the reservoir matrix is faster than loss through the membrane.

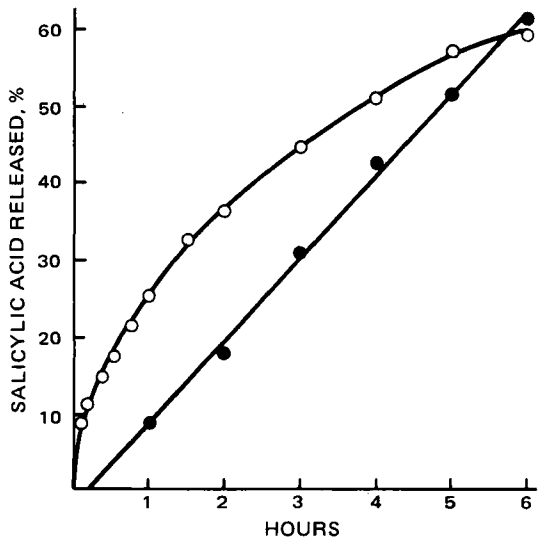

Figure 4—*Comparison of salicylic acid release from single-layer and laminated films. Key: ○, single-layer film composed of 20% drug in hydroxypropyl cellulose–polyvinyl acetate (3:7) (0.156 mm); and ●, laminated film, reservoir is 20% drug in hydroxypropyl cellulose (0.256 mm), and membrane is hydroxypropyl cellulose–polyvinyl acetate (9:1) (0.171 mm).*

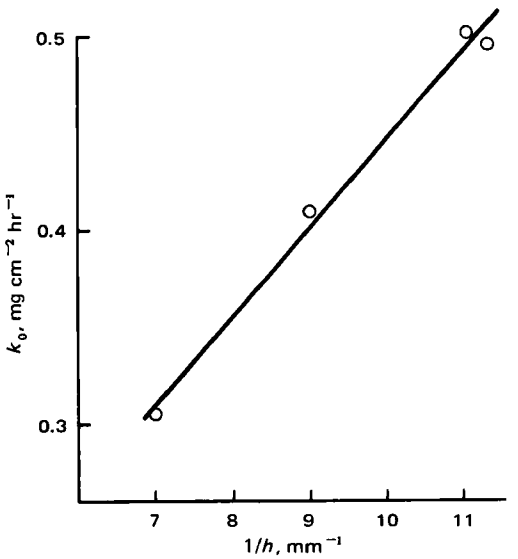

Figure 5—*Relationship of pentobarbital release rate to the reciprocal of membrane layer thickness from laminated films containing pure hydroxypropyl cellulose as the membrane layer.*

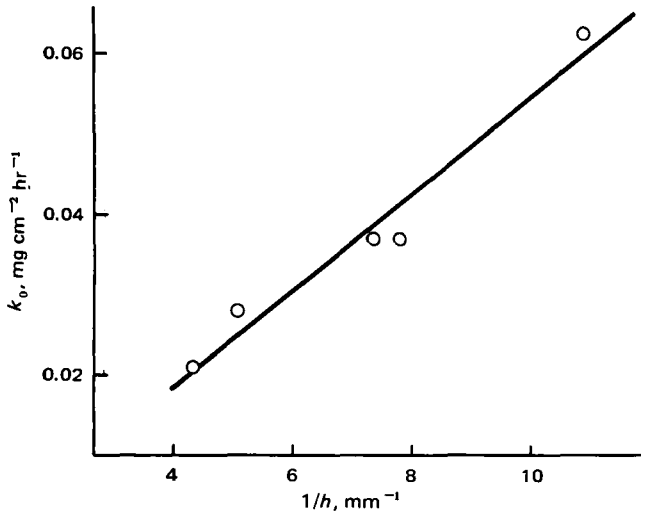

Figure 6—*Relationship of pentobarbital release rate to the reciprocal of membrane layer thickness from laminated films containing hydroxypropyl cellulose–polyvinyl acetate (5:5) as the membrane layer.*

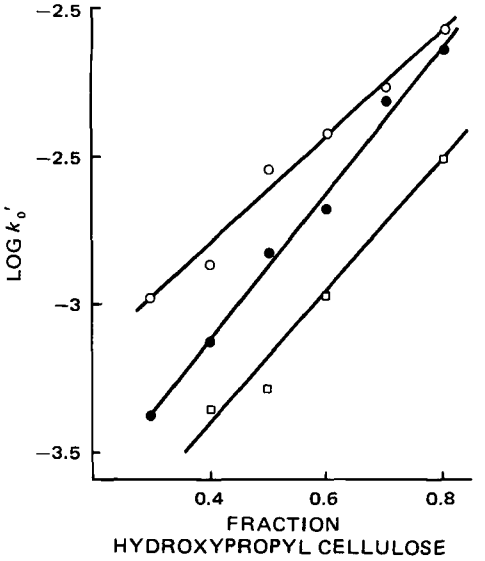

Figure 7—*Relationship of log k_0' to the fraction of hydroxypropyl cellulose in the membrane layer. Key: ○, salicylic acid; ●, methapyrilene; and □, pentobarbital.*

The conditions conducive to maintaining C_0 and zero-order release were achieved by using drug concentrations of greater than 18% and pure hydroxypropyl cellulose as the matrix. This matrix had been shown previously to give the fastest diffusion rates (1). Matrixes with slower diffusion rates were not tested.

The drug concentration in the reservoir layer should not affect the release rate as long as it exceeds the level necessary for maintaining saturation. The data in Table I show that similar k_0' values were obtained for laminated films with similar membrane matrixes but different pentobarbital reservoir concentrations. In studies using less than 10% drug concentration in the reservoir layer and fast releasing membrane layers, zero-order release was not obtained.

Although the drug concentration above the critical level should not affect the release rate, it controls the duration of drug release. The more concentrated the reservoir, the longer it will be able to supply drug to maintain C_0. Similarly, the duration of release, as reflected by the half-life, may be controlled by the thickness of the reservoir layer.

Polymer Ratio in Membrane—As shown in Tables I–III, all three drugs behaved similarly with regard to the hydroxypropyl cellulose–polyvinyl acetate ratio in the membrane layer. Increasing the polyvinyl acetate concentration from 0 to 20% affected the release rate only slightly. Beyond 20%, there was a marked decrease in release rate with further increases in the polyvinyl acetate content, with each 10% reducing the rate by approximately one-third to one-half.

Attempts to relate mathematically the release rate to the hydroxypropyl cellulose–polyvinyl acetate ratio yielded the best results when the logarithm of the thickness-independent rate contant, k_0', was plotted against the fraction of hydroxypropyl cellulose in the membrane (Fig. 7). The relationship may be depicted by the following empirical equation:

$$\log k_0' = k_R F_H + \log (k_0')_p \qquad \text{(Eq. 8)}$$

where F_H is the fraction of hydroxypropyl cellulose in the membrane layer, k_R is the slope specific for a given drug and reservoir, and $(k_0')_p$ is the extrapolated rate constant for a pure polyvinyl acetate membrane ($F_H = 0$). In practice, pure polyvinyl acetate membranes that could be incorporated into laminated films could not be fabricated without plasticizers. Table IV lists the calculated values obtained using Eq. 8. This logarithmic relationship between the rate constant and fraction of hydroxypropyl cellulose in the membrane is quite similar to that found earlier with homogeneous films containing dispersed drug (1).

The greater barrier characteristics obtained with increased polyvinyl acetate percentages in the membrane layer may be attributed to its lower hydrophilicity relative to hydroxypropyl cellulose. Weight gain studies with films suspended in a 100% relative humidity atmosphere at 37° showed very rapid equilibration, with the percentage moisture absorbed increasing with hydroxypropyl cellulose content from 4% with pure polyvinyl acetate to 32% with pure hydroxypropyl cellulose. The lower hydration could cause reduced drug release rates by lower drug solubility, less porosity, or increased tortuosity.

Table IV—Linear Relationship of Log k_0' to Fraction of Hydroxypropyl Cellulose in Membrane Layer

Drug	Concentration in Reservoir Layer, %	Slope (k_R)	$(k_0')_p$, mg cm^{-2} hr^{-1} × 10^3	Correlation Coefficient
Salicylic acid	20.0	1.88	0.282	0.991
Methapyrilene	26.3	2.54	0.074	0.997
Pentobarbital	18.2–45.5	2.29	0.048	0.979

With pure hydroxypropyl cellulose as the membrane layer, it might appear that the membrane would simply be a depleted matrix from a single-phase film and the zero-order release model would not be applicable. However, all results showed zero-order release well beyond the half-life. Apparently, the presence or absence of initial drug imparts sufficiently different characteristics so that the two layers retain individual behavior, with drug saturation in the reservoir layer predominating longer than drug release through the membrane layer.

Drug Effect—With similar polymer compositions, the relative release rates for different drugs in laminated films would be governed primarily by the drug solubility and diffusion coefficient in the membrane layer. The drug solubility in the reservoir layer might also affect C_0 and the release rate through partitioning.

Of the three drugs tested, salicylic acid gave the fastest release rates while pentobarbital gave the slowest. The relatively slower release rates with pentobarbital can be most easily attributed to its much lower solubility in pH 7.0 buffer at 37° (3 mg/ml *versus* greater than 600 mg/ml for methapyrilene and salicylic acid, which are primarily in the ionized form). Although the drug solubility in the external solution should not directly affect the release rate under sink conditions, permeation of buffer into the hydrated membrane layer could give some buffering effect within the membrane.

The faster release rates obtained with salicylic acid relative to methapyrilene may be due primarily to its lower molecular weight (138.1 *versus* 261.4). Since the diffusion coefficient is inversely proportional to the cube root of the molecular weight (10), salicylic acid would give a diffusion coefficient approximately 1.24 times greater than methapyrilene with all other variables equal.

Pharmacokinetics of Polychlorinated Biphenyl Components in Swine and Sheep after a Single Oral Dose

R. E. BORCHARD [*], M. E. WELBORN, W. B. WIEKHORST, D. W. WILSON, and L. G. HANSEN [x]

Abstract □ Single-dose oral administration of a commercial polychlorinated biphenyl product containing 54% chlorine provided data with which to plot the time course of total polychlorinated biphenyl and individual components in the blood of swine and sheep. Pharmacokinetic parameters describing absorption from the gut and elimination from a two-compartment body system were determined for the components in swine and sheep. The absorption half-time for total polychlorinated biphenyl in swine was 1.13 hr while that for sheep was 3.83 hr. The half-time for disposition of total polychlorinated biphenyl from the central compartment was 4.4 hr in swine and 7.7 hr in sheep; the apparent biological half-life was 62.4 hr in swine and 78.8 hr in sheep. Individual components varied significantly from each other and from total polychlorinated biphenyl in all parameters.

Keyphrases □ Polychlorinated biphenyl components—pharmacokinetics in swine and sheep after single oral dose □ Pharmacokinetics—polychlorinated biphenyls in swine and sheep after single oral dose

The ecological persistence of polychlorinated biphenyls and their continual release into the environment in recent years have created a situation in which contamination of animal feed as well as human food is a constant threat. Since commercial preparations are mixtures of some 200 possible isomers and any given residue probably represents more than a single polychlorinated biphenyl mixture, it becomes important to evaluate the individual components as well as total polychlorinated biphenyl. Furthermore, such a mixture permits the simultaneous comparison of several different compounds in the same animal, and studies using single purified components can be used to assess the extent of interactions within the mixture.

One means of assessing exposure to polychlorinated biphenyls and persistence of the chemicals in the body is by way of blood sampling. Previous studies characterized the polychlorinated biphenyl mixture used (1), developed and refined methods of extraction and analysis (2), and determined pharmacokinetic parameters of individual components in swine and sheep after intravenous administration (3). Reports of investigations of pharmacokinetic parameters after feeding contaminated feed are in preparation.

This paper deals with the time course of polychlorinated biphenyls in the animal body as determined by blood sampling after a single oral dose of a commercial polychlorinated biphenyl containing 54% chlorine[1] to swine and sheep.

EXPERIMENTAL

Three sheep and three swine were given a calculated oral dose of a polychlorinated biphenyl containing 54% chlorine by weight[1] in a gelatin capsule. The dosage was 30 mg/kg for the sheep and 15 mg/kg for the swine; pilot studies indicated that these levels were necessary to provide adequate blood concentrations for analysis.

The sheep were mature ewes of mixed mutton-type breeding and weighed 53.5, 57.0, and 66.5 kg; the swine were of Hampshire-Yorkshire breeding and weighed 48.0, 59.5, and 57.2 kg. Both sheep and swine were maintained in individual steel cages with slot floors. Blood samples were obtained from the sheep by jugular puncture for 7 days and from the swine by femoral venous cannulas, fitted 24 hr prior to dosing, for 2 days.

The levels in swine blood collected after 48 hr were not adequate to permit accurate quantitation, and most of the β values were estimated from only one or two points along with the computer-generated tangent; therefore, the parameters for elimination from the tissue compartment in swine should be viewed with reservation. Further investigations will be conducted to determine these values more accurately.

[1] Aroclor 1254, Monsanto electrical grade No. KB-05-612.

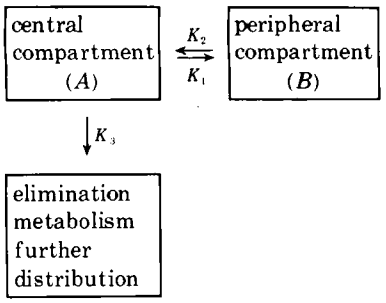


Scheme I

Blood samples were extracted with hexane-saturated acetonitrile and analyzed for polychlorinated biphenyls by electron-capture GLC as previously described (2).

Quantitation of components as well as total polychlorinated biphenyl for each blood sample was accomplished by the methods previously utilized (1–3).

The blood concentrations of each component and total polychlorinated biphenyl were plotted and fit to a two-compartment model utilizing a computer program (4) for the elimination phase and a graphical method for the absorption phase. By using estimates obtained from data plots, the computer program generated four parameters (A, α, B, and β) which describe elimination for a two-compartment open model (Scheme I), where K_1 and K_2 are first-order distribution rate constants between the central compartment *(A)* and the peripheral compartment *(B)*; K_3 is the overall elimination rate constant.

The integrated mathematical equation for Scheme I is:

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where:

C_t = blood concentration at time t
A = blood zero time concentration intercept for the rapid disposition curve
B = blood zero time concentration intercept for the slow disposition curve
α = first-order rate constant for disposition from the central compartment to the peripheral compartment
β = apparent elimination rate constant

It was established previously that the peripheral compartment consists, at least in part, of fatty tissues in sheep and swine[2].

With oral administration, one can modify the model as shown in Scheme II, where G is the enteric reservoir (gut) from where absorption occurs, and K_a is the rate constant of absorption from the gut.

The integrated mathematical model approximates:

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} - C_0e^{-K_a t} \qquad \text{(Eq. 2)}$$

where $C_0 = A + B$ (generally determined from intravenous elimination data).

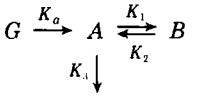
In this paper, the absorption rate constants, K_a, of the components and total polychlorinated biphenyl were determined by a method similar to the conventional one for one-compartment models. The value of K_a was determined from the slope[3] of the line when $(\bar{C}_t - C_t)$ is plotted semilogarithmically against time, where $(\bar{C}_t - C_t)$ = the difference between the predicted elimination line, extrapolated back to zero time, and the actual absorption data points.

The approximate integration of the mathematical model, as used here, then becomes:

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} - Xe^{-K_a t} \qquad \text{(Eq. 3)}$$

where X = the zero time intercept of line $(\bar{C}_t - C_t)$ determined from oral elimination data.

[2] Unpublished data from this laboratory.
[3] Determined with a Wang 500 calculator exponential regression program.



Scheme II

Other parameters were calculated as follows:

$$t\tfrac{1}{2}\alpha = \frac{0.693}{\alpha} \qquad \text{(Eq. 4)}$$

$$t\tfrac{1}{2}\beta = \frac{0.693.}{\beta} \text{ (biological half-life)} \qquad \text{(Eq. 5)}$$

$$t\tfrac{1}{2} \text{ absorption} = 0.693/K_a \qquad \text{(Eq. 6)}$$

$$K_1 = \alpha + \beta - K_2 - K_3 \qquad \text{(Eq. 7)}$$

$$K_2 = \frac{A\beta + B\alpha}{A + B} \qquad \text{(Eq. 8)}$$

$$K_3 = \frac{\alpha\beta}{K_2} \qquad \text{(Eq. 9)}$$

Where applicable, component results were compared statistically by multiple-range and paired t tests (5).

RESULTS

The absolute blood concentrations for components and total polychlorinated biphenyl after a single oral dose are given in Table I for swine and in Table II for sheep. Absolute component concentrations were determined by utilizing the component percentage of the commercial mixture and concentrations relative to the standard mixture as previously discussed (3).

The components were first detected in swine blood at 0.5–1.0 hr after administration, and maximum blood concentrations were seen in 4–8 hr. As seen in Table III, components of a longer relative retention time and a larger percentage of chlorination (1) took longer to attain maximum concentrations. Component 286 attained a significantly greater ($p < 0.05$) relative blood concentration (and blood–dose ratio) than total polychlorinated biphenyl and all other components except Component 332.

The components were first detected in sheep blood at 2–4 hr after administration, and maximum blood concentrations occurred at 8–24 hr. As seen in Table IV, components of a longer retention time and a larger percentage of chlorination attained maximum concentrations later, just as in the swine. Components 286 and 332 attained significantly greater ($p < 0.05$) relative blood concentrations (and blood–dose ratios) than Components 70, 99, and 105 and total polychlorinated biphenyl. Component 286 was also greater than 84.

By comparing blood–dose ratios of swine to those of sheep (Table IV), one sees a significantly greater ratio for all components and total polychlorinated biphenyl in swine. Thus, for a given dose, one would expect to see higher blood concentrations in swine, which is consistent with results obtained after feeding a ration containing the same commercial mixture[2].

The blood concentrations of each commercial mixture component and total polychlorinated biphenyl were plotted as the mean concentration for swine and sheep at each sampling time. The data representing the elimination phase were fit to the two-compartment model for elimination, and the data representing the absorption phase were utilized for calculation of absorption rates, based on the extrapolated elimination curve. Examples of the data plots are given for both swine and sheep in Figs. 1–4 for Component 127. Figures 1 and 3 show the absorption phase of Component 127, and Figs. 2 and 4 show the complete elimination phase.

Fitted elimination curves for all components and total polychlorinated biphenyl are shown for swine in Fig. 5 and for sheep in Fig. 6. The slopes for each component in the figure for swine or sheep are the same as those resulting from plotting the data in Tables I and II; their positions on the graph vary depending on whether the values relative to the commercial mixture (Figs. 5 and 6) or the absolute values (Tables I and II) were used. For example, the relative concentration of Component 286 (Fig. 5) was greater than all others, but the absolute concentration (Table I) was only greater than Component 332.

Table I—Mean Absolute Blood Concentrations (Parts per Billion) of Polychlorinated Biphenyl Components after a Single Oral Dose in Swine

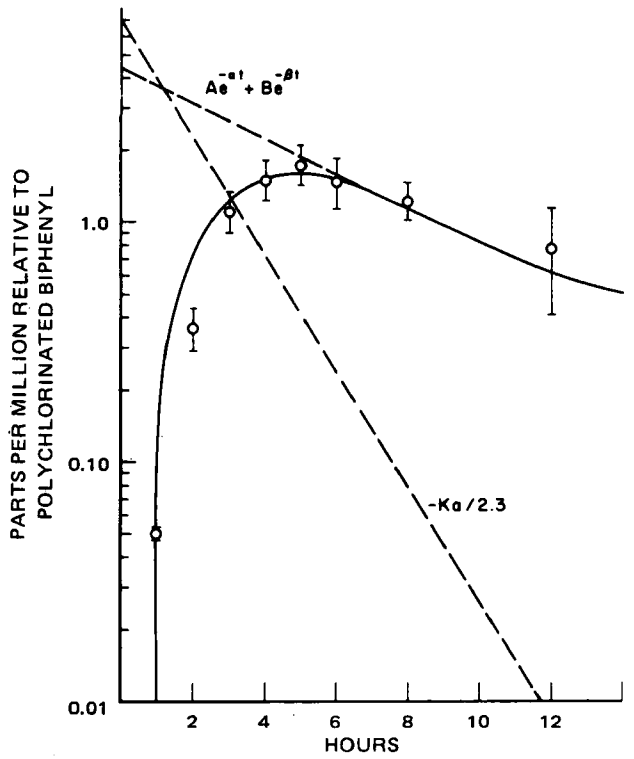

Figure 1—*Absorption phase of Component 127 in swine. The circles represent the mean blood concentrations relative to the standard mixture (concentration of standard necessary to cause the same detector response), the brackets around the circles represent the standard deviations of the means, the broken line designated by* $Ae^{-\alpha t} + Be^{-\beta t}$ *is the extrapolation of the fitted elimination curves, the broken line designated by* $-K_a/2.3$ *is the line describing absorption, and the solid line is the fitted curve for absorption and elimination.*

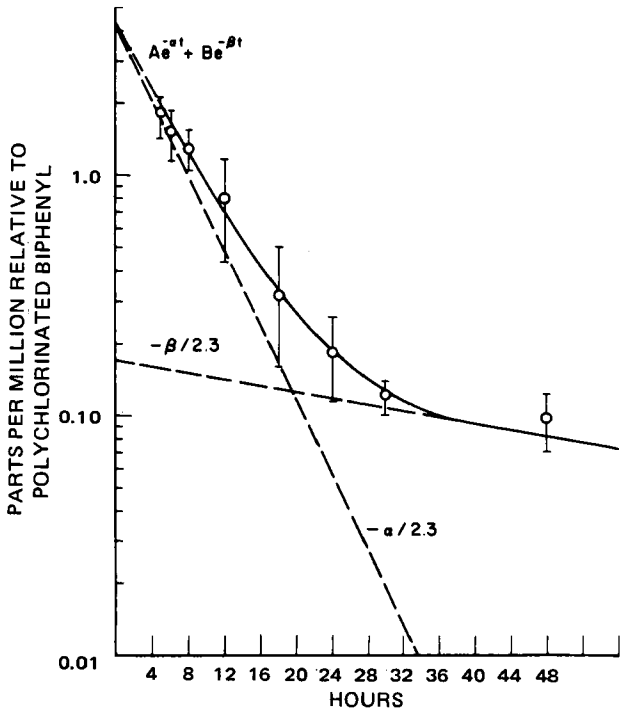

Figure 2—*Elimination phase of Component 127 in swine. The circles and brackets have the same designation as in Fig. 1, the broken line designated* $-\alpha/2.3$ *is the line describing distribution from the central compartment, and the broken line designated* $-\beta/2.3$ *is the extrapolated line describing the slower elimination phase.*

Pharmacokinetic parameters determined for components and total polychlorinated biphenyl after a single oral dose to swine and sheep are listed in Tables V and VI. Parameters A, α, B, and β were generated by the computer program from the elimination phase of the data plots. The parameters were determined as described under *Experimental.*

The pharmacokinetic parameters K_a, α, β, and K_3 were compared statistically. In swine, Component 70 was absorbed and eliminated at a faster rate ($p < 0.05$) than were most other components. In sheep, absorption of Components 70 and 105 was the most rapid, while the elimination of Components 99 and 105 was the most rapid; several components of longer retention time, as well as Component 84, were eliminated at a slow rate relative to the total polychlorinated biphenyl content.

The rate constants K_a, α, β, and K_3, in general, were greater for swine than for sheep. This comparison is consistent with results obtained from studies in which swine and sheep were fed a ration containing the commercial polychlorinated biphenyl.

DISCUSSION

This paper has attempted to provide some basic information on the time course of a polychlorinated biphenyl mixture when administered as a single oral dose to swine and sheep. Previously discussed methods (1–3) were utilized in sample and data analysis. A more precise method for the determination of absorption rate constants may be more desirable and may be adaptable in future studies when more basic information on the distribution of commercial polychlorinated biphenyl mixtures from the gut of swine and sheep is known.

from the same animals (6, 7). Repeated experiments with a polychlorinated biphenyl mixture in the same animal are impractical because of slow excretion, tissue residues, and low metabolic conversion. Similar groups of animals can be utilized for the extrapolation of intravenous data to oral data if the intravenous and oral kinetics are well correlated in terms of dosage, compartmentalization, and extent of absorption. Since the correlation between intravenous and oral kinetics has not been well established for polychlorinated biphenyl mixtures, a method for the determination of absorption rate constants based only on oral dosage data seems to

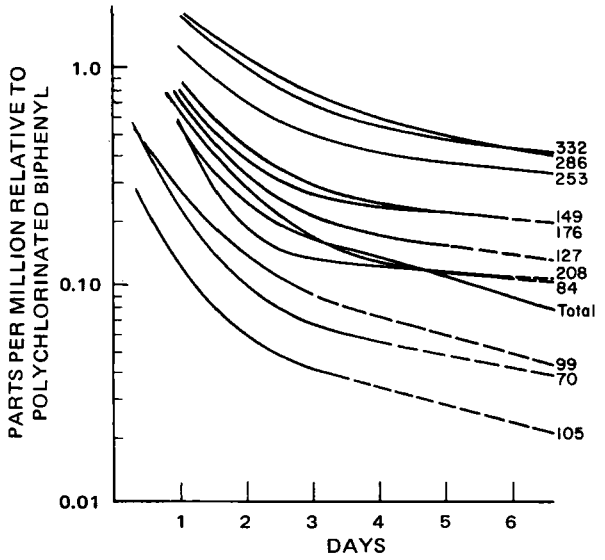

Figure 6—*Elimination of polychlorinated biphenyl components in sheep (relative values).*

be most appropriate, at least for comparison of the components within the commercial mixtures.

The comparisons made between swine and sheep are somewhat predictable, because of obvious species differences in GI physiology, and generally consistent with results obtained from other studies being prepared for publication. The components were absorbed faster, reached higher blood concentrations, and were eliminated faster in swine than sheep. There is a tendency for higher chlorinated components to be absorbed slower but to reach higher maximum concentrations relative to amounts present in the dose.

It is difficult at this time to attempt correlation of kinetic data within each species for each type of administration of the commercial mixture. Variations between intravenous parameters (3) and the oral parameters determined in this study pose questions concerning distribution and dose dependence. Although polychlorinated biphenyls are left intact after treatment with strong acids, their extractability from biological materials such as egg yolk is dependent on pH. Polychlorinated biphenyls, especially the higher chlorinated species, are not readily extractable from aqueous solutions at acid pH; neutralization of the acid can increase recovery up to 10-fold[2]. If this dependence applies to the gastric portions of the central compartment, the redistribution of polychlorinated biphenyl to the blood would reflect a lower K_3 and $t_{1/2}\,\beta$. Although a longer period of sampling after intravenous dosing might reveal closer half-lives, both areas will have to be investigated to resolve this discrepancy.

For total polychlorinated biphenyl, K_3 and $t_{1/2}$ *(B)* were 0.189 hr^{-1} and 15.1 hr, respectively, for swine administered 3 mg/kg iv; the same parameters for sheep were 0.194 hr^{-1} and 14.7 hr, respectively (3). In this study, the values were 0.091 hr^{-1} and 62.4 hr for swine receiving 15 mg/kg and 0.044 hr^{-1} and 78.8 hr for sheep receiving 30 mg/kg. In intravenous studies, however, the blood samples were collected for only 24 hr and the oral dose level in swine should have been followed for a longer duration in the present study. It is obvious that oral and intravenous investigations approximating the same C_0 are required and that the duration of the study needs to be expanded.

A previous report indicated similar poor absorption of the same mixture from the gut of growing pigs, but dilution rather than elimination was responsible for reducing tissue concentrations (8). It is difficult to compare these studies, however, since tissue concentrations were not determined at peak levels in the previous study and analytical methods limited results to an estimation of total polychlorinated biphenyls so that individual components were not assayed.

Accumulation of data from future studies along with analyses of data from studies already undertaken will undoubtedly help to assemble the total picture of polychlorinated biphenyl mixture distribution in the animal body.

Acylation of Ascorbic Acid in Water

ROLF B. PAULSSEN *, DULAL CHATTERJI, TAKERU HIGUCHI, and IAN H. PITMAN ˣ

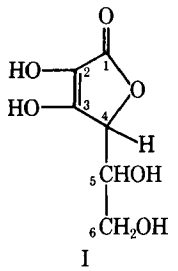
Abstract □ The acylation of ascorbic acid by acetic anhydride was studied in water at 25°. The results indicate that the initial products of reactions between these two compounds were acetic acid and 3-*O*-acetylascorbic acid. The latter product then underwent two parallel reactions: hydrolysis to ascorbic and acetic acids and an intramolecular O → O acyl migration to yield 2-*O*-acetylascorbic acid. The former reaction was predominant at pH values below 4, whereas the latter reaction predominated at pH values between 4 and 7. These results are used as a basis for questioning the structural assignments previously made to some ascorbic acid esters.

Keyphrases □ Ascorbic acid—acylation by acetic anhydride in water, kinetics and products *via* hydrolysis and rearrangement □ Acylation of ascorbic acid in water using acetic anhydride—kinetics and products *via* hydrolysis and rearrangement

A kinetic and product analysis is described for reactions that occur in aqueous solutions initially containing ascorbic acid (I) and acetic anhydride. The purposes of this study were to determine which hydroxy groups of I were acetylated and in what proportion and then to investigate the stability of the formed esters with respect to intramolecular O → O acyl transfers and hydrolysis. Intramolecular O → O acyl transfers were previously reported to occur for ascorbic acid esters (1), and they are well-known reactions of glycerol esters (2) and hydroxyacids (3, 4). The results of these studies will prove useful in the characterization of the structures of mono-, di-, and triacyl derivatives of ascorbic acid existing in water and in understanding the reactivity of these derivatives with respect to hydrolysis and rearrangement.

Considerable interest exists in the synthesis and properties of acyl derivatives of I. The major reasons for this interest are: *(a)* the resistance of ascorbic acid to autoxidation can be increased by esterifying one or both of the hydroxy groups in the enediol system [—(HO)C=C(OH)—] (1), and *(b)* esters can be conferred with almost any desired amount of lipophilic character by appropriate selection of acyl moieties.

Two advantages that esters of ascorbic acid of I might possess are that lipophilic derivatives can be included in nonaqueous preparations [*e.g.*, the use of 6-*O*-palmitoylascorbic acid (6) or 6-*O*-stearylascorbic acid (7) as antioxidants in nonaqueous formulations] and that they may be absorbed percutaneously more efficiently (8)[1]. Administration of ascorbic acid through the skin has been suggested (9) as a means of facilitating wound healing. However, it is believed (10) that both the antioxidant properties and antiscorbutic activity of I depend on the presence within the molecule of the enediol system. Consequently, it is important to know whether a particular ester contains an intact enediol system or whether the intact enediol system will be regenerated in the biological environment.



I

EXPERIMENTAL

Equipment—Spectrophotometric[2] and spectropolarimetric[3] studies were performed using instruments with thermostated cell compartments. All thermostated baths were regulated within ±0.1°.

Reagents—All reagents used were of analytical grade, unless otherwise stated. Acetic anhydride was distilled over magnesium turnings, and the fraction boiling within 137.8–138.2° was collected. Ascorbic acid was recrystallized from its concentrated solution in hot methanol by adding sufficient petroleum ether to make the solution turbid and keeping the resulting mixture overnight at room temperature.

The water used was redistilled from acid permanganate using an all-glass still. 5,6-Isopropolidine-2,3-di-*O*-acetylascorbic acid was synthesized following the Vestling and Rebstock (11) procedure. Unless otherwise mentioned, all experiments were carried out in aqueous solutions.

Measurement of Acetylation—Three milliliters of a solution of I (0.05 *M*) was combined with 2.0 ml of water and titrated with a standard solution of sodium hydroxide to the phenolphthalein end-point. The volume of the required titrant, *a* ml, was noted. Three milliliters of a solution of I (0.05 *M*) was reacted with 0.3 ml of 0.6 *M* solution of acetic anhydride (in dioxane) in a closed vial for 1 hr at 25°. The reaction mixture was then diluted with 2.0 ml of water and titrated to the same end-point. The volume of the titrant, *b* ml, was likewise noted. An equivalent amount of acetic anhydride was titrated after hydrolysis in 5.0 ml of water to the same end-point. The volume of the consumed titrant, *c* ml, was also recorded.

The ratio of ester to acetic anhydride and the percent acetylation were calculated from *a*, *b*, and *c* according to:

$$\frac{\text{ester}}{\text{acetic anhydride}} = \frac{(a + c) - b}{c} \times 2 \qquad \text{(Eq. 1)}$$

$$\%\ \text{acetylation} = \frac{(a + c) - b}{c} \times 100 \qquad \text{(Eq. 2)}$$

Determination of k_1^{obs}—The second-order rate constant (k_1^{obs}) for the initial attack of anhydride on ascorbic acid (Scheme I) was determined by following the loss of UV absorption at 275 nm. The theory is described under *Results and Discussion*. Acetate buffers (2×10^{-1} *M*) containing 1×10^{-4} *M* edetate (to minimize any ca-

[1] This reference describes an absorption study done with ascorbic acid 3-phosphate.

[2] Using Cary 15 and Cary 16 spectrophotometers, Varian Instruments, Inc.

[3] Using a Cary 60 spectropolarimeter, Varian Instruments, Inc.

talysis of the oxidation of ascorbic acid by trace elements) were used in these runs.

The solutions were adjusted to an ionic strength of 1.0 M with potassium chloride, and temperature was maintained at 25.0 ± 0.1°. The amount of ascorbic acid used was such as to give an initial absorption of about 0.9 unit (5×10^{-5} M at pH > 4.5, $1–2 \times 10^{-4}$ M at pH < 4.5). The amount of acetic anhydride added (as a solution in dioxane) was sufficient to produce a 100–400-fold excess of acetic anhydride concentration over that of ascorbic acid.

The loss of absorbance at 275 nm was recorded for about 1 min. About 20 sec (accurately measured) elapsed between mixing the reagents and taking the first reading in the spectrophotometer. The smoothness of the absorbance curve after about 15 sec indicated that the 20 sec allowed for the first point was sufficient for an accurate measurement of absorbance.

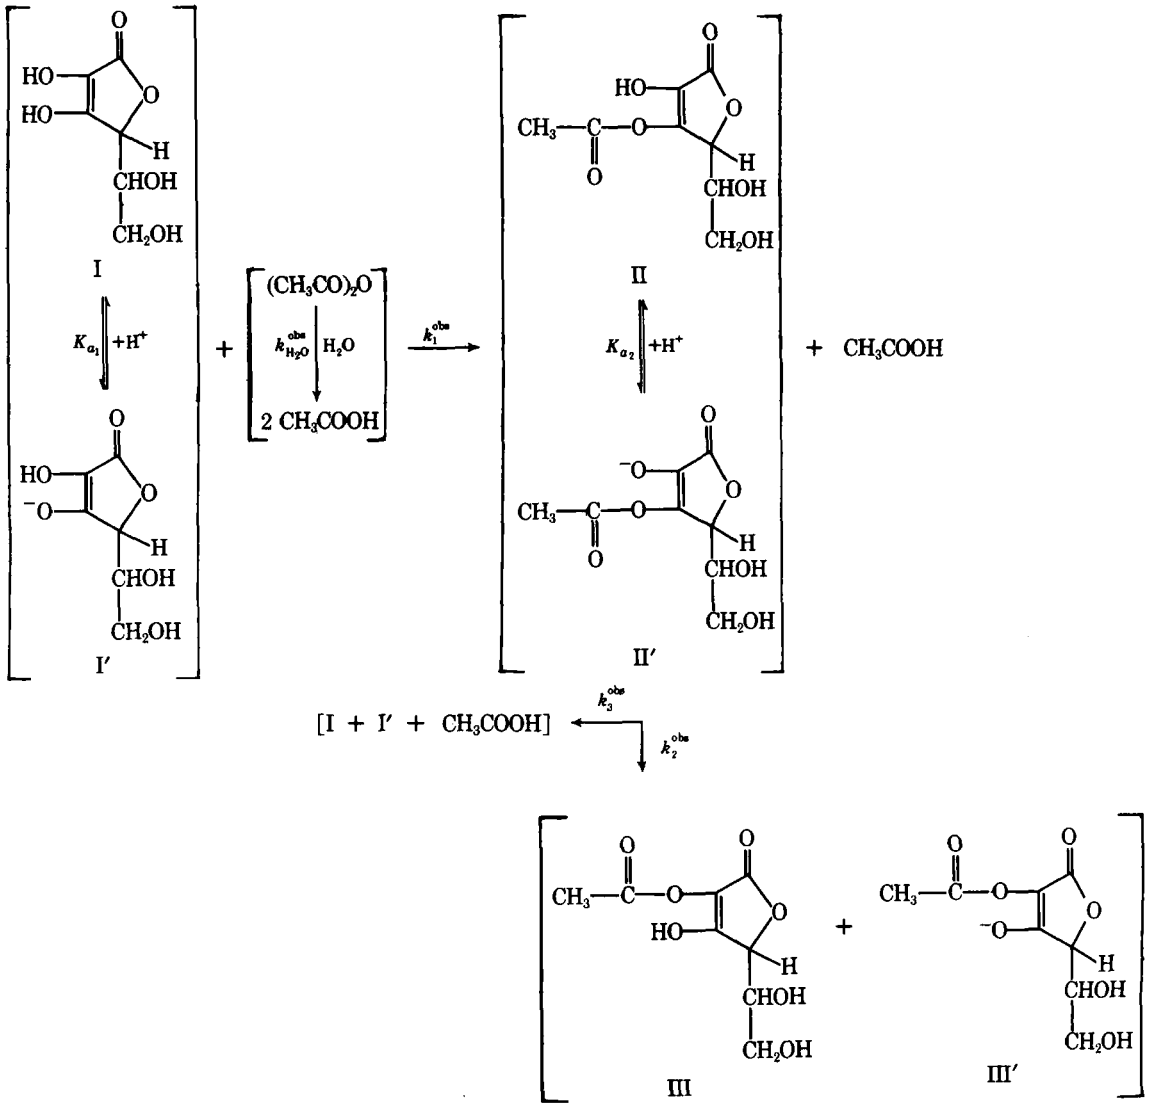
Determination of k_2^{obs}—The first-order rate constants for the loss of 3-*O*-acetylascorbic acid were determined by following the increase of UV absorption at the λ_{max} of 2-*O*-acetylascorbic acid. Citrate buffers (0.01 M) were used to minimize any catalysis of oxidation of ascorbic acid by trace elements (citrate complexes with the metal ions) and also to utilize the broad range of the buffering potential of the citric acid system. The solutions were adjusted to an ionic strength of 0.1 M with potassium chloride, and temperature was maintained at 25.0 ± 0.1°.

Concentrated solutions of 3-*O*-acetylascorbic acid formed *in situ* (see *Results and Discussion*) were diluted in the specified buffers (final concentration of ascorbic acid and its derivatives about 5×10^{-5} M–1×10^{-4} M), and the increase in UV absorbance was recorded until a plateau value was reached. Similarly, hydrolysis rate constants of 5,6-isopropolidine-2,3-di-*O*-acetylascorbic acid were determined by diluting a concentrated methanolic solution in the specified buffers and following the increase in UV absorbance at the λ_{max} of the 3-*O*-acetyl species.

RESULTS AND DISCUSSION

Several pieces of evidence suggest that the major series of reactions that occur when acetic anhydride (initial concentration $1–5 \times 10^{-2}$ M) is added to aqueous solutions of I (initial concentration $1–50 \times 10^{-2}$ M) at 25° are those shown in Scheme I. A qualitative picture of the events following the addition of acetic anhydride to solutions of I comes from the changes of optical rotation (at 350 nm) of the reaction solution as a function of time (Fig. 1). At pH values between 2 and 7, the changes in optical rotation were characterized by an initial rapid decrease followed by a slower increase. At pH values above 4.0, the final optical rotation was greater than the initial value. At lower pH values, the initial and final optical rotation values were similar.

It is believed that the initial decrease in optical rotation is caused by the conversion of I to 3-*O*-acetylascorbic acid (II) and



Scheme I

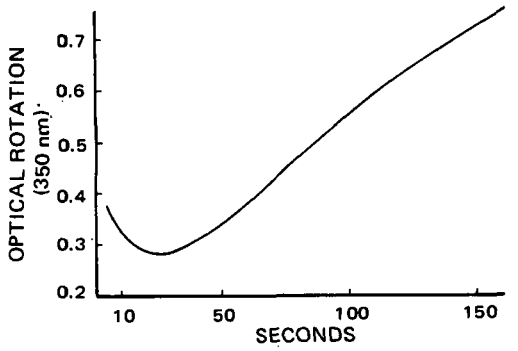


Figure 1—*Change in optical rotation at 350 nm as a function of time for the reactions of acetic anhydride (initial concentration 0.02 M) in a solution of ascorbic acid (initial concentration 0.25 M) (0.2 M acetate buffer, pH 5.25, I = 0.5 M, T = 27°).*

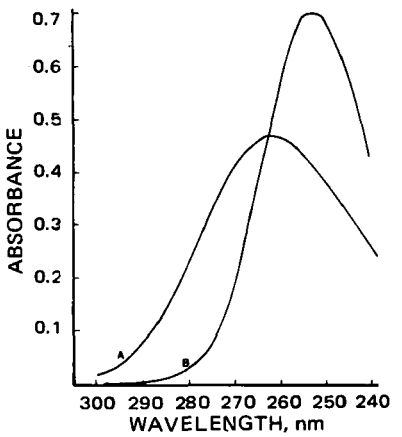

Figure 2—*UV spectra of: A, 5 × 10⁻⁵ M solution of ascorbic acid; and B, reaction mixture containing 5 × 10⁻⁵ M ascorbic acid and 1 × 10⁻² M acetic anhydride after 40 min. The solvent for both solutions was a 1 × 10⁻¹ M acetate buffer at pH 4.65.*

that the subsequent increase in optical rotation results from both the rearrangement of II to 2-*O*-acetylascorbic acid (III) *via* an O → O acyl migration and hydrolysis of II to I and acetic acid. These conclusions concerning the reaction mechanism are in part based on the assumption that the rate-determining step in the acylation reaction in water involves a reaction between an anionic form of I and acetic anhydride. It was previously found (4) that neutral molecules of alcohols, phenols, and hydroxycarboxylic acids are not significantly acylated by acetic anhydride in water whereas their anions, at least in the case of hydroxycarboxylic acids, are rapidly acetylated.

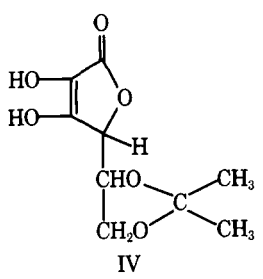
Hence, because the 3-hydroxy group is the most acidic in I (12), it is expected that it would be the first to be acetylated between pH 2 and 7. The large change in optical rotation that accompanies the initial reaction is consistent with the proposed reaction sequence because the 3-hydroxy group is adjacent to a rigid asymmetric carbon atom (C-4) and its derivatization would be expected to result in a relatively large change in optical activity. Additional evidence for this first reaction was obtained from a kinetic study and will be discussed later.

If III were simply hydrolyzed in a subsequent reaction to yield I and acetic acid, the initial and final optical activities of the reaction solutions would be the same. However, apart from the fact that the initial and final optical activities did differ by a small but significant amount, several other pieces of evidence indicate that the final reaction mixture contained at least one compound in addition to I (and I') and acetic acid. Evidence for this conclusion is:

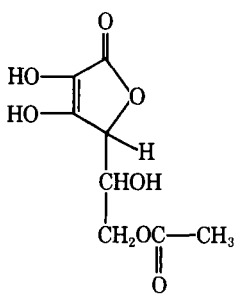
1. The UV spectrum of the initial and final reaction solutions differed significantly (Fig. 2).

2. Titration of the final reaction mixture with sodium hydroxide to the phenolphthalein end-point yielded a smaller titer than that obtained for a mixture containing ascorbic acid and fully hydrolyzed acetic anhydride. For example, 4.8 ml of 0.1 *N* NaOH was required to titrate 3.3 ml of a reaction mixture that originally contained 0.15 m*M* I and 0.18 m*M* acetic anhydride and had stood at 25° for 1 hr. If each mole of acetic anhydride had reacted to yield 2 moles of acetic acid, the titer would have been 5.1 ml.

The major product following these reactions is believed to be III rather than the 5-*O*-acetyl or 6-*O*-acetyl derivatives of ascorbic acid for several reasons. First, 5,6-isopropolidineascorbic acid (IV) and 6-*O*-acetylascorbic acid (V) reacted in a similar manner (both qualitatively and quantitatively) to I in aqueous solutions of acetic



IV



V

anhydride (the 6-hydroxy group cannot be acetylated in either compound and both the 5-hydroxy and 6-hydroxy groups are masked in IV). Second, potentiometric titration of the final reaction mixture of I and acetic anhydride with hydrochloric acid revealed that it contained a compound with a pKa of approximately 2 [it seems unlikely that 5-*O*-acetyl- or 6-*O*-acetylascorbic acid would have significantly different pKa values from that of I (pKa = 3.90 at I = 0.10 *M*)]. And third, titration of a 1-hr-old reaction mixture, made by adding 0.1 ml of a 0.6 *M* solution of acetic anhydride in dioxane to 3.0 ml of a 0.1 *M* solution of sodium ascorbate (at pH 6.0) with 2,6-dichloroindophenol or iodine, gave titers accounting for only between 82 and 84% of the original amount of ascorbic acid. Since both of these reactants detect molecules that contain an intact enediol system (13), the low titers indicate that at least some of the originally added ascorbic acid was derivatized at the 2-hydroxy or 3-hydroxy groups.

The yield of III in the final reaction mixtures could also be calculated from the titers of sodium hydroxide that were required to reach the phenolphthalein end-point. Details of this method were given previously (4). It depends on the fact that esterification of 1 mole of I by acetic anhydride produces 1 mole of acetic acid and 1 mole of ester, whereas hydrolysis of 1 mole of acetic anhydride yields 2 moles of acetic acid.

The experimental details for calculating yields of ester are given under *Experimental*, and a plot of yield of ester $[III]_e$ relative to the initial acetic anhydride $[Ac_2O]_0$ concentration against initial ascorbic acid concentration (at pH 6.0) is shown in Fig. 3. The plot in Fig. 3 reveals that the yield of ester relative to initial anhydride concentrations increases with increasing concentrations of I when these are low but becomes independent of the concentrations of I when these were above 1 × 10⁻¹ *M*. Furthermore, the maximum yield of ester never exceeded 87%. A possible explanation would be that at high concentrations of ascorbic acid relative to initial acetic anhydride concentrations, virtually all of the acetic anhydride reacted with I to yield II. It would then be necessary to conclude that II participated in two parallel reactions, rearrangement to III and hydrolysis, and that the ratio of the rate constants for these

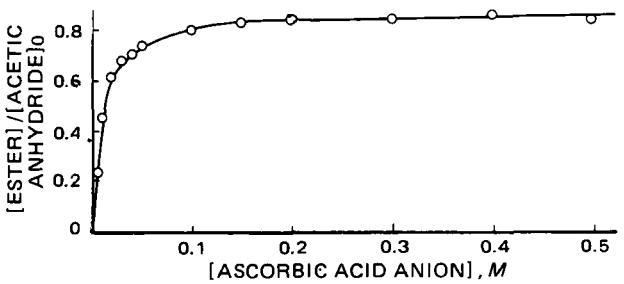


Figure 3—*Plot of yield of mono-O-acetyl ascorbate against initial concentration of sodium ascorbate ($[Ac_2O]_0$ = 0.02 M, pH 8.5, I = 1.5 M, T = 25°).*

reactions was insensitive to concentrations of I. This is considered to be the most likely explanation.

An alternative explanation for the results in Fig. 3 would be that ascorbate ion is catalyzing the hydrolysis of acetic anhydride by acting as a general base as well as by reacting to yield the ester, II. Although this possibility cannot be ruled out completely, evidence is presented subsequently to establish that hydrolysis and O → O acetyl transfer reactions both occur in II. Hence, any general base catalysis by ascorbate or hydrolysis of acetic anhydride will change the reaction sequence only slightly, and the paramount reactions appear to be those described. A strong suggestion that II would be likely to hydrolyze quite rapidly came from the observation that the closely related 5,6-isopropolidine-2,3-di-*O*-acetylascorbic acid hydrolyzed to the corresponding 2-*O*-acetyl derivative, with half-lives ($t_{1/2}$ values) of the order of 10 min in the 3.5–6.5 pH range.

The calculation of rate constants for the reactions in Scheme I is complicated by the fact that hydrolysis of acetic anhydride to acetic acid competes with the formation of I. Estimates of the rate constants for the various reactions were made from the results of experiments designed on the basis of the following considerations:

1. The rate law for the conversion of I and I′ (I + I′ = I_T) to II and II′ would be:

$$-\text{rate}_{[I]_T} = k_1^{obs}[Ac_2O][I]_T \qquad \text{(Eq. 3)}$$

2. Most of the acetic anhydride would be consumed by hydrolysis if the initial acetic anhydride concentration $[Ac_2O]_0$ was greatly in excess of the initial concentration of $[I]_T$. Hence, because the hydrolysis of acetic anhydride in aqueous buffers is a pseudo-first-order reaction:

$$[Ac_2O] = [Ac_2O]_0 e^{-k_{H_2O}^{obs}t} \qquad \text{(Eq. 4)}$$

The $k_{H_2O}^{obs}$ value in Eq. 4 is the pseudo-first-order rate constant for hydrolysis of acetic anhydride in a particular buffer solution at a particular pH value. If I and I′ do not significantly affect the rate of hydrolysis (*e.g.*, by acting as general acids or general bases), then the $k_{H_2O}^{obs}$ value in a reaction solution containing $[I]_T$ would be identical to that in the same solution without $[I]_T$. In experiments designed to study the rate of formation of II, the concentration of $[I]_T$ was approximately 5×10^{-5} *M*. It was assumed that these low concentrations would not significantly affect the value of $k_{H_2O}^{obs}$ and that the value of this latter parameter could be determined from experiments in which no ascorbic acid was included in the reaction solutions. Values of $k_{H_2O}^{obs}$ at several pH values are listed in Table I.

3. Substitution of Eq. 4 in Eq. 3 yields:

$$-\text{rate}_{[I]_T} = k_1^{obs}[Ac_2O]_0[I]_T e^{-k_{H_2O}^{obs}t} \qquad \text{(Eq. 5)}$$

4. If the conversion of I to II and the hydrolysis of acetic anhydride were the only reactions occurring, and if II and acetic anhydride did not absorb UV energy appreciably at a wavelength where I absorbed strongly, then the absorbance at that wavelength would vary with time in accordance with Eq. 6:

$$\log A = \log A_0 + \frac{k_1^{obs}[Ac_2O]_0}{2.303k_{H_2O}^{obs}}(1 - e^{-k_{H_2O}^{obs}t}) \qquad \text{(Eq. 6)}$$

Hence, plots of log *A* against $e^{-k_{H_2O}^{obs}t}$ should be linear with slopes equal to $(k_1^{obs}[Ac_2O]_0/2.303k_{H_2O}^{obs})$, and the slopes of these lines should be linearly related to $[Ac_2O]_0$ and should equal zero when $[Ac_2O]_0$ equals zero. This type of dependence of log *A* on the value of $e^{-k_{H_2O}^{obs}t}$ was observed during the first 1.0 min following the addition of acetic anhydride (initial concentration 0.5–2 × 10^{-2} *M*) to solutions of ascorbic acid (initial concentration ~5 × 10^{-5} *M*).

Plots of log *A* against $e^{-k_{H_2O}^{obs}t}$ yielded straight lines, and Fig. 4 shows a typical plot of the slopes of these lines against $[Ac_2O]_0$. Although acetic anhydride did absorb slightly at 275 nm, it was included in equal concentrations in both sample and reference cells. Hence, the changes in absorbance caused by the hydrolysis of acetic anhydride were minimized. The assumption that II did not absorb UV energy appreciably at 275 nm was justified on the basis that the absorptivity of 5,6-isopropolidine-2,3-di-*O*-acetylascorbic acid was very low at this wavelength (ϵ = <50). Both this latter compound and II do not have a free 3-hydroxy group. It is believed that the conjugated pathway between this group and the C-1 carbonyl group is the major chromophore in I and its derivatives.

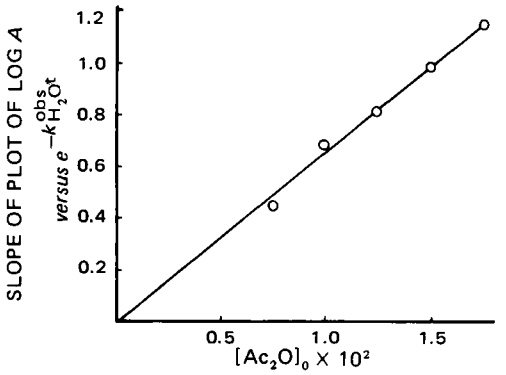

Figure 4—*Plot of slopes of plots of log* A versus $e^{-k_{H_2O}^{obs}t}$ *against initial acetic anhydride concentration (0.2* M *acetate buffer, pH 5.5, I = 1.0* M, T = 25°).

Kinetic evidence will be presented shortly to establish that very little conversion of II to III or back to I occurs during 1 min. Hence, it is believed that these experiments can be analyzed to obtain values of k_1^{obs}, as was done in the present study; values of k_1^{obs} are shown plotted against pH in Fig. 5. The solid line in this figure was calculated on the basis that the major reaction leading to formation of II involves acetic anhydride and the monoanion of I (*i.e.*, I^-). This finding is consistent with the postulate that the 3-hydroxy group of I is the first to be acylated in water at pH values between 2 and 6.

5. Because the reaction leading to the formation of II is a second-order reaction, its rate is very concentration dependent. On the other hand, the rearrangement and hydrolysis of II are postu-

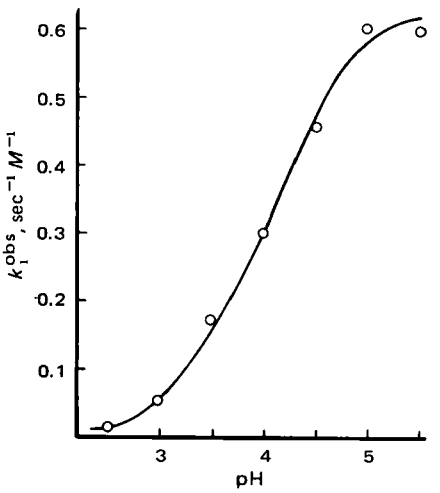

Figure 5—*The pH–rate profile of the second-order rate constants* (k_1^{obs}) *for the initial attack of acetic anhydride on ascorbic acid in a 0.2* M *acetate buffer (I = 1.0* M, T = 25°).

Table I—Rate Constants for Hydrolysis of Acetic Anhydride in 0.2 *M* Acetate Buffers at 25° (*I* = 1.0 *M*)

pH	$t_{1/2}$, min	$10^3 k_{H_2O}^{obs}$, sec^{-1}
2.5	4.55	2.49
3.5	5.12	2.24
4.0	4.80	2.33
4.5	4.73	2.44
5.0	4.26	2.71
5.5	3.72	3.04

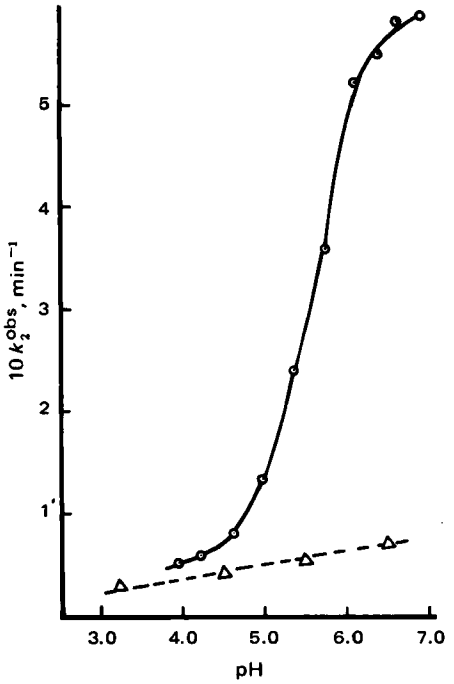

Figure 6—*The pH–rate profile of the overall rate of loss of 3-O-acetylascorbic acid (⊙) and rate of hydrolysis of 5,6-isopropolidine-2,3-di-O-acetylascorbic acid (△) (0.01 M citrate, I = 0.1 M, T = 25°).*

lated to be first-order (or pseudo-first-order) reactions in aqueous buffers, and their rates should be independent of the concentration of II. These postulates are the bases for the experiments employed to estimate the rate of conversion of II to III and I. A solution that was initially 10^{-2} *M* in both I and acetic anhydride and was buffered at pH 4.0 was prepared and kept at 25° for 4 min. The major reactions occurring under these conditions were the hydrolysis of acetic anhydride and the formation of II.

After 2 min, an aliquot of the solution was diluted ~200-fold into a buffer, and changes in UV absorbance at λ_{max} were recorded. Plots of log $(A - A_\infty)$ against time were linear for at least four half-lives, and these plots were used to calculate first-order rate constants, k^{obs} values, for the reactions that were occurring. A plot of k^{obs} values against the pH values of the buffers in which the reactions took place are displayed in Fig. 6.

Upon dilution of the original reaction mixture, any second-order reactions between acetic anhydride and $[I]_T$ (or possibly II or III) would be greatly slowed down. Hence, it is believed that the absorbance changes were caused by both the rearrangement of II to III (with a first-order rate constant k_2^{obs}) and hydrolysis of II (with a pseudo-first-order rate constant k_3^{obs}). On this basis, k^{obs} values would be related to the rate constants for the various reactions by:

$$k^{obs} = k_2^{obs} + k_3^{obs} \qquad \text{(Eq. 7)}$$

The fact that the pH profile in Fig. 6 has an inflection point at pH 5.5 suggests that the substrate has a pKa value of 5.5. This value is believed to be the pKa value of II. Although the second pKa value of I (*i.e.*, ionization of the 2-hydroxy group) is 11.5, the pKa value of II is expected to be much lower because it has an electron-withdrawing *O*-acetyl group adjacent to the ionizing group rather than a negatively charged oxygen atom.

The magnitudes of the rate constants k_2^{obs} and k_3^{obs} could not be calculated from values of k^{obs} alone. However, the fact that the yield of III is 87% at pH 6.0 suggests that the ratio k_2^{obs}/k_3^{obs} has a value of approximately 7 at this pH. Also, the observation that the UV spectra of final reaction mixtures were much closer to those of the initial solutions at pH <4 than at pH 4–6 suggests that the value of the ratio k_2^{obs}/k_3^{obs} is lower at pH 4 than it is at pH 6. Hence, it appears likely that the rearrangement reaction occurs most favorably in the ionized form of II (II′).

Although the ester III was much more stable than II, it slowly degraded in aqueous buffers. After standing at 25° for several days, solutions that originally contained III had identical UV spectra to solutions that contained equivalent amounts of I. Hence, it appears that III is slowly hydrolyzed ($t_{1/2} \simeq 24$ hr at pH 4.5) to ascorbic and acetic acids. Rate constants for the various reactions that were calculated from changes in optical rotation or by using a pH-stat technique were very close to those calculated from measurements of changes in UV absorbance.

No evidence was found for any migration of acyl groups from the 2-hydroxy or 3-hydroxy groups to the 5-hydroxy or 6-hydroxy groups as previously reported (1). These migrations would only be likely at pH values where the 5-hydroxy and 6-hydroxy groups are appreciably ionized. Because these hydroxy groups are so weakly acidic, much higher pH values than 7.0 would be required.

During this study, some questions arose about structural assignments that had been previously made to some ascorbic acid esters. Nomura and Sugimoto (1) synthesized a di-*O*-benzoylascorbic acid, which had a melting point within the 149–151° range and a pKa in methanol of 4.00. It was suggested that this ester was 3,6-di-*O*-benzoylascorbic acid. However, based on the finding in the present study that II has a pKa in water (which probably would be lower than that in methanol) of about 5.5, whereas III has a pKa in water of about 2, it seems likely that Nomura and Sugimoto's compound was the 2,6-di-*O*-benzoyl derivative.

Furthermore, it was reported by Nomura and Sugimoto (1) that 2,6-di-*O*-benzoylascorbic acid rearranged to the 3,6-isomer in base. Again, the present study leads to the conclusion that it was the 3,6-isomer that isomerized to yield the 2,6-isomer. Other workers (13) synthesized a di-*O*-benzoyl ester of ascorbic acid, which had a melting point of 151–152°, and assigned it the structure of 2,6-di-*O*-benzoylascorbic acid. This compound is probably the same one that Nomura and Sugimoto (1) synthesized.

Vestling and Rebstock (11) carried out an acetylation of 5,6-isopropolidineascorbic acid in acetone with ketene. These authors isolated a compound which melted at 113–115° and had the elemental analysis of: C, 51.44%; H, 5.55%. It was suggested that this compound was the 3-*O*-acetate of 5,6-isopropolidineascorbic acid. The theoretical values for the elemental analysis of this latter compound are: C, 51.2%; H, 5.42%. This synthesis was repeated in the present study and a compound was obtained with a melting point of 113–115° and a similar elemental analysis to that found by Vestling and Rebstock (11). However, this product is believed to be 5,6-isopropolidine-2,3-di-*O*-acetylascorbic acid. The reasons for reaching this conclusion are:

1. The theoretical elemental analysis figures for the diacetate are: C, 52.0%; H, 5.33%.
2. The mass spectrum of the compound had a peak at *m/e* 300, which is the molecular weight of the diacetate.
3. The NMR spectrum of the compound in $CDCl_3$ did not contain singlet proton peaks at or near δ 10.8 or 8.0 (which is where the 2-hydroxy and 3-hydroxy protons of I and 5,6-isopropolidineascorbic acid resonate), but it contained two peaks at δ 2.35, which integrated for six protons. These peaks would be caused by the six protons on the two acetyl peaks of 5,6-isopropolidine-2,3-di-*O*-acetylascorbic acid.

When this compound was dissolved in aqueous buffers with pH values between 2 and 7, the solution developed a UV spectrum very similar to that of III. Hence, it is believed that the diacetate hydrolyzes to 2-*O*-acetylisopropolidineascorbic acid, in agreement with the assignment of Sumiki *et al.* (5).

Chemical and Pharmacological Investigations of Constituents of *Eleutherine bulbosa* (Miller) Urb. (Iridaceae)

CAMILLO BIANCHI *ˣ and GIOVANNI CERIOTTI ‡

Abstract □ Eleutherin and eleutherol extracted from bulbs of *Eleutherine bulbosa* (Miller) Urb. (Iridaceae), collected in the Amazonian jungle and grown in Italy, were tested for biological properties. The extraction procedure and the results of antibacterial, cytotoxicity, and pharmacological assays are reported. Eleutherin has a weak and transient effect of decreasing the prothrombin time (*in vivo* in rats) and a weak antibacterial activity on *Bacillus subtilis (in vitro)*.

Keyphrases □ *Eleutherine bulbosa* (Iridaceae)—extraction of eleutherin and eleutherol, pharmacological screening □ Eleutherol and eleutherin—extracted from *Eleutherine bulbosa*, pharmacological screening □ Medicinal plants—extraction of eleutherin and eleutherol from *Eleutherine bulbosa*, pharmacological screening

In 1959, unknown bulbs, collected in the Peruvian part of the Amazonian jungle along the Ucayali River near Pucallpa[1], were sent to Europe[2]. Some bulbs, which arrived presumably a few months after collection, were planted in northern Italy near Milan at about 220 m above sea level, while others were subjected to biological screening.

Following the procedure described in this paper, a crystalline yellow substance was extracted from the dry bulbs. The substance proved to be a mixture of eleutherol and eleutherin[3]. The two compounds were separated, crystallized, and biologically assayed. Through specimens of bulbs and flowers obtained from the plant grown in Italy, the plant was identified[4] as *Eleutherine bulbosa* (Miller) Urb. [*E. plicata* (Ser.) Herb.].

Both eleutherol and eleutherin were described and chemically characterized earlier (1–3) by extracting the compounds from bulbs of *E. bulbosa* (Miller) Urb. (Iridaceae) collected in Java. The plant, cultivated in Java where it was used in a variety of illnesses by natives, originally came from equatorial America (1). A related plant, *E. plicata*, is said to be a popular medicine used by natives of north or northeast Brazil. Some studies on the chemical constituents of the plant have been performed (4).

While data on the chemical properties of eleutherol and eleutherin are abundant (1–3, 5–14), data on their biological properties are scarce (6). This paper reports the results of experiments performed on a sample of eleutherol and eleutherin extracted from bulbs of *E. bulbosa* grown in Italy.

EXPERIMENTAL[5]

Bulbs grown in Amazonia were used in the early phases of the research, while bulbs grown in Italy were used subsequently. The only apparent difference between them was that the yellow crystalline material on the outer scales of dry bulbs was more abundant on those of Amazonian origin than on those of Italian origin. The bulbs planted in Italy were allowed to grow for about 6–7 months; they then were harvested, separated from the aboveground parts, and air dried for about 3 months at room temperature.

Dry bulbs (1 kg) were sliced and left to macerate with 1 liter of 95% ethanol for 2 days; the procedure was repeated once. The filtered alcoholic extracts were combined and brought to dryness at 50° under reduced pressure. The residue was dissolved in warm acetone, and one volume of ether and six volumes of water were added to it. The aqueous phase was separated and extracted four times with a total amount of ether corresponding to 1.5–2 times the volume of the water. All ether extracts were combined, dried over anhydrous sodium sulfate, filtered, and brought to dryness under reduced pressure.

The residue was dissolved in a minimum amount of warm absolute ethanol. Refrigeration of the ethanol solution yielded a yellow crystalline material, which was recrystallized once from absolute

[1] For details about the geographical position of Pucallpa and for a view of the jungle along the Ucayali River, see *National Geographic*, Feb. 1964, and the companion map.

[2] People living in Pucallpa indicated that the aborigines call the plant "Piri-Piri" and use decoctions of the bulbs to stop postpartum hemorrhages.

[3] Identification was carried out by Professor A. Quilico, Istituto di Chimica Generale e Analitica, Politecnico di Milano, Milan, Italy.

[4] Identification was carried out by the late Professor F. Morton of Hallstatt. The specimen is deposited at the Botanischer Garten und Botanisches Museum, Berlin, Dahlem, Germany (herb. D. E. Meyer No. 2286).

[5] Melting points were taken on a Leitz hot-stage microscope and are uncorrected. Optical rotation measurements were determined on a Perkin-Elmer 141 polarimeter. UV spectra were determined in ethanol using a Beckman DU spectrophotometer. TLC was carried out on silica gel G (0.25 mm) plates using benzene–acetone (9:1) (Solvent A) and petroleum ether–ethyl acetate–chloroform (67:33:10) (Solvent B) as developing systems. Separated components on the plates were visualized by their appearance under 254-nm UV light. For TLC, 10 or 20 μg of the material under test was applied.

The two compounds were separated, crystallized, and biologically assayed. Through specimens of bulbs and flowers obtained from the plant grown in Italy, the plant was identified[4] as *Eleutherine bulbosa* (Miller) Urb. [*E. plicata* (Ser.) Herb.].

Both eleutherol and eleutherin were described and chemically characterized earlier (1–3) by extracting the compounds from bulbs of *E. bulbosa* (Miller) Urb. (Iridaceae) collected in Java. The plant, cultivated in Java where it was used in a variety of illnesses by natives, originally came from equatorial America (1). A related plant, *E. plicata*, is said to be a popular medicine used by natives of north or northeast Brazil. Some studies on the chemical constituents of the plant have been performed (4).

While data on the chemical properties of eleutherol and eleutherin are abundant (1–3, 5–14), data on their biological properties are scarce (6). This paper reports the results of experiments performed on a sample of eleutherol and eleutherin extracted from bulbs of *E. bulbosa* grown in Italy.

EXPERIMENTAL[5]

Bulbs grown in Amazonia were used in the early phases of the research, while bulbs grown in Italy were used subsequently. The only apparent difference between them was that the yellow crystalline material on the outer scales of dry bulbs was more abundant on those of Amazonian origin than on those of Italian origin. The bulbs planted in Italy were allowed to grow for about 6–7 months; they then were harvested, separated from the aboveground parts, and air dried for about 3 months at room temperature.

Dry bulbs (1 kg) were sliced and left to macerate with 1 liter of 95% ethanol for 2 days; the procedure was repeated once. The filtered alcoholic extracts were combined and brought to dryness at 50° under reduced pressure. The residue was dissolved in warm acetone, and one volume of ether and six volumes of water were added to it. The aqueous phase was separated and extracted four times with a total amount of ether corresponding to 1.5–2 times the volume of the water. All ether extracts were combined, dried over anhydrous sodium sulfate, filtered, and brought to dryness under reduced pressure.

The residue was dissolved in a minimum amount of warm absolute ethanol. Refrigeration of the ethanol solution yielded a yellow crystalline material, which was recrystallized once from absolute

[1] For details about the geographical position of Pucallpa and for a view of the jungle along the Ucayali River, see *National Geographic*, Feb. 1964, and the companion map.

[2] People living in Pucallpa indicated that the aborigines call the plant "Piri-Piri" and use decoctions of the bulbs to stop postpartum hemorrhages.

[3] Identification was carried out by Professor A. Quilico, Istituto di Chimica Generale e Analitica, Politecnico di Milano, Milan, Italy.

[4] Identification was carried out by the late Professor F. Morton of Hallstatt. The specimen is deposited at the Botanischer Garten und Botanisches Museum, Berlin, Dahlem, Germany (herb. D. E. Meyer No. 2286).

[5] Melting points were taken on a Leitz hot-stage microscope and are uncorrected. Optical rotation measurements were determined on a Perkin-Elmer 141 polarimeter. UV spectra were determined in ethanol using a Beckman DU spectrophotometer. TLC was carried out on silica gel G (0.25 mm) plates using benzene–acetone (9:1) (Solvent A) and petroleum ether–ethyl acetate–chloroform (67:33:10) (Solvent B) as developing systems. Separated components on the plates were visualized by their appearance under 254-nm UV light. For TLC, 10 or 20 μg of the material under test was applied.

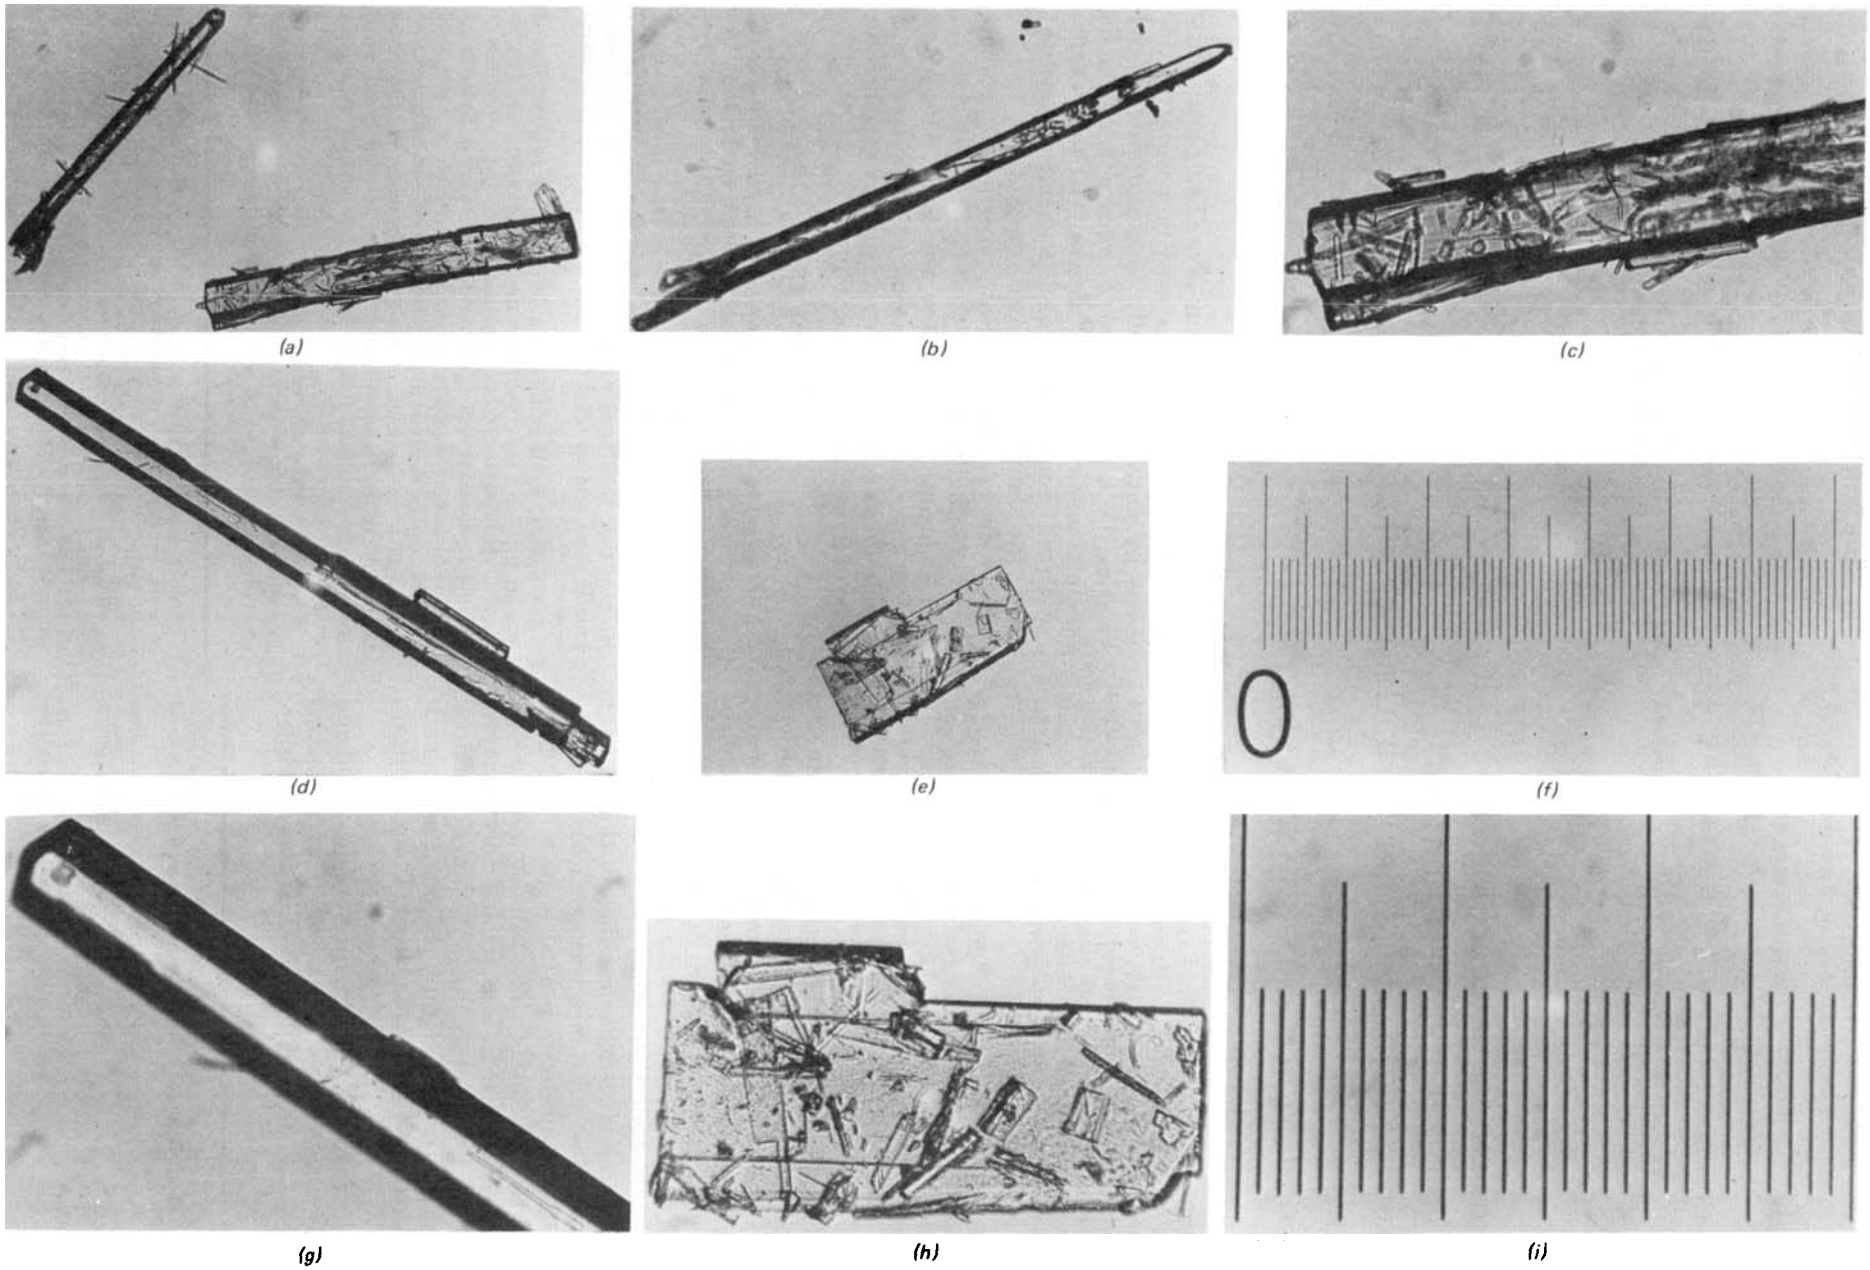

Figure 1—*Photomicrographs of crystals of eleutherol and eleutherin. Key: (a) crystals of eleutherol and eleutherin before fractionation, 40×; (b) crystal of eleutherol before fractionation, 100×; (c) crystal of eleutherin before fractionation, 100×; (d) crystal of eleutherol after fractionation, 40×; (e) crystal of eleutherin after fractionation, 40×; (f) scale 40× (1/10 of a millimeter is subdivided in 10 parts); (g) crystal of eleutherol after fractionation, 100×; (h) crystal of eleutherin after fractionation, 100×; and (i) scale 100× (1/10 of a millimeter is subdivided in 10 parts).*

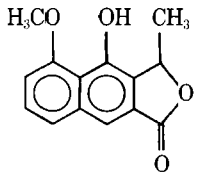
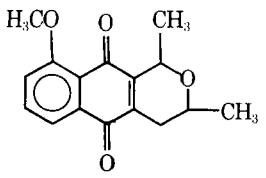


I



II

alcohol, once from acetone, and twice from *n*-butanol, yielding 500 mg, mp 145–147°; $[\alpha]_D^{20}$ + 221° (c. 0.1, chloroform). The material turned red when treated with concentrated sulfuric acid.

TLC showed the presence of two major blue spots, R_f 0.73 and 0.57 with Solvent A and R_f 0.51 and 0.40 with Solvent B. In addition, six minor spots and a tail were seen when Solvents A and B, respectively, were used.

Isolation of Eleutherol—The crystalline material was dissolved in warm benzene (500 mg in 30 ml at 50°). An equal amount of petroleum ether was added to the solution after the undissolved resins were separated by centrifugation. On refrigeration, white crystals precipitated from the solution. They were washed twice with benzene–petroleum ether (1:1) and crystallized twice from methanol, yielding white crystals (120 mg), mp 202–203°; $[\alpha]_D^{20}$ + 91.4° (c 0.1, chloroform). The material turned yellow when treated with concentrated sulfuric acid (1).

TLC showed the presence of a major spot at R_f 0.73 with Solvent A and at R_f 0.51 with Solvent B and only trace amounts of one undetermined substance. The UV spectrum and the analytical data corresponded to those published by Schmid *et al.* (1) for eleutherol (I), mp 202–203°; $[\alpha]_D^{20}$ + 90° in chloroform.

Isolation of Eleutherin—The benzene–petroleum mother liquors remaining from the initial crystallization of eleutherol were taken to dryness under reduced pressure. The residue was crystallized twice from *n*-butanol to give yellow crystals (280 mg), mp 165–170°; $[\alpha]_D^{20}$ + 280° (c 0.1, chloroform). These crystals turned red when treated with concentrated sulfuric acid (3). TLC showed the presence of one major spot at R_f 0.57 with Solvent A and at 0.40 with Solvent B, as well as trace amounts of I and three undetermined substances. The UV spectrum corresponded to that published by Schmid *et al.* (3) for eleutherin (II), except for the presence of a maximum at 313 nm, which indicates the presence of I.

The analytical data are compatible with those for II published by Schmid *et al.* (3), mp 175°; $[\alpha]_D^{15}$ + 346° in chloroform. This sample of eleutherin differed from that described previously (3) in that it had a lower melting point and optical rotation. Such differences may be related to the presence of traces of eleutherol and other unidentified products in the eleutherin sample.

Photomicrographs of the isolated materials are shown in Fig. 1.

Due to the preliminary scope of the biological investigations, the samples of I and II were screened without further purification.

Antibacterial and Cytotoxicity Testing—For testing antibacterial and cytotoxic properties *in vitro*, stock solutions of II were made up in methanol (10 mg in 1 ml of warm methanol diluted to 40 ml with distilled water). The antibiotic activity was tested on *Bacillus subtilis* (ATCC 9466) with the agar plate diffusion method, using medium 1 (15). The antidehydrogenase activity was tested according to Miyamura (16) on sarcoma 180 cells surviving in agar.

General Pharmacological Testing—For testing general pharmacological properties in mice and rats *in vivo*, II was finely ground, sieved through a 200-mesh stainless steel screen, suspended in an aqueous suspending medium [0.1% carboxymethylcellulose (w/v) and 1% polysorbate (v/v)] and given intraperitoneally in the constant volume of 0.2 ml/10 g (mice) or 0.5 ml/100 g (rats).

Mice—Experiments were performed on groups of albino male mice of 20–22 g (five to 10 animals/group).

The general activity was tested according to Irwin (17) on animals observed for 3 hr after treatment. Rectal temperature was measured with an electrothermometer[6] and a rectal probe (RM 6) for instant measuring (18). Motor coordination was controlled for 5 min on a rough-surfaced rod (22 mm diameter) rotating at 7.5 rpm (19, 20).

The response to a noxious stimulus was controlled with the tail pinch method of Bianchi and Franceschini (21) and the hot-plate method (22). The mydriatic effect was tested with the Pulewska method (23, 24), using a binocular microscope and controlled illumination. The diameter of the pupil was expressed in arbitrary units (20 units = 1 mm; basal value of 40 control mice = 11.2 units). The experiments were carried out 1 hr after dosing the animals.

Anticonvulsant properties were tested in animals convulsing after pentylenetetrazol (125 mg/kg sc), strychnine (3 mg/kg sc), or electric shock (15 mamp for 0.2 sec) (25, 26). Antitremor properties were tested in animals showing sustained tremors after oxotremorine (2.5 mg/kg sc) (24), antireserpine properties were tested in animals showing ptosis and hypothermia after reserpine (2 mg/kg sc) (26), and depressant properties were tested in aggregated animals showing an increased sensitivity toward the toxic (26) and motor stimulant (27) effects of amphetamine (25 mg/kg sc using 10 mice/group and 1 mg/kg ip using five mice/group, respectively) and in animals showing loss of the righting reflex following pentobarbital administration (40 mg/kg ip) (28).

The effects on the autonomic nervous system were tested in animals treated with lethal doses of epinephrine (2.5 mg/kg iv) (26) and with doses of oxotremorine (2.5 mg/kg sc) (24) and carbacholine (100 μg/kg sc) (24) provoking parasympathetic overstimulation (salivation, diarrhea, diuresis, and lacrimation). The effects on the intestinal motility were tested with the charcoal bolus method (29). An interval of 60 min was allowed between the administration of II and the tests.

An additional test for analgesia was carried out on animals showing abdominal writhings following intraperitoneal administration of phenylquinone [0.1 ml/10 g of a 0.02% (w/v) solution in 6% (v/v) ethanol] (30). In this test, II was given subcutaneously 1 hr before phenylquinone.

Rats—The anti-inflammatory and analgesic properties were tested in groups of albino male animals of 100–110 g (10 animals/group) showing edema and hyperalgesia in an hindfoot after a subplantar injection of carrageenan (0.1 ml/rat of a 2% solution) (31). The determinations were carried out before and at hourly intervals for 5 hr after the administration of carrageenan. Compound II was given orally 30 min before carrageenan.

The effect on blood pressure was determined in six unanesthetized male animals of 300–400 g. Before and at intervals after II was given intraperitoneally (15, 30, and 60 min), blood pressure was measured by means of a pneumatic cuff and a piezocrystal pulse pick-up applied to the root of the tail. An automatic blood pressure recorder[7] (32) was used.

The Quick prothrombin time (33) was determined on the plasma of male animals of 180–200 g (three or four animals/group) at intervals after II was given intraperitoneally and orally.

Rabbits—The effects on blood pressure and respiration were determined in three male rabbits of about 3 kg, anesthetized with urethan (1 g/kg iv) and with the vagal nerves severed. Blood pressure was recorded by means of a pressure transducer connected to a carotid artery; respiration was measured by means of an impedance pneumograph connected to needle electrodes placed on the chest. A physiograph[8] was used to record the variations in blood pressure and respiration. Epinephrine (3 μg/kg), acetylcholine (3 μg/kg), and carotid occlusion were the methods used to assess the reactivity of the blood pressure-regulating mechanisms. Compound II dissolved in ethanol and normal saline (10 mg in 3 ml of 95° ethanol diluted with saline to 10 ml) was given slowly (0.3–0.6 ml/kg iv).

Isolated Heart—Amplitude, rate of contractions, and coronary flow in Langendorff rabbit isolated heart were recorded in three preparations perfused with II. Isoproterenol (0.04 μg) was used to increase the rate and force of contractions of the heart (34).

Due to a shortage of material, I was tested only for antibiotic and cytotoxic properties *in vitro* and for the general activity in mice *in vivo*. The methods used for the preparation of the necessary solutions or suspensions and for the execution of the assays were as already described.

The solutions or suspensions of I and II were used as soon as they were prepared.

RESULTS

Antibacterial and Cytotoxicity Testing—Compounds I and II were assayed at concentrations ranging from 7.17 to 125 μg/ml.

[6] Ellab, Electrolaboratoriet, Copenhagen, Denmark.

[7] W & W Electronic, Basel, Switzerland.

[8] EMI.

Compound I failed to inhibit the development of *B. subtilis* (ATCC 9466) up to 125 μg/ml. Compound II was found to inhibit the development at various concentrations down to 62.5 μg/ml. Tetracycline hydrochloride was active at doses ranging from 0.3 to 0.5 μg/ml. Compounds I and II, up to 125 μg/ml, did not show any antidehydrogenase activity on sarcoma 180 cells.

General Pharmacological Testing—*Mice*—Compound I was given intraperitoneally to six groups of mice (five animals/group) at various doses (800, 400, 200, 100, 50, and 25 mg/kg) without provoking overt toxic effects within 3 hr of observation. It only provoked abdominal writhing at all doses and hypothermia (mean fall in rectal temperature about 2°) at 800 and 400 mg/kg. The central nervous system, the autonomic nervous system, and the muscular system were not affected by the compound as judged by a direct observation of the treated mice. As indicated under *Experimental*, the compound was not tested further due to the shortage of material.

Compound II was given intraperitoneally at various doses (400, 200, 100, 50, and 25 mg/kg) to groups of mice (five animals/group); the animals were observed for 3 hr after treatment. At 400 mg/kg, II provoked the death of one animal; reduced spontaneous motility and curiosity; did not provoke Straub tail, mydriasis, salivation, lacrimation, diuresis, diarrhea, and piloerection; and did provoke abdominal writhings, twitches, and convulsions. At the same dose, it provoked hypothermia (about 2°), motor incoordination, and analgesia (tail pinch method and hot-plate method). At 200 mg/kg and at lower doses down to 25 mg/kg, it produced abdominal writhings in all mice, with the effect lasting about 30 min.

Compound II, given intraperitoneally at 200 mg/kg to groups of mice (five to 10 animals/group), did not show anticonvulsant properties (pentylenetetrazol, strychnine, and electric seizures), anti-chemotremor properties (oxotremorine tremors), and antireserpine properties (reserpine ptosis and hypothermia). It did not modify the hypnotic effects of pentobarbital, the stimulant properties of amphetamine in aggregated mice (toxicity and hypermotility), the parasympathetic stimulant properties of oxotremorine and carbacholine, the lethal effects of epinephrine, and the intestinal motility. Compound II, 200 mg/kg sc, did not modify the writhing syndrome brought about by an intraperitoneal injection of phenylquinone.

Rats—Compound II, 100 mg/kg po given to groups of rats (10 animals/group), did not show anti-inflammatory (carrageenan foot edema) or analgesic effects in edematous hyperalgesia (Randall–Selitto method using carrageenan as hyperalgic compound). The anti-inflammatory and analgesic tests were performed following oral administration of II, because irritant drugs may simulate anti-inflammatory effects when administered parenterally (35). Compound II has irritant properties, as shown by the writhing syndrome brought about by the compound when administered intraperitoneally in mice.

Compound II, 200 mg/kg po and ip, shortened the Quick prothrombin time from the control value of 13.2 to 8.3 sec (po) and to 8.1 sec (ip). The effect was manifest 15 min after treatment but not 30 min and 1, 4, and 24 hr after treatment. Menadione sodium bisulfite, 200 mg/kg po and ip, was still effective 24 hr after treatment (prothrombin time 10.7 sec po and 10.5 sec ip).

Compound II, 100 mg/kg ip, increased blood pressure 15 and 30 min after dosing (initial blood pressure of 175 mm Hg; increase of 15–20 mm Hg); blood pressure returned to normal within 60 min. Abdominal writhings were present for about 20 min after dosing. Reserpine, 1 mg/kg ip, provoked a long-lasting fall in blood pressure (initial blood pressure of 165 mm Hg; fall of about 30 mm Hg).

Rabbits—Compound II, 300–600 μg/kg, provoked an occasional and modest fall in blood pressure which lasted a few seconds only, but it failed to modify blood pressure considerably and for long periods. It did not alter the responses of the animals to epinephrine, acetylcholine, and carotid occlusion. At higher doses (2 mg/kg), II provoked the arrest of respiration and death.

Isolated Heart—Compound II, perfused at the concentration of 1 μg/ml, did not alter the rate and amplitude of contractions and coronary flow of the Langerdorff rabbit isolated heart and did not modify the positive inotropic and chronotropic effects of isoproterenol.

GLC Analysis of Hydrochlorothiazide in Blood and Plasma

W. J. A. VANDENHEUVEL ˣ, V. F. GRUBER, R. W. WALKER, and F. J. WOLF

Abstract □ GLC with electron-capture detection was successfully applied to the analysis of hydrochlorothiazide in human blood and plasma with a sensitivity (0.05 μg/ml) suitable for use with persons on therapeutic dosage levels. On-column methylation with trimethylanilinium hydroxide in methanol was employed to convert hydrochlorothiazide and its bromo analog, which served as the internal standard, to their tetramethyl derivatives.

Keyphrases □ Hydrochlorothiazide—GLC analysis in human blood and plasma □ GLC, electron-capture detection—analysis, hydrochlorothiazide in human blood and plasma

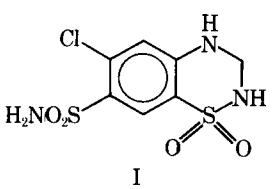
Hydrochlorothiazide[1] (I), 6-chloro-3,4-dihydro-2*H*-1,2,4-benzothiadiazine-7-sulfonamide 1,1-dioxide, is a potent saluretic agent widely used in the treatment of hypertension, congestive heart failure, and other edematous conditions. Although a colorimetric method permits the estimation of urinary levels of this drug (1), it is not sufficiently sensitive for analysis of blood and plasma samples from patients receiving therapeutic doses.

GLC, especially with electron-capture detection, has proven to be a useful method for the determination of submicrogram quantities of biologically active compounds in small volumes of body fluids. Direct GLC analysis of polar compounds at such levels is usually not possible, and derivatization techniques are normally employed to convert these compounds to less polar derivatives with improved chromatographic properties. On-column methylation with trimethylanilinium hydroxide in methanol has been found to effect this conversion by transforming hydrochlorothiazide to its tetramethyl derivative.

This paper describes the successful application of GLC combined with electron-capture detection to the analysis of hydrochlorothiazide in human blood and plasma with a sensitivity (~0.05 μg/ml) suitable for use with persons on medication at normal dosage levels.

EXPERIMENTAL

GLC was carried out with an instrument[2] equipped with an automatic sampler[3] (fitted with a 10-μl syringe[4]) and an electron-capture detector (8 mCi ^{63}Ni, 50-μsec pulse width, 310°). Commercially available, acid-washed support[5] was sieved (80–100 mesh) and then acid washed and silanized (2). This material was coated, using the filtration coating technique (2), with a 1% solution [toluene–chloroform (1:1)] of a mixture of OV-1 and polycyclohexanedimethanol adipate (6:1).



I

The two-component stationary phase approach (3) was employed because the inclusion of a small proportion of polyester resulted in improved chromatographic behavior[6]. Because of the difference in bleed rates between the polyester and the less volatile OV-1 siloxane polymer, the column temperature was reduced to <190° when not in use, resulting in a useful column lifetime of approximately 150 hr. Column conditions were: 1.2-m (4-ft) × 2.5-mm i.d. glass U-tube; 235°; argon–methane (95:5) carrier gas, 60 ml/min; and injector temperature, 280°. The retention time for tetramethyl-I was ~15 min.

On-column conversion of I and the internal standard, 6-bromo-3,4-dihydro-2*H*-1,2,4-benzothiadiazine-7-sulfonamide 1,1-dioxide (II), to the tetramethyl derivatives at the nanogram level was effected by dissolution and injection in a solution of trimethylanilinium hydroxide[7] in methanol (0.005 *M*). Preparative scale methylation of these two benzothiadiazines was carried out independently by dissolving 1 mg of the compound in 0.2 ml of 0.5 *M* trimethylanilinium hydroxide, removing the methanol *in vacuo*, and heating the residue in a sealed tube under nitrogen at 250° for 30 min.

The total reaction mixture was partitioned between ethyl acetate and water, and the crude reaction product was obtained by evaporation of the ethyl acetate solution. Purification was achieved by preparative scale TLC (silica gel G) with benzene–ethyl acetate (90:10) (tetramethyl-I, R_f 0.50) or benzene–ethyl acetate (70:30) (tetramethyl-II, R_f 0.46) and elution of the appropriate zone with ethyl acetate. Purity and identity were established by GLC–mass spectrometry.

The detailed procedure devised for isolation of the drug (and internal standard) in a form suitable for GLC analysis is presented here. The main steps are: (*a*) addition of the internal standard, (*b*) removal of extraneous substances with benzene extraction, (*c*) extraction with ethyl acetate, (*d*) back-extraction into ammonium hydroxide, (*e*) adjustment to pH 3.7 and extraction with ethyl acetate, (*f*) evaporation of the extract to dryness, (*g*) dissolution of the residue in trimethylanilinium hydroxide in methanol, and (*h*) GLC.

One-half milliliter of blood (heparinized) or plasma is placed in a 1.5-ml plastic centrifuge tube[8] to which previously has been added 0.15, 0.20, or 0.30 μg of the internal standard (II) in methanol (taken to dryness with nitrogen). The sample is thoroughly agitated to ensure dissolution of the internal standard. The blood or plasma is extracted with 0.5 ml of reagent grade benzene (a process blank should be run to ensure that none of the solvents or reagents cause interferences at the retention times of the drug and internal standard), the mixture is centrifuged[9], and the benzene layer is removed (disposable pipet) and discarded; this step is repeated. Then the sample is extracted with 0.5 ml of reagent grade ethyl acetate, the mixture is centrifuged, and the ethyl acetate layer is isolated (disposable pipet); this step is repeated.

The ethyl acetate extracts are combined in a second 1.5-ml plas-

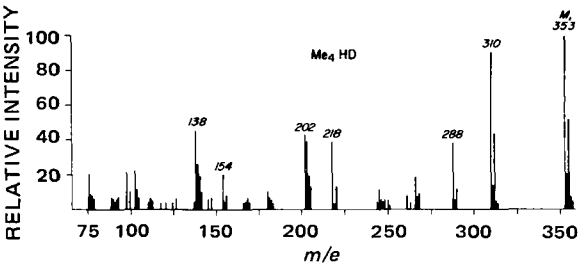

Figure 1—*Mass spectrum of tetramethyl-I as determined by combined GLC–mass spectrometry. Spectrometer conditions were: LKB model 9000; electron energy, 70 ev; source temperature, 270°; accelerating potential, 3.5 kv; and trap current, 60 μamp.*

tic centrifuge tube, and 0.5 ml of 0.1 *N* ammonium hydroxide is added. After thorough and immediate mixing and centrifugation, the ethyl acetate layer is discarded. The aqueous phase is taken to pH ~3.7 with 0.05 ml of acetic acid and extracted with 0.5 ml of ethyl acetate. Following centrifugation, the ethyl acetate layer is isolated; ethyl acetate extraction of the aqueous phase and isolation of the organic phase are repeated.

The ethyl acetate extracts are combined in a 5-ml glass centrifuge tube and taken to dryness with nitrogen (water bath, 45°). The residue is dissolved in 0.05 ml of 0.005 *M* trimethylanilinium hydroxide in methanol and transferred, using a disposable pipet, to a tapered 0.2-ml sampling vessel[10] for automated injection, GLC analysis (~1.8 μl of the final solution is injected).

A working curve for quantitation is obtained as follows. One-half-milliliter portions of control blood or plasma (preferably from the patient prior to medication) are added to 1.5-ml plastic centrifuge tubes containing 0.15, 0.20, or 0.30 μg of internal standard (added as methanol solution and taken to dryness) and sufficient I to result in levels of 0, 0.05, 0.20, 0.40, and 0.60 μg of drug/ml of blood or plasma. These samples are then carried through the isolation procedure and analysis, and the resulting peak height ratios (drug–internal standard) are plotted *versus* micrograms per milliliter of added I. The peak height ratio resulting from analysis of blood or plasma from a patient is then compared to a working curve (obtained as described) to give the concentration of drug in micrograms per milliliter.

RESULTS AND DISCUSSION

Preliminary experiments indicated, not unexpectedly, that I itself is not detected by GLC using column conditions suitable for compounds of similar molecular weight but possessing less polarity. Since derivatization techniques are often employed to allow or improve GLC of polar compounds of moderate molecular weight, this approach was investigated. Trimethylsilylation was found not to be fruitful, nor was methylation with diazomethane.

MacGee (4) reported that a number of polar drugs can be successfully analyzed by GLC by employing an on-column methylation, using a solution of tetramethylammonium hydroxide in methanol as both solvent and reagent. Similarly, Brochmann-Hanssen and Oke (5) described an on-column methylation method for the GLC of polar compounds, using trimethylanilinium hydroxide in methanol. VandenHeuvel *et al.* (6) reported the use of this reagent in a heavy isotope tracer study involving GLC–mass spectrometry. An on-column methylation approach for the determination of the drug bumetanide in urine also was reported (7).

Initial experiments at the microgram level using this reagent with flame-ionization detection were highly encouraging. Compound I was converted to a single product with satisfactory chromatographic properties; this product was shown to be the tetramethyl derivative (mol. wt. 353) by combined GLC–mass spectrometry (Fig. 1). The requirements of an assay for I in human blood and plasma are such that a sensitivity of at least 0.1 μg/ml is needed. Successful derivatization, chromatography, and detection of submicrogram quantities of drug are needed in a reproducible procedure.

The presence of a chlorine atom in I would be expected to lead to moderately good electron-capture sensitivity for the tetramethyl derivative of this drug, and a value of 1.75×10^3 coulombs/mole (8) was found under the described conditions. This sensitivity is sufficient to allow detection and quantification at the nanogram (injected) level; linearity of detector response is observed up to 12 ng with the instrument conditions employed. On-column conversion of I to its tetramethyl derivative is quantitative, since injection of 4 ng of drug in trimethylanilinium hydroxide in methanol results in the same electron-capture detector response as injection of an equivalent amount of authentic tetramethyl-I dissolved in methanol.

Analogous experiments with ^{14}C-labeled I and authentic tetramethyl-I-^{14}C, involving collection and counting of the carbon dioxide resulting from combustion of the appropriate GLC component, using the method of Trenner *et al.* (9), demonstrated that equivalent amounts of radioactivity were eluted from the column in both cases. Only 75% of the theoretically available radioactivity was collected from the tetramethyl-I peaks, however, indicating some loss on the column during chromatography. Experiments with mass standards and I-^{14}C indicated that the yield of drug carried through the entire isolation procedure is ~50%.

The molarity of the methanolic trimethylanilinium hydroxide solution used for on-column methylation is important (10). At reagent concentration of <0.0005 *M* and I concentrations of 1–5 ng/μl, methylation drops off sharply and no peak is observed for tetramethyl-I (or even trimethylhydrochlorothiazide). Maximal tetramethyl-I formation is observed at reagent molarities of ~0.005–0.01 *M*; at higher molarity, the size of the tetramethyl-I peak diminishes until essentially no derivative peak is observed at 0.5 *M*.

At the optimal reagent molarity, the flash heater temperature of the instrument used in this study can be varied from 240 to 320°

		3	—	0.35
		4	—	0.35

[a] These values were obtained without use of the internal standard.

with little effect upon the size of the tetramethyl-I peak. The temperature normally employed, 280°, is similar to that (270–275°) reported for on-column methylation of uric acid with trimethylanilinium hydroxide in methanol (11).

Automated injection is of obvious value in GLC assays. The samples are usually sealed in sampling vials, but occasionally a vial may not be sealed tightly enough to prevent the evaporation of a relatively volatile solvent such as methanol at the temperature (40–45°) of the automatic injector and an increase in sample concentration results. This should not be a problem when an internal standard is employed for the assay; but if the concentration of reagent increases sufficiently, this effect of molarity may be encountered. It is desirable to keep the length of time I is exposed to the basic reagent to a minimum.

The bromo analog of I, II, was chosen as an internal standard. The bromo compound is converted upon injection in methanolic trimethylanilinium hydroxide to its tetramethyl derivative (mol. wt. 397). The retention time of this compound is sufficiently greater than that of the tetramethylated drug to allow its use as an internal standard, and no interfering peaks (for drug or internal standard) are observed when control blood or plasma is carried through the isolation procedure (Fig. 2, top). The chromatogram resulting from analysis of control blood spiked with I and II is illustrated in Fig. 2 (bottom).

Linear relationships are observed when mixtures of these two compounds, containing constant amounts of the internal standard and varying amounts of I, are spiked into control blood or plasma and carried through the assay and the resulting peak height ratios are plotted against micrograms of spiked I per milliliter blood or plasma. Such plots are established each day and are used as working curves in the quantification of blood and plasma levels (see *Experimental*).

A sensitivity limit of ~0.05 μg/ml of blood and plasma is found using the isolation procedure and instrument conditions described in the *Experimental* section. Satisfactory replica of the entire assay results and precision of the GLC analysis were obtained. For example, quadruplicate assay of a spiked plasma sample gave a value of 0.66 ± 0.02, and quintuplicate GLC analysis of one of these isolates gave a value of 0.67 ± 0.01 μg/ml.

The chromatograms resulting from the assay of blood samples from a patient (W) receiving hydrochlorothiazide therapy, but who had ceased medication 4 days prior to resumption, are presented in Fig. 3. Blood drawn immediately after resumption of medication (single dose, 50 mg) gave an insignificant peak at the retention time of tetramethyl-I (Fig. 3, top; referred to as 0 hr but actually 96 hr postdose). The tetramethyl-I peak in the 3-hr postdose chromatogram is greatly enhanced (Fig. 3, middle), whereas this peak is markedly reduced in intensity with the 24-hr sample (Fig. 3, bottom). The concentrations calculated for these two samples are 0.62 and 0.11 μg/ml, respectively. The corresponding 3- and 24-hr urinary concentrations of I, as determined with the GLC method

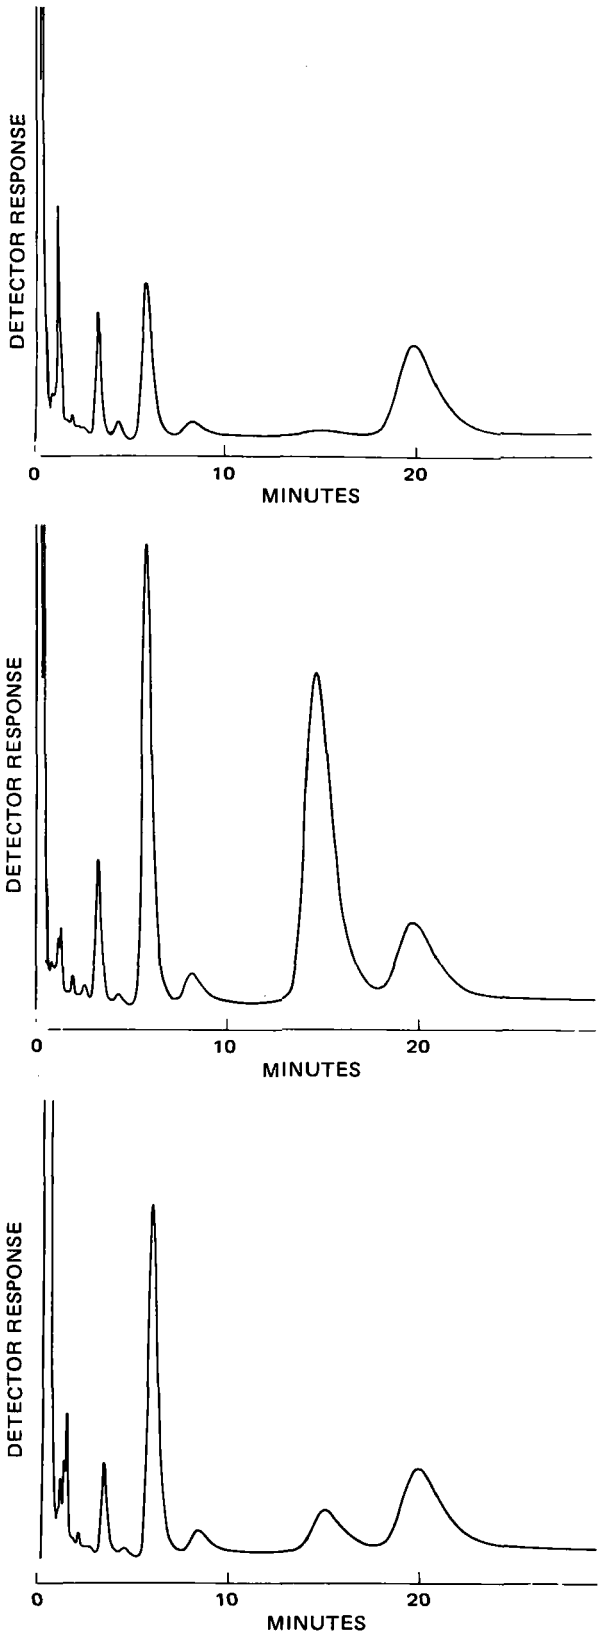

Figure 3—*Gas chromatograms resulting from analysis of blood from Subject W (0 hr but actually 96 hr postdose) (top), blood from Subject W 3 hr postdose (50 mg I) (middle), and blood from Subject W 24 hr postdose (bottom).*

(simply substituting urine for blood), were 19.8 and 6.4 μg/ml, respectively.

The level of drug in the blood of Subject W 2 hr postdose (50

mg) on a single day during an extended medication period was 0.51 μg/ml, in line with earlier findings. The corresponding value during a period in which the dosage was only 25 mg/day was 0.22 μg/ml. Plasma levels corresponding to these two values were 0.31 and 0.10 μg/ml, respectively. These values are presented in Table I, along with plasma levels for three individuals (Subjects G, K, and L) at dosage levels of 50 and 100 mg. Blood levels for Subject W (50 mg) at 1.5, 4, 6, and 24 hr, determined prior to introduction of the internal standard approach, are also presented in the table.

This paper presents a method for the determination of hydrochlorothiazide in small volumes of blood and plasma from persons receiving therapeutic levels of this drug. Drug levels are reported for a limited number of patients, demonstrating the adequacy of the method for measuring the drug in blood and plasma at clinical doses. The method described in this paper should provide the means for carrying out pharmacokinetic and bioavailability studies.

Ocular Evaluation of Polyvinyl Alcohol Vehicle in Rabbits

THOMAS F. PATTON and JOSEPH R. ROBINSON [x]

Abstract □ The flow properties and viscosity of the vehicle into which drugs are incorporated can be determining factors in the bioavailability of topically applied ophthalmic drugs. It is shown, in rabbits, that when polyvinyl alcohol and methylcellulose are compared on a viscosity basis, there is essentially no difference in the two vehicles with regard to their influence on ocular drug bioavailability. Moreover, the rate of drainage loss for polyvinyl alcohol solutions, as determined by the radioactive technetium technique, compares favorably to methylcellulose solutions of similar viscosity. The relationship between viscosity and contact time or drainage loss of a drug is not a direct one, but an optimum viscosity range exists for polyvinyl alcohol solutions. This optimum range of 12–15 cps in rabbits is identical to that found for methylcellulose and differs considerably from the commonly employed viscosity in commercial preparations. Based on the methylcellulose–polyvinyl alcohol comparison, it appears that vehicles exhibiting or approximating Newtonian flow properties show comparable effects as ophthalmic vehicles. Finally, a discussion of non-Newtonian vehicles and their expected behavior in the eye is presented.

Keyphrases □ Polyvinyl alcohol—effect of vehicle viscosity on ocular drug bioavailability in rabbits, compared to methylcellulose □ Ocular bioavailability—effect of vehicle viscosity, polyvinyl alcohol and methylcellulose solutions, rabbits □ Ophthalmic vehicles—evaluation of polyvinyl alcohol, compared to methylcellulose, optimum viscosity range, rabbits

Great time and effort have been expended on determining the optimum liquid vehicle in which to incorporate drugs for instillation into the eye. Most efforts have been based on the premise that a highly viscous solution would prolong contact time of the drug with eye tissues, thus enabling a greater amount of drug to be absorbed into the desired area.

Recently, Adler *et al.* (1) made the important observation that high viscosity solutions do not greatly increase corneal contact time in humans and have only a small effect on bioavailability. An extensive study on methylcellulose solutions (2), however, has shown that there is considerable prolongation of contact time in rabbits and a two- to threefold improvement in bioavailability. This inconsistency apparently is due to differences between humans and rabbits with respect to the effect of medium viscosity solutions in the eye.

The present study explores the influence on ocular drug bioavailability of various polyvinyl alcohol solutions. Methylcellulose and polyvinyl alcohol are both used extensively as vehicles for ophthalmic drugs and the literature is confusing as to which polymer is best for ocular use. The aim of this report is to resolve that confusion as well as to provide a rational basis for predicting ophthalmic vehicle viscosity effects in general.

This inconsistency apparently is due to differences between humans and rabbits with respect to the effect of medium viscosity solutions in the eye.

The present study explores the influence on ocular drug bioavailability of various polyvinyl alcohol solutions. Methylcellulose and polyvinyl alcohol are both used extensively as vehicles for ophthalmic drugs and the literature is confusing as to which polymer is best for ocular use. The aim of this report is to resolve that confusion as well as to provide a rational basis for predicting ophthalmic vehicle viscosity effects in general.

EXPERIMENTAL

Materials—Water was double distilled from alkaline permanganate in an all-glass distillation apparatus. Technetium solutions

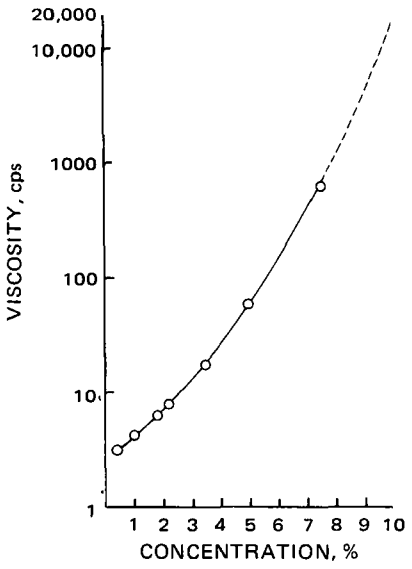

Figure 1—*Viscosity of polyvinyl alcohol solutions as a function of concentration at 30°. The dotted line represents extrapolated values for concentrations greater than 7.5%.*

were prepared using a package of solutions[1] and equipment used to prepare technetium, ^{99m}Tc, colloidal suspensions. The preparative procedure was described previously (3).

Polyvinyl alcohol[2], 20–90 grade, was used. Tritiated pilocarpine was obtained commercially[3] and was purified immediately before use. The reasons for the purification and the methods used were reported earlier (4). The specific activity of pilocarpine was 6.95 Ci/mmole. All other chemicals were either reagent or analytical grade.

Male, albino rabbits[4], 1.8–2.4 kg, were fed a regular diet with no restrictions on food or water intake.

Methods—*Determination of Instilled Solution Drainage Rate*—The general procedure for the determination of drainage rate by the nonsampling method was reported previously (3). In the present studies, twice the desired concentration of polyvinyl alcohol was diluted with an equal volume of technetium suspension to obtain the final concentration. The resulting solution was equilibrated in a water bath at 30° prior to instillation. Then 25 μl of polyvinyl alcohol–technetium solution was instilled with a microliter syringe[5], the probe was positioned, and the experiments were carried out as described previously (3).

Viscosity Studies—Viscosity profiles of the various polyvinyl alcohol solutions were obtained using a viscometer[6] and a No. 1 spindle. Solutions were maintained at 30 ± 0.1° throughout the viscosity measurements.

Aqueous Humor Drug Studies—The experimental details for aqueous humor drug concentration studies were reported previously (5). Unanesthetized rabbits were used in all experiments.

RESULTS

Viscosity Studies—Dilute polymer solutions generally exhibit or approximate Newtonian flow properties (6), and this was the case in the methylcellulose studies mentioned previously (2). It is well known that aqueous solutions of polyvinyl alcohol exhibit non-Newtonian viscosity (7). However, over the concentration range employed, the results approximated Newtonian behavior.

The relationship between viscosity and concentration of polyvinyl alcohol solutions at 30° is illustrated in Fig. 1. It is clear that dilute solutions of polyvinyl alcohol (<3%) show relatively small increases in viscosity with concentration. As the concentration of polyvinyl alcohol is further increased, however, viscosity changes may cover several orders of magnitude. It is known (8) that aqueous solutions of polyvinyl alcohol greater than approximately 1% contain entangled aggregates of hydrogen-bonded molecules. Such solutions may vary in their viscosities with age and with applied shear due to gelling.

Table I—Drainage Rate Constant of Polyvinyl Alcohol Solutions as a Function of Concentration and Viscosity

Concentration, %	Viscosity, cps	k, min^{-1}	Number of Determinations
0.0[a]	1.0	0.54	3
0.5	3.1	0.32 (0.05)[b]	5
1.1	4.2	0.25 (0.03)	5
1.9	6.1	0.25 (0.03)	10
2.25	7.7	0.31 (0.04)	5
3.5	17.5	0.08 (0.02)	7
5.0[c]	57.8	0.14 (0.02)	9

[a] Refers to data obtained using pure technetium suspension (2). [b] Values in parentheses refer to standard error of the mean. [c] Considerable difficulty was encountered in instilling this solution as well as in mixing it with the technetium suspension. These factors may limit the reliability of the drainage rate data.

Drainage Rate of Polyvinyl Alcohol Solutions and Its Relationship to Viscosity and Concentration—Loss of an instilled drug solution through drainage can account for a tremendous decrease in the amount of drug available for absorption (3). Thus, a small drainage rate would favor increased drug absorption. The drainage rates of various concentrations of polyvinyl alcohol were determined as described under *Experimental*. Table I lists these data as well as the viscosities of the various polyvinyl alcohol solutions.

A very dilute (0.5%) solution of polyvinyl alcohol causes a significant decrease in the drainage rate constant over that of an aqueous solution. This decrease occurs over a threefold increase in solution viscosity. From 0.5 to 2.25% polyvinyl alcohol, another two- to threefold increase in viscosity occurs and the drainage rate constant remains essentially unchanged. Somewhere beyond 3% polyvinyl alcohol, the drainage rate undergoes another sharp decrease and then remains fairly constant.

Figure 2 illustrates the drainage rate *versus* viscosity data. Drawing a smooth curve through the points results in a major change in the slope of the line at about 12–15 cps, which is shown as the hatched area in Fig. 2. This area corresponds approximately to a 3% solution (see Fig. 1). The conclusion then is that approximately a 3% polyvinyl alcohol solution is the optimum because large increases in viscosity result in only minor decreases in drainage rate beyond this concentration. The concentration of polyvinyl alcohol commonly used commercially is 1.4%; presumably other factors, such as comfort, account for the difference.

Aqueous Humor Levels of Philcarpine Nitrate in Polyvinyl Alcohol Vehicle—It seemed reasonable to assume that a viscous

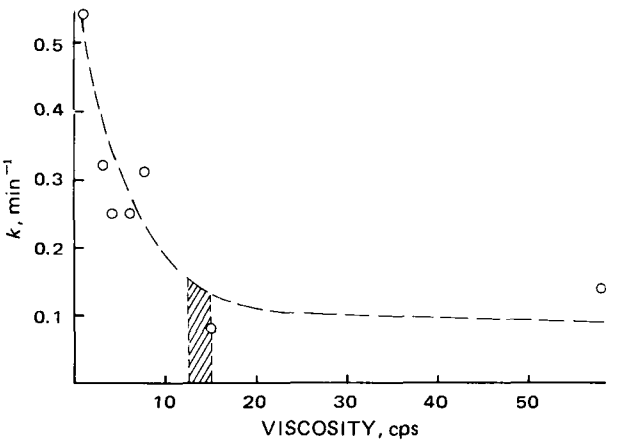

Figure 2—*Drainage rate of various polyvinyl alcohol solutions as a function of solution viscosity.*

Table II—Aqueous Humor Levels of Pilocarpine Nitrate from Various Viscosity Polyvinyl Alcohol Solutions

0.5	1.16 (0.14)	1.38 (0.08)	
1.1	1.26 (0.20)	0.94 (0.06)	0.34 (0.03)
1.9	1.14 (0.09)	2.03 (0.31)	
2.25	1.11 (0.07)	1.28 (0.11)	0.27 (0.04)
3.5	1.65 (0.22)	1.48 (0.20)	
5.0	2.22 (0.20)	2.01 (0.28)	
10.0	5.41 (0.38)	3.18 (0.64)	2.05 (0.19)

[a] At least six determinations at each point. [b] Numbers in parentheses refer to standard error of the mean.

solution would prolong contact time of drug with the eye through decreased drainage loss and would provide the potential for increased drug absorption into and through the cornea. Since the decrease in drainage rate had already been shown for various polyvinyl alcohol solutions, the effect on aqueous humor drug concentration remained to be demonstrated.

Table II shows the results of various polyvinyl alcohol concentrations on aqueous humor drug levels at selected time points. There appears to be little if any improvement in aqueous humor levels until something beyond 2.25% polyvinyl alcohol is used. A rather dramatic increase is noted with 10% polyvinyl alcohol, but the solution is so viscous at this concentration that it probably blocks the drainage duct and would also cause marked blurring of vision. These drawbacks probably would make it impractical for commerical use.

There is greater scatter in some of the data than was experienced in the past; based on experimental technique, an explanation for the deviation in the data cannot be offered. Nevertheless, trends can be discussed. For example, the 3.5, 5.0, and 10.0% polyvinyl alcohol solutions are all consistently higher than the lower concentrations.

DISCUSSION

To discuss viscosity effects, one must first have some understanding of the types of flow exhibited by various systems as well as an appreciation as to how these different systems behave in animal or human studies. For example, rabbits blink considerably less frequently than humans and therefore exert less stress on a polymer system.

The flow properties of any given system can have, in theory, a significant effect on the behavior of that system when instilled into the eye. By knowing the flow properties of a system, it should be possible to make some statements regarding its expected activity in the eye, as well as to account for possible differences in humans and animals. This information is summarized in Table III.

As mentioned, numerous studies have been conducted on methylcellulose and polyvinyl alcohol, both in rabbits and in humans, in an effort to determine the ideal ophthalmic vehicle. Almost all of these studies considered only vehicle contact time or bioavailability and ignored the very important aspects of patient acceptability and desirable properties for pharmaceutical handling, *e.g.*, sterile filtration. Many of these studies were confusing, contradictory, and, at best, incomplete. If, however, these studies are discussed in terms of the information in Table III and the findings reported here, the picture begins to become somewhat clearer.

In one early study, homatropine hydrobromide in 1% methylcellulose was administered to human subjects; this combination induced greater cycloplegia and mydriasis than a simple aqueous solution (9). The increased effectiveness was attributed to an increased contact time of drug with the eye. It was concluded that about double the quantity of drug could be expected to penetrate by increasing the viscosity of the instilled solution.

This effect was substantiated in a study in rabbits where a solution of 0.5% methylcellulose (4000 cps) increased contact time by 334% over an aqueous solution (10). Haas and Merrill (11), using human subjects, determined that a solution of pilocarpine in 0.5% methylcellulose produced greater miosis than a nonmethylcellulose solution of equal drug concentration.

Krishna and Brow (12), comparing vehicles, found that 1.4% polyvinyl alcohol in isotonic saline afforded greater surface contact time than 0.5% methylcellulose in isotonic saline alone. The results of this study, performed in rabbits, seem rather strange since 0.5% methylcellulose has a much higher viscosity than a 1.4% polyvinyl alcohol solution, assuming the standard grades of each were used.

It was found that in rabbits the increase in contact time of methylcellulose ophthalmic vehicles was about proportional to the

Table III—Various Viscosity Types and Their Expected Behavior in the Eye

Flow Type	Characteristics	Example	Potential Ocular Effects
Newtonian	Constant viscosity at constant temperature and pressure; viscosity independent of rate of shear	Simple liquids such as water and glycerin	Drainage loss of drug solution should be inversely proportional to viscosity; due to shear independence, blinking should have no effect on viscosity and such systems should behave the same in rabbits and humans
Non-Newtonian Pseudoplastic	Stress increases more rapidly at low rates of shear than at high rates; the apparent viscosity decreases as shear stress (shear thinning) increases	Concentrated dispersions of small particles and solution of long chain molecules	If the system undergoes shear in the eye, this system would be poor; in humans, if blinking causes shear, the system will thin and drain from the eye; in rabbits, such a system will probably resemble a Newtonian system
Plastic	Resembles pseudoplastic system, but the rate of shear does not acquire a finite value until the stress exceeds a certain yield value	Modeling clay	This system would be good as long as the yield value is not exceeded; in rabbits, this may be true, but in humans the system thins as with pseudoplastic once the yield value is exceeded
Dilatant	The opposite of pseudoplastic; the force increases faster than the rate of shear	Wet sea sand	If blinking in humans produces shear, the system will thicken; this system has good potential in humans, although the advantages of such a system would probably not be observed in rabbits
Thixotropic	A reversible and noninstantaneous decrease in apparent viscosity upon shear; the effect increases with the rate of shear; time-dependent shear thinning	Bentonite magma	Probably not a desirable situation in humans or in rabbits since the system will thin with time

Table IV—Comparison of Methylcellulose and Polyvinyl Alcohol Vehicles in Rabbit Eyes

Methylcellulose (1)		Polyvinyl Alcohol	
From 1 to 15 cps, drainage rate constant decreases by a factor of 3; from 15 to 100 cps, drainage rate constant further decreases by a factor of 3		From 1 to 7.7 cps, drainage rate constant decreases by a factor of 2; another two- to threefold decrease in k from 7.7 to 57.8 cps	
A rapid decrease in drainage rate with a small increase in viscosity, followed by a smaller decrease in drainage with a large increase in viscosity		True with polyvinyl alcohol also	
cps	k, min^{-1}	cps	k, min^{-1}
4.2	0.36	4.2	0.25
12.5	0.19	17.5	0.08
40.0	0.14	57.8	0.14
Approximately a 1.6-fold increase in aqueous humor concentration at 20 min from 1 to 12.5 cps, followed by a 1.2-fold increase in concentration from 12.5 to 100 cps		Approximately a 1.4-fold increase in aqueous concentration at 20 min from 1 to 17.5 cps, followed by a 1.4-fold increase from 17.5 to 57.8 cps	

viscosity of the solution in the lower viscosity region (5–25 cps) and leveled off at 55 cps or above (13). Even though methylcellulose is strictly a pseudoplastic system, Table III predicts Newtonian behavior in rabbits, making the 5–25-cps findings consistent. When a methylcellulose solution at 55 cps was used, mydriasis from a 0.02% solution of scopolamine hydrobromide was doubled.

Linn and Jones (14) contradicted the results of Krishna and Brow (12) by finding that the length of time needed for 0.5% hydroxypropyl methylcellulose to pass through the drainage apparatus was about twice that of 1.4% polyvinyl alcohol. This work, however, was carried out in humans whereas the earlier work was carried out in rabbits.

Bach *et al.* (15), using rabbits, and Waltman and Patrowicz (16), using human subjects, confirmed the superiority of 0.5% methylcellulose over 1.4% polyvinyl alcohol, the former in preventing ocular infections with neomycin sulfate and the latter in producing corneal and aqueous humor fluorescein concentrations. Again, these findings appear reasonable due to the higher viscosity imparted by a 0.5% methylcellulose solution over a 1.4% polyvinyl alcohol solution. Other studies (17, 18) also confirmed this finding.

A comprehensive evaluation of methylcellulose solutions in improving ocular drug bioavailability was conducted (2). Methylcellulose delayed solution drainage from the eye, and the major change occurred in the lower viscosity range. Moreover, it was found that pilocarpine aqueous humor levels could be approximately doubled through the use of methylcellulose solutions.

Despite some of the seeming contradictions in these studies, it does seem reasonable to assume that a viscous solution would prolong the contact time of drug with the eye and provide the potential for greater drug absorption into the desired area. Recently, however, this belief was challenged by Adler *et al.* (1) who concluded that increasing vehicle viscosity does not prolong ocular contact time nor markedly improve ocular drug bioavailability in humans. If the vehicles under consideration are behaving as Newtonian systems, these findings appear intuitively incorrect (Table III); however, if the vehicles are, in fact, pseudoplastic, the shear created by blinking would cause them to thin so that a large increase in instilled solution viscosity might provide only slight increases in contact time and aqueous humor levels. This is exactly what was found.

In almost all studies comparing polyvinyl alcohol and methylcellulose, the conclusion is reached that one vehicle is superior to the other based on contact time or bioavailability. But in many cases, the authors are basing their conclusions on polymer concentrations rather than viscosity. It is intuitively clear that as long as two vehicles exhibit the same flow properties, solutions with the same viscosity should exhibit the same drainage behavior in the eye. The important factors to consider then are the flow properties of the vehicle in question and its viscosity—*not* the concentration. There is no reason to suspect that methylcellulose should behave any differently from polyvinyl alcohol in the eye when a comparison is made on an equal viscosity basis.

A comparison between data obtained in this laboratory for methylcellulose (2) and the present report on polyvinyl alcohol seems to bear out this conclusion. Table IV summarizes the more important points of the polyvinyl alcohol–methylcellulose comparison. Of course, the basis for distinguishing the superiority of one vehicle over another must include factors other than drainage and bioavailability such as patient acceptability, influence on wound healing, and pharmaceutical handling.

It is clear from most of the work that has been conducted in humans (9, 18) or animals (13, 15), as well as from the methylcellulose and polyvinyl alcohol studies in this laboratory, that contact time is *not* proportional to drug bioavailability. Even with as much as a 100-fold increase in viscosity and a 10-fold decrease in drainage rate, the maximum improvement in drug activity, be it miosis, inhibition of infection, or aqueous humor levels, is about twice that of an aqueous solution.

The explanation for this is not clear. However, it is possible that a shear is created in the eye, even in rabbits, which causes these systems to thin. Thus, the responses obtained are not proportional to what would be expected from a consideration of the viscosity of the instilled solutions. Of course, more than a twofold increase in aqueous humor levels was obtained with pilocarpine in 10% polyvinyl alcohol. However, as pointed out earlier, the 10% polyvinyl alcohol is probably not practical because of the blurring of vision which would accompany its use. The relatively large increase in drug levels is probably due to a blockage of the drainage duct.

Large decreases in the drainage rate of instilled solutions can be obtained with relatively minor alterations in solution viscosity, and these large decreases do not lead to significant improvement in aqueous humor levels. With both methylcellulose and polyvinyl alcohol, it appears that the optimum viscosity solution to use would be in the range of 12–15 cps. Further increases in viscosity above this level do not appear to give proportional increases in drug levels. In addition, viscosities greater than 15 cps may present problems with respect to accuracy of instillation and blurring of vision. For these reasons, using polyvinyl alcohol, methylcellulose, or any system which approximates Newtonian behavior, a viscosity of 12–15 cps seems to be the optimum value in rabbits. Further work needs to be done to clarify why the substantial lowering of drainage rate and the corresponding increase in contact time with low to medium viscosity solutions is not reflected in a proportional increase in drug bioavailability.

Absorption, Distribution, and Metabolic Fate of 7-Chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one in Rats, Dogs, and Humans

JEROME EDELSON [x], J. F. DOUGLAS, B. J. LUDWIG, E. B. SCHUSTER, and S. SHAHINIAN

Abstract □ The absorption and metabolic fate of 7-chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one (I) was studied in rats, dogs, and humans. Orally administered I was readily absorbed by all species. In the rat, orally administered I was converted to its metabolite, 5-chlorosalicylic acid, by the intestinal wall. The half-lives of blood radioactivity, after the oral administration of I-9-^{14}C, were about 18 and 12 hr in the rat and beagle hound, respectively. In human subjects, no intact I was detected in the bloodstream; however, the clearance of the metabolite, 5-chlorosalicylic acid, had a half-life of about 33 hr. Cleavage of the oxazine ring of I generated 5-chlorosalicylic acid, which was excreted both in the free form and conjugated with glycine and glucuronic acid. The isoxazole moiety was converted to β-hydroxybutyric acid and its metabolites carbon dioxide and fumaric, citric, α-ketoglutaric, succinic, and malic acids. Binding of I to plasma proteins was extensive but was less than that of 5-chlorosalicylic acid.

Keyphrases □ 7-Chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one—absorption, distribution, and metabolic fate, rats, dogs, and humans □ 5-Chlorosalicylic acid—identified as major metabolite of 7-chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one in rats, dogs, and humans □ GLC—analysis, 7-chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one in plasma

7-Chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one (I) is a new orally active anti-inflammatory agent, which is chemically dissimilar to the steroids. Unlike most other clinically effective nonsteroidal anti-inflammatory agents, I is not ulcerogenic in the rat and does not induce GI blood loss as measured with ^{51}Cr-labeled rat blood cells (1). Studies on the absorption, distribution, metabolism, and excretion of I in rats, dogs, and human subjects are presented in this report.

EXPERIMENTAL

Materials—I-9-^{14}C and I-3-^{14}C were synthesized using a recently patented procedure (2). Since I has asymmetric carbon atoms at positions 2 and 3a and is obtained as a mixture of diastereoisomers, the chromatographic systems employed (Table I) were chosen carefully in order not to resolve the diastereoisomeric pairs.

Absorption in Rats—The small intestine of male Sprague–Dawley rats, 230–250 g, was rapidly filled with a solution of 90 μg/ml of I-9-^{14}C (2.13 μCi/ml), using a previously described technique (3). Constant blood volume was maintained by transfusion with blood from a donor animal. At appropriate intervals, samples were taken of hepatic portal and systemic blood, and portions of the contents of the intestinal lumen were removed. These materials were assayed for radioactivity and subjected to TLC. The developed plates were scanned for radioactivity, and the area under the trace was determined by integration to measure the ^{14}C in each zone.

Rat Intestine Preparation—Mature male Sprague–Dawley rats were exsanguinated, and the entire small intestine was excised. A fine mince was prepared by cutting the tissue with scissors and scalpels, and the preparation was centrifuged at 48,000×*g* at 4°. Three milliliters of the supernatant fluid was incubated at 37° with 2.0 ml of I-9-^{14}C (57 μg/ml, 1.35 μCi/ml) for 1.5 hr with shaking. Then an equal volume of acetone was added, and the mixture was again centrifuged. The supernatant fluid, containing over 95% of the radioactivity, was spotted on thin-layer plates and treated as already described.

Concentration in Circulating Blood—A solution containing 5 mg of I-9-^{14}C (129 μCi) dissolved in 0.5 ml of polyethylene glycol 400 was administered by stomach tube to each of six male Sprague–Dawley rats, weighing an average of 293 g. Six other rats received 0.5 mg of I-3-^{14}C (7.43 μCi) dissolved in 0.5 ml of the same vehicle. Blood samples were taken from the tail vein at appropriate intervals, and radioactivity was determined by liquid scintillation counting (4).

Beagle hounds, 7.6–10.2 kg, received single oral doses of I-9-^{14}C of 30.8 mg/kg (three animals, 42.9 μCi each), 66 mg/kg (one animal, 495 μCi), and 490 mg/kg (one animal, 1.98 μCi). At suitable intervals, blood was taken from the jugular vein and the plasma radioactivity of each sample was determined.

Human Studies—Six human volunteers each received 1500 mg of nonradioactive I. Heparinized blood samples were taken at various times postadministration and immediately centrifuged. The plasma was frozen until assayed by GLC.

Table I—TLC of Urinary End-Products of I

Compound	R_f[a] Solvent System A[b]	Solvent System B[c]
I	0.58	0.63
5-Chlorosalicylic acid	0.47	0.47
5-Chlorosalicyluric acid	0.35	0.16
5-Chlorosalicylic acid glucuronide	—	0.06

[a] Silica gel (Merck). [b] Benzene–methanol–acetic acid (180:32:16). [c] *n*-Butanol saturated with 2 *N* ammonia.

Urine was collected from each subject for 48 hr. A urine aliquot was adjusted to pH 6.4 with hydrochloric acid; then four volumes of 0.07 *M* pH 6.4 phosphate buffer, containing 100 units of β-glucuronidase[1], was added. The mixture was incubated for 18 hr at 37° and then assayed for 5-chlorosalicylic acid.

GLC Assays—The amount of I present in plasma was measured in concentrations of 1–10 μg/ml. Chloroform, 0.2 ml, containing 1.2 μg of dibutyl phthalate as the internal standard, was added to a 1-ml aliquot of plasma. The mixture was agitated on a vortex mixer for 30 sec and centrifuged for 10 min. The aqueous phase was discarded, and the remaining emulsion was disrupted by freezing in dry ice–acetone. The liquid phases were separated by centrifugation, and 1.4 μl of the chloroform extract was injected into a gas chromatograph[2] equipped with a flame-ionization detector.

The GLC conditions were: column, 1.2-m (4-ft) glass, 3-mm i.d. packed with 3.8% W-98 on Diatoport S, 80–100 mesh; column temperature, 198°; flash heater temperature, 250°; detector temperature, 252°; helium flow rate, 86 ml/min; hydrogen flow rate, 34 ml/min; oxygen flow rate, 600 ml/min; and range, 10 with an attenuation of 16×.

Freshly prepared samples of plasma containing known amounts of I were used as standards. The 5-chlorosalicylic acid content of plasma and urine samples was determined by GLC. The conditions for the extraction and assay were reported separately (5).

Stability in Blood and Plasma—Heparinized rat blood was obtained by cardiac puncture. A solution of 60 μg of I-9-^{14}C (136 μCi), dissolved in 1.0 ml of 0.07 *M* pH 7.4 phosphate buffer, was added to 4.0 ml of whole rat blood; the resulting mixture was incubated at 37° with stirring. Aliquots, 1.0 ml, were taken at the start and after 4 hr. The cells were removed by centrifugation, washed, and assayed for radioactivity. An equal volume of acetone was added to the plasma, and the mixture was again centrifuged. The clear supernatant fluid, containing essentially all radioactivity, was examined by TLC. Only one radioactive zone, corresponding to I, was detected.

One-milliliter aliquots of a solution of I in normal dog plasma, 10 μg/ml, were placed in stoppered tubes and stored at 4° or frozen and stored at −18°. At intervals, samples were removed and assayed for I by the described GLC procedure.

Tissue Distribution in Rats—A male Sprague–Dawley rat, 215 g, received 4.0 mg of I-9-^{14}C (95.8 μCi), dissolved in 1.0 ml of polyethylene glycol 400, by stomach tube. A second rat, 198 g, received a solution containing 2.9 mg of I-3-^{14}C (39.8 μCi) orally. Each animal was placed in a metabolism chamber for 24 hr and then sacrificed. The excreta, soft tissue organs, and remainder of the carcass were processed and analyzed for radioactivity as previously reported (4). Respiratory carbon dioxide was collected in 2.5 *N* sodium hydroxide, and the ^{14}C content of an aliquot of this solution was determined.

Isolation of 5-Chlorosalicylic Acid—Nonradioactive I was administered, 50 mg/kg ip, to two male beagle hounds. Pooled 24-hr urine was continuously extracted with carbon tetrachloride for 18 hr. The organic phase was separated, washed with water, and concentrated, and the residue was examined for unchanged I by TLC; no free drug was detected.

The urine remaining from the initial extraction was acidified with concentrated hydrochloric acid to pH 1 and continuously extracted for an additional 24 hr with carbon tetrachloride. The organic phase was separated, washed with acidified water, and evaporated to dryness under vacuum. The residue, which was recrystallized from methanol–water and then from water, was identified as 5-chlorosalicylic acid by melting point (171–172°), TLC characteristics, and IR spectrum, which were identical to those of authentic 5-chlorosalicylic acid.

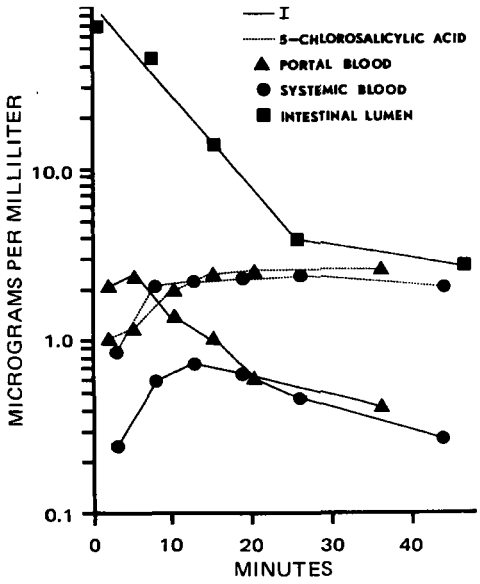

Figure 1—*Disappearance of I-9-^{14}C from rat intestine and the concentration of I and 5-chlorosalicylic acid in systemic and hepatic portal plasma, as determined by the area under a radiochromatogram trace.*

Inverse Isotope Dilutions—Inverse isotope dilution studies were performed using the urine of animals that had received labeled I. Typical procedures are described here.

I-9-^{14}C—A male Sprague–Dawley rat, about 250 g, received 2.5 mg of I-9-^{14}C (63.1 μCi), dissolved in 0.5 ml of polyethylene glycol 400, by stomach tube. Urine was collected for 24 hr and its radioactivity was measured. Inverse isotope dilutions were carried out on separate aliquots of urine.

1. Nonradioactive I, 1000 mg, was added to a 1.0-ml aliquot. Sodium carbonate solution, 5%, was added to adjust the pH to 9–10 and to prevent the extraction of 5-chlorosalicylic acid; the mixture was extracted three times with six volumes of chloroform. The chloroform phases were combined and evaporated to dryness. The

[a] Dog received a capsule containing I-9-^{14}C, 490 mg/kg, 1.98 μCi. [b] By a GLC procedure. [c] From the amount of radioactivity in the plasma.

residue, consisting of crude I, was repeatedly crystallized from ethyl acetate to constant specific activity, mp 150–151°.

2. Details of the procedures for quantitating 5-chlorosalicylic acid and 5-chlorosalicyluric acid by the isotope dilution technique were reported previously (6).

3. The metabolites in the urine present in a bound form were converted to the free form by hydrolysis. An aliquot was treated with an equal volume of concentrated hydrochloric acid, and the mixture was heated on a steam bath for 10 min. Nonradioactive carrier was then added, and the inverse isotope dilutions were carried out as with the free metabolites. Conjugated urinary end-products were calculated by difference.

4. Similar studies were performed on the urine of a dog that had received 502.2 mg of I-9-^{14}C orally.

I-3-^{14}C—A male Sprague–Dawley rat, 251 g, received 4.6 mg of I-3-^{14}C (62.6 μCi), dissolved in 1.0 ml of polyethylene glycol 400, by stomach tube. Urine was collected for 24 hr and assayed for radioactivity.

1. Nonradioactive sodium β-hydroxybutyrate, 1000 mg, was added to a 0.5-ml aliquot. A homogeneous solution resulted from the addition of 5 ml of water, 4 drops of 1 *N* hydrochloric acid, and 10 ml of ethanol. 2,4′-Dibromoacetophenone, 1.0 g, was added, and the mixture was heated at reflux for 2 hr. The resulting *p*-bromophenacyl ester was precipitated by the addition of water, washed with water, dried, and recrystallized from ethyl acetate–heptane to constant specific activity, mp 82–83°. The specific activity was corrected for the difference in the formula weight between the crystalline derivative and the sodium β-hydroxybutyrate added. This ester, *p*-bromophenacyl β-hydroxybutyrate, has not previously been reported.

Anal.—Calc. for $C_{12}H_{13}BrO_4$: C, 47.86; H, 4.35. Found: C, 48.11; H, 4.29.

2. Nonradioactive succinic acid, 1000 mg/kg, was added to another 0.5-ml aliquot of urine, and 10 ml of ethanol was added to give a homogeneous solution. This solution was evaporated to dryness under vacuum, the residue was triturated with hot ethyl acetate, and the insoluble material was discarded. The addition of heptane to the ethyl acetate solution separated crystals of succinic acid. These crystals were removed by filtration and recrystallized from ethyl acetate–heptane to constant specific activity, mp 185–186°.

3. The techniques for the isolation of α-ketoglutaric, fumaric, malic, and citric acids were similar to those for succinic acid.

Plasma Binding—The extent of binding was determined using a previously described procedure (3), except that the dialysis bags were placed in a solution of either 0.4 mg of I-9-^{14}C or 0.5 mg of 5-chlorosalicylic-7-^{14}C acid dissolved in 5 ml of buffer. The flasks were shaken at 20 ± 2° for 18 hr to ensure equilibration. TLC confirmed the stability of both I and 5-chlorosalicylic acid under the experimental conditions.

[a] Dogs received capsules containing I-9-^{14}C, 30.8 mg/kg, 42.9 μCi each. [b] By a GLC procedure. [c] From the amount of radioactivity in the plasma.

RESULTS

Absorption in Rats—The disappearance of radioactivity from the lumen of the intestine of an anesthetized rat, which had been rapidly infused with a solution of I-9-^{14}C, followed apparent first-order kinetics with a half-life of about 6 min. Results with a typical rat are shown in Fig. 1. After 25 min, more than 95% of the radioactivity of the administered dose had been absorbed and the clearance of ^{14}C from the gut lumen declined thereafter. The intestinal lumen contained intact drug for at least 20 min. After 46 min, in a single rat, less than 13% of the I remaining in the intestine had been hydrolyzed.

When the contents of the hepatic portal vein were investigated,

Feces	189,000	0.003	377,000	0.29
Recovery, %	99.7		101.6	

[a]Animals sacrificed 24 hr after drug administration. [b]Animal received 4.0 mg of I-9-^{14}C, 95.8 μCi. [c]Animal received 2.9 mg of I-3-^{14}C, 39.8 μCi. [d]Disintegrations per minute per milliliter.

however, substantial quantities of I had been converted into 5-chlorosalicylic acid. About 8 min after the drug solution filled the intestine, the portal plasma contained equal concentrations of the metabolite and I. Thereafter, more 5-chlorosalicylic acid than intact I was present. Examination of the blood in the systemic circulation showed that the concentration of intact I was less in systemic blood than in portal blood during the initial 20 min. However, after absorption from the intestine had declined, the concentrations of I in the systemic circulation and in the hepatic portal vein were the same (Fig. 1). These results suggest that the I was metabolized during its passage through the intestinal wall. The ability of a preparation of minced intestine to convert 41.5% of the I present into 5-chlorosalicylic acid during a 90-min incubation period confirmed the metabolic activity of intestinal tissue.

Concentration in Circulation—Peak levels of blood radioactivity were found about 2 hr after the oral administration of I-9-^{14}C to the rat. The clearance of ^{14}C from the bloodstream followed apparent first-order kinetics, with a half-life of about 18 hr (Fig. 2). Maximal blood radioactivity values were attained within 90 min of the oral administration of I-3-^{14}C to rats, and the first-order half-life was about 8 hr (Fig. 2).

The absorption and elimination of the radioactivity of 9-labeled drug in two beagle hounds are shown in Fig. 3. Apparent first-order kinetics were followed for the decline in blood radioactivity. After a 0.5-g dose, 66 mg/kg, the half-life was about 11.5 hr; the feces contained only about 5% of the ^{14}C of the dose after 48 hr. After a 5.0-g dose, 490 mg/kg, the half-life was about 13.2 hr; only 27% of the radioactivity of the dose was found in the feces after 48 hr.

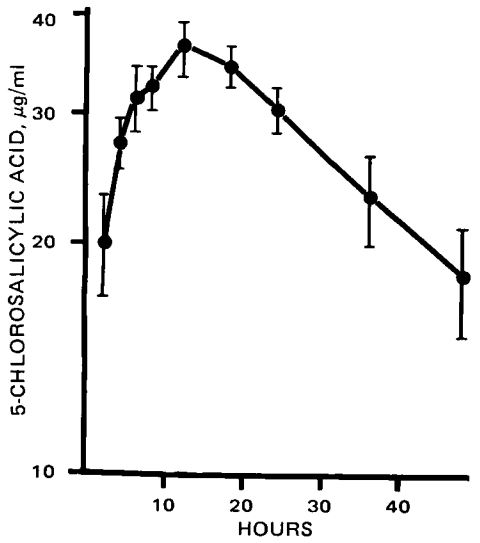

Figure 4—*Concentration of 5-chlorosalicylic acid in human plasma after oral administration of I (average of six subjects).*

Plasma samples from the dog that had received the larger dose were found by the GLC procedure to contain small amounts of I (Table II). Three other beagle hounds received 30.8 mg/kg of I-9-^{14}C; five of the samples, chosen at random, contained less than 1 μg/ml of intact I, as determined by GLC. The radioactivity of the samples was used to calculate the amount of 5-chlorosalicylic acid that would be present theoretically if all of the radioactivity were in that chemical form. The actual concentration of 5-chlorosalicylic acid was determined by GLC; the agreement between the theoretical and actual values is shown in Table III, which vividly demonstrates the extent of degradation of I to 5-chlorosalicylic acid.

Human Studies—Nonradioactive I was readily absorbed after oral administration to humans. No intact I could be detected in the plasma from any of the six subjects at either 2 or 4 hr after drug administration. However, the clearance of 5-chlorosalicylic acid, the metabolite of I, followed apparent first-order kinetics, with an estimated half-life of 33 hr (Fig. 4).

Incubation of the urine from four men who had ingested I with β-glucuronidase resulted in substantially higher levels of 5-chlorosalicylic acid, as determined by GLC (Table IV). Incubation of urine with buffer, in the absence of enzyme, had no effect. The nature of the bond between glucuronic acid and 5-chlorosalicylic acid was not determined.

GLC Assays—The relationship between peak height and the concentration of I was linear in the 1–10-μg/ml range. The repro-

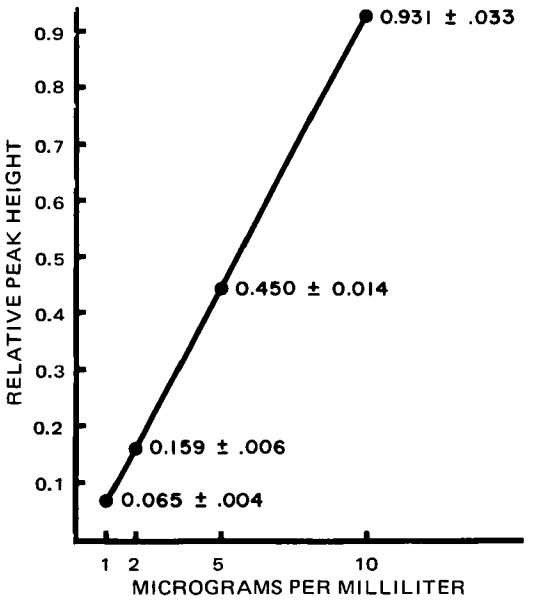

Figure 5—*Relationship between relative peak height and plasma concentration of I. Results are the means of quadruplicate determinations and are shown with their standard errors.*

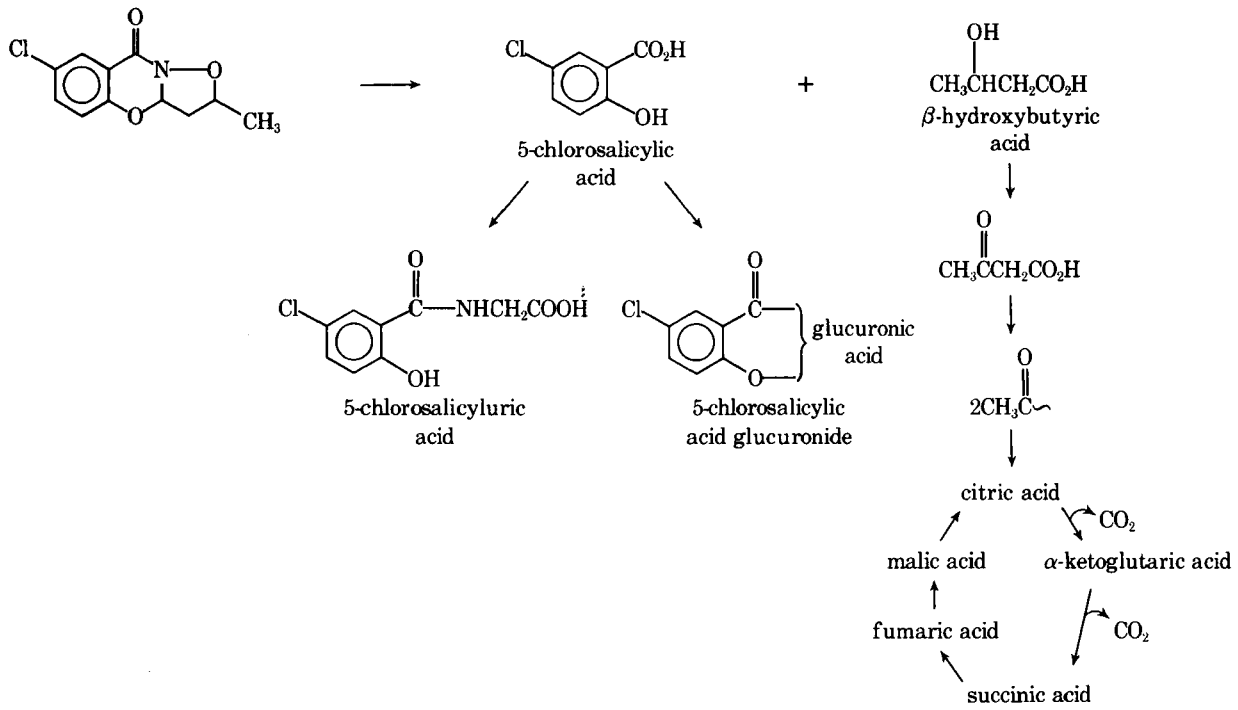

Scheme I

ducibility of the technique was shown by the standard errors of quadruplicate analyses (Fig. 5).

Stability in Blood and Plasma—Compound I was not degraded by incubation with whole rat blood for 4 hr. Furthermore, the compound was stable in dog plasma for at least 51 days when stored in the freezer and for at least a week when refrigerated.

Tissue Distribution in Rats—A study of the distribution of radioactivity after the oral administration of I-9-^{14}C showed that the kidneys were the major route of elimination of ^{14}C within the 24-hr experimental period. Significant amounts of radioactivity were also found in the carcass, GI tract, and liver at that time (Table V).

A similar study with the 3-labeled drug showed that the radioactivity of the isoxazole moiety is also eliminated in rat urine. About one-sixth of the ^{14}C was exhaled as respired carbon dioxide. The location of the remainder of radioactivity is shown in Table V.

Identification and Quantitation of Urinary End-Products—Four radioactive substances were detected by TLC in the urine of dogs that had received I-9-^{14}C (Table I). Assignment of the glucuronide structure to the 5-chlorosalicylic acid conjugate was based upon the liberation of additional compound upon treatment of the urine with β-glucuronidase.

The identities and amounts of the urinary metabolites of I-9-^{14}C in the rat and dog are shown in Table VI. The major end-product was 5-chlorosalicylic acid. In the dog, this metabolite occurred in an unbound form and accounted for three-quarters of the urinary radioactivity. In the rat, there were about equal amounts of free 5-chlorosalicylic acid and its glucuronic acid conjugate. In both species, lesser amounts of the glycine derivative of 5-chlorosalicylic acid, 5-chlorosalicyluric acid, were found. Small quantities of unchanged drug were excreted in the urine of both species.

Isotope dilution experiments on the urine of a rat that had received I-3-^{14}C showed the presence of β-hydroxybutyric acid and other acids of the tricarboxylic acid cycle (Table VII). The presence of these compounds suggests that the labeled carbon dioxide found in respired air (Table V) came from the decarboxylation of the oxidation products of β-hydroxybutyric acid by Krebs' cycle enzymes.

Plasma Binding—Compound I was bound appreciably to the plasma proteins of all species studied (Table VIII), but it was bound less extensively than 5-chlorosalicylic acid.

DISCUSSION

Part of orally administered I is hydrolyzed upon passage through the intestinal wall during the absorption of the drug. The ability of the gut to hydrolyze I was verified by *in vitro* studies. No intact drug could be detected in the systemic circulation, unless the administered dose of I was very large; at a dose of 490 mg/kg, the maximum plasma concentration attained was only 8 μg/ml.

Since I was stable in blood and plasma, the unaltered drug that was absorbed into the circulation and subsequently converted into 5-chlorosalicylic acid was not hydrolyzed by plasma enzymes but was probably degraded by liver enzymes. In any event, labeled 5-chlorosalicylic acid was the metabolite of I-9-^{14}C that was present in the bloodstream, and this metabolite accounted for virtually all of the radioactivity of the administered drug.

Table VI—Quantitation of I-9-^{14}C Urinary End-Products in Rat and Dog

Urinary End-Product	Urinary Radioactivity, % Rat[a]	Dog[b]
5-Chlorosalicylic acid		
Free	46.1	73.6
Conjugated	47.7	7.3
5-Chlorosalicyluric acid		
Free	1.3	4.2
Conjugated	n.d.[c]	5.4
I	0.3	6.2
Total radioactivity recovered	95.4	96.7

[a] This rat received 2.5 mg of drug orally. [b] The dog received 502.2 mg of I-9-^{14}C orally. [c] None detected.

Table VII—Quantitation of I-3-^{14}C Urinary End-Products in Rat

Urinary Metabolite	Urinary Radioactivity[a], %
β-Hydroxybutyric acid	19.1
Citric acid	10.9
α-Ketoglutaric acid	24.9
Succinic acid	15.8
Fumaric acid	18.4
Malic acid	12.9
Total radioactivity recovered	102.0

[a] This rat received 4.6 mg of I-3-^{14}C orally.

Table VIII—Binding of I and 5-Chlorosalicylic Acid to Plasma

Species	Percent Bound[a]	
	I[b]	5-Chlorosalicylic Acid[c]
Human	80.5	99.4
Sprague—Dawley rat	54.6	71.1
Rhesus monkey	83.2	97.2
Beagle dog	78.9	97.5
Control, buffer only	−1.7	0.3

[a] Average of duplicates. [b] Initially there was 0.4 mg of I to be partitioned between 5 ml of plasma and 5 ml of buffer. [c] Initially there was 0.5 mg of 5-chlorosalicylic acid to be distributed between 5 ml of plasma and 5 ml of buffer.

In all three species, rat, dog, and human, cleavage of the oxazine ring of I yielded 5-chlorosalicylic acid, which was excreted into the urine in the free form and as conjugates with glucuronic acid and glycine.

The radioactivity from 3-labeled I appeared as respiratory carbon dioxide in exhaled breath and as β-hydroxybutyric acid and its metabolites fumaric, citric, α-ketoglutaric, succinic, and malic acids in the urine.

The metabolic fate of I is summarized in Scheme I.

CONCLUSIONS

The present study showed that I was converted to 5-chlorosalicylic acid by rats, beagle hounds, and humans and that the chemical entity present in the systemic circulation after the oral administration of I was not the intact drug but was the metabolite, 5-chlorosalicylic acid. The latter compound was excreted through the kidneys either free or conjugated with glucuronic acid and glycine. Elements of the isoxazole ring were converted to β-hydroxybutyric acid, which was metabolized by enzymes of the citric acid pathway.

Comparative Anti-Inflammatory, Analgesic, and Antipyretic Activities of 7-Chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one and 5-Chlorosalicylic Acid in Rats

R. D. SOFIA [x], W. DIAMANTIS, and B. J. LUDWIG

Abstract □ Evidence is presented which indicates that 7-chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one (I) and 5-chlorosalicylic acid, its major metabolic end-product, are equally effective as anti-inflammatory and antipyretic agents, while the former is a somewhat more effective analgesic than its metabolite in the rat. However, at the equimolar doses used in this study, I is not ulcerogenic, while 5-chlorosalicylic acid does possess this untoward effect in the fasted rat. Moreover, the LD_{50} for 5-chlorosalicylic acid (261.0 mg/kg) is approximately 6.5 times less than that of I (1710.0 mg/kg) in the nonfasted rat. These results support the postulation that 5-chlorosalicylic acid is most likely responsible for the pharmacological activity displayed by I; *i.e.*, the latter acts as a carrier or delivery system, allowing attenuation of the toxic properties of its active metabolite.

Keyphrases □ 7-Chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one—anti-inflammatory, analgesic, and antipyretic activities compared to 5-chlorosalicylic acid, rats □ 5-Chlorosalicylic acid—anti-inflammatory, analgesic, and antipyretic activities compared to 7-chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one, rats □ Anti-inflammatory activity—7-chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)-(1,3)-benzoxazin-9-one and 5-chlorosalicylic acid compared in rats □ Analgesic activity—7-chloro-3,3a-dihydro-2-methyl-2*H*,-9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one and 5-chlorosalicylic acid compared in rats □ Antipyretic activity—7-chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3) - benzoxazin-9-one and 5-chlorosalicylic acid compared in rats

7-Chloro-3,3a-dihydro-2-methyl-2*H*,9*H*-isoxazolo-(3,2-*b*)(1,3)-benzoxazin-9-one[1] (I) has been reported to be an orally effective nonsteroidal anti-inflammatory, analgesic, and antipyretic agent in rats (1). Unlike most other clinically useful nonsteroidal anti-inflammatory drugs, I is not ulcerogenic at markedly effective doses nor does it promote GI blood loss. In addition, I has a mild diuretic action, which does not contribute to its anti-inflammatory action.

The preceding study (2) showed that, in both the

rat and dog, orally administered I was converted to its metabolite 5-chlorosalicylic acid by the intestinal wall during absorption. In addition, Edelson *et al.* (2) revealed that very little intact I could be detected in the systemic circulation. Moreover, these investigations (2) showed that absorption of I from the GI tract is not rate limiting. Since 5-chlorosalicylic acid appears to be the major metabolite of I, it was of interest to determine to what extent it might be contributing to the pharmacological properties of I. This report describes the results of a direct comparative study of I and 5-chlorosalicylic acid in various test systems.

EXPERIMENTAL

Animals—Male rats of the Sprague–Dawley strain[2] were used. They were allowed to acclimate to the laboratory environment for at least 5 days prior to use, with food and water allowed *ad libitum*.

Carrageenan-Induced Edema—A modification of the method of Winter *et al.* (3) was used. At least six rats, 100–120 g, were used at each dose level tested. All doses of I and 5-chlorosalicylic acid were prepared as suspensions in a 1% acacia vehicle for this and subsequent experiments unless otherwise stated.

Drugs were administered orally by gavage in a volume of 0.5 ml/100 g of body weight. One hour after dosing, 0.05 ml of a 1% solution of calcium carrageenan was injected subcutaneously into the plantar surface of the right hindpaw of each rat. The volume of the injected foot was measured by water displacement to the lateral malleolus immediately before drug administration and again 3 hr after carrageenan injection. The difference between the two was called the edema volume.

The mean edema volume was determined for each experimental group. An ED_{50} value, defined as that dose at which the edema volume was decreased by 25% or greater in 50% of the rats studied, was determined by the method of Litchfield and Wilcoxon (4).

Adjuvant-Induced Polyarthritis—Polyarthritis was induced in rats, 150–170 g at the start of the experiment, by injection of heat-killed *Mycobacterium tuberculosis* organisms (5). Each animal received 0.1 ml of adjuvant suspension (0.5% in heavy mineral oil) injected subcutaneously into the plantar surface of the right hindfoot. At least eight individually caged rats were used in each test group.

Appropriate concentrations of I and 5-chlorosalicylic acid were blended into a commercial diet, and the resulting mixtures were fed continuously to the test animals beginning immediately after injection of *M. tuberculosis*. The animals were maintained on this drug–diet admixture for the duration of the experiment, *i.e.*, 21 days. Nonarthritic (normal) and arthritic control animals received only the commercial diet. Beginning on Day 0 and subsequently on Days 7, 14, and 21 of the experiment, the following parameters were measured: drug–diet consumption, injected and uninjected hindpaw volumes, and body weight.

Group mean drug dosage was calculated from food consumption and body weight data. Following all measurements on Day 21, each rat was sacrificed by decapitation and a 2- or 3-ml blood sample was collected in heparinized vials. Erythrocyte sedimentation rate (6) and serum albumin/globulin ratios (7) were determined.

Analgesic Activity—The paw pressure method described by Randall and Selitto (8) was used to measure the analgesic effectiveness of I and 5-chlorosalicylic acid in rats (100–120 g). Inflammation was produced in the right hindpaw of each rat by injection of 0.1 ml of a 20% suspension of brewer's yeast in saline. One hour later, all rats (eight per group) received the test drug or vehicle orally (0.5 ml/100 g of body weight).

Pain threshold was measured[3] 1 hr following drug administration by applying pressure to the inflamed paw at a steadily increasing rate of 14 g/sec. The end-point, or pain threshold, was defined as that pressure necessary to cause the animals to struggle and/or vocalize. An analgesic effect was denoted if the individual reaction thresholds were 2 SD or greater than the mean threshold for the vehicle-treated control group (9). An ED_{50} value was determined (4) based on this all-or-none response.

Antipyretic Activity—Eighteen hours before oral drug administration, rats (~200 g) were rendered pyretic by subcutaneously injecting a 15% suspension of brewer's yeast (1.0 ml/100 g of body weight) according to the method of Smith and Hambourger (10). At least eight rats were used for each dose of drug and for fevered and nonfevered control groups.

Rectal temperatures were determined before the yeast injection and immediately before (designated the 0-hr reading) and at 2 and

Table III—Oral Analgesic Effectiveness of Compound I and 5-Chlorosalicylic Acid in Rats as Measured by the Randall–Selitto Paw Pressure Test

Drug	Analgesia		Acute Toxicity		Therapeutic Index, LD_{50}/ED_{50}
	ED_{50} (95% C.L.), mg/kg	m*M*[a]	LD_{50} (95% C.L.), mg/kg	m*M*[a]	
I	84.0 (46.4—152.0)	0.35	1710.0 (1335.0—2190.0)	7.16	20.4
5-Chlorosalicylic acid	182.0 (92.0—360.0)	1.06	261.0 (193.0—352.0)	1.52	1.4

[a] ED_{50} or LD_{50} values are expressed as millimolar.

4 hr after oral drug administration. These measurements were recorded on a telethermometer[4] from a thermistor probe inserted a constant depth of 5.0 cm.

Drug-Induced Gastric Lesions—Ulcerogenic activity was studied by a method similar to that described by Domenjoz (11). Rats (~200 g), in groups of at least six, received the test drug or vehicle orally at 9 am and 4 pm on the test day. These animals were fasted for 18 hr prior to dosing, but they had access to water throughout the experiment beginning 0.5 hr prior to drug administration.

Each rat was sacrificed by chloroform inhalation 24 hr after the first dosing; its stomach was removed, opened along the greater curvature, and examined with a dissecting microscope for the presence of gastric ulcers. Animals with stomachs exhibiting at least one ulcer were considered positive responders. Statistical comparison among groups was carried out using the χ-square test with the Yates correction.

Toxicity—Single-dose oral LD_{50} values for I and 5-chlorosalicylic acid were determined in nonfasted rats (150–170 g) 24 hr and 7 days following drug administration. Ten rats per treatment group and at least three doses were used in this study. The number of animals dead in each group at each time interval was tallied and LD_{50} values were calculated (4).

RESULTS

Carrageenan-Induced Edema—Compound I and 5-chlorosalicylic acid were orally effective inhibitors of carrageenan-induced hindpaw edema in rats (Table I). When a comparison of their ED_{50} values was made, both compounds were equally potent anti-inflammatory drugs. The acute oral LD_{50} values for these compounds and their corresponding therapeutic index (LD_{50}/ED_{50}) were also calculated. Lethalities following a single oral administration of various doses of I or 5-chlorosalicylic acid occurred within the first 24 hr; hence, LD_{50} values for this period and for the 7-day observation period were identical. Although not depicted graphically, this comparison is valid since the slopes of the dose–response curves to determine the ED_{50} and LD_{50} of each drug are parallel. Table I reveals that although both compounds did not differ in their anti-inflammatory potency, I possessed a therapeutic index nearly five times greater than that observed for the metabolite.

Assuming that I (mol. wt. 239) was completely biotransformed to 5-chlorosalicylic acid (mol. wt. 172), justification for transformation of ED_{50} and LD_{50} values to millimolar units was warranted. Although the ED_{50} for I was somewhat, but not statistically significantly, greater than 5-chlorosalicylic acid, its corresponding millimolar value (0.144) was identical to that of its major metabolite (0.150).

Adjuvant-Induced Polyarthritis—Results of a comparative study of the prophylactic effect of I and 5-chlorosalicylic acid on adjuvant-induced polyarthritis in rats are shown in Table II. Dietary concentrations of 0.1 and 0.2% (approximately 75.0 and 150.0 mg/kg/day) of each drug significantly inhibited the development of adjuvant-induced polyarthritis. Enlargement of the injected foot (primary lesion) was markedly inhibited by each drug in a dose-related manner. However, the metabolite was significantly more effective than identical doses of I, with the highest concentration (0.2% or 150.0 mg/kg/day) of the former completely suppressing edema formation.

Similarly, a dose-dependent reduction of swelling in the contralateral, uninjected hindpaw (secondary lesion) was observed for each drug. The high concentration of I (0.2% or 150.4 mg/kg/day), as well as the low concentration of 5-chlorosalicylic acid (0.1% or 74.3 mg/kg/day), completely abolished this secondary involvement associated with adjuvant disease. On the other hand, the volume of the uninjected hindpaw of rats receiving the 0.2% drug–diet admixture of 5-chlorosalicylic acid was markedly less than the nonarthritic control group.

When the milligram per kilogram doses of I and 5-chlorosalicylic acid are converted to millimolar values (Table II), it is apparent that the millimolar doses of the latter compound are approximately 35% greater. This fact most likely accounts for the slightly greater activity of 5-chlorosalicylic acid against adjuvant-induced polyarthritis.

Another prominent manifestation of adjuvant-induced polyarthritis was a significant attenuation of body weight gain over the 21-day period, *e.g.*, 61.0 g for the arthritic controls compared to 139.0 g for the nonarthritic controls or approximately a 56.2% reduction (Table II). Suppression of body weight gain in arthritic animals treated with I or 5-chlorosalicylic acid was not restored to the rate of gain displayed by the nonarthritic control group. However, a trend toward normal body weight gain was noticed in the 0.1% I-treated (91.5 g) and 5-chlorosalicylic acid-treated (82.5 g) groups, since they gained significantly more weight than the arthritic control rats. But 0.2% of 5-chlorosalicylic acid further retarded body weight gain.

Table II also reveals that the erythrocyte sedimentation rate was markedly increased while the serum albumin/globulin ratio was severely lowered in adjuvant-induced polyarthritis. Compound I, as a 0.2% drug–diet admixture, significantly reversed the elevated erythrocyte sedimentation rate to the level of the nonarthritic control group. This effect was dose related, since the lower concentration (0.1%) of I did not significantly affect this measurement, although a trend was apparent.

Both concentrations of 5-chlorosalicylic acid were equally effective in completely reversing this elevated erythrocyte sedimentation rate. Likewise, the altered serum albumin/globulin ratio was partially restored by each concentration of I, whereas the 0.1% drug–diet admixture of the metabolite completely protected rats from this phenomenon. When the concentration of 5-chlorosalicylic acid in the diet was raised to 0.2%, serum albumin/globulin ratios were significantly elevated beyond the value for nonarthritic control rats.

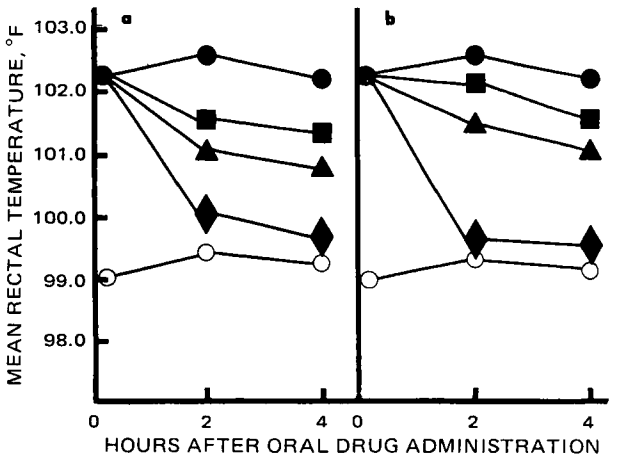

Figure 1—*Antipyretic activity of Compound I (a) and 5-chlorosalicylic acid (b) in rats with yeast-induced fever. Key: ●, fevered controls; ○, nonfevered controls; ■, 25.0 mg/kg; ▲, 50.0 mg/kg; and ♦, 100.0 mg/kg.*

Table IV—Comparative Ulcerogenic Activity of Compound I, 5-Chlorosalicylic Acid, and Phenylbutazone in Rats[a]

Drug	Oral Dose, mg/kg (m*M*) bid	Number of Rats with Stomach Ulcers: Number of Animals Studied	Mortality
1% Acacia	—	0/44	0/44
I	139.0 (0.58)	0/15	0.15
	208.5 (0.87)	0/15	0/15
5-Chloro-	100.0 (0.58)	1/38	0/38
salicylic acid	150.0 (0.87)	11/28**	10/28*
Phenylbutazone	150.0 —	16/18***,†	0/18‡

[a] *$p < 0.05$, **$p < 0.02$, ***$p < 0.001$ when compared to the group receiving the high dose of I (208.5 mg/kg bid). †$p < 0.01$, ‡$p < 0.02$ when compared to the group receiving the high dose of 5-chlorosalicylic acid (150.0 mg/kg bid).

Analgesic Activity—Compound I and 5-chlorosalicylic acid were both orally effective analgesic agents when evaluated in rats using the Randall–Selitto paw pressure test (Table III). However, I was approximately 2.2 and 3.9 times more potent than its metabolite on a milligram per kilogram and millimolar basis, respectively. When the acute lethality of these compounds is considered, I has a substantially higher therapeutic index (20.4) than 5-chlorosalicylic acid (1.4).

Antipyretic Activity—When administered at oral doses (25.0, 50.0, and 100.0 mg/kg) which did not affect rectal temperature in nonpyretic rats, I and 5-chlorosalicylic acid significantly reduced fever 2 and 4 hr after dosing (Fig. 1). This activity was dose related for each compound, with the 100.0-mg/kg dose returning rectal temperature back to normal (nonfevered control). Moreover, the overall antipyretic effectiveness of I and 5-chlorosalicylic acid was nearly identical.

Drug-Induced Gastric Lesions—Following oral administration of markedly effective anti-inflammatory doses (total doses of 278.0 and 417.0), I did not produce gastric ulcers nor was it fatal to rats (Table IV). 5-Chlorosalicylic acid produced ulcers in 39% and killed 36% of the rats receiving a total dose of 300.0 mg/kg, which was equimolar to the high dose of I. Likewise, a 300.0-mg/kg total dose of phenylbutazone, a nonsteroidal anti-inflammatory agent with a propensity for ulcerogenesis, produced ulcers in 89% of the rats dosed but was not lethal. These data indicate that phenylbutazone is significantly more ulcerogenic than 5-chlorosalicylic acid and that each of these compounds is excessively ulcerogenic compared to I.

DISCUSSION

The results of the present investigation clearly demonstrate that both I and 5-chlorosalicylic acid, its major biotransformation product, were effective anti-inflammatory, analgesic, and antipyretic agents in the rat. On a milligram per kilogram basis, I and its metabolite were equally effective inhibitors of carrageenan-induced edema and brewer's yeast-induced pyresis. However, I was slightly, but significantly, less effective than 5-chlorosalicylic acid in the adjuvant-induced polyarthritis test when both were studied as 0.1 and 0.2% drug–diet admixtures. On the other hand, I was approximately 2.2 times as potent as 5-chlorosalicylic acid in its analgesic effectiveness.

A toxic manifestation shared by most clinically useful nonsteroidal antiarthritic compounds, including the salicylates, administered acutely or for long periods to laboratory animals (12) and humans (13) is a propensity to induce GI disturbances such as ulceration. Results obtained with I (Table IV) reveal that total doses as high as 417.0 (or 208.5 mg/kg bid) given orally did not induce ulcer formation in fasted rats. However, an equimolar dose of 5-chlorosalicylic acid (total dose of 300.0 or 150.0 mg/kg bid) not only caused ulcers to occur but proved fatal to a substantial number of the rats dosed. Likewise, phenylbutazone was markedly ulcerogenic but not lethal at 300.0 mg/kg. In a previous study (1), ulcer formation as well as lethality did occur following oral administration of a higher total daily dose of 600.0 mg/kg (or 300.0 mg/kg bid) of I.

Similarly, inspection of the LD_{50} values obtained following a single oral dose of I or its metabolite (Tables I and III) to nonfasted rats points out another striking difference in the toxicity of these two compounds. 5-Chlorosalicylic acid (261.0 mg/kg) was approximately 6.5 times as toxic as I (1710.0 mg/kg). The calculated LD_{50} for I in the present investigation closely correlates with the value of 1660.0 mg/kg for the nonfasted rat obtained in earlier experiments (1). Moreover, all deaths following oral administration of these compounds occurred within the first 24 hr.

The LD_{50} data reported for the nonfasted rat in this study, along with lethality data obtained previously (1) for nonfasted and fasted rats, clearly suggest that I is more toxic to fasted rats. This finding is not unreasonable since Zbinden (14) pointed out that many compounds are more toxic in fasted as compared to nonfasted rats. Therefore, this point may explain the discrepancy observed between the doses that were lethal and induced ulcer formation in the previous study (1) and the findings obtained in this study.

Based on the results of this investigation, it appears reasonable to speculate that 5-chlorosalicylic acid, the major metabolic product of I (2), may be largely responsible for the anti-inflammatory and antipyretic properties of this compound and, to a lesser degree, for its analgesic effectiveness. However, the profound ulcerogenic and lethal activity of 5-chlorosalicylic acid is avoided when this compound is metabolically generated following administration of I. As pointed out previously (2), orally administered I was converted to 5-chlorosalicylic acid as it passed through the intestinal wall. Therefore, I most likely functions as a carrier or unique delivery system for 5-chlorosalicylic acid *in vivo*, permitting manifestation of its beneficial pharmacological properties with complete avoidance of its deleterious GI effects.

Pharmacokinetic Model for a Primary Antibody Response

ARTHUR CAMMARATA ˣ, JOSEPHINE SMITH, and NORMAN P. WILLETT

Abstract □ Antigen distribution and clearance studied *in vivo* may be viewed as a pharmacokinetic problem complicated by the intervention of the immune response. A model characterizing the clearance of the simple antigen ϕX174 from the bloodstream of various experimental animals, as well as the subsequent serum antibody response, was developed. The present model is the simplest of the possible models and no doubt will have to be modified when considering more complex antigens, additional distribution modes, and differences in antibody reactivity. For the primary (IgM) immune response, however, early events in the immunological response can be adequately accounted for in a consistent and quantitative manner.

Keyphrases □ Antibody response, primary—pharmacokinetic model developed □ Antigens—distribution and clearance, pharmacokinetic model described for primary antibody response □ Pharmacokinetic models—primary antibody response

The time course during which drugs are absorbed, distributed, metabolized, and excreted is commonly studied by using pharmacokinetic models (1, 2). A pharmacokinetic model takes into account the various ways by which a drug may be distributed between different body compartments and attempts to account quantitatively for the disposition of drug in any one compartment at any time. Particular compartments, such as blood or urine, may be explicitly identified because there are the biophases assayed for drug content.

However, other compartments, such as adipose tissue, have their presence implied from the nature of the drug concentration–time profile. A model is constructed depicting the transfer of drug from one compartment to another, the transfer being characterized by one or more rate constants, and subsequently a mathematical expression is derived to replicate the observed drug concentration–time profile. As a number of models may serve to fit the same data, it is usual to prefer the scheme that involves the fewest number of possible compartments and is compatible with experimental results.

In certain immunological studies, it is the practice to inject an antigen into a test animal and to assay blood samples, withdrawn at timed intervals, for remaining antigen and for the presence of antibody. Antigen distribution and clearance, when studied in this manner, may be viewed as a pharmacokinetic problem complicated by the intervention of the immune response. With this perspective, a pharmacokinetic model was developed which accounts for the major events taking place in the initiation of the primary (IgM) immune response. This model deals only with early events in the primary antibody response; that is, IgM is considered to be the sole antibody involved in the removal of antigen from the circulation.

In constructing the model, use is made of generally accepted concepts regarding the nature of the primary antibody response. It is shown that this model characterizes the primary immune response toward the bacteriophage ϕX174 in different mammalian species. With antigens more complex than ϕX174, a more involved pharmacokinetic model may be necessary.

MODEL

Construction—Injection of small amounts of an antigen, such as ϕX174, into the circulatory system of guinea pigs (3, 4), mice (5, 6), or fetal lambs (7) provides a means of following the primary antibody response in a quantitative manner. The elimination of antigen from the circulation occurs in two phases (Fig. 1). The first and slower elimination is due to nonimmune catabolism, while the second and rapid elimination is interpreted as being caused by the production and release into the circulation of specific antibody (3, 4). Designating A as the amount of antigen and B as the amount of antibody present at a particular time t, antigen elimination may be represented by either of three generalized competing pathways:

$$A \xrightarrow{k_p} \text{nonimmune elimination}$$

$$A + B \xrightarrow{k_c} \text{immune elimination}$$

Scheme I

$$A \xrightarrow{k_p} \text{nonimmune elimination}$$

$$A + B \xrightarrow{k_c} AB \xrightarrow{k_a} \text{immune elimination}$$

Scheme II

$$A \xrightarrow{k_p} \text{nonimmune elimination}$$

$$A + B \underset{k_r}{\overset{k_f}{\rightleftharpoons}} AB \xrightarrow{k_a} \text{immune elimination}$$

Scheme III

where k_p, k_c, k_a, k_f, and k_r are rate constants and AB represents the amount of antigen–antibody complex. Both the antigen and the antigen–antibody complex are thought to be removed through the reticuloendothelial system (8), which suggests that the pathways (Schemes I–III) should have a common elimination compartment. However, since blood levels of antigen are monitored and not contents of the elimination compartment, it is permissible to view the nonimmune and immune clearances as separate competing elimination modes.

Scheme I shows the more general clearance model; it simply designates that antigen may be removed from the circulation either by nonimmune catabolism or by reaction with antibody. The rate law appropriate to elimination of antigen by this pathway is given by:

$$-\frac{dA}{dt} = k_pA + k_cA(B) \qquad \text{(Eq. 1)}$$

Scheme II designates that, in the immune elimination, the antigen–antibody complex is formed in an irreversible manner and that the complex is eliminated. So long as only antigen blood levels are monitored, the rate law for this pathway is indistinguishable from Eq. 1. Scheme III is similar to Scheme II insofar as the antigen–antibody complex is the species eliminated due to the immune response. However, it differs from Scheme II by considering the formation of the antigen–antibody complex to be reversible. In this instance, the rate law appropriate to antigen elimination, under steady-state conditions, is given by:

$$-\frac{dA}{dt} = k_pA + \left(\frac{k_fk_a}{k_r + k_a}\right)A(B) \qquad \text{(Eq. 2)}$$

Equation 2 differs from Eq. 1 by having a more complex form to the second-order rate constant, but Eqs. 1 and 2 are kinetically indistinguishable in practice. For practical purposes, then, antigen elimination may be represented by the rate law:

$$-\frac{dA}{dt} = k_p A + k_o A(B) \qquad \text{(Eq. 3)}$$

where k_o is the experimental second-order rate constant.

Equation 3 can serve as a basis for interpreting ϕX174 clearance curves if an expression for B can be arrived at that allows integration. This problem may be approached by noting that antigen stimulates lymphocytes toward replication and differentiation into mature plasma cells. Mature plasma cells are nonreplicating, and the number of these cells ultimately produced seems to depend on the amount of initially administered antigen (3, 4, 9). The population P of these nonproliferating antibody-producing cells at any time t may then be denoted by the expression:

$$P = P_A(1 - e^{-k_d t}) \qquad \text{(Eq. 4)}$$

in which P_A is the optimum population of these cells achieved for a particular initial dose of antigen, and k_d is a parameter characterizing the rate of differentiation.

For extended periods, much longer than the time period of present concern, the tendency for mature plasma cells to "die off" after having attained their optimum number must be considered. This can be done by representing the population of antibody-producing cells P as subject to the consecutive process:

$$U \xrightarrow{k_d} P \xrightarrow{k_i} \text{nonantibody producing cells}$$

Scheme IV

where U is the population of replicating cells from which differentiation is occurring, and k_i is a constant characterizing the inactivation of mature plasma cells. By presuming that both differentiation and inactivation are apparent first-order processes, the population of antibody-producing cells is represented by:

$$P = \frac{k_d U_A}{k_i - k_d}(e^{-k_d t} - e^{-k_i t}) \qquad \text{(Eq. 5)}$$

where, by this representation, U_A is viewed as the total number of lymphocytes stimulated to divide by a given dose of antigen. Earlier models for Scheme IV (10, 11) were not as explicit as Eq. 5.

Within the timespan during which Eq. 4 is useful in characterizing the population of antibody-producing cells, it may be presumed that the amount of antibody liberated from the antibody-producing cells is reflective of their population (11). In the simplest instance, the amount of antibody produced is directly proportional to the number of antibody-producing cells:

$$B = k_b P \qquad \text{(Eq. 6)}$$

where k_b is a constant characterizing the average amount of antibody produced per cell. This relationship seems reasonable, since it has been demonstrated that the amount of antibody present has no effect on the production of antibody or on the proliferation of antibody-producing cells (12).

Substitution of Eq. 4 into Eq. 6 provides an expression for the average amount of antibody present at any time:

$$B = B_A(1 - e^{-k_d t}) \qquad \text{(Eq. 7)}$$

where $B_A = k_b P_A$. Upon introducing Eq. 7 into Eq. 3 and solving, the resulting expression is:

$$\ln\left(\frac{A}{A_0}\right) = -(k_p + k_A)t + \frac{k_A}{k_d}(1 - e^{-k_d t}) \qquad \text{(Eq. 8)}$$

Here $k_A = k_o B_A$, and A_0 is the initial amount of antigen in the blood. Equation 8 thus represents the amount of antigen in the circulation at any time.

Application—A typical clearance curve for the elimination of the bacteriophage ϕX174 from the blood of a mouse (Swiss male) is shown in Fig. 1. Equation 8 allows this curve to be readily interpreted. There is minimal production of antibody, implying $k_A = 0$,

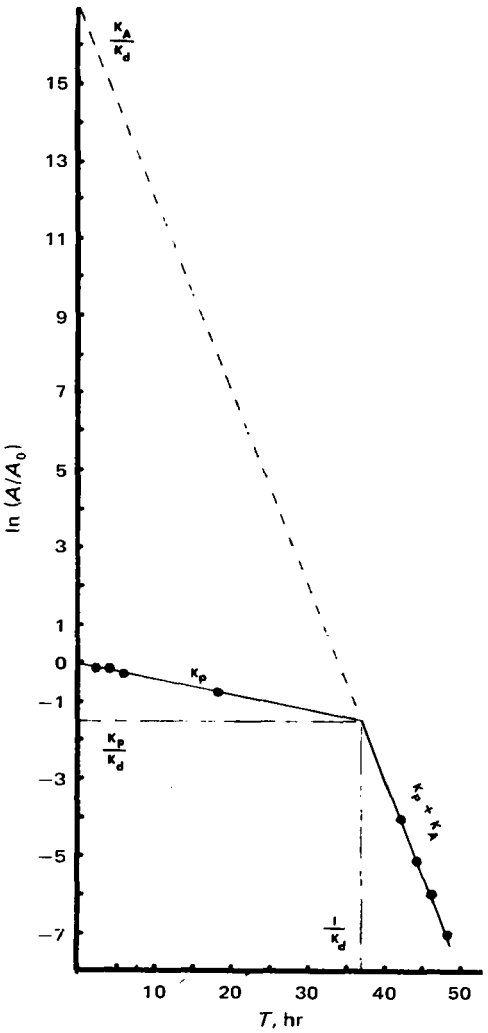

Figure 1—*Clearance curve for the elimination of the bacteriophage ϕX174 from the blood of a mouse (Swiss male).*

in the time period immediately following injection of antigen. During this stage, the elimination of antigen can be characterized by:

$$\ln\left(\frac{A}{A_0}\right) = -k_p t \qquad \text{(Eq. 9)}$$

As antibody production increases, the competition between nonimmune and immune antigen elimination modes becomes evident by a curvature in the clearance curve (not shown in Fig. 1). This competitive elimination is characterized by Eq. 8. When antigen-stimulated antibody production is at its optimum, the exponential term in Eq. 8 becomes negligible and Eq. 8 reduces to:

$$\ln\left(\frac{A}{A_0}\right) = -(k_p + k_A)t + \frac{k_A}{k_d} \qquad \text{(Eq. 10)}$$

Computer simulations showed that, with k_d in the 0.02–0.40 range, Eq. 8 reduces to Eq. 10 well within the time of a clearance experiment.

The linear equations (Eqs. 9 and 10) provide a basis for obtaining the individual rate constants from the clearance curves. A least-squares fit of the experimental points for the nonimmune and immune clearances of antigen is made to gain estimates for the slopes and intercepts represented in the respective relations. Nonimmune clearance provides the slope k_p, while immune clearance gives a slope of $k_p + k_A$. The difference between the two slopes provides an estimate for k_A. The reciprocal of the intercept for the immune clearance least-squares equation is identified as k_d/k_A. Hence, multiplication by k_A provides an estimate of k_d.

An alternative, and more precise, means of gaining an estimate

for k_d involves equating the two least-squares equations for nonimmune and immune clearances to determine the point of intercept. Equating the doses leads to an estimate of the inflection time:

$$t_i = \frac{1}{k_d} \qquad \text{(Eq. 11)}$$

while equating the times leads to an estimate for the inflection dose:

$$\ln\left(\frac{A_i}{A_0}\right) = -\frac{k_p}{k_d} \qquad \text{(Eq. 12)}$$

These estimates are shown schematically in Fig. 1. The reciprocal of the inflection time provides k_d.

RESULTS AND DISCUSSION

Table I summarizes values for the rate constants k_p, k_A, and k_d, which have been estimated from Fig. 1 and from similar studies (3–7). When literature values were used for the estimates, only those clearance curves having at least three experimental values describing nonimmune and immune clearances were analyzed by least squares. A comparison of the values suggests the following:

1. The rate of nonimmune clearance, as measured by k_p, is essentially independent of the administered dose of antigen and seems to differ from one mammalian species to another. This is consistent with the well-known species variation in the phagocytic index (13). The agreement between the values of k_p for the mouse should be noted, because the clearance curves were obtained in three independent laboratories. Comparison between the results gained in separate laboratories is possible since the magnitude of experimental slopes, and not points, is compared. Therefore, while the level of response of an animal toward clearing antigen may vary, the time course of clearance as measured by k_p should be essentially the same, animal to animal, if a similar clearance mechanism operates in each instance.

2. The rate of differentiation to antibody-producing cells, as reflected by k_d, is essentially the same for all mammalian species considered. The average value is 0.027 hr^{-1}. There seems to be a limited trend between the value of k_d and the dose of antigen administered, which can be represented by least-squares equations:

$$k_d(\text{mouse}) = -8.12\,(\pm 0.22) \times 10^{-3} \ln A + 6.80\,(\pm 0.11) \times 10^{-2} \qquad \text{(Eq. 13)}$$

n	r	s
3	0.999	0.00025

$$k_d(\text{guinea pig}) = -5.64\,(\pm 0.92) \times 10^{-3} \ln A + 6.74\,(\pm 0.92) \times 10^{-2} \qquad \text{(Eq. 14)}$$

n	r	s
3	0.986	0.00267

where n is the number of data points, r is the correlation coefficient, s is the standard error of the estimate, and the values in parentheses following each coefficient are the standard errors of the estimate of the slope and intercept, respectively. However, in view of the low values for the slopes of these relationships, one may, to a good approximation, consider k_d to be essentially independent of the dose of antigen administered.

3. The rate of immune clearance, as measured by k_A, seems to differ from one mammalian species to another. This finding is not unexpected, considering that the reticuloendothelial system is involved in both immune and nonimmune clearances (8) and that rates of nonimmune clearance differ among species. No apparent relationship between k_A and the initial dose of antigen is readily discerned. More precise data, involving a larger number of data points for the immune clearance, may make discernible a relationship between k_A and the initial dose of antigen. With the data at hand, however, one may presume that k_A is essentially constant for each species. Under this presumption, the ratio k_A/k_p provides a measure of the magnitude of the immune response for each species. This ratio is about 10.7, 5.9, and 1.8 for the mouse, fetal lamb, and guinea pig, respectively. Of the species considered, the mouse is the most and the guinea pig is the least immunologically sensitive animal toward ϕX174.

Table I—Pharmacokinetic Parameters from ϕX174 Clearance Curves

Species	Antigen Dose, PFU/ml[a]	k_p, hr^{-1}	k_A, hr^{-1}	k_d[b], hr^{-1}	Reference
Mouse	1.5×10^4	0.037	0.371	0.034	5
Mouse	9×10^4	0.033	0.329	0.028	6
Mouse	6×10^5	0.039	0.460	0.021	—
Guinea pig	5×10^4	0.115	0.200	0.042	3
Guinea pig	6×10^6	0.104	0.251	0.027	3
Guinea pig	6×10^8	0.163	0.251	0.019	3
Fetal lamb (116 days)	5×10^6	0.060	0.368	0.023	7
Fetal lamb (103 days)	1×10^{10}	0.064	0.368	0.021	7

[a] PFU = number of plaque-forming units. [b] Determined using point of intercept method.

As is well known (3, 4), there is no detectable specific antibody to ϕX174 (IgM) in the blood during the immune clearance of the antigen; but shortly after antigen clearance, an exponential build-up of antibody is observed and it reaches an optimum value approximately 96 hr after immunization. This build-up of antibody can be expressed by a rearranged form of Eq. 7:

$$\ln\left(\frac{B_A}{B_A - B}\right) = k_d' t \qquad \text{(Eq. 15)}$$

Early (72–96 hr after injection) serum antibody responses toward ϕX174, interpolated from published (3, 5, 7) figures, are essentially linear when plotted in accord with Eq. 15 (Fig. 2). This linear representation is limited in the respect that, when serum antibody levels B are considerably less than the optimum B_A, information content is lost since the ratio $B_A/(B_A - B)$ is near 1 in these instances.

An ambiguity is associated with the determination of k_d' values from serum antibody responses as opposed to k_d values from antigen clearance curves, and it seems related to the immunological sensitivity of the test animal. If the model applies to both antigen clearance and serum antibody response, one expects the k_d values determined from each experiment to agree within the limits of ex-

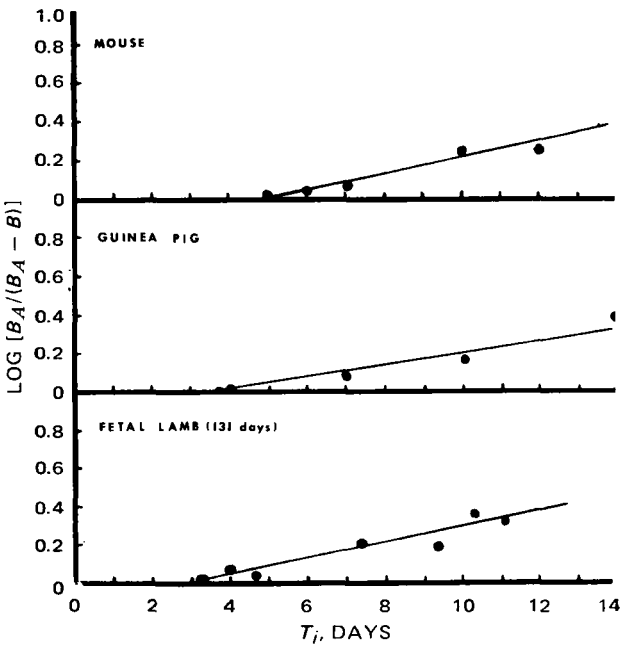

Figure 2—*Linear representation of serum antibody response.*

Table II—Comparison of k_d Values

Species	Antigen Dose, PFU/ml	Optimum Antibody Produced (Estimated)	k_d, hr^{-1} Antigen Clearance	k_d, hr^{-1} Serum Antibody Response	Reference
Guinea pig	2×10^9	50[a]	0.023	0.019	3
Fetal lamb (131 days)	6×10^8	10[a]	0.022	0.0038	7
Mouse	3×10^9	80×10^2[b]	0.021[c]	0.0056	6

[a] Assay in terms of K values. [b] Assay in terms of SD_{50} values. [c] Initial dose of antigen, 6×10^5 PFU/ml.

perimental uncertainty. This appears to be so with the guinea pig as the test animal (Table II). However, for the two other species, mouse and fetal lamb (131 days), the k_d' value determined from the serum antibody response is about 20 times less than the k_d value determined from antigen clearance curves.

Evidently, immunological sensitivity implies that antigen stimulates not only the production of antibody-producing cells but also the production of antibody from these cells. On this basis, animals such as the guinea pig, which are relatively insensitive immunologically toward ϕX174, respond to antigen primarily through the production of antibody-producing cells. Values of k_d determined from clearance curves and from serum antibody responses are then expected to be in agreement. However, animals that are immunologically sensitive toward ϕX174 have their antibody-producing cells stimulated by antigen so as to produce more antibody. Serum antibody responses thus lead to k_d' values characterizing the rate of production of antibody in the absence of antigen, while antigen clearance curves lead to estimates of k_d characterizing the rate of production of antibody in the presence of antigen.

CONCLUSIONS

The developed pharmacokinetic model enables an interpretation of cellular events from *in vivo* experiments on the time course of the primary antibody response toward ϕX174. A modified model may be necessary for more complex antigens, especially in relation to their distribution between blood and body tissues. However, the present model generally describes the major events occurring in the initiation of the primary antibody response. It does so in a quantitative manner, without straining or forcing an interpretation. It provides a basis for comparing results from differing sources, a framework into which kinetic information from the study of isolated events in the immunological initiation process may be fitted, and offers a means of gaining a preliminary mechanistic interpretation.

Antihemolytic and Anticonvulsant Activities of 1-(2,4-Dichloro/2,4,5-Trichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides and Their Inhibition of NAD-Dependent Oxidations and Monoamine Oxidase

BASHEER ALI *, RAJENDRA KUMAR *, SURENDRA S. PARMAR *x, CHANDRADHAR DWIVEDI ‡, and RAYMOND D. HARBISON ‡

Abstract □ Several 1-(2,4-dichloro and 2,4,5-trichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides were synthesized and characterized by their sharp melting points and elemental analyses. All substituted thiosemicarbazides protected *in vitro* hypoosmotic hemolysis of dog red blood cells. These thiosemicarbazides selectively inhibited nicotinamide adenine dinucleotide (NAD)-dependent oxidation of pyruvate and α-ketoglutarate, while NAD-independent oxidation of succinate was not affected. These compounds inhibited the activity of monamine oxidase in rat brain homogenate, and the degree of inhibition ranged from 26.5 to 89.2% at a final concentration of 0.03 m*M*, with kynuramine as the substrate. Almost all thiosemicarbazides possessed anticonvulsant activity; protection against pentylenetetrazol-induced convulsions in mice ranged from 10 to 70% at a dose of 100 mg/kg ip. These results provided evidence of some similarity between the membrane-stabilizing property of these substituted thiosemicarbazides with their ability to exhibit selective inhibition of NAD-dependent oxidations and inhibition of monoamine oxidase. On the other hand, the anticonvulsant activity possessed by these substituted thiosemicarbazides was unrelated to their *in vitro* antihemolytic and enzyme inhibitory properties.

Keyphrases □ Thiosemicarbazides, 1-(2,4-dichloro and 2,4,5-trichlorophenoxyacetyl)-4-alkyl/aryl—synthesis, antihemolytic and anticonvulsant activities, and relationship to inhibition of cellular respiratory activity and inhibition of monoamine oxidase □ Structure–activity relationships—thiosemicarbazides, antihemolytic activity, anticonvulsant activity, enzyme inhibitory properties □ Antihemolytic activity—thiosemicarbazides synthesized and tested □ Cellular respiratory activity—thiosemicarbazides, selective inhibition of NAD-dependent oxidation of pyruvate and α-ketoglutarate, monoamine oxidase, rat brain homogenate □ Monoamine oxidase inhibition—thiosemicarbazides, relationship to antihemolytic (membrane stabilizing) and anticonvulsant properties, inhibition of cellular respiratory activity, selective inhibition of NAD-dependent oxidation

Various hydrazines (1) and semicarbazides (2, 3) have been shown to inhibit monoamine oxidase [EC 1.4.3.4 monoamine O_2 oxido-reductase (deaminating)]. Monoamine oxidase inhibitors also have been shown to possess anticonvulsant properties (4). Furthermore, studies have indicated a relationship between the *in vitro* monoamine oxidase inhibitory property of α-benzoylamino-*N*-[(4-aryl semicarbazide/thiosemicarbazide)benzoyl]-4-substituted cinnamides and their ability to afford protection against pentylenetetrazol-induced convulsions (5). Numerous psychotropic agents have been proposed to affect the physicochemical properties of cell membranes which account for the basis of their mechanism of action (6), and various drug responses have been indicated as the probable result of drug–receptor interactions (7).

Stabilization of the red cell membranes has also been observed in various central nervous system depressants and local anesthetics (8, 9), tricyclic tranquilizers (9, 10), nonphenothiazine tranquilizers (8), and biogenic amines (11). Recently, the synthesis of substituted anilino-[3-methoxy-4-(4-arylthiosemicarbazidocarbonylmethyleneoxy)]benzylidines was reported, and attempts were made to correlate their monoamine oxidase inhibitory effectiveness and their ability to afford protection against hypoosmotic hemolysis in dog erythrocytes with their anticonvulsant property (12). A decrease in the cellular respiratory activity of brain tissue by the inhibition of the mitochondrial membrane-bound oxidase systems was observed with hypnotics (13–15) and anticonvulsants (16, 17), where these changes are presumably responsible for reduced energy production, leading ultimately to depressed neuronal activity.

In the present study, various 1-(2,4-dichlorophenoxyacetyl)-4-substituted thiosemicarbazides and 1-(2,4,5-trichlorophenoxyacetyl)-4-substituted thiosemicarbazides were synthesized and evaluated for: (*a*) their *in vitro* ability to stabilize the red cell membrane; (*b*) their effects on the cellular respiratory activity during oxidation of pyruvate, α-ketoglutarate, NADH, and succinate by rat brain homogenates, and (*c*) their effects on the activity of rat brain monoamine oxidase. The ability of these substituted thiosemicarbazides to provide protection against pentylenetetrazol-induced seizures was also investigated in an attempt to correlate the anticonvulsant activity exhibited by these compounds with their ability to inhibit various enzyme systems as a basis of their biochemical mechanism of action.

EXPERIMENTAL[1]

Preparation of 1-(2,4-Dichlorophenoxyacetyl- or 2,4,5-Trichlorophenoxyacetyl)-4-substituted Thiosemicarbazides—The various 1-(2,4-dichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides and 1-(2,4,5-trichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides were synthesized by refluxing a mixture of an appropriate substituted chlorophenoxyacethydrazide (0.01 mole) and alkyl/aryl isothiocyanate (0.01 mole) in 25 ml of absolute ethanol for 2 hr. The solid mass, which separated on cooling, was collected by filtration, washed with petroleum ether (bp 40–60°), and recrystallized from ethanol (Table I).

[1] All compounds were analyzed for their carbon, hydrogen, and nitrogen content. Melting points were taken in open capillary tubes with a partial immersion thermometer and are corrected.

[a] Melting points were taken in open capillary tubes and are corrected.

Determination of Hypoosmotic Hemolysis—Assay of hypoosmotic hemolysis was carried out by following a slightly modified published procedure (10) in which blood was used without oxygenation. Fresh heparinized blood of healthy mongrel dogs was used. To a 0.1-ml aliquot of dog blood was added 3 ml of a buffer solution (0.425% Na_2HPO_4–NaH_2PO_4 buffer, 5 m*M*, pH 7.4; total osmolality 135 mosmoles/liter) containing the test compounds. The tubes were shaken gently two or three times and were allowed to stand at room temperature (26–28°) for exactly 10 min. These tubes were then centrifuged for 5 min at 1000×*g* to separate the cells.

Under these conditions, hemolysis of the blood cells occurred but in no case exceeded 50%. The absorbance of the supernate was read at 540 nm in a colorimeter. Percent protection was calculated by comparing the absorbance values observed in the presence of the test compounds with those observed in the control tubes without the test compounds. The control value was represented as 100% hypoosmotic hemolysis. Absorbance values for the blank containing 3 ml of 0.85% NaCl (normal saline) were subtracted from the values for both the control and experimental tubes.

All test compounds were dissolved in the buffered saline solution of pH 7.4 (osmolality 135 mosmoles/liter) and were used at a final concentration of 0.05 or 0.1 m*M*. The effective dose$_{50}$ (ED_{50}), the concentration of the the test compound exhibiting 50% antihemolytic activity, was evaluated graphically using different concentrations of these substituted thiosemicarbazides, and this procedure provided comparative effectiveness of the test compounds. From the relationship between the concentration of the test compound and its relative antihemolytic activity, it was possible to determine, either by extrapolation or interpolation, the ED_{50} values

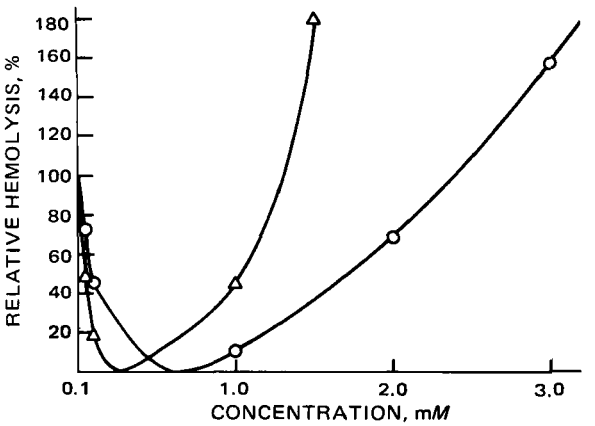

Figure 1—*Biphasic response of varying concentrations of 1-(2,4-dichlorophenoxyacetyl)-4-*m*-tolylthiosemicarbazide (V, △) and 1-(2,4,5-trichlorophenoxyacetyl)-4-ethylthiosemicarbazide (X, ○) on relative hypoosmotic hemolysis of red blood cells of dog. Assay procedures and contents of the reaction mixture are as indicated in the text.*

of these substituted thiosemicarbazides.

Assay of Respiratory Activity of Rat Brain Homogenate[2]—Male albino rats[3], kept on *ad libitum* diet, were used. Rats weighing 150–200 g were sacrificed by decapitation. The brains were taken out immediately and homogenized[4] in the ratio of 1:9 (w/v) in 0.25 *M* cold sucrose. Respiratory activity was determined by measuring the oxygen uptake by the conventional Warburg manometric method at 37° with air as the gas phase (16). Fresh brain homogenate of healthy albino rats, equivalent to 125 mg of wet tissue weight, was used in each flask.

The reaction mixture, in a final volume of 3 ml, consisted of 20 m*M* Na_2HPO_4 buffer (pH 7.4), 6.7 m*M* $MgSO_4$, 1 m*M* AMP (sodium salt), 33 m*M* KCl, and 500 μg of cytochrome c. The central well contained 0.2 ml of 20% KOH solution. Pyruvate, α-ketoglutarate, and succinate were used at a final concentration of 10 m*M*, and the final concentration of NADH was 0.5 m*M*. All substituted thiosemicarbazides were dissolved in propylene glycol (100%) and were used at a final concentration of 1 m*M*. An equivalent amount of propylene glycol was added to the control vessels.

Determination of Monoamine Oxidase Activity—A spectrophotofluorometric method was used for the determination of monoamine oxidase activity of rat brain homogenate, using kynuramine as the substrate (18). The 4-hydroxyquinoline formed during oxidative deamination of kynuramine was measured fluorometrically in a spectrophotofluorometer[5], using activating light of 315 nm and measuring fluorescence at the maximum of 380 nm.

Male albino rats[3], 150–200 g, were allowed food and water *ad libitum* and were sacrificed by decapitation. The brains were removed immediately and homogenized in the ratio of 1:9 (w/v) in ice-cold 0.25 *M* sucrose. The reaction mixture, in a total volume of 3 ml, consisted of phosphate buffer (0.5 ml, pH 7.5; 0.2 *M*), 0.1 m*M* kynuramine, and 0.5 ml of brain homogenate (equivalent to 10 mg of wet brain weight). The monoamine oxidase activity of rat brain homogenate was determined by incubation for 30 min at 37° in air.

The various substituted thiosemicarbazides were dissolved in propylene glycol (100%), added to the brain homogenate at a final concentration of 0.33 m*M*, and then incubated for 10 min before the addition of kynuramine. After the addition of kynuramine, the mixture was incubated for an additional 30 min. The reaction was stopped by the addition of 1 ml of 10% trichloroacetic acid solution (w/v), and the precipitated proteins were removed by centrifugation.

Suitable 1-ml aliquots of the supernate were taken in 2 ml of 1 *N* NaOH solution and were assayed for 4-hydroxyquinoline. An increase in absorbance provided a direct measurement of 4-hydroxyquinoline formation, which was taken as an index of the monoamine oxidase activity. The percentage inhibition was calculated from the decrease observed in absorbance, and this value provided an index of the inhibitory property of these substituted thiosemicarbazides.

Table II—Protection of Hypoosmotic Hemolysis of Dog Erythrocytes by 1-(2,4-Dichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides and 1-(2,4,5-Trichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides

[a] Each experiment was done in duplicate. Assay conditions and the contents of the reaction mixture were as reported in the text. All values represent mean values of percent protection with ±*SE* calculated from three separate experiments. [b] Represents the concentration calculated graphically that would reduce the relative hypoosmotic hemolysis to one-half of the hemolysis of dog erythrocytes.

Determination of Anticonvulsant Activity—Anticonvulsant activity was determined against pentylenetetrazol-induced seizures in albino mice[3] of either sex weighing 25–30 g. The mice were divided into groups of 10, and the group weights were kept as near the same as possible. All substituted thiosemicarbazides were suspended in 5% aqueous gum acacia to give a concentration of 0.25% (w/v). The test compounds were injected intraperitoneally in a dose of 100 mg/kg to one group of 10 mice. Four hours after the administration of these compounds, the mice were injected with pentylenetetrazol (90 mg/kg sc). This dose of pentylenetetrazol has been shown to produce convulsions in almost all untreated mice and to exhibit 100% mortality in these animals during 24 hr. No mortality was observed during 24 hr in mice treated with 100 mg/kg of the test compounds alone.

The mice were observed for 60 min for the occurrence of convulsions. An episode of clonic convulsion persisting for a minimum of 5 sec was considered a threshold convulsion. Transient intermittent jerks and tremulousness were not counted. Animals devoid of threshold convulsions during 60 min were considered protected. The number of mice protected in each group was recorded, and the anticonvulsant activity of these substituted thiosemicarbazides was represented as the percentage protection. The animals were then observed for 24 hr and the mortality was recorded.

RESULTS

The membrane-stabilizing property of various 1-(2,4-dichlorophenoxyacetyl)-4-substituted thiosemicarbazides and 1-(2,4,5-trichlorophenoxyacetyl)-4-substituted thiosemicarbazides (Table I) was evaluated by determining the decrease in the degree of hypoosmotic hemolysis of dog red blood cells. All substituted thiosemicarbazides protected hypoosmotic hemolysis when used at the final concentrations of 0.05 and 0.1 m*M*.

As is evident from Table II, an increase in the ability of 2,4-dichloro-substituted thiosemicarbazides to protect against hypoosmotic hemolysis was mostly observed by the introduction of an ad-

[2] Commercial chemicals were used. Sodium pyruvate, sodium α-ketoglutarate, sodium succinate, NADH, adenosine monophosphate (AMP), cytochrome c, and kynuramine were obtained from Sigma Chemical Co., St. Louis, Mo.

[a] Each experiment was done in triplicate. Assay conditions and vessel contents were as reported in the text. All values represent mean values of percent inhibition with ±*SE* of the mean calculated from three separate experiments. Inhibition was determined by the decrease in the oxygen uptake with 125 mg wet weight of brain/hr. Pyruvate, α-ketoglutarate, and succinate were used at a final concentration of 10 m*M*, while the concentration of NADH was 0.5 m*M*. All substituted thiosemicarbazides were used at a final concentration of 1 m*M*.

ditional chloro substituent (2,4,5-trichloro-substituted thiosemicarbazides) at position 5 of the phenyl nucleus. In the present study, greatest antihemolytic activity was observed with Compounds V, IX, and XIII while 1-(2,4-dichlorophenoxyacetyl)-4-*n*-heptylthiosemicarbazide (III) was the least effective compound. With the use of higher concentrations of two of these thiosemicarbazides (V and X), an increase in hypoosmotic hemolysis, rather than in protection of hemolysis, of the red blood cells was observed (Fig. 1). In the present study, both antihemolytic (Table II) and hemolytic (Fig. 1) properties of these substituted thiosemicarbazides were concentration dependent.

Effects of these substituted thiosemicarbazides on the cellular respiratory activity of the rat brain homogenate are shown in Table III. All thiosemicarbazides at a final concentration of 1 m*M* elicited various degrees of inhibition during oxidation of pyruvate, α-ketoglutarate, and NADH whereas NAD-independent oxidation of succinate remained unaffected. Introduction of a chloro substituent at position 5 of the phenyl nucleus of the 2,4-dichloro-substituted thiosemicarbazides (IV–VII) resulted in an increased inhibitory effectiveness of the corresponding 2,4,5-trichloro-substituted thiosemicarbazides (XIII–XVI). No change in the inhibitory effectiveness was observed by the introduction of the chloro substituent on 4-alkyl- and cyclohexyl-substituted thiosemicarbazides (I–III, VIII–XII, XVII, and XVIII).

The monoamine oxidase inhibitory activity of these substituted thiosemicarbazides and the anticonvulsant activity possessed by these compounds are recorded in Table IV. All thiosemicarbazides inhibited *in vitro* monoamine oxidase activity of rat brain homogenate during oxidative deamination of kynuramine. In the present study, the 2,4,5-trichlorophenoxy-substituted thiosemicarbazides (X, XI, and XIII–XVII) produced greater inhibition of monoamine oxidase than their corresponding 2,4-dichlorophenoxy-substituted derivatives (I, II, and IV–VIII) when used at a final concentration of 0.33 m*M*, with the exception of heptyl- (III and XII) and cyclohexyl- (IX AND XVIII) substituted thiosemicarbazides where the 2,4-dichlorophenoxy-substituted thiosemicarbazides (III and IX) produced higher degree of monoamine oxidase inhibition.

The anticonvulsant activity possessed by these substituted thiosemicarbazides, as evidenced by the protection afforded by these compounds against pentylenetetrazol-induced seizures at a dose of 100 mg/kg, ranged from 10 to 70% (Table IV). Maximum anticonvulsant activity was observed with 1-(2,4-dichlorophenoxyacetyl)-4-*p*-bromophenylthiosemicarbazide (VI) while 1-(2,4-dichlorophenoxyacetyl)-4-*o*-tolylthiosemicarbazide (IV) showed no protection against pentylenetetrazol-induced convulsions. In general, 2,4,5-trichlorophenoxy-substituted thiosemicarbazides afforded greater protection than their corresponding 2,4-dichlorophenoxy-substituted thiosemicarbazides (Table IV). The data on anticonvulsant activity of these compounds and their 24-hr pentylenetetrazol-induced mortality did not indicate clearly an association between increased protection from convulsions and decreased mortality in experimental animals (Table IV).

DISCUSSION

The antihemolytic property of phenothiazines (9), reserpine (9), haloperidol (9), imipramine (10), amitriptyline (10), barbiturates (11), and amphetamine (11) has been proposed to reflect their effects on cell membrane functions. Thus, these thiosemicarbazides presumably prevent or diminish various processes in the cell membranes during protection of hypoosmotic hemolysis. As is evident from Fig. 1, these compounds exhibit a biphasic effect on erythrocyte membrane stabilization and lysis, as has been observed with psychotropic agents (19–21). Such biphasic changes are not abrupt in nature, since membrane stabilization and lysis were found to be concentration dependent and lysis was observed only after a peak of 100% stabilization.

Other studies have indicated that the cells with higher area to volume ratios are associated with a lower osmotic fragility and, consequently, less hypoosmotic hemolysis (22). Thus, the rigidity of the cell membranes may presumably account for the biphasic action of thiosemicarbazides; during the protection of hypoosmotic hemolysis, the surface area to volume ratio is not high enough to warrant the dispersing of the membrane molecules to cause lysis. An increase in the concentration of thiosemicarbazides possibly dominates the dispersing effect which leads to the lysis of the red blood cells.

These thiosemicarbazides seem to possess all necessary structural requirements of other membrane-stabilizing compounds for an

Table IV—Monoamine Oxidase Inhibitory and Anticonvulsant Properties of 1-(2,4-Dichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides and 1-(2,4,5-Trichlorophenoxyacetyl)-4-alkyl/arylthiosemicarbazides

[a] Assay procedure and the contents of the reaction mixture were as indicated in the text. All substituted thiosemicarbazides were used at a final concentration of 0.33 m*M*. Each experiment was done in duplicate, and figures indicate mean values of three separate experiments with ±*SE* of the mean. [b] Screening procedure was as indicated in the text. Each thiosemicarbazide was used at the dose of 100 mg/kg ip, and pentylenetetrazol-induced mortality was observed during 24 hr. In the present study, administration of an equivalent amount of 5% gum acacia solution was found to possess no anticonvulsant activity.

effective antihemolytic agent. These include a basic hydrazino group at one end, a chain of carbon atoms, and a phenyl ring structure at the opposite end. Introduction of an electronegative chloro substituent at position 5 of the phenyl nucleus of 2,4-dichlorophenoxy-substituted thiosemicarbazides in general resulted in a greater antihemolytic property, as reflected by their lower ED_{50} values (Table II). An increase in the number of carbon atoms in the alkyl chain of 2,4-dichlorophenoxy-substituted thiosemicarbazides caused a simultaneous decrease in their antihemolytic effectiveness (I–III); in 2,4,5-trichlorophenoxy-substituted thiosemicarbazides, an increase in activity was observed with *n*-butyl substitution (XI) and further extension of the alkyl chain decreased their antihemolytic activity (XII). Halogen substitution was shown to play some role in enhancing the activity, while thiosemicarbazides possessing a hydrophobic cyclohexyl group (IX and XVIII) possessed significant antihemolytic activity.

The ability of thiosemicarbazides to cause selective inhibition of NAD-dependent oxidations has indicated possible inactivation of the electron-transport chain at the site of the transfer of the electrons from NADH to FAD (17, 23). Introduction of a chloro substituent at position 5 of the 2,4-dichlorophenyl nucleus caused greater inhibition of the cellular respiratory activity by these 2,4,5-trichlorophenoxy-substituted thiosemicarbazides. This increased inhibition of the oxidation of pyruvate, α-ketoglutarate, and NADH was only observed with aryl-substituted compounds since no significant change was observed with alkyl-, allyl-, and cyclohexyl-substituted thiosemicarbazides.

The monoamine oxidase inhibitory effectiveness of 2,4-dichlorophenoxy-substituted thiosemicarbazides was increased by the introduction of a chloro substituent at position 5 of their phenyl nucleus to form 2,4,5-trichlorophenoxy-substituted thiosemicarbazides, with the exception of XII and XVIII where a decrease in enzyme inhibition was observed (Table IV). An increase in the length of the alkyl chain in 2,4-dichlorophenoxy-substituted thiosemicarbazides alone resulted in a gradual increase in their enzyme inhibitory activity. On the other hand, elongation of the alkyl chain from *n*-butyl to *n*-heptyl showed lowering of monoamine oxidase inhibition in 2,4,5-trichlorophenoxy-substituted thiosemicarbazides. The low anticonvulsant activity of these thiosemicarbazides, with the exception of VI, failed to reflect the structure–activity relationship of these compounds.

These results have provided indications of some similarity between the membrane-stabilizing property of the thiosemicarbazides and their ability to inhibit cellular respiratory activity selectively and monoamine oxidase. The membrane-stabilizing property may be unspecific, and some functional groups in thiosemicarbazide molecules could presumably share common properties for cell membrane attachment to exhibit enzyme inhibitory and antihemolytic properties.

Assay of Flucytosine and Furosemide by High-Pressure Liquid Chromatography

ANDREW D. BLAIR, ARDEN W. FORREY, B. TERI MEIJSEN, and RALPH E. CUTLER ˣ

Abstract □ A high-pressure liquid chromatographic method for the analysis of flucytosine and furosemide concentrations in biological fluid is described. The separations were carried out on a pellicular cation-exchange resin eluted with an ammonium phosphate buffer. Detection of elution peaks was by UV absorption at 280 nm and fluorescence monitoring. Advantages of the method are specificity, minimal preanalysis sample workup, and small sample size.

Keyphrases □ Flucytosine and furosemide—high-pressure liquid chromatographic analysis in plasma and urine □ Furosemide and flucytosine—high-pressure liquid chromatographic analysis in plasma and urine □ High-pressure liquid chromatography—analysis, flucytosine and furosemide in plasma and urine

In recent years, high-pressure liquid chromatography (HPLC) has gained increasing use in the analysis for drugs in biological fluids, *e.g.*, barbiturates (1), phenytoin (diphenylhydantoin) (1), and phenacetin (2). The fact that many drugs are highly soluble in water or polar organic solvents but are nonvolatile (troublesome problems for GC analysis and many extraction procedures) is advantageous in HPLC, especially when using aqueous elution from ion-exchange resins. HPLC also has the advantages of specificity, small sample size, and minimal preanalysis sample workup.

These advantages led to the development of an HPLC analysis system for two drugs: flucytosine and furosemide. Flucytosine was recently recognized as a useful antifungal agent in the treatment of systemic *Candida albicans, Cryptococcus neoformans* (3–6), and *Cladosporium trichoides* (7). While studying the pharmacokinetics of both flucytosine and furosemide in normal and uremic volunteers, a rapid and sensitive assay procedure applicable to serum and urine samples was needed to enable the administration of a low drug dosage as an extra margin of safety to the patients. Since 80–95% of flucytosine is excreted unchanged in the urine (8) and dose-related hepatotoxicity has been reported (3), a rapid analysis for plasma drug concentration in clinical samples, particularly in patients with renal insufficiency, was desirable. An HPLC method for the determination of flucytosine concentrations in both serum and urine is reported. With minor modifications of the conditions, an analysis for furosemide for use in pharmacokinetic studies can also be conducted. This method replaces the fluorometric technique reported earlier (9). Although not generally useful for furosemide for clinical purposes, the HPLC method for the pharmacokinetic study of both drugs has shown decided advantages over existing methods (9–15) for the determination of furosemide and flucytosine concentrations in both serum and urine.

EXPERIMENTAL

Flucytosine[1] (5-fluorocytosine) (for assay development), furosemide[2] (4-chloro-*N*-furfuryl-5-sulfamoylanthranilic acid), 4-chloro-5-sulfamoylanthranilic acid[2] (I), ^{35}S-furosemide[2] (for standard and clinical studies), and probenecid sodium[3] were used. All other chemicals were analytical reagent grade.

The high-pressure liquid chromatograph[4] was equipped with an absorbance monitor[5]. The absorbance monitor was equipped with an optical unit[6], a 280–310-nm filter, and high-pressure microflow cells[7], and the output was recorded[8]. For the analysis of furosemide, the eluant from the absorbance monitor was passed through a fluoromonitor[9] (excitation at 320–400 nm; emission at 400–700 nm) and the signal output was recorded on a dual-pen recorder[10]. A pellicular cation-exchange resin, prepared in 304.8 × 0.1-cm i.d. stainless steel tubing[11] with a precolumn[12] containing the same packing material, was used for both serum and urine.

Five-microliter aliquots of urine or serum were injected directly onto the column resin bed (stop-flow technique) with a 10-μl syringe[13] equipped with a 7-cm needle.

For the analysis of flucytosine, the column was eluted with a monobasic ammonium phosphate buffer solution (16 m*M*) with the pH adjusted to 2.00 with phosphoric acid. The column pressure was 2000 psi, the eluent flow rate was 0.24 ml/min, and the column temperature was 78°. Recordings were made at a range of 0.01 absorbance unit and a recorder span of 1 v full scale.

Standard flucytosine samples were prepared in concentrations ranging from 0 to 10 mg/liter in water, serum, and urine. Aqueous samples were stable for at least 1 month at ambient temperature.

Furosemide working standards were prepared fresh each day from injectable furosemide (10 mg/ml) from the same lot number used in each study and was, in turn, standardized against a solution of the pure compound. Compound I standards were prepared from chemically pure compound dissolved in water. All standards, urines, and serums containing furosemide were protected from light.

The column was eluted with the monobasic ammonium phosphate buffer solution (50 m*M*) with the pH adjusted to 2.50 with phosphoric acid. The column conditions were: pressure, 1300 psi; eluent flow rate, 0.33 ml/min; and temperature, 74°. Recordings were made at a range of 0.02 absorbance unit with a recorder span of 10 mv.

Drug concentrations were determined by measuring the net peak height above the baseline. Baselines were determined by a trough-to-trough tangent method. Drug concentrations were calculated by a computer-assisted, unweighted, least-squares fit of the standard concentrations and peak heights to a straight line. When serum samples were analyzed, a preadministration sample was also analyzed to determine if extraneous compounds, which might interfere, were already present in the serum. A preadministration urine sample, suitably diluted in proportion to the increased urine

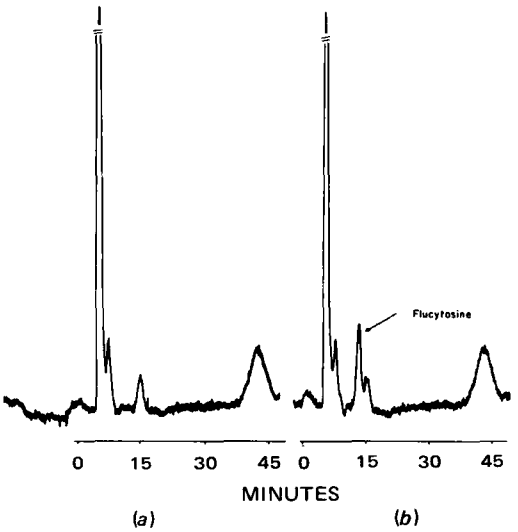

Figure 1—*HPLC elution pattern (280 nm) for serum without (a) and with (b) flucytosine (2.1 mg/liter), depicting the separation of flucytosine from other materials in serum which absorb at 280 nm.*

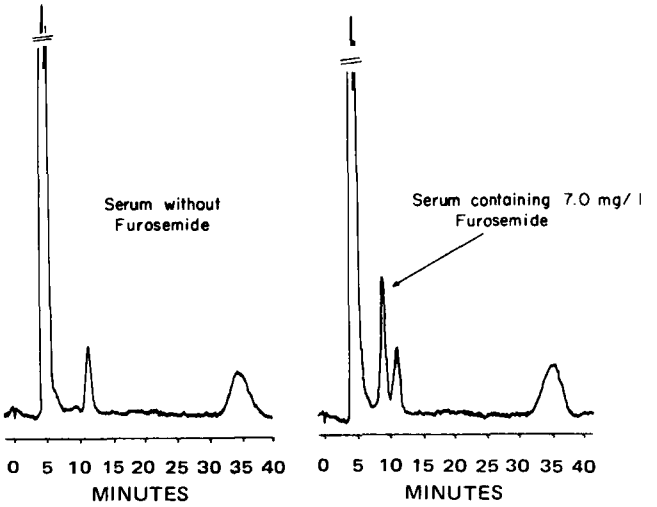

Figure 3—*HPLC elution patterns (280 nm) for serum without and with furosemide, depicting the separation of furosemide (elution time of 9 min) from other serum constituents that absorb at 280 nm.*

flow rate in the case of furosemide (9), was analyzed as a check for interfering substances.

Liquid scintillation counting and quench correction of samples containing ^{35}S-furosemide were carried out as reported earlier (9). Drug concentrations were calculated from the disintegrations per minute resulting from a dilution of the prepared injection solution of known specific activity, which was counted simultaneously.

Due to the high concentration of flucytosine in the urine samples following administration of the drug, both pre- and postadministration urines were diluted by a factor of either 20 or 100, depending on the actual flucytosine concentration, to obtain concentrations within the range of the standard curve.

RESULTS AND DISCUSSION

Following the described chromatographic methods, pure flucytosine or pure furosemide, when added to samples of serum or urine, was particularly well resolved from the other constituents in serum and urine (Figs. 1–4).

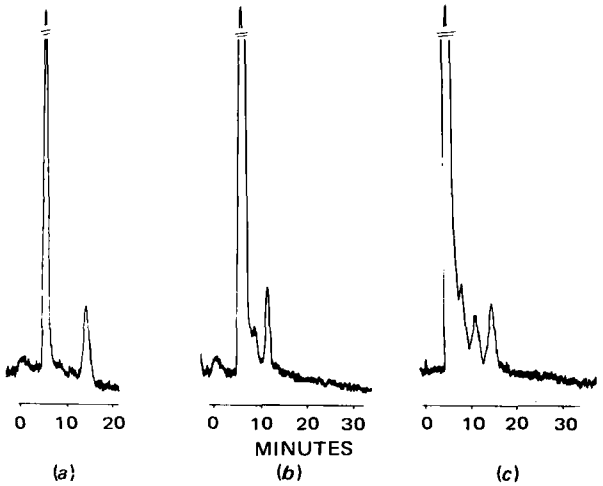

Figure 2—*HPLC elution pattern (280 nm) for patient urine with and without flucytosine. Different dilutions show effect on chromatogram peak height. Peak at 11 min in 1:20 dilution is a urine constituent that is almost diluted out in the 1:100 dilution. Flucytosine concentrations are those calculated after dilution. Key: (a), urine diluted 1:100 containing flucytosine (2 mg/liter); (b), urine diluted 1:20 without flucytosine; and (c), urine diluted 1:20 containing flucytosine (1.5 mg/liter).*

Flucytosine—With the reported conditions, flucytosine elutes from the column 13.5 min after sample injection (Fig. 1). Altering the buffer molarity to a higher concentration reduces the elution time but also tends to cause shifts of elution time, resulting in some overlap of the flucytosine peak with the small serum constituent peak, which normally elutes at approximately 15 min. Increasing the pH to 2.80 has little effect on the elution of flucytosine; however, with pH's higher than 2.00, resolution of flucytosine and the 15-min serum peak disappears.

The time involved to analyze a single serum sample (*i.e.*, for all peaks to elute) is 55–60 min; however, the flucytosine concentration may be calculated within 15 min after injection, making this technique relatively rapid for monitoring patient therapy. Since a large flat area in the elution pattern exists between the 15- and the

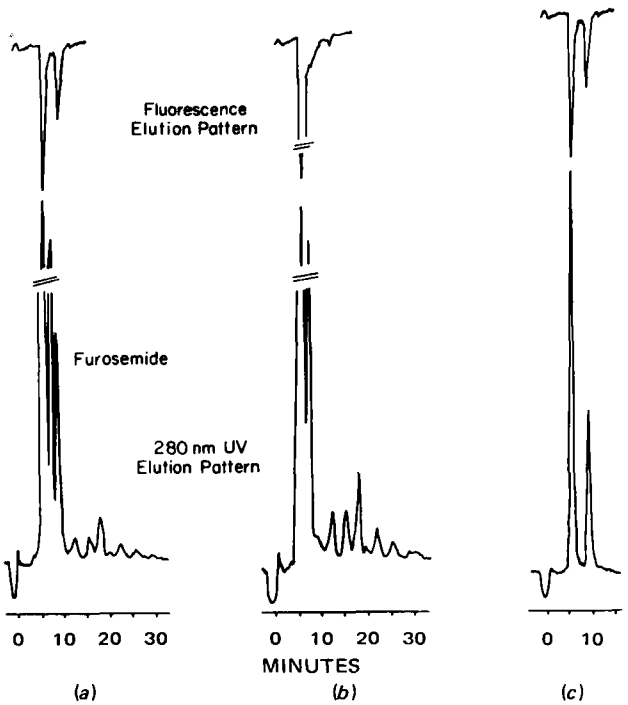

Figure 4—*HPLC elution patterns (280 nm) for urine with and without furosemide. Fluorescence pattern (top) shows clear separation from other fluorescent material in urine. [a] Samples from a second study. [b] Duplicate sample to check reproducibility of the microbiological method.

55-min serum peaks, a second sample can be injected 25–30 min after the first injection, thereby allowing the analysis of at least two samples/hr. The urine samples from normal volunteers treated with flucytosine and diluted 1:20 showed no significant peaks (Fig. 2) due to urine constituents following the elution of flucytosine, thereby allowing a second injection 15 min after the first. Thus, four urine samples may be analyzed per hour.

The differences between peak heights for each set of standards prepared from pure flucytosine added to water, serum, and urine were not outside the relative standard deviation for repetitive injections of the same standard aqueous solution. Therefore, aqueous standards were used for calculation of serum and urine flucytosine concentrations in the clinical studies. The HPLC method was utilized for 3 months for the analysis of flucytosine in serum and urine samples. A standard curve for aqueous standards is shown in Fig. 5. The day-to-day relative standard deviation in the slope of the standard curve was 8%, and daily analysis of the same aqueous standard showed a relative standard deviation of 5.5% at 10 mg/liter. The within-day relative standard deviation for repetitive injections of the same aqueous standard solution was 2% at a concentration of 10 mg/liter.

The results from the HPLC method were also checked against a microbiological method performed by an independent laboratory[14] (Table I). The serum samples correlated reasonably well with a few exceptions, whereas the correlation between methods for urine samples was only fair at best.

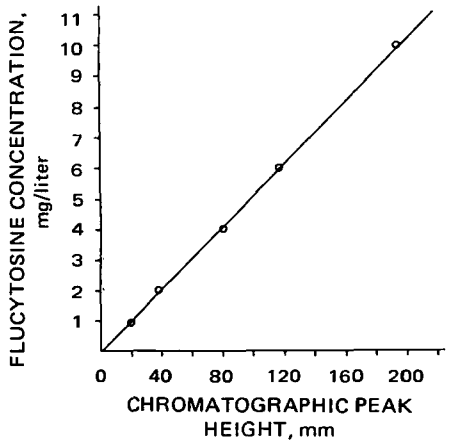

Figure 5—*Standard curve for aqueous flucytosine standards ranging from 1 to 10 mg/liter (slope = 0.052, SE = 0.061, and Y intercept = 0.042).*

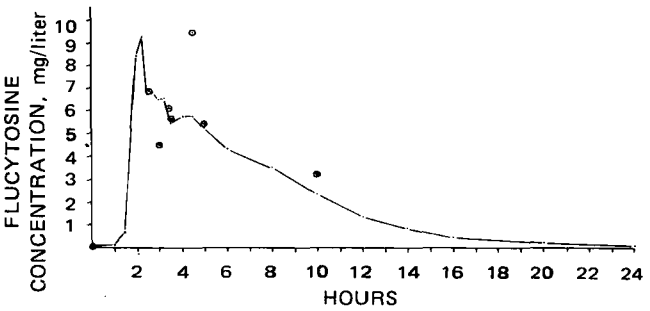

Figure 6—*Pharmacokinetic curve for a normal volunteer receiving 500 mg of flucytosine orally after a meal, comparing duplicate samples assayed by the HPLC method (•—•) and by a microbiological method (⊙).*

When the microbiological assay values are plotted on the same graph as those by HPLC from a complete patient study (Fig. 6), the plot depicts the greater precision of the HPLC method; this increased precision leads to more accurate values of the fitted parameters for the pharmacokinetic curve. When measured by the microbiological method, the quantity of recovered flucytosine for Sample U_2 (Table I) alone was 114% of the ingested dose compared to a total of 135% recovered overall; this example depicts the magnitude of the gross error in the microbiological method. In contrast, 80.5% of the ingested dose was recovered overall when the

same urine samples were assayed by the HPLC method.

The HPLC method for the analysis of flucytosine has certain advantages over existing reported methods (13–15). This method requires no lengthy workup of serum or urine samples. Serum is applied directly to the column, and urine is simply diluted before application to the column. The sample size is small (5 μl), which facilitates analysis of samples derived from uremic patients, who normally have low hematocrits, and from infants. Pharmacokinetic and toxicity studies in small animals would also be facilitated by this method. The method is simple and fast.

Although flucytosine was reported not to be metabolized to fluorouracil in mammalian tissue (4, 16), it was of interest to show that fluorouracil does not interfere with the analysis of flucytosine, for instance, in concomitant therapy with these two drugs. In an aqueous solution under the reported conditions, fluorouracil elutes from the column 6 min postinjection, well resolved from the flucytosine peak (Fig. 7).

Furosemide—Using the chromatographic conditions described for furosemide, this drug was well resolved from other serum and urine constituents (Figs. 3 and 4). Furosemide was also completely resolved from its major breakdown product (I) (Fig. 8), both in biological samples and in aqueous solution. A separation of the two compounds in aqueous solution was shown in Fig. 8. Injectable furosemide is normally alkaline (pH 10.00) to prevent acid-catalyzed degradation to I. Urine, however, may be acidic, and furosemide will be quickly degraded unless alkalinized. Since the reaction is also light catalyzed, urine samples are also protected from light. As a further precaution, the samples are usually analyzed immediately. At the pH of analysis (pH 2.50), furosemide is highly fluorescent, whereas I is only weakly so (9, 10). This attribute allows

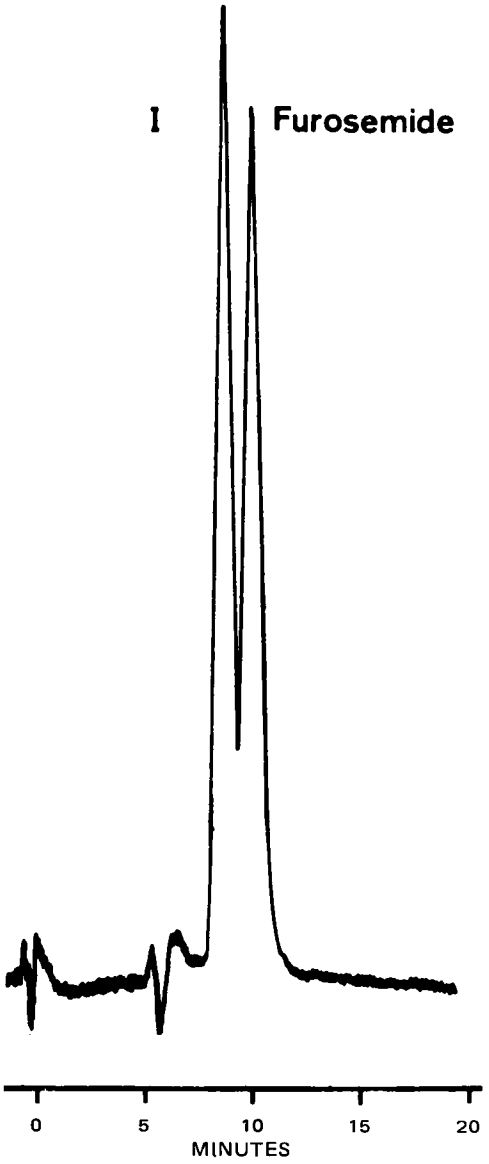

Figure 8—*HPLC elution pattern for an aqueous solution of furosemide and its major breakdown product, 4-chloro-5-sulfamoylanthranilic acid (I), showing that I does not interfere with the determination of the furosemide peak height.*

furosemide to be distinguished from other constituents in urine and plasma. Normally, only two fluorescent peaks are seen in elution patterns, one due to the breakthrough peak and the other due to furosemide. There is no peak in nonfurosemide-containing serum or urine, which exhibits both absorbance and fluorescence, and also elutes at the position corresponding to furosemide shown in Fig. 4.

The urine of patients who respond normally to furosemide shows only one urine peak at the solvent front due to the diluting effect of the drug. In the more concentrated urines from patients who do not respond to furosemide with a diuresis or from the normal concentrated urine from an untreated individual, there are a number of small unidentified peaks (Fig. 4). This figure shows, however, that the furosemide peak is, in all cases, uniquely identified and well resolved from any other fluorescent or absorbing material in the urine.

In these cases, the pH of the monobasic ammonium phosphate buffer is very critical. Changes of the monobasic ammonium phosphate buffer pH affect the retention time of furosemide only minimally over several pH units. However, changes on the order of 0.05 pH unit drastically alter the retention time of the other urine constituents. As a result, analyses during pharmacokinetic studies of

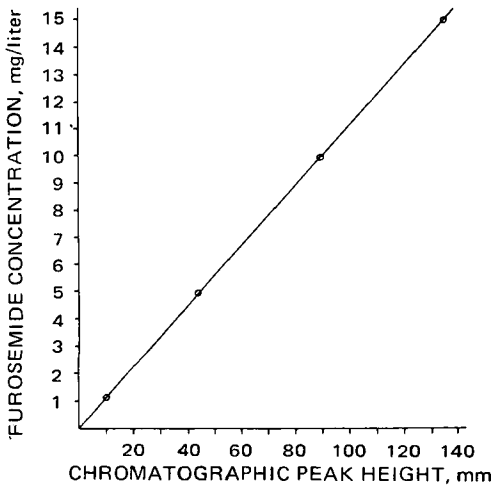

Figure 9—*Standard curve for aqueous furosemide standards ranging from 1 to 15 mg/liter (slope = 0.112, SE = 0.043, and Y intercept = 0.038).*

patients resistant to the diuretic action of furosemide require more careful monitoring of the buffer pH to maintain the separation of furosemide from other urine peaks. This phenomenon is also important in the analysis of urine samples in species such as mice, which do not exhibit a diuretic response to furosemide, even when extremely high doses of up to 400 mg/kg body weight are used (17).

Increasing the buffer molar concentration causes a shortening of the retention time of furosemide. The retention times of many compounds contained in the urine are also greatly affected by changes in buffer molarity, since some compounds undergo ion-exchange processes while others are being ion excluded. These other urine components have not been identified. Thus, while the effects on the elution profile of varying the buffer molarity are more subtle, they turn out to be less predictable than the effects of changing only the eluent pH.

The HPLC method was used for more than 9 months to measure furosemide levels in clinical studies. A standard curve for aqueous standards is shown in Fig. 9. The day-to-day relative standard deviation in the slope of the standard curve was 2.1%, and the day-to-day variation in the analysis of the same aqueous standard showed a relative standard deviation of 1.5%. The relative standard deviation of the concentration of repetitive injections of the same aqueous standard solution (within day variation) was 1.2% at a concentration of 15 mg/liter. Results from repetitive analysis of serum and urine samples containing 10 mg/liter of furosemide on the same day were 3 and 2%, respectively.

To estimate the accuracy of the HPLC method, it was compared to the measurement of ^{35}S-furosemide concentration determined radiochemically by means of the ^{35}S-label after administration to a normal subject by both oral and intravenous routes. In a normal subject, the drug virtually disappeared from the serum by 4 hr. The results (Tables II and III) demonstrate good agreement between the HPLC measurement and that made radiochemically, indicating that little metabolism of furosemide took place.

As with any chromatographic assay method, care must be taken to ensure that other drugs do not interfere with the determination of the drug to be analyzed. In initial studies using a combination of probenecid and furosemide, these two drugs were found to have the same elution time under the conditions described. However, by lowering the column temperature to 60°, furosemide was resolved from the probenecid peak. This lowering of the temperature results in a longer elution time and a 20% reduction in the furosemide peak height, which makes the assay somewhat less sensitive at low drug concentrations.

The size of the sample required for analysis (5 μl) makes this assay particularly attractive in clinical research studies for measuring serum concentrations of furosemide in infants and anemic patients and for pharmacokinetic and metabolism studies in small animals. In the analysis of rat serum and urine, no interferences during measurement of furosemide levels were found. By using the conditions for the separation of flucytosine from serum or urine, furosemide, when it is present, is well resolved from the flucytosine peak. Furosemide elutes at 9 min and flucytosine elutes at 13.5 min (Fig. 10). Thus, the analysis of flucytosine would not be interfered with by concomitant furosemide therapy.

High-Pressure Liquid Chromatographic Analysis of Triflubazam and Its Metabolites in Human and Animal Blood and Urine

RICHARD E. HUETTEMANN [x] and ARVIN P. SHROFF

Abstract □ A high-pressure liquid chromatographic method is described for analyzing triflubazam [1-methyl-5-phenyl-7-trifluoromethyl-1*H*-1,5-benzodiazepine-2,4(3*H*,5*H*)-dione] and its primary metabolites in blood and urine. Adsorption chromatography, using pellicular silica gel as the stationary phase and dioxane–isooctane as the mobile phase, permitted rapid sample analysis. After extraction of blood and urine samples with toluene, quantitation is achieved using liquid chromatography with an internal standard. The method is sensitive above 50 ng/ml of triflubazam and its known metabolites. Recoveries for all compounds from blood or urine averaged above 95%. The specificity of the method was established by collecting samples separated by liquid chromatography and characterizing them by mass spectrometry. Human and animal data are presented to illustrate the utility of the method.

Keyphrases □ Triflubazam (a 1,5-benzodiazepine) and its metabolites—high-pressure liquid chromatographic analysis in human and animal blood and urine □ 1,5-Benzodiazepines—high-pressure liquid chromatographic analysis of triflubazam and its metabolites in human and animal blood and urine □ High-pressure liquid chromatography—analysis, triflubazam (a 1,5-benzodiazepine) and its metabolites in human and animal blood and urine

The quantitative analysis of drugs and their metabolites in physiological fluids is important for correlating pharmacological activity. Various methods requiring preliminary purification and/or lengthy analysis time to obtain the sensitivity and specificity needed to generate an accurate profile of the drug's metabolism have been described. Polarography (1), colorimetry (2), UV spectrophotometry (3), GLC (4), TLC (5), and liquid chromatography (6) have been employed to analyze the benzodiazepine class of compounds in blood and urine. A comprehensive review (7) of all methods for the analysis of benzodiazepines was published recently.

Apparatus—A liquid chromatograph[2] fitted with a standard 254-nm detector[3] was used. The column was a tube (1.0 m × 2.1 mm i.d.) with a stationary phase of pellicular silica gel[4]. The column was operated at 35 kg/cm^2 (500 psi) at 30°, with a mobile phase of 15% dioxane in isooctane at a flow rate of 3 ml/min.

Procedure—Stock solutions (10 μg/ml) of I–IV and 11α-hydroxy-17α-methyltestosterone were prepared in chloroform. A stock standard solution (A) was prepared to contain 1 μg of each of I–IV and 10 μg of internal standard/5 μl of chloroform. Exactly 1.0 ml of the internal standard solution was pipetted into a 10-ml glass-stoppered extraction tube and evaporated to dryness in a 65° water bath under a stream of nitrogen. Exactly 1.0 ml of blood or 5.0 ml of urine was added to the tube. Five milliliters of toluene was added, and the tube was shaken for 5 min.

The tubes were then centrifuged for 2 min and cooled in a dry ice–acetone bath for 20 sec, and the toluene was decanted into a conical centrifuge tube. One milliliter of toluene was added to the extraction tube; the contents were mixed for 30 sec, centrifuged, and cooled in the dry ice–acetone bath; and the toluene was decanted into the respective conical tube. The toluene was evaporated to dryness in a 65° water bath under a stream of nitrogen.

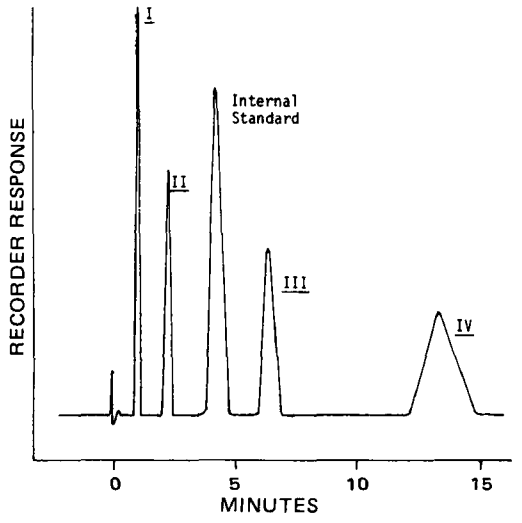

Figure 1—*Chromatogram depicting retention time of internal standard and I–IV.*

The residue was treated with acetone (200-, 50-, and 10-μl portions) and quantitatively transferred to a microflex tube[5]. Five microliters of chloroform was added to the evaporated residue in the microflex tube, mixed[6] for 15 sec, and saved.

Five microliters of Standard Solution A was injected into the liquid chromatograph, and the compounds eluted as shown in Fig. 1. The sample microflex tube contents were injected next. Quantitation was achieved by dividing the ratio of any compound detected in the sample by the ratio of the same compound in the stan-

dard (the ratio is the height of the compound peak divided by the height of the internal standard peak) to give micrograms per milliliter of any compound in blood or micrograms per 5 ml in urine. Typical standard curves demonstrating the detector's response to I–IV over the concentration ranges of 0.1–2.0 and 1.0–5.0 μg/ml are shown in Fig. 2.

Liquid Chromatography–Mass Spectrometry—Compound identification was achieved by evaporating the appropriate aliquot from liquid chromatography and obtaining the mass spectrum[7] of the residue at 70 ev.

RESULTS AND DISCUSSION

The described method using HPLC allows for simultaneous cleanup and analysis and, if necessary, for more rapid identification of sample peaks than is obtained with other methods.

The method used to analyze for I and its metabolites, II–IV, was developed after several stationary phases and solvent systems were investigated to give an ideal separation in a short period. Adsorption chromatography employing a stationary phase[4] and a mobile phase of dioxane–isooctane allowed samples to be analyzed within 15 min. Quantitation was accomplished using an internal standard technique to minimize errors caused by the loss of sample during extraction and transfer steps.

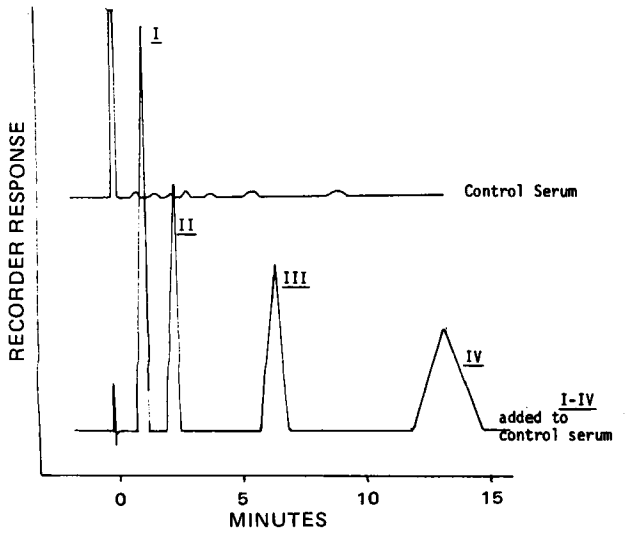

Figure 3—*Liquid chromatogram of I–IV at 1 μg (8×) and a human control serum sample (2×).*

[7] Finnigan model 1015 GC-MS.

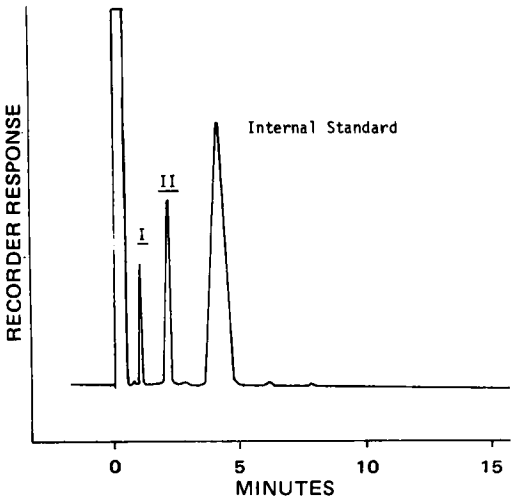

Figure 4—*Chromatogram of a typical human serum sample.*

11α-Hydroxy-17α-methyltestosterone was an ideal internal standard, as demonstrated in Fig. 1. The response of known standard concentrations of I–IV was found to obey Beer's law (Fig. 2). Since studies showed that these slopes varied from day to day due to the quality of the solvent and/or temperature, the daily use of a standard solution is recommended.

The accuracy and precision of the method were determined by the addition of known quantities of I–IV to control human serum and urine samples as well as to rat, rabbit, and dog control serum samples. The samples were then analyzed according to the outlined procedure. Table I summarizes the recoveries from human serum at various levels, Table II summarizes the human urine studies, and Table III summarizes the animal serum studies. All recovery studies were well within acceptable levels. A typical liquid chromatogram obtained by analyzing both spiked and controlled human serums is shown in Fig. 3. No interferences were noted from control serum or urine samples.

To demonstrate the suitability of this methodology for biological materials, blood and urine samples were obtained from patients participating in a clinical trial of I. Table IV depicts the results obtained by both HPLC and TLC densitometry (5) methods for blood samples, while Table V shows the results with urine samples. Both blood and urine samples were obtained 24 hr after dosing. Figure 4 illustrates the chromatogram obtained from typical human serum in the same study.

To obtain a better understanding of the absorption characteristics of this drug, a monkey study was initiated. Blood samples were withdrawn over a 12-hr period, and urine samples were collected

Table V—Urine Levels of I and II in Three Patients by TLC and HPLC

Patient	I, μg/ml		II, μg/ml	
	TLC	HPLC	TLC	HPLC
1	0.15	0.12	0.19	0.19
2	0.20	0.22	0.30	0.35
3	0.68	0.60	1.51	1.63

every 24 hr. Table VI lists the serum results, while Table VII lists the urine results. Figure 5 illustrates the chromatogram of a typical monkey urine extract showing peaks corresponding to I–III. From this study, it appears that I is slowly absorbed and rapidly converted to II in the blood, while urine data suggest slow elimination from the body.

Fractions from the HPLC corresponding to I–IV and any other unknown peaks from any study can be quickly collected, evaporated, and submitted for mass spectrometry to ensure specificity and allow for rapid elucidation of unknown peaks if they appear. The actual cleanup occurs while quantitative analyses are being performed. The HPLC column exhibited good column life even after several weeks of continuous operation.

Synthesis and Cytotoxicity of 6-Selenopurine Arabinoside and Related Compounds

SHIH-HSI CHU ˣ, CHYNG-YANN SHIUE, and MING-YU CHU

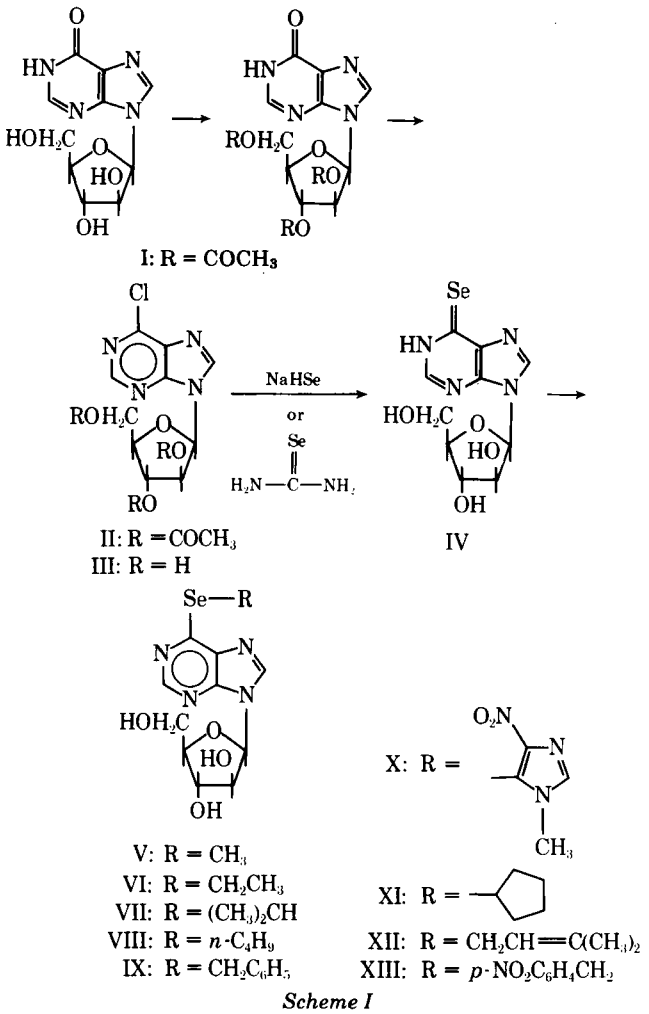
Abstract □ 6-Chloro-9-(β-D-arabinofuranosyl)purine served as an intermediate for the chemical synthesis of a series of 6-substituted selenopurine arabinosides. In an *in vitro* test using murine leukemic cells (L-5178Y) these 6-substituted selenopurine arabinosides showed some cytotoxicity. Lengthening the side chain had no effect on their cytotoxicity. Selenourea was a useful reagent for synthesizing selenopurines, selenopurine nucleosides, and selenopurine arabinoside under mild conditions.

Keyphrases □ 6-Selenopurine arabinoside and related compounds—synthesis and cytotoxicity □ Selenium analogs—synthesis and cytotoxicity of 6-selenopurine arabinoside and related compounds □ Cytotoxicity—6-selenopurine arabinoside and related compounds

Mercaptopurine and thioguanine have been employed widely in the clinical treatment of various types of leukemia (1–5). The selenium isostere, 6-selenopurine (6), was found (7) to inhibit mouse leukemia L-1210 as effectively as mercaptopurine. Unfortunately, it is not a useful compound due to its instability *in vivo*. Subsequently, selenoguanine, an analog of thioguanine, was synthesized (8, 9). It is as effective an inhibitor as thioguanine on the growth of several experimental tumors, is less toxic to the host, and has a superior therapeutic index (9).

Numerous selenium analogs were synthesized to reexplore their biochemical behavior including 6-selenopurine riboside (10), 6-seleno-*N*-alkyl purines (11), ethyl 6-selenoguanine-9-carboxylate (12), 6-selenoguanosine (13, 14), (α,β)-2′-deoxy-6-selenoguanosine (15–17), alkyl-selenopurine ribosides (14, 18, 19), 6-selenoguanosine 5′-monophosphate (20), and 8-substituted selenoadenosines and their cyclic nucleotides (21). 6-Selenoguanosine and β-2′-deoxy-6-selenoguanosine were active inhibitors of several experimental tumors *in vitro* (14, 15) and *in vivo* (17, 20).

Cytarabine (1β-D-arabinofuranosylcytosine) is a potent inhibitor of the growth of tumor cells in culture and also causes striking regression of tumors in mice (22). 6-Mercapto-9-(β-D-arabinofuranosyl)purine was found to have both antitumor (23) and immunosuppressive (24) properties. 6-Mercapto-9-(β-D-arabinofuranosyl)purine also was a competitive inhibitor of L-1210 adenosine deaminase when 9-β-D-arabinofuranosyladenine was used as the substrate. The phosphorylation of adenosine, 9-β-D-arabinofuranosyladenine, and 6-methylthio-9-(β-D-ribofuranosyl)purine did not appear to be affected by 6-mercapto-9-(β-D-arabinofuranosyl)purine (25). These results prompted the synthesis of 6-selenopurine arabinoside and certain related compounds and the evaluation of their cytotoxicity.



Scheme I

RESULTS AND DISCUSSION

Chemical—Acetylation of 9-(β-D-arabinofuranosyl)hypoxanthine with acetic anhydride in pyridine gave 9-(2′,3′,5′-tri-*O*-acetyl-β-D-arabinofuranosyl)hypoxanthine (I) (26). Chlorination of I with phosphorus oxychloride–*N*,*N*-diethylaniline at refluxing temperature gave 6-chloro-9-(2′,3′,5′-tri-*O*-acetyl-β-D-arabinofuranosyl)purine (II) (27). Deacetylation of II with methanolic ammonia at room temperature gave 6-chloro-9-(β-D-arabinofuranosyl)purine (III). Compound III was used for further transformation without purification. Treatment of III with sodium hydrogen selenide in refluxing methanol gave 6-selenoxo-9-(β-D-arabinofuranosyl)purine (IV) in 52% yield.

Compound IV can be synthesized alternatively by the reaction of III with selenourea. This method was found to be a convenient way to synthesize various seleno compounds. Compound IV was relatively unstable; its half-life was 3 days in water at room temperature.

Kikugawa *et al.* (28) reported that lengthening the side chain of 2-thioadenosine increases its activity as an inhibitor of platelet aggregation; therefore, several derivatives of IV were synthesized. Treatment of IV with methyl iodide, ethyl bromide, isopropyl bromide, *n*-butyl bromide, benzyl bromide, 5-chloro-1-methyl-4-nitroimidazole, cyclopentyl bromide, 3,3′-dimethylallyl bromide, and

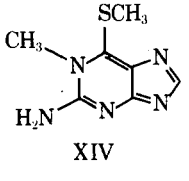
[a] TLC was run on a polygram CEL 300 PEI and developed with water. [b] The solubilities of these compounds are low. [c] The half-life from the height of the 340-nm peak in pH 11 at room temperature was about 1 hr.

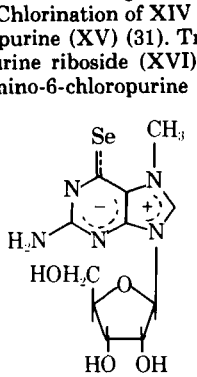
p-nitrobenzyl bromide gave the corresponding purine arabinoside derivatives of 6-(methylseleno) (V), 6-(ethylseleno) (VI), 6-(isopropylseleno) (VII), 6-(*n*-butylseleno) (VIII), 6-(benzylseleno) (IX), 6-[(1-methyl-4-nitro-1*H*-imidazol-5-yl)seleno] (X), 6-(cyclopentylseleno) (XI), 6-[(3-methyl-2-butenyl)seleno] (XII), and 6-(*p*-nitrobenzylseleno) (XIII), respectively (Scheme I).

Alkylations with primary halides were performed in aqueous basic solution, but alkylations with secondary halides or relatively active halides were carried out in anhydrous media. Alkylation of IV with secondary halides in aqueous basic solution gave low yields of products. The low yields may arise from the hydrolysis of these secondary halides into the corresponding alcohols. The 6-selenopurine arabinosides were purified by continuous extraction with ether or by recrystallization from water. The physical properties of the 6-selenopurine arabinosides are shown in Table I. The products were identified by elemental analysis and by a comparison of their UV spectra with known thio analogs (26).

Selenourea has been reported to react with 6-chloropurine, ethyl 2-amino-6-chloropurine-9-carboxylate, and 7-chloro-3-(β-D-ribofuranosyl)pyrazolo[4,3-*d*]pyrimidine to give 6-selenopurine, ethyl 2-amino-6-selenopurine-9-carboxylate, and 7-selenoxo-3-(β-D-ribofuranosyl)pyrazolo[4,3-*d*]pyrimidine (6, 12, 29), respectively. To test the limitation of this procedure, several substituted purines were synthesized. Methylation of 1-methyl-6-thioguanine (30) with methyl iodide in sodium hydroxide solution gave 2-amino-1-methyl-6-(methylthio)purine (XIV). Chlorination of XIV in methanol gave 2-amino-6-chloro-1-methylpurine (XV) (31). Treatment of XV, 2-amino-6-chloro-7-methylpurine riboside (XVI) (32), 6-chloropurine riboside (XVII), 2-amino-6-chloropurine riboside (XVIII), and 2-amino-6-chloropurine (XIX) with selenourea in refluxing methanol or at room temperature gave the corresponding seleno compounds (XX–XXIV) in good yield. The advantages of this procedure are that handling of hydrogen selenide gas is avoided and reaction conditions are milder than in the conventional sodium hydrogen selenide method.



XIV



XXI

Biological Effects—The analogs were evaluated in two studies for their cytotoxicity, using L-5178Y murine leukemic cells grown in culture.

Long-Term Studies—These studies were conducted for 72 hr over a wide range of concentration (10^{-4}–10^{-7} *M*). As shown in Table II, 6-thioguanosine, IV, and X exhibit 50% inhibition at concentrations of 5.6×10^{-6}, 6.6×10^{-5}, and 1.9×10^{-5} *M*, respectively. Compounds V–IX, XI, and XII caused less than 50% inhibition at the highest concentration (10^{-4} *M*) studied, so percent inhibition at 10^{-5} or 10^{-4} *M* was determined as shown in columns 3 and 4 of Table II.

Short-Term Studies—As shown in Table III, L-5178Y cells in the exponential phase of growth were treated with the inhibitory compounds (10^{-4}–10^{-7} *M*) for 2 hr and cell viability was determined by colony formation in dilute agar (33). The cloning efficiency of the untreated cells was approximately 75%. All values were normalized to 100% acute cell kill after 2 hr of incubation.

Compound X, which was shown to be active by long-term and short-term studies, was also evaluated for its ability to cause acute cell death by exposure of cells for 1–5 hr at two concentrations (10^{-4} and 10^{-5} *M*); cell viability was determined by colony formation in dilute agar (33). The results (Table IV) demonstrated that the logarithmic cell kill by X was 29%/hr at 1×10^{-4} *M* and 15%/hr at 1×10^{-5} *M*.

EXPERIMENTAL[1]

9 - (2′,3′,5′ - Tri-*O*- acetyl-β-D- arabinofuranosyl)hypoxanthine (I)—This compound was prepared by the method of Reist *et al.* (26) with 9-(β-D-arabinofuranosyl)hypoxanthine (1.5 g, 0.57 mmole) and acetic anhydride (2.1 ml, 2.25 mmoles) in 90 ml of pyridine in 60% yield.

6-Chloro-9-(2′,3′,5′-tri-*O*-acetyl-β-D-arabinofuranosyl)purine (II)—Into a mixture of 35 ml of phosphorus oxychloride and 2 ml of *N,N*-diethylaniline, 6.0 g (15.8 mmoles) of I was added. The suspension was refluxed rapidly for 3 min. The resulting clear brown solution was evaporated *in vacuo*, and the residue was added to chloroform and ice water. The solution was extracted with chloroform (2 × 50 ml). The organic layer was extracted with 1 *N* HCl (2 × 60 ml) and then water until the aqueous layer was neutral to pH paper. The organic layer was dried and evaporated to dryness to give 3.8 g of crude II.

6-Chloro-9-(β-D-arabinofuranosyl)purine (III)—Into 70 ml of absolute methanol saturated with ammonia, 3.8 g (9.6 mmoles) of II was added. The solution was stirred at room temperature for 6 hr and then evaporated to dryness. The residue was dried *in vacuo* at 65° for 1 day to give 2.4 g (92.7%) of III.

6-Selenoxo-9-(β-D-arabinofuranosyl)purine (IV)—*Method I*—Condensed hydrogen selenide[2] (1.0 ml, 24 mmoles) was bubbled through a solution of 0.2 g (8.7 mmoles) of sodium in 50 ml of absolute methanol. Compound III (2.2 g, 7.7 mmoles) in 10 ml of absolute methanol was added, and the suspension was refluxed for 40 min. The resulting yellow precipitate was filtered by suction, dissolved in 20 ml of 3% Na_2CO_3, and filtered. The filtrate was acidified with acetic acid to pH 4 and cooled. The yellow solid was collected, washed with a small amount of cold water, and dried *in vacuo* to give 1.4 g (52%) of IV, mp 155–157° dec.

Anal.—Calc. for $C_{10}H_{12}N_4O_4Se \cdot H_2O$: C, 34.64; H, 4.04; N, 16.04. Found: C, 34.80; H, 4.07; N, 16.01.

Method II—The suspension of 100 mg (0.36 mmole) of III and 45 mg (0.36 mmole) of selenourea (34) in 5 ml of methanol was refluxed for 20 min. The yellow solution was filtered, cooled in an ice

[1] Melting points were determined on a Gallenkamp melting-point apparatus and are uncorrected. UV spectra were determined on a Perkin-Elmer model 402 spectrophotometer. Elemental analyses were performed either by Midwest Microlab, Indianapolis, Ind., or Robertson Lab, Florham Park, N.J. TLC was run on a polygram CEL 300 PEI and developed with water. Evaporations were accomplished using a Buchler flash evaporator under reduced pressure with a bath temperature of 40°.

[2] Hydrogen selenide, 98.0% minimum purity, from Matheson Co., East Rutherford, NJ 07073

bath, and then poured into 50 ml of ether. The precipitate was held in the refrigerator overnight, filtered, and then dried *in vacuo* to give 45 mg (38%) of yellow solid. The nucleoside isolated was established by UV and TLC to be identical with IV prepared by Method I.

6-(Methylseleno)-9-(β-D-arabinofuranosyl)purine (V)—To a solution of 288 mg (0.82 mmole) of IV in 2.2 ml (0.87 mmole) of 0.4 *N* NaOH, 0.11 ml of methyl iodide was added. The suspension was stirred at room temperature for 2 hr. The solid was filtered by suction, recrystallized from water, and dried *in vacuo* to give 200 mg (84%) of V, mp 171–173°.

Anal.—Calc. for $C_{11}H_{14}N_4O_4Se \cdot H_2O$: C, 36.39; H, 4.45; N, 15.42. Found: C, 36.60; H, 4.66; N, 15.45.

6-(Ethylseleno)-9-(β-D-arabinofuranosyl)purine (VI)—By following the procedure described for V, VI was synthesized from IV and ethyl bromide in 36% yield, mp 160–162°.

Anal.—Calc. for $C_{12}H_{16}N_4O_4Se$: C, 40.12; H, 4.49; N, 15.59. Found: C, 40.56; H, 4.66; N, 15.83.

6-(Isopropylseleno)-9-(β-D-arabinofuranosyl)purine (VII)—To a solution of 145 mg (0.41 mmole) of IV in 5 ml of dry dimethylformamide, 150 mg (1.42 mmoles) of anhydrous sodium carbonate and 65 mg (0.5 mmole) of isopropyl bromide were added. The suspension was stirred at room temperature for 4 hr and partitioned with ethyl acetate–water. The organic layer was dried over anhydrous magnesium sulfate, condensed to a small volume, and partitioned with chloroform–water. The organic layer was dried and evaporated to a small volume. This solution was added dropwise to 200 ml of vigorously stirred hexane. The resulting precipitate was filtered and dried to give 20 mg of VII. The aqueous layer was held at room temperature overnight, and the crystals were collected and dried *in vacuo* to give 40 mg of VII, mp 160–161.5°. The total yield of VII was 60 mg (35%).

Anal.—Calc. for $C_{13}H_{18}N_4O_4Se \cdot H_2O$: C, 39.91; H, 5.15; N, 14.31. Found: C, 39.60; H, 4.88; N, 13.99.

If the reaction was run in aqueous solution at room temperature overnight, the compound isolated was mostly starting material as indicated by UV and TLC.

6-(*n*-Butylseleno)-9-(β-D-arabinofuranosyl)purine (VIII)—To a solution of 288 mg (0.82 mmole) of IV in 2.2 ml of 0.4 *N* NaOH, 120 mg (0.85 mmole) of *n*-butyl bromide was added. The solution was stirred at room temperature overnight and then continuously extracted with ether to give 110 mg (34%) of VIII. The analytical sample was recrystallized from water, mp 142–144°.

Anal.—Calc. for $C_{14}H_{20}N_4O_4Se$: C, 43.42; H, 5.31; N, 14.46. Found: C, 43.02; H, 5.24; N, 14.37.

6-(Benzylseleno)-9-(β-D-arabinofuranosyl)purine (IX)—Compound IX was synthesized in 70% yield from IV and benzyl bromide by the method described for V. The analytical sample was recrystallized from methanol–water, mp 182–184°.

Anal.—Calc. for $C_{17}H_{17}N_4O_4Se \cdot H_2O$: C, 46.48; H, 4.59; N, 12.75. Found: C, 46.48; H, 4.49; N, 12.75.

6-[(1-Methyl-4-nitro-1*H*-imidazol-5-yl)seleno]-9-(β-D-arabinofuranosyl)purine (X)—To a solution of 290 mg (0.82 mmole) of IV in 2.2 ml of 0.4 *N* NaOH, 130 mg (0.81 mmole) of 5-chloro-1-methyl-4-nitroimidazole in 10 ml of methanol was added. The solution was stirred at room temperature for 7 hr and evaporated to dryness, and then 3 ml of water was added. The solid was collected, washed with water, and dried to give 250 mg (64%) of X. The analytical sample was recrystallized twice from water, mp 179–180.5°.

Anal.—Calc. for $C_{14}H_{15}N_7O_6Se \cdot H_2O$: C, 35.46; H, 3.61; N, 20.67. Found: C, 35.89; H, 3.32; N, 20.73.

6-(Cyclopentylseleno)-9-(β-D-arabinofuranosyl)purine (XI)—Compound XI was synthesized in 20% yield from IV and cyclopentyl bromide by the method described for V except that the reaction mixture was stirred at room temperature for 6 days. The analytical sample was recrystallized from methanol–water, mp 96–99°.

Anal.—Calc. for $C_{15}H_{20}N_4O_4Se \cdot H_2O$: C, 43.17; H, 5.31; N, 13.42. Found: C, 43.31; H, 5.27; N, 13.47.

6-[(3-Methyl-2-butenyl)seleno]-9-(β-D-arabinofuranosyl)-purine (XII)—Compound XII was synthesized in 25% yield from IV and 3,3-dimethylallyl bromide by the method described for VII. The analytical sample was recrystallized from methanol–water, mp 113–116° dec.

Anal.—Calc. for $C_{15}H_{20}N_4O_4Se$: C, 45.12; H, 5.05; N, 14.02. Found: C, 44.82; H, 5.20; N, 13.79.

Table II—Inhibition of Reproduction of L-5178Y by 6-Selenopurine Arabinoside and Related Compounds[a]

Compound	Concentration Causing 50% Inhibition	Concentration Causing <50% Inhibition: Concentration	Concentration Causing <50% Inhibition: % Inhibition
6-Thioguanosine	5.6×10^{-6} *M*		
IV	6.6×10^{-5} *M*		
X	1.9×10^{-5} *M*		
V	—[b]	10^{-5} *M*	17
VI	—[b]	10^{-4} *M*	10
VII	—[b]	10^{-5} *M*	10
VIII	—[b]	10^{-4} *M*	24
IX	—[b]	10^{-5} *M*	12
XI	—[b]	10^{-4} *M*	31
XII	—[b]	10^{-4} *M*	45

[a] The leukemic cells L-5178Y were grown from an inoculum of 4×10^3 cells/ml for 72 hr in the presence of different levels (10^{-4}–10^{-7} *M*) of 6-selenopurine arabinoside and its derivatives. The final number of cells were determined in a Coulter particle counter, model B, and the 50% inhibition of each drug was determined as the amount of drug required to cause a 50% decrease in the number of doublings undergone by the cell population when compared with the untreated controls. [b] Compounds V–IX, XI, and XII caused less than 50% inhibition at the highest concentration (10^{-4} *M*) studied.

6-*p*-Nitrobenzylseleno-9-(β-D-arabinofuranosyl)purine (XIII)—To a solution of 144 mg (0.41 mmole) of IV in 1.1 ml of 0.4 *N* NaOH, 94 mg (0.44 mmole) of *p*-nitrobenzyl bromide in 5 ml of methanol was added. The solution was stirred at room temperature for 4 hr. The mixture was evaporated to dryness, and the residue was washed with 50 ml of ether and then with 7 ml of water. The solid was recrystallized from methanol–water and dried *in vacuo* to give 115 mg (60%) of XIII, mp 118–120°.

Anal.—Calc. for $C_{17}H_{17}N_5O_6Se$: C, 43.79; H, 3.68; N, 15.01. Found: C, 43.42; H, 3.72; N, 15.26.

2-Amino-1-methyl-6-(methylthio)purine (XIV)—To a solution of 365 mg (2 mmoles) of 1-methyl-6-thioguanine in 5 ml of 0.4 *N* NaOH, 1.4 ml of methyl iodide was added. The mixture was stirred at room temperature for 30 min. The white precipitate was filtered by suction, washed with water, and dried *in vacuo* to give 290 mg (66%) of XIV, mp 242–245°.

Anal.—Calc. for $C_7H_9N_5S \cdot 1.4H_2O$: C, 38.14; H, 5.40; N, 31.77. Found: C, 37.79; H, 5.24; N, 32.19.

When XIV was heated at 140° *in vacuo*, it dehydrated to give $C_7H_9N_5S$.

Anal.—Calc. for $C_7H_9N_5S$: C, 43.07; H, 4.65; N, 35.86. Found: C, 43.34; H, 4.65; N, 35.73.

1-Methyl-6-selenoguanine (XX)—*Method I*—A mixture of 60 mg (0.27 mmole) of XIV, 300 mg (3.0 mmoles) of potassium bicarbonate, and 0.1 ml (2.6 mmoles) of hydrogen selenide in 3 ml of water was kept at 105° overnight. The solution was cooled to room temperature. The solid was filtered, washed with water, dissolved

Table III—Inhibition of L-5178Y Cells by 6-Selenopurine Arabinoside and Related Compounds[a]

Compound	Control	Survival, % at 1×10^{-7} *M*	at 1×10^{-6} *M*	at 1×10^{-5} *M*	at 1×10^{-4} *M*
IV	100	87 ± 4.08	85 ± 9.98	69 ± 2.53	68 ± 2.08
V	100	87 ± 3.74	83 ± 1.89	79 ± 5.72	73 ± 5.74
VI	100	89 ± 3.56	82 ± 1.89	75 ± 2.06	70 ± 2.63

1×10^{-4}	81 ± 5.36	60.4 ± 2.7	45 ± 5.24	31.2 ± 5.22	18.5 ± 0.71

[a]The L-5178Y cells (2×10^5/ml) in the exponential phase of growth were incubated with X at different time intervals. Cell viability was determined by the dilute agar colony method. Each observation represents the mean value of three experiments with four replicates per experiment. A minimum of 200 colonies was counted for each group. The cloning efficiency of the untreated cells was approximately 75%. All values were normalized to 100%.

in 5 ml of 3% Na_2CO_3 solution, and then acidified with acetic acid to pH 4. The precipitate was collected, washed with cold water, and dried *in vacuo* to give 42 mg (66%) of XX, mp 275–278° dec.

Anal.—Calc. for $C_6H_7N_5Se \cdot 1.1H_2O$: C, 29.07; H, 3.74; N, 28.24. Found: C, 28.81; H, 3.85; N, 28.44.

Method II—A suspension of 93 mg (0.46 mmole) of XV (31) and 61 mg (0.5 mmole) of selenourea in 5 ml of methanol was stirred at room temperature for 1 hr. The yellow precipitate was filtered by suction, washed with 5 ml of methanol, and dried *in vacuo* to give 101 mg (89%) of yellow solid, which was identified as XX by TLC and UV.

2-Amino-7-methyl-6-selenoxo-9-(β-D-ribofuranosyl)purine (7-Methyl-6-selenoguanosine) (XXI)—*Method I*—A solution of 1 g (3.02 mmoles) of 2-amino-6-chloropurine riboside and 1 g (70.4 mmoles) of methyl iodide in 6 ml of dimethylformamide was stirred at room temperature for 40 hr. Then 0.8 g (6.5 mmoles) of selenourea was added, and the solution was stirred at room temperature for an additional 2 hr. At the end of the reaction, the solution was neutralized with methanolic ammonia and diluted with 120 ml of acetone. The precipitate was collected, recrystallized from methanol, and dried *in vacuo* to give 50 mg (6%) of XXI, mp 175° dec.

Anal.—Calc. for $C_{11}H_{15}N_5O_4Se$: C, 36.68; H, 4.20; N, 19.43. Found: C, 36.39; H, 4.14; N, 19.40.

Method II—A solution of 500 mg of XVI in 2.5 ml of dimethylformamide was added to a solution of 50 mg of sodium and 0.5 ml of hydrogen selenide in 5 ml of methanol. The solution was stirred at room temperature for 1 hr and then neutralized with methanolic ammonia. The yellow precipitate was collected and recrystallized from methanol to give 50 mg (10%) of yellow solid, which was verified by UV and TLC to be identical with XXI prepared by Method I.

6-Selenoxo-9-(β-D-ribofuranosyl)purine (XXII)—A suspension of 100 mg (0.36 mmole) of XVII and 45 mg (0.36 mmole) of selenourea in 5 ml of methanol was refluxed for 20 min. The yellow solution was filtered, cooled in an ice bath, and then poured into 50 ml of ether. The precipitate was held in a refrigerator overnight, filtered, and dried *in vacuo* to give 60 mg (50%) of yellow solid, which was identified as XXII (10) by UV and TLC.

2-Amino-6-selenoxo-9-(β-D-ribofuranosyl)purine (6-Selenoguanosine) (XXIII)—A suspension of 200 mg (0.61 mmole) of XVIII and 90 mg (0.72 mmole) of selenourea in 10 ml of methanol was refluxed for 20 min. The solution was filtered, cooled in an ice bath, and poured into 100 ml of ether. The precipitate was filtered and dried *in vacuo* to give 160 mg (76%) of yellow compound, which was identified as XXIII (13, 14) by UV and TLC.

2-Amino-6-selenopurine (6-Selenoguanine) (XXIV)—A suspension of 170 mg (1 mmole) of XIX and 123 mg (1 mmole) of selenourea in 5 ml of methanol was refluxed for 30 min. The yellow precipitate was cooled, filtered, and dried *in vacuo* to give 210 mg (98%) of a yellow solid, which was identified as XXIV (9) by UV and TLC.

Maternal–Fetal Transfer of ^{14}C-Di-2-ethylhexyl Phthalate and ^{14}C-Diethyl Phthalate in Rats

A. R. SINGH, W. H. LAWRENCE, and J. AUTIAN ˣ

Abstract □ ^{14}C-Di-2-ethylhexyl and ^{14}C-diethyl phthalates were administered intraperitoneally to pregnant rats on either Day 5 or 10 of gestation. Rats were sacrificed at 24-hr intervals starting on Days 8 and 11, respectively; maternal blood, fetal tissue, amniotic fluid, and placentas (whenever possible) were obtained. The ^{14}C-activity of each sample was determined by scintillation counting. It was found that both diesters and/or their metabolic products were present in each of these compartments throughout the gestation period, thus suggesting that the embryo–fetal toxicity and teratogenesis reported previously could be the results of a direct effect of the compound (or its metabolites) upon developing embryonic tissue. Additionally, the reduction in concentration of ^{14}C from these tissues as a function of time was found to fit a first-order excretion curve. From this model curve, the half-life for both compounds was calculated; the average was about 2.33 days for di-2-ethylhexyl phthalate and 2.22 days for diethyl phthalate.

Keyphrases □ Phthalate diesters, radiolabeled—distribution and persistence in maternal blood, fetal tissue, amniotic fluid, and placenta, intraperitoneal administration, rats □ Maternal–fetal transfer—phthalate diesters (radiolabeled), distribution and persistence in maternal blood, fetal tissue, amniotic fluid, and placenta, intraperitoneal administration, rats □ Toxicity—phthalate diesters (radiolabeled), maternal–fetal transfer, rats

Phthalic acid esters are the major plasticizers used by the plastics industry, and di-2-ethylhexyl phthalate (I) is the most widely used plasticizer. Compound I is contained in many plastic products (primarily polyvinyl chloride) used in medical, dental, and paramedical applications as well as in household and vehicular furnishings. Some of these plasticizers also are used as solvents in commercial formulations such as perfumes and insect repellents.

The acute and chronic toxicities of these esters have been found to be rather low by conventional routes of administration (oral, intraperitoneal, intravenous, and inhalation) (1–6); their industrial uses have presented few confirmed toxicological problems, although some adverse effects have been suggested (7–9). Jaeger and Rubin (10) reported finding I in the tissues of two patients who had received transfusions of blood stored in plastic bags. *In vitro* experiments, which they conducted using the perfused rat liver, indicated that this organ would accumulate I but would not hydrolyze it. A related plasticizer, butyl glycolyl-butyl phthalate, was hydrolyzed by this system.

Teratogenic effects of the phthalates were reported in chick embryos when the phthalates were injected into the yolk sac of the developing embryo (11–13). Recently, demonstration of mammalian teratogenicity was reported from intraperitoneal injections of phthalates into pregnant rats (14).

When considering potential teratogenic effects, physicochemical properties of the compound often play a highly significant role. It is generally believed that a compound with a molecular weight of less than 1000 (unless highly bound to plasma proteins or other large molecules) can pass through the placental barrier to reach the developing fetus, where it may exert a direct effect (15). Passage through the placenta, however, is not the sole criterion for teratogenicity, since many drugs are known to reach the fetus without having any adverse effect upon its development. Moreover, a compound that does not pass this barrier may cause metabolic disturbances in the mother which secondarily interfere with development of the fetus (15).

The purposes of this study were to investigate the maternal–fetal transfer in rats of two phthalic acid esters and to determine whether they and/or their metabolites pass through the placental barrier to the developing fetus where they may elicit potential direct embryo–fetal toxicity and/or teratogenic effects.

EXPERIMENTAL

Materials—Carboxy-labeled ^{14}C-di-2-ethylhexyl phthalate (^{14}C-I) and ^{14}C-diethyl phthalate (^{14}C-II)[1] were mixed with unlabeled I and II[2], respectively, to provide the desired level of radioactivity. Test animals were adult virgin female rats of the Sprague–Dawley strain[3], weighing 175–225 g. Male rats of the same strain and age were used as the "stud pool."

Methods—Female rats were selected for experimentation only after observation of at least two complete 4- or 5-day estrus cycles. Females were bred and vaginal smears were obtained each morning. The date of appearance of sperm in the vaginal smear was recorded as Day 0 of pregnancy, as previously described (14).

A group of 13 pregnant rats was injected with 5 ml/kg ip of ^{14}C-I (4.0123×10^7 dpm/ml or 7.16×10^{-3} mCi/mmole) on Day 5 of gestation. A second group of 10 pregnant rats was injected intraperitoneally with the same dosage of ^{14}C-I on Day 10 of gestation. A similar group of pregnant rats was injected with 1.0116 ml/kg ip of ^{14}C-II (1.121×10^8 dpm/ml or 1.00×10^{-2} mCi/mmole) on Day 5 of gestation, and another group was injected on Day 10.

From groups injected on Day 5 of gestation, one rat was sacrificed with an overdose of ether by inhalation 72 hr after the ^{14}C-I or ^{14}C-II injection and then every 24 hr through Day 20 of gestation to obtain specimens for analysis. From the groups injected on Day 10, one rat was sacrificed every 24 hr through Day 20 of gestation.

About 4–5 ml of maternal blood was collected by cardiac puncture using a heparinized syringe, and amniotic fluid was aspirated from the gravid uterus. The whole fetuses and, whenever possible, the placentas were removed by uterine incision and isolated from the maternal tissue to avoid cross-contamination during subsequent dissection. Whole fetuses (and placentas when collected) were blotted gently with a surgical sponge and transferred to chilled, tared bottles for weighing. The tissues (whole fetuses and placentas) were minced with scissors and diluted three- to fivefold with distilled water. The diluted tissues were then homogenized[4]

[a] Mean counts of one to five samples for each tissue. [b] Total blood in the rat was assumed to be 7% of its body weight. [c] Percent of injected dose was based upon quantity of radioactivity administered and total radioactivity estimated for each organ. [d] Less than 0.001% of injected dose.

at medium speed while the flask was immersed in dry ice.

Aliquots of blood, amniotic fluid, placentas, or fetal tissues (usually 100–150 mg) were solubilized[5]. The tissues (only) were warmed for about 2 hr at 50° in a water bath to minimize chemiluminescence. The samples were bleached when necessary with benzoyl peroxide[6] (up to 3 ml) and adjusted to pH 6.4 with acetic acid (67%). The samples treated with benzoyl peroxide exhibited significant chemiluminescence, which was minimized by storing the prepared samples in the dark for 24 hr. Ten milliliters of preblended liquid scintillation cocktail[7] was added to the samples of blood, amniotic fluid, or homogenized placentas or fetal tissues. Finally, these prepared samples were counted in a liquid scintillation spectrometer[8].

After the samples were counted, a standard aliquot of ^{14}C-toluene[9] (5000 dpm) was added to each, and these samples were recounted to obtain an estimate of the counting efficiency. The absolute radioactivity of the samples was calculated based upon the specific activity of the internal standard, ^{14}C-toluene.

Counts, counting efficiency, and original weight of sample were used to calculate the radioactivity of each specimen in terms of disintegrations per minute per gram or disintegrations per minute per organ. These values were used in conjunction with the specific activity of the injected ^{14}C-I and ^{14}C-II to estimate their molar concentrations (assuming all radioactivity was still present as the diesters) in the maternal blood, embryonic fluid, placentas, and whole fetuses. For this purpose, the total blood in the rat was assumed to be 7% of its body weight.

RESULTS

A total of 46 pregnant rats and their fetuses were studied following ^{14}C-I and ^{14}C-II administration on Days 5 or 10 of gestation. Radioactivity was detected in maternal blood, placentas, amniotic fluid, and developing fetuses at all gestational stages investigated. No grossly obvious toxic effects were seen in the pregnant females during the gestation period after injection of either radioactive phthalate. Tables I and II present a summary of the mean counts per gram of tissue, estimated counts per organ, and percent of injected dose taken up by various tissues after ^{14}C-I was injected on Day 5 or 10 of gestation. Similar data following ^{14}C-II injection are shown in Tables III and IV.

Both radioactive phthalates and/or their metabolites were widely distributed and were found in maternal blood, placentas, amniotic fluid, and fetal tissues. Less than 1% of the injected dose was present in these tissues at any of the measured times. Generally, the level of radioactivity in the placenta, amniotic fluid, and whole fetus seemed to be related to the concentration in the maternal blood, but none of these tissues exhibited a consistently higher level than that found in the maternal blood for either compound.

Radioactivity in the maternal blood increased, reaching a peak during the first 48 hr following injection of ^{14}C-I and during the first 24 hr after radioactive II injection. The concentration of radioactivity then diminished quickly for both compounds. A similar pattern was observed in the amniotic fluid and fetal tissues. Some radioactivity was detected in all tissues examined throughout the experimental period (10–15 days postinjection).

A first-order rate equation was fitted to that portion of the experimental data where radioactive counts were declining with respect to time. Least-square slopes were obtained from the logarithm of radioactivity *versus* time in days for maternal blood, amniotic fluid, and fetal tissue compartments. For three of the four cases (administration of ^{14}C-I at Days 5 and 10 and of ^{14}C-II at Day 10), the 95% confidence intervals of the least-square slopes were overlapping for all of these compartments. In the other case (^{14}C-II administration on Day 5), the confidence intervals of the least-square slopes failed to overlap, but the gap was present only in the third decimal place. From this treatment of the experimental data, it is not possible to determine that the slopes (or rate constants) are significantly different from one another.

DISCUSSION

Previous studies (14) revealed embryo–fetal toxicity and teratogenicity in rats from intraperitoneal injections of these phthalate esters. This study clearly demonstrated the presence of phthalates and/or their metabolites in the developing fetus from early embryogenesis to birth, including the critical period of teratogenic sensitivity. The embryo–fetal toxicity and fetal abnormalities produced by these phthalates, together with the demonstration of their presence in the early embryo, suggest that phthalate esters and/or their metabolites may act directly on embryonic tissues in the induction of teratogenicity.

Using ^{14}C-radioactivity data, a half-life was calculated for each compound. The half-life of II was 2.22 days; for I, it was 2.33 days. These values are in reasonably good agreement with those reported by Daniel and Bratt (18), who gave a half-life of 1–2 days for I in rat liver and of 3–5 days for fat.

These studies showed that radioactivity from ^{14}C-II and ^{14}C-I is transmitted across the placenta from mother to fetus in pregnant rats and that the radioactivity is detectable for at least 15 days postinjection. Although the exact chemical nature of the radioactive compound(s) transmitted to the fetus was not determined, some of them probably were mixtures of parent compounds, monoesters, and phthalic acid.

Studies on absorption, distribution, metabolism, and excretion of carboxy-labeled ^{14}C-I in rats were reported previously (16–18). The three studies found that increased water-soluble products were formed and excreted primarily in the urine and feces. Albro *et al.* (17) suggested there is probably an initial hydrolysis of the compound to the monoester, mono-2-ethylhexyl phthalate (III), with subsequent side-chain oxidation to the alcohol, ketone, and acids or hydrolysis to phthalic acid. Daniel and Bratt (18) reported finding only the diester in the liver of treated animals, while Schultz and Rubin (16) found both water-soluble and organic-extractable fractions in the liver at 1 and 24 hr after intravenous administration of ^{14}C-I.

Studies[10] with ^{14}C-I in mice revealed the presence of ^{14}C-III and other metabolites in tissues of the treated animals as well as in urine and feces. Dillingham and Autian (19) reported that approximately 83% of an intraperitoneal dose of ^{14}C-I was excreted in the urine of mice in 14 days and that no significant radioactivity was found in the mice after 35 days. In another study[10], both mice and rabbits metabolized and excreted ^{14}C-II in a fashion somewhat similar to that for I.

Autian (20) reported inhibition of mammalian cell growth

[10] Unpublished data, Materials Science Toxicology Laboratories.

(mouse fibroblasts or L-cells) in culture from both I and II. Using a protein assay system for quantitation of cell growth, 3×10^{-3} mole/liter of II reduced growth by 50%; a similar effect was observed for I at a concentration of 5×10^{-5} mole/liter. These original data also revealed that approximately 10% growth inhibition was produced by II at a level of 5×10^{-4} mole/liter and that a similar effect was elicited by 4.7×10^{-5} mole/liter of I. In the present study, fetal concentrations of II (based upon ^{14}C counts) ranged from 1.5×10^{-4} to 2.8×10^{-6} mole/kg; similar ranges of I were from 5.9×10^{-4} to 4×10^{-6} mole/kg. Thus, these data suggest the phthalates may be reaching developing fetal tissues in concentrations comparable to those that have been demonstrated to affect growth of mammalian cells in culture.

It was found that maternal blood levels reached a peak radioactive concentration in 24 hr or less after intraperitoneal administration of ^{14}C-II and within 48 hr after ^{14}C-I. Counts (disintegrations per minute per gram) obtained 48 hr or more after ^{14}C-I injection were invariably higher in maternal blood than in fetal tissues; concentrations in maternal blood also appeared to influence the concentrations in the amniotic fluid and placenta.

Radioactivity following a single injection of the ^{14}C-phthalate was observed in maternal blood and fetal tissues throughout the observation period (10–15 days). The relatively long *in vivo* half-life (about 2.2–2.3 days) for these compounds suggests that repetitive maternal exposures during pregnancy might lead to accumulation of toxicologically significant quantities of such compounds within the major organs of the fetus. To explore this potential problem further, a comparative study should be conducted to quantitate the phthalate and/or its metabolites in various major maternal and fetal organs. Concurrently, investigations should be conducted to determine the effects of varying levels of the phthalate esters (and/or metabolites) upon developmental structures and functions of the various organs.

Metabolism of Triamcinolone Acetonide-21-phosphate in Dogs, Monkeys, and Rats

K. J. KRIPALANI ˣ, A. I. COHEN, I. WELIKY, and E. C. SCHREIBER

Abstract □ The absorption, distribution, and metabolic fate of triamcinolone acetonide-^{14}C-21-phosphate were studied in the dog, monkey, and rat. A comparison of levels of radioactivity in blood or plasma, reached after intramuscular or intravenous administration, indicated that the drug was completely absorbed from the site of intramuscular injection within 10–15 min in all three species. Within 1–5 min after intramuscular or intravenous administration, the 21-phosphate ester was completely hydrolyzed to triamcinolone acetonide, which was present in the blood. The radioactivity was eliminated rapidly ($t_{1/2}$ = 1–2 hr) from plasma (dogs, monkeys, and rats) and tissues (rats) after intramuscular or intravenous administration. In the three species, the major route of excretion was *via* the bile; however, the ratio of biliary to urinary excretion among the species varied considerably (from 1.5 to 15). In rats, excretion of radioactivity as expired carbon dioxide accounted for only 2–3% of the dose. 6β-Hydroxytriamcinolone acetonide was the major metabolite in urine of the three species. Hydrolytic cleavage of the acetonide group did not appear to be significant.

Keyphrases □ Triamcinolone acetonide-21-phosphate, ^{14}C-labeled—absorption, distribution, and elimination after intravenous and intramuscular administration, dog, monkey, rat □ Absorption—triamcinolone acetonide-^{14}C-21-phosphate after intravenous and intramuscular administration, dog, monkey, rat □ Distribution—triamcinolone acetonide-^{14}C-21-phosphate after intravenous and intramuscular administration, dog, monkey, rat □ Elimination—triamcinolone acetonide-^{14}C-21-phosphate after intravenous and intramuscular administration, dog, monkey, rat □ Metabolism—triamcinolone acetonide-^{14}C-21-phosphate after intravenous and intramuscular administration, dog, monkey, rat

Esterification of steroid alcohols has a marked influence on their absorption and excretion. After intramuscular administration, water-soluble esters (*e.g.*, phosphates, succinates, and glycinates) are absorbed and excreted rapidly (1–4), whereas water-insoluble esters (*e.g.*, acetates) are absorbed and excreted more slowly (1, 5). After administration, the steroid esters seem to be readily hydrolyzed to the corresponding steroid alcohols.

Hydrolysis of the phosphate esters of hydrocortisone, prednisolone, and dexamethasone appears to be rapid and complete, possibly as a result of the activity of phosphomonoesterases in plasma (2). The steroid alcohol resulting from such hydrolysis may then be metabolized as if it had been administered directly. In dogs, 6-methylprednisolone-^{3}H-21-acetate was metabolized in a manner similar to that of prednisolone (5).

No data are available for the relative blood levels obtained after intravenous and intramuscular administration of water-soluble esters of synthetic anti-inflammatory steroids, nor has the distribution of such drugs in tissues been reported. It is important to determine the distribution in blood and other tissues at various times after administration, because the increased water solubility of a steroid ester may alter its distribution in the body and, hence, influence its concentration at the target site.

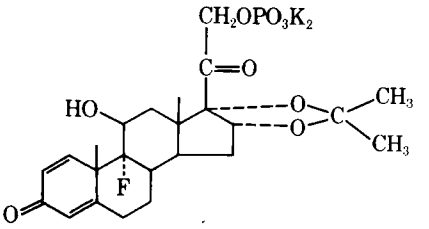
Triamcinolone acetonide-21-dipotassium phosphate (I) is a water-soluble 21-phosphate ester of triamcinolone acetonide (9-fluoro-11β,16α,17,21-tetrahydroxypregna-1,4-diene-3,20-dione cyclic 16,17-acetal with acetone, 21-phosphate, dipotassium salt). It is about 80 times more active than cortisone acetate in the liver glycogen deposition assay[1], and 10–50 times more active than hydrocortisone acetate in the antigranuloma assay in the rat[2].

Metabolic transformations of triamcinolone acetonide-21-phosphate may be similar to those of triamcinolone acetonide. Triamcinolone was metabolized in dogs and humans to the 6β-hydroxy compound (6), and triamcinolone acetonide was converted in rat liver *in vitro* to 6β-hydroxytriamcinolone acetonide (7). However, biotransformation *in vivo* of triamcinolone acetonide or of its phosphate ester has not been reported.

The 17-hydroxy group, considered necessary for the glucocorticoid activity of hydrocortisone, is blocked by the presence of the 16,17-acetonide group in the triamcinolone acetonide molecule. Inasmuch as triamcinolone acetonide has greater glucocorticoid activity than does hydrocortisone, it is of interest to find out whether the 16,17-acetonide group is hydrolyzed *in vivo* to give rise to a 17-hydroxy group. The present studies were carried out to determine this hydrolysis as well as the absorption, excretion, tissue distribution, and biotransformation of triamcinolone acetonide 21-phosphate after intramuscular or intravenous administration to dogs, monkeys, and rats.

EXPERIMENTAL

Measurement of Radioactivity—All samples were counted in a liquid scintillation spectrometer[3], using the method of automatic external standardization. Feces were homogenized in a volume of



I

[1] L. J. Lerner, Endocrinology Department, Squibb Institute for Medical Research, Apr. 18, 1961, unpublished data.

[3] Packard Tri-Carb model 3375 or 3380.

methanol equivalent to half the weight of the sample. After portions of fecal homogenate, blood, plasma, and tissues were combusted in an oxygen atmosphere and the resulting carbon dioxide was trapped in a solution containing phosphor, the samples were counted.

Portions of bile and urine were counted in Bray's solution (8). Nonaqueous samples were counted in a solution containing 5 g of 2,5-diphenyloxazole and 0.3 g of 1,4-bis(4-methyl-5-phenyloxazolyl)benzene in 1 liter of spectral grade toluene. Portions (0.5 ml) of solutions containing trapped, expired $^{14}CO_2$ were counted after the addition of 2 ml of a solubilizer[4] and 15 ml of toluene phosphor solution.

Purity and Specific Activity of Triamcinolone Acetonide-^{14}C-21-phosphate—Triamcinolone acetonide-21-phosphate (dipotassium salt), labeled with ^{14}C in the 2-position of the acetonide group, was synthesized[5] and had a specific activity of 5.8 μCi/mg and a radiochemical purity of 96%, as determined by paper chromatography[6] in *n*-butanol–ethanol–2 *N* ammonium hydroxide (10:2:4).

Extraction of "Unconjugated" Metabolites—Plasma samples were extracted once with 10 volumes of methylene chloride. Urine and bile samples were extracted four times with an equal volume of ethyl acetate; the pooled extracts were washed with 0.1 volume of water.

Extraction of "Conjugated" Metabolites—Conjugated metabolites were separated from the extracted urine or bile by use of a nonion-exchange resin[7], according to the procedure described by Bradlow (9). Hydrolysis of the conjugated steroid fraction was carried out by incubation at 37° for 48 hr in 0.1 *M* acetate buffer, pH 4.6, containing 10% (v/v) of a solution containing β-glucuronidase[8].

After incubation, samples were extracted with ethyl acetate by the procedure described for urine and bile. The ethyl acetate extracts represented hydrolyzed metabolites originally present as glucuronides. The resulting aqueous fraction was subjected to solvolysis (10) to cleave and isolate the steroids originally present as sulfate conjugates.

Chromatographic Methods—TLC was carried out on precoated 0.25- and 2.0-mm silica gel H and silica gel F-254 plates[9]. Prior to use for preparative purposes, the plates were predeveloped, first in benzene and then in methanol. Three solvent systems were used for developing the thin-layer chromatograms: A, methanol–chloroform (8:92); B, methanol–ethyl acetate (2:98); and C, acetone–benzene (35:65). The radioactive zones on TLC plates were located by use of a scanner[10].

Paper chromatography[6] was carried out with 50% aqueous methanol–benzene (1:1) as the developing solvent. Radioactive zones were located by uniform sectioning of a lengthwise portion of the paper chromatogram, followed by liquid scintillation counting of each section in Bray's solution.

Silica gel[11] (100–200 mesh) was used for column chromatography. The eluting solvents were 10-ml portions of mixtures that contained increasing amounts of ethyl acetate in benzene (5% increase per successive 10-ml portion up to 100%). The elution was then continued with similar mixtures containing increasing amounts of methanol in ethyl acetate. Portions of the fractions collected were counted to locate the labeled compounds.

Partition chromatography[12] was carried out in a 1.5 × 60-cm column, with chloroform–toluene–ethylene glycol (1:6:7) as the solvent system. Fractions (10 ml) were collected at a rate of three per hour. Portions of the fractions collected were counted to locate the labeled compounds.

Drug Administration—The ^{14}C-labeled drug was dissolved in a vehicle formulated for the injectable product. The vehicle consisted of saccharin sodium, 40 mg; sodium citrate, 10 mg; sodium bisulfite, 3 mg; polyethylene glycol 300, 250 mg; benzyl alcohol, 15 mg; and water for injection to make 1.0 ml. Triamcinolone acetonide-21-phosphate was stable in this vehicle.

Purebred beagles (9.2–9.6 kg), female rhesus monkeys (*Macacca mulatta*, 3.6–5.6 kg), and Sprague–Dawley rats[13] (0.2 kg) were used. Dogs and rats were placed in individual metabolism cages, and monkeys were seated in restraining chairs[14]. Dogs and monkeys were fitted with urinary catheters. All animals were deprived of food, but not of water, for 24 hr before dosing.

At 60 and 30 min prior to drug administration, the dogs and monkeys were hydrated by oral administration of 20 ml of water/kg. A bile-cannulated dog was maintained under gaseous anesthesia (methoxyflurane) and infused with isotonic saline at a rate of 3 ml/min; thiamylal sodium[15], 0.4 ml of 4% solution/kg iv, was used as the preanesthetic. Intramuscular doses were injected into the gastrocnemius muscle of dogs, monkeys, and rats. The saphenous vein of dogs and monkeys and the tail vein of rats were used as the sites of intravenous injections.

Sampling Procedure—Heparinized syringes were used to withdraw blood (5–10 ml) from the jugular vein of dogs or the saphenous vein of monkeys. A portion of the blood sample was saved for radioassay, and the remainder was centrifuged under refrigeration at 2000 rpm for 10 min to separate the plasma.

During the first 8 hr after administration to dogs, urine was collected through catheters; thereafter, urine was collected in metabolism cages. After ligation of the gallbladder of the dog, bile was collected through a catheter inserted into the common bile duct. With monkeys, urine was collected through catheters throughout the experiment. Feces were collected every 24 hr from dogs and monkeys.

Urine and feces from rats were collected from the metabolism cages. To measure the $^{14}CO_2$ evolved, each rat was placed in a plastic metabolism cage enclosed in a plastic bag. Air was drawn from the cages through two carbon dioxide-absorbing traps, connected in series with a vacuum line and containing a solution of monoethanolamine and 2-methoxyethanol (1:3). Tissues were excised from rats after decapitation.

Incubation with Dog Blood—Triamcinolone acetonide-^{14}C-21-phosphate (0.2 mg) was incubated with 50 ml of freshly drawn heparinized blood at 37° with gentle shaking. Blood samples (5 ml) were removed at various times and centrifuged to separate plasma. Portions of plasma (1 ml) were extracted with 5 ml of methylene chloride. Portions of blood, plasma, extracted plasma, and methylene chloride extracts were assayed for radioactivity. Triamcinolone acetonide-^{14}C-21-phosphate was incubated with phosphate buffer (0.15 *M*, pH 7.4) as a control.

Incubation with Rat Muscle—Femoral muscles from four female rats were minced in a meat grinder, and a 10% suspension of this minced muscle in 0.25 *M* sucrose was prepared. Muscle homogenate was prepared from a portion of the minced muscle suspension (11). Minced muscle suspension or muscle homogenate, each containing the equivalent of 1.2 g of minced muscle and 0.2 μmole of glucose, was incubated with 40 μg of triamcinolone acetonide-^{14}C-21-phosphate at 37° for 24 hr. An equivalent amount of muscle homogenate, immersed for 30 min in boiling water, was used as a control.

Portions of each mixture (1 ml) were removed at various times during the incubation period. Each portion was extracted with 5 ml of methylene chloride, and 0.5 ml of each methylene chloride extract was assayed for radioactivity.

Isolation of Triamcinolone Acetonide (Metabolite 1) and 6β-Hydroxytriamcinolone Acetonide (Metabolite 2) from Urine—*Dog*—An ethyl acetate extract of the first 8-hr urine sample from Dog Q9-191 was subjected to preparative TLC in Solvent System B. Metabolite 1 was eluted from silica gel in an area corresponding in R_f value to that of authentic triamcinolone acetonide and was purified by paper chromatography.

Metabolite 2 was isolated by preparative TLC (Solvent System A) of an ethyl acetate extract of an 8-hr urine sample from a bile-cannulated dog (Q9-156). The radioactive material, isolated from an area corresponding to R_f 0.3 (triamcinolone acetonide, R_f 0.45), was purified by TLC in Solvent System B.

Monkey—Silica gel column chromatography of the combined ethyl acetate extracts of the 24-hr urine samples (from the four ex-

periments with Monkeys 65 and 66) yielded two peaks of radioactivity. Metabolites 1 and 2 were isolated by TLC in Solvent System A from the fractions corresponding to the first and second peaks off the column, respectively. Metabolite 2 was further purified by TLC in Solvent System B.

Rat—For isolation of metabolites from urine, 10 mg of triamcinolone acetonide-^{14}C-21-phosphate was administered intramuscularly daily to each of four female rats (0.25–0.30 kg) for 4 days. Urine collected for 4 days from the four rats was pooled. TLC (Solvent System A) indicated that radioactive metabolites in this pooled urine were the same as those in the urine collected after administration of a single dose (1.5 mg/kg).

The pooled urine was extracted with ethyl acetate. After evaporation of the solvent from the ethyl acetate extract, the residue was partitioned between benzene and water. The aqueous fraction was then extracted with ethyl acetate (ethyl acetate fraction). Metabolite 1 and a portion (20%) of Metabolite 2 were isolated from the benzene extract by preparative TLC in Solvent System A. Metabolite 1 was crystallized from methanol. Metabolite 2, isolated from the benzene fraction, was purified by silica gel column chromatography and crystallized from ethyl acetate. The major portion of Metabolite 2 (80% of the total) was isolated from the ethyl acetate fraction by silica gel column chromatography and then crystallized from ethyl acetate.

NMR and Mass Spectrometry—The 100-MHz NMR spectra were obtained on an NMR spectrometer[16] homolocked to the protons in the tetramethylsilane reference. All chemical shifts are given in tau (τ) values. The low- and high-resolution mass spectra were obtained on a mass spectrometer[17], using the direct insertion probe. The source temperature was maintained at 180° above ambient; data were collected on a frequency-modulated analog tape recorder and were subsequently processed on a computer using Squibb programs (12).

RESULTS

The dose of triamcinolone acetonide-21-phosphate and the levels of radioactivity are expressed as triamcinolone acetonide equivalents.

Hydrolysis of Triamcinolone Acetonide Phosphate to Triamcinolone Acetonide by Incubation with Dog Blood—Based on an hematocrit value of 0.44 and relative concentrations in blood and plasma, it was established that at least 98% of the radioactivity in blood was present in the plasma. One minute after incubation of triamcinolone acetonide-^{14}C-21-phosphate with blood (4 μg/ml), 46% of plasma radioactivity was extractable into methylene chloride. No radioactivity was extracted into methylene chloride from the phosphate buffer control incubation. During the 2-hr incubation, methylene chloride extracts of plasma samples, obtained at nine different times, contained 44–62% of the radioactivity in plasma, whereas extracts of control incubation contained no more than 3% of the total radioactivity.

TLC (Solvent System A) of the methylene chloride extracts of plasma samples showed a single peak of radioactivity, which had the same R_f value (0.45) as did triamcinolone acetonide.

A portion (8000 dpm) of the combined methylene chloride extracts of plasma samples was mixed with unlabeled triamcinolone acetonide (8.0 mg), and the mixture was crystallized from ethyl acetate three successive times. The specific activity of each successive batch of crystals was 930, 1005, and 962 dpm/mg.

These results demonstrate that triamcinolone acetonide-21-phosphate is hydrolyzed to triamcinolone acetonide by plasma esterases.

Hydrolysis of Triamcinolone Acetonide-21-phosphate to Triamcinolone Acetonide by Incubation with Rat Muscle—One minute after incubation of triamcinolone acetonide-^{14}C-21-phosphate with rat minced muscle or rat muscle homogenate (33 μg/g of muscle), 3% of the radioactivity in the incubation mixture could be extracted with methylene chloride. Successively greater quantities were extractable: 28% in 2 hr and 42% after 4 hr. The percentage of radioactivity extracted from a control incubation with a boiled muscle homogenate was 0.6–1.1% during the first 4 hr of incubation.

Methylene chloride extracts of the incubation mixtures contained only one radioactive compound, which had the same R_f as did triamcinolone acetonide (Solvent System A).

These results show that hydrolysis of the 21-phosphate ester of triamcinolone acetonide could occur in the rat muscle. The rate of hydrolysis in the rat muscle incubations appeared to be much slower ($t_{1/2}$ = 4.5 hr) than that in plasma, in which case 46% was hydrolyzed after 1 min of incubation.

Plasma Levels—Levels of radioactivity in the plasma of two dogs and four monkeys are shown in Table I. In addition, plasma levels in a bile-cannulated dog (Q9-156)[18] are shown in Fig. 1. Plasma samples collected during the first 10 or 15 min after intravenous administration to Dog Q9-156 (bile cannulated) and Monkey 65 showed a rapid and precipitous drop in the level of radioactivity during this interval, indicating rapid distribution of the drug into the extravascular compartments. The plasma half-life of radioactivity during this distribution phase was calculated[19] to be 1 min for the dog and 1.5 min for the monkey.

After the first 10 or 15 min, elimination of radioactivity from plasma of the three dogs and the four monkeys followed a biphasic pattern. The half-life values, calculated by the method of residuals, are shown in Table II. The plasma half-life during the first phase (10–240 min) was 35 min in each of the three dogs and 65–85

Key: O, experimental values; and Δ, residual values, calculated by subtracting from the experimental value the value obtained at the corresponding time on the extrapolated part of the curve. The ordinate values are expressed as microgram equivalent of triamcinolone acetonide based on radioassay.*

min in the four monkeys. In the same animals, the rate of disappearance during the second phase (240–480 min) was slower and more variable than that during the first phase. The half-life values during the second phase were 170–270 min in the dogs and 250–720 min in the monkeys; however, the levels of radioactivity during this phase were less than 5% of the initial radioactivity in plasma observed after intravenous administration to dogs or monkeys.

Levels of radioactivity in rats after intramuscular or intravenous administration are shown in Tables III and IV (with tissue distribution data). The elimination of radioactivity from plasma followed first-order kinetics during the interval of 30–360 min after dosing. The half-life for disappearance of radioactivity during this phase was 95 or 110 min after intramuscular or intravenous administration, respectively[20]. After this initial phase, the plasma levels declined at a slower rate ($t_{1/2}$ = 420 min) between 360 and 1440 min. Plasma levels during the latter phase were less than 3% of the initial levels seen after intravenous administration.

In all three species, peak levels of radioactivity in plasma were observed 10–15 min after intramuscular administration, and the subsequent plasma levels were substantially the same as those observed after intravenous administration. These results indicate a rapid and complete absorption of the drug from the site of intramuscular injection.

Distribution in Rat Tissues—Concentrations of the labeled drug in different tissues at various times between 1 and 1440 min after intravenous or intramuscular administration are shown in Tables III and IV. After intramuscular administration, peak levels of radioactivity were measured at 15 min in the plasma, liver, adrenals, ovary, and stomach and at 30 min in other tissues (except the intestine plus contents). The levels of radioactivity between 30 and 1440 min after intramuscular or intravenous administration were approximately equal in all tissues, indicating rapid and complete distribution of the drug when given by the intramuscular route.

[20] Due to insufficient data points on the plasma level curves, the half-life values were calculated from the slope of the semilogarithmic plots and not by the method of residuals.

Table II—Half-Life Values for Disappearance of Radioactivity from Plasma of Dogs and Monkeys after Intramuscular or Intravenous Administration of Triamcinolone Acetonide-^{14}C-21-phosphate

Animal	Route of Administration	Dose, mg/kg	Half-Life, min: Between 10 and 240 min	Half-Life, min: Between 240 and 480 min
Dog Q9-191	Intramuscular	0.9	35	270
Dog Q9-156	Intravenous	0.9	35	250
Dog Q9-156[a]	Intravenous	1.2	35	170
Monkey 65	Intramuscular	1.3	65	250
Monkey 66	Intramuscular	1.3	65	720
Monkey 65	Intravenous	1.3	85	380
Monkey 66	Intravenous	1.3	70	360

[a] Anesthetized bile-cannulated dog; 7 weeks after previous dosing.

At 1 min after drug administration (intravenous or intramuscular), as one might expect, plasma had a higher concentration of radioactivity than did any of the tissues examined. At subsequent times, the concentrations in liver were 3–10 times greater than those in plasma; those in adrenals were 1.3 to 8 times greater. Concentrations in the kidneys increased from 0.7 to 2 times those in plasma. The concentration in the brain was the lowest (less than one-tenth the concentration in plasma) of all tissues. The amount of radioactivity in the intestines and their contents increased continuously throughout the 1440-min period, suggesting biliary excretion of the drug; this suggestion was confirmed by excretion studies.

The half-life values for disappearance of labeled drug from tissues were calculated. Although the concentrations in various tissues varied widely, the half-life values for disappearance of labeled drug from all tissues (except the intestine plus contents) were in good agreement with the half-life in plasma. Between 120 and 360 min, the half-life values after intravenous or intramuscular administration ranged from 96 to 120 min in plasma and from 84 to 180 min in the tissues other than intestine plus contents.

The half-life for transfer of radioactivity from the site of injection after intramuscular administration was 12 min during the first 30 min; this half-life represents the rate of drug transfer. After 120 min, when most of the injected drug would be expected to have left the injection site, the half-life observed, *i.e.*, 102 min, was in good agreement with the measurements of half-lives in the other tissues.

Characterization of Radioactive Material in Plasma—The percentage of radioactivity extracted into methylene chloride from plasma samples obtained at various times from the three species is shown in Table V. When triamcinolone acetonide-^{14}C-21-phosphate was added to plasma (4 μg/ml) *in vitro*, no radioactivity was extracted into methylene chloride; however, under the same conditions, triamcinolone acetonide-^{14}C was completely extractable. For the plasma samples obtained within the first 10 min after administration of the labeled drug, 91–98% of the radioactivity in plasma was extracted into methylene chloride; with subsequent samples, the extractable radioactivity generally decreased with time.

Radioscans after TLC of methylene chloride extracts of plasma samples, obtained during the first 60 min after dosing of dogs, monkeys, and rats, showed one major peak (90–95% of the radioactivity in the extracts), corresponding in R_f values to triamcinolone acetonide in Solvent Systems A (R_f 0.45) and B (R_f 0.40). At later times (up to 24 hr), smaller peaks with R_f values lower than that of triamcinolone acetonide were also seen; these peaks accounted for 15–25% of the radioactivity in the plasma extracts.

The radioactivity present in the first 60-min plasma samples of each species was eluted with ethyl acetate from the silica gel plates. The isolated material for each species (approximately 4000–8500 dpm) was mixed with an authentic sample of unlabeled triamcinolone acetonide (6–7 mg) and crystallized from ethyl acetate to constant specific activity. For labeled material isolated from dog plasma, the specific activity of each successive batch of

[a] Expressed as micrograms of triamcinolone acetonide per gram of tissue. [b] 1.5-mg equivalents of triamcinolone acetonide/kg. [c] Each value shown is the average and range of the mean for two determinations, each in a separate rat, with the exception of the 1-min values. [d] Micrograms per milliliter.

crystals was 729, 736, 709, and 710 dpm/mg; calculated specific activity was 731 dpm/mg. Similar values obtained in plasma samples from the monkey were 1290, 1245, 1179, and 1220 dpm/mg; those for the rat were 954, 942, and 941 dpm/mg. Calculated values for specific activity were 1214 and 1095 dpm/mg for the monkey and rat, respectively.

Based on chromatography in the two solvent systems and on isotope dilution, the major radioactive metabolite found in the plasma of dog, monkey, and rat was identified as triamcinolone acetonide.

These results show that as early as 1–10 min after its administration, triamcinolone acetonide-21-phosphate is almost completely hydrolyzed to triamcinolone acetonide, probably by plasma esterases, and is then further metabolized. Other water-soluble esters of corticosteroids have also been shown to undergo hydrolysis to corresponding steroid alcohols after being administered to humans (1–4).

Excretion in Urine and Feces of Dogs, Monkeys, and Rats—Table VI shows the data for excretion in urine and feces. Elimination of radioactivity from the body took place rapidly. In all but one animal (Monkey 65 after intravenous or intramuscular administration), two-thirds of the total excretion in urine occurred during the first 6–8 hr after administration. For Monkey 65, 24 hr was required for elimination of two-thirds of the total excretion in urine.

In all species, excretion in urine was essentially complete after 48 hr and excretion in feces was essentially complete between 48 and 96 hr. Total excretion in urine and feces accounted for 95, 85, and 87% of the intravenously or intramuscularly administered dose in dogs, monkeys, and rats, respectively. Excretion of radioactivity

1440	—	—	52	41	76	51

[a] Dose: 0.9 mg/kg for dogs (male), 1.2 mg/kg for monkeys (female), and 1.5 mg/kg for rats (female).

in feces was always greater than that in urine. The ratio of fecal to urinary excretion varied among the species, however; it was 15:1 for dogs, 4.7:1 for monkeys, and 1.4:1 for rats. The results indicate that excretion *via* bile is the major route of elimination in all three species.

Excretion in Bile and Urine of a Dog—Excretion of radioactivity in bile and urine after intravenous administration (1.2 mg/kg) of triamcinolone acetonide-^{14}C-21-phosphate is shown in Table VII. A total of 81% of the dose was accounted for during the 8-hr period, 10% in urine and 71% in bile. The apparent half-life for excretion of radioactivity in bile and urine was 2 hr during the first 3 hr and 5 hr between 3 and 8 hr after dosing. The results show that excretion *via* bile is a major route of elimination of this drug in the dog.

Based on the findings that *(a)* the plasma $t_{1/2}$ of radioactivity in the intact dogs and the bile-cannulated dog was the same (Table II) and *(b)* the ratio of excretion of radioactivity in urine to that in feces was no higher for intact dogs than for the bile-cannulated animal, it appears that the drug is not reabsorbed after excretion *via* bile in the canine species.

Excretion of Radioactivity as Respiratory $^{14}CO_2$ in Rats—During 48 hr after intravenous and intramuscular administration (1.5 mg/kg) of triamcinolone acetonide-^{14}C-21-phosphate to rats, the administered radioactivity found in the expired air was 2.6 and 2.4%, respectively. Of this total radioactivity expired as $^{14}CO_2$, 90% was eliminated during the first 8 hr.

Table VII—Excretion of Radioactivity in Urine and Bile of Dog Q9-156[a] after Intravenous Administration of Triamcinolone Acetonide-^{14}C-21-phosphate (1.2 mg/kg)

Collection Period, min	Cumulative Percent of Dose	
	Urine	Bile
0–6	0	0
6–15	0	1.7
15–30	1.1	7.2
30–45	—	19.0
45–60	2.0[b]	27.0
60–90	3.8	39.0
90–180	6.2	56.0
180–300	8.0	65.0
300–420	9.3	69.0
420–480	9.8	71.0

[a] Seven weeks after the previous dose. [b] A 30–60-min collection.

The triamcinolone acetonide-21-phosphate used in these studies was labeled with ^{14}C in the acetonide group (2-position). The appearance of only 2 or 3% of the administered radioactivity as $^{14}CO_2$ indicates that hydrolysis and subsequent oxidation of the acetonide group are not significant metabolic reactions in the rat. In addition, because the total recovery in urine and feces (in 4 or 7 days) accounted for 95 and 85% of the dose in dogs and monkeys, respectively, elimination of radioactivity as $^{14}CO_2$ and, hence, degradation of the acetone-derived portion also may not be significant in these species.

Isolation and Identification of Metabolites in Urine—TLC (Solvent System A) of urine or ethyl acetate extract of urine from the dog, monkey, and rat showed three peaks of radioactivity, A, B, and C. Peak A had the same R_f value (0.45) as that of triamcinolone acetonide, peak B had an R_f value of 0.30, and peak C remained at the origin. TLC of ethyl acetate extracts of urine, collected sequentially from dogs and monkeys, revealed a pattern of change in the levels of each peak with time. The data in Table VIII show the percent of urinary radioactivity associated with peaks A and B. In addition, Table VIII shows the percent of radioactivity as X, which represents the radioactivity in peak C plus that not extracted with ethyl acetate.

In the rat, TLC was carried out on urine samples prior to any extraction. The mean values (intramuscular or intravenous administration) for percent of urinary radioactivity associated with peaks A, B, and C were 17 ± 1, 73 ± 1, and 10 ± 1%, respectively, in the 0–6-hr urine, and 10 ± 2, 76 ± 4, and 15 ± 1% in the 6–24-hr urine, respectively. The pattern of urinary metabolites in each species, as seen in these chromatograms, was the same after intravenous or intramuscular administration.

In characterization studies of metabolites in the test species, pooled urine was collected during the first 8 hr from Dog Q9-156 (bile cannulated) and during the first 24 hr from each monkey (65 and 66, four experiments) and each of four rats; these samples

[a] A and B represent percent of urinary radioactivity associated with peaks A and B (described in text) calculated by measuring areas under the peaks seen in radioscans after TLC (Solvent System A) of ethyl acetate extracts of urine; X represents percent radioactivity associated with peak C in the same radioscans plus radioactivity in urine not extracted in ethyl acetate.

were extracted with ethyl acetate. The ethyl acetate extract accounted for 53% of the radioactivity in urine of the dog. In the monkeys and rats, the ethyl acetate urinary extracts accounted for 41 ± 7 and 90 ± 3% of the radioactivity, respectively.

Radioscans after TLC (Solvent System A) of these ethyl acetate extracts showed the three peaks of radioactivity noted previously, *i.e.*, A, B, and C. Peak B was the major peak in all three species. Based on the area under the peak, peak B accounted for 30, 29, and 72% of the radioactivity in the urine of the dog, monkey, and rat, respectively. Similarly, peak A accounted for 8, 2, and 17% in the dog, monkey, and rat, respectively.

Metabolites 1 and 2, associated with peaks A and B, respectively, were isolated from the urine of the three species, as described under *Experimental*.

Chromatography of a portion of Metabolite 1, isolated from urine samples of each species, showed a single peak of radioactivity, with R_f values of 0.45 and 0.40 in Solvent Systems A and B, respectively. Authentic triamcinolone acetonide had R_f values of 0.45 and 0.40 in Solvent Systems A and B, respectively.

Samples of Metabolite 1, isolated from urine of each species, were mixed with an authentic sample of triamcinolone acetonide and crystallized from ethyl acetate to constant specific activity (Table IX).

A low-resolution mass spectrum of Metabolite 1, isolated from the urine of rats, exhibited a fragmentation pattern similar to that of authentic triamcinolone acetonide. A molecular ion peak at *m/e* 434 and a base peak at *m/e* 375, resulting from the loss of $C_2H_3O_2$ (side chain) through cleavage between carbon atoms 17 and 20, were seen in the mass spectra of both triamcinolone acetonide and Metabolite 1. The mass spectrum of triamcinolone acetonide was discussed by Florey (13).

On the basis of data from chromatography, isotope dilution, and mass spectrometry, Metabolite 1 was identified as triamcinolone acetonide.

TLC of Metabolite 2 from the urine of rats showed a single radioactive peak with R_f values of 0.30 and 0.28 in Solvent Systems A and B, respectively. A triamcinolone acetonide standard had R_f values of 0.45 and 0.40 in these systems, respectively.

A mass spectrum of Metabolite 2 from the urine of rats showed a molecular ion peak at *m/e* 450 and an intense peak at *m/e* 391. If the peaks resulting from low molecular weight impurities (*m/e* 41–44) are excluded, the peak at *m/e* 391 was the most intense in the spectrum. The relative intensity of the molecular ion peak at *m/e* 450 was 6% that of the peak at *m/e* 391. Compared with the mass spectrum of triamcinolone acetonide, the spectrum of Metabolite 2 showed an increase of 16 amu which suggested addition of one oxygen atom. The mass spectrum also demonstrated an M−18 ion at *m/e* 432, corresponding to the loss of a hydroxy group through dehydration on electron impact. The mass spectrum of triamcinolone acetonide did not exhibit a significant M−18 ion, even though there are two hydroxy groups in the compound (13).

The 100-MHz NMR spectrum of Metabolite 2 was obtained in deuteromethanol containing tetramethylsilane as internal reference. Based on this analysis, the following proton assignments were made: C-1H, 2.63 τ (doublet, 10 Hz); C-2H, 3.72 τ (multiplet, 10 Hz); C-4H, 3.80 τ (multiplet); C-18H, 9.07 τ; C-19H, 8.25 τ; α-acetonide methyl, 8.59 τ; and β-acetonide methyl, 8.85 τ. The NMR spectrum of triamcinolone acetonide was discussed by Florey (13). Comparison of the two spectra indicated that the C-19 proton resonance had been shifted downfield by 0.21 ppm. The introduction of a hydroxy group in the *cis* 1,3-axial position to the axial methyl group will cause a downfield shift of this magnitude (14).

In a C-19 steroid, four positions can have a 1,3-diaxial relationship to the C-19 methyl group: C-2, C-6, C-8, and C-11. In triamcinolone acetonide, C-2 is not available and there already is a C-11 hydroxy in a 1,3-diaxial relationship to the C-19 methyl group. C-8 is excluded, because the C-8 β-hydroxy group causes a downfield

Table IX—Specific Activity after Isotopic Dilution of Metabolite 1 Isolated from Urine after Administration of Triamcinolone Acetonide-^{14}C-21-phosphate to Dogs, Monkeys, and Rats

Source of Metabolite	Metabolite 1, dpm	Unlabeled Triamcinolone Acetonide, mg	Calculated Specific Activity	Specific Activity after Crystallization, dpm/mg			
				1	2	3	4
Dog	4,000	7.3	545	624	469	456	470
Monkey	10,050	9.9	1015	1025	1010	1015	—
Rat	10,470	9.0	1115	1140	1125	1135	—

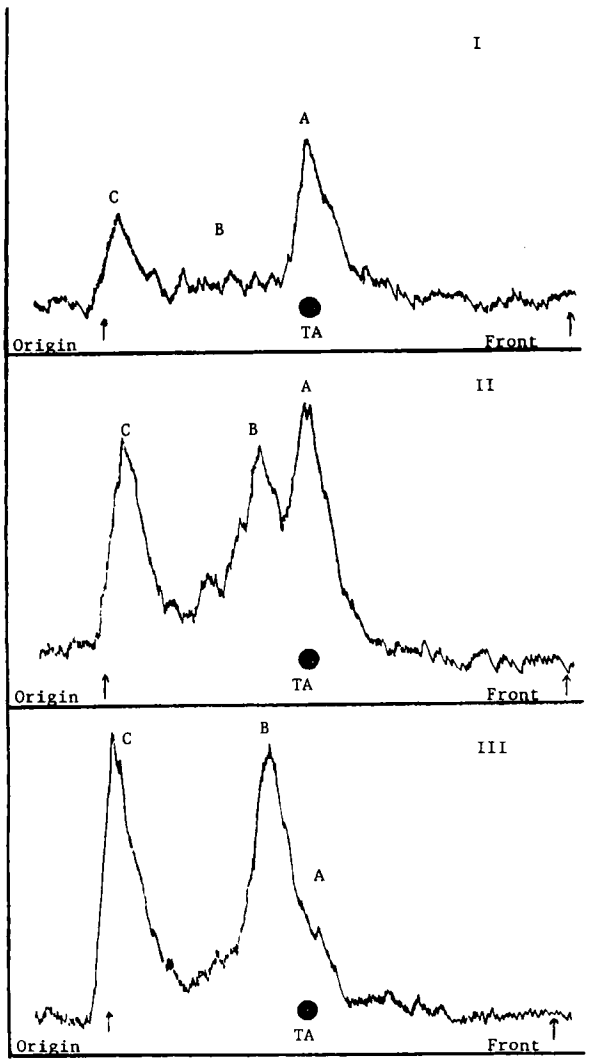

Figure 2—*Radioscans after TLC (Solvent System A) of ethyl acetate extracts of bile collected at various times after intravenous administration of triamcinolone acetonide-^{14}C-21-phosphate (1.2 mg/kg) to Dog Q9-156. Time of bile collection after dosing was: I, 6–15 min; II, 30–45 min; and III, 60–90 min. TA represents authentic triamcinolone acetonide chromatographed in the same solvent system.*

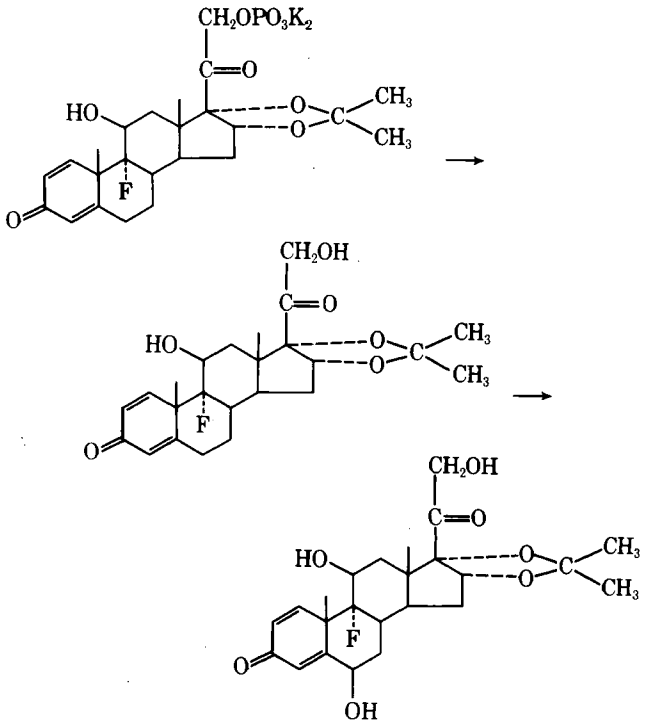

Scheme I—Biotransformations of triamcinolone acetonide-21-dipotassium phosphate

shift of both the C-18 and C-19 protons (15). Therefore, the downfield shift (0.21 ppm) of the C-19 protons must be due to a hydroxy group in the 6β-position.

Based on evidence from mass and NMR spectra, Metabolite 2, isolated from the urine of rats, was identified as 6β-hydroxytriamcinolone acetonide. Fifty-nine percent of the total urinary radioactivity was associated with the isolated compound, but this value is a minimum based only on the material recovered.

TLC of Metabolite 2 from the urine of the monkey showed a single radioactive peak in Solvent Systems A (R_f 0.30) and B (R_f 0.28). These R_f values were similar to those of 6β-hydroxytriamcinolone acetonide isolated from the rat urine. A portion of Metabolite 2 (6000 dpm) isolated from the monkey urine was mixed with an equal amount (6000 dpm) of 6β-hydroxytriamcinolone acetonide isolated from the rat urine. TLC of the mixture in Solvent Systems A, B, and C showed only a single radioactive peak in each system.

The mass spectrum of Metabolite 2 from the monkey urine was similar to that of 6β-hydroxytriamcinolone acetonide from the rat urine; both spectra showed a molecular ion peak at *m/e* 450 and a base peak at *m/e* 391.

On the basis of chromatographic characteristics and mass spectral analysis, Metabolite 2 from the monkey urine was identified as 6β-hydroxytriamcinolone acetonide. A total of 12% of the radioactivity in urine was recovered in the isolated 6β-hydroxytriamcinolone acetonide.

Metabolite 2 isolated from the urine of the dog had the same R_f values as did 6β-hydroxytriamcinolone acetonide in Solvent Systems A, B, and C. This metabolite was not obtained in a sufficiently pure form to allow analysis by mass spectrometry.

6β-Hydroxylation was reported (6) to occur in dogs and humans after dosing with triamcinolone and in studies *in vitro* (rat liver) with triamcinolone acetonide as the substrate (7). The results of the present study show that triamcinolone acetonide undergoes this biotransformation (6β-hydroxylation) in the rat and monkey and, apparently, in the dog as well.

Metabolites present in the urine as glucuronide conjugates accounted for 21, 6, and 4% of the radioactivity in urine of dogs, monkeys, and rats, respectively. In each species, incubation of the glucuronide fraction with β-glucuronidase yielded equal amounts of radioactive metabolites corresponding to peaks B and C (Solvent System A). Sulfate conjugates, which accounted for 11% of the radioactivity in the dog urine, remained at the origin when chromatographed in Solvent System A.

Characterization of Metabolites in Dog Bile—TLC (Solvent System A) of ethyl acetate extracts of bile samples that had been collected sequentially (Dog Q9-156) showed a pattern of radioactive peaks that was similar to that of ethyl acetate extracts of urine samples from the same dog; *i.e.*, with time, peak A decreased, whereas peaks B and C increased. This finding is illustrated by radioscans shown in Fig. 2 for bile samples collected at 15, 45, and 90 min after dosing.

Metabolites extracted into ethyl acetate (unconjugated fraction) accounted for 23% of the radioactivity in total bile collected during the first 8 hr after dosing. Another 23% of the remaining radioactivity was extracted into ethyl acetate after incubation with β-glucuronidase (glucuronide fraction). Radioscans after TLC (Solvent System A) showed peaks A, B, and C in the ratio of 1:3:2 for the unconjugated fraction and peaks B and C (4:1) for the glucuronide fraction. The TLC (Solvent System A) of radioactive material not extracted by ethyl acetate showed only peak C.

From the unconjugated fraction, Metabolite 1, which corresponded to peak A, was isolated by column chromatography, followed by preparative TLC (Solvent System A) of the radioactive material eluted in fractions 32–62 from the column. Metabolite 1 was identified as triamcinolone acetonide, based on evidence from TLC (Solvent Systems A and B), mass spectrometry, and isotope

dilution. Three percent of the total radioactivity in bile was associated with the isolated triamcinolone acetonide.

A metabolite corresponding to peak B in the unconjugated fraction was eluted from the silica gel plate; it had the same R_f value as that of 6β-hydroxytriamcinolone acetonide in Solvent Systems A and B.

The sequence of biotransformations is shown in Scheme I.

CONCLUSIONS

Within 10–15 min after intramuscular administration of triamcinolone acetonide-^{14}C-21-phosphate to dogs, monkeys, and rats, levels of radioactivity in blood and other tissues were approximately equal to those obtained after intravenous administration. These results indicate that triamcinolone acetonide-21-phosphate is absorbed rapidly from the site of intramuscular injection.

Plasma half-life values of 0.5–2 hr in dogs, monkeys, and rats and the rate of excretion in a bile-cannulated dog ($t_{1/2}$ = 2 hr) suggest a short biological half-life for triamcinolone acetonide-21-phosphate after intramuscular or intravenous administration. Excretion *via* the bile seems to be the major route of drug elimination; in all species studied, excretion in the feces after intramuscular or intravenous administration was higher than that in the urine, although the ratio of fecal to urinary excretion varied among the species. Reabsorption of the drug after its excretion in the bile did not appear to take place in the dog.

In the rat, only 2–3% of the ^{14}C label in the acetonide portion of the molecule appeared as $^{14}CO_2$. Most of the remaining radioactivity (81–94%) was recovered in the urine and feces. These results indicate that hydrolysis of triamcinolone acetonide to give acetone-^{14}C and, therefore, a subsequent yield of $^{14}CO_2$ is not a significant metabolic reaction in the rat. Although $^{14}CO_2$ was not measured in dogs or monkeys, 95 and 85%, respectively, of the labeled dose was recovered in urine and feces, suggesting the existence of a metabolic pathway similar to that in the rat.

Triamcinolone acetonide-21-phosphate was rapidly and extensively hydrolyzed to triamcinolone acetonide after intramuscular or intravenous administration. This hydrolysis apparently occurred prior to any other metabolic transformation. Unchanged triamcinolone acetonide-21-phosphate was not found in plasma, urine, or bile samples collected as early as 1–5 min after its administration to dogs, monkeys, and rats.

Hydrolysis of triamcinolone acetonide phosphate also could be determined *in vitro* in dog plasma and rat muscle. Triamcinolone acetonide was identified in the plasma and urine of all species studied and in the bile of the dog. 6β-Hydroxytriamcinolone acetonide was a major metabolite in the urine of rats and monkeys and apparently in the urine of dogs as well.

The presence of 6β-hydroxytriamcinolone acetonide as a major metabolite in the urine of rats and monkeys and the absence of any metabolites resulting from the reduction of Δ^4-3-keto or C-20-keto groups in any of the species studied indicate that the Δ^1, 9α-fluoro, and 16,17-acetonide substituents may block the normal reduction reactions undergone by hydrocortisone. Similar results were reported by other investigators for different corticosteroids possessing Δ^1 or 9α-fluoro substituents (16, 17).

Metabolism of Minoxidil, a New Hypotensive Agent I: Absorption, Distribution, and Excretion following Administration to Rats, Dogs, and Monkeys

RICHARD C. THOMAS ˣ, RICHARD S. P. HSI, HARRY HARPOOTLIAN, and RAY W. JUDY

Abstract □ Minoxidil (2,4-diamino-6-piperidinopyrimidine 3-oxide), a potent new hypotensive agent, was ^{14}C-labeled in the 2-position of the pyrimidine ring in 17% yield from $Ba^{14}CO_3$. This material was used to study the absorption, distribution, and excretion of the drug in rats, dogs, and monkeys. Following oral administration of a single dose, the drug was rapidly and well absorbed and rapidly eliminated by each species as judged by plasma levels and urinary excretion of unchanged drug and total drug-related materials. Chronic oral administration of the drug at a high level (10 mg/kg) for 30 days slightly increased the rate of clearance of minoxidil and minoxidil-related material from circulation. Water diuresis, resulting from water loading of dogs, caused an even greater increase in the rates of disappearance of the drug and drug-related material. Whole-body autoradiography studies in rats showed that minoxidil was rapidly distributed following its oral and intravenous administration. It was subsequently concentrated, primarily in the excretory system. Minoxidil-related material was detected in aorta walls, but not in the CNS, following both routes of drug administration.

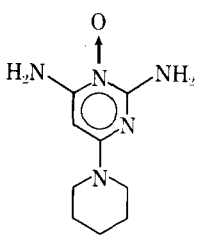
Keyphrases □ Minoxidil, ^{14}C-labeled—absorption, distribution, and excretion after oral and intravenous administration, rats, dogs, and monkeys □ Absorption—^{14}C-labeled minoxidil after oral and intravenous administration, rats, dogs, and monkeys □ Distribution—^{14}C-labeled minoxidil after oral and intravenous administration, rats, dogs, and monkeys □ Excretion—^{14}C-labeled minoxidil after oral and intravenous administration, rats, dogs, and monkeys

Minoxidil (2,4-diamino-6-piperidinopyrimidine 3-oxide, I) is a potent, orally active hypotensive agent. Studies in laboratory animals indicate that its activity is due primarily to a direct relaxant effect on peripheral vascular smooth muscle (1). It has been shown to be orally active in humans (2, 3).

As part of the development of this drug, studies were undertaken in several animal species to determine which most resembles the human in its metabolism of minoxidil. This report is concerned with the preparation of ^{14}C-labeled minoxidil and a study of its disposition, as shown by measurements of unchanged drug and total radioactivity, in three animal species: the rat, dog, and monkey.

EXPERIMENTAL

Preparation of ^{14}C-Labeled Drug—Labeled minoxidil was prepared by a six-step synthetic sequence from barium carbonate-^{14}C in 17% overall yield. Barium carbonate-^{14}C was converted to guanidine-^{14}C hydrochloride *via* barium cyanamide-^{14}C in 84% yield by the method of Bennett (4). Guanidine-^{14}C hydrochloride was then converted to 2,4-diamino-6-hydroxypyrimidine-2-^{14}C monohydrate in 77% yield by the method of VanAllan (5).



I

The ^{14}C-labeled hydroxypyrimidine was heated with phosphorus oxychloride, essentially as described by Israel *et al.* (6) to prepare 2,4-diamino-6-chloropyrimidine-2-^{14}C. By carefully heating the reaction mixture in an oil bath at 95–100° rather than under reflux, a reproducible yield of 69% was obtained in this step. The ^{14}C-labeled chloropyrimidine was oxidized with an equimolar quantity of *m*-chloroperbenzoic acid in ethanol at 3° for 3 hr.

The resulting precipitate of 2,4-diamino-6-chloropyrimidine-2-^{14}C 3-oxide, as the *m*-chlorobenzoic acid salt, was filtered, washed successively with cold ethanol and ether, and air dried. This material, having a specific activity of 1.71 mCi/mmole, was obtained in 68% yield. Its melting point was 199–200° dec. and its IR, UV, and NMR spectra were consistent with the proposed structure.

Anal.—Calc. for $C_{11}H_{10}Cl_2N_4O_3$: C, 41.66; H, 3.18; Cl, 22.36; N, 17.67. Found: C, 41.42; H, 3.41; Cl, 22.25; N, 17.71.

The *m*-chlorobenzoic acid salt of ^{14}C-labeled 2,4-diamino-6-chloropyrimidine 3-oxide (2.72 g) was mixed with 25 ml of piperidine, and the mixture was heated with stirring under nitrogen in an oil bath at 130° to give a clear solution. The solution was refluxed for 1.5 hr, during which time a precipitate formed. After standing overnight at room temperature, the precipitate was filtered. The crude product was washed three times in the filter funnel with 1.5 *N* sodium hydroxide, followed by repeated washing with water. After air drying, 1.10 g (62%) of ^{14}C-minoxidil, 2,4-diamino-6-piperidinopyrimidine-2-^{14}C 3-oxide, having a specific activity of 1.72 mCi/mmole, was obtained. Its melting point was 262–262.5° dec. and its IR, UV, and NMR spectra corresponded to those of authentic minoxidil.

Anal.—Calc. for $C_9H_{15}N_5O$: C, 51.66; H, 7.23; N, 33.46. Found: C, 51.42; H, 7.36; N, 33.42.

When chromatographed in paper and thin-layer systems, the product and its associated radioactivity had mobilities identical to that of authentic minoxidil.

Dosage of Animals and Collection of Samples—Each of three female rats[1], weighing approximately 200 g, was given 1.01 mg (8.2 μCi) of ^{14}C-minoxidil in 1 ml of water by oral intubation. One hour prior to and immediately following administration of the drug, each rat was given 10 ml of deionized water by oral intubation. The

[a] Three animals.

[1] Sprague–Dawley (Upjohn strain).

rats were housed in metabolism cages, designed for the separation and collection of urine and feces, and samples were collected at predetermined intervals for 72 hr. Water and food[2] were permitted *ad libitum*.

In a separate study, each of two 120-g male rats[1], which had been fitted, under ether anesthesia, with bile-duct cannulas [polyethylene (PE-10) tubing], was given 2.55 mg (20.8 μCi) of ^{14}C-minoxidil in 2 ml of water by oral intubation. The rats were placed in restraining cages, and bile was collected continuously for 40 hr in 4-hr fractions. Water was permitted *ad libitum*.

Each of three female dogs[3], weighing approximately 9 kg, was given 5.0 mg (41.0 μCi) of ^{14}C-minoxidil in 10 ml of water by oral intubation. One-half hour before, immediately following, and 1 and 2 hr following administration of the drug, each dog was given 100 ml of deionized water by oral intubation. The dogs were housed in metabolism cages, designed for the separation and collection of urine and feces, and samples were collected at predetermined intervals for 168 hr.

Urine was obtained by catheter up to and including the 16-hr sample and combined with the appropriate voided sample. Blood samples (7 ml) were collected by jugular venipuncture in tubes containing potassium oxalate as an anticoagulant at predetermined times for 168 hr. Except for a 4-hr period following drug administration, water was permitted *ad libitum*. Food[4] was given 12 hr following drug administration and once a day thereafter.

In a separate study, each of four dogs[3], weighing approximately 11 kg, was given a 1.00-mg/kg dose of ^{14}C-minoxidil (8.2 μCi/mg) in 10 ml of water by oral intubation. On each of the next 30 days, each dog was given a 10-mg/kg oral dose of nonradioactive minoxidil in a hard gelatin capsule. This dose was followed on the 31st day with another 1.00-mg/kg dose of ^{14}C-minoxidil. The dogs were kept in metabolism cages during the entire period.

Separate urine collections 0–12 and 12–24 hr following administrations of the labeled drug were made for each dog. Blood samples were collected at predetermined times for 12 hr following labeled drug administrations. Fecal collections were not made.

Each of three male rhesus monkeys, weighing approximately 4 kg, was given a 1.00-mg/kg dose of ^{14}C-minoxidil (8.2 μCi/mg) in 10 ml of water by intubation through a nose tube. The monkeys were placed in restraining chairs, designed for the separate collection of urine and feces, and samples were collected at predetermined intervals for 72 hr.

Blood samples (5 ml) were collected by venipuncture of the femoral vein in the inner midthigh region at predetermined times for 48 hr. The blood was transferred from the syringe to a tube containing potassium oxalate immediately after collection. Water was permitted *ad libitum*, and food[5] was given 8 hr after drug administration and once a day thereafter.

Measurement of Radioactivity in Biological Samples—Blood samples were centrifuged at 1100×*g* for 30 min at 5° to obtain plasma. Feces samples were homogenized with water to a suitable consistency using a blender[6] or homogenizer[7]. Plasma, urine, feces, and bile samples were stored in the frozen state prior to analysis. All samples were counted in liquid scintillation spectrometers[8] interfaced to keypunches[9]. Computations were performed with a computer[9].

Duplicate 0.1- or 0.5-ml aliquots of urine and bile were counted in 15 ml of counting solvent [toluene–dioxane–methanol (350:350:210 v/v) containing 73 g of naphthalene, 4.6 g of 2,5-diphenyloxazole, and 0.080 g of 1,4-bis-2-(5-phenyloxazolyl)benzene/liter]. Counting efficiencies were determined by the internal standard technique using toluene-^{14}C. Duplicate 0.2- or 0.5-ml blood plasma samples and duplicate aliquots, approximately 0.5 g each, of feces homogenates were dried in cellophane sacs at room temperature, combusted[10] (8), and counted. Counting efficiencies were determined by the external standard technique.

[a] Two animals.

Preparation of Samples for Chromatography—Samples of urine, blood plasma, and bile containing sufficient radioactivity were applied directly to the paper for chromatography, usually as 2.5-cm streaks. Samples containing lower levels of radioactivity were lyophilized, and the residues were reconstituted at a greater concentration with water or were leached three times with methanol.

The methanol was removed with a nitrogen stream, and the residue was dissolved in a small volume of 1-butanol–methanol (1:2 v/v) for application to paper in a manner similar to that used for whole urine and blood plasma. The leaching procedure resulted in chromatographic metabolite patterns quantitatively identical to those obtained by direct chromatography of whole urine, blood plasma, and bile.

Paper Chromatography and TLC—Paper chromatography was carried out on 86 × 15-cm sheets[11] by a descending technique in the 1-butanol–piperidine–water (82:2:16 v/v) system (System I). Occasionally, the 1-butanol–acetic acid–water (4:1:1 v/v) system (System II) was used. TLC was carried out on 20 × 5-cm films of silica gel, 0.25 mm thick, in the benzene–methanol–ammonium hydroxide (1:1:0.01 v/v) system (System III).

Standard minoxidil was run on each chromatogram. In certain cases, minoxidil was mixed with samples prior to chromatography to act as an internal standard. Following solvent development, the chromatograms were viewed under UV light to locate the standard and, when possible, drug-related materials by their UV absorption.

Quantification of Minoxidil by Radiochromatogram Scanning—Paper and thin-layer chromatograms, when they contained sufficient radioactivity, were scanned for radioactivity using chromatogram scanners[12] having Geiger detectors. The resulting chart-strip tracings were integrated with a mechanical planimeter[13] or with an electronic digitizer system[14] to determine quantitatively the relative distribution of radioactivity along the length of the chromatogram.

When a chromatogram did not contain sufficient radioactivity for quantification by Geiger detection, it was cut into sequential

segments (1 cm in the case of paper chromatograms and 0.5 cm in the case of thin-layer chromatograms). Then the segments, each in a vial with 10 ml of counting solvent containing 3% water, were counted by liquid scintillation spectrometry. The resulting raw data were processed by the computer system to give a plot of the distribution of radioactivity along the length of the chromatogram, in a format similar to that of a chart-strip tracing, together with a tabular printout of derived data. Based on the plot, the tabular data were used to quantify the relative distribution of radioactivity along the length of the chromatogram.

Whole-Body Autoradiography—Each of 10 male rats[1], weighing approximately 110 g, was given 2.25 mg (18.2 μCi) of ^{14}C-minoxidil, five by oral intubation and five by intravenous administration in the tail vein. At intervals of 0.5, 2, 4, 8, and 24 hr following oral administration and 1 and 10 min and 0.5, 2, and 4 hr following intravenous administration, the rats were quickly frozen by immersion in dry ice-cooled acetone while under ether anesthesia. The rats were then embedded by freezing in blocks of 4% aqueous carboxymethylcellulose sodium and sectioned for whole-body autoradiography essentially as described by Ullberg (7).

Sections 30 μm thick were collected on cellophane tape[15] as they were being cut with a microtome[16] equipped with a 55° tungsten carbide-tipped knife[16] at −20° in a cryostat[17]. The sections were allowed to dehydrate in the cryostat and then were placed in contact with X-ray film[18] for 1–6 weeks at −15°. The film was developed by standard methods.

RESULTS

As shown in Tables I and II, the rat eliminated minoxidil rapidly, primarily *via* urine. Following a 5-mg/kg oral dose of ^{14}C-minoxidil, 88% of the radioactivity was excreted in urine and 5.8% was excreted in the feces. More than 80% of the dose was accounted for in urine during the 11 hr immediately following drug administration. Approximately 35% of the drug-related material excreted in urine was minoxidil. Bile duct-cannulated rats (Table III) secreted an average of 12.8% of a 21-mg/kg oral dose of ^{14}C-minoxidil in bile over 40 hr. Most of this amount (11% of the dose) was secreted during the 8 hr following drug administration. Less than 4% of the drug-related material secreted in bile during this 8-hr period was minoxidil.

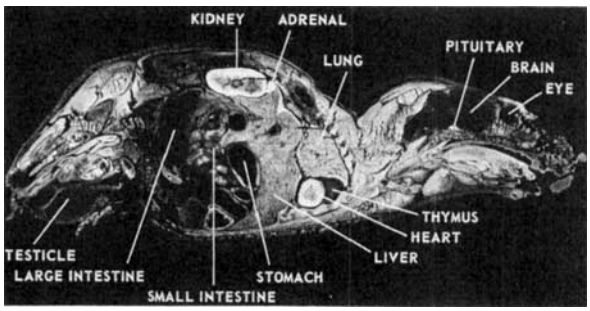

Figure 1—*Distribution of radioactivity (light areas) in a rat 1 min following intravenous administration of ^{14}C-minoxidil. Film was exposed to the tissue slice for 1 week.*

Plasma levels of minoxidil, total drug-related material, and areas under plasma level curves (expressed as microgram-equivalents of drug) following oral administration of 1 mg of minoxidil/kg to monkeys are presented in Table IV. An average peak plasma level of 0.037 μg of minoxidil/ml was attained 0.25–0.5 hr after drug administration. Minoxidil and total radioactivity levels in plasma decreased rapidly thereafter. Unchanged drug accounted for only about 10% of the total drug-related material in circulation.

Minoxidil disappeared from plasma with a 1.9-hr average half-life during the 8-hr interval following attainment of the peak plasma level. Excretion of minoxidil by the monkey also was rapid and primarily *via* urine (Tables V and VI). Approximately 94% of the dose was excreted in urine and 2.68% was excreted in feces. More than 90% of the dose was excreted in urine during the 14 hr immediately following drug administration. Approximately 10% of the drug-related material excreted in urine was minoxidil.

Plasma levels of minoxidil, total drug-related material, and areas under plasma level curves (expressed as microgram-equivalents of drug) following oral administration of 0.55 mg ^{14}C-minoxidil/kg to water-loaded dogs are presented in Table VII. An average peak plasma level of 0.37 μg of minoxidil/ml was observed at the first sampling time, 15 min after drug administration.

Minoxidil disappeared from plasma with a 0.8-hr average half-life during the 5-hr period following the peak plasma level. Excretion of radioactivity by the dog was rapid and primarily *via* urine (Tables VIII and IX). Nearly 91% of the dose was excreted in urine

[a] Three animals.

and 7.1% was excreted in feces. More than 80% of the dose was excreted in urine during the 12 hr immediately following drug administration. Approximately 13% of the drug-related material excreted in urine was minoxidil.

Plasma levels of minoxidil, total drug-related material, and areas under plasma level curves (expressed as microgram-equivalents of minoxidil) following oral administration of 1 mg of ^{14}C-minoxidil/kg to dogs before and after 30 successive 10-mg/kg daily oral doses of minoxidil are presented in Table X. Before chronic drug treatment, an average peak plasma level of 0.84 μg of minoxidil/ml was observed at the first sampling time, 15 min after drug administration; the corresponding value after chronic drug treatment was 0.535 μg/ml and occurred about 45 min following administration of the labeled drug.

For approximately 5 hr following attainment of the peak plasma level, minoxidil disappeared with an average half-life of 1.2 hr prior to, and 1.0 hr following, chronic drug treatment. The corresponding areas under the plasma level curves are presented in Table XI. The cumulative areas under the minoxidil-level curves during the 12 hr following drug administration were 1.27 hr × μg/ml prior to, and 1.08 hr × μg/ml following, chronic drug treatment.

Urinary excretion of radioactivity during this chronic study is presented in Table XII. Both before and after chronic drug treatment, approximately 89% of the radioactive dose was excreted in urine during the 24 hr following administration of the labeled drug. In each case, more than 80% of the dose was excreted during the first 12 hr. Approximately 18% of the drug-related material excreted in urine was minoxidil in both cases.

Within 1 min after injecting the rat intravenously with ^{14}C-minoxidil, radioactivity had penetrated into most tissues (Fig. 1). The distribution was relatively uniform except for a notable lack of radioactivity in the brain, testicles, stomach, large intestine, spleen, and bone. The level of radioactivity was low in the thymus. Ten minutes after intravenous injection (Fig. 2), levels of radioactivity were highest in the kidneys, liver, bladder, and aorta walls, although most other tissues, including the testicles and stomach, contained moderate concentrations of radioactivity. Little, if any, radioactivity was present in the brain and large intestine.

One-half hour following intravenous injection (Fig. 3), radioactivity levels were relatively high in the liver, kidneys, small intestine, bladder, and aorta walls. Little radioactivity remained in other tissues, including blood, and none was apparent in the brain. Four hours following intravenous administration, levels of radioactivity were relatively high in the large intestine and bladder, moderate in the liver, low in the kidneys, and not detectable in most other tissues, including the brain and blood.

One-half hour after oral administration of ^{14}C-minoxidil to the rat, the radioactivity (Fig. 4) was most concentrated in the kidneys, stomach, bladder, and small intestine. The liver and aorta walls had nearly as high a concentration. Other tissues had a rather uniform concentration but to a lesser degree. The brain was de-

void of radioactivity. The relative distribution of radioactivity 2 hr following oral drug administration (Fig. 5) was similar to that at 30 min. However, the levels of radioactivity in the stomach and kidneys had decreased somewhat.

Four hours following oral drug administration (Fig. 6), radioactivity levels were relatively high in the bladder, the large intestine, and some sections of the small intestine; moderate in the stomach, liver, and kidneys; very low in most other tissues; and lacking in the brain. Eight hours following oral administration, the large intestine had the highest levels of radioactivity relative to other tissues. The liver and kidneys, as well as the compact portion of bone, had somewhat lower levels. Most other tissues contained very little radioactivity; none was detectable in the brain.

Twenty-four hours following oral drug administration (Fig. 7), the large intestine contained the highest level of radioactivity. Somewhat lower levels were observed in the stomach and in the compact portion of bone. The liver and kidneys had very low levels; other tissues, including the brain, appeared to be devoid of radioactivity.

DISCUSSION

As judged by plasma levels and excretion of minoxidil and by total radioactivity, labeled minoxidil, administered as a single oral dose, was well absorbed and rapidly cleared from the circulation and the body by the rat, dog, and monkey. Each species absorbed nearly 90% or more of the drug based on the amount of radioactivity excreted in urine. More than 80% of the administered drug was cleared from the body of each species within 12 hr. With the monkey and dog, peak plasma levels of minoxidil were attained 15–45 min following drug administration. The disappearance of minoxidil from plasma was rapid, corresponding to average half-lives of 1.9 and 1.2 hr for the monkey and dog, respectively. This difference in half-lives is significant ($p < 0.10$ by t test).

Minoxidil was at least as well absorbed by the human (9), with 97% of the radioactivity associated with an orally administered dose of labeled drug appearing in urine. It was cleared somewhat more slowly from circulation by the human, with a plasma half-life

of 4.2 hr, and more slowly from the body, with 70% of the dose appearing in urine within 12 hr after drug administration.

Oral administration of 30 successive daily doses of minoxidil, at a level of 10 mg/kg, to dogs resulted in an apparent small increase in the rate of removal of minoxidil from circulation. When 1.00-mg/kg doses of labeled minoxidil were administered, the average half-life for removal of minoxidil from plasma and the area under the plasma minoxidil level *versus* time curve both were 20% lower following, as compared to immediately preceding, chronic drug treatment. The average half-life changed from 1.2 to 1.0 hr, and the area changed from 1.27 to 1.08 hr × μg/ml. These small changes ($p < 0.05$ for half-life and $p < 0.20$ for area differences by paired t tests) could have resulted from an increase in the rate of drug metabolism, caused by stimulation of an enzyme system metabolizing minoxidil, or from an increase in urinary excretion rates for the drug and its metabolites.

The dogs used in the single-dose kinetic study, in which a 0.55-mg/kg dose of labeled minoxidil was used, were water loaded to obtain frequent urine samples. The dogs used in the chronic study, however, were not water loaded since frequent urine sampling was not planned. The water diuresis resulting from water loading appears to have increased the rate of removal of minoxidil-related material from circulation. The half-life for removal of minoxidil from plasma and the area under the plasma minoxidil level curve (0–8 hr) for the water-loaded dogs both were approximately 35% lower than the corresponding values obtained following the first dose of radioactive drug in the chronic study ($p < 0.10$ for half-life and area differences by paired t tests). This effect is even greater than that due to chronic drug administration. This effect could be due to an increase in urinary excretion rates for the drug and its metabolites caused by their decreased renal reabsorption under conditions of water diuresis.

Biliary secretion of minoxidil-related materials following oral administration of the drug to the rat was significant, accounting for 13% of the dose. Since only 6% of an oral dose (in a separate study) was accounted for in feces of normal rats, there is some indication of enterohepatic recirculation of the drug and its metabolites by the rat.

As determined by autoradiography, radioactivity associated with labeled minoxidil was very rapidly and widely distributed in the body of the rat following intravenous and oral drug administration. Shortly thereafter, radioactivity began concentrating, primarily in the digestive and excretory system. These systems, particularly the liver, kidneys, bladder, stomach, and intestines, generally contained the highest relative concentrations of radioactivity at increasing times following drug administration. These concentrations were relative to other tissues of the body, since previous excretion studies showed that at least 38, 41, 57, 76, and 92% of the administered radioactivity had been eliminated by the rat 1, 2, 4, 8, and 24 hr, respectively, following oral administration of the labeled drug.

Although accumulation of a drug (and, particularly, only the radioactivity initially associated with the drug) in a certain tissue does not necessarily indicate the site of pharmacological action, certain observations are informative. Little, if any, minoxidil-related material was detected in the central nervous system relative to other tissues at any time following drug administration. Radioactivity concentrated in aorta walls, but not in nonsmooth vascular

muscle such as the myocardium, for at least 2 hr following drug administration. This concentration may well have continued beyond 2 hr, as reported by Pluss *et al.* (10), without being detected because of the relatively low sensitivity of whole-body section autoradiography. In any event, these observations are consistent with minoxidil having a direct relaxant effect on peripheral vascular smooth muscle.

Metabolism of Minoxidil, a New Hypotensive Agent II: Biotransformation following Oral Administration to Rats, Dogs, and Monkeys

RICHARD C. THOMAS [x] and HARRY HARPOOTLIAN

Abstract □ The biotransformation of minoxidil (2,4-diamino-6-piperidinopyrimidine 3-oxide) was studied in the rat, dog, and monkey and compared to reported results in the human. Chromatographic profiles of urinary metabolites show that each species excreted substantially the same metabolites but in quite different relative amounts. The monkey and the human exhibited similar metabolite profiles, whereas the dog and rat were quantitatively different from each other and from the monkey and human. The major excretory product for the monkey and human was a glucuronide conjugate of minoxidil. Substantially smaller amounts of unchanged minoxidil, 2,4-diamino-6-(4′-hydroxypiperidino)pyrimidine 3-oxide, and more polar metabolites also were excreted by these two species. The major excretory product in the rat was unchanged minoxidil. Almost as much (combined) of the two acidic metabolites, 2,4-diamino-6-(4′-carboxy-*n*-butylamino)pyrimidine and its 3-oxide, also were produced. Smaller amounts of the glucuronide of minoxidil, 2,4-diamino-6-(4′-hydroxypiperidino)pyrimidine 3-oxide, its 3′-hydroxy isomer, and 2,4-diamino-6-piperidinopyrimidine also were excreted by the rat. The major metabolite of minoxidil excreted by the dog was the 4′-hydroxy metabolite. Smaller amounts of unchanged minoxidil and polar metabolites and much smaller amounts of the glucuronide of minoxidil, the 3′-hydroxy metabolite, and 2,4-diamino-6-piperidinopyrimidine also were excreted by the dog. Evidence was obtained for a glucuronide conjugate of the 4′-hydroxy metabolite in this species. The major circulatory material in dog plasma was the 4′-hydroxy metabolite, whereas it was the glucuronide of minoxidil in monkey plasma.

Keyphrases □ Minoxidil—biotransformation in rat, dog, and monkey after oral administration, compared to reported human metabolism □ Metabolism, minoxidil—biotransformation in rat, dog, and monkey after oral administration, compared to reported human metabolism

As part of a program to develop minoxidil (2,4-diamino-6-piperidinopyrimidine 3-oxide, I) as an orally active hypotensive agent, metabolism studies with the drug were undertaken in three animal species: the rat, dog, and monkey. Previous reports described studies that showed that minoxidil, following its oral administration, was rapidly and well absorbed, rapidly and widely distributed, and rapidly eliminated, primarily *via* urine, by the rat, dog, and monkey (1) and by the human (2). Tissue distribution studies in the rat using ^{14}C-minoxidil were reported previously (1, 3).

These results, based on measurements of unchanged drug and total drug-related material, were not sufficient for selecting one species as being most like the human in its disposition of minoxidil. Such a selection was of particular importance for this drug because it causes an apparently species-specific, right-atrial lesion in the dog (4). Therefore, studies were undertaken to compare the biotransformation of minoxidil in the three animal species and to see if at least one of them was similar to the human in this aspect of the drug's disposition. These studies were extended to identify the metabolites of minoxidil produced by each animal species and to determine the kinetics of absorption, distribution, and excretion of the unchanged drug and its metabolites by each species.

This report is concerned with comparing the biotransformation of minoxidil in the three animal species and humans, including characterization, isolation, identification, and quantification of metabolites in urine and blood plasma. A subsequent report will deal with the kinetics of absorption, distribution, and excretion of minoxidil and its metabolites by each animal species.

muscle such as the myocardium, for at least 2 hr following drug administration. This concentration may well have continued beyond 2 hr, as reported by Pluss *et al.* (10), without being detected because of the relatively low sensitivity of whole-body section autoradiography. In any event, these observations are consistent with minoxidil having a direct relaxant effect on peripheral vascular smooth muscle.

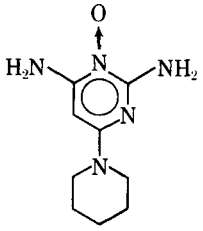
Almost as much (combined) of the two acidic metabolites, 2,4-diamino-6-(4′-carboxy-*n*-butylamino)pyrimidine and its 3-oxide, also were produced. Smaller amounts of the glucuronide of minoxidil, 2,4-diamino-6-(4′-hydroxypiperidino)pyrimidine 3-oxide, its 3′-hydroxy isomer, and 2,4-diamino-6-piperidinopyrimidine also were excreted by the rat. The major metabolite of minoxidil excreted by the dog was the 4′-hydroxy metabolite. Smaller amounts of unchanged minoxidil and polar metabolites and much smaller amounts of the glucuronide of minoxidil, the 3′-hydroxy metabolite, and 2,4-diamino-6-piperidinopyrimidine also were excreted by the dog. Evidence was obtained for a glucuronide conjugate of the 4′-hydroxy metabolite in this species. The major circulatory material in dog plasma was the 4′-hydroxy metabolite, whereas it was the glucuronide of minoxidil in monkey plasma.

Keyphrases □ Minoxidil—biotransformation in rat, dog, and monkey after oral administration, compared to reported human metabolism □ Metabolism, minoxidil—biotransformation in rat, dog, and monkey after oral administration, compared to reported human metabolism

As part of a program to develop minoxidil (2,4-diamino-6-piperidinopyrimidine 3-oxide, I) as an orally active hypotensive agent, metabolism studies with the drug were undertaken in three animal species: the rat, dog, and monkey. Previous reports described studies that showed that minoxidil, following its oral administration, was rapidly and well absorbed, rapidly and widely distributed, and rapidly eliminated, primarily *via* urine, by the rat, dog, and monkey (1) and by the human (2). Tissue distribution studies in the rat using ^{14}C-minoxidil were reported previously (1, 3).

These results, based on measurements of unchanged drug and total drug-related material, were not sufficient for selecting one species as being most like the human in its disposition of minoxidil. Such a selection was of particular importance for this drug because it causes an apparently species-specific, right-atrial lesion in the dog (4). Therefore, studies were undertaken to compare the biotransformation of minoxidil in the three animal species and to see if at least one of them was similar to the human in this aspect of the drug's disposition. These studies were extended to identify the metabolites of minoxidil produced by each animal species and to determine the kinetics of absorption, distribution, and excretion of the unchanged drug and its metabolites by each species.

This report is concerned with comparing the biotransformation of minoxidil in the three animal species and humans, including characterization, isolation, identification, and quantification of metabolites in urine and blood plasma. A subsequent report will deal with the kinetics of absorption, distribution, and excretion of minoxidil and its metabolites by each animal species.



I

EXPERIMENTAL

Radioactivity Measurements—Samples were counted with liquid scintillation spectrometers[1] interfaced to keypunches[2]. Routine calculations were made with a computer[3]. Duplicate (usually 0.1- or 0.5-ml) aliquots of solutions were counted in 15 ml of counting solvent [toluene–dioxane–methanol (350:350:210 v/v) containing 73 g of naphthalene, 4.6 g of 2,5-diphenyloxazole, and 0.080 g of 1,4-bis-2-(5-phenyloxazolyl)benzene/liter]. Counting efficiencies were determined by the internal standard technique using toluene-^{14}C.

Radiochromatogram Scanning—Paper and thin-layer chromatograms, when they contained sufficient radioactivity, were scanned for radioactivity using chromatogram scanners[4] having Geiger detectors. The resulting chart-strip tracings were integrated with a mechanical planimeter[5] or with an electronic digitizer system[6] to determine quantitatively the relative distribution of radioactivity along the length of the chromatogram.

When a chromatogram did not contain sufficient radioactivity for quantification by Geiger detection, it was cut into sequential segments (1 cm in the case of paper chromatograms and 0.5 cm in the case of thin-layer chromatograms). Then the segments, each in a vial with 10 ml of counting solvent containing 3% water, were counted by liquid scintillation spectrometry. The resulting raw data were processed by the computer system to give a plot of the distribution of radioactivity along the length of the chromatogram, in a format similar to that of a chart-strip tracing, together with a tabular printout of derived data. Based on the plot, the tabular data were used to quantify the relative distribution of radioactivity along the length of the chromatogram.

Preparation of Samples for Chromatography—Samples of urine and blood plasma containing sufficient radioactivity were applied directly to the paper or thin-layer medium for chromatography, usually as 2.5-cm streaks. Samples containing lower levels of radioactivity, as well as all enzyme incubation samples, were lyophilized and the residues were reconstituted at a greater concentration with water or were leached three times with methanol. The methanol was removed with a nitrogen stream, and the residue was dissolved in a small volume of 1-butanol–methanol (1:2 v/v) for application to the chromatography medium in a manner similar to that for whole urine and blood plasma. The leaching procedure resulted in chromatographic metabolite patterns quantitatively identical to those obtained by direct chromatography of whole urine and blood plasma.

Enzyme Hydrolysis—Samples of whole urine and extracts of urine and blood plasma were incubated with β-glucuronidase[7] at a concentration of approximately 1000 Fishman units/ml in 0.05 *M*, pH 5.5 sodium acetate buffer for 24 hr at 37°. Occasionally, samples were hydrolyzed under similar conditions with a mixture of β-glucuronidase and sulfatase[8].

Paper Chromatography and TLC—Paper chromatography was carried out on 86 × 15-cm sheets[9] by a descending technique in the 1-butanol–piperidine–water (82:2:16 v/v) system (System I). Occasionally, the 1-butanol–acetic acid–water (4:1:1 v/v) system (System II) was used. TLC was carried out on 20 × 5-cm films of silica gel, 0.25 mm thick, in the benzene–methanol–ammonium hydroxide (100:100:1 v/v) system (System III). Occasionally, solvent systems containing 2% piperidine in water and 10% methanol in chloroform (Systems IV and V, respectively) were used.

Appropriate standard compounds were run on each chromatogram. In certain cases, standard compounds were mixed with samples prior to chromatography to act as internal standards. Following solvent development, the chromatograms were viewed under UV light to locate standards and, when possible, drug-related materials by the UV absorption. In addition, certain chromatograms were sprayed with a 10% solution of ferric chloride in water. Minoxidil and its metabolites containing the *N*-oxide group produced a blue color (against a yellow background), whereas minoxidil metabolites not containing an *N*-oxide group produced no color.

Preparation of 2,4-Diamino-6-(4′-hydroxypiperidino)pyrimidine 3-Oxide (III)—A mixture of 0.160 g (1 mmole) of 2,4-diamino-6-chloropyrimidine 3-oxide and 0.505 g of 4-hydroxypiperidine was heated with stirring under nitrogen in an oil bath at 130° for 2.5 hr. After standing at room temperature overnight, the viscous oil was leached with acetone. The acetone leaching was evaporated *in vacuo* and the residue was taken up in methanol and applied to a 4 × 15-cm silica gel bar[10]. The silica gel bar was developed by the ascending technique in a mixture of acetone–methanol (70:30 v/v).

The UV light-absorbing zone near the origin of the bar was removed and eluted with methanol, the methanol was evaporated *in vacuo*, and the residue was recrystallized from acetone–methanol to yield 0.050 g of a crystalline solid. Its IR, UV, and NMR spectra were reasonable for the subject compound. Mass spectrometry revealed a molecular ion of 225 and a fragmentation pattern consistent with that expected for the subject compound.

Anal.—Calc. for $C_9H_{15}N_5O_2$: C, 47.98; H, 6.71; N, 31.09. Found: C, 47.67; H, 6.55; N, 30.65.

Chromatography in Systems I and III revealed a single UV-absorbing zone in each case.

Preparation of 2,4-Diamino-6-(3′-hydroxypiperidino)pyrimidine 3-Oxide (IV)—Compound IV was prepared from 3-hydroxypiperidine in a manner identical to that described for the 4′-hydroxypiperidino compound; 0.030 g of product was obtained. Its IR, UV, and NMR spectra were reasonable for the subject compound. Mass spectrometry revealed a molecular ion of 225 and a fragmentation pattern consistent with that expected for the subject compound.

Anal.—Calc. for $C_9H_{15}N_5O_2$: C, 47.98; H, 6.71; N, 31.09. Found: C, 47.07; H, 6.53; N, 30.14.

Chromatography in Systems I and III revealed a single UV-absorbing zone in each case.

Isolation of Dog Metabolites—The 0–2-hr urine of a dog which had received a tracer dose of ^{14}C-minoxidil was mixed with the urine of four dogs which had received two successive 10-mg/kg oral doses of nonradioactive minoxidil (1). The urine mixture was adjusted to pH 10 with ammonium hydroxide and passed through a 4.8 × 68-cm column of polystyrene polymer resin[11]. The column then was rinsed with three column volumes of water and eluted with three column volumes of acetone.

The acetone eluate was evaporated to dryness *in vacuo*, and the residue was taken up in methanol and applied to a 8 × 90-cm column of silica gel[12] packed with a mixture of benzene–methanol–ammonium hydroxide (75:25:1 v/v). The column was eluted with 3 mixtures of benzene–methanol–ammonium hydroxide while collecting 50-ml fractions as follows: 10 liters of a 75:25:1 (v/v) mixture, 4 liters of a 70:30:1 (v/v) mixture, and 8 liters of a 60:40:1 (v/v) mixture.

Two major zones of radioactivity emerged. Chromatographically, the first zone was a mixture of minoxidil and a more polar material and the second zone was essentially the more polar material alone. The fractions comprising each zone were combined and

Table I—Urinary Excretion of Minoxidil and Metabolites for the 0–24-hr Period following Oral Administration of ^{14}C-Minoxidil to the Rat, Dog, and Monkey

Species	Percent of Total Drug-Related Material in Urine						
	Total Polar	Carboxy Metabolites (VI/VII)	Minoxidil Glucuronide (V)	4′-Hydroxy-minoxidil (III)	3′-Hydroxy-minoxidil (IV)	Minoxidil (I)	Reduced Minoxidil (II)
Rat[a]	38	—[f]	6	12	1	43	<1
Rat (chronic)[b]		—[f]					
Before	43	(34)[g]	4	14	1	29	4
After	38	(28)[g]	2	9	1	35	10
Dog[c]	42	—[f]	5	29	4	13	<1
Dog (chronic)[d]							
Before	27	—[f]	2	47	4	19	<1
After	33	—[f]	4	35	4	18	3
Monkey[e]	21	—[f]	51	8	0	10	<1

[a] A single 5-mg/kg radioactive dose to each of three rats. [b] A 15-mg/kg radioactive dose to each of six rats before and after nine successive, daily, 150-mg/kg nonradioactive doses. [c] A single 0.55-mg/kg radioactive dose to each of three dogs. [d] A 1-mg/kg radioactive dose to each of four dogs before and after 30 successive, daily, 10-mg/kg nonradioactive doses. [e] A single 1-mg/kg radioactive dose to each of three monkeys. [f] Included in Total Polar but not differentiated. [g] Included in Total Polar.

evaporated to dryness *in vacuo*, and the residues were further purified by chromatography on 4 × 12-cm silica gel bars[10] in a benzene–methanol (70:30 v/v) mixture. The material corresponding to the first zone of the silica gel column was recrystallized from ethanol–water, water, and methanol–water (with the aid of charcoal[13]) to yield 0.015 g of white crystals. This material corresponded to minoxidil according to UV, IR, and mass spectrometry.

Anal.—Calc. for $C_9H_{15}N_5O$: C, 51.66; H, 7.23; N, 33.47. Found: C, 51.55; H, 7.19; N, 34.03.

Chromatography in Systems I and III–V revealed a single UV-absorbing zone corresponding to minoxidil. The material corresponding to the second zone on the silica gel column was recrystallized three times from methanol–acetone (with the aid of charcoal[13]) to yield 0.030 g of white crystals. This material corresponded to 2,4-diamino-6-(4′-hydroxypiperidino)pyrimidine 3-oxide according to UV, IR, and mass spectrometry.

Anal.—Calc. for $C_9H_{15}N_5O_2$: C, 47.98; H, 6.71; N, 31.09. Found: C, 48.02; H, 6.76; N, 30.72.

Chromatography in Systems I and III revealed a single UV-absorbing zone corresponding to the 4′-hydroxypiperidino compound. NMR spectrometry showed that the carbinol hydrogen was not at the C-2′, C-3′, C-5′, or C-6′ position of the piperidino ring, so it must have been at the C-4′ position. The coupling to the C-3′ and C-5′ methylene hydrogens of the piperidino ring indicated that the hydroxy group was equatorial.

Isolation of Rat Metabolites—Each of six female rats[14], weighing approximately 200 g, was given a 3-mg (24.4 μCi) dose of ^{14}C-minoxidil, nine successive 30-mg daily doses of nonradioactive minoxidil, and a final 3-mg (24.4 μCi) dose of ^{14}C-minoxidil by oral intubation of a solution or suspension in water. The rats were placed in individual metabolism cages, and urine was collected at 24-hr intervals and frozen for the duration of the study. Small samples of each urine collection for the 0–24-hr period following administration of the radioactive doses were set aside for analysis. The bulk of the radioactive urine collections was combined with the nonradioactive collections for metabolite isolation.

The composite urine was adjusted to pH 9 with ammonium hydroxide and passed through a 2.8 × 77-cm column of polystyrene resin[11]. The column was rinsed with three column volumes of water, which had been adjusted to pH 9, and then eluted with three column volumes of 50% methanol in water. The methanol eluate was evaporated to dryness *in vacuo* and set aside. The aqueous wash was adjusted to pH 4 with acetic acid and passed through a 2.8 × 77-cm column of polystyrene resin[11]. The column was rinsed with three column volumes of water, which had been adjusted to pH 4, and then eluted with three column volumes of 50% methanol in water. The rinse water was discarded and the methanol eluate was evaporated to dryness *in vacuo*.

A 10% aliquot of the pH 9 polystyrene resin[11] column eluate in 5 ml of benzene–methanol–ammonium hydroxide (50:50:1 v/v) was applied to a 2.5 × 51-cm column of silica gel[15]. The column was eluted with the same solvent mixture while collecting 10-ml fractions. Two major zones of radioactivity emerged. Chromatographically (Systems I–V), the first zone corresponded to 2,4-diamino-6-piperidinopyrimidine and the second zone corresponded to minoxidil. The contents of the tubes corresponding to the second zone were combined and evaporated to dryness, and the residue was recrystallized three times from ethanol–water (with the aid of charcoal[13]) to yield 0.010 g of crystals. This material corresponded to minoxidil according to UV spectrometry and chromatography in Systems I and III–V.

Anal.—Calc. for $C_9H_{15}N_5O$: C, 51.66; H, 7.23; N, 33.47. Found: C, 51.67; H, 7.48; N, 32.94.

This material gave a positive *N*-oxide test with ferric chloride solution, whereas the material that corresponded chromatographically to 2,4-diamino-6-piperidinopyrimidine did not.

The pH 4 polystyrene resin[11] column eluate was subjected to countercurrent distribution in the 1-butanol–acetic acid–water (9:1:10 v/v) system; 100 ml of each phase was used per tube for 20 transfers of the lower phase. The contents of tubes 11–16, which contained the major radioactive zone, were combined and evaporated to dryness in a nitrogen stream. The residue was recrystallized twice from acetone–water (with the aid of charcoal[16]) to obtain 0.026 g of crystals. Mass spectrometry, using an electron-impact technique, revealed an apparent molecular ion of 225 mass units and a fragmentation pattern consistent with 2,4-diamino-6-(4′-carboxy-*n*-butylamino)pyrimidine. UV spectrometry supported this structure.

NMR spectrometry suggested that the material was actually a mixture of the proposed compound and its 3-oxide (in a ratio of approximately 2 to 1) on the basis of comparisons with the spectra of 2,4-diamino-6-piperidinopyrimidine and its 3-oxide (minoxidil). This finding was supported by resolution of the material into two radioactive and UV-absorbing zones, only one of which gave a positive *N*-oxide test with ferric chloride solution, when subjected to chromatography in Systems I (for 6 days) and IV. In this case, the ratio of *N*-oxide to the reduced form was found to be nearly 1:1 based on radioactivity.

Mass spectrometry with a different instrument, using a field-desorption technique[17], revealed two molecular ions, one at 225 mass units, attributable to the initially proposed compound, and the other at 241 mass units, attributable to its 3-oxide. Use of an electron-impact technique and careful regulation of the probe temperature with this same instrument[17] revealed an apparent molecular ion at 241 mass units and a fragmentation pattern consistent with a mixture of the two materials.

Anal.—Calc. for a 1:1 mixture of $C_9H_{15}N_5O_2$ and $C_9H_{15}N_5O_3$: C, 46.40; H, 6.49; N, 30.03. Found: C, 46.08; H, 6.52; N, 30.41.

Table II—Areas under Minoxidil and Metabolite Plasma Level Curves for the 0–8-hr Period following Oral Administration of ^{14}C-Minoxidil to the Dog and Monkey

Species[a]	Percent of Total Drug-Related Area				
	Total Polar	Minoxidil Glucuronide (V)	4′-Hydroxy-minoxidil (III)	3′-Hydroxy-minoxidil (IV)	Minoxidil[b] (I)
Dog	14	<1	46	3	23
Dog (chronic)					
Before	12	<1	49	<1	26
After	17	<1	46	<1	27
Monkey	17	64	7	<1	9

[a]See Table I for drug dosages and numbers of animals. [b]Includes possible reduced minoxidil (II).

RESULTS AND DISCUSSION

Initial studies involved comparative paper and thin-layer radiochromatography of urine from rats, dogs, and monkeys which had received ^{14}C-minoxidil orally. In each case, radioactivity zones were detected, indicating extensive metabolism of minoxidil. One of these zones for each species had the same chromatographic mobility as minoxidil. The other zones were attributed to then unidentified metabolites of minoxidil. Judging from the relative amount of radioactivity in each zone, the major metabolite was different for each species. However, each species produced certain amounts of the major metabolites of the others. The urinary metabolite patterns for the three animal species are illustrated in Fig. 1; the metabolite pattern for the human will be discussed later. The peak designated I/II had the same mobility in System I as standard minoxidil.

Attention was next turned to identifying the urinary excretion products of minoxidil in the three animal species. In the case of the dog, the peak designated I/II in Fig. 1 was tentatively identified as unchanged minoxidil on the basis of its paper and thin-layer chromatographic mobilities. Subsequently, mass spectrometry of this material, isolated by preparative paper chromatography and TLC, gave spectra that were identical to that of minoxidil.

Finally, this material was isolated in crystalline form from dog urine and identified as minoxidil by elemental and spectral analyses. Material of the mobility designated I/II in Fig. 1 also was isolated in crystalline form from rat urine and identified as minoxidil. In the case of the monkey, the characterization of peak I/II in Fig. 1 was based entirely on paper chromatography and TLC.

During isolation of the rat urinary minoxidil, a radioactive material was detected with the same mobility as minoxidil in System I but with a greater relative mobility in Systems III–V. In contrast to minoxidil, it did not produce a blue color when treated with ferric chloride solution and, therefore, was considered to lack an *N*-oxide function. Since it had the same mobility in Systems I and III–V as 2,4-diamino-6-piperidinopyrimidine (II), it was characterized as this reduced form (II) of minoxidil. That particular study involved chronic administration of minoxidil to rats [labeled Rat (chronic) in Table I].

In another rat study, involving single 50-mg/kg doses of ^{14}C-minoxidil, II also was found in urine. However, in a third study, using single 5-mg/kg doses of ^{14}C-minoxidil in rats, II was not detected in urine. Thus, at least when large or chronic doses of minoxidil were administered to rats, II was excreted in urine. This also was the case with the dog. This metabolite was not detected in monkey urine.

Mass spectrometry of the material designated III in Fig. 1, isolated by preparative paper chromatography and TLC of urine from dogs that had received ^{14}C-minoxidil, indicated that this material was a hydroxypiperidino form of minoxidil. Therefore, both 2,4-diamino-6-(4′-hydroxypiperidino)pyrimidine 3-oxide (III) and 2,4-diamino-6-(3′-hydroxypiperidino)pyrimidine 3-oxide (IV) were prepared and characterized as standards. Paper chromatography and TLC showed that the 4′-hydroxy standard had the same mobility as the major peak designated III and the 3′-hydroxy standard had the same mobility as the minor peak designated IV.

Subsequently, III was isolated from dog urine in crystalline form and identified as such by elemental and spectral analyses. NMR was particularly valuable in confirming the 4′-position for the hydroxy group and showing that it was equatorial. With the rat and monkey, characterization of peak III in Fig. 1 was based entirely on paper chromatography and TLC. The characterization of IV in Fig. 1 for the dog and rat was based solely on this small peak having the same mobility as standard IV in System I. This metabolite was not detected in monkey urine.

Characterization of the peak designated V in Fig. 1 was based principally on results obtained by incubating urine containing this radioactive metabolite with β-glucuronidase. For each animal species, such incubation resulted in loss of peak V and a concomitant and equivalent increase in peak I/II. Mass spectrometry of eluates of the zone corresponding to I/II from preparative thin-layer chromatograms, following enzyme incubation of monkey urine, confirmed that minoxidil was being released. Metabolite V was thereby characterized as a glucuronic acid conjugate of minoxidil. It is likely that conjugation was with the *N*-hydroxy tautomeric form of minoxidil (Scheme I), giving an *O*-glucuronide[18]. Never-

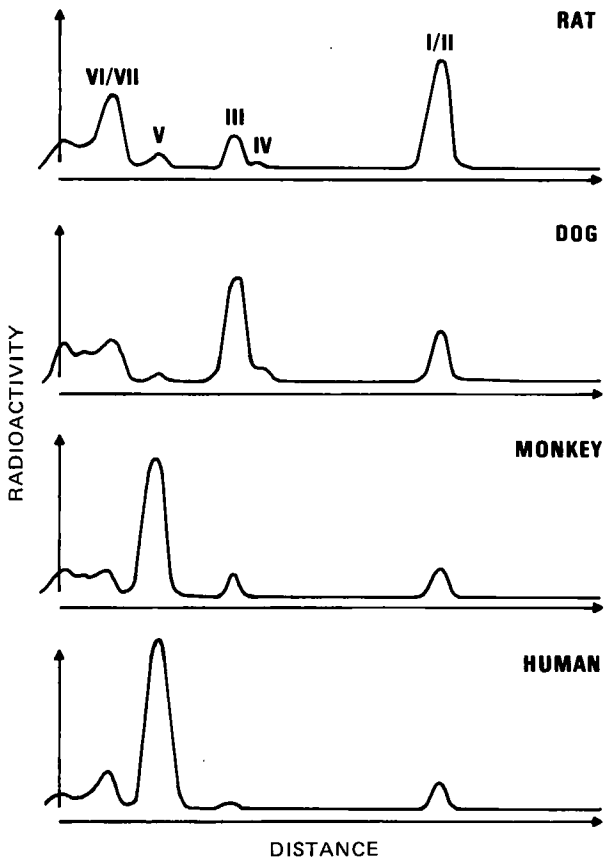

Figure 1—*Composites of radiochromatograms (System I) representing 0–24-hr urine collections for the rat, dog, monkey, and human.*

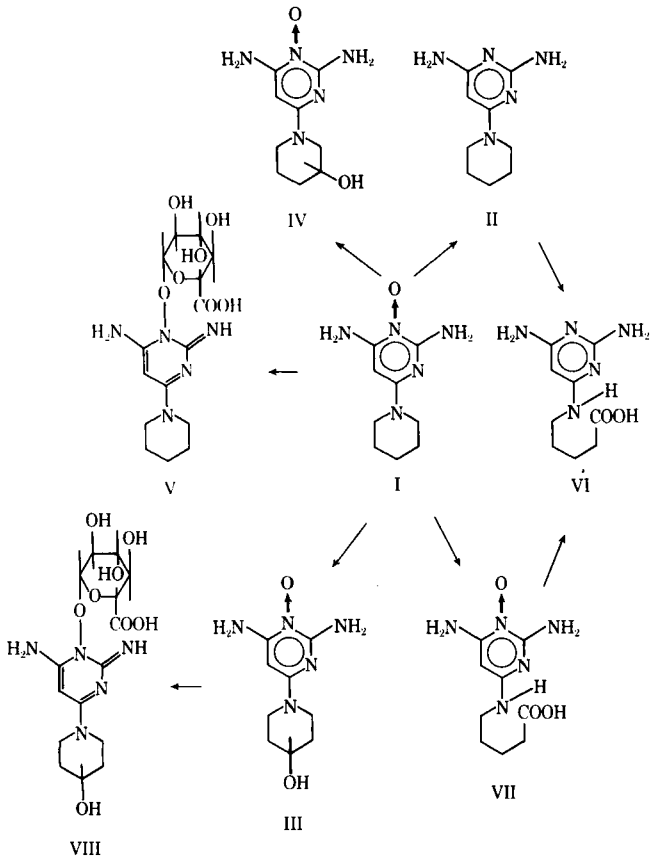
[18] The glucuronide conjugate is stable to hydrolysis in 0.1 *N* HCl at 35°; *N*-glucuronides generally are hydrolyzed by such treatment.



Scheme I—Biotransformation of minoxidil (the points of attachment of the glucuronic acid moiety to V and VIII have not been definitely established)

theless, conjugation through one amine nitrogen to give an *N*-glucuronide has not been completely ruled out.

Preliminary characterization of the metabolite peak designated VI/VII in Fig. 1 was accomplished by mass spectrometry of appropriate eluates of preparative paper and thin-layer chromatograms of urine from rats that had received ^{14}C-minoxidil. These results indicated that this metabolite was 2,4-diamino-6-(4′-carboxy-*n*-butylamino)pyrimidine (VI), derived from minoxidil *via* oxidative cleavage of the piperidine ring at the C—N bond. Subsequently, the metabolite(s) was isolated in crystalline form from rat urine and shown by elemental analysis and spectrometry to be a mixture of VI and 2,4-diamino-6-(4′-carboxy-*n*-butylamino)pyrimidine 3-oxide (VII) in a ratio of 1:1 or 2:1. The only evidence that these materials were metabolites of minoxidil in dog and monkey urine was that each species produced a urinary metabolite of minoxidil having a mobility corresponding to the carboxy metabolites in System I. Studies are in progress to determine the importance of these metabolites in the dog and monkey.

Evidence for urinary excretion of a glucuronide conjugate (VIII) of the 4′-hydroxy metabolite by the dog was obtained. Incubation with β-glucuronidase of urine from dogs that had received ^{14}C-minoxidil resulted in loss of radioactivity from the origin and a concomitant and equivalent appearance of radioactivity in peak III when chromatographed in System I. This could be an *O*-glucuronide of the *N*-hydroxy group or the C-hydroxy group or perhaps an *N*-glucuronide of one amino group of the 4′-hydroxy metabolite. This material was not detected as a metabolite of minoxidil in rat and monkey urine.

The results described thus far are summarized in Fig. 1 and Scheme I. In Fig. 1, an attempt was made to present true, quantitative relationships among the drug and its metabolites for the various species. Scheme I shows the structures of the various metabolites produced by the three animal species as well as their possible relationships to one another. The points of attachment of the glucuronic acid moiety to minoxidil and one of the metabolites are somewhat speculative, but there is substantial evidence in each case for the structure of the aglycone and for its conjugation with glucuronic acid.

Once chromatographic profiles of urinary minoxidil metabolites were obtained and most metabolites were identified, it was possible to quantify the biotransformation of minoxidil for each animal species. Minoxidil and its metabolites in urine were quantified by determining the amount of radioactivity associated with the drug or a particular metabolite following separation by paper chromatography and TLC. The results presented in Table I and Fig. 1 clearly show that the principal drug-related material excreted by the rat was unchanged minoxidil, closely followed by the carboxy metabolites. With the dog, the 4′-hydroxy metabolite was the principal excretion product. The monkey excreted predominantly the glucuronide conjugate of minoxidil.

The various drug-related materials in the circulation of the dog and monkey were characterized and quantified by radiochromatography of blood plasma samples taken sequentially following oral administration of ^{14}C-minoxidil. The results (Table II) are presented as the percent contribution each drug-related material makes to the total area under the plasma radioactivity level *versus* time curve during the 8-hr period following drug administration. This method should take into account the persistence, as well as the concentration, of each drug-related material in plasma.

As can be seen from Table II, the principal circulatory material in the dog was the 4′-hydroxy metabolite; in the monkey, it was the glucuronide of minoxidil. Substantial amounts of minoxidil and the polar group of metabolites were circulated by both species. The major drug-related material in circulation for the human was not identified by Gottlieb *et al.* (2), but it was not minoxidil. Since the major urinary excretion product in the human and the monkey was the glucuronide of minoxidil, it seems reasonable that this was also the major circulatory material in the human.

Gottlieb *et al.* (2) reported that the human excretes four minoxidil-related products in urine following oral administration of ^{14}C-labeled drug. They were characterized as minoxidil, a glucuronide of minoxidil, and two unidentified metabolites, designated M-II and M-I. Their relative amounts in 0–24-hr urine collections were 12, 48, 18, and 21%, respectively, as determined by radiochromatography in System I.

Experience with paper chromatography of monkey urine and urine extracts containing the minoxidil glucuronide has shown this glucuronide to have two apparent migration rates in System I. Although the glucuronide usually migrated to one or the other of two similar R_f values (0.2 and 0.3), at times it would appear as a doublet occupying both locations. Certain samples, particularly those with relatively great solids content, were more susceptible than others to this variation in migration, including doublet formation. Replicate paper chromatograms of such a sample over time could result in the glucuronide displaying either, or both, R_f value unpredictably.

Regardless of the particular chromatographic behavior, however, hydrolysis of each sample resulted in complete loss of the glucuronide and a concomitant and equivalent appearance of minoxidil. The existence of two glucuronides of minoxidil (such as an *O*-glucuronide and an *N*-glucuronide) would not explain these observations. At the same time, these results do not preclude the presence of two such materials. These results can be explained best by a single glucuronide which, depending on its environment, either can be partially modified by application to the paper or can exist in several ionic forms having different migration rates in System I.

Chromatography in System I of human urine samples, collected by Gottlieb *et al.* (2), resulted in separation of three major zones of radioactivity rather than four. These zones corresponded, in order of increasing polarity, to minoxidil, the glucuronide of minoxidil, and a very polar zone, sometimes resolvable into two components. Integration of these chromatograms showed that our glucuronide accounted for the sum of the glucuronide and Metabolite M-II or M-I described by Gottlieb *et al.* (2). Hydrolysis of these urine samples with β-glucuronidase resulted in the complete loss of the material herein designated as the glucuronide and a concomitant and equivalent appearance of minoxidil, as judged by chromatography in System I. Similar hydrolysis studies using System III showed

that minoxidil, not 2,4-diamino-6-piperidinopyrimidine, was released from the glucuronide.

It appears that, as with monkey urine, a single glucuronide best explains the results with human urine. In addition to minoxidil, the glucuronide of minoxidil, and the very polar minoxidil-related material in human urine, small (less than 3%) amounts of 2,4-diamino-6-(4′-hydroxypiperidino)pyrimidine 3-oxide and, in a few samples, traces of 2,4-diamino-6-piperidinopyrimidine were found. The more mobile component of the very polar zone of radioactivity corresponded to the migration of the carboxy metabolites of minoxidil. The urinary metabolite profile for the human is based on the results reported by Gottlieb *et al.* (2) modified by our chromatographic results with human and monkey urine containing the glucuronide of minoxidil as discussed.

The urinary metabolite profile for minoxidil in the human is compared to those in the rat, dog, and monkey in Fig. 1. This comparison shows that each species, including the human, excreted substantially the same metabolites but in quite different relative amounts. The monkey and human exhibited similar metabolite profiles, whereas the dog and rat were quantitatively different from each other and from the monkey and human. Thus, of the three animal species studied, the monkey is most like the human in its biotransformation and disposition (1) of minoxidil.

Antiradiation Compounds XV: Condensations of Carbon Disulfide with Amino, Chloro, Cyanomethyl, and Sulfonamido Heterocycles

WILLIAM O. FOYE [x], JOEL M. KAUFFMAN, JOSEPH J. LANZILLO, and EDWARD F. LaSALA

Abstract □ Condensations of carbon disulfide were carried out with amino, chloro, and diamino heterocycles to give condensed ring thiazoline-2-thiones and imidazoline-2-thiones, with cyanomethyl heterocycles to give dithio acid derivatives, and with heterocyclic sulfonamides to give sulfonyldithiocarbamates. Of several examples tested, pyrido[3,2-*d*]thiazoline-2-thione, disodium 2-(5-chloro-2-thienyl)-3,3-dimercaptoacrylonitrile, triethylammonium 4-sulfamoylphenyldithiocarbamate, ammonium β-phenethyldithiocarbamate, and methyl *N*-(thiophene-2-sulfonyl)dithiocarbamate, only the last-named compound showed any radiation protection for mice. Several compounds gave negative tests for antimalarial activity.

Keyphrases □ Antiradiation compounds—condensations of carbon disulfide with amino, chloro, cyanomethyl, and sulfonamido heterocycles □ Carbon disulfide—condensation products with amino, chloro, cyanomethyl, and sulfonamido heterocycles, potential antiradiation agents □ Heterocycles (amino, chloro, cyanomethyl, and sulfonamido)—condensation products with carbon disulfide, antiradiation activity

Condensation products of carbon disulfide with amines (1, 2) and mercaptans (3), as well as with active methylenes adjacent to cyano groups (4), have all shown some degree of protection for animals against ionizing radiation. With the dithiocarbamates, the presence of heterocyclic rings, particularly when strongly basic (5), provided greater protective properties. In the case of the dimercaptoacrylonitriles derived from active methylene compounds, the presence of heterocyclic rings on the carbon alpha to the dimercapto acid function generally resulted in hygroscopic products and sometimes compounds of low stability.

The attempt accordingly has been made to obtain condensation products of carbon disulfide with heterocyclic rings that have greater stability and also a mercapto group two or three atoms distant from a basic nitrogen or heteroatom, to provide an analogy with the more protective aliphatic mercapto amines.

DISCUSSION

Condensations with Amino and Chloro Heterocycles—The finding (6) that 4-chloro-5,6-diaminopyrimidine gave a thiazoline-2-thione (I) with replacement of amino and chloro groups and not the imidazoline-2-thione prompted a trial of this reaction on several suitably substituted heterocycles (Scheme I).

The pyridine analog (II) was prepared previously by Yamamoto and Takahashi (7), who reported a decomposition point of 294° and stated no percentage yield. Their product was obtained from 2-chloro-3-nitropyridine, sodium sulfide, hydrogen sulfide, and carbon disulfide; sulfide reduction of the nitro group was involved. In the present research, II was obtained in 73% yield, mp 310–314° dec., from 3-amino-2-chloropyridine and carbon disulfide, with dimethylformamide as the solvent.

that minoxidil, not 2,4-diamino-6-piperidinopyrimidine, was released from the glucuronide.

It appears that, as with monkey urine, a single glucuronide best explains the results with human urine. In addition to minoxidil, the glucuronide of minoxidil, and the very polar minoxidil-related material in human urine, small (less than 3%) amounts of 2,4-diamino-6-(4′-hydroxypiperidino)pyrimidine 3-oxide and, in a few samples, traces of 2,4-diamino-6-piperidinopyrimidine were found. The more mobile component of the very polar zone of radioactivity corresponded to the migration of the carboxy metabolites of minoxidil. The urinary metabolite profile for the human is based on the results reported by Gottlieb *et al.* (2) modified by our chromatographic results with human and monkey urine containing the glucuronide of minoxidil as discussed.

The urinary metabolite profile for minoxidil in the human is compared to those in the rat, dog, and monkey in Fig. 1. This comparison shows that each species, including the human, excreted substantially the same metabolites but in quite different relative amounts. The monkey and human exhibited similar metabolite profiles, whereas the dog and rat were quantitatively different from each other and from the monkey and human. Thus, of the three animal species studied, the monkey is most like the human in its biotransformation and disposition (1) of minoxidil.

Condensations with Amino and Chloro Heterocycles—The finding (6) that 4-chloro-5,6-diaminopyrimidine gave a thiazoline-2-thione (I) with replacement of amino and chloro groups and not the imidazoline-2-thione prompted a trial of this reaction on several suitably substituted heterocycles (Scheme I).

The pyridine analog (II) was prepared previously by Yamamoto and Takahashi (7), who reported a decomposition point of 294° and stated no percentage yield. Their product was obtained from 2-chloro-3-nitropyridine, sodium sulfide, hydrogen sulfide, and carbon disulfide; sulfide reduction of the nitro group was involved. In the present research, II was obtained in 73% yield, mp 310–314° dec., from 3-amino-2-chloropyridine and carbon disulfide, with dimethylformamide as the solvent.

Scheme III

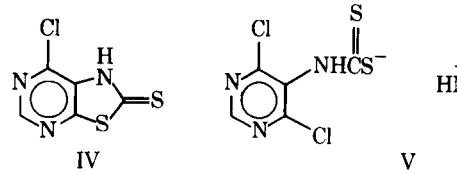
Most evidence indicates that 2-mercaptothiazole (8) and 2-mercaptobenzothiazole (9) are present in neutral media mainly as the thiones (8). The pyridine derivative has a melting point 150° higher than the benzo analog, dissolves instantly in cold, aqueous alkali, and is insoluble in cold, dilute, mineral acid. This behavior can be explained by the existence in neutral media of the thione form as a hydrogen-bonded dimer, in equilibrium with a small amount of thiol (II*b*) (Scheme II).

A broad, intense IR absorption band at 2650–2900 cm^{-1} supports the existence of the hydrogen-bonded dimer with a significant amount of proton transfer, as postulated for 2-mercaptobenzothiazole (10). Absorption at 2550 cm^{-1} also indicates the presence of thiol. The UV absorption in dimethylformamide was identical to that for 2-mercaptobenzothiazole.

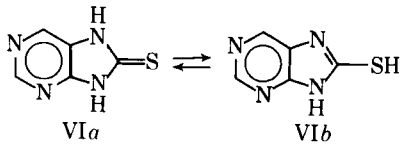
Reaction of 4-amino-3-bromopyridine with carbon disulfide in dimethylformamide failed to give the isomeric pyrido[4,3-*d*]thiazoline-2-thione. Pyrido[2,3-*c*]imidazoline-2-thione (III), however, was synthesized from 2,3-diaminopyridine and carbon disulfide in ethanol; a melting point of "over 300°" had previously been reported for this compound (11). By recrystallizing the product from dimethylformamide and propanol, a melting point of 326–330° dec. was obtained. The IR absorption at 2700–2900 cm^{-1}, as well as the high melting point, again indicated that the hydrogen-bonded dimeric thione was the predominant form of the compound. A small absorption band at 2600 cm^{-1} and solubility in alkali indicated some thiol form (III*b*) (Scheme III).

Condensation of carbon disulfide with 5-amino-4,6-dichloropyrimidine did not give the expected thiazoline-2-thione (IV) but the dithiocarbamate salt (V) instead. Reaction of 4,5-diaminopyrimidine with carbon disulfide, however, gave a 35% yield of purine-8-thiol (VI) (Scheme IV). Previous syntheses of this compound from pyrimidine and thiourea (12) and from purine and sulfur (13) are known. The IR absorption of this compound between 2700 and 2900 cm^{-1} was complex, and its breadth was characteristic of that of the hydrogen-bonded dimeric thione of 2-mercaptobenzothiazole (10). An IR absorption band at 2550 cm^{-1} also indicated the presence of some of the thiol form. Reaction of 2-amino-3-chloropyrazine with carbon disulfide in dimethylformamide at 110° for 22 hr gave only a small amount of orange solid, mp 380° dec., which was not characterized.

Condensations with Cyanomethyl Heterocycles—One attempt to obtain more stable heterocyclic-substituted dimercaptoacrylonitriles involved the use of heterocycles with electron-attracting substituents. 2-Chloro-5-cyanomethylthiophene was prepared from 2-chlorothiophene *via* chloromethylation, and condensation with carbon disulfide was carried out in the presence of sodium hydride. Although the reaction was carried out in anhydrous ether, a hydrated product (VII) was obtained, similar to previous compounds of this type (4). Attempts to prepare the corresponding phenyl and sulfonamido derivatives failed; the electron-withdrawing effects of the substituents apparently deactivated the rings to chloromethylation.

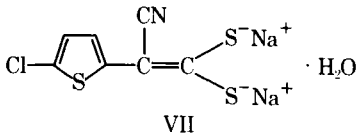


IV V



VIa VIb

Scheme IV



VII

The carbon disulfide condensation product from benzoylacetonitrile (4) was found to be more stable than the condensation products having aromatic rings attached directly to the cyanomethyl group, apparently due to extension of conjugation and shifting of a negative charge from sulfur to the more electronegative oxygen (VIII) (Scheme V). The IR absorption did not show the presence of a carbonyl group, indicating VIIIb to be the predominant form. Condensation of 2-furoylacetonitrile with carbon disulfide and sodium methoxide gave the monothio anion (IX). The IR absorption showed the presence of hydroxy and cyano groups, carbon–carbon unsaturation, and carbon–sulfur unsaturation. When potassium hydroxide was used as the base, an unidentifiable water-soluble red salt was obtained.

Condensation of 2-thenoylacetonitrile with carbon disulfide in the presence of potassium hydroxide, however, gave the dithio dianion (X). The IR absorption showed the presence of the cyano group, carbon–carbon unsaturation, and carbon–sulfur unsaturation but no evidence of a carbonyl group, analogous to the product from benzoylacetonitrile. Neither IX nor X was obtained in a hydrated or solvated form.

Condensations with Sulfonamides—Gompper and Hägele (14) first described the reaction of sulfonamides with carbon disulfide and alkali to give *N*-sulfonylimidodithiocarbonates (XI). These compounds were not isolated but could be converted to derivatives such as mono- or diethers or *N*-sulfonyldithiourethanes (XII) (Scheme VI).

Attempts were made to prepare the *N*-sulfonylimidodithiocarbonates and thioesters of N^4-acetylsulfanilamide, thiazole-2-sulfonamide, benzothiazole-2-sulfonamide, 4-phenylthiazole-2-sulfonamide, and thiophene-2-sulfonamide. Only the thiophene-2-sulfonamide gave products that could be characterized. These compounds were the *N*-sulfonylimidodithiocarbonate (XIII) and the methyl ester of the sulfonyl dithiocarbamate (XIV).

Treatment of sulfanilamide with carbon disulfide and alkali gave 4-sulfamoylphenyldithiocarbamate (XV); both the potassium and triethylammonium salts were isolated. Evidence for the attack of carbon disulfide at the aromatic amine rather than at the sulfonamide nitrogen was found by an IR absorption peak for C=S, the presence of only one cation in the product, and the failure of carbon disulfide to react with N^4-acetylsulfanilamide. Attempts to prepare an *N*-sulfonylimidodithiocarbonate monothioester of XV were also unsuccessful.

X

RESULTS[1]

Tests were carried out in mice (groups of six) *versus* 825 rads (X-rays), with an observation period of 30 days. The compounds were administered intraperitoneally in a carboxymethylcellulose–polysorbate vehicle at dose levels of 80–400 mg/kg. Compounds II, VII, and XV and ammonium β-phenethyldithiocarbamate, which had been previously prepared (15), were inactive. Compound XIV provided slight protection (17% survival) in this test at a dose of 400 mg/kg ip.

Several compounds were also screened for antimalarial activity in mice infected with *Plasmodium berghei*, according to the method of Osdene *et al.* (16), and in *Aedes aegypti* infected with *Plasmodium gallinaceum*, according to the method of Gerberg *et al.* (17). In the former test, II, XIV, and XV were listed as inactive; XV, however, showed a test/control survival ratio of 2.2 at a dose of 640 mg/kg. In the latter test, XIV, XV, and ammonium β-phenethyldithiocarbamate were inactive.

On the basis of the radiation-protective test results reported here and in previous papers (4, 18), it may be concluded that compounds with thiol anions or potential thiol anions, capable of rapid hydrogen atom transfer, may be radiation protective without the presence of a strongly basic nitrogen in the molecule. Nevertheless, the presence of an electron-rich heterocyclic ring system or other group capable of binding to DNA or other essential macromolecules appears to be required in the absence of a strongly basic nitrogen. However, by far the most potent of the basic thiol radiation-protective compounds do contain strongly basic amine functions (19).

EXPERIMENTAL[2]

Pyrido[3,2-*d*]thiazoline-2-thione (II)—A mixture of 3-amino-2-chloropyridine[3] (6.43 g, 0.05 mole), carbon disulfide (50 ml), and dimethylformamide (50 ml) was heated at reflux for 47 hr, cooled, and evaporated at 50° and 50 mm pressure to remove excess carbon disulfide. The solution was poured into 300 ml of ice and water with stirring. The precipitate was dried to give 7.2 g of tan powder,

mp 304–306° dec., and recrystallized from a mixture of 40 ml of dimethylformamide and 100 ml of 1-propanol.

The first crop of tan crystals weighed 5.8 g (69%), mp 310–314° dec. The compound was soluble in acetone and cold dilute sodium hydroxide solution and insoluble in water and hot 8% sulfuric acid. Recrystallization from dimethylformamide–propanol and drying at 100°/0.3 mm gave the analytical sample of off-white spars, mp 312–315° dec. [lit. (7) mp 294°]; IR ν_{max} (KBr): 2650–2900 (NH), 2550 (SH), and 1040 (C=S) cm^{-1}; UV λ_{max} (dimethylformamide): 265 nm.

Anal.—Calc. for $C_6H_4N_2S_2$: C, 42.8; H, 2.4; N, 16.6; S, 38.1. Found: C, 43.0; H, 2.3; N, 16.4; S, 37.8.

Pyrido[2,3-*d*]imidazoline-2-thione (III)—The procedure of Petrow and Saper (11) gave an 89% yield of product, mp 326–330° [lit. (11) mp >300°]. Recrystallization of 9.1 g from a mixture of 40 ml of dimethylformamide and 100 ml of 1-propanol gave 6.9 g (76%), mp 326–330°; IR ν_{max} (KBr): 2700–2900 (NH), 2550 (SH), and 1200 (C=S) cm^{-1}.

Anal.—Calc. for $C_6H_5N_3S$: C, 47.7; H, 3.3; N, 27.8; S, 21.2. Found: C, 48.1; H, 3.4; N, 27.5; S, 21.0.

4,6-Dichloro-5-aminopyrimidinium 4,6-Dichloropyrimidine-5-dithiocarbamate (V)—A mixture of 4,6-dichloro-5-aminopyridine[4] (0.82 g, 0.005 mole), carbon disulfide (5 ml), and dimethyl sulfoxide (5 ml) was heated at reflux for 5 days, freed of carbon disulfide by evaporation, and diluted with 30 ml of water. The yellow powder that separated was dried at 125°/3 mm for 3 hr, giving 0.2 g, mp 239–242° dec.

Anal.—Calc. for $C_9H_6Cl_4N_6S_2$: C, 26.8; H, 1.5; N, 20.8; S, 15.9. Found: C, 27.2; H, 1.4; N, 21.2; S, 16.1.

Purine-8-thiol (VI)—A mixture of 4,5-diaminopyrimidine[5] (4.7 g, 0.043 mole), carbon disulfide (10 ml), and 95% ethanol (50 ml) was heated at reflux for 70 hr. Hydrogen sulfide was liberated, and product separated during the reaction. Addition of 10 ml of water and chilling in an ice bath gave a tan solid. This product was washed with 30% ethanol, dried at 130°/3 mm for 3 hr, and recrystallized from 150 ml of water, yielding 2.3 g (35%) of light-yellow spars, mp 312–318° dec. [lit. (12) mp 268° dec. and (13) mp 295–297° dec.]; IR ν_{max} (KBr): 2700–2900 (NH) and 1200 (C=S) cm^{-1}.

The compound was soluble in cold, dilute sodium hydroxide solution, cold, dilute sulfuric acid, dimethylformamide, and hot 1-propanol.

Anal.—Calc. for $C_5H_4N_4S$: C, 39.4; H, 2.7; N, 36.8; S, 21.0. Found: C, 39.6; H, 3.0; N, 36.4; S, 20.6.

Disodium 2-(5-Chloro-2-thienyl)-3,3-dimercaptoacrylonitrile Hydrate (VII)—Sodium hydride[6] (1.05 g, 0.025 mole, 57% in petroleum ether) was washed three times with anhydrous ether and suspended in ether (12 ml). To this mixture was added carbon disulfide (0.8 ml, 0.013 mole) and 2-chloro-5-cyanomethylthiophene (20) (2 g, 0.013 mole) dropwise during 20 min. The reaction mixture was stirred at room temperature for 7 days.

The precipitate was filtered and washed with anhydrous ether to give a 60% yield of a green powder, mp >360°; IR ν_{max} (KBr): 3450 (OH), 2160 (C≡N), and 1625 (C=C) cm^{-1}.

Anal.—Calc. for $C_7H_2NNa_2S_3 \cdot H_2O$: C, 28.40; H, 1.35; N, 4.75. Found: C, 27.98; H, 1.67; N, 4.50.

Sodium 2-Furoylacetonitrile-2-dithiocarboxylate (IX)—2-Furoylacetonitrile (21) (1 g, 0.0074 mole) and sodium methoxide (0.4 g, 0.0074 mole) were suspended in anhydrous benzene (15 ml) and heated at reflux for 1 hr. Heating was stopped, and carbon di-

[1] Antiradiation screening of several compounds was carried out at the Walter Reed Army Institute of Research. Results were reported through the courtesy of Capt. Gene Withrow.

[2] Melting points were determined in capillaries with a Mel-Temp melting-point block and are corrected. IR absorption spectra were obtained with a Perkin-Elmer model 137 B spectrophotometer with sodium chloride optics. UV absorption spectra were obtained with a Beckman DB-GT spectrophotometer. Elemental analyses were done by Dr. F. B. Strauss, Oxford, England, or by Dr. Carol K. Fitz, Carlisle, Mass. TLC was carried out using silica gel, and products were detected by exposure to iodine vapor.

sulfide (0.56 g, 0.0074 mole) in methanol (5 ml) was added to the warm mixture. An additional 0.4 g of sodium methoxide was added, and stirring and refluxing were continued for 0.5 hr. The yellow precipitate was filtered, washed with anhydrous ether, and dried *in vacuo*, giving 0.9 g (90%) of yellow powder, mp 275–278°; IR ν_{max} (KBr): 3500 (OH), 2190 (C≡N), 1592 (C=C), and 1015 (C=S) cm^{-1}.

Anal.—Calc. for $C_8H_4NNaO_2S_2$: C, 41.20; H, 1.72; N, 6.01. Found: C, 41.52; H, 2.08; N, 6.29.

Dipotassium 2-(2-Thenoyl)-3,3-dimercaptoacrylonitrile (X)—Potassium hydroxide (0.47 g, 0.007 mole), dissolved in 10 ml of absolute ethanol, was added to a solution of thenoylacetonitrile (21) (0.5 g, 0.0035 mole) and carbon disulfide (0.22 ml, 0.0035 mole) in 10 ml of dry benzene and 5 ml of absolute ethanol. The mixture was stirred at room temperature for 4 days, filtered, and washed with ether, giving a 50% yield of brown powder, mp 208–210°; IR ν_{max} (KBr): 3450 (OH), 2198 (C≡N), 1640 (C=C), and 1000 (C=S) cm^{-1}.

Anal.—Calc. for $C_8H_3K_2NOS_3$: C, 31.70; H, 0.99; N, 4.63; S, 31.70. Found: C, 31.27; H, 1.38; N, 4.75; S, 31.40.

Triethylammonium 4-Sulfamoylphenyldithiocarbamate (XV)—To a solution of 1.72 g (0.01 mole) of sulfanilamide in 20.8 ml of triethylamine were added 10.5 ml (0.15 mole) of carbon disulfide and 60 ml of absolute ethanol. The solution was stirred for 6 hr at room temperature, allowed to stand overnight, and filtered. The product was washed with absolute ethanol and ether, giving 2.65 g (75%) of yellow crystals, mp 138–141°; IR ν_{max} (KBr): 990 (C=S) cm^{-1}.

Anal.—Calc for $C_{13}H_{23}N_3O_2S_3$: C, 44.70; H, 6.59; N, 12.03; S, 27.51. Found: C, 44.67; H, 6.77; N, 12.00; S, 27.91.

Potassium 4-Sulfamoylphenyldithiocarbamate—The potassium salt was prepared from sulfanilamide (1.72 g, 0.01 mole), dimethylformamide (5 ml), absolute ethanol (20 ml), and carbon disulfide (10.5 ml, 0.15 mole) in a manner similar to that described for XV. A yield of 2.25 g (71%) was obtained, mp 219° dec.

Anal.—Calc. for $C_7H_7KN_2O_2S_3$: C, 29.37; H, 2.45; N, 9.79; S, 33.60. Found: C, 29.58; H, 2.71; N, 10.00; S, 33.66.

Dipotassium Thiophene-2-sulfonylimidodithiocarbonate (XIII)—A solution of 1.63 g (0.01 mole) of thiophene-2-sulfonamide (22) in 20 ml of absolute ethanol was mixed with 10.5 ml (0.15 mole) of carbon disulfide and 8 ml of ethanol containing 0.03 mole of potassium hydroxide. The mixture was stirred overnight at room temperature, and the precipitate was washed with absolute ethanol, dry ether, and acetone, giving 1.5 g (47%) of hygroscopic yellow powder, mp 202–204° dec.

Anal.—Calc. for $C_5H_3K_2NO_2S_4$: C, 19.05; H, 0.95; N, 4.44; S, 40.64. Found: C, 18.63; H, 2.06; N, 4.05; S, 41.03.

Methyl *N*-(Thiophene-2-sulfonyl)dithiocarbamate (XIV)—A solution of 3.26 g (0.02 mole) of thiophene-2-sulfonamide (22) in 15 ml of dimethylformamide was treated with 1.2 ml of sodium hydroxide solution (16 g in 20 ml of water) and 0.7 ml (0.01 mole) of carbon disulfide with stirring. After 10 min, 0.6 ml of sodium hydroxide solution and 0.35 ml (0.005 mole) of carbon disulfide were added, and this addition was repeated 10 min later.

After being stirred for an additional 10 min, the solution was placed in an ice bath and treated with 1.1 ml (0.02 mole) of methyl iodide; the resulting solution was stirred for 2 hr and poured into 50 ml of water. Hydrochloric acid (concentrated) was added dropwise to the point of disappearance of turbidity, and the red oil which separated was isolated and shaken with several 50-ml portions of water. The resulting crystals were collected and recrystallized from benzene with a small amount of petroleum ether, giving 1.2 g (24%), mp 104–105°; IR ν_{max} (KBr): 1050 (C=S) cm^{-1}.

Anal.—Calc. for $C_6H_7NO_2S_4$: C, 28.42; H, 2.78; N, 5.53; S, 50.63. Found: C, 28.76; H, 3.01; N, 5.70; S, 51.02.

Analogs of the Anorexic Mazindol

T. L. LEMKE ˣ, L. A. CATES, M. STEENBERG, and Y. M. CHO

Abstract □ Mazindol, 5-(*p*-chlorophenyl)-2,5-dihydro-3*H*-imidazo[2,1-*a*]isoindol-5-ol, has been shown to be an effective anorexic. To explore the structure–activity relationships, several 1-ethyl-3-substituted-4-aryl-4-hydroxyindeno[1,2-*c*]pyrazoles were prepared and subjected to various animal screens. The 1-ethyl-3-*tert*-butyl-4-aryl-4-hydroxyindeno[1,2-*c*]pyrazoles are capable of significantly depressing forced and spontaneous motor activity in mice but have low LD_{50}'s. Two of these compounds were tested in an Ehrlich ascites tumor screen. The 1-ethyl-3-phenyl-4-aryl-4-hydroxyindeno-[1,2-*c*]pyrazoles depressed forced and spontaneous motor activity at low doses and were relatively nontoxic.

Keyphrases □ Mazindol analogs—synthesis, effect on forced and spontaneous motor activity, mice □ Indeno[1,2-*c*]pyrazoles, 1-ethyl-3-substituted-4-aryl-4-hydroxy (mazindol analogs)—synthesis, effect on forced and spontaneous motor activity, mice

Recently, a new, chemically unique anorexic was introduced for use as an adjunct in the treatment of obesity. Mazindol (I) is a derivative of the imidazo[2,1-*a*]isoindole nucleus. Not only does this nucleus represent a new basic structure with anorexic activity, but the site of action of mazindol is reportedly different from that of previously used agents (1). This drug, in addition to suppressing appetite, has been reported to cause a mild central nervous system (CNS) stimulation in both laboratory animals and humans (2–4).

The relationship between this unique structure and the anorexic effect apparently has not been explored. Because of an interest in novel tricyclic nuclei, an investigation of the indeno[1,2-*c*]pyrazoles, which have structural features in common with the imidazo[2,1-*a*]isoindole nucleus, was undertaken. The synthesis and initial biological screening of these analogs (II) of mazindol are now reported[1].

EXPERIMENTAL[2]

Chemistry—The indeno[1,2-*c*]pyrazol-4-ones were prepared by the procedure of Braun and Mosher (5) as shown in Scheme I. Grignard addition of arylmagnesium bromides to the 1-ethylindeno[1,2-*c*]pyrazol-4-ones (V) gave the appropriate tertiary alcohols (II*a*–II*f*).

*1-Ethyl-3-*tert*-butylindeno[1,2-c]pyrazole-4(1*H*)-one (V)*—A 9.7-g (0.043-mole) sample of IV (R_1 = *tert*-butyl) (5) was added to 3 liters of 10% sodium hydroxide and heated to boiling. The solution was filtered and cooled, and the resulting solid was collected and dried at 70°, mp > 300°. The solid was added to a solution of 20.0 g (0.18 mole) of ethyl bromide and 150 ml of 100% ethanol and heated at reflux for 16 hr. The solution was cooled to give 9.9 g of material which, after recrystallization from 95% ethanol, gave 7.7 g of product, mp 115–117°; NMR ($CDCl_3$): δ 1.47 (9H, s), 1.63 (3H, t, J = 7 Hz), 4.3 (2H, q, J = 7 Hz), and 7.0–7.5 (4H, m).

Anal.—Calc. for $C_{16}H_{18}N_2O$: C, 75.56; H, 7.13; N, 11.02. Found: C, 75.63; H, 7.24; N, 10.93.

*1-Ethyl-3,4-diphenyl-4-hydroxyindeno[1,2-c]pyrazole (II*a*)*—To 0.96 g (0.04 g-atom) of magnesium in 40 ml of previously distilled tetrahydrofuran was added dropwise 6.28 g (0.04 mole) of bromobenzene in 140 ml of tetrahydrofuran. The reaction was initiated by heating at 70° and stirring under a nitrogen atmosphere. Once the reaction started, addition was at such a rate so as to maintain a gentle reflux. To the Grignard product was added 5.48 g (0.02 mole) of IV (R_1 = C_6H_5) (1) in 80 ml of tetrahydrofuran. The addition took 1.5 hr and was followed by 2 hr of reflux, entirely under a nitrogen atmosphere.

The solvent was removed by distillation, and the residue was added to 200 ml of ice water and allowed to stand overnight. The solid was collected by filtration, dried, and chromatographed on 600 g of silica gel, using methylene chloride as the eluting solvent. The solid coming off the column was recrystallized with ethyl acetate to yield 4.3 g (61%), mp 217–218.5°; NMR ($CDCl_3$–dimethyl sulfoxide-d_6): δ 1.60 (3H, t, J = 7 Hz), 3.07 (1H, b, OH), 4.42 (2H, q, J = 7 Hz), and 6.9–7.8 (14H, m).

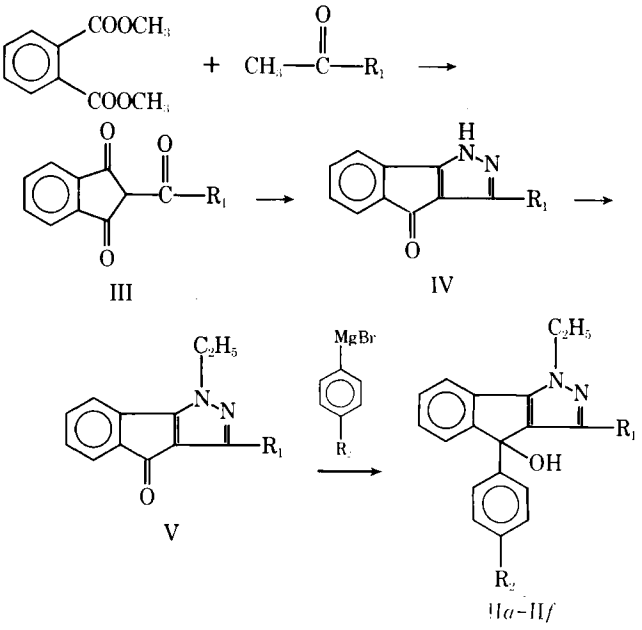

Scheme I

[1] Since this manuscript was submitted, several reports on the chemistry and structure–activity relationship have appeared: P. Aeberli, P. Eden, J. H. Gogerty, W. J. Houlihan, and C. Penberthy, *J. Med. Chem.*, **18**, 177(1975); *ibid.*, **18**, 182(1975); and S. Barcza and W. J. Houlihan, *J. Pharm. Sci.*, **64**, 829(1975).

[2] Melting points were determined with a Thomas-Hoover Unimelt melting-point apparatus and are uncorrected. Chromatography was done on Brinkmann silica gel 60, particle size 0.063–0.2 mm. All products were submitted for NMR analysis on a Varian Associates T-60 or EM-360 and for IR analysis on a Perkin-Elmer 700 spectrophotometer and were consistent with proposed structures. Microanalyses were performed by Atlantic Microlab, Inc., Atlanta, Ga.

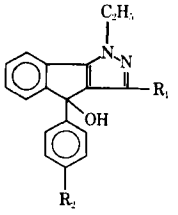

Table I—Acute LD_{50}[a], ED_{50}[b], and Safety Indexes of Mazindol Analogs in Mice

Compound	R_1	R_2	LD_{50}, mg/kg ip	ED_{50}, mg/kg ip	Safety Index, LD_{50}/ED_{50}
IIa	C_6H_5	H	>1000	115	>8.7

IIf	$C(CH_3)_3$	CH_3	485.0	42.5	11.4

[a] The 72-hr LD_{50}. [b] Calculated from Table IV.

1-Ethyl-3-phenyl-4-(p-chlorophenyl)-4-hydroxyindeno[1,2-c]-pyrazole (IIb)—When the same procedure and molar quantities were used as for IIa, 4 g of product was recovered. The solid was chromatographed using chloroform as the eluting solvent to remove the impurity and 5% methanol–chloroform to remove the product. Recrystallization of the product from isopropyl alcohol gave 2.5 g (IIb), mp 230–233°; NMR (dimethyl sulfoxide-d_6): δ 1.57 (3H, t, J = 7 Hz), 4.5 (2H, q, J = 7 Hz), 6.57 (1H, s, OH), and 7.2–8.0 (13H, m).

Anal.—Calc. for $C_{24}H_{19}ClN_2O$: C, 74.51; H, 4.95; Cl, 9.15; N, 7.24. Found: C, 74.36; H, 5.02; Cl, 9.26; N, 7.15.

1-Ethyl-3-phenyl-4-(p-tolyl)-4- hydroxyindeno[1,2-c]pyrazole (IIc)—When the same procedure and molar quantities were used as for IIa, 6.0 g of material was isolated. This material was chromatographed using methylene chloride as the eluting solvent. The product was recrystallized from ethyl acetate to give 4.0 g (IIc), mp 220.5–222.5°; NMR ($CDCl_3$): δ 1.85 (3H, t, J = 7 Hz), 2.22 (3H, s), 3.3 (1H, b, OH), 4.18 (2H, q, J = 7 Hz), and 6.8–7.8 (13H, m).

Anal.—Calc. for $C_{25}H_{22}N_2O$: C, 81.93; H, 6.05; N, 7.65. Found: C, 81.90; H, 6.08; N, 7.63.

1-Ethyl-3-tert-butyl-4-phenyl-4-hydroxyindeno[1,2-c]pyrazole (IId)—The same procedure and molar quantities were used as for IIa, and the concentrated reaction mixture was added to ice water and extracted with ether. The combined ether extract was dried over anhydrous magnesium sulfate. Removal of the solvent followed by chromatography on 600 g of silica gel, using 5% methanol–chloroform as the eluting solvent, resulted in recovery of the product. This product was recrystallized from cyclohexane, mp 142–144°; NMR ($CDCl_3$): δ 1.1 (9H, s), 1.53 (3H, t, J = 7 Hz), 2.43 (1H, b, OH), 4.37 (2H, q, J = 7 Hz), and 7.0–7.5 (9H, m).

Anal.—Calc. for $C_{22}H_{24}N_2O$: C, 79.48; H, 7.28; N, 8.43. Found: C, 79.41; H, 7.29; N, 8.37.

1-Ethyl-3-tert-butyl-4-(p-chlorophenyl)-4-hydroxyindeno[1,2-c]pyrazole (IIe)—When the same procedure and molar quantities were used as for IIa and the ether extraction was performed as for IId, a solid was recovered. This solid was chromatographed using chloroform as the eluting solvent. Recrystallization from cyclohexane gave 3.1 g of IIe, mp 143–148°; NMR ($CDCl_3$): δ 1.07 (9H,s), 1.47 (3H, t, J = 7 Hz), 3.12 (1H, s, OH), 4.27 (2H, q, J = 7 Hz), and 6.9–7.4 (8H, m).

Pharmacology—Ascites survival studies were performed on male Swiss albino mice, which were implanted intraperitoneally with 4×10^6 Ehrlich ascites cells. Drug treatment was started 24 hr after implantation and injections were given intraperitoneally once daily for 9 days. Drugs were suspended in 0.5% carboxymethylcellulose–saline.

Male Swiss-Webster mice[3], 20–25 g, were used for forced and spontaneous motor activity tests after being acclimated to laboratory conditions for 3–4 days. Each dose was usually tested in six mice, which were permitted food and water *ad libitum*. The six compounds were suspended in 5% polysorbate 80–95% isotonic saline and administered in doses of 10 ml/kg ip. The injection time was 15 sec. The results that differed from control values at the $p < 0.05$ level (Student t-test) were considered statistically significant.

Method—The acute 72-hr intraperitoneal lethal dose effects were determined in mice using three dose levels, and the LD_{50} was estimated using the method of Litchfield and Wilcoxon (6).

Forced and Spontaneous Motor Activity—The effects of the compounds on forced motor activity of mice were studied using the rotarod. The wood rod rotated at 4 rpm for the first 30 sec, at 6 rpm during the next 30 sec, and at progressively increasing speeds thereafter at 30-sec intervals (maximum 50 rpm) until the mouse fell off. Six animals were tested simultaneously and were given four trials with two spaced 4–6 hr apart on each of 2 consecutive days. The fourth trial was preceded by an interval of 50 min for the administration of vehicle or one selected dose of the experimental compounds. The drug or placebo effect for each animal was computed on a ratio of performance time on the fourth trial divided by performance time on the third trial.

The effects of the compounds on the spontaneous motor activity in mice were measured in three photocell cages[4]. Two animals treated with identical doses of the same compound were placed in each photocell cage 10 min after the initiation of the rotarod test, and a 15-min count was initiated 5 min after the animals were placed in the cages. To negate the differences in sensitivity among

[a] $p < 0.05$.

units, each dose was tested in a factorial design in each of the three activity cages. Control animals were tested simultaneously at the same time intervals after administration of an equal volume of vehicle, and the ED_{50} of each compound (defined as the dose that decreased the level of performance to 50% of the control scores) was calculated (6).

The percent of control activity (spontaneous and forced motor activity) at each dose level of the compounds used was plotted in an attempt to evaluate the possible types of activity of each compound.

RESULTS AND DISCUSSION

The products synthesized and investigated are shown in Table I along with their LD_{50}, ED_{50}, and safety index values. Derivatives

of 1-ethyl-3-phenyl-4-aryl-4-hydroxyindeno[1,2-c]pyrazoles (IIa–IIc) are relatively nontoxic, while the compounds in which a tertiary butyl group has been substituted for the 3-phenyl group are toxic in mice. All compounds, with the exception of IIe, are less toxic than mazindol (LD_{50} 106 mg/kg po).

For all compounds, death was a result of respiratory stimulation and clonic convulsions. Due to a strong interest in potential anticancer agents and, especially, agents possessing the hydrazino moiety (7) such as that found in the pyrazole ring, several of the more toxic agents were submitted to an Ehrlich ascites tumor screen. The results of this preliminary evaluation are shown in Table II.

The compounds were next tested in mice for their effects on forced and spontaneous motor activity, and the results are presented in Tables III and IV, respectively, and in Figs. 1 and 2. Gogerty *et al.* (3) reported that mazindol produced moderate to marked CNS stimulation, appetite suppression, and antidepressant activity in both mice and rats. In studies with the derivatives of mazindol, just the opposite effects were noted, with impressive decreases in spontaneous and forced motor activity. The 1-ethyl-3-*tert*-butyl-4-aryl-4-hydroxyindeno[1,2-*c*]pyrazoles (II*d* and II*e*) were the most potent compounds in reducing both forced and spontaneous motor activity. However, these agents were the more toxic derivatives and for IIe the highest dose used was about 50% of the LD_{50}; the effects may, therefore, be due to a toxic effect. The 1-ethyl-3-phenyl-4-aryl-4-hydroxyindeno[1,2-*c*]pyrazoles (II*a*–IIc) showed a slight decrease in spontaneous and forced motor activity. In two cases (II*a* and II*b*), this decrease was followed by an upward trend in motor activity at higher doses. Perhaps this effect would show an increase at higher doses but the studies were not carried that far.

The antidepressant drugs like imipramine and desipramine when administered in doses of 40 and 60 mg/kg ip to untreated mice, led to ptosis, a decrease in body temperature, and a decrease in both forced and spontaneous motor activity. It is only possible to discover their antidepressant effects by doing a more detailed study of each compound using a battery of tests, including the effects of each compound in reversing the effect of reserpine in mice and rats.

Effect of Self-Association on Rate of Penicillin G Degradation in Concentrated Aqueous Solutions

JOHN T. H. ONG [*] and HARRY B. KOSTENBAUDER [x]

Abstract □ The apparent rate of degradation of penicillin G potassium micellar solutions of 500,000 units/ml, a concentration commonly encountered in vials reconstituted for storage in the refrigerator, was investigated and compared to that of nonmicellar solutions of 8000 units/ml at 25°, ionic strength of 1.1 *M*, and pH range from 5.0 to 9.5. In the micellar solutions the apparent rate of the H^+-catalyzed degradation was increased twofold but that of water- and OH^--catalyzed hydrolysis was decreased two- to threefold. Consequently, the pH–rate profile of the micellar solutions was shifted to higher pH values and the pH of minimum degradation was found to be at 7.0 compared to 6.5 for the nonmicellar solution of the same ionic strength. Compared at their respective pH–rate profile minima, micellar penicillin G is 2.5 times as stable as the nonmicellar solution under the conditions of constant pH and ionic strength.

Keyphrases □ Penicillin G potassium degradation—concentrated aqueous micellar solutions compared to nonmicellar solutions, pH–rate profiles □ Degradation of penicillin G potassium—concentrated micellar aqueous solutions compared to nonmicellar solutions, pH–rate profiles □ Micellar solutions of penicillin G—degradation compared to nonmicellar solutions, pH–rate profiles

The kinetics of penicillin G degradation in aqueous solution have been studied extensively. The effects of pH, temperature, buffers, ionic strength, metal ions, and model catalysts that simulate penicillinase and other enzymes have been investigated (1–6). The effect of surfactants below and above their critical micelle concentration (CMC) was also studied, with the finding that at pH 6.5 all surfactants studied enhanced the rate of penicillin G degradation (7).

The present study was undertaken to assess the kinetics of penicillin G degradation at concentrations above the CMC, particularly at 500,000 units/ml as encountered in hospital usage, and to obtain a comparison of the pH of minimum degradation for solutions above and below the CMC. Instead of buffer, the pH-stat technique was utilized to maintain a constant pH in these studies. The dilution obtained in all studies was negligible due to the very high concentration of titrant (15 *M* KOH) used.

BACKGROUND

In the earlier studies (1–7), relatively low concentrations of penicillin G were used (8000 units/ml or 0.5% w/v). Literature pertaining to the kinetics of penicillin G degradation at high concentration is limited to observations of the percent degraded after a certain time under specific conditions. Although several results tend to indicate that penicillin G degrades faster at higher concentration, no definitive comparison between the degradation rates at the high and low concentrations can be made because the solutions studied were either unbuffered (8, 9) or inadequately and not proportionally buffered (10, 11). Inadequate buffering of concentrated solutions of penicillin G could give an inordinately large apparent rate of degradation due to a marked pH decrease from the production of large quantities of penicilloic acid.

It has been common practice, particularly in hospitals, to batch-reconstitute buffered penicillin G solutions at a concentration of 500,000 units/ml (30% w/v) and store them frozen until needed. Periodically, the frozen solutions are moved into the refrigerator and kept in a liquid state ready to be diluted with intravenous infusion fluid and administered to patients. According to the manufacturer, sterile solutions in the refrigerator may be kept for 1 week without significant loss of potency. Knowledge of the pH of minimum degradation at this high concentration becomes essential.

The formation of micelles of penicillin G in aqueous solution was first observed by Hauser *et al.* (12). Later studies (13, 14) found the CMC to be relatively high, *i.e.*, 0.25 molal, 130,000 units/ml, or 8.26% (w/v). This value was further confirmed using the data of the NMR (100 MHz) chemical shift of the aromatic protons (15). It was indicated that the number of penicillin G ions that come together to form the aggregates is probably not very large.

In recent years, reactions in micellar systems have been increasingly investigated. Extensive reviews of the kinetic and mechanistic implications of micellar catalysis have been presented (16, 17). From the drug product stability point of view, micellization is important because it can either increase or decrease the stability of a drug, depending on the nature of the micelle and the reaction involved. Thus, catalytic effects of micelles have been observed when both reactants are enriched within the micelles for a bimolecular process. A study (18) of the accelerated fading of cationic triphenylmethane dyes in alkaline solutions of the quaternary surfactant cetyltrimethylammonium bromide has become classic. The micelle itself can serve as a substrate for the reaction, *e.g.*, micellization enhances the rate of H^+-catalyzed hydrolysis of sodium lauryl sulfate by 30-fold over that in a single ion state (19). Conversely,

The formation of micelles of penicillin G in aqueous solution was first observed by Hauser *et al.* (12). Later studies (13, 14) found the CMC to be relatively high, *i.e.*, 0.25 molal, 130,000 units/ml, or 8.26% (w/v). This value was further confirmed using the data of the NMR (100 MHz) chemical shift of the aromatic protons (15). It was indicated that the number of penicillin G ions that come together to form the aggregates is probably not very large.

In recent years, reactions in micellar systems have been increasingly investigated. Extensive reviews of the kinetic and mechanistic implications of micellar catalysis have been presented (16, 17). From the drug product stability point of view, micellization is important because it can either increase or decrease the stability of a drug, depending on the nature of the micelle and the reaction involved. Thus, catalytic effects of micelles have been observed when both reactants are enriched within the micelles for a bimolecular process. A study (18) of the accelerated fading of cationic triphenylmethane dyes in alkaline solutions of the quaternary surfactant cetyltrimethylammonium bromide has become classic. The micelle itself can serve as a substrate for the reaction, *e.g.*, micellization enhances the rate of H^+-catalyzed hydrolysis of sodium lauryl sulfate by 30-fold over that in a single ion state (19). Conversely,

when one reactant is enriched and the other reactant is excluded from the micelle, a rate decrease in the micellar phase is observed. Thus, sodium lauryl sulfate has been shown to inhibit the OH^--catalyzed hydrolysis of benzocaine (20).

EXPERIMENTAL

Materials—Penicillin G potassium, 1595 units/mg[1], was used. All reagents were of analytical grade. Imidazole[2] was recrystallized twice from benzene and washed with anhydrous ether. Double-distilled water[3] was used in all studies.

Analytical Method—The intact penicillin G concentration was determined according to a spectrophotometric[4] method (21). Molar absorptivity at 325 nm, determined from the standard curve, was 26.3×10^3 which is in excellent agreement with that previously reported (21).

Kinetic Studies—The pH of the penicillin G potassium solution was maintained constant at the desired value with the aid of pH-stat[5]. A 50-ml reaction vessel (V520) was immersed in the thermostated jacket (V525), through which water of 25° was circulated from a constant-temperature bath and circulator[6] (sensitivity ±0.1°). Inserted into the reaction vessel was a glass electrode (G 202C), a saturated calomel reference electrode (K 401), a stirrer, and a delivery tube for titrant (15 *M* KOH). The proportional band of the titrator was set to provide small incremental additions of titrant.

Penicillin G potassium solutions above the CMC were prepared at a concentration of 30% (w/v) in solutions of 0.3 *M* potassium chloride so that the final solutions had an ionic strength of 1.1 *M*. At selected time intervals, 40 μl of sample was withdrawn with a microsyringe[7] and diluted with water to 100 ml in a volumetric flask. Two 1-ml samples of the diluted solution were then pipetted into two separate 10-ml test tubes, and each was assayed separately according to the method described by Bundgaard and Ilver (21).

Solutions of penicillin G potassium below the CMC were prepared at a concentration of 0.5% (w/v) in solutions of 1.1 *M* potassium chloride. The same procedure was followed, except that 1 ml of sample was withdrawn and diluted with water to 50 ml in a volumetric flask.

In both micellar and nonmicellar solutions, the initial rate was determined by following 5–10% of the entire course of the reactions. The observed pseudo-first-order rate constants were then calculated by linear regression analysis of a plot of the logarithm of penicillin G concentration against time.

RESULTS AND DISCUSSION

The concentration of micellar penicillin G used was very high (500,000 units/ml, 0.8 *M*, or 30% w/v). It would not be possible to keep the pH constant using buffer systems, because a very high buffer capacity would be required. Many buffer systems are known to have marked catalytic effects so that a high buffer concentration is not desirable. Although citrate buffer has little catalytic effect at neutral pH (3), the buffer capacity is quite low under these conditions. Large citrate concentrations increase the ionic strength of the solution, which, in turn, enhances the rate of the OH^--catalyzed reaction (3) as well as that at the pH of minimum degradation. Therefore, the concentration of citrate buffer found in commercial products is limited to 1.5% (w/v). The present study was conducted at a constant ionic strength of 1.1 *M* to take into account the contributions of 30% penicillin G potassium and 1.5% citrate buffer. The change in ionic strength due to counterion binding to the penicillin G micelle was assumed to be negligible for these apparently small aggregates.

The results of kinetic studies in nonmicellar and micellar solutions of penicillin G are recorded in Table I. The rates at pH 5 and 5.5 were increased and those at pH 8.5 and 9.0 were decreased twofold in micellar systems relative to nonmicellar solutions.

Penicillin G is an acid with a pKa of 2.80. The degradation is known to be first order with respect to penicillin G and is catalyzed by acid and base. The pH–rate profile is linear in the pH region of 4–6 and above 8 and has a minimum at pH 6.50–6.75. Above pH 5, penicillin G exists mostly in the anionic form. In the pH region investigated, the principal reactions in both nonmicellar and micellar states are attacks of H^+, water, and OH^- on penicillin G anion. It is also conceivable that in the micelle the molecules could be aligned to facilitate intramolecular or intermolecular attack on the β-lactam carbonyl carbon by the amide carbonyl oxygen (22). The acid-catalyzed reaction of undissociated penicillin G was not significant under the study conditions.

According to Thakkar and Wilham (15), penicillin G ions aggregate primarily by hydrophobic interactions involving the benzyl side chains. The ionized carboxylate groups on the thiazolidine ring form the periphery of the micelle in intimate contact with the surrounding water. Therefore, the micelles formed are of the anionic type. The greater negative charge density of the micelles would exert stronger electrostatic attraction toward hydrogen and sodium ions to be bound as counterions. This would facilitate isomerization to penicillenic acid, since it is known that the formation of penicillenic acid is a result of the reaction of penicillin G ion with hydrogen ions or the kinetically equivalent spontaneous rearrangement of undissociated penicillin (3, 23).

The association between penicillin G ion and hydrogen ions to form the reactive species, undissociated penicillin G, might also be favored by a larger positive entropy change for the micellar reaction. This can be explained in terms of hydration and electrostatic entropy changes. In terms of hydration of ions, the explanation of the entropy factor is that the two oppositely charged ions coming together to form a neutral molecule become partially dehydrated and cause breakdown of the "iceberg" structure of coordinated water molecules around the ions, leading to a decreased orientation of solvent molecules or an increase of entropy (24). The larger charge density of the micelle causes the formation of a more ordered structure, consisting of water molecules and counterions about its outer, polar surface. Thus, there would be a greater overall change in randomness in micellar systems, since the number of electrostatically bound water molecules released in the formation of neutral undissociated penicillin G would be greater for the micelle state than for the single ion state.

In terms of electrostatic theory, the entropy change resulting solely from bringing two ions from infinite separation to the equilibrium distance r is given by (25):

$$\Delta S_{el} = \frac{Z_A Z_B e^2}{Dr}\left(\frac{\partial \ln D}{\partial T}\right)_p \qquad \text{(Eq. 1)}$$

where Z_A and Z_B are the charges of the two reacting ions, and D is the dielectric constant of the medium. The quantity $(\partial \ln D/\partial T)$ is always negative, because thermal motion overcomes the orienta-

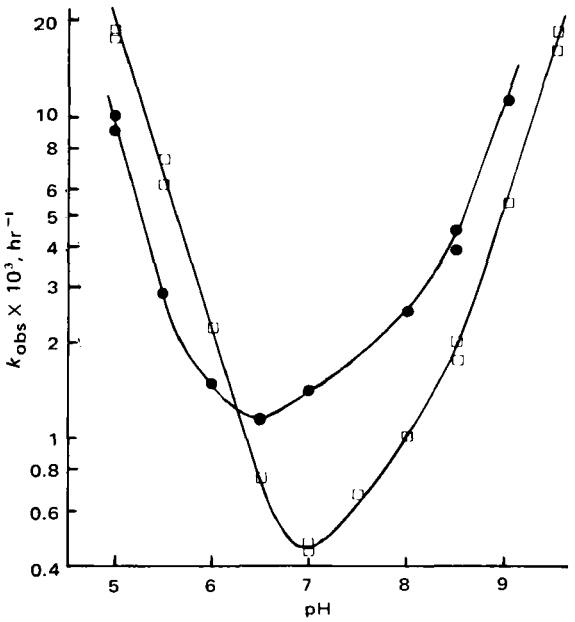

Figure 1—*The pH–rate profiles of penicillin G in 0.5% (w/v) nonmicellar (●) and 30% (w/v) micellar (□) concentrations.*

tion of dipoles in an electric field (26). Thus, for a reaction of oppositely charged penicillin and hydrogen ions, ΔS_{el} has a positive value and is inversely proportional to the dielectric constant of the medium. The surface of micelles appears to be less polar than water itself (27). In the present micellar system, the carboxylate group of the penicillin G ion might be regarded as being attached to a region of lower dielectric constant than water in the bulk of the solution; therefore, ΔS_{el} is larger and more positive than in nonmicellar solution.

At pH around and above neutrality, the main degradation is the water- and OH^--catalyzed hydrolysis of the β-lactam ring to form penicilloic acid. The micellar state somewhat protects the β-lactam ring from nucleophilic attack, because it is located farther inside the micelle surface. Furthermore, the OH^- is excluded from the anionic micelle by electrostatic repulsion. In contrast with the H^+-catalyzed degradation, the OH^- attack on the negatively charged penicillin G ion is not favored by entropy change. The transition state is a more highly charged ion which would be expected to be strongly hydrated, leading to a decrease of entropy. The electrostatic entropy change becomes more negative in the micellar phase than in the bulk of the solution. These unfavorable factors lead to a decrease of rate in the micellar system at pH around and above neutrality.

Figure 1 shows the pH–rate profiles of penicillin G in nonmicellar and micellar concentrations of 0.5 and 30% (w/v), respectively. The profile of micellar penicillin G was shifted to higher pH values. The pH of minimum degradation was obtained at 7.0 for micellar and 6.5 for nonmicellar penicillin G. The present results clearly indicate that micellar solutions of penicillin G degrade slower than nonmicellar solutions above pH 6.25, provided the pH of the solution is held constant. Under the conditions of the previous studies where the penicillin G solutions were either unbuffered (8, 9) or inadequately and not proportionally buffered (10, 11), the faster degradation rate observed at higher concentration can be attributed to a faster decrease of the pH of the solution since penicillin G itself has no buffering activity. The decrease in pH renders the H^+-catalyzed reaction more significant, leading to a faster degradation rate.

Based on the present results, micellar solutions of penicillin G are most stable if they are buffered at pH 7.0, although solutions of concentration less than the CMC (130,000 units/ml or 8.26% w/v) are most stable at pH 6.5. Micellar solutions buffered at pH 7.0 are approximately 2.5-fold more stable than nonmicellar solutions buffered at the pH of the minimum hydrolysis rate.

Nonisothermal Kinetic Studies III: Rapid Nonisothermal–Isothermal Method for Stability Prediction

M. A. ZOGLIO ×, H. V. MAULDING *, W. H. STRENG, and W. C. VINCEK ‡

Abstract □ A continuous nonisothermal–isothermal method for stability prediction was developed. The approach yields all necessary parameters for prediction, including reaction order. The experimental procedure involves changing the temperature of the samples being studied until degradation is rapid enough to proceed at a convenient isothermal rate for a sufficient number of half-lives with adequate analytical sensitivity so that the reaction order can be unambiguously determined. The analytical information obtained during the nonisothermal and isothermal portions of the experiment is utilized without curve matching in calculating the activation energy and determining the reaction order, reaction rate, and stability prediction at any desired temperature. Model experiments include the acid-catalyzed hydrolysis of acetylcholine bromide and the inversion of sucrose.

Keyphrases □ Nonisothermal kinetic studies—rapid nonisothermal–isothermal method for stability prediction □ Kinetics—rapid nonisothermal–isothermal method for stability prediction □ Stability prediction—rapid nonisothermal–isothermal kinetic method

Since the primary contribution to the field of nonisothermal kinetics by Borchardt and Daniels (1) in 1957, publications on this subject have appeared at a steady rate (2–8). When compared to isothermal methods, nonisothermal technology generally reduces the time and analytical effort needed to generate kinetic parameters. Although there are limitations (9) to the methods, these are being dealt with wherever possible (8).

Classical isothermal kinetics are often too burdensome to incorporate into predosage form development studies. A need exists for alternative short-term methodology so that the kinetic parameters needed for a knowledge of drug stability are known early in the preformulation phase. The nonisothermal methodology published to date has been subject to limitations (6, 7) of fixed time–temperature relationships, nonlinear curve fitting, and assumptions of reaction order. The method presented offers flexibility of time–temperature relationships, direct calculation of activation energy, and determination of reaction order.

In the proposed method, the investigator searches (through temperature adjustment and analytical determinations) for a temperature to run an isothermal experiment. Whereas this problem would normally be considered a screening study, it has been developed into a total experiment by mathematical treatment of data from the initial probing and subsequent isothermal rate determination.

THEORETICAL

A general method was developed which results in values for the reaction order, activation energy, and reaction rates from a single experiment without time–temperature restrictions or curve matching (5, 6). A time–temperature profile (Fig. 1) is obtained when using this technique, and it consists of two distinct parts: (*a*) a nonisothermal region from t_a to t_b, for which temperature can be any function of time, and (*b*) an isothermal region from t_b to t_c.

The concentration–time profile for the acid-catalyzed hydrolysis of acetylcholine bromide is shown in Fig. 2. The concentration function used is determined by the isothermal part. A function of concentration, $f(c)$, can be chosen that is linear under the isothermal conditions existing from t_b to t_c to describe a concentration, c, at time t when $c = c_b$ at $t = t_b$ (Eq. 1):

$$-[f(c) - f(c_b)] = k_f(t - t_b) \qquad \text{(Eq. 1)}$$

The $f(c) - f(c_b)$ is $c - c_b$ for a zero-order reaction [$f(c) = c$], is 2.303 log c/c_b for a first-order reaction [$f(c) = 2.303 \log c$], and is $1/c_b - 1/c$ for a second-order reaction [$f(c) = 1/c$]. The chosen function must hold for a reaction of a given order at all other temperatures. When the function of concentration, $f(c)$, which is linear against time under isothermal conditions, is plotted against time for the nonisothermal period from times t_a to t_b, it can be considered as a series of sequential isothermal reactions. Although it is relatively easy to describe the change in concentration from t_b to t_c, it is not easy to do so for t_a to t_b where the temperature is changing.

The approach used to resolve this problem is to divide this portion of the curve into a large number of equal segments. If these segments are "short enough," then the concentration function from t_a to t_b can be considered as a series of independent rates, each with its own rate constants (5, 6):

$$-\frac{f_b(c) - f_a(c)}{t_b - t_a} = \frac{k_1 + k_2 + k_3 \ldots k_i \ldots k_n}{n} = \bar{k}_n \qquad \text{(Eq. 2)}$$

According to this equation, the change in the concentration function with time equals the sum of the individual rate constants divided by the total number of constants. This result will equal the average rate constant. The relationship between the rate constant and activation energy, where a^* is the frequency factor, is:

$$k_i = a^* e^{-E_a/RT_i} \qquad \text{(Eq. 3)}$$

These equations can be combined to give Eq. 4, where Δt is the time interval of each short segment:

$$-\frac{f_b(c) - f_a(c)}{n\,\Delta t} = \frac{a^*}{n}\sum_{i=0}^{n-1} e^{-E_a/RT_i} = \bar{k}_n \qquad \text{(Eq. 4)}$$

Replacing the temperature in Eq. 4 by its corresponding time function gives Eq. 5, in which $G(t_i)$ is the time function:

$$\frac{a^*}{n}\sum_{i=0}^{n-1} e^{-E_a/RG(t_i)} = \bar{k}_n = -\frac{f_b(c) - f_a(c)}{n\,\Delta t} \qquad \text{(Eq. 5)}$$

It remains to be determined how large n must be to define the nonisothermal curve. This is accomplished by utilizing the relationship given in Eq. 6:

$$\lim_{n\to\infty}\left[1 + \sum_{i=2}^{n} e^{(E_a/R)(T_i - T_1)/(T_i T_1)}\right]/n = L \qquad \text{(Eq. 6)}$$

The origin of this relationship was described previously (6). It can be shown that the value of this expression approaches a constant value for a specific activation energy as n becomes larger. Therefore, by evaluating the expression for increasing values of n, a

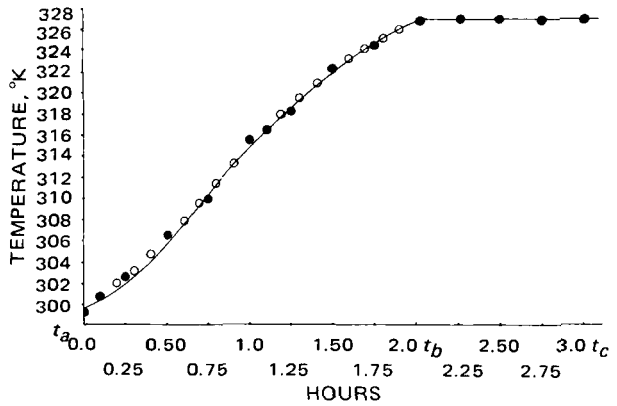

Figure 1—*Time-temperature relationship for the acid-catalyzed hydrolysis of acetylcholine bromide. Key:* O, *mathematical fit; and* ●, *experimental points.*

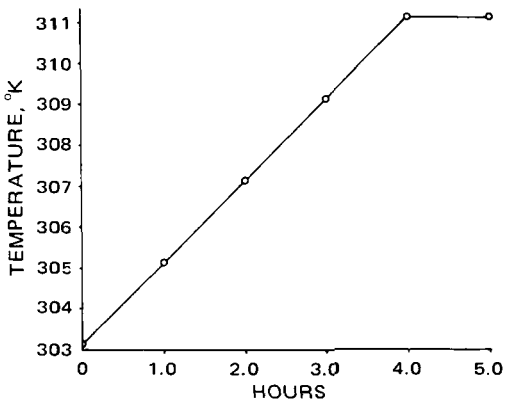

Figure 3—*Time-temperature relationship for the acid-catalyzed inversion of sucrose.*

value of n can be chosen that results in a constant not significantly different from the preceding one.

Finally, an expression can be derived that relates the activation energy to the average rate constant over the nonisothermal region, the rate constant for the isothermal region (k_j), and the length of time of each short segment:

$$-\frac{n[f_b(c) - f_a(c)]}{(t_b - t_a)k_j} = \frac{n\bar{k}_n}{\Delta t k_j} = \sum_{i=0}^{n-1} \exp\left[\frac{E_a}{R}\left(\frac{T_i - T_j}{T_i T_j}\right)\right] = C \quad \text{(Eq. 7)}$$

Making a series expansion of the exponentials results in Eq. 8, in which a, b, c, *etc.*, are the temperature terms and X is E_a/R. This equation can be evaluated by Newton's method to obtain the energy of activation:

$$n + (a + b + c \ldots)X + \frac{(a^2 + b^2 + c^2 \ldots)}{2!}X^2 + \frac{(a^3 + b^3 + c^3 \ldots)}{3!}X^3 + \ldots = C \quad \text{(Eq. 8)}$$

EXPERIMENTAL

Acetylcholine Bromide—A solution of 25 g of acetylcholine bromide (recrystallized from absolute ethanol) in 500 ml of 0.1 *N* HCl was prepared, and 20-ml aliquots were pipetted into 50-ml ampuls which were heat sealed. These ampuls were immersed in a water bath fitted with a thermoregulator[1] and thermometer (0.1° graduations). The thermometer was immersed in an unsealed ampul containing the acetylcholine bromide solution, and the temperature of this solution was allowed to equilibrate before the nonisothermal run was begun. An initial sample was taken, and the nonisothermal run was begun by hand manipulation of the thermoregulator at an appropriate rate of temperature increase. Samples were taken for analysis at convenient times, and the temperature was continuously recorded.

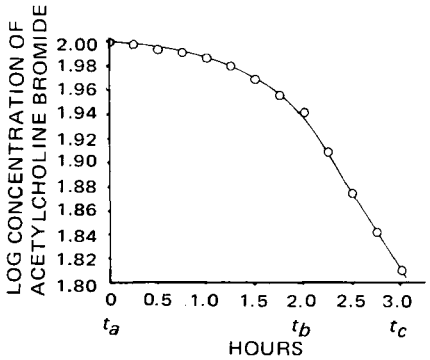

Figure 2—*Log concentration* versus *time relationship for the nonisothermal–isothermal hydrolysis of acetylcholine bromide.*

For analysis, the ampuls were quickly cooled under ice water. Five milliliters of solution was pipetted into a 250-ml erlenmeyer flask containing 50 ml of ice water, and the flask was immersed in ice water. A titration with 0.05 *N* NaOH (three titrations per sample) was performed, using phenolphthalein as the indicator. Correction was made for the initial hydrochloric acid content of the solution, with the remainder of sodium hydroxide consumed being proportional to the amount of acetic acid present. The moles (average of the three titrations) of acetic acid present were subtracted from the acetylcholine bromide initially in solution and used in the first-order calculations.

Sucrose—A 40% (w/v) sucrose solution in distilled water (400 ml) was thoroughly mixed with 0.05 *N* HCl (200 ml) in a 1-liter erlenmeyer flask. The flask was then immersed in a water bath fitted with a thermoregulator[1] and thermometer (0.1° graduations). This mixture was constantly stirred with a magnetic stirrer to prevent a temperature gradient. Sufficient time was allowed for equilibration of the temperature in the reaction solution before the nonisothermal run was begun. Following temperature equilibration, an initial sample was taken and the thermoregulator was fitted with a 2-rpm motor, which increased the temperature of the water bath by 2°/hr. The samples were removed for analysis every 15 min while the temperature was continuously recorded.

For analysis, aliquots (30 ml) were pipetted into 100-ml beakers and immediately diluted with 50 ml of 0.1 *N* NaOH. This solution was read on a polarimeter[2], using the sodium D line. Sucrose concentration is directly proportional to $(\alpha_t - \alpha_\infty)$, where α is the optical rotation. The rotation at time infinity, α_∞, is determined by heating a sample at 90° for 2–3 hr, diluting with 0.1 *N* NaOH, and then reading in the usual manner.

RESULTS AND DISCUSSION

The time-temperature relationship for the nonisothermal segment of Fig. 1 for the acid-catalyzed hydrolysis of acetylcholine bromide may be described by Eq. 9:

$$T = 298.5 + 14.743t + 33.742t^2 - 1.8099t^3 \quad \text{(Eq. 9)}$$

This equation was utilized in testing the convergence of Eq. 6 in order to determine the value of n to be used in Eq. 8. Table I shows that a value for n of 200 is adequate to describe the nonisothermal portion of the curve in Fig. 2. The criterion used to estimate convergence is a variation of less than 1% in Eq. 6 per change in n of 100. The value of n and Eq. 9 allow calculation of the coefficient terms of Eq. 8. The constant C is evaluated for the total experiment by use of the total nonisothermal concentration loss (2.90×10^{-2} hr^{-1}), the isothermal rate (1.38×10^{-1} hr^{-1}), and the value of n.

[1] A 115-v, 60-cycle thermoregulator, Bronwell Scientific Division, Will Corp., Rochester, N.Y.

[2] Model 70, O. C. Rudolph and Sons, Inc., Caldwell, N.J.

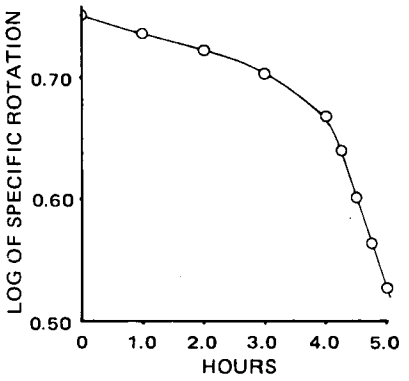

Figure 4—*Log specific rotation* versus *time relationship during a nonisothermal–isothermal acid-catalyzed inversion of sucrose.*

The coefficient terms for Eq. 8 were evaluated for hours 0–2 of the nonisothermal segment, and an equation was formed as follows:

$$157.15 - 0.03668 \times 10^{-1}X + 0.8288 \times 10^{-5}X^2 - 0.2125 \times 10^{-8}X^3 + 0.5867 \times 10^{-12}X^4 - 0.1695 \times 10^{-15}X^5 + 0.5049 \times 10^{-19}X^6 - 0.1537 \times 10^{-22}X^7 = 0 \quad \text{(Eq. 10)}$$

When each set of analytical points was considered and Eq. 8 was revised to include the time segment between these values, the mean activation energy calculated was 17.4 ± 0.9 kcal. The reported value was 17.5 kcal (10). Since the number of analytical points was nine, the number of equations and activation energies considered was $[m!/2(m-2)!]$ or 36 where $m = 9$. The plus or minus value represents 1 *SD* from the mean. For the sucrose experiment (Figs. 3 and 4), the nonisothermal time–temperature relationship is linear and may be expressed by:

$$T = 303.16 + 2t \quad \text{(Eq. 11)}$$

The convergence testing, as shown in Table II, yields a value of $n = 200$. The total loss in drug concentration (Fig. 4) during the nonisothermal portion of the experiment (1.843×10^{-2} hr^{-1}), the isothermal rate (1.539×10^{-1} hr^{-1}), and the value of n are used to calculate a value of 78.24 for C of Eq. 8 for the total experiment. When the coefficient terms of Eq. 8 are calculated, the expression for the total experiment is:

$$78.24 - 0.1278 \times 10^{-1}X + 0.1872 \times 10^{-5}X^2 - 0.2816 \times 10^{-9}X^3 + 0.4343 \times 10^{-13}X^4 - 0.684 \times 10^{-17}X^5 + 0.1097 \times 10^{-20}X^6 - 0.1788 \times 10^{-24}X^7 = 0 \quad \text{(Eq. 12)}$$

Newton's method of solution for this equation yielded a value of 29.2 kcal, which is higher than the literature values of 25.5–27.0 kcal (8). When the five analytical points were used in sets, the 10 resulting equations yielded a mean activation energy of 29.2 kcal (*SD* ± 0.9 kcal). This high value may be due to nonapplicability of the Arrhenius equation over the entire temperature span of the experiment. For each experiment, the linearity of the isothermal segment of Figs. 2 and 4 was assumed to be indicative of reaction order.

The parameters necessary for prediction of stability, that is, activation energy, an isothermal rate, and reaction order were thus obtained from a single continuous experiment. Predictive calculations can easily be made with these parameters by use of the Arrhenius equation and integration of the proper rate equation. It is not necessary to consider all of the mathematically possible sets of nonisothermal analytical values in setting up equations of the type depicted by Eqs. 10 and 12, as was done in this study. Experience in this technique does, however, suggest the use of at least five nonisothermal analytical points and 10 equations to yield 10 activation energies, which then may be considered in determining a mean activation energy.

Table I—Convergence of the Acid-Catalyzed Hydrolysis of Acetylcholine Bromide According to Eq. 6

n	E_a = 10 kcal	E_a = 20 kcal	E_a = 30 kcal
100	2.519	7.361	23.97
200	2.506	7.312	23.76

Table II—Convergence of the Acid-Catalyzed Inversion of Sucrose According to Eq. 6

n	E_a = 10 kcal	E_a = 20 kcal	E_a = 30 kcal
100	1.677	2.981	5.627
200	1.668	2.962	5.584

SUMMARY

This general method for determining activation energy, order of reaction, and rate constants might be very useful for studying reactions that occur slowly at room temperature. The method is subject to limitations imposed by assay precision, the constancy of activation energy, and the applicability of the Arrhenius equation. Equilibrium situations and kinetic salt effects may also present problems in this and other reported nonisothermal methods.

High-Pressure Liquid Chromatographic Analysis of Penicillin G Potassium and Its Degradation Products

JEAN M. BLAHA *§, ADELBERT M. KNEVEL ‡, and STANLEY L. HEM *x

Abstract □ An anion-exchange high-pressure liquid chromatographic system capable of separating penicillin G potassium from five of its degradation products was developed. The retention times were: penicillin G potassium, 17.5 min; DL-penicillamine, 4.5 min; benzylpenilloic acid, 7.0 and 8.0 min; benzylpenamaldic acid, 13.0 min; benzylpenicilloic acid, 19.5 min; and benzylpenillic acid, 22.0 min. In addition, the system permits quantification using linear calibration curves.

Keyphrases □ Penicillin G potassium and degradation products—high-pressure liquid chromatographic analysis □ High-pressure liquid chromatography—analysis, penicillin G potassium and degradation products

It has been suggested that penicillin degradation products may have a role in eliciting penicillin allergy (1). Since most analytical methods are directed at identifying and quantifying intact penicillin, a method of detection, separation, and quantification is needed to determine the presence of specific degradation products. Such a method would also be useful in pharmacokinetic studies.

Penicilloic acids have been separated from their parent penicillins using low-voltage electrophoresis (2), TLC (3), and solvent extraction (4). TLC has also been used to separate penicillin G potassium and four model decomposition products (5).

Recent reviews (6, 7) indicated that high-pressure liquid chromatography (HPLC) could be useful for the separation and quantification of compounds of pharmaceutical interest. Thus far, limited use has been made of HPLC in analyzing penicillins. The separation of the methylbenzyl ester of penicillin G from its impurities was reported (8), where a stationary polyamide phase was used with a hexane–ethanol mobile phase. An anion-exchange column with a pH 9.1 disodium borate buffer as the mobile phase was used to separate penicillin from additives in a penicillin dosage form[1]. The anion-exchange mode also was used to determine the amount of ampicillin contamination of nitrofurantoin preparations (9). The system separated ampicillin from the nitrofurantoin and other unidentified impurities.

An anion-exchange HPLC method for the separation and quantification of penicillin G potassium and five of its decomposition products was developed and is the subject of this report.

EXPERIMENTAL

Materials—All chemicals used were USP or reagent grade.

Penicillin G potassium[2], 1585 units/mg, and DL-penicillamine[3] were obtained commercially.

Benzylpenillic acid was synthesized following a procedure reported by Cook (10). Penicillin G potassium (0.05 *M*) was allowed to stand in a 0.03 *M* citric acid–0.0067 *M* disodium phosphate buffer, pH 2.70, at 25° for 24 hr. The white crystalline precipitate was collected and dried in a stream of air. Its identity was confirmed by potentiometric titration [pKa 3.25 and 7.7; literature (10) pKa 3.2–3.4 and 7.7], elemental analysis[4], IR spectroscopy, and mass spectrometry.

Benzylpenilloic acid was synthesized by a standard method (11, 12). Two grams of penicillin G potassium was placed in a round-bottom flask with 568 ml of water and 56.2 ml of 0.1 *N* hydrochloric acid (molar equivalent) and refluxed for 3 hr. The product was cooled, frozen, lyophilized[5], and recrystallized from methanol. An NMR spectrum of the product in deuterated chloroform gave signals that agree with the structure for benzylpenilloic acid.

Benzylpenamaldic acid was obtained using HPLC. Penicillin G potassium (0.05 *M*) was dissolved in the pH 2.7 citric acid–disodium phosphate buffer and aged at 37° for 2 hr. Ten-microliter samples were withdrawn and injected onto an anion-exchange[6] column in a high-performance liquid chromatograph[7]. The compounds were eluted with a mobile phase of 15.4 ml of 0.1 *M* citric acid and 7.0 ml of 0.2 *M* disodium phosphate diluted to 650 ml with double-distilled water. The fraction of eluent containing the compound with a retention time of 13 min was collected immediately and then lyophilized. The compound was identified as benzylpenamaldic acid based upon its UV spectrum, which possesses a unique ϵ_{max} in methanol at 282.5 nm, its instability to acid, and its partitioning properties (13).

Benzylpenicilloic acid was prepared using a standard synthesis (11). Exactly 70.6 ml of 0.05 *N* sodium hydroxide was added dropwise over 1 hr to a solution of 1.16 g of penicillin G potassium in 10 ml of double-distilled water. The mixture was allowed to stand at room temperature for 1.5 hr and then was brought to pH 5.6 with the addition of 1.25 ml of 0.1 *N* hydrochloric acid. The resulting solution was lyophilized and the product was shown to be benzylpenicilloic acid by a positive reaction to the arsenomolybdic acid–mercuric chloride test (4).

Instrumentation—The liquid chromatograph[7] was equipped with a UV detector operating at 254 nm and a double-beam refractive index detector. The UV detector was used for the quantitative aspects of all compounds. The double-beam refractive index detector, referenced against a cell filled with mobile phase, was used in the preparation of a calibration curve of benzylpenamaldic acid. The recorder was operated at a chart speed of 2.54 cm/5 min.

The stationary phase was an anion-exchange resin prepacked into a 0.61-m (2-ft) stainless steel column, 2.3 mm i.d.[6]. The mobile phase was a citric acid–disodium phosphate buffer prepared from stock solutions of 0.1 *M* citric acid and 0.2 *M* disodium phosphate. All injections were made on stream with a 25-μl high-pressure syringe[8].

The instrument was operated at ambient temperature at a flow

rate of 0.7 ml/min. With a single 0.61-m (2-ft) column, this flow rate was achieved with a pressure of 600–700 psi. When a pair of 0.61-m (2-ft) columns was coupled together, a pressure of 1000–1200 psi was required.

Methods—UV scans were run using a double-beam spectrophotometer[9]. IR[10] spectral samples were prepared as KBr pellets. Mass spectra[11] were obtained at 75 ev. NMR spectra[12] were determined using tetramethylsilane as the internal reference.

The least-squares regression line and standard error of estimate, $S_{y \cdot x}$, calculated using a standard program[13], were used to construct each calibration curve. The standard error of estimate has properties analogous to those of the standard deviation. For example, if lines parallel to the regression line of y on x at respective vertical distances $S_{y \cdot x}$, $2S_{y \cdot x}$, and $3S_{y \cdot x}$ were constructed, there would be included between these lines about 68, 95, and 99.7% of the sample points, respectively.

RESULTS AND DISCUSSION

Development of HPLC Separation System—An assay developed for the separation of penicillin from additives in a penicillin dosage form used an anion-exchange column, with 0.01 *M* disodium borate buffer (pH 9.1) as the mobile phase[1]. The system was the first one investigated for the separation of penicillin degradation products. Intact penicillin G potassium was separated from penicillin degradation products; however, the degradation products were not resolved.

Majors (14) suggested that the pH of the mobile phase for the separation of weakly basic or acidic solutes should be approximately 1.5 pH units above the pKa of the solute. The pKa of penicillin G is 2.76 (12), indicating that a mobile phase having a pH of approximately 4.25 would best achieve separation if the pKa's of the decomposition products were close to that of penicillin G. A 0.135 *M* citric acid–disodium phosphate buffer, which could be adjusted over a pH range of 2.2–7.8 (15), was varied from pH 3.45 to 4.60. Benzylpenicilloic acid, which had been stored at room temperature for 1 year, was used to test the efficiency of the mobile phase. The number of peaks obtained when this sample dissolved in water was injected into the column varied from four to six. The optimum separation was observed when the pH of the mobile phase was 3.58–3.80.

Once the optimum pH for the mobile phase had been established, the length of the column was increased by coupling a pair of 0.61-m (2-ft) columns. The longer column increased the number of peaks obtained from an aged benzylpenilloic acid sample from two to three.

Decreasing the buffer concentration of the mobile phase led to improved separation of the sample peaks. Optimum separation was achieved at pH 3.8 with a 0.0045 *M* mobile phase of a final composition of 15.4 ml of 0.1 *M* citric acid and 7 ml of 0.2 *M* disodium phosphate diluted to 650 ml with double-distilled water. This buffer system was used as the mobile phase with a 1.22-m (4-ft) anion-exchange column for the separations reported. The buffer salts, possibly by displacement of anionic species at the time of sample injection, produced a single peak with a retention time of 4.0 min.

Penicillin G Potassium—Accurately weighed samples of about 2 mg/ml of penicillin G potassium were dissolved in water and injected into the HPLC system. A single peak with a retention time of 17.5 min was eluted. A calibration curve was prepared each day by injecting freshly prepared samples of 1–11 μl and calculating the peak areas by multiplying peak height by the width at half-height. A least-squares linear regression program was used to construct a calibration curve. A typical calibration curve had a slope of 24.6 $mm^2/\mu g$ and an intercept of -2.5 mm^2. The correlation coefficient for the linear region from 2 to 22 μg was 0.999, and the standard error of estimate was 20.9 mm^2.

Benzylpenillic Acid—A similar technique was followed with benzylpenillic acid, except that it was dissolved in 0.05 *M* sodium hydroxide in concentrations ranging from 1 to 2 mg/ml to prepare samples for injection. It was eluted from the column as a single peak with a retention time of 22 min. Linear calibration curves over a range of 1–20 μg were obtained. Benzylpenillic acid is relatively stable in dilute alkali (16), and no chromatographic changes were observed in the freshly prepared samples used to prepare the calibration curves. Values such as 185.2 $mm^2/\mu g$ for the slope and -18.6 mm^2 for the intercept were obtained. The lowest correlation coefficient was 0.982 with a standard error of estimate of 114.4 mm^2.

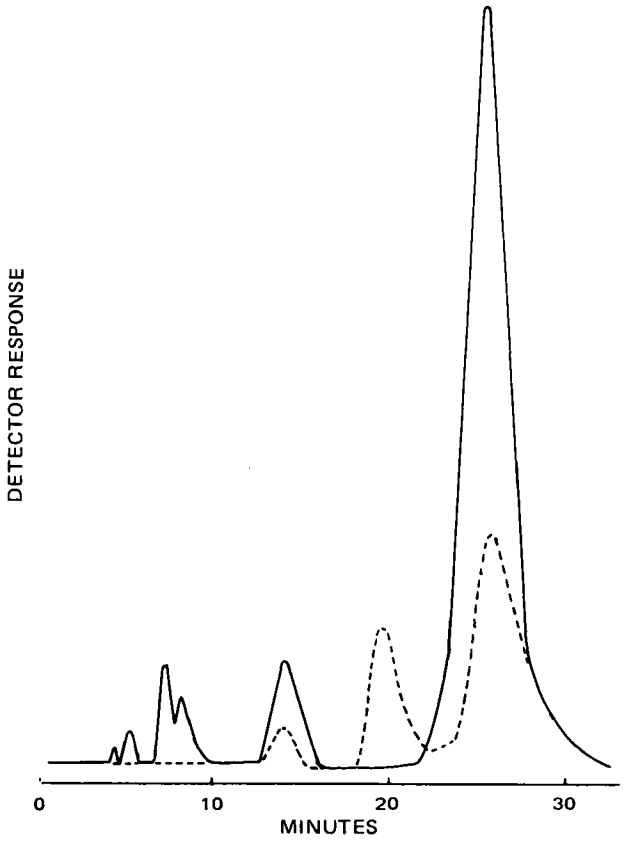

Figure 1—*Liquid chromatogram of a 0.05* M *penicillin G potassium solution aged in a 0.03* M *citric acid–0.0067* M *disodium phosphate buffer, pH 2.7, 37°; UV detector sensitivity, 254 nm; 0.04 auf except 0.08 auf for 31.5-hr benzylpenillic acid peak. Reported retention times are for single-component injections. Key: buffer salts, 4.0 min; penicillamine, 4.5 min; benzylpenilloic acid, 7.0, 8.0 min; benzylpenamaldic acid, 13.0 min; penicillin G potassium, 17.5 min; benzylpenillic acid, 22.0 min; - - - -, aged 7 min at 37°; and —, aged 31.5 hr at 37°.*

Penicillamine—Solutions of DL-penicillamine were prepared in concentrations of 0.49 and 0.90 mg/ml in 0.025 *M* NaOH, and 1–16 μl was injected. A single peak with a retention time of 4.5 min was observed. A linear calibration curve with a slope of 15.8 $mm^2/\mu g$ and an intercept of -12.49 mm^2 was typically obtained. The linear region between 0.9 and 7.8 μg had a correlation coefficient of 0.982. The standard error of estimate was 7.0 mm^2.

Benzylpenamaldic Acid—Benzylpenamaldic acid had a retention time of 13 min. It could not be isolated from the buffer component of the eluent by extraction into acetone, chloroform, octanol, or other organic solvents. Acidification of the eluent caused degradation of benzylpenamaldic acid, as evidenced by the appearance of new peaks when reinjected into the chromatograph.

To construct a calibration curve, the response of the refractive index detector to a blank solution of column eluent, which had been lyophilized and then reconstituted with water, was monitored. The buffer salts produced a single sharp peak 4 min after injection whose height was linear over a range of 50–365 μg of citric acid–disodium phosphate buffer salts. A known weight of the ly-

[9] Cary model 17 spectrophotometer, Cary Instruments, Monrovia, Calif.

[13] CAL 360-STAT-4, Wang Laboratories, Inc., Tewksbury, Mass.

ophilized benzylpenamaldic acid–buffer mixture was also redissolved in double-distilled water, and 3–20 μl was injected.

Since the refractive index response for benzylpenamaldic acid came at a retention time of 13 min, the difference between expected and actual responses for the buffer salts at retention time of 4 min was used to calculate the weight of benzylpenamaldic acid that had been injected to produce the corresponding peak from the UV detector. This information was used to construct a calibration curve of UV spectral peak areas *versus* weight of benzylpenamaldic acid. The detector response was linear over a range of 0.45–5.4 μg of benzylpenamaldic acid. A least-squares regression analysis typically gave a line of slope of 94.5 $mm^2/\mu g$, an intercept of 22 mm^2, a correlation coefficient of 0.9976, and a standard error of estimate of 27.4 mm^2.

Benzylpenilloic Acid—Aqueous solutions of benzylpenilloic acid (0.75–2.1 mg/ml) were injected in volumes ranging from 1 to 23 μl and consistently produced a pair of overlapping peaks of approximately equal size at retention times of 7 and 8 min. Florey *et al.* (12) reported that two isomers of benzylpenilloic acid are obtained from the decarboxylation of benzylpenicilloic acid, possibly accounting for the pair of peaks on the chromatograph. Because of the overlapping peaks, the total peak area of the double peak was determined using a planimeter. Linear calibration curves in the 5–27-μg range typically had a slope of 0.0021 planimeter unit/μg, an intercept of −0.0024 planimeter unit, and a correlation coefficient of 0.9950. The standard error of estimate was 0.0021 planimeter unit.

Benzylpenicilloic Acid—Benzylpenicilloic acid was eluted from the column with a retention time of 19.5 min.

CONCLUSIONS

The HPLC system is expected to have great utility in kinetic studies to monitor the occurrence of specific penicillin degradation products. For example, Fig. 1 is a chromatogram of a 0.05 *M* penicillin G potassium solution aged for 7 min and 31.5 hr at 37° in a 0.03 *M* citric acid–0.0067 *M* disodium phosphate buffer, pH 2.70. Peaks suitable for quantification are seen having retention times corresponding to penicillin G potassium, benzylpenillic acid, benzylpenamaldic acid, benzylpenilloic acid, and penicillamine. No other analytical method is available that allows the direct detection and quantification of penicillin degradation products forming during aging.

Differentiating Nonaqueous Titration of Aspirin, Acetaminophen, and Salicylamide Mixtures

H. J. RHODES, J. J. DeNARDO, D. W. BODE, and M. I. BLAKE *

Abstract □ Mixtures containing aspirin, acetaminophen, and salicylamide were assayed potentiometrically by nonaqueous titration. The difference in pKa values for these weak acids was sufficient to permit successful differentiation. The titrant was tetrabutylammonium hydroxide, and the titration solvent was dimethylformamide. The procedure was applied to commercial dosage forms.

Keyphrases □ Aspirin mixtures with salicylamide or salicylamide/acetaminophen—differentiating nonaqueous titration □ Salicylamide mixtures with aspirin or aspirin/acetaminophen—differentiating nonaqueous titration □ Acetaminophen, aspirin, and salicylamide mixtures—differentiating nonaqueous titration □ Titrimetry, nonaqueous, differentiating—mixtures of aspirin, salicylamide, and acetaminophen

Aspirin, acetaminophen, and salicylamide are frequently used analgesic–antipyretics in tablet dosage forms, individually, in a variety of combinations, and often with other drugs. Suitable analytical procedures are available for estimating the individual components, but generally methods are not available for

ophilized benzylpenamaldic acid–buffer mixture was also redissolved in double-distilled water, and 3–20 μl was injected.

Since the refractive index response for benzylpenamaldic acid came at a retention time of 13 min, the difference between expected and actual responses for the buffer salts at retention time of 4 min was used to calculate the weight of benzylpenamaldic acid that had been injected to produce the corresponding peak from the UV detector. This information was used to construct a calibration curve of UV spectral peak areas *versus* weight of benzylpenamaldic acid. The detector response was linear over a range of 0.45–5.4 μg of benzylpenamaldic acid. A least-squares regression analysis typically gave a line of slope of 94.5 $mm^2/\mu g$, an intercept of 22 mm^2, a correlation coefficient of 0.9976, and a standard error of estimate of 27.4 mm^2.

Benzylpenilloic Acid—Aqueous solutions of benzylpenilloic acid (0.75–2.1 mg/ml) were injected in volumes ranging from 1 to 23 μl and consistently produced a pair of overlapping peaks of approximately equal size at retention times of 7 and 8 min. Florey *et al.* (12) reported that two isomers of benzylpenilloic acid are obtained from the decarboxylation of benzylpenicilloic acid, possibly accounting for the pair of peaks on the chromatograph. Because of the overlapping peaks, the total peak area of the double peak was determined using a planimeter. Linear calibration curves in the 5–27-μg range typically had a slope of 0.0021 planimeter unit/μg, an intercept of −0.0024 planimeter unit, and a correlation coefficient of 0.9950. The standard error of estimate was 0.0021 planimeter unit.

Benzylpenicilloic Acid—Benzylpenicilloic acid was eluted from the column with a retention time of 19.5 min.

CONCLUSIONS

The HPLC system is expected to have great utility in kinetic studies to monitor the occurrence of specific penicillin degradation products. For example, Fig. 1 is a chromatogram of a 0.05 *M* penicillin G potassium solution aged for 7 min and 31.5 hr at 37° in a 0.03 *M* citric acid–0.0067 *M* disodium phosphate buffer, pH 2.70. Peaks suitable for quantification are seen having retention times corresponding to penicillin G potassium, benzylpenillic acid, benzylpenamaldic acid, benzylpenilloic acid, and penicillamine. No other analytical method is available that allows the direct detection and quantification of penicillin degradation products forming during aging.

Differentiating Nonaqueous Titration of Aspirin, Acetaminophen, and Salicylamide Mixtures

H. J. RHODES, J. J. DeNARDO, D. W. BODE, and M. I. BLAKE *

Abstract □ Mixtures containing aspirin, acetaminophen, and salicylamide were assayed potentiometrically by nonaqueous titration. The difference in pKa values for these weak acids was sufficient to permit successful differentiation. The titrant was tetrabutylammonium hydroxide, and the titration solvent was dimethylformamide. The procedure was applied to commercial dosage forms.

Keyphrases □ Aspirin mixtures with salicylamide or salicylamide/acetaminophen—differentiating nonaqueous titration □ Salicylamide mixtures with aspirin or aspirin/acetaminophen—differentiating nonaqueous titration □ Acetaminophen, aspirin, and salicylamide mixtures—differentiating nonaqueous titration □ Titrimetry, nonaqueous, differentiating—mixtures of aspirin, salicylamide, and acetaminophen

Aspirin, acetaminophen, and salicylamide are frequently used analgesic–antipyretics in tablet dosage forms, individually, in a variety of combinations, and often with other drugs. Suitable analytical procedures are available for estimating the individual components, but generally methods are not available for

complex mixtures of these components. Methods for the determination of acetaminophen in dosage forms, whether present as the only active ingredient or combined with other drugs, were reviewed previously (1). In that paper, a potentiometric nonaqueous titration procedure was proposed for determining acetaminophen in dosage forms. Sodium methoxide was used as the titrant and dimethylformamide was used as the titration solvent.

Procedures for analyzing mixtures containing acetaminophen and salicylamide in combination with other drugs also were reviewed (2). A differentiating nonaqueous titration method was described for this combination, using tetrabutylammonium hydroxide as the titrant and dimethylformamide as the titration solvent. Differentiating nonaqueous titration methods were reported for dosage forms containing combinations of aspirin and acetaminophen (3), acetaminophen and barbiturates (4), and aspirin and barbiturates (5). Each of these mixtures is composed of weak acids having pKa values sufficiently divergent to permit successful differentiating titrations in the appropriate nonaqueous system. Preliminary extraction and separation of the active components were not necessary, and dosage form excipients apparently did not interfere in the titration.

The present study was an extension of previous work and involved the differentiating nonaqueous titration of mixtures of aspirin (pKa 3.50), acetaminophen (pKa 9.92), and salicylamide (pKa 8.31), using tetrabutylammonium hydroxide as the titrant and dimethylformamide as the titration solvent. The procedure was applied to commercial dosage forms.

EXPERIMENTAL

Apparatus—All titrations were performed potentiometrically with a titrimeter[1] equipped with a glass–calomel electrode system or a platinum–calomel electrode system.

Reagents, Chemicals, and Dosage Forms—Acetaminophen, aspirin, and salicylamide were obtained from commercial sources and were the best quality available. Dosage forms were obtained from commercial sources. All other chemicals and solvents employed were reagent grade and were used without further purification.

Tetrabutylammonium hydroxide, 0.1 *N* in benzene–methanol, was prepared according to the method of Cundiff and Markunas (6) and was standardized potentiometrically against reference standard benzoic acid dissolved in dimethylformamide. The solution was restandardized with each series of titrations.

Titration of Individual Components—Approximately 0.5 mEq of aspirin powder, accurately weighed, was dissolved in 50 ml of dimethylformamide in a 150-ml beaker. The solution, magnetically stirred, was titrated potentiometrically with 0.1 *N* tetrabutylammonium hydroxide. Salicylamide and acetaminophen were titrated similarly as individual components.

Differentiation of Two-Component Mixtures—The differentiation of mixtures containing acetaminophen and salicylamide or aspirin and acetaminophen was reported earlier (2, 3). In the present study, mixtures of aspirin and salicylamide were prepared in the following ratios: 1:1, 1:2, and 2:1. Aliquots of these mixtures, containing at least 0.5 mEq of each component, accurately weighed, were analyzed by dissolving the aliquot in 50 ml of dimethylformamide contained in a 150-ml beaker. The solution, magnetically stirred, was titrated potentiometrically with 0.1 *N* tetrabutylammonium hydroxide.

[1] Fisher model 35.

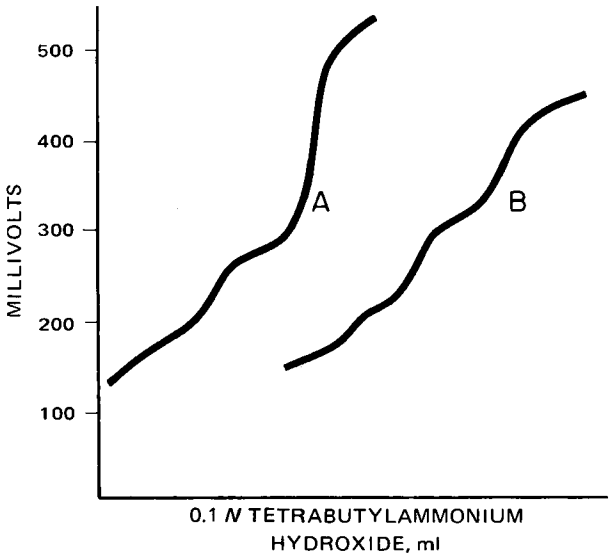

Figure 1—*Titration curves for: (A) binary mixture containing aspirin and salicylamide and (B) ternary mixture containing aspirin, salicylamide, and acetaminophen.*

The equivalence points for the differentiating titrations were determined by plotting $\Delta E/\Delta V$ *versus* V (milliliters). The volume reading where $\Delta E/\Delta V$ was a maximum was taken as an equivalence point. This procedure was not necessary for single-component systems, since the curve obtained by plotting the volume of titrant *versus* millivolt readings permitted the detection of the equivalence point by inspection. A typical titration curve (A) is shown in Fig. 1, and recovery data are presented in Table I.

Titration of Three-Component Mixtures—Mixtures of the three components were prepared so that aspirin–salicylamide–acetaminophen ratios were 1:1:1, 2:1:1, 3:1:1, and 3:2:1. Appropriate amounts of each component were accurately weighed and transferred to a 150-ml beaker. Fifty milliliters of dimethylformamide was added to the beaker, and the resulting solution was stirred magnetically. The solution was titrated potentiometrically with 0.1 *N* tetrabutylammonium hydroxide as the titrant. A typical titration curve (B) is shown in Fig. 1, and recovery data are presented in Table I.

Analysis of Dosage Forms Containing Three-Component Mixture—Twenty tablets from each of two commercial products

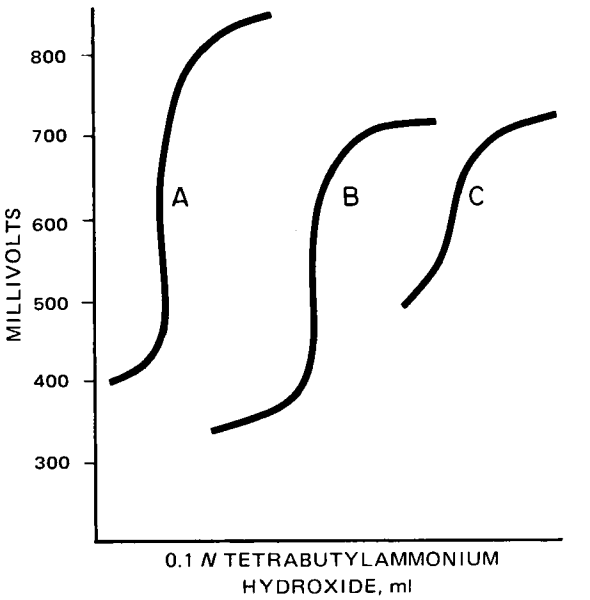

Figure 2—*Typical titration curves: (A) aspirin, (B) salicylamide, and (C) acetaminophen.*

Table I—Analytical Data

Sample	Ratio of Components	Recovery, %		
		Aspirin	Salicylamide	Acetaminophen
Aspirin		99.4 ± 0.6		
Salicylamide			100.9 ± 0.6	
Acetaminophen				101.2 ± 0.4
Aspirin–salicylamide	1:1	95.4 ± 0.4	100.4 ± 1.0	
	2:1	99.7 ± 1.0	95.7 ± 1.1	
	1:2	96.3 ± 5.0	100.3 ± 0.7	
Aspirin–salicylamide–acetaminophen	1:1:1	97.3 ± 1.5	102.3 ± 1.3	100.1 ± 1.1
	2:1:1	95.4 ± 1.9	97.8 ± 1.2	99.3 ± 0.4
	3:1:1	97.8 ± 0.3	97.8 ± 0.4	98.9 ± 2.7
	3:2:1	97.1 ± 0.2	100.6 ± 2.8	96.1 ± 1.1
Tablet dosage form				
A	3:2:1.5	98.5 ± 1.3	96.6 ± 1.7	97.9 ± 2.0
B	3:2:1.5	98.9 ± 0.8	101.5 ± 2.3	100.1 ± 2.0

were accurately weighed and then reduced to a fine powder in a mortar. An aliquot of the powder mass, accurately weighed, was transferred to a 150-ml beaker; then 50 ml of dimethylformamide was added, and the mixture was magnetically stirred for about 10 min. The resulting suspension was filtered through filter paper, which had been wetted with dimethylformamide. The beaker was rinsed with two 10-ml portions of dimethylformamide, which were then passed through the filter. The filtrate containing the active components of the dosage form was titrated potentiometrically as previously described.

RESULTS AND DISCUSSION

Mixtures of weak acids are readily analyzable by differentiating nonaqueous titration if the pKa values of the individual acids are sufficiently divergent and a suitable titrant, titration solvent, and electrode system are selected. This procedure is applicable to pharmaceutical dosage forms if excipients and other active ingredients do not interfere.

Typical two-component weak acid mixtures related to the systems reported in the present study were already mentioned. Other examples of two-component weak acid mixtures that have been successfully titrated differentially include benzoic acid and salicylic acid (6) as synthetic mixtures and in ointment dosage forms, cyclamates and saccharin (7) in liquid dosage forms, and *p*-aminosalicylic acid and its decomposition product *m*-aminophenol (8). The present study reports the analysis of mixtures containing aspirin and salicylamide and three-component mixtures containing acetaminophen in addition to aspirin and salicylamide.

Typical titration curves for the individual components are shown in Fig. 2. Curve A, Fig. 1, is a typical differentiating curve for mixtures containing equimolar amounts of aspirin and salicylamide. The first inflection is for aspirin, and the second end-point is for salicylamide. Curve B, Fig. 1, depicts a typical titration curve for the three-component system in which the components are present in about equimolar concentrations. The third inflection of the curve corresponds to acetaminophen.

Analysis data for the individual components, for the components of the binary and ternary synthetic mixtures, and for some typical tablet dosage forms are listed in Table I. The presence of other components and excipients apparently did not interfere in the titration. Although a preliminary extraction of the active components was performed, separation of the individual compounds was not necessary.

Two electrode systems were used in this study: the glass–calomel and the platinum–calomel pairs. The latter appeared to give sharper end-points, although both systems proved applicable.

Liquid Chromatography in Pharmaceutical Analysis IV: Determination of Antispasmodic Mixtures

I. L. HONIGBERG ˣ, J. T. STEWART, A. P. SMITH, R. D. PLUNKETT, and E. L. JUSTICE

Abstract □ Parameters associated with the separation of antianxiety–antispasmodic agents were investigated using high-pressure liquid chromatography. Eight widely prescribed drugs were studied. The compounds were chromatographed on reversed-phase octadecyltrichlorosilane (C_{18}) or diphenyldichlorosilane (phenyl) columns, using mixtures of absolute methanol and distilled water buffered with ammonium dihydrogen phosphate, ammonium acid phosphate, or ammonium carbonate. A mixture of phenobarbital–propantheline bromide was selected to demonstrate the utility of the separation and quantification method. The mixture was chromatographed on a phenyl column, using absolute methanol–aqueous 1% ammonium dihydrogen phosphate (60:40) (pH 5.85) at a flow rate of 1.4 ml/min. Each determination can be achieved in approximately 15 min with an accuracy of 1–2%.

Keyphrases □ Antispasmodic mixtures—high-pressure liquid chromatographic analysis, method parameters □ Antianxiety–antispasmodic agents—high-pressure liquid chromatographic analysis, method parameters □ High-pressure liquid chromatography—analysis, antispasmodic mixtures

This paper reports an investigation of the parameters associated with the separation and quantification of antianxiety–antispasmodic agents as a continuation of the study into the use of high-pressure liquid chromatography (HPLC) in the analysis of multicomponent dosage forms. Previous reports (1–3) dealt with the separation, detection, and quantification of cough–cold and diuretic–antihypertensive mixtures by HPLC.

The compounds studied are included in listings of most prescribed drugs used singly or in combination for treatment of functional or organic disorders of the GI tract. The drugs included were scopolamine hydrobromide, hyoscyamine sulfate, isopropamide iodide, prochlorperazine dimaleate, clidinium bromide, chlordiazepoxide hydrochloride, propantheline bromide, and phenobarbital.

Scopolamine and hyoscyamine in dosage forms have been analyzed by many methods including aqueous and nonaqueous titrimetry (4, 5), UV and visible spectrophotometry (6, 7), and TLC and GLC (8–10). Isopropamide iodide was determined by colorimetry (11) and nonaqueous titrimetry (12). GC (13), polarographic (14), and fluorometric (15) methods were reported for prochlorperazine. Clidinium bromide and chlordiazepoxide were determined by nonaqueous titrimetry (16, 17). Other methods for chlordiazepoxide include fluorescence (18), GC (19), and colorimetry (20). Spectrophotometry (21) and nonaqueous titrimetry (22) are used in the analysis of propantheline bromide, while spectrophotometry (23), TLC (24), and GLC (25, 26) are available for the detection and quantification of phenobarbital.

The investigated HPLC operating parameters were limited to solvent composition, pH, and stationary phase polarity. The use of these data can be readily applied to the separation and quantification of selected multidrug dosage forms. The quantification of a typical antispasmodic mixture is described.

EXPERIMENTAL[1]

Reagents and Chemicals—Powdered samples of scopolamine hydrobromide[2], hyoscyamine sulfate[2], isopropamide iodide[3], prochlorperazine dimaleate[3], clidinium bromide[4], and chlordiazepoxide hydrochloride[4] were used. In addition, propantheline bromide[5] and phenobarbital[6] were used in the analytical procedure and in the preparation of standard curves. All other chemicals and solvents were the highest commercially available materials.

Table I—Calibration Data for Standard Drug Solutions

Compound	Final Concentration, mg[a]	D/IS Ratio[b]	Slope	Intercept	$r + s$
Phenobarbital	7.5	0.2397 ± 0.002[c]	0.03390	—0.03075	0.9985 ±0.017
	15.0	0.4534 ± 0.001			
	30.0	0.9944 ± 0.007			
Propantheline bromide	7.5	0.7079 ± 0.040	0.08094	0.13931	0.9985 ±0.041
	15.0	1.4110 ± 0.032			
	30.0	2.5484 ± 0.008			

[a] Total mg/10 ml solution. [b] Data represent three to five replicate injections of standard solutions. D/IS is the ratio of the integrated area of the drug at some concentration divided by the integrated area of *m*-terphenyl at a concentration of 1 mg/10 ml. [c] Confidence limits at $p = 0.05$.

Mobile Phases—The mobile phases consisted of various concentrations of absolute methanol mixed with aqueous solutions containing: *(a)* 1% ammonium dihydrogen phosphate, *(b)* 1% ammonium dihydrogen phosphate and 1% ammonium acid phosphate, or *(c)* 0.5% ammonium carbonate. The solutions were prepared fresh daily.

Preparation of Drug Solutions—Separate solutions (150 mg/10 ml) of scopolamine hydrobromide, hyoscyamine sulfate, isopropamide iodide, and clidinium bromide were prepared by dissolving each powder in absolute methanol. Solutions of chlordiazepoxide hydrochloride (3 mg/10 ml), prochlorperazine dimaleate (30 mg/10 ml), and phenobarbital (30 mg/10 ml) were also prepared using methanol.

Internal Standard Solution—The stock internal standard solution (10 mg/10 ml) was prepared by dissolving *m*-terphenyl[7] in absolute methanol. *m*-Terphenyl, mp 85–87°, was purified before use by the method of France *et al.* (27).

Standard Solutions for Calibration Curves—Separate stock solutions (750 mg/100 ml) of phenobarbital and propantheline bromide were prepared in absolute methanol. Accurately pipetted volumes of 1.0, 2.0, and 4.0 ml of each stock solution were placed in 10-ml volumetric flasks. One milliliter of the internal standard stock solution was added to each flask, followed by the addition of absolute methanol to volume.

The three concentrations of each drug were subjected to a linear regression analysis, and the slope and intercept were calculated (Table I).

Chromatographic Separation and Quantification—The degassed mobile phase was pumped through columns containing monomolecular layers of octadecyltrichlorosilane (octadecyl) or diphenyldichlorosilane (phenyl) chemically bonded to a high efficiency pellicular packing, consisting of solid glass cores with a porous silica surface[8], at a flow rate of 1.4 ml/min (2000 psig) at room temperature until a stable baseline was obtained. Replicate 15-μl injections of sample and standard solutions were made using a 25-μl syringe[9]. The chart recorder provided a record of drug elution from the column as peaks on a chromatogram. In all cases, the solute was measured by digital integration of the peak area[1].

RESULTS AND DISCUSSION

The purpose of this study was to determine the operating conditions for HPLC that would optimize the resolution of chemically unrelated therapeutic agents most commonly found in antispasmodic mixtures. Three operating parameters were studied: *(a)* variations in solvent composition containing absolute methanol with changing concentrations of distilled water; *(b)* variations in pH within the 5.5–8.8 range using ammonium acid phosphate, ammonium dihydrogen phosphate, or ammonium carbonate as inorganic buffers; and *(c)* variations in the nonpolar (reversed-phase) stationary phase in which the pellicular packing differed in polarity. The effects of these parameters on retention times and base

E	7.90	2.20
F	7.60	2.40
I	8.80	3.60

[a] Letters refer to solvent compositions in Table III. [b] See Footnote 10.

peak widths of the drugs are shown in Table II. In addition, Table II indicates those solvent systems that generate multiplets or tailing of single drug entities.

For the investigated drugs, the following generalizations can be inferred from the data in Table II. Retention time for most drugs on the octadecyl column increases at all pH ranges as the polarity of the mobile phase increases. This effect is also observed with the phenyl column in the acidic pH range. In basic pH ranges on the phenyl column, there is little change in retention time with a change in mobile phase polarity. In most cases, retention time for a drug is longer on the octadecyl column than on the phenyl column.

Changes in solvent polarity have a greater effect on the retention times of the drugs on either the octadecyl or phenyl column than do changes in pH of the mobile phase. However, clidinium bromide and prochlorperazine dimaleate show appreciable changes in retention time with changes in pH of the mobile phase. Drugs containing an ester group give multiple peaks in basic pH ranges, probably because of hydrolysis on the column.

Modifications in the polarity of stationary and mobile phases provided the following observations for the drugs examined. Chlordiazepoxide hydrochloride produces multiple peaks on the octadecyl column in almost all solvent systems while giving only single peaks on the phenyl column. Resolution of the frequently prescribed chlordiazepoxide–clidinium bromide combination can be observed in Solvent Systems B, C, D, E, F, and I (Tables II and III).

The concentration levels of scopolamine and hyoscyamine detected in this study were 100 times higher than the level commonly found in commercial dosage forms. In several cases, the more basic solvents (*i.e.*, G, H, and I) led to tailing and/or multiple peaks for hyoscyamine on the phenyl column. The tailing and/or multiple peaks are probably due to decomposition in alkaline media (28). Neither scopolamine nor hyoscyamine could be detected at therapeutic dose levels with the present instrumentation.

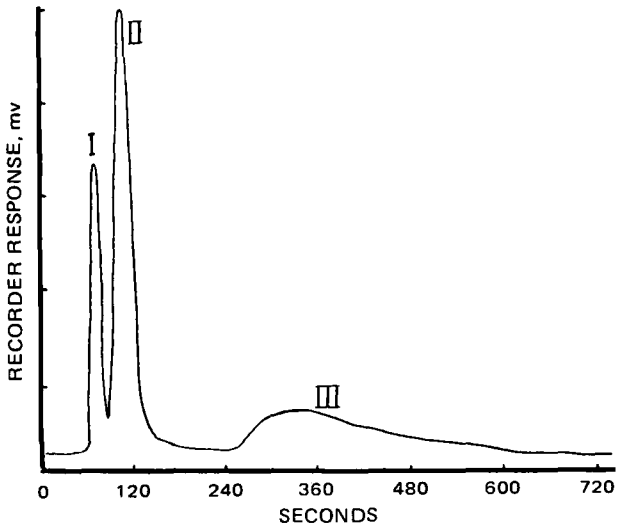

Figure 1—*Chromatogram of a phenobarbital–propantheline bromide mixture on diphenyldichlorosilane (phenyl) column with absolute methanol–1% ammonium dihydrogen phosphate (60:40). Key: I, phenobarbital; II, propantheline bromide; and III, m-terphenyl.*

Table V—Analysis of Phenobarbital–Propantheline Bromide in Known Mixture

Mixture	Milligrams Added	Milligrams Found[a]	Accuracy, %
Phenobarbital	15.0	15.262 ± 0.27[b]	1.75
Propantheline bromide	15.0	15.209 ± 0.20	1.39

[a] Based on five replicate determinations of known mixture. [b] Confidence limits at $p = 0.05$.

A combination of long retention time and basic pH of the mobile phase resulted in multiple peaks for propantheline bromide on the octadecyl column.

A peak associated with iodide ion in isopropamide iodide appeared at the solvent front in all solvent systems and on both columns (not recorded in Table II).

Long retention times in basic solvents (*i.e.*, G, H, and I) led to multiple peaks for clidinium bromide, possibly due to hydrolysis.

Phenobarbital traveled close to the solvent front in all systems, and its retention time could not be distinguished from that of the solvent front.

Prochlorperazine dimaleate exhibited extremely long retention times and considerable tailing in all solvents at all pH's. This compound also produced a peak for maleate near the solvent front (not recorded in Table II).

Satisfactory quantification of a multicomponent dosage form is dependent on adequate resolution of the components. The value *Rs* (29), a theoretical parameter, is a reasonable measurement of the separation of two species on a column. It can be approximated for any two drugs included in this investigation from information contained in Table II[10]. A mixture of phenobarbital–propantheline bromide[11] was selected to exemplify this situation. Table IV shows calculated *Rs* values for the drug combination in various solvent systems and pH ranges on the phenyl column. Mobile phase A was chosen for the quantification since adequate resolution could be achieved in the shortest time.

Figure 1 illustrates a chromatogram of the assayed drugs. Various concentrations of standard solutions of each drug dissolved in the absolute methanol–aqueous 1% ammonium dihydrogen phosphate (60:40) mixture were chromatographed using the phenyl column. *m*-Terphenyl was added to each solution as the internal standard. The area under the curve for each peak on the chromatograms was determined with a digital integrator[1]. The ratio of each peak area to the area of the internal standard was calculated for each chromatogram. A linear regression line of these data at three concentrations of each drug gave the slope, intercept, and correlation coefficient for each calibration curve (Table V).

A known mixture containing a quantity of each drug was chromatographed, and the ratios of drug peak areas/internal standard peak areas (D/IS) were calculated for each drug. The constants (slope and intercept) for the linear regression equation shown in Table I were used to solve for drug concentration [D/IS = slope (concentration) + intercept]. The calculations were performed on a programmable calculator[12].

The data in Table V demonstrate the quantitative results obtained for the simulated dosage form. The utility of HPLC in the analysis of a phenobarbital–propantheline bromide mixture is clearly demonstrated with an accuracy of 1–2%.

[10] It is possible to calculate the approximate resolution (*Rs*) of two components by the equation: $Rs = 2(t_2 - t_1)/(w_1 + w_2)$, where t_1 and t_2 are retention times and w_1 and w_2 are base peak widths of Compounds 1 and 2, respectively. In past experience, two components with an *Rs* value >1.5 showed satisfactory resolution for quantification by this analytical technique if the peak areas were approximately equal. A significant difference in peak areas for two components may require *Rs* values of 2 or greater.

Analysis of Individual Thyroid Tablets

JOSEPH H. GRAHAM

Abstract □ A procedure was developed for the assay of individual thyroid tablets or composite samples equivalent to as little as 0.033 g (0.5 gr) of thyroid. The sample is ignited in a closed atmosphere of oxygen and, after a series of redox reactions, the iodine is determined spectrophotometrically as the triiodide ion. The results agree well with those obtained by the USP thyroid tablet assay.

Keyphrases □ Thyroid—analysis of individual tablets, spectrophotometric method measuring triiodide ion □ Iodine—analysis of individual thyroid tablets □ Spectrophotometry—analysis, individual thyroid tablets, measurement of triiodide ion

The USP thyroid tablet monograph assay (1) is not suitable for individual tablet analysis because the level of iodine in an individual tablet is usually too low to produce an acceptable titration volume. In an effort to provide an individual tablet analysis, the following method was developed. It also provides a satisfactory alternative to the compendial assay method (1).

The proposed method utilizes essentially the same chemical transformations that form the basis of the compendial monograph assay (Scheme I).

$$\text{thyroid} + Na_2CO_3 \longrightarrow I^- + \text{fusion products}$$

$$I^- + 3Br_2 + 3H_2O \xrightarrow{\text{boil}} IO_3^- + 6Br^- + 6H^+$$

$$IO_3^- + 5I^- + 6H^+ \longrightarrow 3I_2 + 3H_2O$$

Scheme I

In contrast to the compendial assay, which requires alkaline fusion of the equivalent of 1 g of thyroid and a final thiosulfate titration, the proposed procedure requires oxygen flask ignition of the equivalent of 30 mg of thyroid and a final spectrophotometric determination. The procedure is applicable to coated or uncoated tablets ranging from 0.033 to 0.4 g (0.5 to 6 gr) of thyroid. Potassium iodate is used as the standard, and the measurement is made on aliquots of the iodate solutions equivalent to 5–35 μg of iodine.

EXPERIMENTAL

Reagents—The standard potassium iodate solution is prepared by quantitatively diluting 0.05 *M* potassium iodate (2) stepwise to 1 in 2500 to obtain a solution equivalent to 2.538 μg I_2/ml.

The bromine–sodium acetate test solution is prepared as directed in Ref. 3.

Acetate buffer, pH 3.9, consists of 1.0 *M* sodium acetate in 5.5 *M* acetic acid.

Buffered potassium iodide is prepared just prior to use by mixing 1.5% (w/v) potassium iodide in pH 3.9 acetate buffer. The solution should remain colorless for several hours.

Assay Preparation—Oxygen ignition[1] was performed using 1-liter conical ignition flasks fitted with all-glass stopper sample holders.

Individual Tablets—Securely fasten one thyroid tablet in a suitable platinum basket in contact with a small strip of black Schöniger ignition paper. Suspend the basket from the sample

Analysis of Individual Thyroid Tablets

JOSEPH H. GRAHAM

Abstract □ A procedure was developed for the assay of individual thyroid tablets or composite samples equivalent to as little as 0.033 g (0.5 gr) of thyroid. The sample is ignited in a closed atmosphere of oxygen and, after a series of redox reactions, the iodine is determined spectrophotometrically as the triiodide ion. The results agree well with those obtained by the USP thyroid tablet assay.

Keyphrases □ Thyroid—analysis of individual tablets, spectrophotometric method measuring triiodide ion □ Iodine—analysis of individual thyroid tablets □ Spectrophotometry—analysis, individual thyroid tablets, measurement of triiodide ion

The USP thyroid tablet monograph assay (1) is not suitable for individual tablet analysis because the level of iodine in an individual tablet is usually too low to produce an acceptable titration volume. In an effort to provide an individual tablet analysis, the following method was developed. It also provides a satisfactory alternative to the compendial assay method (1).

The proposed method utilizes essentially the same chemical transformations that form the basis of the compendial monograph assay (Scheme I).

$$\text{thyroid} + Na_2CO_3 \longrightarrow I^- + \text{fusion products}$$

$$I^- + 3Br_2 + 3H_2O \xrightarrow{\text{boil}} IO_3^- + 6Br^- + 6H^+$$

$$IO_3^- + 5I^- + 6H^+ \longrightarrow 3I_2 + 3H_2O$$

Scheme I

In contrast to the compendial assay, which requires alkaline fusion of the equivalent of 1 g of thyroid and a final thiosulfate titration, the proposed procedure requires oxygen flask ignition of the equivalent of 30 mg of thyroid and a final spectrophotometric determination. The procedure is applicable to coated or uncoated tablets ranging from 0.033 to 0.4 g (0.5 to 6 gr) of thyroid. Potassium iodate is used as the standard, and the measurement is made on aliquots of the iodate solutions equivalent to 5–35 μg of iodine.

EXPERIMENTAL

Reagents—The standard potassium iodate solution is prepared by quantitatively diluting 0.05 *M* potassium iodate (2) stepwise to 1 in 2500 to obtain a solution equivalent to 2.538 μg I_2/ml.

The bromine–sodium acetate test solution is prepared as directed in Ref. 3.

Acetate buffer, pH 3.9, consists of 1.0 *M* sodium acetate in 5.5 *M* acetic acid.

Buffered potassium iodide is prepared just prior to use by mixing 1.5% (w/v) potassium iodide in pH 3.9 acetate buffer. The solution should remain colorless for several hours.

Assay Preparation—Oxygen ignition[1] was performed using 1-liter conical ignition flasks fitted with all-glass stopper sample holders.

Individual Tablets—Securely fasten one thyroid tablet in a suitable platinum basket in contact with a small strip of black Schöniger ignition paper. Suspend the basket from the sample

[1] Thomas-Ogg oxygen flask ignitor.

holder into the ignition flask containing 15 ml of water. (For a large coated tablet, use 15 ml of 60% acetic acid.) Flush the flask thoroughly with oxygen, remove the oxygen inlet, and quickly inject 1–2 ml of bromine–sodium acetate test solution into the flask with a medicine dropper. Clamp the stopper securely and ignite the sample.

After the flask has cooled sufficiently for handling, swirl the contents for 4–5 min, allowing the solution to wet *all* internal surfaces repeatedly. Then chill the flask in cold water. In an efficient hood, carefully release the stopper and rinse it and the walls of the flask with water. Add a few silicon carbide boiling chips, and gently boil the solution until its vapors are negative to a moistened potassium iodide–starch test paper and the volume of the solution is conveniently reduced to facilitate its transfer. Do not reduce the volume below 10 ml.

Quantitatively transfer the cooled solution with the aid of water through a funnel, containing a small, tightly packed pledget of fine glass wool, into a volumetric flask of suitable size to obtain a solution concentration in the range equivalent to 0.5–3.5 μg of I_2/ml when diluted to volume.

Sample Composites—Weigh into a No. 0 or 00 gelatin capsule an amount of powdered sample composite equivalent to 65–130 mg of thyroid. Proceed as already described, transferring the solution to a 100-ml volumetric flask, and dilute to volume with water.

Procedure—Pipet 10-ml aliquots of sample, standard, and water to serve as a blank into separate 25-ml volumetric flasks. Add 10 ml buffered potassium iodide solution to each flask, and dilute to volume with water. Mix well and let stand for at least 5 min.

With a suitable spectrophotometer, record the spectrum relative to the blank in 1-cm cells from 460 to 340 nm. Correct the maximum absorbance at about 350 nm by subtraction of the absorbance at 450 nm.

Calculate the percent of iodine per grain of thyroid per tablet by the formula:

$$\%\,I_2 = \frac{(A_u350 - A_u450) \times C \times V_u \times 0.1}{(A_s350 - A_s450) \times D \times 64.8} \qquad \text{(Eq. 1)}$$

where C = concentration of standard (micrograms of I_2 per milliliter), V_u = volume of sample preparation (milliliters), D = declared content of thyroid (grains), and 64.8 = milligrams per grain. When assaying a sample composite, the formula is multiplied by average weight/weight, where average weight = average weight per tablet (milligrams), and weight = sample weight (milligrams).

RESULTS

Various thyroid tablets, coated and uncoated, ranging from 0.033 to 0.4 g (0.5 to 6 gr) in declared thyroid content, were assayed by the developed procedure. However, to emphasize the more significant stages in the evolution of the method, the analytical results obtained at these developmental stages are included in Table I with results using the proposed procedure. The validity of the results was established by comparison with results obtained by the USP thyroid method (1).

DISCUSSION

The primary concerns in the development of this assay of individual thyroid tablets were: *(a)* the suitability and ease of sample preparation and *(b)* the sensitivity and accuracy of the determinative step. This latter concern was adequately dealt with by Graham *et al.* (4) in the development of a procedure for the determination of levothyroxine sodium or liothyronine sodium in tablets. The first concern required a considerable amount of experimentation until a set of conditions was established that gave acceptable results with the various thyroid tablets studied.

In contrast to the free iodoamino acids (4), thyroid-bound iodine cannot be conveniently oxidized directly to iodate with bromine–sodium acetate test solution. No iodate appeared to have been produced by this process in several attempts, thus eliminating this most direct approach to sample preparation.

The remaining immediate options were: *(a)* scale down the USP ignition technique (1) and *(b)* adapt the oxygen flask procedure of Moody *et al.* (5). The first was rejected in favor of the second when the number of operations required to obtain the test solution was considered to be too large.

The results obtained under the conditions used by Moody *et al.* (5) for ignition—*viz.*, 1 liter of oxygen and 30 ml of 0.5 *M* sodium hydroxide as the absorbing solution, are shown in Table I. When the averaged individual tablet analyses were compared with the compendial assay, only Samples B, C, and H gave good agreement. Other anomalies were notable when comparisons were made among the averaged individual tablet assays, composite assays, and compendial assays:

1. Composite and individual tablet assays did not agree (Samples C, D, and F).
2. Composite and compendial assays agreed but individual tablet assays did not (Sample F).
3. Composite assay did not agree with the compendial assay but the individual tablet assay did (Sample C).
4. Composite and individual tablet assays agreed but did not agree with the compendial assay (Samples A and G).

At this point, the observation that some of the large coated tablets burned with a white incandescence while others did not suggested that there may be an insufficiency of oxygen for the combustion of some samples. It was also evident that the degree of subdivision of the sample affected the combustion.

When composite samples were ignited using 2 liters of oxygen with the same absorbing solution, significant changes were noted in Samples C, D, and G (Table I). This modification appeared to be adequate until attention was focused on Sample A. The change in assay was hardly significant, yet there must have been sufficient oxygen for complete combustion of the sample, since ignition of twofold amounts of the sample did not result in decreased assay values.

It was recalled that difficulty was encountered during an attempted determination of the iodine content of iopanoic acid by a similar ignition procedure[2], and it appeared that the same or an analogous situation was occurring with this thyroid sample. When applied to iopanoic acid, the oxygen flask combustion technique produces elemental iodine. The sodium hydroxide solution appeared to have absorbed the iodine during the scrubbing stage; but on the subsequent acidification preliminary to bromine oxidation, iodine vapor was released from solution. This loss was completely circumvented by substituting an aqueous solution of the acidic bromine–sodium acetate reagent in place of the sodium hydroxide solution. Although no iodine was visible during the ignition of the thyroid sample, this scrubbing technique was applied to a composite of Sample A (2 liters of oxygen) with complete success, giving an assay of 0.195%, which agreed well with the compendial assay. The procedure was repeated using a 1-liter flask, which gave an assay of 0.196%.

Since the ignition in 2-liter flasks was cumbersome and reduced the number of samples that could be conveniently handled, all samples were reassayed in 1-liter flasks, using the bromine oxidizing reagent as the scrubbing solution (Table I).

One further modification was made in view of the behavior of coated Samples E–H. When these samples were ignited in 2-liter flasks, the white ash remaining appeared inert when it came in contact with the acidic scrubbing solution. The ash remaining when these same samples were ignited in a 1-liter flask effervesced vigorously when it came in contact with the absorbing solution and the color of the solution was greatly diminished. Since it is desirable to maintain a low pH and an excess of free bromine for the oxidation to iodate, the recommended vehicle for the scrubbing reagent is 60% acetic acid.

The discrepancy remaining in the individual tablet and composite assays of Sample G is attributed to the sampling of this product.

SUMMARY

The developed procedure provides the same information as the USP thyroid and thyroid tablet monograph assays. Neither the compendial procedure nor this proposed procedure provides the highly desirable detailed information concerning the thyroxine and liothyronine content of thyroid samples.

This procedure is recommended for adoption by the USP because of its convenience and comparable accuracy to the compen-

NMR Spectroscopic Analysis of 2-Mercapto-5-methyl-1,3,4-thiadiazole in Cefazolin

D. B. STAIGER, R. J. WARREN ˣ, J. E. ZAREMBO, and A. POST

Abstract □ A rapid, sensitive, and accurate method for the quantitative analysis of 2-mercapto-5-methyl-1,3,4-thiadiazole in cefazolin is presented. The method utilizes NMR spectroscopy and is based on the difference in the chemical shift of the methyl protons on free thiadiazole and the thiadiazole moiety of cefazolin.

Keyphrases □ Cefazolin and cefazolin sodium—NMR analysis of free 2-mercapto-5-methyl-1,3,4-thiadiazole □ 2-Mercapto-5-methyl-1,3,4-thiadiazole—NMR analysis in cefazolin and cefazolin sodium □ NMR spectroscopy—analysis, 2-mercapto-5-methyl-1,3,4-thiadiazole in cefazolin and cefazolin sodium

Free thiadiazole may be found in cefazolin (sodium salt and free acid) as a decomposition product or as unreacted starting material. The contaminant may be determined by high-pressure liquid chromatography[1], but the procedure is tedious and time consuming. The NMR method presented in this paper is specific for free thiadiazole and provides a rapid, sensitive, and accurate quantitative analysis. The method takes advantage of the difference in the chemical shift of the methyl protons on free thiadiazole and the thiadiazole moiety of cefazolin; the NMR signals appear at 2.54 and 2.84 ppm, respectively (Fig. 1).

Quantitative analysis of pharmaceuticals and chemical mixtures by NMR spectroscopy has generally been accomplished with the use of an internal standard such as hexamethylcyclotrisiloxane (1, 2), succinic acid (3), fumaric acid (4), *tert*-butanol (5), and 2,3,5-tribromothiophene (6). However, for the quantitation of free thiadiazole in cefazolin, a calibration curve was derived from spectral data on known mixtures prepared from pure thiadiazole and pure cefazolin (sodium salt or free acid). Considerable time is saved, and potential weighing errors are

avoided by not using an internal standard, particularly when many cefazolin samples are involved.

EXPERIMENTAL

A 90-MHz NMR spectrometer[2] with 5-mm o.d. NMR tubes was used.

The necessary reagents included deuterium oxide[3] (99.7% D minimum isotopic purity) and trifluoroacetic acid[4].

Sample Preparation and NMR Conditions—Approximately 100 mg of cefazolin or cefazolin sodium is transferred to a small glass vial. For cefazolin, trifluoroacetic acid (0.5 ml) is added; for cefazolin sodium, deuterium oxide (0.5 ml) is added. The contents then are agitated to effect complete solution, and the solution is filtered through a cotton plug into an NMR tube.

The NMR spectrum is run on a 10-ppm sweep width and 10-min scan time for identification purposes (Fig. 1). For quantitative purposes, the spectrum is run at 300-Hz sweep width and 10-min scan time in the 135–300-Hz region (Fig. 2). This region is carefully integrated five times.

Preparation of Calibration Curve—Known mixtures, ranging from 0.5 to 8.0% free thiadiazole in cefazolin or cefazolin sodium, were prepared. The NMR spectra were obtained on the mixtures with integrations as already described. The integrations over the methyl resonances provided the data to construct the calibration curve (Fig. 3). Precision was determined for the lowest and the highest levels (Table I).

The ratio *(A)* of the thiadiazole integration to the sum of the thiadiazole and cefazolin or cefazolin sodium integrations was determined. The ratio *(A)* was plotted against the percent of free thiadiazole *(B)* in the mixture (Fig. 3). Sample quantitation followed by determining the ratio *(A)* and comparing it to the standard curve for free thiadiazole content.

Alternatively, a linear regression analysis can be applied to the data pairs to obtain the "best-fit" curve, $(A = mB + C)$, and its slope, m. Since $C = 0$, $A(1/m) = B$. Thus, the thiadiazole content is found by multiplying the factor $(1/m)$ by the ratio *(A)*.

Table II—NMR Analytical Data

Sample	Weight of Cefazolin Sodium, mg	Weight of Thiadiazole, mg	Thiadiazole in Mixture, %	Thiadiazole by NMR, %
1	48.321	1.213	2.45	2.31
2	48.672	1.682	3.34	3.26
3	48.607	2.088	4.12	4.11
4	47.592	2.128	4.28	4.23
5	49.952	1.048	2.05	2.16

RESULTS AND DISCUSSION

The calibration curves are linear for the range of thiadiazole concentrations studied, as indicated by the correlation coefficients of 0.9997 and 0.9952 for cefazolin and cefazolin sodium, respectively. These values were calculated by the method given by Snedecor and Cochran (7).

The sensitivity limit for the trifluoroacetic acid solutions of cefazolin is 0.5%; the sensitivity limit for the deuterium oxide solutions of cefazolin sodium is 0.2%. The sensitivity advantage obtained in deuterium oxide is due to the better resolution achieved with this solvent. Precision values at each concentration for the two solvents are about the same and show a drop in precision as lower concentrations of free thiadiazole are encountered. This finding reflects the limitation in measuring very small integral values. The reproducibility at the 1% level is 8.1%.

Although the NMR spectra of the trifluoroacetic acid solutions were obtained immediately after preparation, it was not of paramount importance to obtain them within this timespan. Studies showed that trifluoroacetic acid solutions of cefazolin are stable for at least 2 hr, and no discernable decomposition was observed from the integrations obtained from repetitive scans during this period.

Five mixtures of thiadiazole in cefazolin sodium were prepared and analyzed by the described NMR method (Table II).

Unit-Dose Assay of Tropine Alkaloids and Their Synthetic Analogs

CAMELIA GOMAA and ALY TAHA ˣ

Abstract □ A charge-transfer spectrophotometric method was developed for unit-dose assay of the tropine alkaloids and some of their synthetic analogs. The high molar absorptivities of the charge-transfer bands of the alkaloids with iodine in ethylene dichloride resulted in improved recoveries and good precision, particularly at the low dose levels of pediatric and hypodermic tablets.

Keyphrases □ Tropine alkaloids and synthetic analogs—unit-dose analysis, charge-transfer UV spectrophotometry □ UV spectrophotometry—analysis, tropine alkaloids, and synthetic analogs, unit-dose sensitivity

Quantitative methods for microamounts of the solanaceous alkaloids are few, and those depending on simple and convenient direct measurement in the UV range are lacking. The absorption bands of the tropine alkaloids, which have molar absorptivities of less than 150 (1), are not suitable for analytical purposes. The low sensitivity of the direct UV assay precludes its adoption in unit-dose determinations where amounts of the alkaloids as small as 0.3 mg/single dose are handled (2).

Accordingly, various approaches to the single-dose analysis of the tropine alkaloids were reported (3–13) which do not include direct UV measurement. They include dye–complex methods (3, 4), colorimetry *via* nitration and reduction followed by diazotization and coupling (5, 6), colorimetry as ferric hydroxamates (7), fluorometry (8), indirect spectrophotometry *via* cerimetric oxidation to benzaldehyde (9), TLC with densitometry (10), and GLC procedures (11–13).

With the possible exception of the last approach, most procedures suffer from some drawbacks. Acid–dye methods were reported to yield erratic results (14) owing to extreme sensitivity to pH variations. The colorimetric method (5) is not specific and is quite cumbersome. The ferric hydroxamate procedure requires a prolonged reaction time at low temperature, the colors are not very stable, and, more significant, no great improvement in sensitivity is achieved since reported molar absorptivities are in the 350–600 range (7). Photodensitometry on thin-layer chromatograms gave low recoveries of hyoscyamine (10).

The purpose of the present study was to develop a UV spectrophotometric procedure, for the analysis of the tropine alkaloids and some of their synthetic analogs, of sufficient sensitivity to allow single-dose assay.

Recently, Taha *et al.* (15) reported that about a 50-fold increase in the values of molar absorptivities of the tropine alkaloids could be achieved *via* charge-transfer complex formation with iodine in chlorinated solvents. This method, being of sufficient sensitivity, was adopted in the analytical technique described here.

EXPERIMENTAL[1]

Material—Pharmaceutical grade atropine base, atropine sulfate, scopolamine hydrobromide, hyoscyamine hydrobromide, homatropine hydrobromide, eucatropine hydrochloride, and *N*-butylscopolammonium bromide were utilized as working standards and in the construction of calibration curves.

Atropine sulfate tablets containing 0.3, 0.4, and 0.6 mg alkaloidal salt/100-mg tablet (prepared by direct compression using microcrystalline cellulose[2] as vehicle), atropine sulfate injection[3], tablets of total belladonna alkaloids as malates with phenobarbital[4], atropine sulfate ophthalmic solution[5], and *N*-butylscopolammonium bromide tablets[6] were subjected to the analytical procedure.

Reagents—*Iodine Solution (10^{-3} M)*—Dissolve 25.5 mg resublimed iodine in spectrograde ethylene dichloride in a 100-ml volumetric flask to obtain a solution of 0.255 mg/ml. The solution is stable for 1 week at 4°.

Buffer—Prepare 0.2 *M*, pH 9.0 buffer, standardized against the glass electrode, by dissolving 34.8 g of dibasic potassium phosphate in 900 ml of water. Adjust to pH 9.0 and make to 1 liter with water.

Standard Preparation—*Alkaloidal Salts*—Dissolve an accurately weighed amount of the appropriate working standard in water and dilute the solution quantitatively and stepwise to obtain a concentration of the salt equivalent to 1.0 mg of base/ml. Pipet 1.0 ml of this solution into a 30-ml separator containing 5 ml of buffer. Extract with 10 ml of ethylene dichloride, passing the separated organic layer through 2 g of anhydrous sodium sulfate supported by glass wool in a small funnel. Collect the filtrate in a 10-ml volumetric flask, wash the filter with a few drops of ethylene dichloride, and dilute to volume with the same solvent.

Atropine Base and N-Butylscopolammonium Bromide—Dissolve an accurately weighed amount of the appropriate standard in ethylene dichloride and dilute to obtain a concentration of 0.1 mg/ml.

Assay Preparation—*Atropine Sulfate Tablets*—Place one powdered tablet, or its equivalent from a composite of 20 tablets, in 5 ml of buffer in a 30-ml separator. Extract with two 10-ml fractions of ethylene dichloride, passing the separated organic layers through the same 2 g of anhydrous sodium sulfate suitably supported in a small funnel. Wash the filter with about 3 ml of ethylene dichloride and collect the filtrate and washings in a 25-ml volumetric flask. Dilute to volume with the same solvent.

This procedure is also applicable to tablets of total belladonna alkaloids with phenobarbital.

N-Butylscopolammonium Bromide Tablets—Place one powdered tablet, or its equivalent from a composite of 20 tablets, in a 30-ml beaker. Extract with two 10-ml portions of warm (40–50°) ethylene dichloride. Filter the fractions through a small piece of cotton wool, wash the filter with a small amount of warm solvent, and collect the filtrate and washings in a 25-ml volumetric flask. Cool to room temperature and dilute to volume with ethylene dichloride.

Atropine Sulfate Injection—Proceed as directed under *Atropine Sulfate Tablets*, substituting 1.0 ml, or the measured contents of a single-dose container of the injection, for the tablets.

Atropine Sulfate Ophthalmic Solution—Dilute an appropriate volume of the solution in a volumetric flask so as to represent 0.5 mg/ml. Proceed as directed under *Atropine Sulfate Tablets*, substituting 1.0 ml of the diluted ophthalmic solution for the tablets.

Table I—Peak Position and Intensity in Two Solvents

Compound	Ethylene Dichloride		Chloroform	
	λ_{max}, nm	ϵ_{max}[a]	λ_{max}, nm	ϵ_{max}[a]
Atropine	295	15,900	270	8,200
	375	6,200	410	2,900
Scopolamine	295	8,100	270	1000
	375	4,800	—	—
N-Butylscopolammonium bromide	280	33,500	280	44,200
Homatropine	295	10,500	—[b]	—
	375	4,700		
Eucatropine	295	18,500	—[b]	—
	375	10,200		
Hyoscyamine hydrobromide	—[c]	—	275	856
Scopolamine hydrobromide	—[c]	—	270	613
Homatropine hydrobromide	—[c]	—	275	783

[a] Based on molecular weight of free base. [b] Undetermined. [c] Salts are insoluble in ethylene dichloride.

Procedure—Pipet 1.0 ml of the standard preparation and a volume of the assay preparation equivalent to 0.05–0.15 mg of alkaloid into separate 10-ml volumetric flasks. Add 1.0 ml of iodine reagent solution to each flask and dilute to volume with ethylene dichloride. Determine the absorbance of the assay and standard solutions at the proper λ_{max} (295 nm for atropine, scopolamine, homatropine, and eucatropine and 280 nm for *N*-butylscopolammonium bromide) *versus* a blank prepared from 1.0 ml of iodine reagent solution diluted to 10.0 ml with ethylene dichloride.

Calculate the amount of drug, in milligrams, in the sample taken from the formula: $(f)C(A_u/A_s)$, in which f is a conversion factor derived from the ratio of the formula weight of the alkaloid salt to the molecular weight of its free base, C is the concentration in milligrams per milliliter of the standard preparation, and A_u and A_s are the absorbances of the solutions from the assay preparation and the standard preparation, respectively.

Ferric Hydroxamate Colorimetric Method—The basic procedure of Feldman and Robb (7) was followed.

RESULTS AND DISCUSSION

Peak Position and Intensity—In the preliminary report (15), which included the theoretical background of the method and the determination of the basic thermodynamic constants of the complexes, chloroform and carbon tetrachloride were examined as solvents for charge-transfer complex formation. The present investigation revealed the superior qualities of ethylene dichloride as the assay solvent. It has a favorable boiling point and a low cutoff point. More important, the dilution effects previously reported for chloroform and carbon tetrachloride (15), which resulted in a decrease in peak intensity, were not observed with ethylene dichloride. This finding was probably due to the decreased tendency of ethylene dichloride to form contact charge-transfer pairs (16) with the nitrogen of the alkaloid because of the lower ratio of chlorine to carbon atoms in its molecule.

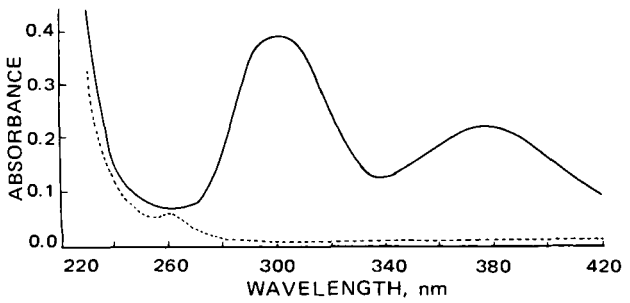

Figure 1—*Spectra of uncomplexed and iodine-complexed atropine in ethylene dichloride. Key: —, atropine (7 μg/ml) with iodine (25.5 μg/ml); and - - - -, atropine (70 μg/ml).*

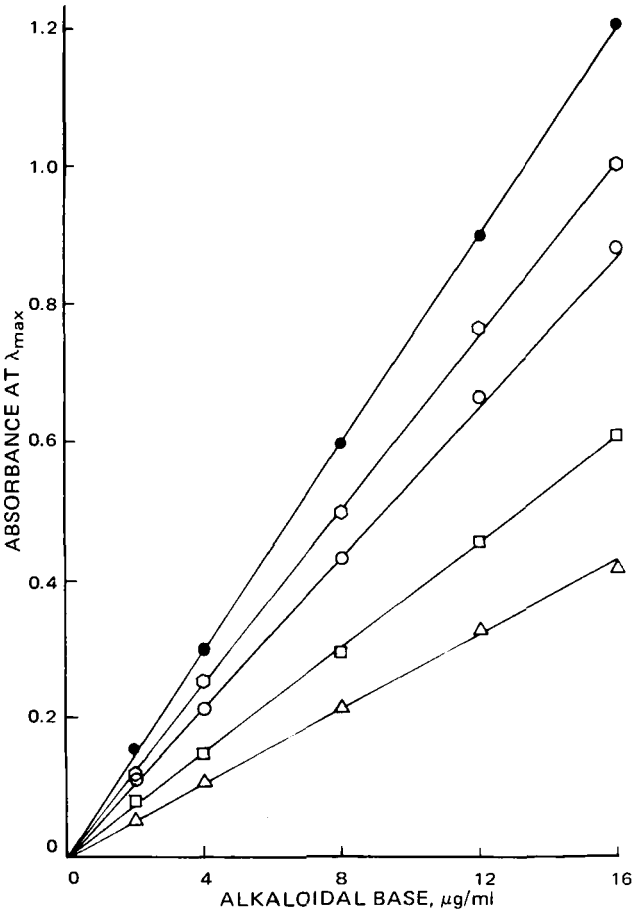

Figure 2—*Calibration curves of* N*-butylscopolammonium bromide (●), eucatropine (○), atropine (○), homatropine (□), and scopolamine (△). The λ_{max} of* N*-butylscopolammonium bromide is at 280 nm; it is at 295 nm for all other compounds.*

Peak positions of the complexes in ethylene dichloride are also different from those in chloroform (Table I). The spectra of complexed and uncomplexed atropine are presented in Fig. 1 as typical examples.

Linearity of Beer's Plots, Accuracy, and Precision—Standard curves for the different compounds were constructed by plotting observed absorbance readings *versus* the concentration of the alkaloid base in micrograms per milliliter of the final dilution. The results are presented in Fig. 2; conformance to Beer's law is evident. The slopes of the curves, determined by the method of least squares, were 0.076, 0.0635, 0.055, 0.0375, and 0.027 for *N*-butylscopolammonium bromide, eucatropine, atropine, homatropine, and scopolamine, respectively (Fig. 2). The slopes may be utilized for computation of unknown alkaloid concentration by applying the relation:

$$\text{concentration of base } (\mu g/ml) = A/\alpha \qquad \text{(Eq. 1)}$$

where A = absorbance of the solution from the assay preparation, and α = slope of the calibration curve of the corresponding alkaloid.

The validity of Eq. 1 was tested by taking 10 standards of atropine and of scopolamine through the procedure. As low as 0.01 mg of atropine and 0.02 mg of scopolamine could be determined, with recoveries of 99.4 and 98.7% and coefficients of variation in the assays of 1.14 and 2.13%, respectively.

Application to Dosage Forms—The charge-transfer method was applied to specially prepared lots of atropine sulfate tablets, conforming to the specifications of the USP XVIII (2), at three dose levels of 0.3, 0.4, and 0.6 mg of alkaloid salt/100-mg tablet. A tablet composite from each lot was assayed by the charge-transfer

Table II—Comparison of Two Assay Methods for Atropine Sulfate

Tablet, mg	Charge Transfer			Ferric Hydroxamate		
	Found[a], mg	Recovery, %	SD, ±%	Found[a], mg	Recovery, %	SD, ±%
0.3	0.308	102.6	2.83	0.263	87.6	7.19
0.4	0.406	101.5	2.24	0.369	92.3	5.30
0.6	0.593	98.8	1.59	0.576	96.0	6.34

[a] Average of six determinations of tablet composite.

and ferric hydroxamate methods (Table II). Placebos were utilized in the preparation of blanks.

Data of Table II suggest that the presented spectrophotometric method could be applied to assay individual dose units of the tropine alkaloids with good accuracy and precision. The poorer recoveries of the colorimetric method reflect differences in molar absorptivities of the absorbing chromogens in the two methods, *e.g.*, ϵ of 15,900 for the charge-transfer band of the atropine–iodine complex compared to ϵ of 420 for the ferric hydroxamate chromogen reported for atropine sulfate (7).

The applicability of the procedure to commercial dosage forms and to content uniformity determination was checked (Table III). Since placebos of commercial products were not available, the method of standard addition was adopted. The results of Table III further confirm the suitability of the charge-transfer spectrophotometric method for control analysis and unit-dose assay of the tropine alkaloids and some of their synthetic analogs.

Comments on Procedure—The charge-transfer method was unaffected by the presence of phenobarbital, commonly prescribed with the belladonna alkaloids. The single partition at the alkaline pH of the procedure effectively separated the acidic barbiturate from the basic alkaloids.

Chlorobutanol and esters of *p*-hydroxybenzoic acid, frequently present as preservatives in ophthalmic solutions, are known to interfere in the ferric hydroxamate method (7, 17). No interference of these compounds could be observed in the presented procedure.

However, the charge-transfer method must be considered nonspecific with regard to differentiation between members of the tropine alkaloids, and it is not directly applicable as a stability-indicating assay since tropine, the major product of degradation of the belladonna alkaloids, was found to give a strong charge-transfer band.

Table III—Assay of Commercial Dosage Forms

Preparation	Label Claim	Found[a], % of Label Claim	Standard	
			Added[b]	Recovered[c], %
Tablets of total alkaloids with phenobarbital	0.25 mg/tablet	104.8 106.5 97.6	0.25 mg/tablet	98.2
Atropine sulfate injection	1.0 mg/ampul	101.6 102.0 101.3	—	—
Atropine sulfate ophthalmic solution	0.50%	97.5[c]	0.25%	101.5
N-Butylscopolammonium bromide tablets	10.0 mg/tablet	100.8 96.6 99.1	5.0 mg/tablet	99.3

[a] Single-dose determination. [b] Added to tablet composite or ophthalmic solution. [c] Average of three determinations.

These shortcomings do not affect the utility of the method in routine analysis and content uniformity determination of singly prescribed alkaloids. The drawbacks may also be overcome by coupling the charge-transfer method to a separation procedure reported for the tropine alkaloids such as paper chromatography (18, 19), partition column chromatography (5, 6, 20), countercurrent distribution (21), or TLC (22–24). The enhanced sensitivity of the method allows for additional handling without fear of increasing error.

Colorimetric Determination of Peptide Antibiotics: In-Process Assay of Cyclic Octapeptidic Antibiotics in Fermentation Broths

EUGENE IVASHKIV

Abstract □ A spectrophotometric method is presented for monitoring the biosynthesis of a new complex of cyclic octapeptidic antibiotics in fermentation broths. The method is based on the extraction of antibiotic from alkaline broth with butanol. An ion-pair, formed between the octapeptides and bromthymol blue, is extracted into chloroform from a solution buffered to pH 7.5. The absorbance of the colored solution is measured at 420 nm. Results are in good agreement with those obtained by microbiological assay. The method is also applicable to other peptidic antibiotics such as polymyxin B and gramicidin.

Keyphrases □ Octapeptide (cyclic) antibiotic biosynthesis—colorimetric monitoring in fermentation broths, ion-pair formation with bromthymol blue □ Antibiotic biosynthesis, cyclic octapeptide—colorimetric monitoring in fermentation broths, ion-pair formation with bromthymol blue □ Colorimetry—monitoring, in-process cyclic octapeptide biosynthesis, ion-pair formation with bromthymol blue

A new complex of cyclic octapeptidic antibiotics[1] (I) is produced by a strain of *Bacillus circulans*. The antibiotic has broad spectrum antibacterial activity and displays considerable antifungal and antiprotozoal activities (1–3). Proper control of the fermentation of I requires an analytical method that can monitor biosynthesis at any stage and that requires a comparatively short time.

With a microbiological assay[2], one can determine the amount of I in a fermentation broth about 48 hr after sampling. Chemical methods for the determination of polypeptidic antibiotics (4–8) are tedious and time consuming. In these laboratories, a rapid and simple colorimetric method was developed for estimating the amount of I in a fermentation broth. The reaction of bromthymol blue with I to form a chloroform-soluble colored complex is the basis of the method; the amount of colored complex is proportional to the amount of I present.

EXPERIMENTAL

Reagent grade *n*-butanol, chloroform, sodium chloride, sodium hydroxide, and absolute ethanol were used.

Phosphate buffer, pH 7.5, was prepared by dissolving 10 g of dibasic sodium phosphate, 2 g of monobasic potassium phosphate, and 5 ml of 85% phosphoric acid in 900 ml of distilled water. The pH was adjusted to 7.5 with 5 *N* sodium hydroxide, and the solution was diluted to 1 liter with distilled water.

Bromthymol blue, 0.15%, was prepared by dissolving 0.15 g of bromthymol blue and 0.15 g of anhydrous sodium carbonate in distilled water to give 100 ml of reagent.

The I standard, of known purity, was dissolved in distilled water and diluted to a concentration of about 500 μg/ml.

Table I—Effect of pH on Extraction of I—Bromthymol Blue Ion-Pair

pH	Absorbance at 420 nm
2.5	0.000
6.0	0.490
6.5	0.690
7.0	0.780
7.5	0.824
8.0	0.525
9.0	0.419
10.0	0.000
12.0	0.000

PROCEDURE

Extraction—A 5.0-ml sample of fermentation broth and 5.0 ml of standard I solution are pipetted into screw-type test tubes containing 2 g of sodium chloride, 5.0 ml of *n*-butanol, and 2 ml of 5 *N* sodium hydroxide solution. Each tube is covered with a plastic cap and shaken mechanically for 5 min. After centrifugation, 0.2 ml of the butanolic upper layer is pipetted into a screw-type test tube and the solvent is evaporated completely under a stream of air. Immersion of the tube in a water bath at about 70° is used to speed the evaporation of butanol.

Color Development—To each tube, 10.0 ml of pH 7.5 phosphate buffer is added. A reagent blank is prepared by pipetting 10.0 ml of pH 7.5 phosphate buffer into a screw-type test tube. To each tube, 1.0 ml of 0.15% bromthymol blue is added; then the contents are mixed. After the addition of 10.0 ml of chloroform, the tubes are covered with plastic caps and shaken mechanically for 5 min. The tubes are centrifuged at 2500 rpm for 1 min, and the aqueous upper layer is aspirated completely.

A 5.0-ml portion of the chloroform layer is transferred to a test tube containing 0.5 ml of absolute ethanol, and the contents are mixed. The absorbance of the sample and of the standard solutions is measured at 420 nm in a spectrophotometer[3] equipped with 1-cm cells, with the reagent blank in the reference cell. The amount of I is calculated from the concentration and the absorbance of the I standard.

RESULTS AND DISCUSSION

Positively and negatively charged ions can associate as uncharged ion-pairs. These neutral combinations exhibit considerably diminished water solubility and can be readily extracted into organic solvents. The principles of ion-pair formation were reviewed in detail previously (9).

Bromcresol purple, bromphenol blue, bromthymol blue, and methyl orange were tested for possible ion-pair formation with I. Of these indicators, only methyl orange and bromthymol blue formed a precipitate with I. At pH 7.5, both bromthymol blue and methyl orange couple with the positively charged basic molecule of I, but only the yellow I–bromthymol blue ion-pair can be extracted from aqueous solutions into chloroform and other organic solvents such as methylene chloride, ethylene dichloride, and ether. Carbon tetrachloride extracts only 8% of the color, and toluene extracts 25%. Cyclohexane, hexane, and heptane precipitate the ion-pair at the interface of the two phases. Butyl alcohol, isobutyl acetate, and

Table II—Recovery of I from Broths

Added I, mg/ml of Broth	Recovery, %
2.0	101.0
1.6	101.0
1.2	99.0
0.8	99.4
0.4	100.0
0.2	101.0
0.1	98.5
0.0	0.0

ethyl acetate extract free bromthymol blue, thus producing very high blanks.

Study of the effect of pH of the aqueous solution on the reaction and extraction of the I–bromthymol blue ion-pair gave the results shown in Table I. Less color was extracted from acidic and alkaline solutions than from a neutral solution. An excessive amount of free bromthymol blue was extracted with chloroform from acidic solutions with pH up to 6.5. For example, the absorbance of the reagent blank at pH 6.0 was 0.730, contrasted with the absorbance of 0.100 from a pH 7.5 buffer. The amount of phosphate used in the preparation of the pH 7.5 buffer proved important. An increase in the phosphate content of the buffer solution led to an increase in the extraction of the ion-pair, but too high a concentration of phosphate in the buffer produced high reagent blanks.

The volume of pH 7.5 buffer used also affects the extraction of the ion-pair with chloroform. The best results were obtained with 10.0 ml of pH 7.5 buffer. For reproducible results, the phosphate buffer should be transferred with a volumetric pipet. The volume of chloroform proved to be unimportant; when the I–bromthymol blue ion-pair was extracted from 10.0 ml of phosphate buffer with 5, 10, 15, or 25 ml of chloroform, the same amount of color was extracted in each case.

Chloroform extracts of the ion-pair are cloudy. They can be clarified by centrifugation, but they become cloudy again on standing. The addition of anhydrous sodium sulfate clarifies the chloroform extract, but the readings of absorbance vary. Reproducible measurements of absorbance are obtained when chloroform extracts are clarified with absolute ethanol.

The I–bromthymol blue ion-pair shows maximum absorbance at 420 nm. Solutions containing up to 200 μg I/ml of chloroform, with an absorbance of 1.16, obey Beer's law.

Various solvents were tried for the extraction of I from aqueous solutions. Isobutyl acetate, ethyl acetate, benzene, isopentyl acetate, chloroform, and ethylene dichloride did not extract I. When the ratio of solvent to the aqueous solution was 1:1, methyl ethyl ketone extracted 30%, isoamyl alcohol extracted 19%, and isobutyl alcohol extracted 53% of the I present. Of the solvents tried, only *n*-butanol extracted about 96% of I. Complete extraction of I with *n*-butanol was obtained when an inorganic salt such as sodium chloride, ammonium chloride, or sodium sulfate was used to salt out the antibiotic. The use of one of these salts also prevented emulsification of the broth during extraction.

The effect of pH on the extraction of I was studied. The pH of solutions was adjusted with 5 *N* sodium hydroxide or 6 *N* hydrochloric acid to points between 1 and 12. Complete extraction of I occurred from solutions adjusted to pH 5 or higher; but at pH 1.0, only 57% of the I was extracted. Extraction of I from highly alkaline broths eliminates blanks from samples.

Table III—Reproducibility of Colorimetric Assay of I in Fermentation Broth

70	902	894	795	886
78	896	900	750	886
86	893	880	886	796
96	901	892	909	886

The ratio of the volume of broth to the volume of butanol did not appreciably affect the efficiency of extraction. Compound I was extracted completely even when the ratio of broth to *n*-butanol was 2:1.

Recovery of I was studied by the addition of the antibiotic to a broth medium. As shown in Table II, complete recovery of I from the medium was obtained in the range tested.

Samples of fermentation broth were analyzed in duplicate. From the data given in Table III, it appears that results can be reproduced within ±2%.

Results from the colorimetric assay were compared with those from the microbiological assay of I. Broth samples were extracted in duplicate from solutions at about pH 12, and portions of the extracts were assayed both colorimetrically and microbiologically. *Bordetella bronchiseptica* (ATCC 4617) was used in the bioassay. As shown in Table IV, the results of the colorimetric assay were more reproducible than those of the microbiological procedure. When mean values for two assays by each method were compared, better correlation of methods was obtained at completion of the fermentation. The greater concentration of I shown by the microbiological assay could be attributable to fermentation products that do not form ion-pairs with bromthymol blue but are used up later in the process.

Broth samples were stable for at least 1 week when refrigerated at 5°. The I standard solutions showed a decrease of about 15% in color intensity after being kept at room temperature for 2 days. The butanolic extracts were stable for at least 1 week at room temperature.

This colorimetric assay of I in fermentation broths can be used to monitor the biosynthesis of other peptide antibiotics such as polymyxin B, gramicidin, and tyrocidine. Gramicidin, a component of the antibiotic tyrothricin, has to be separated from tyrocidine as described (10) before ion-pairs are formed. The $E^{1\%}_{1cm}$ of each polypeptidic antibiotic seems to depend on the number of free amino groups in the compound. The $E^{1\%}_{1cm}$ values of I, polymyxin B, gramicidin[4], and tyrocidine[5] are 772, 775, 193, and 319, respectively.

This new colorimetric assay can also be used for the determination of polymyxin B and gramicidin in pharmaceutical formulations.

Colorimetric Determination of Isoniazid with 9-Chloroacridine

JAMES T. STEWART ˣ and DAVID A. SETTLE

Abstract □ A colorimetric method based on the interaction between isoniazid and 9-chloroacridine was developed. Analytical solutions are shaken for 30 min at 50°, and the absorbance is measured at 500 nm. The procedure is sensitive for isoniazid in the 10^{-5} *M* range. The method was applied to the analysis of isoniazid in pharmaceutical dosage forms and found to be comparable to the USP XVIII assay. Preliminary investigations suggested that the procedure is useful for the determination of free isoniazid in urine and plasma samples containing isoniazid metabolites.

Keyphrases □ Isoniazid—colorimetric analysis with 9-chloroacridine □ 9-Chloroacridine—colorimetric reagent for determination of isoniazid □ Colorimetry—analysis, isoniazid with 9-chloroacridine

The interaction of isoniazid (isonicotinic acid hydrazide) with 9-chloroacridine to give highly colored solutions has been observed in this laboratory. This observation led to the development of a new colorimetric method for determining isoniazid with 9-chloroacridine. The reagent was shown previously to be applicable to the colorimetric analysis of primary aromatic amines and aromatic hydroxylamines (1–4).

Existing analytical procedures for the assay of isoniazid include visible and UV spectrophotometry, polarography, and titrimetry. The colorimetric methods involve the interaction of the drug with 1-chloro- or 1-fluoro-2,4-dinitrobenzene (5, 6) and/or 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (7). Although highly sensitive and specific, these procedures have the disadvantages of instability of color formation and preparation of multireagent solutions. Vanillin has also been used as a chromogenic reagent in the analysis of isoniazid (8).

A procedure involving the hydrolysis of isoniazid to hydrazine, with subsequent color development with *p*-dimethylaminobenzaldehyde, was reported (6). This method is subject to interference by aldehydes and/or ketones. UV spectrophotometry (6) and polarography (6) also have been utilized in the analysis of microgram quantities of isoniazid. The USP XVIII method (9) involves an iodometric titration and is laborious and time consuming.

This paper presents a new colorimetric method for determining microgram quantities of isoniazid with 9-chloroacridine. The method has been successfully applied to the analysis of the drug in pharmaceutical dosage forms. In addition, preliminary investigations suggest that the procedure is useful for the determination of free isoniazid in urine and plasma samples.

[a] Based upon two replicate determinations of each solution. [b] Dosage form contained only isoniazid as active ingredient. [c] Confidence limits at $p = 0.05$. [d] Dosage form also contained pyridoxine hydrochloride (10 mg).

zone, acetylhydrazine, and 1,2-diacetylhydrazine were synthesized by procedures listed by Boxenbaum and Riegelman (8). Isonicotinuric acid was prepared by the method of Gardner *et al.* (11). The melting points of the synthesized compounds were in agreement with literature values. All other chemicals were commercially available and were utilized as received.

Solutions were prepared by dissolving weighed amounts of isoniazid in water or ethanol and the remaining compounds in ethanol. The reagent solution of 9-chloroacridine was prepared by dissolving a weighed amount in tetrahydrofuran[6] and storing in a light-resistant volumetric flask[7].

General Procedure—A quantity of an aqueous or ethanolic solution containing isoniazid was placed in an appropriate volumetric flask. A tetrahydrofuran solution containing an approximate twofold excess of 9-chloroacridine was added to the flask. The solution was acidified with 2 drops of a 5% (v/v) aqueous hydrochloric acid solution and shaken in a constant-temperature water bath–shaker[8] at 50 ± 1° for 30 min. Ethanol was added to volume so that the final concentration of isoniazid in the flask was equal to or greater than 4×10^{-6} *M*. The absorbance was measured at 500 nm, and measurements were corrected for reagent blanks in the procedure.

Analysis of Solid Dosage Form—Tablets were weighed and powdered, and a weighed aliquot was dissolved in distilled water by shaking vigorously for 5–10 min and filtering, if necessary, to give a 10^{-3} *M* solution. Then 1 ml was removed and assayed according to the *General Procedure*.

RESULTS AND DISCUSSION

9-Chloroacridine interacts with isoniazid in the analytical procedure to yield a highly colored orange solution. The absorption curve in the visible spectrum for an analytical solution of isoniazid shows an absorption maximum at 500 nm (Fig. 1).

The interaction between 9-chloroacridine and isoniazid is affected by the temperature and time of heating and the quantity of acridine reagent utilized. Adherence to the Beer–Lambert law was not observed for various concentrations of isoniazid at room temperature for 30–45 min (Fig. 2). However, when the analytical solutions were heated at 40, 50, and/or 60° for 30–45 min, linearity was observed. The results showed that 50° represented the lowest temperature at which both maximum sensitivity and linearity could be obtained. Thus, it was chosen as the desired temperature for the analytical procedure.

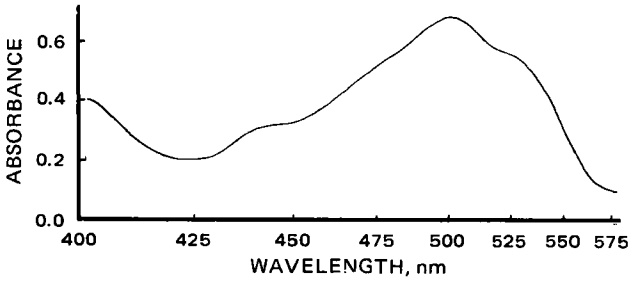

Figure 1—*Absorption spectrum of reaction product at isoniazid concentration of* 4×10^{-5} M.

The minimum heating time was then determined by following the color development. Absorbance values increased through 30 min and then stabilized. A heating period of 30 min at 50 ± 1° was satisfactory for reproducible readings. The color produced appeared to be stable for at least 1 day after the heating. Under these conditions, the reference blank was colorless.

The intensity of the color produced was directly affected by the concentration of 9-chloroacridine employed. Higher absorbance values were obtained up to a twofold excess of the reagent. Quantities of the acridine beyond the twofold excess did not effectively increase the absorbance readings for isoniazid. The stability of the 9-chloroacridine reagent solution was discussed previously (3, 4).

Standard curves can be prepared by plotting observed absorbance readings *versus* volumes taken of equimolar concentrations of isoniazid.

The analysis method is a microprocedure, and sensitivity is in the 0.6–5-μg/ml range (10^{-5} *M*) of isoniazid. Reagent preparation is simple and rapid since 9-chloroacridine is commercially available and easily purified. The time involved in the actual analysis procedure is about 45 min; some existing colorimetric and titrimetric methods involve longer heating and sample preparation times (5–7, 9).

Data from several systems (Table I) reveal that this procedure permits the determination of isoniazid in mixtures containing drugs, preservatives, and isoniazid metabolites which might be present in commercial dosage forms or biological samples containing the drug. Aminosalicylic acid interferes with the analysis method if it is present in final concentrations greater than 2×10^{-5} *M*. Since aminosalicylic acid is normally present in greater quantities than isoniazid in dosage forms and biological fluids where the drugs are given concurrently, it would be desirable before analyzing for isoniazid by this method to separate the two drugs *via* some type of separation technique or to employ the technique of simultaneous spectrophotometric assay. The latter technique should be possible since both aminosalicylic acid and isoniazid interact with 9-chloroacridine to produce maximum absorption at 435 and 500 nm, respectively.

Results obtained by applying the assay procedure to commercially available isoniazid tablets are shown in Table II. The method is comparable to the USP XVIII procedure (9). Extraction of the drug from tablets by shaking the tablet mass with distilled water for 5–10 min at room temperature appears to be as efficient as the USP extraction procedure utilizing heat and methanol. In addition, the colorimetric method is quicker and requires the preparation of only one reagent solution.

Table III—Analysis of Isoniazid Mixtures in Urine for Isoniazid

Mixture	Components, 4×10^{-5} M	Isoniazid[a] Found, $M \times 10^{-5}$	Isoniazid[a] % of Theory
1	Isoniazid Acetylisoniazid Isonicotinic acid Isonicotinuric acid	4.00 ± 0.04[b]	100.00
2	α-Ketoglutaric acid isonicotinoylhydrazone[c]	4.03 ± 0.18	100.75
3	Pyruvic acid isonicotinoylhydrazone[c]	3.95 ± 0.21	98.75
4	Isoniazid 1,2-Diacetylhydrazine	3.95 ± 0.01	98.75
5	Isoniazid *N*-Acetylhydrazine[d]	3.93 ± 0.04	98.25

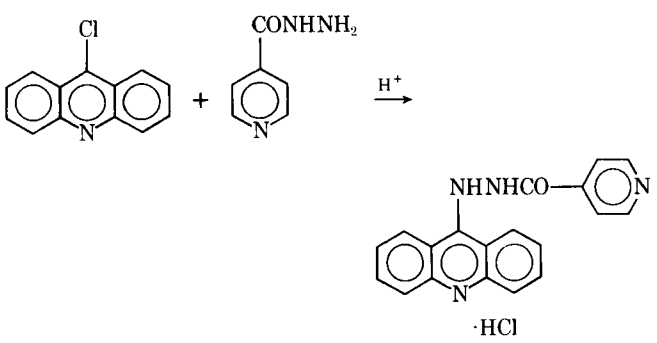
[a] Based upon three replicate determinations of each solution. Percent recovery of isoniazid from urine was 99.38 ± 0.26%. [b] Confidence limits at $p = 0.05$. [c] Hydrazones were hydrolyzed to isoniazid by treatment with 0.2 *N* HCl in a 52° water bath for 60 min; the solution was adjusted to pH 5 with aqueous potassium carbonate followed by the addition of a 9-chloroacridine solution. [d] Final concentration in mixture was 2×10^{-5} *M*.

A preliminary investigation of the analysis of isoniazid in urine and plasma was performed utilizing the 9-chloroacridine method. The biological fluids were spiked with various combinations of isoniazid and its metabolites. For each assay, freshly prepared isoniazid standards in urine and plasma were run concomitantly with the mixtures.

In the determination of isoniazid in urine, isoniazid can be quantitated satisfactorily in the presence of its metabolites (Table III). Since the amounts of α-ketoglutaric acid and pyruvic acid isonicotinoylhydrazones present in the urine are usually expressed in terms of *free* isoniazid (8), urine samples containing each hydrazone were quantitatively hydrolyzed to isoniazid using the procedures of Hughes *et al.* (12) and Short (13). After adjusting the solution pH to 5 with aqueous potassium carbonate, 9-chloroacridine was added and the color developed. Results indicate that the 9-chloroacridine method will detect isoniazid released from hydrolysis of the hydrazones. However, the method will not allow the detection of free isoniazid in the presence of the hydrazones since acid present in the analytical solution promotes hydrolysis of the hydrazones during the color development period.

For plasma samples, the results (Table IV) indicate that isoniazid can be successfully analyzed in mixtures containing its metabolites. The spiked plasma samples were denatured with equal volumes of 5% trichloroacetic acid and centrifuged. A portion of the supernatant liquid was transferred to a volumetric flask, and the pH of the sample was then adjusted to approximately 5–6 with aqueous potassium carbonate before addition of the 9-chloroacridine solution. Any cloudiness in the final solutions was clarified by centrifugation.

The color produced from the interaction of isoniazid with 9-chloroacridine suggested that a free amino function in the molecule is necessary for the reaction. This finding is in agreement with previous results from this laboratory concerning the interaction of primary aromatic amines and/or aromatic hydroxylamines with the acridine (1–4) to form highly colored solutions. The latter functional groups produce maximum absorption around 435 nm compared to isoniazid at 500 nm. Therefore, it should be possible to analyze for isoniazid in the presence of any drugs containing primary aromatic amines and/or aromatic hydroxylamine moieties with the use of the simultaneous spectrophotometric assay.



Scheme I

Table IV—Analysis of Isoniazid Mixtures in Plasma for Isoniazid

Mixture	Components, 4×10^{-5} M	Isoniazid[a] Found, $M \times 10^{-5}$	Isoniazid[a] % of Theory
1	Isoniazid Acetylisoniazid Isonicotinic acid Isonicotinuric acid	3.96 ± 0.04[b]	99.00
2	Isoniazid 1,2-Diacetylhydrazine *N*-Acetylhydrazine	3.93 ± 0.04	98.25

[a] Based upon three replicate determinations of each solution. Percent recovery of isoniazid from plasma was 82.70 ± 1.15%. [b] Confidence limits at $p = 0.05$.

Present studies indicated that amides, phenols, heterocyclic amines, alcohols, carboxylic acids, and hydrazines did not produce any color with 9-chloroacridine under the analysis conditions (Table I). Although one cannot exclude the possibility that these other functional groups react with the acridine in typical nucleophilic displacement reactions, only isoniazid produced any colored product under the conditions of the analytical reaction. Therefore, it is concluded that the reaction between isoniazid and 9-chloroacridine under the experimental conditions likely proceeds as depicted in Scheme I.

Determination of Polythiazide in Pharmaceutical Dosage Forms by High-Pressure Liquid Chromatography

R. E. MOSKALYK ˣ, R. A. LOCOCK, L. G. CHATTEN, A. M. VELTMAN *, and MONIQUE F. BIELECH

Abstract □ A method is presented for the quantitative analysis of polythiazide tablets by high-pressure liquid chromatography. The powdered tablets are extracted with methanol, containing quinoline as the internal standard, and assayed by comparison of peak heights after liquid chromatography. The chromatographic conditions employed may be adapted for the determination of many other thiazide and nonthiazide diuretics.

Keyphrases □ Polythiazide—high-pressure liquid chromatographic analysis in pharmaceutical dosage forms □ High-pressure liquid chromatography—analysis, polythiazide dosage forms □ Diuretics—high-pressure liquid chromatographic analysis of polythiazide dosage forms

The NF XIII procedure for the analysis of polythiazide tablets requires a time-consuming TLC separation prior to spectrophotometric measurement of the isolated material (1). A similar approach using column chromatography was proposed recently as the official method; however, vanillin commonly added to tablet formulations of this drug interferes with the assay (2). Other available methods include a polarographic procedure (3) and several techniques involving hydrolysis and colorimetric measurement after diazotization and coupling with compounds such as *N*-(1-naphthyl)ethylenediamine dihydrochloride (4), thymol (5), and potassium guaiacolsulfonate (6).

High-pressure liquid chromatography (HPLC) allows for the direct analysis of polythiazide in pharmaceutical dosage forms not only in the presence of the excipient vanillin but also in formulations containing reserpine. The method reported here is simple, rapid, specific, and free of the analytical problems associated with the aforementioned procedures. Furthermore, the proposed assay is sufficiently sensitive that it can be carried out on individual tablets and therefore can serve equally well for the content uniformity determinations of this diuretic in pharmaceutical dosage forms. The application of this technique to the determination of polythiazide and its major metabolite in urine will be the subject of a subsequent publication.

EXPERIMENTAL

Apparatus—A high-pressure liquid chromatograph[1], equipped with a dual detector system, capable of operating at inlet pressures up to 6000 psig was used. The UV detector (254 nm) was also utilized.

Column—The column was purchased from the instrument manufacturer and consisted of a monomolecular layer of diphenyldichlorosilane bonded to a pellicular packing[2] [0.6 m × 0.3 cm (2 ft × 0.125 in.) o.d.].

Chromatographic Conditions—The chromatographic solvent was methanol–water (35:65 v/v). The temperature was ambient, and the solvent flow was approximately 0.4 ml/min (at an inlet pressure of 200 psig). The precision photometer detector (254 nm) was set at a sensitivity of 0.08 absorbance unit full-scale. The injection volume was 5 μl, and the chart speed was 0.5 cm (0.2 in.)/min.

Materials and Reagents—The chromatographic internal standard was quinoline[3]. Polythiazide reference material[4] was used without further purification. The methanol was ACS grade. All other reagents and solvents were of the best grade commercially available and were used without further purification.

Solutions—*Internal Standard Solution*—The quinoline (230 mg) was dissolved in methanol and diluted with methanol to a final volume of 1000 ml.

Polythiazide Standard Solution—Approximately 20 mg of polythiazide reference material was weighed accurately into a 100-ml volumetric flask. The polythiazide was dissolved in the internal standard solution and diluted to 100 ml with this solution.

Preparation of Standard Curve—Two, four, six, and eight milliliters of the polythiazide standard solution were accurately transferred into four 10-ml volumetric flasks and diluted to volume with the internal standard solution. Three injections (5 μl) of each of these solutions and of the undiluted polythiazide standard solution were made into the chromatographic system. The heights of the peaks were measured, and the ratios of the peak height of the polythiazide to that of the internal standard were calculated for each injection. The average peak height ratio for each dilution was plotted against the quantity of polythiazide in the solution.

HPLC Analysis of Polythiazide in Tablets—Twenty tablets were weighed and finely powdered. An accurately weighed portion, equivalent to one tablet weight, was transferred to a 30-ml glass-stoppered centrifuge tube. Ten milliliters of the internal standard solution was added, and the sample was shaken[5] mechanically for 30 min (for the 2-mg tablets, 20 ml of internal standard solution was added). The sample was then centrifuged[6] at 1500 rpm for 15 min, and three 5-μl injections of the clear supernate were made into the chromatographic system. The ratios of the heights of the peaks were calculated for each injection and then averaged. The quantity of polythiazide in the sample then was determined graphically.

NF XIII Analysis of Polythiazide in Tablets—The three different samples of polythiazide tablets were assayed following the compendial procedure (1).

Colorimetric Analysis of Polythiazide in Tablets—The BP 1973 assay for bendrofluazide[7] tablets (7) was adapted for this determination, the method being essentially that described under content uniformity for polythiazide tablets in NF XIII (1).

RESULTS AND DISCUSSION

Column and Mobile Phase Selection—Preliminary experiments indicated that qualitative separation of many thiazide as well as nonthiazide diuretics could be obtained on the diphenyldichlorosilane-bonded column[2], using methanol–water as the mobile phase. The retention times for 12 thiazide and 10 nonthiazide diuretics under the chromatographic conditions described in the *Experimental* section are given in Tables I and II, respectively.

Benzthiazide	Cl	H	$CH_2SCH_2C_6H_5(\Delta^{3,4})$	4.9

[a] Chromatographic conditions as described under *Experimental.*

These retention times could be varied considerably by changing the proportions of methanol and water in the mobile phase. Very little resolution was obtained using a similar type of column bonded with octadecyltrichlorosilane[8]. Honigberg *et al.* (8) found that some antihistaminic, antitussive, and analgesic drugs were separated better on the phenyl[2] than on the C_{18}[8] column.

In general, sharp symmetrical peaks were obtained, the only exception being triamterene, which gave a relatively broad peak after a comparatively long retention time. The selection of 35% methanol in water as the mobile phase for this work was dictated by the presence of the interfering excipient vanillin in the commercially available tablet formulations. Maximum separation of the polythiazide and vanillin peaks was obtained by employing this ratio of solvents. Under these chromatographic conditions, vanillin showed a retention time of 3.9 min compared to 7.0 min for polythiazide.

Internal Standard—To minimize injection and apparatus errors, a study was undertaken to find a suitable internal standard. Many compounds in Tables I and II with short retention times could have been selected. For example, by using acetazolamide (3.3 min) as the internal standard, a highly satisfactory quantitative relationship was obtained when analyzing pure polythiazide. However, since vanillin is extracted along with the polythiazide from the powdered tablets and since it is eluted after 3.9 min, a significant overlap of peaks occurs.

After screening a large number of compounds, quinoline (retention time 10.0 min) was found to be an excellent internal standard.

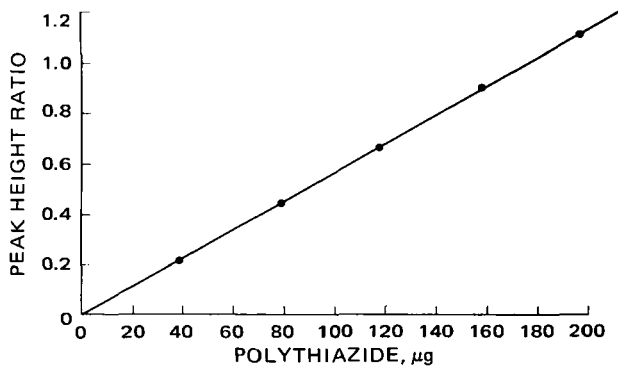

Figure 1—*Standard curve for polythiazide with quinoline as the internal standard.*

[8] Bondapak C_{18}/Corasil, Waters Catalog No. 98159.

Isoquinoline and carbazole, with retention times similar to quinoline, could have been employed, but their peaks were not as well developed.

Response and Linearity—The response *versus* concentration curve for polythiazide demonstrated that sample concentration was linear with peak height and that elution times were reproducible. Peak height rather than peak area was chosen as the method of measurement because previous studies (9, 10) had shown that peak height varies less with fluctuations in inlet pressure (flow rate) than does peak area.

Five different concentrations of polythiazide, ranging from 40 to 200 μg/ml, were injected. Figure 1 shows the linear relationship resulting from plotting varying concentrations of polythiazide against the ratios of the heights of the polythiazide peaks to those of the internal standard.

Analysis of Dosage Forms—Replicate assays were performed, as described under *Experimental,* on three different commercially available polythiazide preparations. Figure 2 illustrates a typical chromatogram obtained from each formulation. As is evident from the chromatograms, vanillin is separated sufficiently from polythiazide and does not interfere in the analysis. The 2-mg tablets (Product II) and the 1-mg tablets with reserpine (Product III) contain a second excipient which is extracted into the methanol, but it is also eluted well before the polythiazide and likewise shows no interference. Reserpine is present in a very low concentration in Product III; this fact, coupled with the limited solubility of reserpine in methanol, likely explains why it is not detected in the chromatogram and, accordingly, why it does not interfere with the analysis of polythiazide.

The assay results for three formulations are given in Table III.

Table II—Chromatographic Behavior[a] of Some Nonthiazide Diuretics

Compound	Retention Time, min
Acetazolamide	3.3
Amisometradine	3.9
Chlorthalidone	4.4
Clopamide	4.3
Dichlorphenamide	3.5
Ethacrynic Acid	3.1
Ethoxzolamide	6.9
Furosemide	3.1
Quinethazone	4.1
Triamterene	11.0[b]

[a] Chromatographic conditions as described under *Experimental.* [b] Very broad peak. Compound is only very slightly soluble in methanol.

Table III—Comparative Analyses of Three Commercially Available Polythiazide Tablet Preparations

Product	Components	Analyses, % of Labeled Claim			
		NF XIII	Colorimetric[a]	Manufacturer's Data	Proposed Method (HPLC)[a]
I[b]	Polythiazide, 1 mg	113.2	106.4	105.0[c]	110.2 ± 0.4
II[b]	Polythiazide, 2 mg	113.0	101.8	105.0[c]	108.1 ± 0.7
III[d]	Polythiazide, 1 mg Reserpine, 0.25 mg	—[e]	—[e]	105.5[f]	112.0 ± 0.6

[a] Average of four determinations. [b] Renese, Pfizer Co. Ltd. [c] TLC method. [d] Renese-R, Pfizer Co. Ltd. [e] Erratic results, reserpine interferes. [f] Spectrophotometric method.

The values obtained by the NF XIII procedure and by a colorimetric method are also given, along with the values received from the manufacturer for these lot numbers; the proposed method gives results that are slightly lower than the NF XIII procedure but somewhat higher than those found by the manufacturer. The standard deviations are quite comparable to those normally obtained with other related analytical techniques.

This procedure was repeated for Product I, using 10 ml of the internal standard solution containing 0.20 mg of added polythiazide reference material. The absolute recovery of the added polythiazide was calculated to be 0.212 ± 0.003 mg based on four replicate determinations.

CONCLUSION

HPLC provides a convenient and efficient method for the quantitative determination of polythiazide in its dosage forms. There was no interference from excipients in the products examined, so no additional extraction or separation procedures are required. The method is rapid and sensitive enough to be used for single-tablet assays.

Although the detailed chromatographic conditions were not explored for the quantitative determination of the other thiazide and nonthiazide diuretics, this method may provide a suitable starting point for the estimation of these diuretics in dosage forms and, possibly, in biological fluids.

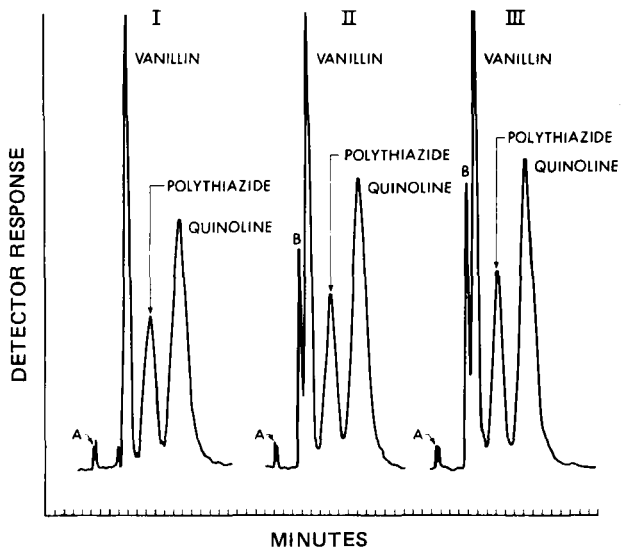

Figure 2—*Typical chromatograms of polythiazide dosage forms. Key: I, polythiazide 1-mg tablets; II, polythiazide 2-mg tablets; III, tablets containing 1 mg of polythiazide and 0.25 mg of reserpine; A, sample injection; and B, unknown excipient. Sieve Cuts as Monodisperse Powders in Dissolution Studies

DANA BROOKE

Abstract □ *Dissolution profiles are calculated for sieve cuts of varying width based on a derived equation, which assumes diffusion rate-limited dissolution under sink conditions from spherical particles. It is shown that even the narrowest of sieve cuts may vary from cube root law expectations by as much as 3%, depending on the distribution of particles across the cut. Much smaller deviations from the cube root law occur when the weight distribution of diameters is constant across a sieve cut. It is concluded that when experimental data are treated on the assumption that sieve cuts act like monosized powders, errors generally will be acceptable except in cases of critical tests of dissolution rate theory. In those cases, more information about the powder distribution should be given.*

Keyphrases □ Sieve cuts—dissolution studies, assumption of monodisperse powders □ Dissolution—error introduced from assumption of monodisperse powders in sieve cuts □ Particle size—sieve cuts, monodisperse powders from sieve cuts, introduction of error □ Powder distribution—sieve cuts, assumption of monodisperse powders, introduction of error in dissolution testing

Sieve cuts from powders have often been used as substrates in dissolution experiments. The idea that a narrow distribution of particle sizes can be treated as a monodisperse distribution seems to be fairly well established (1). Some workers have staked quantitative treatments of experimental data on the correctness of the assumption that sieve cuts from powders can be treated like monosized powders.

For example, Niebergall and Goyan (2) calculated dissolution rate constants from data on 20–30-mesh salicylamide and 80–100-mesh benzoic acid by extension of the Hixson–Crowell (3) cube root law. In another paper, Niebergall *et al.* (4) suggested that particles under rapid agitation followed a square root law on the basis of the dissolution behaviors of sieve cuts from various powders. Later, Goyan (5) used some of their data (4) to support a Danckwerts' penetration model for dissolution of particles under rapid agitation. Recently, Pothisiri and Carstensen (6) tested an equation for the nonsink dissolution of monosized particles against experimental data. They used data from their own laboratory and from Hussain (7) on the dissolution of narrow cuts from powders.

Since dissolution rate theory is being proposed or tested on the basis of experimentation with sieve cuts from powders, it seemed worthwhile to examine the validity of the assumption that sieve cuts behave like monodisperse powders. This paper does not consider errors that might arise in dissolution studies from other popular assumptions; for example, when the hydrodynamics of the experimental system do not conform to theory, when dissolution is anisotropic, when particles are not spherical, or when particles agglomerate. This paper seeks to define the limits on errors that might occur in the treatment of dissolution data solely because the particles within a sieve cut are not all the same size.

Dissolution profiles are calculated for narrow cuts of spherical particles wherein the probability frequency, on a weight basis, of diameters is some linear function of particle size. These profiles are compared with that expected for a monodisperse powder in which the diameter is an average of the largest and smallest diameters possible in the sieve cut. Diffusion rate-limited dissolution under sink conditions is assumed.

As will be seen, the assumption that a sieve cut behaves like a monosized distribution should lead to no more than about 3% error, as reflected in a cube root law slope, if the narrowest sieve cuts are used. Wider cuts lead to greater inherent errors. If the frequency of occurrence of diameters on a weight basis is fairly constant across the cut, errors will tend to be much smaller than if the frequency changes sharply, as

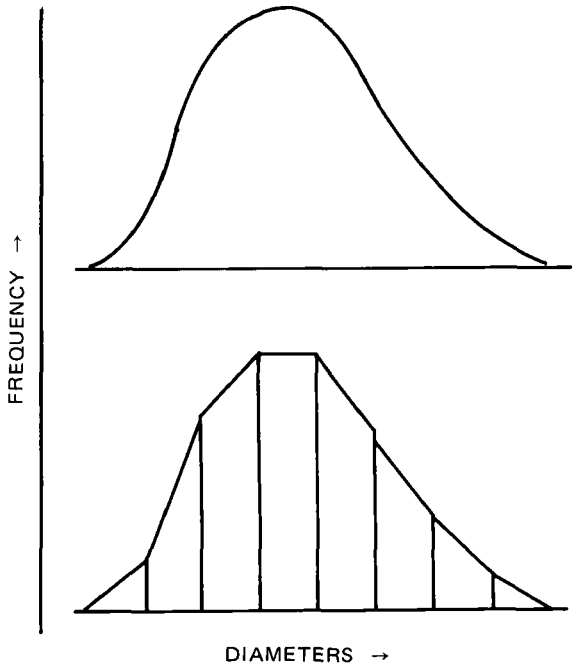

Figure 1—*Approximation of a continuous powder distribution as a series of sieve cuts.*

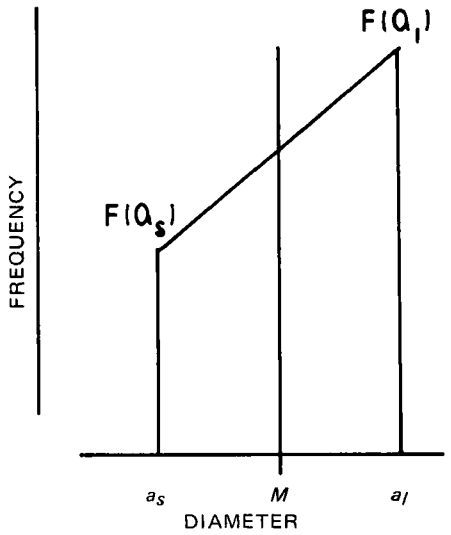

Figure 2—*Representation of a sieve cut from a powder as a separate distribution in which the probability frequency is taken as a linear function of particle size. See text.*

might be the case in a cut from near the tail of a powder.

THEORY AND CALCULATIONS

Consider a powder containing spherical particles of diameters a_0, which are distributed, on a weight basis, according to a continuous probability frequency $f(a_0)$. Let there be a series of cuts approximating the distribution (Fig. 1), and assume that $f(a_0)$ is a linear function of a_0 in each cut (Fig. 2). Once a cut is segregated from the parent distribution, it must be considered a separate distribution with characteristics determined by the original powder.

If the cut is not too wide, it is not unreasonable to consider $f(a_0)$ linear with a_0. However, the derivations of dissolution profiles do not depend on this simplification, since derivations based on considerably more complicated distributions are possible (8, 9). The assumption of linearity does allow a much more general treatment of dissolution profiles than might otherwise be possible.

In Fig. 2, the smallest and largest possible diameters (a_s and a_l, respectively) are averaged to gain a mean diameter M. It is convenient to express[1] a_s as sM and a_l as lM where $s + l = 2$. The probability frequency $f(a_l)$ of particles of diameter a_l is conveniently expressed in terms of $f(a_s)$ by $f(a_l) = Rf(a_s)$. The probability frequency $f(a_0)$ of diameters a_0 can now be derived in terms of a_0, R, s, l, and M based on the recognition that the slope of the linear function $f(a_0)$ is:

$$\text{slope} = \frac{Rf(a_s) - f(a_s)}{lM - sM} \qquad \text{(Eq. 1)}$$

and that the area under the curve is unity so that:

$$\text{area} = 1.0 = (lM - sM)f(a_s) + \frac{1}{2}(lM - sM)[Rf(a_s) - f(a_s)] \qquad \text{(Eq. 2)}$$

Thus, the probability frequency of particle sizes on a weight basis is:

$$f(a_0) = \frac{2[l - Rs + (R - 1)a_0/M]}{(R + 1)(l - s)^2M} \qquad \text{(Eq. 3)}$$

The contribution dw_0 of particles of size a_0 to the total initial weight w_0 can be expressed as:

$$dw_0 = w_0 f(a_0)da_0 \qquad \text{(Eq. 4)}$$

The number dn of particles of size a_0 can be calculated by dividing dw_0 by the weight of a single particle $\pi p a_0^3/6$, where p is particle density:

$$dn = \frac{w_0 f(a_0)da_0}{\pi p a_0^3/6} \qquad \text{(Eq. 5)}$$

Dissolution profiles for sieve cuts can now be derived using the same philosophical approach used in deriving an expression for the dissolution of powders that follow a log-normal distribution (9, 10).

The diameter a_τ of a particle exposed to a medium for some function τ of time can be expressed by:

$$a_\tau = a_0 - \tau \qquad \text{(Eq. 6)}$$

where τ is $2kC_st/p$ and k is a dissolution rate constant, C_s is solubility, and t is time. This notation is essentially that of Carstensen and Musa (11). The equation is based on assumptions of diffusion rate-limited dissolution under sink conditions, isotropic behavior, and a particle-size-independent solubility.

As long as particles that were initially of size a_0 exist (that is, if $\tau < a_0$), the particles will grow smaller but the number of those particles dn will not change. Therefore, the contribution dw_τ to the weight undissolved of particles of size a_τ can be calculated by:

$$dw_\tau = \frac{\pi p a_\tau^3}{6}dn = \frac{\pi p}{6}(a_0 - \tau)^3 dn \qquad \text{(Eq. 7)}$$

Substitution for dn using Eq. 5 and for $f(a_0)$ using Eq. 3 completes the derivation, except for an integration, to achieve w_τ. As far as the integration is concerned, τ is a constant. The integration is over all of the initial particle sizes a_0 of particles remaining because dn is based on initial sizes a_0. Thus, for $\tau \le a_s = sM$, the integration is from $a_s = sM$ to $a_l = lM$. After the smallest particles begin to disappear, the integration is from τ to a_l. That is, after $\tau > a_s$, the smallest nonzero particle remaining at τ was initially of size a_0 such that $a_0 - \tau \to 0$. Thus, it can be shown that the weight fraction undissolved (w_τ/w_0) after some τ is:

$$w_\tau/w_0 = [2/(1 + R)(l - s)^2] \times \left[\begin{array}{l}(l - Rs)(l - t) + (R - 1)(l^2 - t^2)/2 \\ - 3[(R - 1)(l - t) + (l - Rs)\ln(l/t)]\tau/M \\ + 3[(R - 1)\ln(l/t) + (l - Rs)(l - t)/lt]\tau^2/M^2 \\ - [(R - 1)(l - t)/lt + (l - Rs)(l^2 - t^2)/2l^2t^2]\tau^3/M^3\end{array}\right] \qquad \text{(Eq. 8)}$$

where $t = s$ when $\tau \le sM$ and $t = \tau/M$ when $\tau > sM$.

Dissolution profiles for sieve cuts like those shown in Fig. 3 (R =

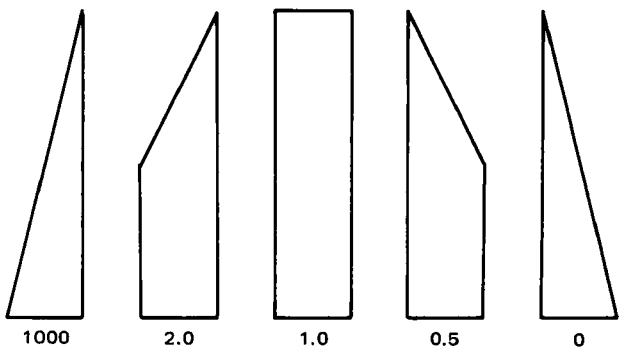

Figure 3—*Representation of various narrow powder distributions for which dissolution profiles are calculated. The plots are similar to the one in Fig. 2, and values for* R *are indicated. See text for additional details.*

[1] It should be obvious that $2 \ge l > s \ge 0$ and that Eq. 1 and others in these derivations are undefined for $s = l$. It further should be recognized that since $2 - l = s$, it is not strictly necessary to use both parameters in all equations.

	270/400	

0, 0.5, 1.0, 2.0, and 1000) were calculated using a computer[2]. Weight fractions undissolved (w_τ/w_0) are given in Table I as a function of τ/M. The choice of a relative time value (τ/M) allows direct comparisons of all dissolution profiles. Also presented in Table I is a dissolution profile for a monosized powder of diameter M, *i.e.*, a powder that exactly follows the cube root law. This profile was calculated using Eq. 9, where the slope β is chosen to be unity (10):

$$(w_\tau/w_0)^{1/3} = 1 - \beta(\tau/M) \qquad \text{(Eq. 9)}$$

The initial slope β for each calculated profile is also given in Table I based on Eq. 9.

The values for s were chosen to be 0.75, 0.83, and 0.91 because these values represent the three narrowest sieve cuts possible when using standard sieves as described in USP XVIII (12). Table II relates these values of s to certain possible sieve cuts.

DISCUSSION

A brief comparison of the dissolution profile for a powder that follows the cube root law, with profiles calculated for various sieve cuts (Table I), will indicate that it is probably acceptable to treat sieve cuts as monosized powders for all but the most critical work. The data also show that the approximation is better for narrower sieve cuts.

The errors that might occur when the approximation is applied to sieve cuts where s = 0.91 are shown graphically in Fig. 4. For distributions that might come from the large or small particle tail of a powder (R = 0 or 1000), the errors are greatest and exceed 10% as the weight fraction remaining falls below 10%. The characteristics of the sieve cut, as reflected by R, influence both the size of the errors expected and their direction (sign). It is clear from Fig. 4 that when the probability frequency is constant (R = 1.0), the dissolution profile for a sieve cut approximates that of a monosized powder excellently. When R = 1.0, the error through 90% dissolution is generally less than 0.2% for the narrowest sieve cut (s = 0.91). A graph of errors when sieve cuts with s = 0.83 are compared to a monodisperse powder would look identical to Fig. 4, except that all errors would be twice as large as those in Fig. 4.

Another way of judging the degree to which a sieve cut approximates the cube root law would be to examine the values for the slope (β) when the data are fitted to Eq. 9. In the ideal case, β will be unity. When the slopes were calculated on the initial portion of the profiles for cuts where s = 0.91, the calculated values ranged from 0.9725 to 1.0328. When all points in the profiles were subjected to least-squares regression, the values for β ranged from 0.9680 to 1.0252.

The exact value calculated for the slope depends on the number of data points and the extent to which dissolution is followed, because all cube root plots based on dissolution of sieve cuts will show some curvature. In some cases the curvature may be too small to identify because of random experimental errors. Nevertheless, it is clear that cuts from the large particle tail of a powder (R = 0) will tend to dissolve faster than might be expected while a cut from the small particle end (R = 1000) will dissolve more slowly than expected.

It can be said that dissolution data based on the narrowest pos-

sible sieve cut (s = 0.91) might contain up to 3.0% error if the treatment of results included the assumption that sieve cuts are equivalent to monosized powders. If, however, sufficient particle-size data are presented with the dissolution data to show that R is close to or equal to 1.0, then the errors could be considered much less than 1.0%. For the next widest sieve cut (s = 0.83), the errors in a cube root law slope could be as great as 6.0%. Errors of 7–10% would be possible if wider sieve cuts (s = 0.75) were treated according to the cube root law. If, on the other hand, the particle sizes within a sieve cut could be described, then an exact equation like Eq. 8 might be useful.

It is concluded that when dissolution data are based on sieve cuts with no further definition of powder sizes and the assumption of a monosized powder is used in the data treatment, then the results may be in error by as much as 3% even for the narrowest sieve cuts. For wider sieve cuts, errors of 6 or even 10% should not be ruled out. These errors would occur solely from the assumption that sieve cuts behave like monosized powders.

ethylene oxide. Late in 1972, an ad hoc committee was formed within Z79 made up of industrial, regulatory, and academic representatives. One charge to this committee was to establish uniform analytical test procedures for ethylene oxide, ethylene glycol, and 2-chloroethanol in plastic materials. The present report deals with the first part of this objective: the evaluation of methods for residual ethylene oxide analysis.

Methods for residual ethylene oxide analysis fall into four categories: colorimetric (1), titrimetric (2), gravimetric (3), and GC (4–12). A round-robin study was designed by the ad hoc committee to evaluate four of these methods. The major objective of this round robin was not to point out a single method to be used by the entire industry but rather to point out which method or methods could be used to check the validity of an in-house method. Six laboratories participated[1].

EXPERIMENTAL

Methods—Four methods of analysis were studied: a gravimetric method (3) and three GC approaches (9–12). The main difference between the GC methods is sample workup. The vacuum extraction technique (10) vaporizes the ethylene oxide and traps it in a cold coil before injection into the gas chromatograph. The head-space method (11) extracts the ethylene oxide by vaporizing it into the head space of an enclosed vial. An aliquot of the head-space gas is injected into the gas chromatograph. The vial is purged with nitrogen, and the process is repeated until all of the ethylene oxide is extracted from the sample.

Both the vacuum extraction and the head-space methods exhaustively extract the ethylene oxide. In the acetone extraction technique (9, 12), the ethylene oxide in the sample partitions between the sample and the acetone. An aliquot of the acetone solution is injected into the gas chromatograph. This extraction is not generally considered to be exhaustive unless the sample dissolves in the acetone.

Materials—In some cases, analytical results depend on the material being analyzed; *i.e.*, not all of the ethylene oxide may be extracted into acetone due to a highly polar sample. The ad hoc committee discussed this matter at length. The final decision was to use polyvinyl chloride tubing[2]. Specifically, the material was 0.3 cm (0.125 in.) i.d. × 0.6 cm (0.25 in.) o.d. [0.15-cm (0.06-in.) wall]. The material was to contain approximately 5000, 1000, 500, 100, or 10 ppm of ethylene oxide.

The tubing was cut into 2-cm lengths and then into quarters along the length. These quarters weighed about 0.25 g. They were placed into a small glassine envelope and sterilized with pure ethylene oxide gas in a small laboratory sterilizer[3]. At predetermined times during degassing, samples were removed from the sterilizer and the contents of each envelope were placed into 7-ml vials with aluminum-lined septa caps. The vials were then stored in dry ice.

All samples were prepared at one location. Each laboratory received enough material to perform six replicate analyses at each level of ethylene oxide. The samples were shipped by air in insulated dry-ice chests and were received within 24 hr. Samples stored in this manner were shown to be stable for at least 18 days.

The laboratories were instructed to analyze the samples immediately upon opening a vial. All laboratories handled the samples in the same manner as follows. A vial was removed from the dry-ice chest, allowed to thaw for 5 min, and opened. One piece was weighed immediately for the gravimetric method. A second piece was placed in a tared vial of acetone for the acetone extraction method. Another was placed into a tared empty vial for head-space analysis. The final piece was weighed into the stoppered vacuum extraction flask.

The head-space and vacuum extraction methods were run concurrently, followed by the acetone extraction method. The gravimetric samples were stored in an open, dust-free area and weighed

to constant weight. All of these procedures were required to ensure the four pieces in a vial would be at the same level of ethylene oxide when analyzed. In this way a comparison of the four methods was possible. It was assumed that the vial-to-vial variability would be large since, in effect, these samples are different although at the same nominal level of ethylene oxide. A total of 4 weeks was allowed for the analyses.

RESULTS AND DISCUSSION

Tables I–VI show the raw data reported by the six laboratories. The laboratories are only identified by number, and the order of numbering does not correlate with the order in Footnote 1. Lab-6 only performed the head-space and acetone methods, and each reported result is the average of two determinations. Lab-3 did not perform the required six replicates at the lower levels of ethylene oxide.

Upon examining the data, it is obvious that the original hypothesis of a large laboratory-to-laboratory variability was correct, although all laboratories found the five ethylene oxide levels to be in the same order of magnitude for all methods. Another obvious fact is that the correlation between the GC methods and the gravimetric method breaks down below the highest levels of ethylene oxide studied.

Since most statistical treatments depend on equal replication and similar treatments, the data from Lab-6 could not be included in the statistical evaluations. For this same reason, only the two highest levels from Lab-3 were included. Since the noncorrelation of the gravimetric method is obvious, this method was not included in the statistical evaluation. These exclusions somewhat simplified the data, but a monumental statistical problem remained.

Three approaches were taken in an attempt to make some statistically significant statements concerning the data. The data averages were graphed, subjected to analysis of variance, and subjected to a nonparametric ranking treatment.

Graphing of Averages—An accepted method of testing data interactions is the graphing of the averages. The following assumptions were made: (*a*) comparison between methods can only be

Table VI—Comparison of Methods by Lab-6

done within an ethylene oxide level, and (*b*) all samples within a level are identical or at least less variable than the variability between methods.

For each set of data, at each level, a method average was computed for each laboratory. These averages were then plotted *versus* the method on an arbitrary scale (Figs. 1–5). There were no obvious trends, *i.e.*, one method was not always low or high. What is obvious is that some laboratories were able to get consistently good correlations between methods while others were not.

The next step was to take the method average for each level of ethylene oxide, regardless of the laboratories, and plot these values *versus* method (Fig. 6). These data show that the methods gave similar results; however, the acetone extraction technique usually gave higher results than the other two methods. This result could be due to the loss of ethylene oxide in both the vacuum and headspace methods. Conversely, acetone impurities or other factors may cause high ethylene oxide results in the acetone method. The important point to note is that sample-to-sample and laboratory-to-laboratory variability was high, so only very general trends can be noted.

Analysis of Variance—Analysis of variance allows one to test statistically the significance of differences between sets of data by computing ratios of variance (*F* ratio test) and comparing these to critical values found in tables. The following qualifications were made in testing the data: (*a*) levels were tested individually, (*b*) all results reported as ND were assumed to be zero, and (*c*) where a data point was missing (only in a few cases), the method average at that level was substituted. With these qualifications, the data were coded and fed into a computer for processing. Table VII gives the results.

A significant difference among methods was found at the very high and very low levels of ethylene oxide. In the area where the industry generally works (1000–50 ppm), no significant difference was found among methods.

A significant difference was found among all laboratories at all levels. This result was expected since samples were "different" and the time of analysis was not the same. However, the possibility that the laboratories made errors in standardization cannot be ruled out. In this case, all results would be internally consistent but a significant difference in the results from the laboratories would occur.

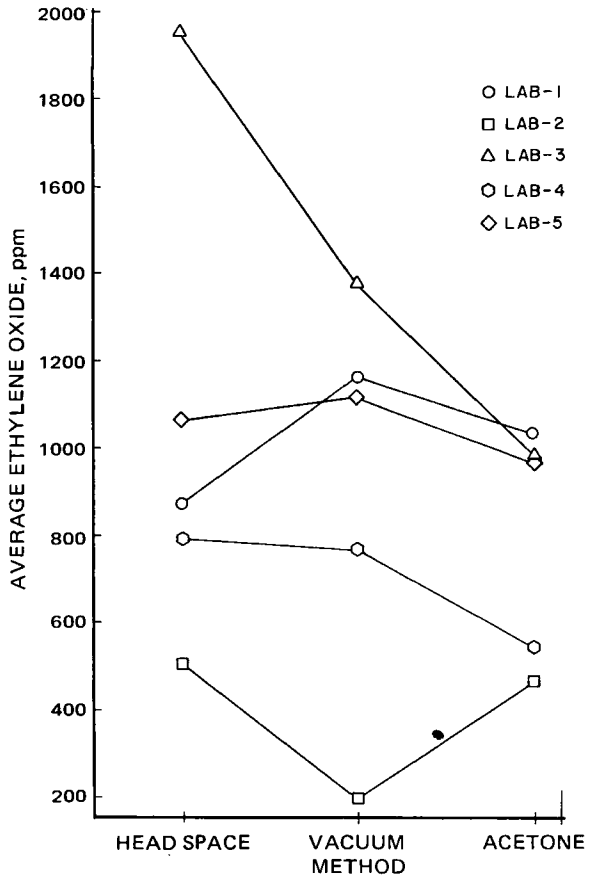

Figure 2—*Level 2 interaction.*

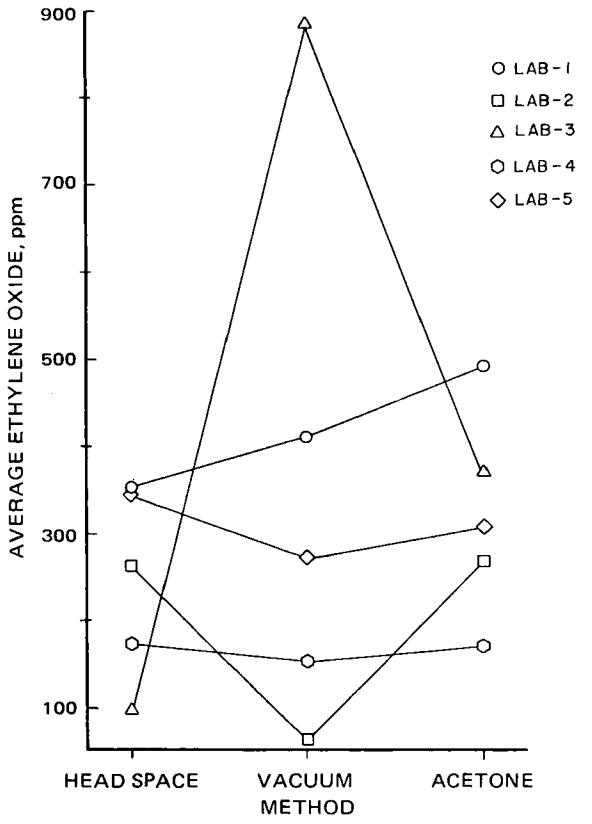

Figure 3—*Level 3 interaction.*

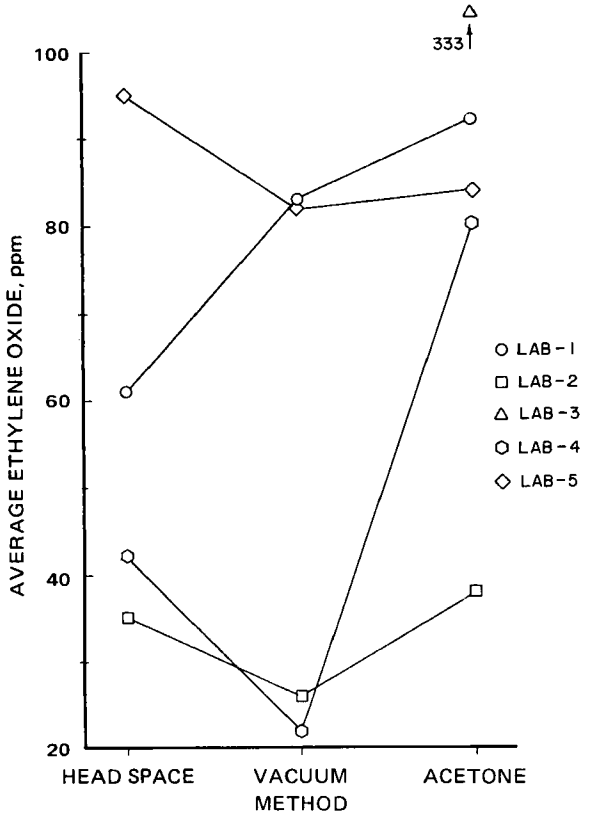

Figure 4—*Level 4 interaction.*

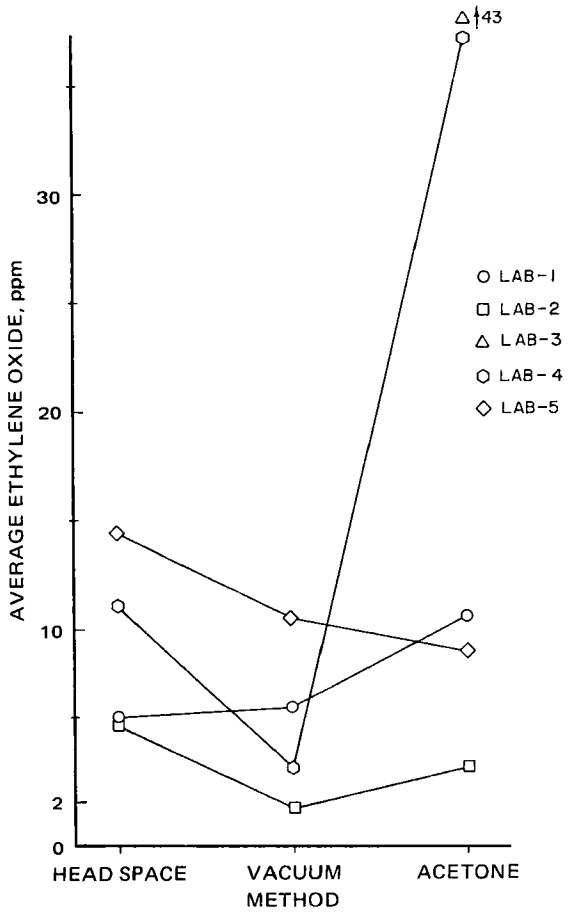

Figure 5—*Level 5 interaction.*

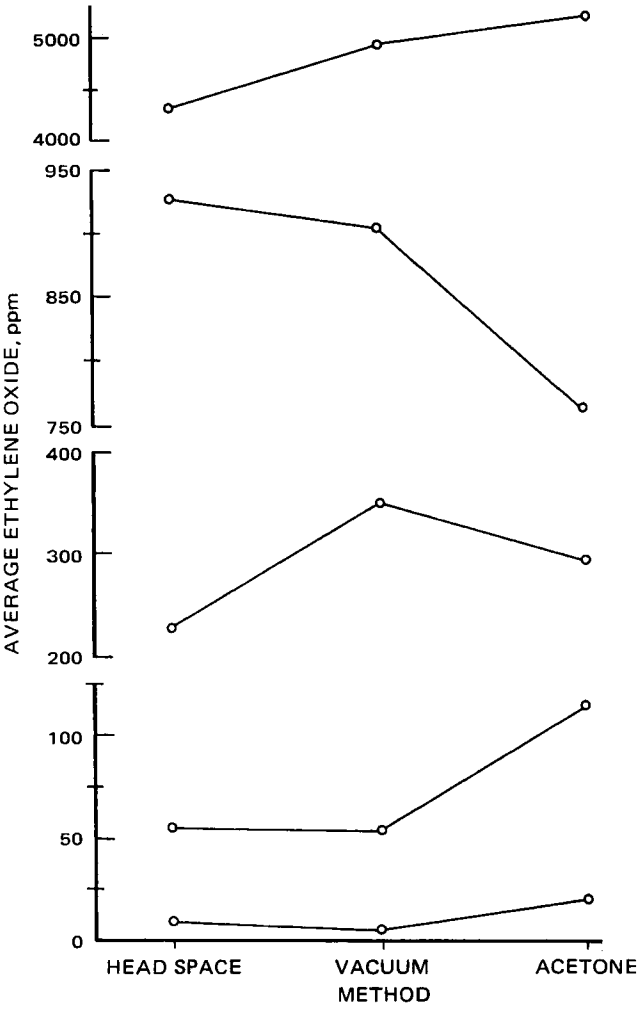

Figure 6—*Method average.*

No significant difference was found among the six replicates within a method in each individual laboratory. This finding is surprising, since there appears to be large differences among replicates. They are, after all, different samples taken from different parts of the sterilizer. This point was conceded at the start of the study, since the only samples thought to be the same are the four samples in the same vial used for the four methods. This data analysis, however, indicates that the differences among samples at a particular level are not significant. The overall interaction showed no significant differences among laboratories, replicates, and methods.

This data analysis indicates the three methods give comparable results and supports the claim that the methods are equivalent in the hands of an experienced operator.

Nonparametric Ranking—Ranking is a rapid statistical procedure based on the assignment of serial numbers, or ranks, to the experimental observations arranged in order of their magnitude. Conclusions are drawn about the significance of differences between categories under study from the sums of the assigned ranks. Such methods are called nonparametric or distribution free. They are simple to compute and require few assumptions about the nature of the sampled population (13).

Results of the ranking of data indicated there was no significant difference among the methods overall. However, some slight differences were detected within each laboratory. For example, Lab-1 found the head-space method to be lower in general than either the vacuum or acetone extraction method (possibly the vials used leaked during heat up), and Lab-2 found the vacuum method gave generally lower results than either of the other two methods (ethylene oxide may have been lost through a warm trapping coil).

These three data treatments are by no means the only statistical

[a] + indicates a significant difference; — indicates no significant difference.

treatments which could be applied to the data, but other treatments probably would draw the same conclusions.

Regardless of the results of this study, one must deal with realistic samples on a daily schedule, and each method has its strong and weak points. The following is a subjective evaluation of each technique studied in the round robin.

The gravimetric method presents the ultimate in simplicity, since it does not use complex apparatus or equipment. However, it is a nonspecific method. Therefore, it also measures other volatile residues such as carbon dioxide or dichlorodifluoromethane[4] from the sterilizing gas and absorbed water as ethylene oxide. The tendency is toward positive errors.

Acetone extraction GC is a relatively simple procedure with which most laboratories have little trouble. However, acetone has impurities which could interfere in the analysis, particularly at low levels. The solvent and plasticizers extracted reduce the life of GC columns. Unless the sample is swollen or dissolves in acetone, one cannot be certain that all of the ethylene oxide has been extracted. Therefore, acetone extraction is not a universal method.

The head-space method is rather simple to perform, and it is very fast and sensitive. The GC columns last indefinitely since no solvents are injected. It is a universal method. Nevertheless, errors may occur due to leaky vials or syringes. Also reabsorption of ethylene oxide on the sample may occur if the sample is allowed to cool.

The vacuum extraction method is a universally applicable method and gives long GC column life and extreme sensitivity since sample size is unlimited. It has the disadvantage of using complex equipment, which could be subject to leaks and, therefore, low results. It also requires more operator time than the other methods.

CONCLUSIONS

In general, it may be concluded from this work that the three GC methods give comparable results in the hands of experienced operators. The correlation between the gravimetric and the GC methods breaks down below the highest levels of ethylene oxide studied. At the lower levels of ethylene oxide, the gravimetric method seems to give very high results overall. At higher ethylene oxide levels than were studied here, *i.e.*, above 0.5% ethylene oxide, the correlation possibly could be better. One should be cautious in its use, however, due to the large errors possible at low levels.

In general, for polyvinyl chloride, the use of whichever GC method feels the most comfortable is recommended. If GC is not available, then the method of choice should be checked against any or all of the GC methods used in this study. Also, since this study pointed out the large variability that could be expected between laboratories and samples, care must be exercised in choosing a statistically significant number of samples when validating an in-house method.

Facile Preparation of 6-Chloro-9-amino-2-hydroxyacridine, a Urinary Metabolite of Quinacrine and Quinacrine Mustard

K. C. TSOU ˣ, S. LEDIS, E. STEIGER, and R. NIETRZEBA

Abstract □ 6-Chloro-9-amino-2-hydroxyacridine was found to be a metabolite of both quinacrine and the antimalarial alkylating agent quinacrine mustard. Its structure was confirmed by a one-step reaction of quinacrine with 48% hydrobromic acid. The presence of this compound as a metabolite of quinacrine mustard suggests a possible *in vivo* activation mechanism for its antitumor activity and a pharmacological basis for its toxicity to the liver. *In vitro* experiments showed that this new compound does react with chromosomes and, therefore, can be both a useful chromosome stain and an intercalating agent.

Keyphrases □ 6-Chloro-9-amino-2-hydroxyacridine—synthesis from quinacrine □ Quinacrine and quinacrine mustard metabolite—synthesis of 6-chloro-9-amino-2-hydroxyacridine from quinacrine

For the investigation of *in vivo* alkylation mechanisms related to cancer chemotherapy, the use of bisbenzimidazole fluorescent alkylating agents was studied (1, 2). Since quinacrine mustard (I*b*) is a known alkylating agent possessing both fluorescence and antitumor activity (2), it was of interest to study its metabolism. Although the design of I*b* was based on the activity of quinacrine (I*a*) in mouse tumors (3), no fluorescence uptake was observed in tumors tested with I*b* or I*a*. In rats treated with I*b*, there was extensive liver damage, resulting in death. Urine samples collected from these rats contained the same fluorescent metabolite, 6-chloro-9-amino-2-hydroxyacridine (II).

TLC and other data supported the identity of the metabolite found in quinacrine-treated rats, and it is now confirmed by a facile synthesis from quinacrine. Its presence was previously suggested (4) in a reaction of I*a* with concentrated hydrochloric acid[1]. Although several *in vivo* studies[2] (5–7) also suggested that this compound could be a metabolite of quinacrine, the antimalarial properties of II are not known.

EXPERIMENTAL

Animal Study—Compound I or II was dissolved in the medium and fed intravenously to Lewis–Wistar rats; urine samples were collected for 24 hr. The urine samples were freeze dried and analyzed by TLC on a silica gel plate [chloroform–methanol (1:1)]. In both samples, a fluorescent green-yellow (R_f 0.58) spot could be seen in addition to other tailing products. Other solvent systems were unsatisfactory. Two groups of experiments were run in triplicate, and no I (R_f 0.45) or II (R_f 0.74) was seen. An authentic synthetic sample produced a spot with the same R_f value.

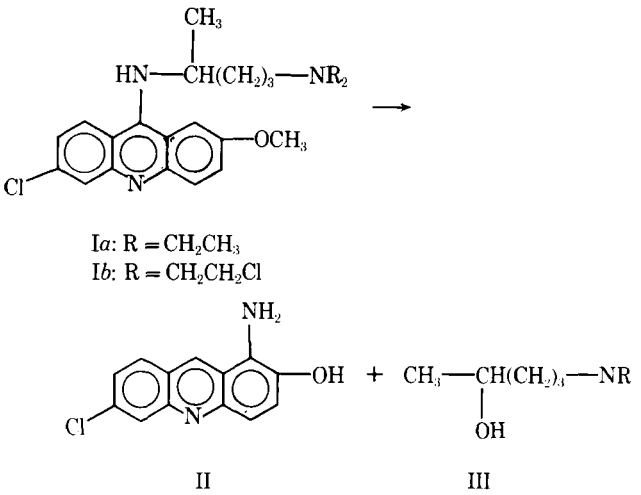
Preparation of 6-Chloro-9-amino-2-hydroxyacridine—A mixture of 5.0 g of quinacrine hydrochloride and 150 ml of 48% hydrobromic acid was refluxed overnight. Upon cooling, the yellowish-orange precipitate was collected and allowed to dry for 3 hr, yielding 3.2 g. Recrystallization from alcohol gave pure II as a light-yellow powder, 2.8 g (88%). The NMR spectra obtained in D_2O showed the loss of the alkyl, methylene, and methoxy protons of I. The IR spectra also showed the loss of methylene protons. The UV spectra showed an absorption at 272 nm, and the fluorescence emission was at 485 when excited at 435 nm.

Reaction of II with Chromosome Preparation—This new derivative was tested in a standard procedure of chromosome staining to compare it with quinacrine or quinacrine mustard. The resulting chromosomes were stained uniformly with no banding. The details will be reported elsewhere (8).

RESULTS AND DISCUSSION

The finding that II is a metabolite of both I*a* and I*b* demonstrated that both I*a* and I*b* could have been degraded *in vivo* to this compound. Therefore, both compounds could probably be biochemically converted *in vivo* by a hydroxylase-mediated mechanism, as shown in Scheme I.

There are ample examples in the literature to support the demethylation of the phenolic compound, even though the degradation of a long chain from an aromatic substituted amine is not known. Therefore, the final support for this mechanism will have to await the isolation of 4-hydroxypentyl nitrogen mustard (III) or another related product. The present data illustrate that the study of alkylation at the biological level is important and that such in-



Scheme I

[1] Reference 4 reported that treatment of atabrine with concentrated hydrochloric acid at 120–125° gave a mixture of 9-amino-6-chloro-2-methoxyacridine and 9-amino-6-chloro-2-hydroxyacridine. However, no proof was given and no attempt was made to separate the mixture.

[2] Based on polarographic evidence, 9-amino-6-chloro-2-hydroxyacridine and methoxy were suggested to be present in urine.

formation can be obtained with fluorescent alkylating agents (1). In addition, the *in vivo* activation mechanism for I*b* may account for the divergent physiological results of numerous other analogs (10).

Interactions of Acetylcholine Mustard with Acetylcholinesterase

PATRICIA M. HUDGINS and JAMES F. STUBBINS [x]

Abstract □ The hydrolysis of acetylcholine and acetylcholine mustard by acetylcholinesterase was compared over a substrate concentration range of 1–10 m*M*. Reactions were allowed to proceed for 2 min at 25°. Results of these experiments reveal that the substrates have similar affinities for the enzyme, whereas the maximum velocity for the hydrolysis of acetylcholine mustard was significantly lower than for acetylcholine. These findings suggest that acetylcholine mustard has the ability to inactivate acetylcholinesterase.

Keyphrases □ Acetylcholine and acetylcholine mustard—hydrolysis by eel electroplax acetylcholinesterase □ Acetylcholinesterase—hydrolysis of acetylcholine and acetylcholine mustard

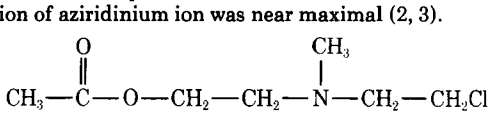
The synthesis of acetylcholine mustard [2-(chloroethylmethylamino)ethyl acetate] (I) was first reported by Hanby and Rydon (1). It was demonstrated that acetylcholine mustard can cyclize in buffered aqueous solutions to form an aziridinium ion (II) with alkylating ability (2, 3). This aziridinium ion is a close structural analog of acetylcholine.

In isolated muscle systems, it was found that acetylcholine mustard had about one-fifth the agonist potency of acetylcholine on the muscarinic receptors of the rat jejunum preparation or the nicotinic receptors of the frog rectus abdominis preparation (3). During a 1- or 2-hr exposure of the jejunum segments to either acetylcholine (1.0×10^{-4} *M*) or acetylcholine mustard (1.0×10^{-4} *M*), the contractions slowly declined; after washing, response to freshly applied acetylcholine was inhibited compared to control values. The decline in response was greater in the case of acetylcholine mustard, and the tissue did not fully recover even upon prolonged washing. Although the observed inhibition of response by acetylcholine and some of the effect of acetylcholine mustard could be accounted for by desensitization of receptors, the long-acting inhibition of the mustard was attributed to an irreversible inhibition brought about by alkylation of the receptors by the aziridinium ion (3).

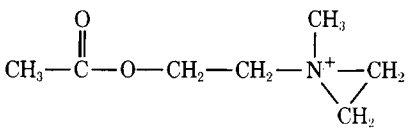
A comparable agonist effect of acetylcholine mustard on guinea pig ileum was found, but no irreversible inhibition was observed (2). An increase in the resting tonus of the muscle after exposure to the mustard was also observed and might have been due to an inhibition of acetylcholinesterase (2). Therefore, this study was undertaken to examine the interaction between acetylcholine mustard and acetylcholinesterase.

EXPERIMENTAL

In all experiments, acetylcholine mustard was dissolved in buffer solution and allowed to stand for 1 hr at room temperature before use. Previous experiments indicated that at this time the concentration of aziridinium ion was near maximal (2, 3).



I



II

formation can be obtained with fluorescent alkylating agents (1). In addition, the *in vivo* activation mechanism for I*b* may account for the divergent physiological results of numerous other analogs (10).

Interactions of Acetylcholine Mustard with Acetylcholinesterase

PATRICIA M. HUDGINS and JAMES F. STUBBINS [x]

Abstract □ The hydrolysis of acetylcholine and acetylcholine mustard by acetylcholinesterase was compared over a substrate concentration range of 1–10 m*M*. Reactions were allowed to proceed for 2 min at 25°. Results of these experiments reveal that the substrates have similar affinities for the enzyme, whereas the maximum velocity for the hydrolysis of acetylcholine mustard was significantly lower than for acetylcholine. These findings suggest that acetylcholine mustard has the ability to inactivate acetylcholinesterase.

Keyphrases □ Acetylcholine and acetylcholine mustard—hydrolysis by eel electroplax acetylcholinesterase □ Acetylcholinesterase—hydrolysis of acetylcholine and acetylcholine mustard

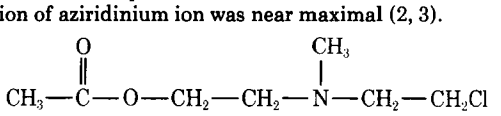
The synthesis of acetylcholine mustard [2-(chloroethylmethylamino)ethyl acetate] (I) was first reported by Hanby and Rydon (1). It was demonstrated that acetylcholine mustard can cyclize in buffered aqueous solutions to form an aziridinium ion (II) with alkylating ability (2, 3). This aziridinium ion is a close structural analog of acetylcholine.

In isolated muscle systems, it was found that acetylcholine mustard had about one-fifth the agonist potency of acetylcholine on the muscarinic receptors of the rat jejunum preparation or the nicotinic receptors of the frog rectus abdominis preparation (3). During a 1- or 2-hr exposure of the jejunum segments to either acetylcholine (1.0×10^{-4} *M*) or acetylcholine mustard (1.0×10^{-4} *M*), the contractions slowly declined; after washing, response to freshly applied acetylcholine was inhibited compared to control values. The decline in response was greater in the case of acetylcholine mustard, and the tissue did not fully recover even upon prolonged washing. Although the observed inhibition of response by acetylcholine and some of the effect of acetylcholine mustard could be accounted for by desensitization of receptors, the long-acting inhibition of the mustard was attributed to an irreversible inhibition brought about by alkylation of the receptors by the aziridinium ion (3).

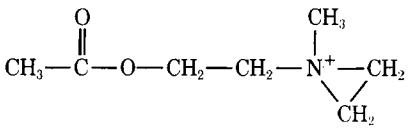
A comparable agonist effect of acetylcholine mustard on guinea pig ileum was found, but no irreversible inhibition was observed (2). An increase in the resting tonus of the muscle after exposure to the mustard was also observed and might have been due to an inhibition of acetylcholinesterase (2). Therefore, this study was undertaken to examine the interaction between acetylcholine mustard and acetylcholinesterase.

EXPERIMENTAL

In all experiments, acetylcholine mustard was dissolved in buffer solution and allowed to stand for 1 hr at room temperature before use. Previous experiments indicated that at this time the concentration of aziridinium ion was near maximal (2, 3).



I



II

Acetylcholinesterase Activity Assay—Acetylcholinesterase, prepared from electric eel[1], was used to catalyze the hydrolysis of acetylcholine or acetylcholine mustard. Disappearance of the substrate was determined by a colorimetric method (4). Briefly, to 2 ml of buffered substrate solution, 5 μl of acetylcholinesterase stock solution was added. The reaction was allowed to proceed for 2 min at 25° before it was stopped by the addition of freshly prepared alkaline hydroxylamine solution. After an additional 1 min, 4 *M* HCl and 0.37 *M* ferric chloride were added and the absorbance was read at 540 nm in a spectrophotometer.

Determination of Kinetic Constants—Estimations of kinetic constants for the hydrolysis of acetylcholine or acetylcholine mustard by acetylcholinesterase were made by determining the velocity of hydrolysis at substrate concentrations between 1 and 10 m*M*. At acetylcholine concentrations above 20 m*M*, substrate inhibition occurred. Kinetic constants were obtained by linear regression analysis of Hofstee plots of experimental data. The *F* test for "goodness of fit" for each curve was significant ($p < 0.05$).

Incubation of Enzymes with Substrates—In separate experiments, acetylcholinesterase was exposed to varying concentrations of either acetylcholine or acetylcholine mustard for 1 hr in buffer solution at 25° and then dialyzed against buffer at 0° for 2 hr to remove the remaining substrate or hydrolysis products. An aliquot of the enzyme solution was then taken for measurement of enzymatic activity as already described.

RESULTS AND DISCUSSION

Nickerson and Gump (5) were the first to demonstrate that the 2-haloethylamine moiety incorporated into α-adrenergic antagonists gave long-lasting activity. Ample evidence has been presented that this persistent antagonism is caused by formation of a covalent bond between the drug molecule in the form of a highly reactive aziridinium ion and a nucleophilic group on or near the receptor site (6–8).

Alkylation of the muscarinic receptor by an antagonist was first shown by Gill and Rang (9). These workers demonstrated that benzilylcholine mustard could produce selective and persistent antagonism of methylfurtrethonium-induced contractions of the isolated guinea pig ileum. Employing some elegant techniques, these workers found that the rate of dissociation of the aziridinium-ion–receptor complex was slow compared to the rate of receptor alkylation. Therefore, the mustard was a highly effective alkylating agent.

The acetylcholine analog, bromoacetylcholine, was shown to be capable of covalent bond formation with nicotinic receptors of eel electroplax (10). In this case, persistent stimulation rather than inhibition resulted. This example was apparently the first one of an irreversible agonist action at a receptor, although the agent was presumably covalently bound to a group just beyond the receptor site rather than within the receptor site proper. The aziridinium ion derived from acetylcholine mustard (II) is also a cholinergic agonist, but alkylation proceeded at a slow rate to yield a prolonged inhibition (3). It was decided to determine whether the acetylcholine mustard could also act as an irreversible inhibitor of acetylcholinesterase.

In some experiments, the effect of prolonged exposure of acetylcholinesterase to acetylcholine or acetylcholine mustard upon subsequent hydrolysis of acetylcholine was measured. In numerous trials, acetylcholinesterase was treated with either substrate as described under *Experimental*. The activity of the enzyme after such treatment proved to be considerably lower than that from controls using freshly prepared enzyme solutions. Although the hydrolysis rate was somewhat lower with enzyme exposed to the mustard than with enzyme exposed to acetylcholine, the difference was not significant.

In the next series of experiments, the initial hydrolysis rates for acetylcholine or acetylcholine mustard were determined at various concentrations of the two substrates. The Michaelis constant (K_m) and maximum velocity (V_m) were obtained by linear regression analysis of data from experiments in which the concentration of substrate was 1–10 m*M*. On the basis of these data (Table I), acetylcholine and the aziridinium ion from acetylcholine mustard appear to have similar affinities for acetylcholinesterase. This finding might be expected because of their close structural similarity. It is also evident from a comparison of the V_m's that acetylcholine mustard is hydrolyzed at a significantly lower maximum velocity than acetylcholine ($p < 0.001$).

Table I—Kinetic Constants for Hydrolysis of Acetylcholine and Acetylcholine Mustard, over a Substrate Concentration Range of 1—10 m*M*, Obtained by Linear Regression Analysis of Hofstee Plots of the Data

Substrate	K_m, m*M* ± *SE*	V_m, μmoles/min/mg ± *SE*	n[a]
Acetylcholine	1.05 ± 0.30	267.4 ± 19.2	166
Acetylcholine mustard	1.06 ± 0.44	135.8 ± 17.2	99

[a] Total number of observations at 1, 2, 3, 4, 5, 6, 8, and 10 m*M*.

In further experiments, the hydrolysis rate as a function of the substrate concentration was studied for acetylcholine, acetylcholine mustard, and a combination of equimolar parts of the two at a concentration range near the K_m. It can be seen in Fig. 1 that the relationship between velocity and substrate concentration is more nearly linear in the case of acetylcholine hydrolysis. A statistical comparison between the velocity of hydrolysis at each substrate concentration revealed acetylcholine was hydrolyzed significantly faster than acetylcholine mustard ($p < 0.001$).

The ratios of the velocities at two substrate concentrations (1.5 and 0.75 m*M*) for the hydrolysis of acetylcholine and acetylcholine mustard were 1.95 and 1.66, respectively. Thus, in the case of acetylcholine, the velocity of hydrolysis was nearly doubled as the substrate concentration was doubled; however, in the case of the mustard, there was a considerably smaller increase in velocity. The ratio of velocities at 1.5 and 0.75 m*M* substrate concentrations for the combination of acetylcholine and acetylcholine mustard was 1.88.

The question arises as to whether the lower V_m (Table I) and the curvature in the rate of hydrolysis at increasing acetylcholine mustard concentrations (Fig. 1) are caused by alkylation of the active site. It was shown (11) that acetylcholinesterase can be inhibited irreversibly by the alkylating agent *N,N*-dimethyl-2-phenylaziridinium chloride. This alkylating agent is not a close structural analog of acetylcholine, and alkylation may have taken place at an anionic site other than that at which the cationic head of acetylcholine normally binds to the enzyme. It is well known that certain quaternary ammonium ions can inhibit cholinesterase at sites different from the acetylcholine binding site (12). Alkylation of such allosteric sites might account for the irreversible inhibition by the aziridinium ion. In fact, O'Brien (13) summarized evidence

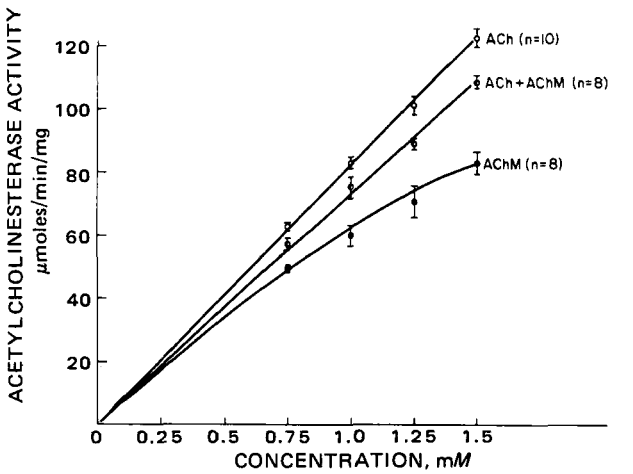


Figure 1—*Hydrolysis of acetylcholine (ACh), acetylcholine mustard (AChM), and an equimolar combination of acetylcholine and acetylcholine mustard (ACh + AChM) by acetylcholinesterase after 2 min of incubation at 25°. Numbers in parentheses refer to the number of separate experiments. Vertical bars represent standard error of the mean.*

[1] Type V, Sigma Chemical Co.

suggesting that the cationic head of acetylcholine may bind to the active site by nonpolar interactions rather than by ionic or polar forces. If such is the case, there may not be any nucleophilic group capable of being alkylated at this position on the enzyme.

Present results do not exclude the possibility that alkylation of the enzyme by the mustard could be occurring at sites other than the acetylcholine binding site. Alkylation by the mustard at the active site or at other sites would tend to lower the velocity of its hydrolysis. This was observed both in the experiments designed to provide kinetic constants (Table I) and in a separate series where each substrate and equimolar concentrations of each substrate were assayed (Fig. 1).

In summary, results of the present study reveal that acetylcholine is hydrolyzed at a significantly faster rate than the mustard, even though their affinities for the enzyme appear to be comparable. In the light of previous results obtained in cholinergic receptor systems, which demonstrated alkylation of a portion of receptors (3), it is possible that the mustard is capable of covalent bond formation with, and subsequent inactivation of, acetylcholinesterase. Due to rapid turnover of enzyme–substrate complexes, conditions for alkylation may not be favorable. In any case, it appears likely that alkylation and enzyme inactivation are occurring during hydrolysis of acetylcholine mustard by acetylcholinesterase. Hydrolysis of mixtures of the substrates would be expected to yield mixed-type inhibition.

Effects of Nitrogen Dioxide and 3-Methylcholanthrene on Pulmonary Enzymes

F. C. P. LAW [x], J. C. DRACH, and J. E. SINSHEIMER [x]

Abstract □ Guinea pig lung phenol-*O*-methyltransferase, catechol-*O*-methyltransferase, and benzpyrene hydroxylase activities were examined after nitrogen dioxide and 3-methylcholanthrene treatment. While benzpyrene hydroxylase activity was enhanced by 3-methylcholanthrene, none of the pulmonary enzyme activities was altered after exposure to either 40 or 70 ppm of nitrogen dioxide for 2 hr.

Keyphrases □ Nitrogen dioxide—effects on guinea pig lung phenol-*O*-methyltransferase, catechol-*O*-methyltransferases, and benzpyrene hydroxylase □ 3-Methylcholanthrene—effects on guinea pig lung enzymes □ Enzymes, pulmonary—effects of nitrogen dioxide and 3-methylcholanthrene

A previous report (1) from this laboratory demonstrated that guinea pig lung contains appreciable phenol-*O*-methyltransferase and catechol-*O*-methyltransferases. Furthermore, catechol-*O*-methyltransferases were present both in the supernatant and the microsomal fractions. The presence of these enzymes also has been indicated in rat lungs (2, 3). In addition, benzpyrene hydroxylase activity has been reported in rat lung (4) and is inducible by a wide range of chemicals including cigarette smoke (5), 3-methylcholanthrene (4, 6), flavones (7), and *Cannabis* (6).

The question was raised as to the influence of air pollutants on the primary pulmonary enzyme identi-

[a] Hydroxylation activities are expressed as fluorescence units per gram of tissue. [b] Transmethylation activities are expressed as nanomoles of O-methylated product per gram of tissue. [c] Values are given as means ± *SE*, with the number of animals used in parentheses.

fied to date. Thus, the effects on benzpyrene hydroxylase, phenol-*O*-methyltransferase, and catechol-*O*-methyltransferases were studied in guinea pigs after treatment with nitrogen dioxide by inhalation. Also included in this report, as a control, are the effects of 3-methylcholanthrene subcutaneous injection upon the same lung enzyme systems in guinea pigs.

EXPERIMENTAL

Guinea pigs, 300–500 g, of either sex were used. 3-Methylcholanthrene, dissolved in arachis oil, was administered at a dose of 20 mg/kg ip. Control animals were injected with arachis oil only. Exposures of animals to nitrogen dioxide at 40- and 70-ppm levels for 2 hr were carried out in a dynamic exposure chamber as described previously (8). Chamber concentrations were controlled by flowmeters which were checked periodically during the exposure.

At 24 hr after 3-methylcholanthrene or nitrogen dioxide treatment, the animals were sacrificed. The lungs were removed, rinsed, blotted, and weighed. Preparation of subcellular fractions and assays of *O*-methyltransferase enzyme activities were carried out as previously described (1). The substrates employed were phenol for phenol-*O*-methyltransferase and isoproterenol for catechol-*O*-methyltransferase activities. Benzpyrene was the substrate for the determination of hydroxylase activity using the procedure of Wattenberg *et al.* (9).

The Student *t* test and the U test (10) were used for statistical comparisons. Results confined to the same day and with the same animal shipment were used in these statistical analyses.

RESULTS AND DISCUSSION

3-Methylcholanthrene administration increased guinea pig lung benzpyrene hydroxylase activity about twofold. However, neither microsomal phenol-*O*-methyltransferase nor microsomal and supernatant catechol-*O*-methyltransferase activities were affected (Table I). During these experiments, the basal levels of benzpyrene hydroxylase varied considerably with different shipments of guinea pigs from the supplier. These results are consistent with the findings (4, 6) that pulmonary benzpyrene hydroxylase activity varies with rats and is inducible by 3-methylcholanthrene.

The LD_{50} of nitrogen dioxide exposure for 2–4 hr to guinea pigs was reported to be about 75 ppm (11). The concentrations of 40 and 70 ppm of nitrogen dioxide used in this study were chosen to study the effects of maximally tolerated nitrogen dioxide levels. Lung weights and enzyme activities were not significantly different from experiments carried out on the same day and with the same animal shipment. Table II shows lung enzyme activities from several experiments after nitrogen dioxide treatments. There is no evidence from these studies that nitrogen dioxide affects pulmonary phenol-*O*-methyltransferase, catechol-*O*-methyltransferase, and benzpyrene hydroxylase activities after short-term exposure to nitrogen dioxide even at levels as high as 70 ppm[1].

Synthesis and Blood Pressure Lowering Activity of Benzylic Ethers of 2-Diethylaminoethanol and a Related Diamine

SAMIR M. EL-ANTABLY*, TAITO O. SOINE[x], NADIM A. SHAATH, and PREM K. GUPTA ‡

Abstract □ Based upon the unpublished finding that 3′-hydroxy-4′-(β-diethylaminoethoxy)-3′,4′-dihydroseselin possessed a potent blood pressure lowering effect in the cat at a dose of 1 mg/kg, the present study examined the activities of several related compounds. These compounds were derived by dissection of the parent compound to give four benzylic ethers of 2-diethylaminoethanol and a diamine, derived by replacing the ether oxygen of the parent compound with an N—CH_3 function. The simplest compounds were the benzyl and 2,6-dimethoxybenzyl ethers of the aminoalcohol. Closely related to the benzyl compound was a congener with a hydroxymethyl group on the benzylic carbon. The β-diethylaminoethyl ether of 4-chromanol was the most complex of the ethers. The blood pressure measurements were carried out on male cats and compared to papaverine hydrochloride as a standard. In all cases, the most potent blood pressure lowering activity resided in the parent compound, which was not greatly superior to the diamine but substantially more active than the other compounds.

Keyphrases □ 2-Diethylaminoethanol benzylic ethers and related diamine—synthesis, screened for blood pressure lowering activity □ Antihypertensive activity—synthesis and screening of 2-diethylaminoethanol benzylic ethers and related diamine

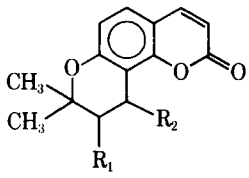
VI: *e* with substitution of N—CH_3 for O as indicated in I*a*

Scheme I



I*a*: R_1 = —OH, R_2 = —$OCH_2CH_2N(C_2H_5)_2$
I*b*: R_1 = —$OOCCH(CH_3)CH_2CH_3$, R_2 = —$OOCCH_3$
I*c*: R_1 = —$OOCCH_3$, R_2 = —$OOCC(CH_3)=CH-CH_3$
I*d*: R_1 = —$OOCCH_3$, R_2 = —$OOCCH_2CH(CH_3)_2$

related congeners pteryxin (I*c*) and suksdorfin (I*d*), were reputed (2, 3) to possess this interesting and potentially useful activity. Preliminary observations in these laboratories indicated that I*a* was lethal to rabbits and cats when administered in doses of 3–4 mg/kg iv. Further experimentation indicated that the cause of death was an acute blood pressure drop and that a dose of 1 mg/kg in the cat, while causing a significant blood pressure drop, was not lethal. Because of these observations, some of the simpler forms envisioned within the molecular structure of I*a* were proposed as candidates to determine whether significant activity could be generated in the structural modifications.

DISCUSSION

Consideration of the molecular structure of I*a* immediately suggested that its most important feature was that of being a benzylic ether of 2-diethylaminoethanol, since other compounds in which the ether function was replaced with a variety of acyloxy functions (*e.g.*, α-methylbutyroxy, angeloyloxy, and isovaleroxy) were without significant effect on the blood pressure at comparable dose levels. However, the necessity of the coumarin moiety as an activity-contributing part of I*a* had not been demonstrated, so the dissection of this moiety became the prime focus of this investigation.

The dissections employed are indicated in Scheme I, where the letters *a*, *b*, *etc.*, indicate the points of scission of I*a* and correlate with the numbers of the actual compounds prepared, *i.e.*, II, III, IV, V, and VI.

In II, the molecule has been stripped to the bare essentials of being a benzylic ether; in III, the simple benzylic ether has the oxygen functions of I*a* restored as methoxy groups. In IV, the hydroxy corresponding to that at the 3′-position of I*a* has been retained in a simple benzylic ether. The modification in V restores the benzopyran portion of I*a* (minus the *gem*-dimethyls). Compound VI represents the compound in which all of the elements of I*a* are kept intact except for the introduction of an N—CH_3 group in place of the ether oxygen, although one cannot be sure that the replacing group has the same steric orientation as the C-4′ group in I*a*.

Compound II was prepared by the method of Rericha *et al.* (4). Compound III was readily obtained by reduction of ethyl 2,6-dimethoxybenzoate to the corresponding alcohol with lithium aluminum hydride, followed by treatment of the sodium salt of the alcohol with 2-diethylaminoethyl chloride. 2-Phenyl-2-(β-diethylami-

noethoxy)ethanol (IV) was prepared by the method of Bottari and Macchia (5), which involved the interaction of the sodium salt of 2-diethylaminoethanol with ethyl-α-bromophenyl acetate, followed by lithium aluminum hydride reduction of the resulting product to give IV. The synthesis of V was accomplished by the alkylation of 4-chromanol with 2-diethylaminoethyl chloride. Compound VI was readily accessible from the reaction of Ic with *N,N*-diethyl-*N'*-methylethylenediamine, followed by acid hydrolysis.

Determination of the vasodepressor activity of Ia and the prepared compounds was made using cats as the test animal and papaverine hydrochloride as a standard. All blood pressure drops were compared to the standard drop in pressure achieved with papaverine. The order of vasodepressor activity determined in this manner was: Ia > VI >>> III > II > V > IV. It was clear that Ia and its close structural analog were virtually equivalent in activity and were both substantially superior to the others. Nevertheless, the fact that activity was evident in compounds without the coumarinic lactone feature suggests that additional studies might be desirable.

EXPERIMENTAL[1]

Synthesis—*3'-Hydroxy-4'-(β-diethylaminoethoxy)-3',4'-dihydroseselin (Ia)*—Pteryxin (Ic, 10 g, 0.025 mole) in tetrahydrofuran (40 ml) was treated with sodium amide (1.95 g, 0.05 mole), and the solution was stirred at room temperature for 1 hr. 2-Diethylaminoethanol (5.9 g, 0.05 mole) in tetrahydrofuran (5 ml) was added dropwise and the solution was stirred at room temperature for 2 hr. The contents then were diluted with water (1 liter) and acidified with sulfuric acid.

The aqueous acid solution was washed with ether and made alkaline with 10% aqueous sodium carbonate, and the precipitated base was thoroughly extracted with ether. The ethereal solution was washed with water, dried, and then evaporated to provide a brown oil. On standing in the refrigerator for a few days, the oil crystallized and was then recrystallized from ethanol–water to give white needles, mp 105–108°. The methiodide salt gave a melting point of 191–193°.

Anal.—Calc. for $C_{20}H_{27}NO_5 \cdot H_2O$: C, 63.30; H, 7.65; N, 3.69. Found: C, 63.60; H, 7.32; N, 3.59.

1-Benzyloxy-2-diethylaminoethane (II)—The synthesis was as described by Rericha *et al.* (4), bp 70–74°/0.1 mm [lit. (4) bp 72–76°/0.1 mm].

1-(2',6'-Dimethoxy)benzyloxy-2-diethylaminoethane (III)—2,6-Dimethoxybenzyl alcohol (0.5 g, 0.062 mole), prepared by lithium aluminum hydride reduction of ethyl 2,6-dimethoxybenzoate according to Hejno and Arnold (6), was treated with metallic sodium (1.43 g, 0.062 mole). A solution of 2-diethylaminoethyl chloride (8.5 g, 0.062 mole) in xylene (25 ml) was added dropwise to this solution, and the reaction mixture was refluxed for 12 hr; the contents then were diluted with water and extracted with aqueous 10% hydrochloric acid.

The acid extract was washed with ether, made alkaline with aqueous 10% sodium hydroxide, and extracted with ether to obtain the free base. The ethereal extract was washed with water, dried, filtered, and finally subjected to evaporation. The oily residue was distilled to obtain a product (7.6 g, 45.5%), bp 170–180°/2.5 mm.

The hydrochloride of the base, prepared by the use of ethereal hydrogen chloride, was recrystallized from ethyl acetate–ether to give an analytical sample, mp 98–99°.

Anal.—Calc. for $C_{15}H_{26}ClNO_3$: C, 59.30; H, 8.56; N, 5.26. Found: C, 59.20; H, 8.88; N, 5.59.

2-Phenyl-2-(β-diethylaminoethoxy)ethanol (IV)—Ethyl-α-bromophenyl acetate (19.5 g, 0.08 mole) was prepared according to the method of Narayanan and Martin (7), dissolved in anhydrous toluene (60 ml), and added dropwise to a solution of 2-diethylaminoethanol (10.6 g, 0.09 mole) in anhydrous toluene (25 ml), which had been pretreated with sodium (1.84 g, 0.08 mole) as in the preparation of III. The resultant mixture was refluxed for 2 hr with stirring, cooled, washed with water (50 ml), and extracted thoroughly with aqueous 10% hydrochloric acid. The combined acidic extract was washed with ether (50 ml) and made alkaline with 10% aqueous sodium hydroxide, and the free base was extracted into ether.

The ethereal extract was washed with water, dried, and evaporated to provide 4.6 g (20.7%) of an oil. The oil, after drying overnight in an evacuated desiccator over phosphorus pentoxide, was dissolved in anhydrous ether and added dropwise to a suspension of lithium aluminum hydride (0.7 g) in anhydrous ether. The reaction mixture was refluxed for 0.5 hr, cooled, and decomposed by the cautious addition of water. The organic phase was then dried and evaporated to dryness to yield a yellow oil (2.6 g, 66.6%). This oil was distilled under reduced pressure at bp 130–142°/2 mm [lit. (5) bp 135–140°/1.6 mm].

The hydrochloride salt was prepared by the addition of ethereal hydrogen chloride to a saturated solution of the free base in absolute alcohol. Recrystallization of the salt from acetone–ether yielded colorless crystals, mp 118–119°.

4-(β-Diethylaminoethoxy)chroman (V)—To a stirred suspension of sodium hydride (0.6 g of a 50% suspension in mineral oil) in anhydrous dimethylformamide (15 ml) under nitrogen was added dropwise a solution of 4-chromanol (1.6 g, 0.01 mole) in dimethylformamide (2 ml). The reaction mixture was stirred for 1 hr, and then a solution of 2-diethylaminoethyl chloride (2.7 g, 0.02 mole) in dimethylformamide (2 ml) was added dropwise (25 min). Stirring was continued at room temperature for 21 hr.

The mixture was poured into water and extracted with ether, and the ethereal extract was washed with water before being extracted with 10% aqueous hydrochloric acid (4 × 100 ml). The acidic extract was washed with ether and made alkaline with 20% ammonium hydroxide solution, and the free base was extracted with ether. The ethereal extract was washed with water and dried, and the ether was evaporated to obtain a pale-yellow oil (2 g, 76.9%). This oil was distilled at bp 115–120°/0.2 mm.

The picrolonate salt was prepared by mixing the free base (0.124 g) and picrolonic acid (0.132 g) in absolute ethanol to obtain large brown needles, mp 141–143° dec.

Anal.—Calc. for $C_{25}H_{31}N_5O_7$: C, 58.46; H, 6.08; N, 13.63. Found: C, 58.65; H, 6.27; N, 13.40.

3'-Hydroxy-4'-[methyl(N,N-diethylaminoethyl)amino]-3',4'-dihydroseselin (VI)—A mixture of visnadin (Ib, 19.5 g, 0.05 mole) in anhydrous benzene (250 ml) and *N*-methyl-2-diethylaminoethylenediamine (13 g) was refluxed for 19 hr. The solvent was removed under reduced pressure; the residue was extracted with 10% aqueous hydrochloric acid, alkalinized as before, and extracted with ether; and the ethereal extract was dried and evaporated to give 4 g of an oil. This oil was refluxed with sulfuric acid (20%, 30 ml) for 6 hr; after cooling, the reaction mixture was diluted with water and alkalinized with 20% ammonium hydroxide, and the free base was extracted into ether.

The ethereal extract was dried, concentrated to a small volume, and then treated with ethereal hydrogen chloride. The resulting salt (1.5 g) was chromatographed over neutral alumina (45 g), and

Table I—Blood Pressure Lowering Effects

Compound	Dose, mg/kg	Mean Blood Pressure Drop, mm/Hg	Percent Blood Pressure Drop[a]	Duration, min
Ia	0.5	43.3	72.0	5.0
	1.0	48.2	80.3	6.0
	2.0	74.0	123.0	10.0

[a] Papaverine hydrochloride = 100.

[1] Melting points were determined in capillary tubes in a Thomas-Hoover melting-point apparatus and are uncorrected. NMR spectra were determined on a Varian A-60D instrument. Analysis were carried out by the Microanalytical Laboratory, School of Chemistry, University of Minnesota, Minneapolis, Minn., or by Schwarzkopf Laboratories, Woodside, N.Y. Anhydrous sodium sulfate was used to dry solvent extracts unless otherwise specified.

the free base was eluted with ethyl acetate. Reconversion of the free base to the hydrochloride salt with ethereal hydrogen chloride and recrystallization from acetone–ether provided pale-yellow crystals, mp 108–110° dec.

Anal.—Calc. for $C_{21}H_{32}Cl_2N_2O_4$: C, 56.37; H, 7.21; N, 6.26. Found: C, 56.53; H, 7.20; N, 6.11.

Pharmacology—The blood pressure lowering activities of the compounds studied were compared to papaverine hydrochloride, the standard, in three male cats weighing an average of 3 kg. The animals were anesthetized with pentobarbital sodium (30 mg/kg), with additional small doses being given as needed. The blood pressure was monitored continuously by a force transducer[2] connected to a polyethylene catheter placed in the femoral artery and coupled[3] to a recording polygraph[4] at a chart speed of 1 cm/min. The average blood pressures for the cats at the beginning and end of the experiments were 146 and 132 mm/Hg, respectively.

The compounds tested were simply dissolved in normal saline if they were in a salt form. If in the free base form, they were solubilized in the least amount of 0.02 *N* hydrochloric acid and made up to the normal saline concentration with appropriate amounts of sodium chloride and water. The compounds tested were injected as a bolus *via* a femoral venous catheter in doses ranging from 0.5 to 3 mg/kg, followed by a 3-ml saline flush. The results reported (Table I) for each dose are the results of three or more readings. The blood pressure was allowed to return to preinjection levels before additional injections were given.

The protocol for the administration of the several agents being tested was to administer them according to the Latin-square method, whereby each new animal preparation was tested with a different order of the agents. In addition, administration of papaverine hydrochloride at the beginning, during the course of, and at the end of the experiment indicated that the blood pressure was still normally responsive in each cat throughout the experiment. The drop in blood pressure by an average dose of 1.67 mg/kg of papaverine hydrochloride was 60 mm/Hg, and this value was assigned as a 100% drop in the blood pressure because increasing the dose failed to elicit a further drop. All compounds were rated as a percentage against the standard on this basis.

Cyanogen Condensations as a Route to 3-Amino-2-imino-1,3-benzothiazin-4-ones with CNS Depressant Potential

NED D. HEINDEL ˣ and LEE A. SCHAEFFER

Abstract □ Seven new 3-amino-2-imino-1,3-benzothiazin-4-ones, prepared from the condensation of cyanogen and 2-mercaptobenzhydrazides, were evaluated in a neuropharmacological mouse profile. CNS depression was observed in several members of the class.

Keyphrases □ 3-Amino-2-imino-1,3-benzothiazin-4-ones—synthesized and screened as CNS agents □ CNS agents, potential—synthesis and screening of seven 3-amino-2-imino-1,3-benzothiazin-4-ones □ 1,3-Benzothiazin-4-ones, 3-amino-2-imino—synthesized and screened as CNS agents

Recent interest in the synthesis and pharmacological properties of certain 1,3-benzothiazin-4-ones, particularly as central nervous system (CNS) agents with marked mydriatic activity (1–5), prompted this report on a new synthesis of some uniquely substituted analogs of this class and their biological activities. 2-Mercaptobenzhydrazides (I) and cyanogen (II) were found to undergo facile condensation, in 50–74% yield, to 3-amino-2-imino-3,4-dihydro-2*H*-1,3-benzothiazin-4-ones (III), a reaction that represents cyanogen acting as a one-carbon insertion unit to close a six-membered ring (Scheme I).

Previous examples are known in which cyanogen in heterocyclic syntheses completes a cycle by insertion of a single carbon (6), two carbons (7), or one carbon and a nitrogen (8). An earlier synthetic study with 2-mercaptobenzhydrazide reported its condensation with formaldehyde to form a seven-membered ring, but no biological testing data were provided on the resulting benzo-1,3,4-thiadiazepinone (9).

The benzothiazinone products, III*a*–III*c*, could be structurally distinguished from the equally plausible, and isomeric, seven-membered alternatives, IV*a*–IV*c*, by characteristic chemical reactions. Hydrolysis generated Compound VII, which possessed a free amino group as evidenced by formation of an anil, VIII. Furthermore, condensation of III*a* with phosgene and/or benzoyl chloride produced *s*-triazolo systems, which would have been impossible from the alternative structure, IV. In addition, the pendant amino on III*a* underwent facile anil formation with both *p*-nitro- and *p*-dimethylaminobenzaldehydes.

From a practical viewpoint, solutions of up to 5 *M* cyanogen in anhydrous tetrahydrofuran, stable to

the free base was eluted with ethyl acetate. Reconversion of the free base to the hydrochloride salt with ethereal hydrogen chloride and recrystallization from acetone–ether provided pale-yellow crystals, mp 108–110° dec.

Cyanogen Condensations as a Route to 3-Amino-2-imino-1,3-benzothiazin-4-ones with CNS Depressant Potential

NED D. HEINDEL ˣ and LEE A. SCHAEFFER

Abstract □ Seven new 3-amino-2-imino-1,3-benzothiazin-4-ones, prepared from the condensation of cyanogen and 2-mercaptobenzhydrazides, were evaluated in a neuropharmacological mouse profile. CNS depression was observed in several members of the class.

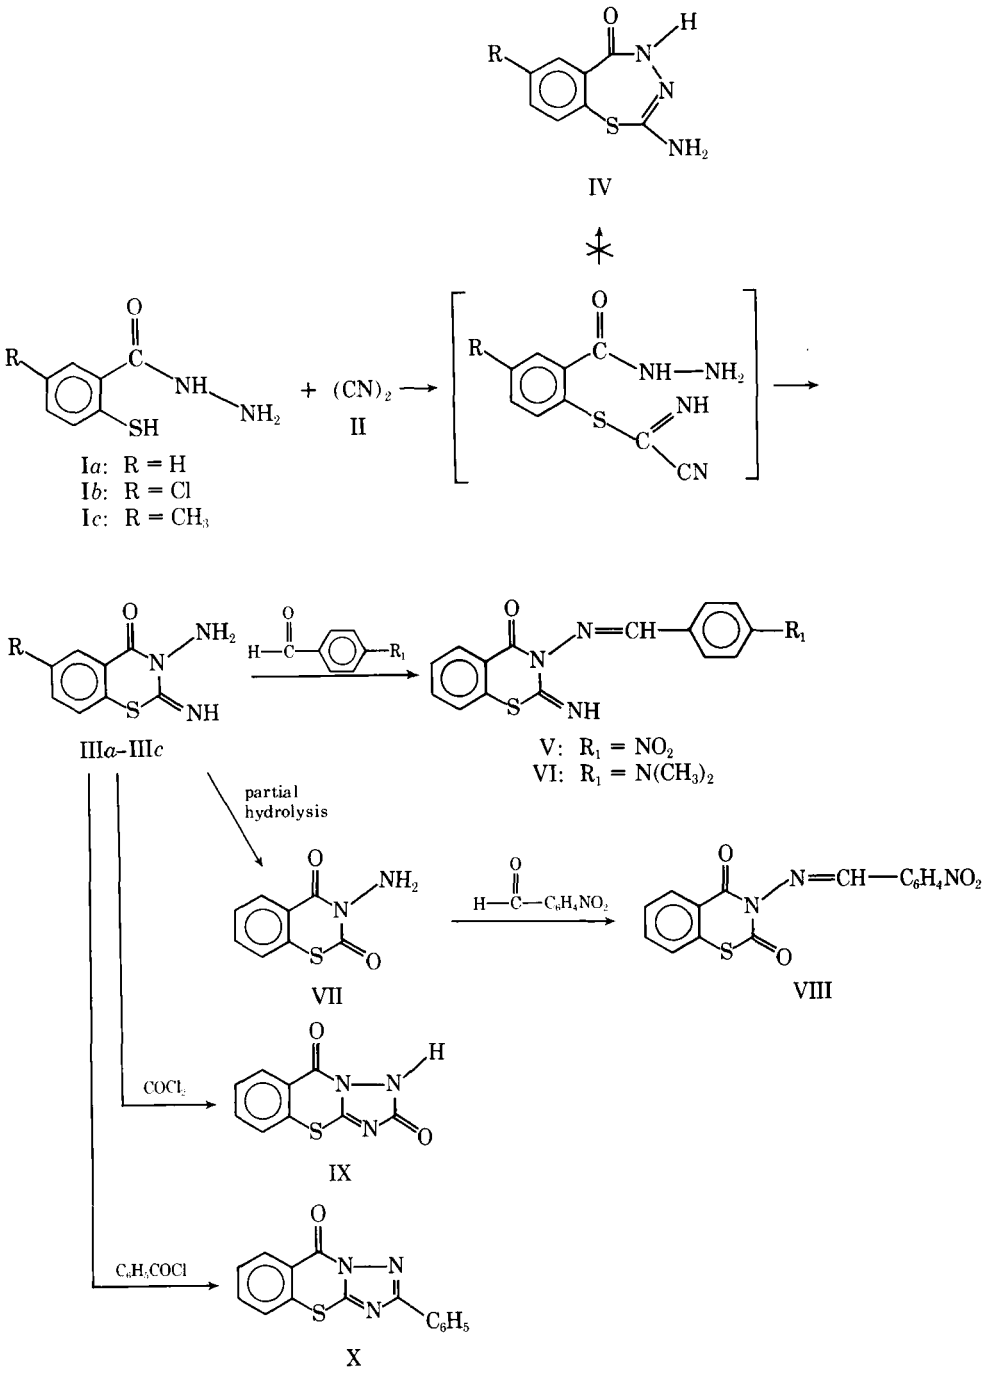
Keyphrases □ 3-Amino-2-imino-1,3-benzothiazin-4-ones—synthesized and screened as CNS agents □ CNS agents, potential—synthesis and screening of seven 3-amino-2-imino-1,3-benzothiazin-4-ones □ 1,3-Benzothiazin-4-ones, 3-amino-2-imino—synthesized and screened as CNS agents

Recent interest in the synthesis and pharmacological properties of certain 1,3-benzothiazin-4-ones, particularly as central nervous system (CNS) agents with marked mydriatic activity (1–5), prompted this report on a new synthesis of some uniquely substituted analogs of this class and their biological activities. 2-Mercaptobenzhydrazides (I) and cyanogen (II) were found to undergo facile condensation, in 50–74% yield, to 3-amino-2-imino-3,4-dihydro-2*H*-1,3-benzothiazin-4-ones (III), a reaction that represents cyanogen acting as a one-carbon insertion unit to close a six-membered ring (Scheme I).

Previous examples are known in which cyanogen in heterocyclic syntheses completes a cycle by insertion of a single carbon (6), two carbons (7), or one carbon and a nitrogen (8). An earlier synthetic study with 2-mercaptobenzhydrazide reported its condensation with formaldehyde to form a seven-membered ring, but no biological testing data were provided on the resulting benzo-1,3,4-thiadiazepinone (9).

The benzothiazinone products, III*a*–III*c*, could be structurally distinguished from the equally plausible, and isomeric, seven-membered alternatives, IV*a*–IV*c*, by characteristic chemical reactions. Hydrolysis generated Compound VII, which possessed a free amino group as evidenced by formation of an anil, VIII. Furthermore, condensation of III*a* with phosgene and/or benzoyl chloride produced *s*-triazolo systems, which would have been impossible from the alternative structure, IV. In addition, the pendant amino on III*a* underwent facile anil formation with both *p*-nitro- and *p*-dimethylaminobenzaldehydes.

From a practical viewpoint, solutions of up to 5 *M* cyanogen in anhydrous tetrahydrofuran, stable to



Scheme I

prolonged storage, are readily prepared by dissolving measured volumes of the condensed cyanogen into the solvent. The hydrogen cyanide gas evolved during the condensations of cyanogen with *Ia–Ic* is collected in a caustic trap and the heterocyclic products, IIIa–IIIc, precipitate directly in the tetrahydrofuran solution, not as salts but as their free base forms.

RESULTS[1]

Compounds IIIa, IIIb, IIIc, IIIa-HCl, V, VI, and VII were administered intraperitoneally in solution or as a suspension in water–methylcellulose to groups of four mice. Physiological signs were observed and evaluated according to the Irwin method (10). Compound IIIa and its hydrochloride salt, IIIa-HCl, gave virtually identical profiles with the exception of the rapidity of onset of the physiological effects. Both agents effected tonic convulsions and death at any dose above 30 mg/kg with an estimated LD_{50} of 18 mg/kg. Presumably because of accelerated absorption from the peritoneal cavity, IIIa-HCl caused death in less than 3 min post-dosing with 300 mg/kg while IIIa required 10 min. All other signs—hypothermia (4° at 100 mg/kg), salivation, body drop, Staub tail phenomenon, and loss of righting reflexes and of spontaneous motor activity—which were common to both agents, appeared more rapidly in IIIa-HCl.

The methyl analog IIIc gave a similar profile to IIIa but was considerably less toxic (LD_{50} of 178 mg/kg) and less active. At 100 mg/kg, IIIc functioned as a mild CNS depressant sedative with marked reduction in spontaneous motor activity, loss of righting reflexes, and hypothermia (4°). The chloro compound IIIb was

[1] Evaluations were carried out at Pharmakon Laboratories, Inc., Scranton, Pa., under the supervision of Dr. Richard Matthews.

nontoxic and inactive at doses up to 300 mg/kg. Therefore, the nature of the substituent at C-6 appears to influence activity markedly.

The 2-imino moiety apparently is involved in the toxic and depressant effects since there was no activity or toxicity with the hydrolyzed carbonyl counterpart, VII, at the highest dose tested, *i.e.*, 1000 mg/kg. Conversion of the 3-aminobenzylidene to a 4-dimethylaminobenzylidene led to a nontoxic compound, VI, which still evidenced mild catatonia and loss of motor activity at the maximum dose employed of 300 mg/kg. The 4-nitrobenzylidene compound, V, had an LD_{50} of 240 mg/kg; at 100 mg/kg, it too displayed mild CNS depressant effects including abnormal gait, lacrimination, hypothermia, and loss of motor activity. None of the compounds was judged sufficiently active to merit more extensive studies.

EXPERIMENTAL[2]

2-Mercaptobenzhydrazides (Ia–Ic)—The method of Katz *et al.* (9), involving thiolation of the diazonium salt of the corresponding anthranilic acid, esterification of the resulting 2-mercaptobenzoic acid, and its displacement with hydrazine, was employed in the syntheses of the 2-mercaptobenzhydrazides, Ia and Ib. The preparation and properties of Ic have not been reported previously, but by following the exact procedure for conversion of 5-chloroanthranilic acid to Ib, 5-methylanthranilic acid was converted in 26% yield to 2-mercapto-5-methylbenzhydrazide (Ic), mp 146–148°; IR (KBr): 3240 (br) (bonded N—H), 2560 (S—H), and 1610–1580 (C=O) cm^{-1}.

Anal.—Calc. for $C_8H_{10}N_2OS$: C, 52.73; H, 5.53; N, 15.37. Found: C, 52.58; H, 5.57; N, 15.36.

3-Amino-2-imino-3,4-dihydro-2*H*-1,3-benzothiazin-4-ones (IIIa–IIIc)—To a solution of 5.2 g (0.10 mole) of II, 4 drops of triethylamine, and 20 ml of anhydrous tetrahydrofuran at 0° was added dropwise a solution of 1–4 mmoles of the mercaptobenzhydrazide, Ia–Ic, in 65 ml of anhydrous tetrahydrofuran. Crystallization of the product commenced almost immediately, and the mixture was stirred at 5° for 4 hr after the completion of the addition. Dilution of the medium with 100 ml of benzene completed the precipitation of product, which was filtered and recrystallized from benzene. A 74% yield of IIIa, mp 141.5–142.5°, was obtained.

Anal.—Calc. for $C_8H_7N_3OS$: C, 49.73; H, 3.65. Found: C, 49.63; H, 3.54.

A 50% yield of IIIb, mp 144–145°, was obtained.

Anal.—Calc. for $C_8H_6ClN_3OS$: C, 42.20; H, 2.66. Found: C, 42.26; H, 2.62.

A 67% yield of IIIc, mp 154–155°, was obtained.

Anal.—Calc. for $C_9H_9N_3OS$: C, 52.16; H, 4.38. Found: C, 52.01; H, 4.35.

A hydrochloride salt of IIIa was prepared by introducing hydrogen chloride gas into a saturated solution of IIIa in benzene to precipitate IIIa-HCl, mp 206–209°; IR (KBr): 2600 broad (NH salt) cm^{-1}.

Anal.—Calc. for $C_8H_7N_3OS$·HCl: Cl, 15.44. Found: Cl, 15.15.

3-Arylideneimino-2-imino-3,4-dihydro-2*H*-1,3-benzothiazin-4-ones (V and VI)—A solution of 5.0 mmoles of IIIa and 5.0 mmoles of *p*-nitrobenzaldehyde in 50 ml of methanol containing 0.5 ml of acetic acid was refluxed for 2 hr, concentrated *in vacuo* to 20 ml, and filtered. The yellow solid (1.2 g, 76%) was recrystallized from dimethyl sulfoxide to yield the analytical sample of V, mp 307.5–308.5°.

Anal.—Calc. for $C_{15}H_{10}N_4O_3S$: N, 17.17. Found: N, 17.35.

In a similar fashion, 5.0 mmoles of IIIa and 5.0 mmoles of *p*-dimethylaminobenzaldehyde were reacted to yield VI (0.80 g, 48%), mp 264–265°.

Anal.—Calc. for $C_{17}H_{16}N_4OS$: N, 17.27. Found: N, 17.55.

3-Amino-3,4-dihydro-2*H*-1,3-benzothiazin-2,4-dione (VII)—A hydrolysis solution of 2 ml of acetic acid, 35 ml of ethanol, 10 ml of chloroacetaldehyde, and 10 ml of water was employed to dissolve 1.9 g (0.01 mole) of IIIa. The solution was then warmed to 45–55° and held at that temperature for 20 hr, during which time a buff-white solid precipitated. This solid, VII (1.07 g, 55%), was filtered and recrystallized from methanol, mp 199.0–199.5°; IR (KBr): 3310, 3245 (NH), and 1688 (C=O) cm^{-1}.

Anal.—Calc. for $C_8H_6N_2O_2S$: C, 49.48; H, 3.11; N, 14.42. Found: C, 49.85; H, 3.22; N, 14.80.

3-(4-Nitrobenzylideneimino)-3,4-dihydro-2*H*-1,3-benzothiazin-2,4-dione (VIII)—After refluxing equimolar (1.0 mmole) amounts of VII and *p*-nitrobenzaldehyde in 20 ml of methanol containing 5 drops of acetic acid for 1 hr, a 67% yield of VIII was obtained. Recrystallization from methanol gave the analytical sample, white microneedles, mp 220.5–221.5°; IR (KBr): no N—H bands, 1690 (C=O) cm^{-1}.

Anal.—Calc. for $C_{15}H_9N_3O_4S$: C, 55.04; H, 2.77; N, 12.84. Found: C, 54.87; H, 2.81; N, 12.79.

1,2-Dihydro-*s*-triazolo[5,1-*b*]benzo[1,3]-thiazin-2,9-dione (IX)—A well-stirred solution of 5.0 mmoles of IIIa, 15 mmoles of triethylamine, and 50 ml of anhydrous tetrahydrofuran was treated to the dropwise addition over 15 min of 7.5 mmoles of phosgene in 6 ml of benzene. A solid began to precipitate immediately; after 3 hr of stirring, the crystals were removed by filtration, washed with cold methanol, and recrystallized from dioxane to yield 0.56 g (51%) of white solid, IX, mp 310–312°.

Anal.—Calc. for $C_9H_5N_3O_2S$: C. 49.31; H, 2.30; N, 19.17. Found: C, 49.25; H, 2.42; N, 19.12.

2-Phenyl-3-triazolo[5,1-*b*]benzo[1,3]-thiazin-9-one (X)—The reaction in 65 ml of refluxing dioxane of 5.0 mmoles of IIIa and 10 mmoles of benzoyl chloride after 4 hr of reflux produced an insoluble off-white solid. The reaction mixture was filtered hot to separate the product, X, 0.15 g or 11%, from the unreacted starting materials. Recrystallization from dioxane gave the analytical sample, mp 281–282°.

Anal.—Calc. for $C_{15}H_9N_3OS$: C, 64.50; H, 3.25; N, 15.04. Found: C, 64.26; H, 3.64; N, 14.82.

Fluorinated Quinazolones III: Synthesis and CNS Depressant Activity of Fluorinated Quinazolone Derivatives

KRISHNA C. JOSHI *x, VIRENDRA K. SINGH *, DAULAT S. MEHTA *, RAMESH C. SHARMA ‡, and LALIT GUPTA ‡

Abstract □ The synthesis of 2-allylthio-3-(4′-fluorophenyl)-5,6,7,8-tetrafluoro-4-quinazolone, 2-*n*-propylthio-3-(4′-fluorophenyl)-5,6,7,8-tetrafluoro-4-quinazolone, 3-(4′-bromophenyl)-5,6,7,8-tetrafluoro-2,4-quinazolinedithione, and seven fluorinated 2-alkyl/phenyl-3-aryl-4(3*H*)-quinazolones is described. The synthesized compounds were screened for CNS depressant activity using pentobarbital sleeping time, pentylenetetrazol convulsions, and condition avoidance test as the parameters. Most of the screened compounds exhibited significant depressant activity.

Keyphrases □ Quinazolone derivatives, fluorinated—synthesis and CNS depressant activity □ CNS depressant activity—synthesis and evaluation of fluorinated quinazolone derivatives

Since the introduction of methaqualone [2-methyl-3-(*o*-tolyl)-4(3*H*)-quinazolone] into clinical therapy as a nonbarbiturate hypnotic drug (1, 2), various 4(3*H*)-quinazolones and thioquinazolones have been investigated for pharmacological activity, including analgesic (3, 4), antispasmodic (5, 6), antihistaminic (7), hypotensive (8), muscle relaxant (9), sedative (10–13), anesthetic (10–13), and tranquilizing (10–13) activities.

Recently, the synthesis and pharmacological evaluation of a number of fluorinated 2-alkyl-3-aryl-4(3*H*)-quinazolones, thioquinazolones (14, 15), 2-mercapto-3-alkyl/aryl- and 2-alkylthio-3-aryl-4(3*H*)-quinazolones, and 3-aryl-2,4-quinazolinedithione were reported. Some compounds exhibited pronounced CNS activity. This finding prompted the investigation of the polyfluorinated analogs of the more active fluorinated quinazolone derivatives. This paper reports the preparation and CNS depressant activity of such compounds.

EXPERIMENTAL[1]

Compounds I–III (Table I) were prepared by the condensation of *N*-acyl derivatives of tetrafluoroanthranilic acid with an appropriate aromatic amine in the presence of phosphorus trichloride. Compounds IV–VII were prepared similarly from *N*-acyl/aroyl derivatives of 3- or 4-fluoroanthranilic acids. Compounds VIII and IX were prepared in good yield by refluxing tetrafluoroanthranilic acid and the corresponding phenylisothiocyanate in ethanol. On treatment with allyl chloride and *n*-propyl chloride, VIII was converted into the corresponding allylthio (X) and *n*-propylthio (XI) derivatives, respectively.

The treatment of IX with phosphorus pentasulfide in dry xylene gave 3-(4′-bromophenyl)-5,6,7,8-tetrafluoro-2,4-quinazolinedithione (XII) in quantitative yield.

Synthesis—*2-Methyl-3-(4′-bromophenyl)-5,6,7,8-tetrafluoro-4(3H)-quinazolone (I, Table I)*—To a solution of *N*-acetyl-2,3,4,5-tetrafluoroanthranilic acid (0.01 mole) and *p*-bromoaniline (0.01 mole) in dry toluene (20 ml) was added a solution of phosphorus trichloride (0.46 g, 0.0033 mole) in 5 ml of dry toluene, dropwise with constant stirring over 20 min. The resulting solution was further refluxed for 4 hr with constant stirring. After cooling, the reaction mixture was treated with 20 ml of 10% aqueous sodium carbonate solution and steam distilled to remove the toluene. The precipitated solid mass was removed by filtration, washed well with water, and recrystallized from ethanol using activated charcoal.

Other quinazolones (II–VII, Table I) were synthesized in a similar manner.

2-Mercapto-3-(4′-fluorophenyl)-5,6,7,8-tetrafluoro-4-quinazolone (VIII)—To a solution of tetrafluoroanthranilic acid (2.09 g, 0.01 mole) in 20 ml of ethanol, 4-fluorophenylisothiocyanate (1.53 g, 0.01 mole) was added. The resulting solution was heated under reflux for 2 hr when a crystalline solid mass was obtained. The solid mass was separated by filtration, washed with cold water, and recrystallized from acetic acid.

2-Mercapto-3-(4′-bromophenyl)-5,6,7,8-tetrafluoro-4-quinazolone (IX) was prepared in a similar manner.

2-Allylthio-3-(4′-fluorophenyl)-5,6,7,8-tetrafluoro-4-quinazolone (X)—To a solution of sodium hydroxide (0.63 g, 0.019 mole) in 15 ml of 50% ethanol, 2-mercapto-3-(4′-fluorophenyl)-5,6,7,8-tetrafluoro-4-quinazolone (1.77 g, 0.005 mole) was added and the mixture was stirred until a clear solution was obtained. Allyl chloride (0.456 g, 0.006 mole) was then added, and the solution was further stirred for 2 hr at room temperature. After cooling the resulting solution to 0°, the product was removed by filtration, washed with cold water, and recrystallized from aqueous ethanol to give a pure compound.

2-*n*-Propylthio-3-(4′-fluorophenyl)-5,6,7,8-tetrafluoro-4-quinazolone (XI) was prepared in a similar manner using *n*-propyl chloride.

3-(4′-Bromophenyl)-5,6,7,8-tetrafluoro-2,4-quinazolinedithione (XII)—A suspension of 2-mercapto-3-(4′-bromophenyl)-5,6,7,8-tetrafluoro-4-quinazolone (2.02 g, 0.005 mole) and phosphorus pentasulfide (1.21 g, 0.006 mole) in dry xylene (10 ml) was heated under reflux with constant stirring for 4 hr. After cooling, the reaction mixture was treated with sodium carbonate solution and steam distilled to remove the xylene. The precipitated solid was separated and recrystallized from ethanol to afford a pure sample.

The IR spectra of some typical compounds are: I, 1618, 1590, and 1478–1517 cm^{-1}; II, 1610–1620, 1588, and 1480–1520 cm^{-1}; III, 1610, 1560–1590, and 1490–1520 cm^{-1}; IV, 1610, 1560–1595, and 1490–1520 cm^{-1}; and V, 1618, 1570–1590, and 1480 cm^{-1}. These absorption bands correspond to the quinazolone identifying bands (16). Similar quinazolone identifying bands were observed with the other quinazolones reported in this paper.

Biological—All compounds reported in Table I, except VIII and IX, were screened for CNS depressant activity by three tests.

Pentobarbital Sleeping Time—The method followed was similar to one used by Arora *et al.* (17). Albino mice, 24–30 g, were divided into 11 groups of four animals each. The first group received pentobarbital only (40 mg/kg ip) and served as the control group, while the other 10 groups received 10 different drugs at a dose of 100 mg/kg ip. The drugs were given 30 min prior to pentobarbital (40 mg/kg ip).

After pentobarbital administration, the stopwatch was started; as soon as the mice lost the righting reflex, they were kept on their backs separated from each other. The time from the loss of the righting reflex to the regaining of the reflex was noted as the sleeping time.

The results are given in Table II. The most potent compound was XI. Compounds IV and VII were also potent but were not as effective as XI. Compound I exhibited some activity.

Pentylenetetrazol[2] *Convulsions*—The method of Swinyard *et al.* (18) was used for the evaluation of this activity. Albino mice of either sex, 18–25 g, were randomly divided into 11 groups. Each group consisted of five animals. Group I served as the control group and was injected with an equal volume of solvent. The remaining 10 groups received the test compounds at 100 mg/kg ip. The animals were maintained on an adequate diet and were allowed free access to food and water except during the short time when they were removed from their cages for testing. The animals were tested 30 min after drug administration, since the peak effect of these compounds, determined from preliminary experiments, was between 25 and 40 min.

Seizures were induced by a subcutaneous injection of 85 mg/kg of pentylenetetrazol in agar solution. This dose produces maximal convulsions in control mice. The effectiveness of the drugs was studied by their ability to prevent the tonic phase of the seizures. Animals were observed for 30 min only after pentylenetetrazol administration.

The results of the screening data are recorded in Table III. As in the previous test, XI was the most potent anticonvulsant and IV and VII were also potent. Compounds III, IV, and XII increased the initial time for the onset of tonic phase.

Condition Avoidance Tests in Rats—The equipment employed was similar to that used by Cook and Wiedley (19). The uncondi-

10	XI	100	—	—
11	XII	20	15.00 ± 1.58	<0.05

[a] For the control group, the solvent was administered in an equal volume. All other groups received 100 mg/kg ip of the test compound.

Table IV—Comparative Condition of Avoidance Response in Rats with Screened Compounds

Group	Compound[a]	Animals Showing Absence of Conditioned Response, %
1	I	60
2	II	40
3	III	20
4	IV	80
5	V	20
6	VI	40
7	VII	80
8	X	20
9	XI	80
10	XII	40

[a] 100 mg/kg ip.

tioned response was provided to the rats through a grass stimulator (0.1 mamp of 50 cycles ac at 150 v) for 5 sec; a buzzer was used as a conditioning stimulus 12 sec earlier. Rats of either sex, 150–200 g, were trained by an electric shock to climb a pole (unconditioned response) and were then conditioned by the buzzer maintained for 15 sec to climb a pole.

Such conditioned rats were divided into 10 groups of five each. Each group received different drugs at 100 mg/kg ip. Thirty minutes after drug administration, the test was performed for observing the conditioned avoidance response.

The results of screening are recorded in Table IV; VII, XI, and IV were equally potent and I, II, VI, and XII also showed some activity.

Monoamine Oxidase Inhibiting Activity of a Series of (±)-4-Methoxy-β-hydroxyphenethylamines

GARY G. FERGUSON ˣ and WILLIAM J. KELLER

Abstract □ The synthesis and selected pharmacological testing of (±)-4-methoxy-β-hydroxyphenethylamine [1-(4-methoxyphenyl)-2-aminoethanol] and its *N*-methylated derivatives are presented. Members of this series were found to exert partial prevention of reserpine-induced hypothermia in mice and to inhibit monoamine oxidase in Warburg studies. Activity was essentially dose dependent. The secondary amine was the most active member of the series. The tertiary amine was least active, and the primary amine exhibited intermediate activity.

Keyphrases □ (±)-4-Methoxy-β-hydroxyphenethylamine and *N*-methyl derivatives—synthesis, screened for monoamine oxidase inhibition □ Monoamine oxidase inhibition—synthesis and screening of (±)-4-methoxy-β-hydroxyphenethylamine and *N*-methyl derivatives □ β-Hydroxyphenethylamines, 4-methoxy and *N*-methyl derivatives—synthesis, screened for monoamine oxidase inhibition

The cactus genus *Coryphantha* is known to produce a variety of β-hydroxyphenethylamines (1–7). 4-Methoxy-β-hydroxyphenethylamine [1-(4-methoxyphenyl)-2-aminoethanol], for instance, has been detected in extracts of *Coryphantha cornifera* (DC.) Br. and R. var. *echinus* (Engelm.) L. Benson (1). This compound and its *N*-methylated derivatives have been synthesized and used in this laboratory as chromatographic references when screening extracts of *Coryphantha* species for the presence of alkaloids.

Prior to its detection in a plant system, 4-methoxy-β-hydroxyphenethylamine was reported to be a weak vasoconstrictor and, in large doses, a cardiac depressant (8). The lack of additional reports concerning the pharmacology of this compound and its *N*-methyl homologs prompted a pharmacological investigation. Preliminary studies of hexobarbital sleeping times in mice suggested the possibility of monoamine oxidase inhibition. The present report describes the monoamine oxidase-inhibiting activity of (±)-4-methoxy-β-hydroxyphenethylamine, (±)-*N*-methyl-4-methoxy-β-hydroxyphenethylamine [1-(4-methoxyphenyl)-2-(methylamino)ethanol], and (±)-*N,N*-dimethyl-4-methoxy-β-hydroxyphenethylamine [1-(4-methoxyphenyl)-2-(dimethylamino)ethanol].

EXPERIMENTAL

Synthesis—Synthesis of racemic 4-methoxy-β-hydroxyphenethylamine hydrochloride (mp 168–169°), *N*-methyl-4-methoxy-β-hydroxyphenethylamine hydrochloride (mp 117–118°), and *N,N*-dimethyl-4-methoxy-β-hydroxyphenethylamine hydrochloride (mp 145°) involved a Houben–Hoesch condensation of anisole[1] with aminoacetonitrile hydrochloride[2], *N*-methylaminoacetonitrile hydrochloride[2], and *N,N*-dimethylaminoacetonitrile hydrochloride[2], respectively, followed by a sodium borohydride reduction of the ketone intermediate (9). The UV, IR, and NMR spectra verified the structure of the desired product in each case.

Table I—Effects of Compounds in Prevention of Reserpine-Induced Hypothermia

Compound	Control[a]	Experimental[a]	Reference[a] (Iproniazid)
Unsubstituted	7.1 ± 0.6[b]	4.3 ± 0.9[b]	4.1 ± 1.3[b]
N-Methyl substituted	8.1 ± 0.7[b]	4.3 ± 0.7[b]	3.6 ± 0.7[b]
N,N-Dimethyl substituted	6.2 ± 0.5[b]	3.8 ± 1.3[b]	4.1 ± 1.3[b]

[a] Values represent changes in rectal temperature after 6 hr. [b] Mean ± standard error. Differences between control–experimental and control–reference groups were significant at $p \leq 0.05$. Controls received distilled water in a volume equal to that of the drug solution. All animals received reserpine (2.5 mg/kg ip) 1 hr after pretreatment. For details of treatment, see text.

Preliminary Studies—Initial screening for possible monoamine oxidase inhibition was done using the reserpine reversal technique of Pletscher (10). Male, Swiss–Webster albino mice, 21–54 g, were randomly divided into three groups of nine animals each for each study and were injected intraperitoneally as follows:

Group 1 (Control)—Distilled water (same volume as drug solution) 1 hr prior to injection of reserpine (2.5 mg/kg ip).

Group 2 (Experimental)—Phenethylamine derivative (200 mg/kg) 1 hr prior to injection of reserpine (2.5 mg/kg ip).

Group 3 (Reference)—Iproniazid (100 mg/kg) (reference compound) 1 hr prior to injection of reserpine (2.5 mg/kg ip).

Immediately after injection with reserpine, all animals were placed in individual plastic restraining housings. Rectal temperatures were monitored initially and at hourly intervals for 6 hr, using electronic thermometers[3].

Warburg Studies—As a further evaluation of possible monoamine oxidase inhibition, the effects of the compounds on the oxidation of tyramine hydrochloride[4] by rat brain mitochondria were investigated. Brain mitochondria (containing monoamine oxidase) were prepared from albino Wistar female rats, 150–200 g, according to the method of Brody and Bain (11), and monoamine oxidase activity was determined in the presence and absence of the respective compounds by conventional manometric techniques (12)[5].

In the manometric determinations, the main compartment of the Warburg flasks contained the compound studied (or buffer), 1 ml of mitochondrial suspension (representing 500 mg wet weight of original brain tissue), and sufficient 0.01 *M* phosphate buffer (pH 7.4) to make a total volume of 2.7 ml. The side arm of each flask contained 0.3 ml of 0.1 *M* tyramine hydrochloride. After the flasks were allowed to equilibrate for 15 min at 37°, the manometer valves were closed and the side arm contents of each were tipped in.

Manometers were set at 150 mm, and readings were taken at 15-min intervals for 90 min. Values for the 90-min reaction period were obtained for each flask and were multiplied by the respective flask constants after adjusting for changes in the thermobarometer. The total microliters of oxygen uptake for each flask was thus obtained.

Statistical Analysis—The mean ± standard error was determined for each control or treated group. Values thus obtained were compared, using the difference between the means and the standard error of the difference between the means for the respective control-treated pairs of groups. The Student *t* test was applied to the results, and the probability was determined.

Table II—Effects of Compounds on Oxidation of Tyramine Hydrochloride by Rat Brain Mitochondria

Compound	Concentration, *M*	Control[a]	Experimental[a]	Inhibition, %	*t* Value[b]
Unsubstituted	0.003	35.0 ± 1.6	28.5 ± 2.0	19	2.5
	0.006	42.6 ± 1.6	29.5 ± 1.2	31	6.6
	0.012	25.7 ± 1.1	12.0 ± 1.0	53	9.5
	0.024	40.6 ± 1.5	16.5 ± 0.8	59	14.8
N-Methyl substituted	0.003	48.9 ± 3.4	31.9 ± 2.5	35	4.0
	0.006	44.9 ± 3.0	26.0 ± 2.2	42	5.0
	0.012	60.6 ± 2.5	27.9 ± 1.5	54	11.3
	0.024	77.2 ± 5.0	23.5 ± 1.3	70	10.5
N,N-Dimethyl substituted	0.013	30.4 ± 1.4	24.8 ± 1.5	18	2.7
	0.025	27.5 ± 2.0	20.2 ± 1.1	27	3.2
	0.050	32.0 ± 1.7	20.5 ± 1.4	36	5.2
	0.100	33.3 ± 2.3	13.3 ± 1.2	61	7.7

[a] Each value represents the microliters of oxygen uptake (mean ± standard error) for 12 flasks. [b] All differences between means were significant at $p \leq 0.05$.

RESULTS AND DISCUSSION

In studies of reserpine reversal (prevention or partial prevention of reserpine-induced hypothermia), the compounds produced significant ($p \leq 0.05$) effects at a dose of 200 mg/kg (Table I). Iproniazid, a known monoamine oxidase inhibitor, also partially prevented reserpine-induced hypothermia at a dose of 100 mg/kg ($p \leq 0.05$). While these results are not conclusive proof of monoamine oxidase inhibition by the compounds, they do suggest the possibility, since monoamine oxidase inhibitors usually exhibit the reserpine-reversal phenomenon (10).

Direct measurements of inhibition using Warburg studies showed that all three compounds inhibited monoamine oxidase in the concentration ranges employed (Table II). (±)-4-Methoxy-β-hydroxyphenethylamine hydrochloride, in concentrations of 0.003–0.024 *M*, produced significant ($p \leq 0.05$) inhibition of monoamine oxidase when compared to controls. Likewise, (±)-*N*-methyl-4-methoxy-β-hydroxyphenethylamine hydrochloride, in concentrations of 0.003–0.024 *M*, and (±)-*N,N*-dimethyl-4-methoxy-β-hydroxyphenethylamine hydrochloride, in concentrations of 0.013–0.1 *M*, also significantly inhibited monoamine oxidase.

A number of compounds possessing a phenethylamine nucleus are capable of inhibiting monoamine oxidase (13). The phenyl and nitrogen moieties of these compounds are usually unsubstituted. Phenylethanolamine derivatives exhibiting monoamine oxidase inhibition have all been unsubstituted (14). All *para*-methoxylated phenylethanolamines examined in this study inhibited monoamine oxidase. The fact that the secondary amine exhibited the greatest activity, followed by the primary amine, supports previous data. Based on available information, further speculation dealing with competition for the site of action on the enzyme and reversibility of the binding at this site would be difficult since these parameters are dependent on the particular substrate and tissue examined.

Effect of Plasma Protein Binding on Elimination of Bilirubin

Keyphrases □ Bilirubin—effect of plasma protein binding on elimination □ Protein binding, plasma—effect on elimination of bilirubin

To the Editor:

It is generally appreciated that interindividual differences in plasma protein binding can have a pronounced effect on the elimination kinetics of extensively protein bound drugs, but relatively little is known about the quantitative aspects of this relationship. Levy and Yacobi (1) recently presented an analysis of the pharmacokinetic aspects of plasma protein binding, which led to the prediction of a linear relationship between total plasma (or serum) clearance (P.C.) and the free fraction (f) of a highly protein bound drug in the plasma:

$$\text{P.C.} = k''f \qquad \text{(Eq. 1)}$$

where k'' is an intrinsic clearance constant for the free drug. Experimental support for this hypothesis was presented by demonstrating an excellent linear relationship between the total serum clearance of warfarin and the free fraction of this drug in the serum of individual rats (1).

We now report the results of a study of the relationship between plasma protein binding and total plasma clearance of bilirubin, another highly protein bound substance and one that is eliminated by conjugative pathways (2) rather than by oxidative processes [as is the case with warfarin (3)]. Seven adult male Sprague–Dawley rats, 335–374 g, received an infusion of ^{14}C-bilirubin (4) into the right jugular vein. An infusion rate of 0.8 mg/kg/min was maintained for 150–240 min. Three animals received an initial "loading" infusion of 2 mg/kg/min for 15 min.

Figure 1—*Relationship between total plasma clearance of bilirubin and the fraction of free bilirubin in the plasma of individual rats. The regression line, obtained by the vector least-squares method (7), is described by the equation P.C. = 0.19 + 7880f.*

Blood samples (0.6 ml) were obtained at 2, 3, and 4 hr or at 1, 2, and 2.5 or 3 hr and were assayed for free (5) and total (6) unconjugated bilirubin. The total plasma clearance of bilirubin was calculated by dividing the infusion rate by the steady-state concentration of total bilirubin in plasma.

Essentially constant concentrations of bilirubin in plasma were obtained within 60–120 min after the start of infusion. Steady-state concentrations were determined by averaging the concentrations of the three plasma samples; they differed by less than 6% on the average in individual animals. The steady-state concentrations of bilirubin in the plasma ranged from 11.7 to 20.7 mg/100 ml, and the total plasma clearance ranged from 3.9 to 6.8 ml/kg/min in the seven rats.

The free fraction of bilirubin in plasma, representing the mean of three separate determinations for each animal, ranged from 4.3×10^{-4} to 9.0×10^{-4}, equivalent to from 99.910 to 99.957% protein binding. There was a strong ($r = 0.82$) and statistically highly significant ($p < 0.02$) linear correlation between plasma clearance and free fraction of bilirubin in the plasma of individual rats (Fig. 1).

The results of this investigation are consistent with the theoretical model of Levy and Yacobi (1) and show that the elimination rate of bilirubin is proportional to the concentration of free rather than total (*i.e.*, free and protein bound) bilirubin in plasma.

REVIEWS

Emulsions and Emulsion Technology, Part I (Volume 6 in Surfactant Science Series). Edited by KENNETH J. LISSANT. Marcel Dekker, 305 E. 45th St., New York, NY 10017, 1974. 440 pp. 15.5 × 23 cm. Price $39.50.

The purpose of the book is to attempt to bring the status of emulsion technology up to date and to introduce the concept of emulsions to a wider group of people.

The first three chapters are introductory. Chapter 1 is entitled Basic Theory (by K. J. Lissant) and is unique in that it deliberately avoids most of the classical mathematical derivations and concentrates on a geometrical approach. This approach was chosen since many emulsion systems behave as though their performance properties were more dependent on their physical and topological configuration than on the chemical properties of their constituents. Thus, emulsions are discussed with regard to low-, medium-, and high-internal-phase-ratio type classifications rather than to classify them according to type of emulsifier employed.

Chapter 2 is entitled Making and Breaking Emulsions (by K. J. Lissant). This chapter also uses the geometric approach and is geared to answer the following questions:

1. Is an emulsion really needed, or would a solution or suspension do a better job?
2. If an emulsion is required, what type would be most suitable?
3. What emulsifiers and what equipment should be used?
4. When dealing with an undesirable emulsion, what techniques should be used for breaking such emulsions?

Chapter 3 is entitled Microemulsions (by L. M. Prince). This still controversial topic is treated well by Prince. Both theoretical and practical aspects are discussed and although some may disagree with the theories presented, it provides a good working basis for practical application.

A reading of the first three chapters should provide enough theoretical basis for the remaining five chapters which deal with applications in specialized areas of interest. These chapters are entitled Agricultural Emulsions (by P. L. Lindner), Food Emulsions (by M. W. Lynch and W. C. Griffin), Medicinal Emulsions (by B. A. Mulley), Emulsion Paints (by G. Allyn), and Asphalt Emulsions (by R. L. Ferm).

Each of these chapters is well written and extensively referenced. While the terminology varies slightly in each area, this does not present a major problem. Part II (not yet available) will deal with additional specialized areas of interest. These include Emulsion Polymerization, Emulsions in the Paper Making Industry, Emulsions in Printing and the Graphic Arts, Hydraulic Fluid Emulsions, and Emulsions in the Cosmetic Industry.

In summary, the book is recommended to all those in industry who must have a working knowledge of emulsions in any of the specialized areas mentioned. Those who want a more fundamental, theoretical basis would be well off first purchasing a text geared to this need such as "Emulsions, Theory and Practice" by Paul Becher.

Synthetic Methods of Organic Chemistry, Volume 28, Yearbook 1974. WILLIAM THEILHEIMER, Editor. S. Karger AG, Medical and Scientific Publishers, Arnold-Böcklin-Strasse 25, CH-4011 Basel, Switzerland, 1974. xx + 652 pp. (Albert J. Phiebig, Inc., U.S. Representative of S. Karger, P.O. Box 352, White Plains, NY 10602) 16 × 23 cm. Price $178.75.

Volume 28 of *Synthetic Methods of Organic Chemistry* is the latest volume of a multivolume work which has probably by this time become a standard reference in the field of organic synthesis.

The main portion of the work is a 476-page section devoted to abstracts of descriptions of the methods for the synthesis of specific compounds. The abstracts are of articles published in selected major journals, generally during 1971–1973. Accompanying almost every abstract is a brief structural representation depicting the starting material(s) and the product of the reaction sequence. This affords a rapid visualization of the structural change achieved by the synthetic method. The abstracts are highly but effectively condensed. They present the principal points of information (reactants, solvents, yield, *etc.*) of the method which allow one to judge if that particular synthetic method may or may not be helpful in the formulation of his or her own particular synthetic procedures. If a method appears to have utility, the details can then be found by consulting the original publication for which the literature citation is given after each abstract.

The method of classification of the abstracts is highly systematized. In brief, the major divisions are decided by the bonds formed between elements in the course of the reaction. These divisions are subdivided by the four ways by which the bonds are considered to be formed (addition, rearrangement, exchange, and elimination). A further subdivision is then made based upon the reagent used in the reaction.

The classification system and the abbreviations and symbols it employs, although logical, are by necessity somewhat arbitrary, and so the classification scheme requires some study and practice for mastery and easy usage. If one wishes to avoid using the classification system to find an abstract, he or she may proceed alternatively *via* the extensive subject index (pages 477–612). Here, classes of compounds, methods, and reagents are alphabetically listed along with references to where the appropriate abstracts are found in the main portion of the work. The subject index is cumulative for volumes 26, 27, and 28.

The cross-referencing of this nature contributes greatly to the value of the work by facilitating the location of the abstracts. Also, the abstracts themselves appear to represent a good cross-section of specific organic synthetic conversions, although specialists in certain areas of synthesis might possibly detect that their area of specialization is not treated as thoroughly as they might wish.

Synthetic Methods of Organic Chemistry impresses, then, as a work of considerable value to the medicinal chemist engaged in the synthesis of potentially bioactive compounds. Its value lies principally in the fact that it affords a quick entry into the literature of organic synthesis, especially when one wants to find a specific method for the synthesis of a specific compound. The cost probably precludes its inclusion in a personal library, but it at least ought to be, in this reviewer's opinion, readily accessible in an institutional or company library.

BIOAVAILABILITY DATA—USEFUL OR USELESS?

We are confused! The "we" here is an editorial "we" and is not intended to reflect upon anyone beyond the writer of this column—although there appears to be ample justification for many of our colleagues and associates to share in our confusion.

Readers of this Journal know that bioavailability has been a leading subject of interest within the pharmaceutical sciences community for at least the past 10 years. Numerous articles have been published on the subject, several conferences have been conducted, various reports have appeared, a number of symposia have been presented, and, in general, reference to drug bioavailability has regularly appeared in speeches, testimony before congressional committees, and filings made to regulatory agencies.

The APhA Academy of Pharmaceutical Sciences was largely responsible for the definition which seems to have won general acceptance; namely, bioavailability means the rate and extent to which the therapeutic moiety is absorbed from a drug product and becomes available to the site of drug action.

Consequently, determination of bioavailability can be an important factor in evaluating the effectiveness and expected performance of a drug product. By the same token, determination of the respective bioavailabilities of two or more different products can be an important means of objectively and critically comparing the effectiveness and expected performance of such products.

On the basis of this approach, or strategy, in comparatively evaluating drug products, APhA launched its "Bioavailability Project." This program was developed with the active assistance of both the scientific and practitioner components of the Association membership. Moreover, the background chapter and individual drug monographs that have been published to date seem to have been well received by all elements of the profession.

More recently, the Food and Drug Administration indicated that it, too, regards this general approach as a viable and valid one in determining the suitability of a drug product and the equivalence of multiple products. This was clearly revealed in the agency's proposed regulations published in late June pertaining specifically to "Bioavailability" and "Bioequivalence." APhA and its Academy of Pharmaceutical Sciences reviewed these proposed regulations and gave them a solid vote of approval.

So far, so good. It looked like everyone finally was on the same track and now in agreement on this long-debated, emotionally charged issue.

At least, it looked that way until we saw a recent full-page advertisement proclaiming in big bold print: "Bioavailability Data is Useful . . . as a measure of the absorption of a drug product . . . but not as a measure of equivalence between two or more products."

If bioavailability data are not useful as one of the factors to be considered in comparing, evaluating, and measuring the equivalency between drug products, then we have somehow been misled. And it seems to us like a lot of other people and groups concerned with drug quality have likewise been fooled.

The source of this ad is a major pharmaceutical firm with a large battery of highly qualified scientific personnel.

So we are confused. Does this company really mean to say that bioavailability data aren't useful in comparing product equivalence? Or is this company actually trying to discourage or dissuade pharmacy practitioner readers from utilizing bioavailability data in making product comparisons now that competing firms are releasing such data and inviting objective comparisons based upon hard data rather than catchy slogans?

The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N.W., Washington, DC 20037. Printing Offices: 20th & Northampton Streets, Easton, PA 18042

Annual Subscriptions—United States and foreign, industrial and government institutions $50, educational institutions $50, individuals *for personal use only* $30; single copies $5. All foreign subscriptions add $5 for postage. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $55 (foreign $60) APhA membership dues.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N.W., Washington, DC 20037, of any change of address.

Digoxin Tablets Dissolution Test

The Communication to the Editor from Ylitalo *et al.*[1] in the July 1975 issue and, to a lesser degree, the earlier article by Klink *et al.*[2] appeared to embody a basic misunderstanding of compendial specifications.

Specifically, both of these articles report findings to the effect that certain batches of digoxin tablets failed to pass the dissolution specifications in the USP but yet were found on *in vivo* testing to give satisfactory serum concentrations of the drug.

Although the respective authors did not explicitly so state, the implications were that the USP specification was unsatisfactory or unsuitable and, specifically, that the dissolution requirement did not correlate with *in vivo* performance.

Dissolution specifications, as in the case of all other *in vitro* specifications in the official compendia, are intended to be established at a level, or to be designed in a manner, so that all clinically unsatisfactory products will be excluded. In doing so, it is recognized that, to provide such a level of assurance, at least some otherwise clinically acceptable lots will be excluded also.

For example, typical tablet monographs will specify that the assay show between 95 and 105% of the label amount of the active ingredient to be present. In establishing this tolerance level, it is recognized that a lot assaying 93 or 90%, or perhaps even 85%, may be clinically satisfactory but will nonetheless be rejected on the basis of this *in vitro* specification.

The point is that we do not generally have dose–response information that is so precise, or control over the biological system that is so complete, that a broader range can be safely established. As a consequence, a specification is adopted based upon the biological information that is known, and the tolerances are then drawn sufficiently tight so as to err on the safe side.

Consequently, the batches of digoxin tablets described by the above-mentioned authors were formulated in a manner that fell into a gray zone, where they were not good enough to pass the compendium *in vitro* specification but yet were not quite bad enough to exhibit *in vivo* unsuitability.

In conclusion, the two reports cited here should not be interpreted as reflecting adversely on the USP digoxin tablet specification. On the contrary, these reports demonstrate that the specification is sufficiently stringent that products passing the test can be regarded with confidence as being biologically and, therefore, clinically satisfactory.

REVIEW ARTICLE

Asbestosis: A Reassessment of the Overall Problem

THOMAS J. HALEY

Keyphrases □ Asbestosis—review of chemistry, industrial hygiene, animal and human toxicology, and carcinogenic aspects □ Toxicology, asbestos—review of chemistry, industrial exposure, carcinogenic aspects in animals and humans □ Carcinogenicity, asbestos—review of chemistry, industrial hygiene, animal and human toxicology □ Mesothelioma, asbestos induced—review of asbestos chemistry, industrial exposure, animal and human toxicology, and carcinogenic aspects

It has been established that occupational exposure to asbestos fibers induces mesothelioma of the pleura and peritoneum and carcinoma of the lungs, esophagus, and stomach after a latent period varying from 20 to 40 years (1). The daily dumping, since 1955, of 67,000 short tons of taconite tailings containing amosite asbestos fibers into Lake Superior, the potable water supply for Duluth, has raised the issue of the possibility of an increased cancer risk for the inhabitants of the area. Air pollution by the same type of fibers adds an additional risk. However, legal action against the polluter resulted in the decision that there was no demonstrable hazard from asbestos dumping and that therefore it could be continued (2). At this point in time, it has not been established, either experimentally or in humans, that ingestion of asbestos fibers causes cancer of the GI tract.

The wide use of asbestos and the observation of asbestos bodies in sputum specimens from individuals with no known exposure call for a review and reassessment of the overall problem of asbestosis. It is also essential that problem areas be discussed and that solutions be suggested.

SOURCES AND USES

The generic term "asbestos" describes naturally occurring incombustible mineral silicates that are separated into filaments. The varieties are actinolite [$CaO{\cdot}3(MgFe)O{\cdot}4SiO_2$], amosite [$(FeMg)SiO_3$], anthophyllite [$(MgFe)_7Si_8O_{22}(OH)_2$], chrysotile ($3MgO{\cdot}25{:}O_2{\cdot}2H_2O$), crocidolite [$NaFe(SiO)_2{\cdot}FeSiO_3{\cdot}H_2O$], and tremolite [$Ca_2Mg_2Si_8O_{22}(OH)_2$] (3).

Smither (4) tabulated the amounts and sources of asbestos in current use throughout the world for 1969 (Table I). Asbestos is used in the construction industry, floor tiles, asbestos cements, roofing felts, shingles, insulation materials, cement powders, acoustical products, textiles, brake linings, clutch facings, paper, paints, roof coatings, plastics, and miscellaneous other products. Asbestos filter pads are used in the beverage industry, in processing blood and its fractions, and in clarifying intravenous fluids.

Each and every one of these uses has exposed various segments of the population to the threat of asbestosis; the extent of exposure will be explored industry by industry. It must also be remembered that primary exposure in the insulation industry results in secondary exposure to between 3 and 5 million workers in the construction and shipyard industries (5).

ANALYTICAL CHEMISTRY

The chemical composition of the various forms of asbestos presents a difficult problem of analysis, particularly in cases of asbestosis where the amount of

Table I—Annual World Production of Asbestos (3,000,000 Tons)

Type	Percent Production	Amount[a] and Location
Amosite	3.0	90,000, South Africa
Anthophyllite	0.5	10,000, Finland
Chrysotile	93.0	1,250,000, Canada
		750,000, USSR
		250,000, South Africa
		100,000, United States
		100,000, Europe
		350,000, Others
Crocidolite	3.5	110,000, South Africa

[a] In tons.

offending chemical is small. The situation with air or water samples is much less complicated. Another complication is the contamination of amosite and crocidolite asbestos with benzo[*a*]pyrene and oils (6). Blood serum can elute benzo[*a*]pyrene from crocidolite fibers, but oil is far less efficiently removed (7). Canadian chrysotile asbestos has a very low content of polycyclic aromatic hydrocarbons but becomes contaminated with C_{14}–C_{35} *n*-alkanes during the milling process (8). Storage of the fibers in polyethylene bags results in a reaction which produces a yellow oil with strong absorption at 421 nm. The material has been identified as 3,3′,5,5′-tetra-*tert*-butyldiphenoquinone and is absent from fibers stored in glass (9).

Various asbestos fiber types can be identified with the polarizing microscope using specific refractive index media if the fibers are thicker than 0.5 μm (Table II). Smaller fibers can be identified with the transmission electron microscope, and selected area electron diffraction is more dependable than elemental analysis with the scanning electron microscope (3).

X-ray diffraction has been used for the quantitative determination of amosite, chrysotile, and crocidolite samples by measuring the area under the major diffraction peak and comparing it with a standard. The method is applicable to amosite and crocidolite in the 1–8-mg range and to chrysotile in the 1–10-mg range (10). This method has been applied to bulk and settled dust samples, but they must contain at least 5% chrysotile before the method is usable and more than 20% for accurate results (11). Similar analyses have been made of amosite and crocidolite (12).

X-ray diffraction analysis has been utilized for the accurate analysis of asbestos in lung tissue (13). The technique can be applied to related occupational lung diseases and can quantitatively differentiate between causative agents (14). When amosite, chrysotile, crocidolite, and tremolite are reduced to particles under 10 μm in size by cutting, the accuracy of the X-ray diffraction method decreases and the background increases. Impact reduction does not decrease the fine fibers, and accurate quantitative results are obtained (15).

IR spectrophotometry has been used in the determination of chrysotile asbestos, but difficulties are encountered in preparing disks with a chrysotile content <100 μg. Moreover, at the 2.7-μm absorption band, other serpentine minerals present can invalidate the results (16). A similar situation exists for the other forms of asbestos in that their IR spectra are almost identical. Other problems include reproducible particle size, uniform mixing of the fibers and halide matrix, chemical exchange in the fiber matrix, and chemical alteration of the sample during grinding (17).

The use of atomic absorption spectrophotometric methods in the analysis of asbestos fibers has been confined to the determination of nickel, chromium, cobalt, and manganese, which apparently contaminate the fibers during processing. The actual fibers are destroyed by treatment with hydrofluoric acid; thus atomic absorption spectrophotometric procedures at present cannot directly determine the asbestos content of bulk or environmental samples (18). However, it has been suggested that these trace metals may be associated with the carcinogenic process and that all experimental animal studies should have the asbestos monitored for trace metals (19). Similar studies should be undertaken in industry, *e.g.*, asbestos textiles, because trace metals have been associated with the etiology of asbestosis (20).

It has been suggested that electromotive phenomena are involved in the unexplained exacerbations of asbestos carcinogenesis and that unless trace metal determinations are made the results obtained may exclude important data (21). Neutron activation analysis has been employed to determine the iron, chromium, cobalt, nickel, and scandium content of amosite, anthophyllite, chrysotile, and crocidolite. Milling apparently did not significantly change the trace metal content. The difficulty with the method is the prolonged irradiation time, the time for decay for the short-lived nuclides, and the necessity for chemical separation to improve the accuracy of detection of individual radionuclides (22).

The difficulties in the determination of bulk asbestos is compounded when body tissues are analyzed for their asbestos fiber content. Normal mineral extraction methods including acid, alkali, or peroxide digestion destroy the asbestos fibers, so fiber recovery depends on the fiber type involved and the use of milder methods for tissue destruction. Analysis for tissue fiber types by X-ray diffractometry is of limit-

Table II—Crystallographic Properties and Refractive Indexes of Asbestos

Type	Crystal System	Specific Gravity	Refractive Index	Dispersion Staining Color	
				Parallel	Perpendicular
Amosite	Monoclinic	2.6–3.0	1.66–1.70	Red magenta	Golden yellow
Anthophyllite	Orthorhombic	2.85–3.5	1.60–1.66	Blue green	Golden yellow
Chrysotile	Monoclinic	2.36–2.5	1.49–1.57	Light blue	Magenta
Crocidolite	Monoclinic	3.0–3.45	1.69–1.71	Magenta	Blue magenta

Table III—Dust Limit Values for Asbestos[a]

Country	Mass Concentration	Particle Concentration	
		Limit Value	Measuring Instrument
England	0.24 mg/m³ asbestos, respirable	4 fibers/cm³ > 5 μm (25 years exposure)	Membrane filter
United States	—	12 fibers/cm³ > 5 μm 7.0 particles/cm³	Membrane filter Impinger
USSR and CSSR	2.0 mg/m³ total dust	—	—
East Germany	—	100 particles/cm³ (A > 40 wt. %), 250 particles/cm³ (A > 40 wt. %)	Konimeter
West Germany	Total dust: 1.0 mg/m³ (A^b = 50 wt. %), 1.5 mg/m³ (A = 10–50 wt. %), 2.0 mg/m³ (A = 10 wt. %)	fibers = $\frac{C_s \cdot C_f}{100} \leq 20$ fibers = 20 $C_{max} = \frac{450}{VA_T}$ particles/cm³	Konimeter

[a] Reference 35. [b] A = asbestos component in wt. %; A_T = asbestos component in particle percent.

ed value. The same is true for the IR spectrophotometric method.

Differential thermal analysis also fails as a procedure because residual organic phases produce a series of strong exothermic reactions in the same range as asbestos. Electron beam instruments are the best for identification of asbestos fibers in tissue and allow long-term examination without physical or chemical artifacts interfering (23).

BIOCHEMICAL ASPECTS

Earlier studies suggested that the protein coating of asbestos bodies was collagen or a collagen-like substance (24). It has also been suggested that such bodies adsorb ferritin or a preformed iron–protein complex or that the protein and iron are adsorbed separately to build up the total complex. Histological evidence indicates that the alveolar macrophage cytoplasm contributes to the coating, with the iron being derived from phagocytized erythrocytes (25).

Newer studies on asbestos body coating indicate that the protein is not collagen based upon its hydroxyproline, glycine, leucine, and phenylalanine content (26). A histochemical study suggests that acid mucopolysaccharides are present in asbestos bodies and that such material acts as a matrix for iron deposition (27). This study supports the view that colloidal iron deposits on the acid polysaccharides during the formation of these bodies (28). The iron involved may be derived from hemolyzed erythrocytes (29).

Asbestos also can cause pleural calcification without fibrosis, but the biochemical mechanisms involved have not been elucidated (30). It has been reported that total and free serum amino acids, total protein, and globulins are higher in asbestos workers than in a control population (31). Asbestos workers also show a decrease in prealbumin and albumin and an increase in α-glycoprotein, α_2-lipoprotein, and transferrin and in serum IgG, IgM, and IgA fractions. There was no correlation between the length of asbestos exposure or the degree of asbestosis (32). There was an increase in the antinuclear antibody related to these parameters, but other immunological tests were negative (33).

INDUSTRIAL HYGIENIC ASPECTS

Dust Measurement—Such measurements have been highly controversial, because the instrumentation produced artifacts in the collected particles. Past standards for asbestos dust in the United States were based upon dust collection with an impinger, which collected few fibers and many grains. Moreover, it was not amenable to long personnel sampling, even though such sampling actually best approximated actual worker exposure (34). Therefore, more precise measurements were sought utilizing better instrumentation.

Table III gives the results of such investigations with different types of instruments and the dust limits obtained (35). These values are subject to change as new instrumentation is available and better correlation with epidemiological studies is obtained. It is now possible to evaluate each method in light of its good and bad points.

The British have checked many methods of dust estimation and found that the Owens jet counter is of value for taking snap samples but that efficiency decreases with increasing particle size and increasing air sampled. The konimeter suffers from the same defects and, in addition, the glycerin or petroleum coverslips cannot be ignited to remove combustible contaminants. The thermal precipitator is generally used in the United Kingdom and Europe, but its efficiency decreases for long fibers. The impinger is useful for particles 1 μm and larger but gives low values for asbestos.

The membrane filter method is good for 1-μm and larger fibers. It is consistent and covers the sampling rate between 10 and 500 cc/min. Moreover, samples can be taken for short or long periods, and the apparatus operates either electrically or by hand pump, is

robust, and can be used as a personnel monitor. The gravimetric method is in wide use in the United Kingdom but gives no indication of particle-size or fiber-size distribution. Tyndallometric methods (light scattering) count particles equal to spheres from 0.3 to 10 μm in 15 size ranges covering several counting rates but give a 25% lower value than a membrane filter with 5-μm and larger fibers. Moreover, it is doubtful that light scattering will work with all asbestos fiber types. Other limitations include counting all particles passing the light beam, the large size of equipment, and the necessity of checking by the membrane filter technique (36).

The U.S. Public Health Service has developed a more sophisticated membrane filter technique using counting under phase contrast microscopy and data reduction and statistical analysis by computer. The method is highly suitable for developing basic data for delineating the limits for airborne asbestos dust more accurately (34). Other investigators compared the membrane filter and electrostatic collector methods and found that the former gave excellent results but that the latter was inaccurate in measuring high concentrations of coarse particles because of short circuits and dust adherence to the discharge electrodes (37).

A comparison between the impinger and the membrane filter instruments revealed that the latter was probably better for the evaluation of fibers related to disease induction and, therefore, was more relevant to setting hygienic criteria (38). For measurement of total dust in a given environment or working area, the high volume sampler gives good results but does not, in general, give a direct measurement of individual exposure to dust and fibers. Such fixed-site samplers are used to obtain data on the efficiency of operation of dust control equipment (39).

Specifications for the evaluation of asbestos exposures in the working environment were defined by an international committee (40). Recently, these hygienic standards were extended to include amosite asbestos (41). Plant safety is only one aspect of the problem, because without effluent controls the outside environment can become contaminated and expose nonasbestos workers to the health threat of asbestosis. Moreover, it has been shown that such atmospheric contamination varies with the season, being greater during the winter months (42). The threshold limit for asbestos, 5 million particles/ft^3, or the German MAK value of fibers of 5 μm or more/cm^3 covers only inhalation and not ingestion; ingestion also must be addressed if the total environmental exposure to asbestos is to be realistically assessed (43, 44). Moreover, the threshold limit and MAK values must be modified as better measuring equipment becomes available. The fiberglass industry has recently been evaluated to determine its possible contribution to pneumoconiosis, and the survey indicated that the industry should not be put in the hazardous occupation category (45).

Protective Equipment—Dust in the work environment carries a certain risk, large or small, to health. There is no known absolute zero response because individual responses vary from one person to another and there is often a long latent period in the final development in the disease state (46). Methods for worker protection from airborne dust include: (*a*) enclosed working areas with or without a local exhaust system, (*b*) general room ventilation with large quantities of air, (*c*) water spraying to moisten dust, (*d*) use of a separate building, (*e*) local exhaust system over the work area, (*f*) work during evenings or on weekends to reduce the number of workers exposed, and (*g*) respiratory equipment (47).

All of these methods are used in prevention of asbestos exposure, but only the last, respiratory equipment, is useful in preventing individual exposure to the fibers. Continuous evaluation is necessary to develop performance characteristics of new and, perhaps better, dust respirators for fibrous dusts (48). Spray operators should be protected with a self-powered supplied air respirator or a constant-flow airline respirator with a belt control assembly and a quick-release coupling. For those not subjected to high asbestos dust concentrations, regular approved asbestos dust respirators can be used. All users should be instructed in the proper care and use of the respirator, particularly the necessity of changing filters (49).

The types of respirators required in the United Kingdom for protection against various concentrations of three types of asbestos are listed in Table IV (50). Table V indicates the magnitude of the problem in the English asbestos textile industry and the fact that particles did not include the fibers between 5 and 100 μm. A comparison of the data for 1952 and 1960 shows that the introduction of better hygienic practices reduced the dust exposure in various operations (51). In the dockyard, positive pressure power respirators are used and showering and changing from work clothes have reduced asbestosis cases and prevented further asbestos contamination of the environment (52). Spraying fibrous insulation can produce concentrations with fiber counts of 100 F/cc, requiring the use of air-supplied respirators because conventional filter-type respirators do not provide adequate protection (53). It has been shown that breakdown of the sealant covering sprayed asbestos insulation can introduce potential health hazards to occupants of such areas (54).

From the foregoing review of the industrial hygienic aspects of the asbestos problem, it is evident that

Table IV—Respiratory Protection against Asbestos Dust[a]

Concentration of Chrysotile or Amosite Asbestos, Fibers/cc Air	Concentration of Crocidolite Asbestos, Fibers/cc Air	Respirator
Up to 40	Up to 4	Dust respirator
Up to 200	Up to 20	Positive-pressure dust respirator
Up to 800	Up to 80	Ultrahigh-efficiency dust respirator
Greater than 800	Greater than 80	Positive-pressure airline breathing apparatus

progress in worker protection has occurred but that problems will constantly arise in other areas.

ANIMAL TOXICOLOGY AND CARCINOGENESIS

All forms of asbestos have been administered to many animal species by various routes except orally.

Intraperitoneal—Heating asbestos powder for 3 hr at 1000° and then cooling produced forsterite (Mg_2SiO_4) and enstatite ($MgSiO_3$) which, when administered intraperitoneally to CF-1 mice, killed 30 of 50 animals within 48 hr. Unheated asbestos did not have this effect. In another experiment with CF-1 mice, intraperitoneal injection of 0.5 ml of a 50% suspension of asbestos and serial sacrifice of the animals over 343 days gave evidence of a progressive, proliferative, granulomatous, invasive fibrosis histologically similar to mesothelioma (55).

Administration of five doses of 20 mg of amosite, anthophyllite, and crocidolite asbestos to female Wistar strain rats showed that the abdominal granulomas produced and the lymph nodes contained fibers of various lengths. Short fibers were intracellular while long fibers were not. Transport of fibers from the site of injection depends upon the length and begins with those measuring 20 μm and increases with decreasing length (56). Injection of chrysotile asbestos in fiber lengths of <5 and <3 μm produced the same percentage of tumors, but the time to tumor was prolonged with the smaller size fibers. The critical size for tumor induction appears to be longer than 2–3 μm. The addition of benzo[a]pyrene did not distinctly influence tumor induction (57).

Intratracheal—When 3.5 mg/ml of an aqueous suspension of chrysotile was administered to rats in total doses of 10.5–14 mg in 3–4 days and the animals were sacrificed at 4 days, the lungs showed a proliferative inflammation of the smaller bronchi and bronchioles. There were polypoid processes of avascular fibroblastic tissue originating from ulcerated areas in the mucosa and bronchial lumen. With time, 12–24 months, this inflammatory tissue converted to collagenous scars, which caused permanent deformities of the bronchi and bronchioles. There was also a macrophage reaction with a minimal stromal participation. It was suggested that the polypoid lesions were artifactual and related to the mode of administration because they did not occur in inhalation studies (58).

Russian chrysotile induced pulmonary carcinomas, sarcomas, premesotheliomas, and mesotheliomas in rats when 2 mg was injected three times monthly. Fiber sizes varied from 5 to 15 μm. When benzo[a]pyrene, 0.14 mg, was adsorbed on the asbestos, the number of lesions increased over the 9–28-month observation period. Moreover, asbestos alone had no effect during the first 6 weeks, but the addition of benzo[a]pyrene produced definite lesions in that time interval (59).

A study of asbestosis in guinea pigs showed that only crystalline chrysotile produced lung lesions. The dose instilled was 60 mg of fibers, 5 and 10 μm in length. The collagen content of the lungs was significantly increased (60). Other studies employing rabbits instilled with 2.5- or 15-μm fibers at a total dose of 100 mg at monthly intervals of 2–19 months showed foreign body reactions in the lungs, nodular reticulinosis, and diffuse interstitial reticulinosis (61).

Intrapleural—Injection of 10 mg of a saline suspension of chrysotile asbestos into the lower right pleural cavity of mice, with sacrifice intervals varying from 1 week to 6 months, resulted in pleural granulomas containing asbestos bodies in 2 weeks. The fibers were coated with acid mucopolysaccharide impregnated with ferritin or hemosiderin. Similar results were obtained with rats injected with a dose of 25 mg of the fibers (62).

Injection of 0.05 ml of a 50% lanolin suspension of asbestos into the right pleural cavity of female Osborne–Mendel rats monthly for 6 months did not produce any neoplasms in the lungs, pleurae, mediastium, or thoracic wall. This lack of carcinogenesis may have been due to the vehicle used, because saline suspensions do induce neoplasms (63). Administration of 20 mg of amosite, chrysotile, crocidolite, or extracted crocidolite intrapleurally in SPF or standard Wistar strain rats of both sexes produced a rapid onset of mesotheliomas. The time to onset was dependent on the type of asbestos, being longer for amosite than for the other varieties, although the fiber lengths (<2–200 μm) were the same. Solvent extraction of the crocidolite did not influence the results (64). A mathematical model was developed to describe the times to occurrence of the mesotheliomas (65).

In another study employing female Sprague–Dawley rats, injection with 66.7 mg of the three asbestos varieties produced mesotheliomas of the pleura and undifferentiated lung carcinomas (66). It has been shown that the carcinogenicity of amosite, chrysotile, and crocidolite asbestos fibers is related to structural

shape rather than to physicochemical properties. In contrast to a previous investigation (64), this study showed that amosite produced a more rapid onset of mesotheliomas (67). Injection of 20 mg of Russian chrysotile produced premesotheliomas and 42.26% mesotheliomas in the animals after 8 months (68).

Because the amount of asbestos required for the induction of mesotheliomas is small, it has been suggested that trace metal contamination may be involved (69). Neutron activation of chrysotile asbestos indicated that trace amounts of scandium, chromium, iron, and cobalt were present and were leached out and excreted and that 90% of the radionuclides were at the injection site at sacrifice. These findings indicate that fiber translocation is a slow process and that trace metal may not be involved in the neoplasm induction (70). Intrapleural injection of 25 mg of chrysotile asbestos into guinea pigs induced pleural granulomas in 14 days (62). This observation was confirmed (71).

Inhalation—Rats were exposed to chrysotile dust (quantity and fiber size not specified) for 18 hr/day for 50 days. The dust was found in the alveolar macrophages, which underwent changes to fibroblasts. There were also small nodular giant cell lesions. Changes occurred in the basement membrane with numerous impocketings in the cytoplasm of both epithelial and endothelial cells (72). Inhalation by rats of chrysotile dust (size range of <1–>20 μm) for 100 hr over 1 month showed that particles <3 μm rapidly produced fibrotic lesions in the lungs. Phagocytic ingestion is required to produce the lesion (73).

Inhalation of 86 mg/m^3 of chrysotile dust by rats for 2 years resulted in lung cancer. The incidence was greater in animals subjected to the additional insult of intratracheal instillation of 0.05 ml of 5% aqueous sodium hydroxide. It was suggested that traces of nickel, cobalt, and chromium might be involved in cancer induction (74). Another study showed that particles <20 μm long were fibrogenic, with this activity limited to groups of alveoli (75). Exposure of guinea pigs to amosite, chrysotile, and impure crocidolite dusts with particle sizes ranging from <0.3 to 2.2 μm produced asbestos bodies and diffuse interstitial fibrosis. Cuboidal metaplasia of the epithelium of the alveoli was also observed, and it had a pseudoadenomatous appearance at the 7th month. Amosite dust induced the asbestosis more rapidly than the other forms of asbestos. The lesions from chrysotile dust were severe and the impure crocidolite caused respiratory infection in the guinea pigs (76). These observations were confirmed for chrysotile fibers (72).

Peribronchiolar fibrosis of the rabbit lung was produced by inhalation of the various types of asbestos fibers (77). Lung lesions appeared earlier and were more severe in rabbits inhaling amosite fibers than in those exposed to chrysotile fibers (76). Rabbits inhaling fibers of amosite (3–5 and 0.2–0.5 μm), chrysotile (6–15 and 0.2 μm), and crocidolite (3–6 and 0.5 μm) in concentrations of 48.2 ± 1.4, 47.4 ± 1.7, and 48.7 ± 2.4 mg/m^3, respectively, developed a pulmonary fibrosis (78).

The selection of the animal species for asbestosis studies is critical because of the differences in the respiratory tract. When asbestos-exposed rats are maintained for more than a year, there is a considerable reduction in the lung dust burden because the alveolar clearance mechanism is more efficient than that of hamsters and guinea pigs (79). Vervet monkeys exposed to amosite, chrysotile, and crocidolite fibers developed the usual signs and symptoms of asbestosis and succumbed more readily to respiratory tract infections (76). Focal areas of interstitial fibrosis were found in a donkey that worked in an amosite mine, in a baboon living in the vicinity, and in rats *(Rattus namaquensis)* whose burrows were near an asbestos mill (80).

Other Routes of Administration—Injection of 58 mg of asbestos in lanolin into the marrow cavity of rats and rabbits resulted in oligocellular lesion but no tumors. Injection of asbestos into the paranasal sinuses of Osborne–Mendel rats gave similar negative results (63). Injection of chrysotile asbestos into the stomachs of rats indicated migration of the fibers *via* the bloodstream into the spleen, omentum, heart, brain, and lungs (81). However, it has been suggested that this mode of administration could have torn stomach blood vessels and that the asbestos suspension under pressure directly entered the bloodstream (82).

***In Vitro* Studies**—Tissue culture studies with guinea pig macrophages and mouse L line fibroblasts in the presence of chrysotile fibers (20–30 or 300 μm long or 10–20 or 100 μm long) were not lethal to, and did not impair glycolytic activity of, the former. The mice fibroblasts were not killed but did produce more collagen than the controls (83). Further studies of guinea pig macrophages indicated that both chrysotile and crocidolite fibers were cytotoxic because there was decreased lactic acid production, a loss of fluorochromasia by the cells, and a marked release of lactate dehydrogenase into the medium. Crocidolite was more toxic than chrysotile and pretreatment of the fibers with chelating agents, edetic acid (EDTA) and polyvinylpyrrolidone *N*-oxide, did not reduce the cytotoxic effect, indicating that the phenomenon was connected with physical and not chemical characteristics of the fibers (84).

Incubation of rat macrophages with amosite, chrysotile, and crocidolite dusts resulted in cell toxicity as measured by changes in acid phosphatase activity, 2,3,5-triphenyl-2*H*-tetrazolium chloride reducing power, and lactic acid production. Acid phosphatase activity was increased by chrysotile but not affected by the others. Chrysotile also slightly decreased the 2,3,5-triphenyl-2*H*-tetrazolium chloride reducing power and inhibited lactic acid production. Only chrysotile hemolyzed rat erythrocytes, and this action was prevented by polyvinylpyrrolidine *N*-oxide (85).

Increased lactic dehydrogenase activity and cell membrane permeability were seen after exposure of guinea pig alveolar and peritoneal macrophages to chrysotile fibers (86). Chrysotile asbestos has a high hemolytic activity whereas amosite, crocidolite, and anthophyllite lack this activity or are only weakly

lytic. This effect was attributed to the adsorptive capacity of chrysotile dust for erythrocyte membrane components (87). Comparison of the hemolytic activity of heated and unheated chrysotile fibers showed that the lytic properties were not identical because the lytic effect of the former was antagonized by carboxymethylcellulose and the latter by polyvinylpyrrolidone *N*-oxide (88). Chrysotile fibers adsorb globulins, and the adsorption bond strength was related to their fibrogenic activity (89).

It was demonstrated that amosite, anthophyllite, chrysotile, and crocidolite dusts absorb both serum IgG and rheumatoid factor, and it was suggested that the amount of the latter in asbestos workers correlated with the intensity of exposure (90). Stimulation of collagen synthesis by crocidolite fibers first elevates and then depresses proline hydroxylase activity; the latter effect occurs as the fibrotic lesion develops (91). Chrysotile produced a marked increase in tritiated thymidine uptake in the rat pleural mesothelium as early as 5–7 days after treatment, indicating a high degree of sensitivity to chrysotile. There was a rapid loss of the label after 7 days (92).

HUMAN TOXICOLOGY AND CARCINOGENESIS

The first case involving asbestos and human disease was recorded in 1907; the first case in the United States was reported in 1930. However, protective standards were not adopted until 1972. The extent of occupational and nonoccupational exposure is unknown, but the use of asbestos in the manufacture of cement pipes, sheets, shingles, floor tiles, millboard, roofing felts, pipe covering, insulation paper, flooring felts, friction and packing material, paints, roof coatings, caulks, sealants, safety clothing, curtains, brake linings, clutch facings, spray insulation, asphalt paving, welding rod coatings, and filter mediums in the pharmaceutical and beverage industries results in widespread exposure of the entire population (93). Such exposures have resulted in lung and pleural carcinoma and mesothelioma (94, 95). To understand the asbestos problem more fully, we shall discuss it industry by industry and point out the salient features of asbestosis from a clinical viewpoint.

Diagnosis—One preliminary sign of exposure to asbestos is the finding of asbestos bodies or asbestos fibers in sputum specimens (96, 97), but this sign does not indicate the presence nor the extent of disease or disability (98). Clinical observation of progressive dyspnea out of proportion to radiological changes in the lung and finger clubbing is indicative of asbestosis. The progression of the disease includes nonspecific interstitial fibrosis of the perihilar region, granular ground-glass-type infiltration, fibrosis extending throughout both lungs and pleura, marked emphysema with blebs and bulba, pleural diaphramatic plaques, and, finally, carcinoma and mesothelioma of the lungs, pleura, and peritoneum (99). Calcification of the parietal pleura and pleural plaques are distinct signs of asbestosis (100).

Definitive diagnosis of asbestosis requires the finding of asbestos fibers or asbestos bodies in affected tissue; but unless a biopsy is performed, such findings usually occur only at necropsy (101). The following diagnostic tests are also useful: a chest X-ray, vital capacity, 1-sec vital capacity, and lung compliance. The latter two tests progressively decrease during asbestos exposure, and the frequency of dyspnea is related to the decreased vital capacity (102).

Pleural calcifications by themselves are of little diagnostic significance (103) but can be helpful when a biopsy specimen shows asbestos bodies (104). "Asbestos pleural effusion" recently were added to the diagnostic signs of asbestosis (105). It also has been suggested that the ventilation perfusion ratio and the determination of blood gases should be included in asbestosis evaluation (106) because this condition is a restrictive disease with decreased diffusion capacity (107). This idea has been disputed, and it has been suggested that radiological changes in the lung coupled with measurements of forced vital capacity and 1-sec forced expiratory volume give a better assessment of the patient's condition (108). Whole body plethysmography and spirography have proven useful in following the progression of asbestosis, but chronic bronchitis can complicate the diagnosis (109).

Major clinical signs of asbestosis include diminished breath sounds, basilar crepitations, limited chest expansion, clubbing, and cyanosis. The latter two signs occur in advanced stages of the disease. Chronic bronchitis and a localized emphysema as well as right ventricular cardiac enlargement are seen. Cor pulmonale is the major complication and cause of death in asbestosis. Pulmonary endarteritis with intimal hyperplasia consistent with pulmonary hypertension and bronchioelectasia are present.

Measurement of pulmonary function is vital for a good diagnosis, because a chest roentgenogram can resemble the picture seen in viral pneumonia, lymphangtic carcinoma, Haman-Rich syndrome, and other diseases (110). Although there is a mixed impairment of the gas transport mechanisms in asbestosis, there is no relation between physical performance or radiological findings and diffusing capacity (111). Examination of 1069 men in the asbestos industry showed that only vital capacity and forced vital capacity could indicate the beginning phases of asbestosis (112).

In asbestosis, pleural reactions may occur in conjunction with mixed fibrotic reactions, making radiographic interpretation difficult. Moreover, the histological changes do not always correlate with the radiological pattern (113). In asbestos workers, vital capacity reduction precedes radiological changes by 10–15 years; the latter occurs after 20 years of exposure. After 30 years of exposure, the incidence of functional and radiographic abnormalities is the same (114). Difficulties in interpretation of radiographic changes in the various pneumoconioses have resulted in an international standard for rating the various degrees of pulmonary damage from dust exposure (115).

Radiocardiographic examination of eight patients with pulmonary asbestosis showed a reduction in

mean pulmonary circulation time and pulmonary blood flow and an increase in total blood volume, right ventricular telediastolic volume, and right ventricular postsystolic residual volume, indicative of a reduced pulmonary vascular bed (116). ECG changes consisting of left axis deviation, partial or complete bundle branch block, and right ventricular hypertrophy correlated with radiological findings in 29 cases of asbestosis (117).

Pulmonary radiological changes in asbestos workers have been related to age and years of employment (118). Examination by radioiodinated albumin scintography of 20 patients with asbestosis revealed pulmonary changes characteristic of fibrosis, with reduced radioelement in the peripheral lung field (119). Mucociliary function, as measured by inhalation and pulmonary clearance of ^{51}Cr or ^{99m}Tc microspheres, was normal in asbestosis (120). Severe asbestosis symptoms can be confused with mitral insufficiency, even when ECG and pulmonary function studies and occupation indicated asbestos was the agent involved in the residual function deficit (121).

From a diagnostic viewpoint, it is necessary not only to define the degree of cardiopulmonary impairment in obstructive pulmonary disease but to do a retrospective analysis of the patient's employment record to arrive at a positive diagnosis of asbestosis.

Pathology—The pathological changes occurring during the development of, and death from exposure to, asbestos have been well documented. It was shown that "folded lung," an extremely rare form of lung pathology, occurs in asbestosis. Folding occurred due to a fibrous membrane on the costal surface of the visceral pleural of the lower lobe. No adhesions were observed (122).

Pathological changes in the lungs in asbestosis include diffuse interstitial fibrosis with collagenization, ground-glass appearance of the parenchymal tissue, thickening of the pleura with calcified plaques, thickening of the alveolar walls and intraalveolar septa, alterations in the capillary network, macrophages containing asbestos fibers, and alveolar dilation with cuboidal metaplasia (123–127).

Asbestos does induce squamous cell carcinoma and adenocarcinomas in the lungs, and cigarette smoking increased the incidence by 8.05 times. Moreover, lung carcinoma exceeded mesothelioma by five to six times (128). In asbestosis, squamous cell carcinoma is usually in the lower lobes where the greatest number of fibers are found (129). Another complication of asbestosis is mesothelioma of the lungs and pleura. One serosal cavity is usually involved, but the underlying viscera are rarely involved. Spread is *via* the local lymph nodes with direct extension to the chest wall and spine. Distant metastases are rare (130). The latent period is usually 20 or more years.

The malignant elements are of both epithelial and mesenchymal character, with a tubular or tubo-papillary pattern containing cuboidal or flattened cells and masses of collagen. Hyaluronic acid is often present (131). The disease is rapidly progressive, averaging 2 years from onset to death (132). Microscopic examination of the malignant mesothelioma cell reveals an epithelial cell, which is large and polygonal with amphophilic cytoplasm and a clear cytoplasmic membrane. The round nucleus occupies one-third of the cell and has a loose vesicular chromatin. There are a large round eosinophilic nucleolus and multiple nucleoli. The nuclear membrane is folded or crenated, and there are many small intracytoplasmic vacuoles. Mitoses are uncommon, but multinucleated tumor cells are seen (133).

Mesotheliomas can be confused with other metastatic tumors if diagnosis is made on histological evidence alone (134). Some confusion has arisen as to the significance of pleural calcification in the development of mesothelioma (135). On the other hand, the association of asbestos exposure, occupational or nonoccupational, with malignant mesothelioma has been confirmed by investigators throughout the world (136–143).

The United Kingdom instituted a mesothelioma register where comparisons are made with carcinoma of the bronchus and lung in cases of asbestosis. Mesotheliomas occur earlier than the other pulmonary cancers. Table VI gives a comparison of mesotheliomas by site and sex for the years 1967–1968 and covers the United Kingdom. It has been suggested that even these data may be an understatement of the prevalence of the disease (144).

Asbestos Bodies in Pulmonary System—Having considered the consequences of asbestos exposure, it is necessary to discuss the actual means used for identification of the fibers themselves in asbestos bodies. The finding of asbestos bodies in the lungs does not indicate that asbestosis or pleural mesothelioma will occur or has occurred, because such bodies have been detected in 50% of the general population in certain areas. Moreover, other fibrous materials produce similar bodies, so asbestos must be positively identified (145). These other bodies may be formed from nonfibrous particulates and carbonaceous fibrous particles. Those with black fibrous core probably are derived from burning leaves, wood, or coal (146). These observations were confirmed (147). Electron micrographs have identified a large variety of dusts and fibers, which become iron coated in the lungs but do not give rise to pulmonary complications like asbestosis (148).

Classification of asbestos *versus* nonasbestos fibers

Table VI—246 "Definite" Mesotheliomas Analyzed by Sex and Site of Tumor[a]

Pathologists	Site of Tumor	Percent of All Mesothelial Tumors		Total
		Males	Females	
UICC[b] panel	Pleural	96	22	118
	Peritoneal	14 (12.8%)	2 (8.3%)	16 (11.9%)
Other pathologists	Pleural	81	17	98
	Peritoneal	10 (10.9%)	4 (19.0%)	14 (12.5%)
All	Pleural	177	39	216
	Peritoneal	24 (12.0%)	6 (13.3%)	30 (12.2%)

[a] Reference 144. [b] Unio Internationale Contra Cancerum.

is difficult, but ultramicroscopic criteria have been developed. At magnifications of 20,000 or 25,000×, asbestos fibers have profiles characterized by steplike interruptions up or down from each other and a surface characterized by parallel longitudinal lines delineating the fibrils. Nonasbestos fibers have uninterrupted linear profiles, and their surface is devoid of longitudinal parallel lines (149). Inhaled fibers become coated with an iron–protein envelope, and the central fiber can be identified as asbestos by electron microscopy.

As the asbestos body matures it changes from a thin yellow headed shape to a shorter, thicker, dark-brown segmentated form with a granulated coating which fragments and is phagocytized. This change in form can make identification difficult (150). Asbestos bodies have been demonstrated in lung smears in 30% of males and 20% of females in 500 autopsies in an urban area, but no pulmonary changes were reported (151). Another study found no correlation between nonoccupationally exposed individuals with asbestos bodies and inflammatory or neoplastic pulmonary disease (152).

An Israeli study could not evaluate the biological and clinical significance of asbestos bodies in the absence of pulmonary carcinoma (153). A New York study, in which 28 cases showed asbestos bodies, suggested that urban dwellers were being subjected to nonoccupational asbestos exposure (154). A Swedish study also reported asbestos bodies in lungs of nonoccupationally exposed individuals (155).

Methods suggested for positive identification of asbestos bodies in lung smears and sections include X-ray diffraction, phase contrast optical microscopy, optical microscopy, and electron microscopy (156–159). The last procedure is the best, particularly when combined with the scanning electron microscope. Isolation of fibers from asbestos bodies requires a digestion procedure that will not dissolve the fibers and still will allow quantitation of the total fiber population in a tissue specimen. Formamide dissolves the fibers while perchloric acid does not, and further solvent removes the excess carbonaceous material, resulting in a more exact determination (160).

Epidemiology—Occupational and environmental exposure to asbestos has been correlated with both pulmonary carcinoma and mesothelioma; but in an area where diagnostic procedures are in a state of flux, an epidemiological study is extremely difficult and unknown factors can make the results of limited value. Cohort studies of individuals in the same geographic areas and in a similar type of industry are required to obtain meaningful information (161). Epidemiological studies of asbestosis point out the long latent period before cancer development and the difficulty in determining the degree of exposure. However, when total deaths for a given locale and age group are compared by the life table technique, it is evident that asbestos does increase both pulmonary and bronchiolar neoplasia (162).

To standardize asbestos epidemiological surveys, the International Union Against Cancer suggested

Table VII—Cause of Death in Insulation Workers, Belfast, Northern Ireland, 1940–1965 (Total: 107; Mean Age: 55.3 ± 11.25 Years)[a]

Cause	Observed	Expected
Malignant:		
Intrathoracic neoplasms	28	5.3
Abdominal neoplasms	15	9.0
Other neoplasms	4	6.7
Nonmalignant:		
Pulmonary disease	31	25.6
Cardiac and circulatory	21	37.1
Other causes	5	21.3
Unknown	3	—

that detailed information covering social (smoking habits), occupational, environmental, and medical history from early childhood be collected for the individual and family units. As much information as can be obtained should be compiled on cardiopulmonary diseases and various fibroses and carcinoma of the lung, pleura, peritoneum, GI tract, and ovaries. Retrospective, cross-sectional, and prospective epidemiological surveys should be conducted, and one or more control groups should be included. Consultation with statisticians should occur prior to data collection and good experimental design should be employed (163).

The usefulness of a retrospective study is illustrated in Table VII, where the intrathoracic and abdominal neoplasms in insulation workers is excessive compared to the general population. The nonmalignant pulmonary deaths are related to the tuberculosis incidence (164). A cohort study of 1265 white males and 228 white females employed in an asbestos plant in 1938–1939 was analyzed in mid-1964, using Social Security records. Methodology was refined by including both age and duration of employment as well as all causes of death, asbestosis, cardiovascular disease, and malignant neoplasms. Upon this basis, it was possible to relate exposure to asbestos directly to a general increase in mortality rate from all of these causes (165). A further substantiation of the relationship between asbestos exposure and mesothelioma in this same plant was reported in which three more cases of mesothelioma not in the previous cohort were found (166). Further confirmation of the relationship between mesothelioma and slight asbestos exposure 20–30 years previously was shown (167).

Validation of death certificates using the British Registrar General and correlating necropsy reports with histological observations showed that bronchial carcinoma was not underestimated but that mesothelioma was (168). A German epidemiological study associated pleural mesothelioma with asbestos exposure many years previously (169). Material for future epidemiological studies will be obtained from the many industries involved in mining and processing asbestos.

Mining and Milling—The difficulties in associating asbestosis with mining are illustrated by a Bulgarian study of 3325 people living near an asbestos mine. Out of 155 cases of pleural asbestosis, only 23 were involved in mining; the remaining 132 cases

were tobacco workers. Air pollution was not involved, but the farms were composed of rocky soil containing asbestos minerals (170).

An Italian study of 288 cases of asbestosis gave the following distribution: mining, 32; friction products, 161; cement, 60; and insulation, 35; the indication was that finer asbestos dust was more dangerous (171). Exposure to Finnish anthophyllite asbestos in two mines resulted in an excess number of deaths from asbestosis and lung cancer (172, 173). Asbestosis has been reported in Australian miners but no mesotheliomas because the latent period for their development has not been passed (174).

Exposure to South African crocidolite asbestos produced 33 cases of diffuse pleural mesothelioma in the asbestos mining area of the country (175). Thirty-one other cases of asbestosis were examined but no pulmonary carcinomas were observed. This result is probably related to the short-time interval of exposure and the known latency for mesothelioma development (176).

There appears to be a difference between the development of mesotheliomas after exposure to crocidolite and amosite fibers, which suggests that the latter may be the least carcinogenic of the two forms of asbestos or require a longer time interval for tumor induction (177). This difference between the two varieties of asbestos is not evident when fibrosis is considered because they are then equally potent (178).

In a study of mortality in Quebec chrysotile mines covering 9981 individuals, only 97 lung cancers and three mesotheliomas were found. It was suggested that this form of asbestos may be less carcinogenic than the other varieties. Accumulated dust exposure and duration of employment apparently influenced the figures (179). Present dust exposures in these mines and mills are now 10 million particles/ft^3 down from the 75 million particles/ft^3 in 1948; thus estimation of total dust exposure must be adjusted not only for time but for work area and must take into account both fibrous and nonfibrous dust (180). Respiratory symptoms and function tests were related to dust exposure of 1015 individuals in these industries, but the other parameters had little or no influence (181, 182). Mining and milling in other countries do not differ from those reported here, but the types of asbestos do.

Asbestos Friction Materials—One occupation in which exposure to asbestos dust occurs in unsuspecting individuals is routine brake and clutch maintenance of automobiles and trucks. The amount of dust evolved in blowing out the brake drums varies from 1.42 to 3.62 fibers/cm^3; personnel samplers give an average of 0.68 fiber/cm^3 in the breathing area for automobiles, 7.09 fibers/cm^3 for brakes, and 2.25 fibers/cm^3 for trucks. Thus, over a time period, daily exposure could result in the development of asbestosis (183). Most of these figures are above the recommended level of 2 fibers/cm^3 (46).

On the other hand, the temperature generated on braking, 600°, causes the asbestos fibers to be converted into a series of olivine minerals which are unlike asbestos chemically, physically, and physiologically. It was suggested that dust clouds from brake drums are filthy but much less harmful than asbestos (184). Vacuum cleaning reduces the number of escaping particles to a minimum and should be used (185), but a vacuum brush is even better (186).

Asbestos Textiles—All areas of textile production (fiberizing, carding, spinning, plaiting, and weaving) have contributed to the induction of asbestosis, with subsequent development of peritoneal mesothelioma. In one factory, with asbestos exposures ranging from 10 months to 32 years, there were 11 cases of the disease; survival time varied from 20 to 46 years following the initial exposure (187). In the London area, textile industry asbestos exposure produced 83 cases of mesothelioma: 27 peritoneal and 56 pleural tumors. Terminal illness ranged between 16 and 55 years. In nine of these cases, domestic exposure occurred from asbestos dust on work clothes, pointing out one of the many ways the disease may be brought about (188). A factory in Pennsylvania had 68 cases of asbestosis with 21 malignancies; again the time to induction was long, 10–36 years (189). In 42 cases of mesothelioma, 10 persons worked in the factory, eight lived nearby, three were family members, 10 had some degree of asbestos exposure, and 11 had no history of exposure. Thus, environmental exposure was involved to a great extent (190).

Overall mortality from cancer of the respiratory and digestive tracts and cor pulmonale in asbestos textile workers was 21% above the U.S. national average in 1948–1951 (191). German experience indicates a similar type of response to asbestos, complicated with tuberculosis (192). An example of English textile workers dying of pleural mesothelioma is given in Table VIII. Again, long latency is evident (193). In Hamburg, 119 cases of pleural mesothelioma, 79 men and 40 women, were reported for 1958–1968 and 51 cases were definitely linked to asbestos exposure. The average latency for tumor development was 35.2 years (194).

A survey of 1160 asbestos textile workers revealed excess deaths from lung and pleura cancer and cancer at other sites in workers receiving heavy asbestos exposures. Excessive mortality from respiratory disease was also found in this group (195). Examination of smoking records in asbestos workers indicated possible synergism between these lung irritants and the induction of pulmonary fibrosis (196). Study of over 900 female asbestos workers showed that low to moderate exposure produced excess death from cancer; high exposure produced excess death from lung and pleural cancer as well as respiratory disease. Synergism between asbestos and smoking was observed (197).

Asbestos Insulation—The use of asbestos fibers in the insulation of homes and high-rise structures has been a source of asbestosis not only to the appliers but also to those occupying the building and those passing by in the area. Even with a history of prolonged exposure to asbestos, it may be difficult to reach a diagnosis of pleural mesothelioma because so-called benign mesotheliomas do occur and tuberculosis can stimulate the mesothelial cells to give the ap-

Table VIII—Occupational and Pathological Data Relating to Asbestos Workers Dying with Pleural Mesothelioma: All Employees[a]

Year of Death	Sex	Age, Years	Occupation	Period of Exposure	Duration of Exposure, Years			Necropsy		Death Certificate	
					Total	Before Jan. 1, 1933	From Beginning to Death	From End to Death	Performed	Asbestosis Present	Asbestosis Mentioned	Attributed Cause of Death
1936	Male	65	Fiberizer	1913–1936	23	19	23	<1	+	+	+	Endothelioma of pleura
1964	Male	57	Carder, spinner	1922–1923[b]	1 5/12	1 5/12	42	41	+	0	+	Malignant pleural tumor
1966	Female	55	Carder, spinner	1926–1935	9	6	40	31	+	0	0	Carcinoma of lung
1966	Male	59	Weaver	1937–1938[c] 1960–1965	6	0	29	1	+	+	+	Carcinoma of lung
1967	Male	72	Weaver	1914 1919–1920	0 7/12	0 7/12	53	47	+	0	0	Myeloid leukemia (carcinoma of lung associated)

[a] Reference 193. [b] Also employed for 15 years in the rubber department (1929–1944) and 20 years in the warehouse (1944–1964). [c] Also employed in the warehouse (1929–1930).

pearance of neoplasia (198). Examination of 632 building insulation workers revealed 45 deaths from lung or pleural cancer and 39 deaths from cancer of the stomach, colon, or rectum. The relationship of the latter to asbestos exposure could not be definitely proven (199).

The risk for asbestos insulation workers of developing mesothelioma of the pleura or peritoneum is much greater than for the general population, 10 per 307 *versus* 3 per 31,652 (200). Long exposure to asbestos fibers may not be required for the induction of mesothelioma of the lung, because an accountant exposed to asbestos insulation for 1 month developed the disease 6 years later (201).

Asbestosis has also been observed in hardboard and transformer winding workers but the minor exposure, while producing fibrotic changes in the lungs, gave no evidence of pulmonary cancer (202). Studies on 152 asbestos insulation workers revealed 46 deaths with 23 due to malignancy. All workers had 15 years of exposure to asbestos dust, and the range of ages was 33–81 (203). An increase in pleural mesothelioma was projected for Australian insulation workers since increased amounts of asbestos are being used in that country (204). A survey of 370 asbestos insulation workers indicated that those who smoked cigarettes have a 92 time greater risk of developing pulmonary cancer than those who did not smoke (205).

The most hazardous area in the insulation trade is the removal of old asbestos and its replacement, during which pounding of asbestos blocks and mixing finishing muds lead to high environmental fiber levels (206). The high risk of death from asbestos exposure, 300 out of 632 union members, resulted in a modern industrial hygiene program sponsored by the union, industry, government, and medical science. This preventative program should decrease the exposure of insulation workers (207).

Asbestosis has been shown to be a major cause of pulmonary disease in Northern Ireland, Sweden, and Finland (208–211). It had been suggested that insulation workers exposed to amosite might not get cancer, but 25 cases of lung cancer occurred in 230 workers exposed to this form of asbestos (212). A recent report indicates that there is a relationship between asbestosis and cancer of the larynx (213).

Pipe Insulation—The installation and removal of insulation on pipes in ships, power stations, factories, and buildings are very dusty operations. Pipe sections, slabs, powder, and mattresses are composed of 85% magnesia and 15% amosite asbestos. Exposure occurs during sawing and fitting pipe sections, mixing asbestos plaster, and stripping off old lagging (214). A comparison of fiber glass, polyurethane, and asbestos pipe insulation showed that only the latter could be considered hazardous. An evaluation of 33 death certificates gave a 24.2% incidence of malignant neoplasms in the asbestos workers (215). A revision of the threshold limit value for asbestos was suggested when it was discovered that pipe coverers working for 20 or more years had a 38% incidence of asbestosis when exposed to apparently "safe" dust concentrations (216).

Table IX—Ranges of Dust Concentrations in Various Dockyard Areas[a]

Process	Range, Fibers/cm³
Storerooms	0.1–36
Application of amosite sections	9–40
Application and stitching of asbestos cloth	0.05–0.26
Removal of amosite sections (boiler room)	29–1040
Removal of blue sprayed asbestos	112–1906
Removal of asbestos acoustic board	48–683
Bagging asbestos debris	106–3815

[a] Reference 219.

Ship Repairs—Shipboard pipe covering and insulation during overhaul and repairs are extremely hazardous, and it is difficult to prevent massive exposures (217). Diffuse mesothelioma was related to asbestos exposure in 14 shipyard workers in Liverpool (218). The range of fiber counts in various occupations in a dockyard is given in Table IX; removal of asbestos gives the highest counts and the greatest worker exposure (219). Asbestos exposure in English shipyards has been shown to produce pleural fibrosis (28%) but only a few cases of mesothelioma (220, 221).

Dutch investigators found an unusually high incidence of pleural and peritoneal mesotheliomas in shipyard asbestos workers (222). A Scottish retrospective study, covering 1950–1967, discovered 80 cases of malignant mesothelioma in shipyard workers handling asbestos (223). In 1965–1970, 25 cases of pleural mesothelioma were reported in Plymouth shipyard workers (224). A similar observation was made for Italian (225) and Dutch (226) shipyard workers.

In a cohort study, it was found that asbestosis in shipyard workers was 11 times more prevalent than in the controls and prolonged exposure to asbestos, even at low dust concentrations, was hazardous (227, 228). Continuous surveys of British dockyard workers turned up 37 cases of mesothelioma since 1965 and many cases may go undetected (229).

Other Sources of Exposure—The widespread use of asbestos, including asbestos-cement water pipes, beverage filter media, household iron-holders, and asbestos in cigars, is a nonoccupational route of exposure which contributes to the worldwide distribution of cancer (230). The incidence of English males dying from asbestosis and having lung cancer during 1924–1963 is given in Table X. The percent of those with lung cancer has been increasing because the victims have been living longer (231).

Table X—Incidence of Lung Cancer in Males Dying with Asbestosis[a]

Period	Deaths from Asbestosis	Percent with Contaminant Cancer of Lung	Average Age at Death from Uncomplicated Asbestosis, Years
1924–1940	79	16.4	49.3
1941–1950	92	22.8	55.9
1951–1960	144	31.3	58.1
1961–1963	77	54.5	60.4

[a] Reference 231.

Protective asbestos clothing (aprons, gloves, and aluminized asbestos garments) give rise to high fiber counts in the respiratory area (232).

Asphalt–asbestos or vinyl–asbestos tile contains 15–25% asbestos, which becomes airborne during the sanding operation associated with their installation. Mesotheliomas have resulted from inhalation of this dust (233).

Fire-eater's asbestosis has occurred from extinguishing the torch by placing it in the mouth (234).

Coke oven or silo construction requires effective insulation containing asbestos, and workers have developed asbestosis with lung carcinoma and/or mesothelioma (235, 236).

Asbestos cement and wall board present hazards to both the producer and the user. In the latter case, sawing such boards without using a respirator has resulted in the development of asbestosis years later (237, 238).

Asbestosis has also been associated with severe rheumatoid disease with necrobiotic foci similar to those encountered in subcutaneous rheumatoid nodules (239, 240). In 80 cases of asbestosis, antinuclear and rheumatoid factors were found in 28 and 27%, respectively. There was a relationship between these autoantibodies and the degree of radiographic abnormality but not between the duration of asbestos exposure (241).

COMMENT AND CONCLUSIONS

In the controversy concerning amosite fibers in water supplies, it is necessary to identify and establish exact amounts of asbestos per unit volume. It has been established that the Duluth water supply contains 1–30 × 10^6 fibers/liter, equivalent to 1–30 μg/liter (242). This amount would appear to present a hazard to the individuals exposed daily (243). An analysis of cancer mortality in the region indicated no increase in cancer mortality patterns of persons of any age group. However, only 14 years have passed and asbestos-induced cancer requires at least 20 years (244). It was suggested that this lack of carcinogenic effect is related to the inability of particle transmigration through the intestinal mucosa (245). The size of the fibers, less than 5 μm in length, may be incapable of causing fibrosis or cancer (246).

Thus, after reviewing the asbestosis problem, covering chemistry, industrial hygiene, animal and human toxicology, and carcinogenic aspects, it becomes evident that more attention must be paid to analytical chemistry, particle size, and epidemiology. The difficulties encountered in the analysis of asbestos reside in the fact that its chemical composition differs only slightly from one variety to another and, depending upon the method of preparation, it may become contaminated with other metallic ions. Since particle size appears to be the controlling factor in the induction of asbestosis and cancer, accurate sizing must be done to prevent a negative result. Epidemiology should include a continuing follow-up of known cases of asbestosis and the addition of new cases as they become apparent. Cohort studies should

be initiated where possible, and assessment of the degree of exposure should be undertaken to correlate the amount of asbestos inhaled with individual response as related in time.

Experimental studies covering ingestion of various forms of asbestos should be initiated to ascertain the effect of such ingestion on GI penetration and the development of fibrosis and carcinoma. A good statistical design should be employed, utilizing both physical (fiber glass of the same particle-size distribution) and chemical control groups. In the latter case, the chemical should have its major carcinogenic effect on the GI tract. The animal species selected for this experiment should have a low spontaneous incidence of carcinoma of the target tissue and, hopefully, an overall low incidence of tumors in other tissues. The observation of time to tumor should also be included. Diet variations (*e.g.*, ulcerogenic) should be considered as a possible additional aspect of the problem.

Effects of Normal Alcohols on Intestinal Absorption of Salicylic Acid, Sulfapyridine, and Prednisolone in Rats

WILLIAM L. HAYTON

Abstract □ The rates of intestinal absorption of salicylic acid, sulfapyridine, and prednisolone from solutions containing no alcohol or 0.5% ethanol, *n*-butanol, or *n*-hexanol were determined. At the concentrations used, ethanol did not significantly affect drug absorption. Butanol reduced the rate of absorption of sulfapyridine but did not significantly affect the absorption rates of prednisolone or salicylic acid. Hexanol reduced the rates of absorption of sulfapyridine and salicylic acid and increased the rate of absorption of prednisolone. The absorption-altering effects of the alcohols were concentration dependent and rapidly reversible. Histological studies indicated that the structure of the epithelium was not altered by the alcohols. While the absorption rate of water from the drug solutions was increased by the alcohols, their absorption-altering effects could not be attributed solely to increased water flux. In addition, the absorption-altering effects of the alcohols could not be attributed to formation of drug–alcohol complexes nor to alcohol-induced alterations in the extent of binding of the drugs to nondialyzable materials in the intestinal drug solution.

Keyphrases □ Alcohols, normal—effects on intestinal absorption of salicylic acid, sulfapyridine, and prednisolone, rats □ Salicylic acid—effects of normal alcohols on intestinal absorption, rats □ Sulfapyridine—effects of normal alcohols on intestinal absorption, rats □ Prednisolone—effects of normal alcohols on intestinal absorption, rats □ Absorption, intestinal—salicylic acid, sulfapyridine, and prednisolone, effects of normal alcohols, rats

Several changes in the structure and function of the epithelial lining of the small intestine may occur when it is exposed to aqueous solutions of normal alcohols. For example, ethanol inhibited the active transport of amino acids in the small intestine of humans (1), and several alcohols, including ethanol and *n*-butanol, inhibited the active transport of amino acids and glucose through the everted rat intestine (2). Acute oral administration of aqueous solutions of 5% ethanol to the rat produced hemorrhagic erosions in the intestine and reduced the activities of lactase and thymidine kinase; oxygen consumption by jejunal slices was also reduced by ethanol (3).

Such changes suggest that the capacity of the intestine to absorb drugs may be altered by exposure of the intestine to alcohols. Two percent ethanol in solutions of theophylline recirculated through segments of rat jejunum increased the rate of absorption of theophylline, apparently due to an ethanol-induced increase in the rate of water absorption (4). However, the presence of 2% ethanol in solutions of barbiturates, sulfaguanidine, and promethazine did not significantly alter the rate of drug absorption (5).

The purpose of this study was to determine the effects of low concentrations of ethanol, *n*-butanol, and *n*-hexanol on the rates of intestinal absorption of salicylic acid, sulfapyridine, and prednisolone. These drugs were used because of their diverse physicochemical properties. Salicylic acid was ionized at the pH of these experiments, while sulfapyridine and prednisolone were not. The *n*-butanol–pH 7.0 aqueous buffer partition coefficients of salicylic acid, sulfapyridine, and prednisolone were 0.5, 3, and 40, respectively.

The concentration of alcohol used was 0.5% or less. This concentration of ethanol is readily achieved in the intestinal lumen of humans following oral ingestion of relatively small quantities of ethanol. For example, oral administration of 40 g of ethanol as a 10 or 20% aqueous solution produced ethanol concentrations in the upper jejunum above 1% for 30–60 min (1). While the intestinal mucosa is exposed to a number of aliphatic alcohols following consumption of some alcoholic beverages, exposure to levels of 0.5% butanol or hexanol would only be found after accidental ingestion of preparations containing relatively high concentrations of the alcohols.

EXPERIMENTAL

Materials—Sodium salicylate[1], salicylic acid[1], sodium sulfapyridine monohydrate[2], sulfapyridine[3], prednisolone[4], and ^{3}H-prednisolone[5] were used as received. The labeled radiochemical purity (>95%) of ^{3}H-prednisolone was verified periodically by TLC on glass plates coated with silica gel G and developed with benzene–2-propanol (4:1). Reagent grade absolute ethanol[6], *n*-butanol[7], *n*-pentanol[8], and *n*-hexanol[9], 98%, were used as received. Isopropyl myristate[10] was purified by passing it through a column packed with aluminum oxide. Following purification, no free acid was detected by the USP XVII method (6).

Complex Formation—Apparent association constants for drug–hexanol complexes with assumed 1:1 stoichiometry were determined by the solubility method (7). Fifteen milligrams of prednisolone, 15 mg of sulfapyridine, or 200 mg of salicylic acid was placed in each of a series of 10-ml ampuls; then 5 ml of solutions of hexanol in isopropyl myristate (0.0–0.20 *M*) or water[11] (0.0–0.05

[11] 0.1 *M*, pH 6.5 sodium phosphate buffer for sulfapyridine.

M) were added. The ampuls were flame sealed and rotated for 72 hr in a 25 ± 0.1° water bath. After suspended drug particles were allowed to settle, the ampuls were opened, a sample of supernate was removed and filtered through a 0.25 ± 0.03-μm filter[12], and the concentration of drug was determined.

Hexanol did not interfere with the analytical methods used to determine drug concentration; when solutions of the drugs in isopropyl myristate or water were filtered, no change in drug concentration was observed. All phase solubility diagrams were type A_L, and association constants were determined from the slopes and intercepts of lines fitted to the diagrams by least squares (7).

Intestinal Clearance—Male Sprague–Dawley rats, 200–350 g, were housed in wire mesh cages in a room maintained at approximately 20° and lighted automatically 12 hr/day. The clearance of prednisolone, sulfapyridine, and salicylic acid from solutions recirculated at 6 ml/min through a 20-cm segment of *in situ* jejunum was measured by a technique described previously (8). When present, the concentration of alcohol in the recirculating drug solution was maintained constant by infusing the alcohol into the solution at the same rate that it was absorbed by the intestine.

Ethanol and butanol were infused into the recirculating drug solution as aqueous solutions. Due to its low solubility in water, hexanol was infused undiluted. Prednisolone (0.28 mM), containing 0.1 μCi/ml of ^{3}H-prednisolone, was dissolved in 154 mM NaCl solution; sulfapyridine (0.40 mM) and salicylic acid (13 mM) were dissolved in 67 mM sodium phosphate buffer at pH 6.6 and made isotonic with 82 mM NaCl. The amount of sodium chloride in the drug solutions was not reduced when alcohol was present.

The drug solution was sampled periodically and the drug concentration was determined. The drugs were absorbed by apparent first-order kinetics (Fig. 1), and absorption rate constants were determined from the slopes of lines fitted by least squares to plots of drug concentration *versus* time on semilogarithmic coordinates. The initial point was omitted from the least-squares fit to ensure stationary-state conditions; while the initial point was close to the line in the control experiments, it tended to fall above the line when the alcohols were present. This tendency for positive deviation, indicating transient rapid absorption of the drugs, increased with the molecular weight of the alcohol.

The absorption rate constants were converted to clearance per centimeter of intestine by multiplying the rate constant by the volume of perfusate, correcting for drug removed due to sampling, and dividing by the length of the intestine. The absorption rate of water per centimeter of intestine was calculated by dividing the difference between the amount of water added to the drug solution to maintain its volume and alcohol concentration constant and the amount removed as samples by the duration of the experiment and by the length of the intestine. When alcohol was present, its concentration was determined at the beginning, middle, and end of each experiment and the three values were averaged. Not more than 10% of the LD_{50} of any alcohol was absorbed during any experiment.

Drug Binding in Perfusate—Isotonic sodium phosphate buffer, alone or containing 0.3% hexanol, was recirculated through segments of intestine for 1 hr. The perfusate was placed in one chamber of a dialysis cell separated by a cellulose membrane from an equal volume of buffer containing drug and 0.3% hexanol when it was present in the perfusate. The dialysis cell was agitated in a 37° incubator, and the drug concentration on each side of the membrane was measured until successive determinations were the same. The percent of drug bound to nondialyzable substances in the perfusate was found as follows:

$$\% \text{ drug bound} = \frac{C_p - C_b}{C_p} \times 100 \qquad \text{(Eq. 1)}$$

where C_p and C_b refer to the concentration of drug in the perfusate and buffer, respectively, at equilibrium.

Histology—Segments of intestine were perfused with isotonic sodium phosphate buffer, alone or containing 0.5% ethanol, butanol, or hexanol. When present, the concentration of alcohol was maintained by infusion. After 1 hr, each segment was removed and fixed immediately in 10% buffered neutral formalin. Pieces of each segment were embedded in paraffin, and sections of 4–6-μm thickness were cut and stained with hematoxylin and eosin-phloxine (9).

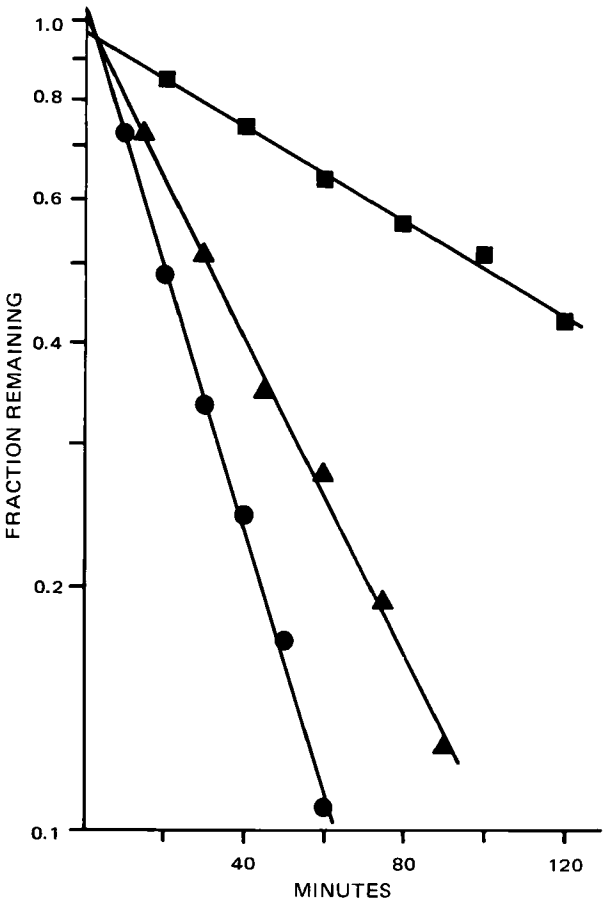

Figure 1—*Fractions of the initial concentrations of prednisolone (■), sulfapyridine (▲), and salicylic acid (●) remaining in the intestinal drug solution as a function of time. Each plot is from a single, representative experiment.*

Analytical Methods—Tritium was determined in 50-μl samples of intestinal perfusate and 1-ml samples of blood plasma by mixing with scintillation fluid[13] and counting in a liquid scintillation spectrometer[14]. For the intestinal perfusate samples, the efficiency of the counting system was constant at approximately 40% and was not affected by the small amounts of alcohol; therefore, correction for quenching was not made routinely. The counting efficiency of the plasma samples was 20–30%, and ^{3}H-toluene was used as the internal standard for quench correction. In studies on complex formation, prednisolone was determined by the USP colorimetric procedure (6). Sulfapyridine and salicylate in samples of intestinal perfusate and in studies on complex formation were determined by colorimetric methods (10, 11). The drugs were extracted from 1-ml samples of isopropyl myristate with 5 ml of 1% Na_2CO_3; 0.5 g of NaCl was added to prevent emulsification.

Ethanol in 0.1-ml samples of intestinal perfusate was determined by a GC method (12). Each sample was placed in a 10-ml serum bottle, which was then sealed with a rubber septum. The sample was incubated for 20 min in a 37° water bath and 0.50 ml of the vapor phase was injected onto a glass column, 4 mm i.d. by 1.8 m (6 ft), packed with 5% Carbowax 1500 on Haloport F (30–60 mesh). The temperatures of the injection port, oven, and flame-ionization detector were 110, 70, and 240°, respectively. The flow rates of helium, hydrogen, and air were 30, 30, and 500 ml/min, respectively. The retention time for ethanol was 3.5 min, and a plot

Table I—Effect of 0.5% *n*-Hexanol on the Distribution of Radioactivity following 30-min Perfusion of *In Situ* Rat Intestine with Solution of ^{3}H-Prednisolone

	Control[a]	*n*-Hexanol[a]	*p*
Percent of dose absorbed	21.3 (6.24)	33.2 (5.21)	<0.01
Plasma concentration[b]	4.89 (1.78)	8.70 (1.60)	<0.01
Length of intestine perfused, cm	19.4 (1.72)	19.9 (1.46)	>0.50

[a]Mean from seven experiments; *SD* in parentheses. [b](dpm/ml ÷ dpm administered) × 10^4.

of peak height *versus* concentration of ethanol was linear over the 0.1–0.5% range.

Butanol and hexanol in 0.1-ml samples of intestinal perfusate were also determined by GC. The samples were mixed with 0.1 ml aqueous 1-pentanol, which was used as an internal standard; approximately 1 μl was injected onto a stainless steel column, 0.31 cm (0.125 in.) o.d. by 1.8 m (6 ft), packed with Porapak Q, 80–100 mesh. The temperatures of the injection port, oven, and flame-ionization detector were 240, 225, and 230°, respectively. The flow rates of helium, hydrogen, and air were 40, 30, and 500 ml/min, respectively. Plots of the ratios of peak heights of butanol or hexanol to pentanol *versus* concentration were linear over the 0.1–1.0% range. No apparent alcohol was detected in samples of intestinal perfusate without alcohol.

RESULTS AND DISCUSSION

The effects of 0.5% ethanol, butanol, and hexanol on the rates of disappearance of prednisolone, sulfapyridine, and salicylic acid

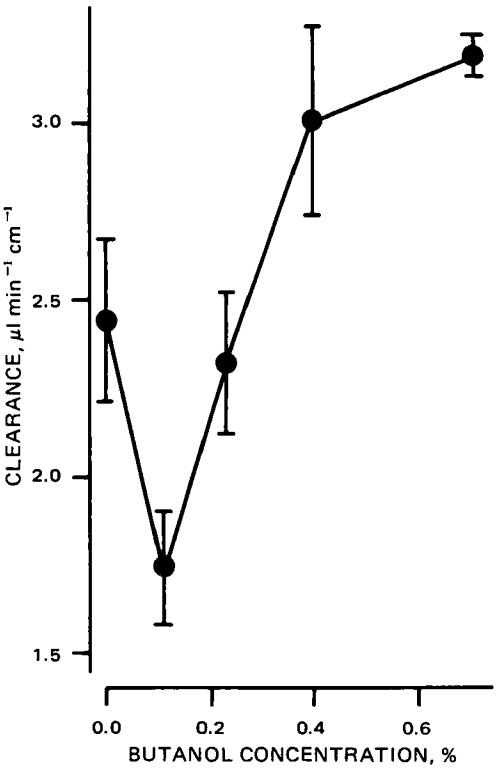

Figure 3—*Effect of various constant concentrations of butanol on the absorption of prednisolone from solutions recirculated through the* in situ *rat jejunum. Each point represents the mean from four or more experiments; bars indicate ±1* SE.

from solutions recirculated through the *in situ* rat jejunum are shown in Fig. 2. Ethanol did not significantly affect the rate of drug disappearance. The rate of disappearance of sulfapyridine was reduced by butanol, while the rates of disappearance of prednisolone and salicylic acid were not significantly altered. Hexanol increased the rate of disappearance of prednisolone and decreased the rates of disappearance of salicylic acid and sulfapyridine. The concentration dependence of the effects of butanol on the rates of disappearance of prednisolone and sulfapyridine is shown in Figs. 3 and 4.

To verify that the alcohol-induced changes in the rates of drug disappearance from the intestinal lumen reflect changes in absorption rates, the tritium concentration in the plasma was measured after perfusing intestinal segments for 30 min with a solution of ^{3}H-prednisolone and 0.5% hexanol. Compared to the control experiment in which no hexanol was present, the tritium concentration in the plasma and the amount of prednisolone absorbed were significantly increased (Table I). The increased rate of prednisolone absorption in the presence of hexanol cannot be attributed to differences in the length of intestine perfused.

A similar experiment with sulfapyridine showed no difference

Table II—Clearance of Prednisolone and Salicylic Acid by Perfused *In Situ* Rat Intestine during Two Consecutive 1-hr Periods

between the control and hexanol in either the extent of absorption of the drug or its blood plasma concentration. The lack of effect at 30 min was apparently due to the transient rapid absorption[15] of sulfapyridine that occurred in the presence of hexanol. Such behavior illustrates the importance of characterizing the intestinal clearance of drugs by monitoring the drug concentration in the intestinal lumen over a period of time rather than making "single-point" determinations.

The absorption-altering effects of the alcohols may have resulted from damage to the intestinal epithelium exposed to the alcohols. To check this possibility, segments of jejunum were perfused for 60 min with an isotonic sodium phosphate buffer containing no alcohol or 0.5% ethanol, butanol, or hexanol. Thin sections of perfused intestine were prepared and examined by a veterinary pathologist. No differences were detected in the structure of the intestine perfused with 0.5% alcohol compared to the intestine not exposed to alcohol (Fig. 5).

In addition, the absorption-altering effects of hexanol were rapidly reversible. The clearance of prednisolone and salicylic acid was measured during two consecutive 1-hr periods in the same segment of intestine. During the first period, 0.5% hexanol was present. This solution was then removed; during the second period, the intestine was perfused with a solution of drug without hexanol.

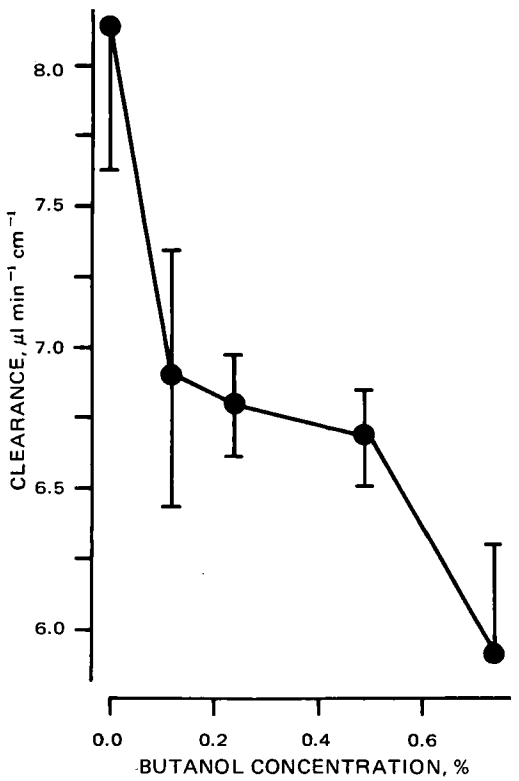

Figure 4—*Effect of various constant concentrations of butanol on the absorption of sulfapyridine from solutions recirculated through the* in situ *rat jejunum. Each point represents the mean from four or more experiments; bars indicate ±1* SE.

Prednisolone	4.2	2.3

[a]Liters per mole. [b]High solubility precluded measurement.

The results of this experiment (Table II) show that the increased clearance of prednisolone produced by hexanol returns immediately to the control value when hexanol is removed from the intestinal perfusate.

The clearance of salicylic acid did not return to the control value during the period following exposure of the intestine to hexanol. However, the control experiment for salicylic acid indicates that the lack of reversibility was due primarily to exposure of the intestine to salicylate rather than hexanol. Reduced absorption of salicylic acid following its repetitive instillation to the stomach in humans (13) and intestine in rats (14) was reported. Thus, it appears that the alcohols do not alter drug absorption rates by damaging the intestinal epithelium.

Salicylic acid and sulfapyridine are weakly acidic, pKa of 3.0 and 8.4, respectively (15), so an alcohol-induced change in the pH of the intestinal drug solution could explain the effects of the alcohols on the rates of drug absorption. The pH of the intestinal drug solution decreased slightly during the absorption experiments when no alcohol was present (Table III), and neither ethanol nor butanol influenced the magnitude of the decrease. Although at the end of the experiment the pH of the drug solution containing hexanol was slightly greater than the control value, it is not likely that this small difference in pH could account for the effect of hexanol on the absorption rates of salicylic acid and sulfapyridine.

The rate of drug absorption may be increased or decreased by formation of molecular complexes, depending on the relative extent of complexation of the drug in the luminal solution and the intestinal epithelium (16). To explore this possibility, the extent of complex formation between the drugs and the alcohols was determined by phase solubility analysis. The apparent 1:1 association constants for sulfapyridine–hexanol and prednisolone–hexanol complexes in water were quite low (Table IV). Not more than 9% of sulfapyridine or prednisolone would be complexed with 0.5% hexanol in the intestinal perfusate. The extent of complexation between the drugs and alcohols in isopropyl myristate was also small, indicating that formation of drug–alcohol complexes in the lipoid barrier of the intestine would be insignificant.

Thus, the lack of appreciable interaction between any of the drugs and alcohols suggests that the absorption-altering effects of the alcohols are not due to formation of drug–alcohol complexes. Another possible mechanism for the absorption-altering effects of the alcohols is an alcohol-induced change in the extent of drug binding to macromolecules released possibly from the intestinal mucosa. Dialysis studies on intestinal perfusates, however, revealed that the extent of drug binding was low and not affected significantly by hexanol (Table V).

The rate of water absorption by the intestine was shown theoretically (17) and experimentally (4, 18) to influence the rate of drug absorption by the intestine. Generally, the rate of drug absorption increases linearly with the rate of water absorption. Al-

Table V—Percent of Drug Bound in the Perfusate to Nondialyzable Material from the Intestinal Mucosa

	Percent Drug Bound[a]

though the presence of the alcohols increased the osmotic pressure of the drug solutions, the average rate of water absorption by the intestinal segment was increased significantly by ethanol and butanol compared to the control (Table VI). Hexanol did not appear to alter the rate of water absorption. Ethanol produced a similar increase in water absorption by the rat intestine (4), and butanol increased the permeability coefficient of water in frog eggs (19).

While the rate of water absorption probably influenced the rate of drug absorption by the intestine in this study, there was no significant correlation between drug clearance from solutions con-

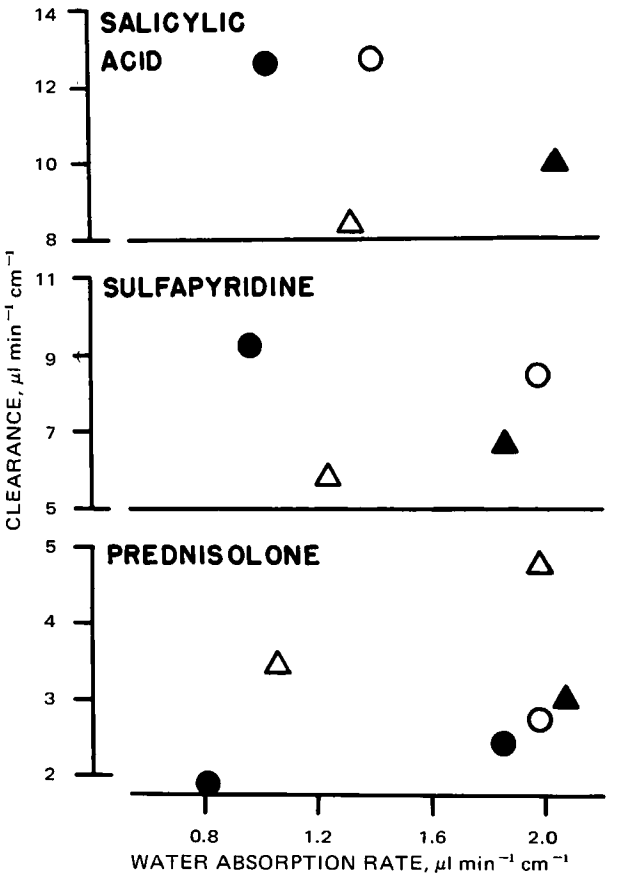

Figure 6—*Clearance of salicylic acid, sulfapyridine, and prednisolone* versus *water absorption rate from solutions containing no alcohol (●) or 0.5% ethanol (○), butanol (▲), or hexanol (△). The clearance of prednisolone from both isotonic sodium chloride and sodium phosphate solutions is shown.*

taining alcohols and the rate of water absorption (Fig. 6). It appears, therefore, that the absorption-altering effects of the alcohols did not result entirely from an alteration in the absorption rate of water. In the control experiment, the rate of water absorption from the solution containing prednisolone was greater than that from the solutions containing salicylic acid or sulfapyridine (Table VI). The latter drugs were in isotonic sodium phosphate buffer, and prednisolone was in isotonic sodium chloride solution.

When the effect of hexanol on the intestinal clearance of prednisolone from the sodium phosphate buffer was examined, hexanol was found to increase the clearance of prednisolone, as it did in the sodium chloride solution (Table VII). Thus, the ionic composition of the perfusate appears to influence the rate of water absorption.

These experiments show that normal alcohols can either increase or decrease the apparent permeability of the rat jejunal mucosa. The magnitude of the change in permeability depends on the concentration and lipophilicity of the alcohol, and the direction of change depends on the drug. The absorption-altering effects of the alcohols cannot be attributed to mucosal damage, pH changes, or complex formation. It is possible that the effects of the alcohols result from a single change in the structure or function of the intestinal mucosa.

For example, the alcohols may displace water from the lipoidal cell membrane, causing a decrease in the polarity of the membrane and thereby increasing the permeability of the membrane to prednisolone, which is relatively nonpolar, and decreasing its permeability to the relatively polar sulfapyridine and salicylate. Alternatively, if the barrier to absorption is structured water, as was suggested (20, 21), the alcohols may increase the degree of structuring of water (22), causing the permeability of the barrier toward nonpolar drugs to increase and toward polar drugs to decrease.

On the other hand, the absorption-altering effects of the alcohols may result from two or more alcohol-induced alterations in the structure or function of the intestinal epithelium. One or more

[a] μl min⁻¹ cm⁻¹ of intestine; mean from four or more experiments; *SD* in parentheses. [b] Sodium chloride, 154 mmoles/liter. [c] Sodium phosphate, 67 mmoles/liter; sodium chloride, 82 mmoles/liter.

of the alterations may tend to increase the permeability of the intestine, while the remaining alterations tend to decrease its permeability. The effect observed would then be the net effect of all alterations in the barrier properties of the mucosa. Whether the observed effect of the alcohols is positive or negative would depend on the relative magnitudes of all individual alterations in the intestine as they relate to the particular drug.

Possible structural or functional alterations, which could be caused by the alcohols and which may affect the apparent permeability of the intestinal mucosa, are mucosal blood flow (23), water absorption rate (4), "fluidity" of lipid bilayers (24), thickness of unstirred layers on the luminal side of the absorbing cell (25), dimensions of polar pathways through the epithelium (26), and solute drag (27). Thus, with the limited data available, it is not now possible to establish unequivocally the mechanisms by which normal alcohols alter the permeability of the intestinal epithelium to prednisolone, salicylic acid, and sulfapyridine.

Chromatographic, Mass Spectral, and Visible Light Absorption Characteristics of Toluidine Blue O and Related Dyes

MICHAEL R. McKAMEY ˣ and LARRY A. SPITZNAGLE

Abstract □ Contrary to earlier literature reports, the impurities in toluidine blue O were shown by column chromatography, TLC, and mass spectrometry to be *N*-methyl homologs of 2-methylthionine rather than *N*-methyl homologs of thionine. Small amounts of 2-methyl-3-amino-7-methylaminophenothiazine and 2-methyl-3,7-diaminophenothiazine were identified in commercial samples of toluidine blue O. However, sample handling and a warm alkaline environment can cause rapid demethylation of the dye.

Keyphrases □ Toluidine blue O and related dyes—chromatography, mass spectra, and visible light absorption □ Dyes—chromatographic, mass spectral, and visible light absorption characteristics of toluidine blue O and related dyes □ Mass spectrometry—impurities, toluidine blue O and related dyes

In recent years there has been increased interest in the medical use of the dye toluidine blue O (3-amino-7-dimethylamino-2-methylphenazathionium chloride, C.I. Basic Blue 17). It recently has been used for the identification of the parathyroids during surgery (1, 2) and as an aid in the diagnosis of small oral cancers (3) and has been suggested as a potential parathyroid and pancreatic scanning agent if labeled with a suitable radionuclide (4).

BACKGROUND

During an investigation into the synthesis of radioactive analogs of toluidine blue O, some problems were encountered in obtaining pure dye samples. Elemental analysis, column chromatography, TLC, and mass spectrometry all indicated the presence of impurities which could not be separated from the dye.

Similar difficulties in analyzing samples of toluidine blue O by TLC were reported (5, 6). The investigators observed three spots for the commercial dye, two blue and one violet. They identified the violet spot as thionine (I) on the basis of its R_f value and visible light absorption spectrum. Extraction of one of the two blue spots and rechromatography again produced two blue spots, which were attributed to different ionic forms of the dye or "solvent effects." In addition, Apgar and Patel (6) reported that visible light absorption experiments indicated that toluidine blue O lost a methyl group (in this case an aryl methyl group) and was converted to azure A (III) upon standing in aqueous solution.

Normann and Normann (7) succeeded in isolating five contaminants from a sample of tritiated toluidine blue O by TLC. The resulting spots were extracted from the thin-layer chromatograms and identified by their absorption maxima (Table I). Their identification of various compounds on the basis of the absorption maxima was not consistent with earlier work (8), which is summarized in Table II.

In 1953, Ball and Jackson reported on chromatographic and spectrophotometric studies of various samples of toluidine blue O and azure A (9). Descending paper chromatograms[1] developed in butanol–acetic acid–water (40:10:50 v/v) indicated that the various samples, supplied by different manufacturers, were indeed not the same dyestuff. Column chromatography on aluminum oxide with varying solvents yielded a number of fractions.

The confusion in the assignment of consistent visible light absorption maxima to the various related dyes was disturbing. In the authors' laboratory, commercial toluidine blue O shows a significant change in absorption characteristics as the pH of the solution is changed. In saline at pH 2, toluidine blue O exhibits a λ_{max} value of 630 nm, while at pH 10 a broad absorption maximum from 550 to 630 nm is observed. Differences in reported λ_{max} values (6, 7) may have been due to sample preparation, since the pH of the solutions studied was not mentioned. In addition, the assignment of the structure of azure A (III) to the degradation product of toluidine blue O implies an aryl-demethylation rather than the more probable *N*-demethylation.

The purposes of the present study were to explain the chromatographic behavior of toluidine blue O and to clarify the interpretation of the visible light absorption data.

EXPERIMENTAL[2]

Column Chromatography—Columns [5.1-cm (2-in.) diameter] were packed with dry silica gel (70–325 mesh) to a depth of 45.7 cm (18 in.). Samples were dissolved in ethanol and applied to the tops of the dry columns. Columns were eluted with ethanol followed by

Chromatographic, Mass Spectral, and Visible Light Absorption Characteristics of Toluidine Blue O and Related Dyes

MICHAEL R. McKAMEY ˣ and LARRY A. SPITZNAGLE

Abstract □ Contrary to earlier literature reports, the impurities in toluidine blue O were shown by column chromatography, TLC, and mass spectrometry to be *N*-methyl homologs of 2-methylthionine rather than *N*-methyl homologs of thionine. Small amounts of 2-methyl-3-amino-7-methylaminophenothiazine and 2-methyl-3,7-diaminophenothiazine were identified in commercial samples of toluidine blue O. However, sample handling and a warm alkaline environment can cause rapid demethylation of the dye.

Keyphrases □ Toluidine blue O and related dyes—chromatography, mass spectra, and visible light absorption □ Dyes—chromatographic, mass spectral, and visible light absorption characteristics of toluidine blue O and related dyes □ Mass spectrometry—impurities, toluidine blue O and related dyes

In recent years there has been increased interest in the medical use of the dye toluidine blue O (3-amino-7-dimethylamino-2-methylphenazathionium chloride, C.I. Basic Blue 17). It recently has been used for the identification of the parathyroids during surgery (1, 2) and as an aid in the diagnosis of small oral cancers (3) and has been suggested as a potential parathyroid and pancreatic scanning agent if labeled with a suitable radionuclide (4).

BACKGROUND

During an investigation into the synthesis of radioactive analogs of toluidine blue O, some problems were encountered in obtaining pure dye samples. Elemental analysis, column chromatography, TLC, and mass spectrometry all indicated the presence of impurities which could not be separated from the dye.

Similar difficulties in analyzing samples of toluidine blue O by TLC were reported (5, 6). The investigators observed three spots for the commercial dye, two blue and one violet. They identified the violet spot as thionine (I) on the basis of its R_f value and visible light absorption spectrum. Extraction of one of the two blue spots and rechromatography again produced two blue spots, which were attributed to different ionic forms of the dye or "solvent effects." In addition, Apgar and Patel (6) reported that visible light absorption experiments indicated that toluidine blue O lost a methyl group (in this case an aryl methyl group) and was converted to azure A (III) upon standing in aqueous solution.

Normann and Normann (7) succeeded in isolating five contaminants from a sample of tritiated toluidine blue O by TLC. The resulting spots were extracted from the thin-layer chromatograms and identified by their absorption maxima (Table I). Their identification of various compounds on the basis of the absorption maxima was not consistent with earlier work (8), which is summarized in Table II.

In 1953, Ball and Jackson reported on chromatographic and spectrophotometric studies of various samples of toluidine blue O and azure A (9). Descending paper chromatograms[1] developed in butanol–acetic acid–water (40:10:50 v/v) indicated that the various samples, supplied by different manufacturers, were indeed not the same dyestuff. Column chromatography on aluminum oxide with varying solvents yielded a number of fractions.

The confusion in the assignment of consistent visible light absorption maxima to the various related dyes was disturbing. In the authors' laboratory, commercial toluidine blue O shows a significant change in absorption characteristics as the pH of the solution is changed. In saline at pH 2, toluidine blue O exhibits a λ_{max} value of 630 nm, while at pH 10 a broad absorption maximum from 550 to 630 nm is observed. Differences in reported λ_{max} values (6, 7) may have been due to sample preparation, since the pH of the solutions studied was not mentioned. In addition, the assignment of the structure of azure A (III) to the degradation product of toluidine blue O implies an aryl-demethylation rather than the more probable *N*-demethylation.

The purposes of the present study were to explain the chromatographic behavior of toluidine blue O and to clarify the interpretation of the visible light absorption data.

EXPERIMENTAL[2]

Column Chromatography—Columns [5.1-cm (2-in.) diameter] were packed with dry silica gel (70–325 mesh) to a depth of 45.7 cm (18 in.). Samples were dissolved in ethanol and applied to the tops of the dry columns. Columns were eluted with ethanol followed by

[1] Whatman No. 1.

[2] The dyes used were obtained from National Aniline and Eastman Kodak and were labeled 80–90% pure. All other chemicals were reagent grade and were used as received. Elemental analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., and by Strauss Microanalytical Laboratory, Oxford, England.

Table I—Fractions of ^3H-Labeled Commercial Toluidine Blue O Separated by TLC[a]

Dye	Absorption Maximum, nm	Approximate R_f Values[b]
Thionine (violet)	600	0.81
Toluidine blue O (blue)	616	0.64
Azure A (blue green)	632	0.36
Methylene blue (green)	652	0.17
Methylene blue (gray)	—	0.00

[a] From Ref. 7. [b] R_f values were determined by measurement of a photograph of the chromatogram provided in the text. Values were not reported in Ref. 7.

ethanol–concentrated hydrochloric acid (99:1 v/v). Fractions obtained from the columns were evaporated under reduced pressure.

TLC—Commercially prepared aluminum-backed silica gel plates were used. Developing solvents were: I, methanol–2 *N* HCl (93:7 v/v); and II, ethanol–concentrated hydrochloric acid (99:1 v/v).

Mass Spectrometry—Mass spectra (70 ev) were obtained on a high-resolution mass spectrometer[3] coupled to a computer[4]. All samples were introduced on a direct-insertion probe. Source temperatures varied from 150 to 250°. The computer allowed the spectrometer magnet to decay and recorded multiplier current *versus* time at 85-μsec intervals.

The center of gravity of each peak was determined and compared to perfluorokerosene peaks of known *m/e* values. High-resolution *m/e* values and empirical formulas were calculated with software under control of the operator. Only formulas within ±3 mmass of calculated values are presented here.

Rapid Scan Mass Spectrometry—Rapid, repetitive mass spectra were taken from *m/e* 350 to 180 every 35 sec while under computer control. Scanning commenced when the sample (on the direct-insertion probe) was placed into the source and continued until the monitor current returned to preinsertion levels. Data were stored on magnetic tape and processed like other spectra.

Visible Light Absorption Spectrometry—Visible light absorption spectra were obtained on a recording spectrophotometer[5]. All samples were dissolved in water at pH 3.5. A path length of 1 cm was used.

RESULTS AND DISCUSSION

Elemental Analysis of Toluidine Blue O—Elemental analysis of the commercial dye revealed 51.6% C, 5.45% H, 10.46% N, and 9.22% S. This composition yields an empirical formula of $C_{15}H_{19}N_{2.6}S$ (toluidine blue O should be $C_{15}H_{15}N_3S$). Since it was suspected that the depression of nitrogen from the calculated value was due to incomplete burning, a repeat analysis was requested. This analysis included drying the sample to constant weight, burning over vanadium pentoxide, and estimating the chloride ion. This analysis revealed 48.6% C, 4.92% H, 11.86% N, 11.19% S, and 18.24% Cl, which calculates for $C_{11.6}H_{13.9}N_{2.4}SCl_{1.5}$.

TLC of Commercial Toluidine Blue O—TLC (Solvent System I) revealed that the commercial preparation was separable into three colored fractions with R_f values equal to 0.55 (intense blue), 0.69 (blue), and 0.72 (faint violet observable only when rather large amounts of the commercial dye were spotted). Extraction of the intense blue spot (R_f 0.55) with methanol–2 *N* HCl, evaporation of the solvent under reduced pressure at 70–100°, and rechromatography of the blue residue yielded an identical chromatogram to that obtained originally, with the exception that the violet band was not visible.

Treatment of the violet spot at R_f 0.72 in a like manner yielded a chromatogram with only a single spot at R_f 0.72. Other solvent systems were tried with analogous results. Elemental analysis of the fractions was impossible to interpret due to the large amounts of silica gel that dissolved in the solvent and could not be removed from the dye.

Table II—Absorption Maxima for Related Phenothiazine Dyes[a]

Dye	Absorption Maximum, nm	Structure
Thionine (I)	602	Azure C (II)	611	Azure A (III)	638	Toluidine blue O (IV)	635	Azure B (V)	652	Methylene blue (VI)	667	
[a] From Ref. 8.

Mass Spectrometry of Toluidine Blue O and Related Dyes—To identify and confirm the presence of contaminants in commercially prepared toluidine blue O, a series of mass spectra (Table III) was obtained for a group of related phenothiazine dyes: toluidine blue O (IV), thionine (I), azure A (III), azure B (V), azure C (II), and methylene blue (VI). For the sake of simplicity, only unit masses are presented in the discussion.

Toluidine Blue O—Inspection of the mass spectrum of commercial toluidine blue O indicates peaks at *m/e* 299 ($C_{17}H_{21}N_3S$), 285 ($C_{16}H_{19}N_3S$), 271 ($C_{15}H_{17}N_3S$), 257 ($C_{14}H_{15}N_3S$), and 243 ($C_{13}H_{13}N_3S$). Since the molecular weight of toluidine blue O is 271, it was apparent that the mass spectrum indicated the presence of contaminants. Since the major fragments were separated by 14 mass units (CH_2), they could not arise by fragmentation, say from the *m/e* 299 peak, because loss of methylene is highly improbable.

It was possible that thermal transfer of methyl groups had occurred in the high temperature source (250°) used to vaporize the samples. Thermal transfer of methyl groups has been reported (10), but data to be presented later indicate that this is probably not the case with toluidine blue O.

Azures A, B, and C—Mass spectra of the azure dyes[6] A (III), B (V), and C (II) are shown in Table III. These spectra are consistent with the presence of contaminating homologs of the parent structure. This finding is easily understood since they are prepared commercially by the oxidative demethylation of methylene blue with chromic acid (11).

Methylene Blue—The methylene blue spectrum (Table III), like the others, indicated that the dye contained a contaminant at *m/e* 299 ($C_{17}H_{21}N_3S$).

Phenothiazine Dyes—In general, phenothiazine systems are characterized by the high abundance of the molecular ion, which is due to the resonance stabilization of the radical ion. Phenothiazine ($C_{12}H_9NS$) fragments primarily to $C_{12}H_9N$ (53%), $C_{12}H_8NS$ (22%), $C_{12}H_8N$ (19%), and $C_{11}H_7S$ (3%) (12). Addition of an exocyclic amine, as in the case of thionine, increases the probability of losing 27 mass units (presumably by the loss of HCN) from the molecular ion.

Addition of *N*-methyl groups favors fragmentation by loss of CH_3; however, the spectra are confusing, due, evidently, to contamination by homologs of the parent with at least one or two ad-

[6] Eastman Kodak.

ditional methyl groups (*i.e.*, differing in empirical formula by one or two CH_2 groups). The loss of HCN (27 mass units) was not observed with the parent structures of azure A, toluidine blue O, and methylene blue.

Rapid Sequence Mass Spectrometry of Commercial Toluidine Blue O—A sample of commercial toluidine blue O was subjected to rapid sequence mass spectral analysis (Fig. 1). The spectra are characterized by the change in the relative abundance of the *m/e* 285 ($C_{16}H_{19}N_3S$), 271 ($C_{15}H_{17}N_3S$), and 257 ($C_{14}H_{15}N_3S$) peaks, which is consistent with a mixture of materials having different volatilities in the source of the mass spectrometer.

Chromatography of Toluidine Blue O—TLC with Solvent System II consistently separated toluidine blue O into four fractions (Fig. 2). A faint violet band at R_f 0.67 (A), a faint blue band at R_f 0.59 (B), an intense blue band at R_f 0.4 (C), and a very faint blue band at R_f 0.17 (D) were routinely observed.

Column chromatography with silica gel and 95% ethanol yielded small amounts of the violet band, A, and somewhat larger quantities of the light-blue fraction, B. The intense blue band, C, was eluted from the column by the addition of hydrochloric acid to the solvent.

The mass spectrum of C is presented in Fig. 3 and seems to be identical to other determinations of the commercial dye. Evidence for all homologs of toluidine blue O was present. Masses at *m/e* 299 ($C_{17}H_{21}N_3S$), 285 ($C_{16}H_{19}N_3S$), 271 ($C_{15}H_{17}N_3S$), and 257 ($C_{14}H_{15}N_3S$) were all present as before.

The mass spectrum of the light-blue fraction, B (Fig. 4), indicated that the mass at *m/e* 257 ($C_{14}H_{15}N_3S$) was the only significant homolog present. This finding was confirmed by rapid sequence

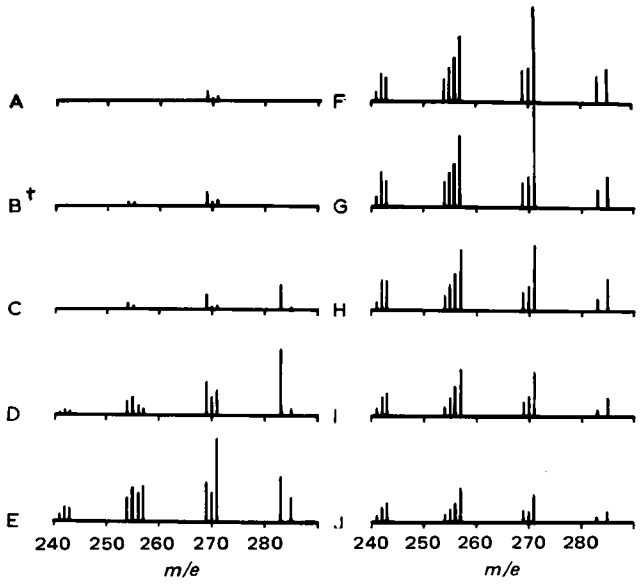

Figure 1—*Rapid sequence mass spectra (70 ev) of commercial toluidine blue O. Peak heights are shown relative to the highest peak seen during an experiment. (†The start of scan B was 35 sec after the beginning of scan A and so on through scan J.)*

mass spectral scans. The scans indicated that the sample did not behave like those in other studies with toluidine blue O; essentially only *m/e* 257 ($C_{14}H_{15}N_3S$) was seen to any extent during the experiment.

Examination of the leading violet band, A, was not successful as the sample could not be volatilized from the direct-insertion probe of the mass spectrometer.

Degradation of Commercial Toluidine Blue O in Aqueous Base—A sample of the light-blue fraction, B, isolated from the commercial dye, previously identified as being $C_{14}H_{15}N_3S$, was ad-

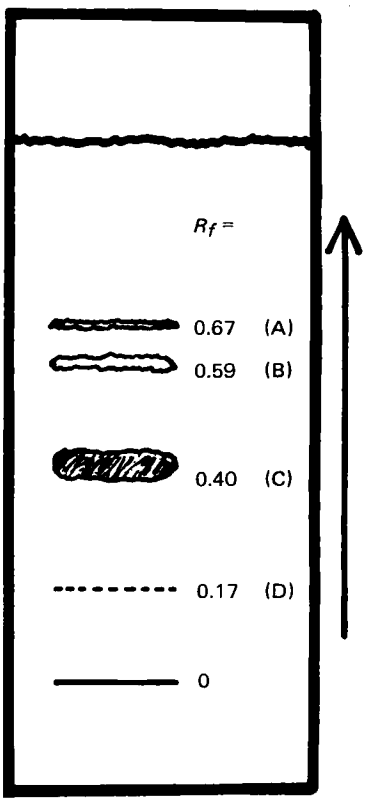

Figure 2—*Thin-layer chromatogram of toluidine blue O [silica gel, ethanol–concentrated hydrochloric acid (99:1 v/v)].*

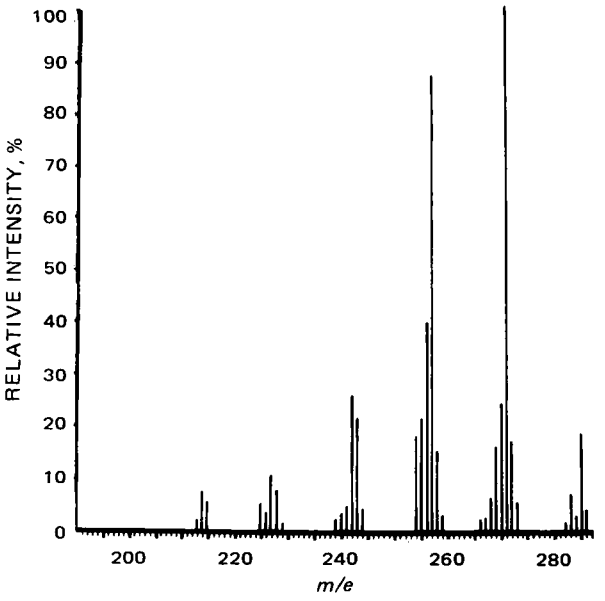

Figure 3—*Mass spectrum (70 ev) of Fraction C isolated by column chromatography from commercial toluidine blue O.*

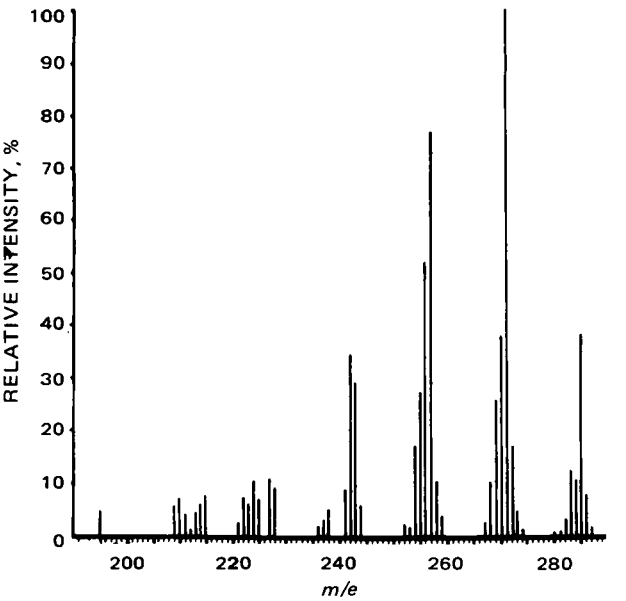

Figure 5—*Mass spectrum (70 ev) of Fraction C isolated from the alkaline degradation of toluidine blue O.*

justed to pH 9 to neutralize the hydrochloric acid used in the chromatography and was evaporated to dryness over a steam bath. Inadvertently, the sample was left on the bath overnight. In the morning the sample was examined and was violet to red in color. Chromatography indicated that B had been converted to the leading violet fraction, A.

Attempts to duplicate this experiment by heating acidic solutions of B and commercial toluidine blue O failed. However, addition of small amounts of base, pH 8–9, showed almost instant degradation of B to A and degradation of toluidine blue O to larger quantities of B and A as well as a red fraction at R_f 0.69. Attempts to isolate large samples of the various impurities from the commercial dye were abandoned in favor of the alkaline degradation of the dye, which did supply large amounts of the principal contaminants for visible light absorption spectroscopy and mass spectrometric studies.

Mass Spectral Analysis of Fractions Isolated from Degraded Commercial Toluidine Blue O—Aqueous solutions of base-treated commercial toluidine blue O were adjusted to pH 1 with hydrochloric acid and were evaporated to dryness under reduced pressure at or below room temperature. The residue was dissolved in a minimum amount of ethanol–concentrated hydrochloric acid, and the fractions were isolated by dry column chromatography. Thin-layer chromatograms indicated that separation was not complete, and the fractions were again chromatographed on silica gel columns.

The fractions were chromatographically (TLC) identical with those isolated directly from the commercial preparation. Mass spectra are presented for the intense blue band, C, the light-blue band, B, and the leading violet band, A (Figs. 5, 6, and 7, respectively). The spectrum of C is consistent with all of the others done on commercial toluidine blue O, with evidence for homologs at *m/e* 257, 271, and 285. However, the spectrum of the light-blue band, B, previously identified as *m/e* 257 ($C_{14}H_{15}N_3S$), contained no higher order homologs.

The spectrum of the leading violet fraction, A (Fig. 7), is similar to the mass spectrum of thionine (Table III). Of note is the +14 mass shift of both the M^+ and M − HCN ions, indicating the addition of a methyl group to the molecule in such a fashion as to provide no additional fragmentation as *N*-methylation would. This observation would be consistent with Structure VII, 2-methylthionine.

By inference, the structure of the light-blue fraction, B, would be VIII, 2-methyl-3-amino-7-methylaminophenothiazine, or IX, 2-methyl-3-methylamino-7-aminophenothiazine.

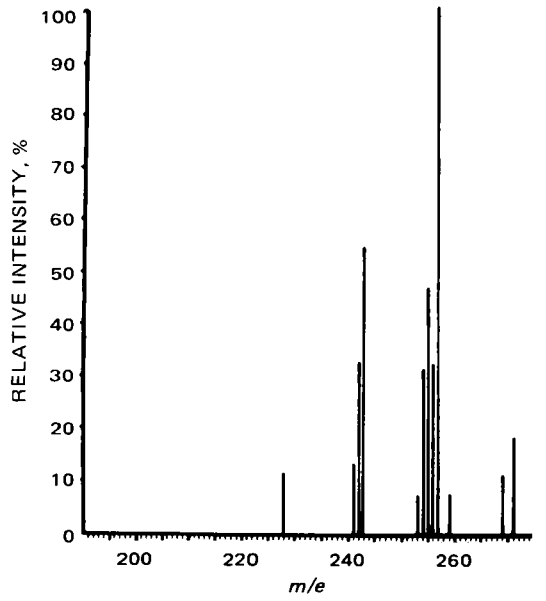

Figure 4—*Mass spectrum (70 ev) of Fraction B isolated by column chromatography from commercial toluidine blue O.*

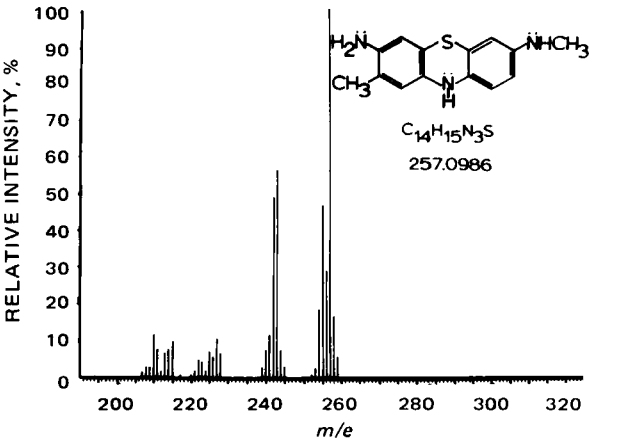

Figure 6—*Mass spectrum (70 ev) of Fraction B isolated from the alkaline degradation of toluidine blue O.*

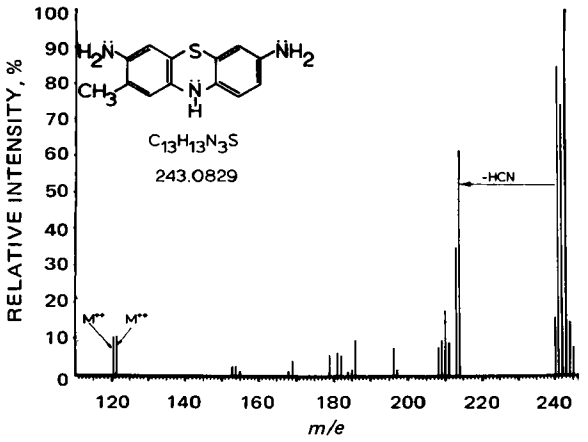

Figure 7—*Mass spectrum (70 ev) of Fraction A isolated from the alkaline degradation of toluidine blue O.*

Mass Spectral Analysis of Red Fraction Isolated from Degradation of Toluidine Blue O in Aqueous Base—In addition to the fractions already mentioned, a fraction with R_f 0.69 was also isolated by TLC with Solvent System II. Mass spectral examination indicated it to be an oxygen-bearing compound of empirical formula $C_{13}H_{10}N_2OS$ (calculated *m/e* 242.0512, found *m/e* 242.0516), potentially of Structure X or XI. Major ions found were $C_{13}H_{10}N_2OS$ (M^+, 100%), $C_{13}H_9N_2OS$ (5%), $C_{12}H_{10}N_2S$ (100%), $C_{12}H_9N_2S$ (38%), and $C_{11}H_8NS$ (48%). Loss of CO to $C_{12}H_{10}N_2S$ would be consistent with the structures drawn.

Visible Light Absorption Spectra of Fractions Isolated from Commercial Toluidine Blue O and Degraded Toluidine Blue O—A summary of the absorption maxima for toluidine blue O, its isolated fractions, and some related dyes is given in Table IV.

Spectra of toluidine blue O at different concentrations are shown in Fig. 8. Of interest is the appearance of an absorption maximum at about 590 nm as the concentration of the dye was increased. Figure 8 is in qualitative agreement with work done by Ohkuma and Furuhata (13). This secondary absorption maximum was reported as being due to dimerization of the dye molecules in solution (14). At the concentrations studied, toluidine blue O apparently does not follow the Lambert–Beer relationship (*i.e.*, the absorbance is not proportional to the concentration of the dye in a linear fashion). Thionine and methylene blue have been reported to not follow the relationship even at concentrations as low as 10^{-7} *M* (15).

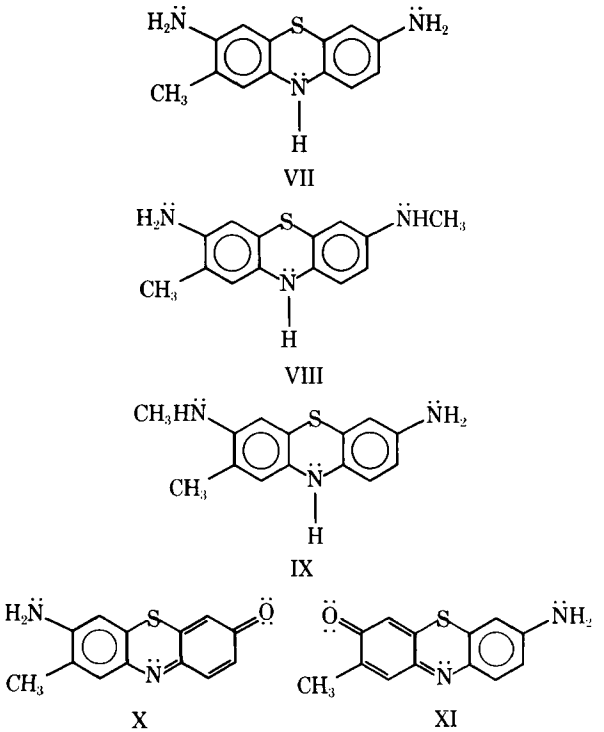
Table IV—Visible Light Absorption Maxima for Toluidine Blue O, Its Isolated Fractions, and Some Related Dyes in Water at pH 3.5

Sample	Absorption Maximum, nm	Concentration, *M*
Commercial methylene blue	652	10^{-4}
Commercial toluidine blue O	634	10^{-5}
Fraction C from commercial dye	638	$\sim 10^{-5}$
Fraction B from commercial dye	618	$\sim 10^{-5}$
Fraction B from degraded dye	613	$\sim 10^{-5}$
Thionine	596	10^{-5}
Fraction A from commercial dye	595	$\sim 10^{-5}$
Fraction A from degraded dye	595	$\sim 10^{-5}$

The mechanism of dimer formation has been discussed previously (15, 16). In dilute aqueous solution, the free energy of dimerization is 4.1 kcal/mole for thionine and 4.9 kcal/mole for methylene blue (15). The association constant has been determined to be about 10^5 for thionine (16).

Interpretation of the Thin-Layer Chromatograms—The data suggest that toluidine blue O and the related dyes are separated on silica gel on the basis of the number of *N*-methyl groups present. Figure 9 gives the chromatographic analysis of the six related dyes. Thionine, which has no *N*-methyl groups and is spectroscopically pure, has the same R_f value as 2-methylthionine (Fraction A) found in toluidine blue O (Fig. 2). 2-Methylthionine also contains no *N*-methyl groups.

Fraction B, isolated from commercial toluidine blue O (R_f 0.59), contains one *N*-methyl group and corresponds (same R_f) to the monomethyl derivative found in azures A and C and, to a lesser extent, azure B. Other bands probably correspond to dimethyl-, trimethyl-, and tetramethylamine derivatives of thionine or 2-methylthionine. The two bands identified as corresponding to dimethylamino derivatives presumably arise from the situation where two methyls are on the same amino group for one compound and one methyl is on each amino group for the other. Since toluidine blue O has both methyls on one amino group, the band at R_f 0.50 probably corresponds to the latter possibility.



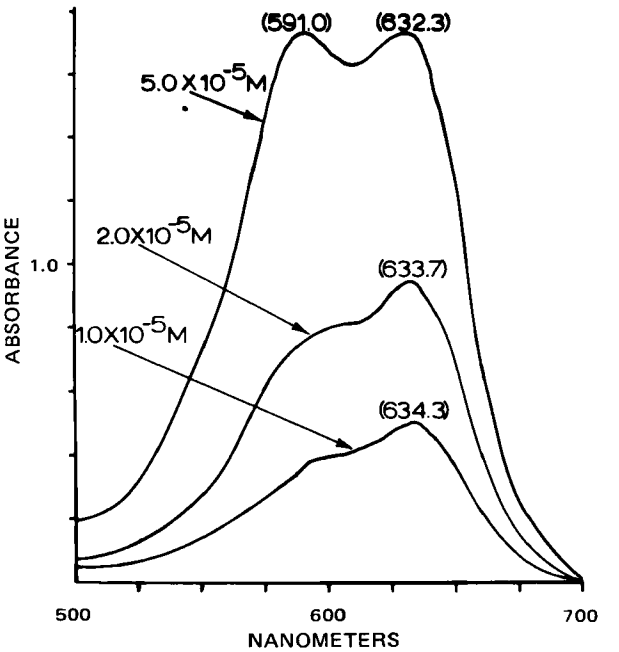


Figure 8—*Visible light absorption spectra of commercial toluidine blue O at various concentrations in water at pH 3.5.*

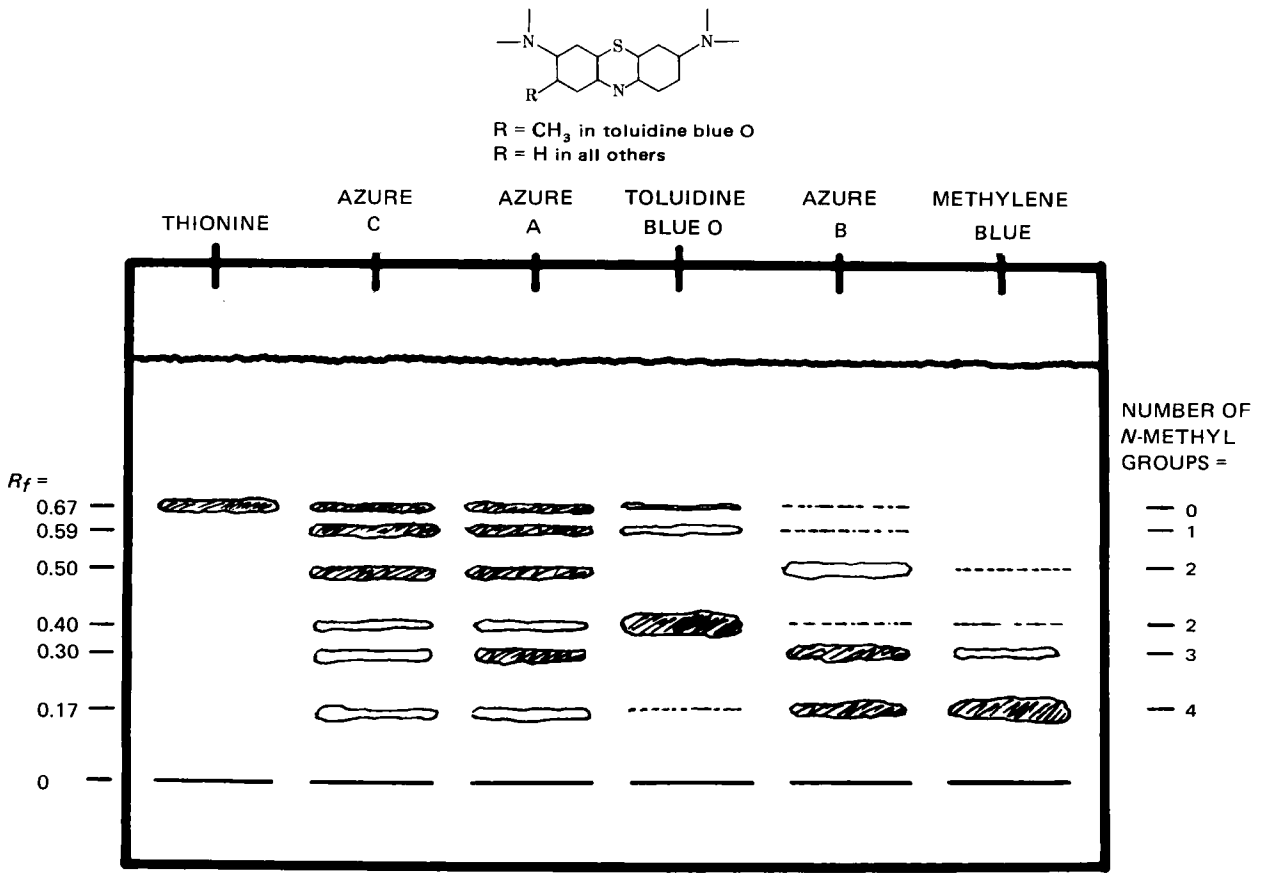

Figure 9—*Thin-layer chromatogram of related phenothiazine dyes [silica gel, ethanol–concentrated hydrochloric acid (99:1 v/v)]. Shaded areas are visibly darker than others. Dotted lines indicate spots that are extremely faint.*

Although the chromatographic correlations mentioned are tentative, they were arrived at by the known purity of thionine, the mass spectral identification of the fractions isolated from commercial toluidine blue O, and the visible light absorption experiments presented here. This system should prove satisfactory for the analysis of the purity of any of the dyes discussed.

Demethylation is known to occur for methylene blue and toluidine blue O by photoreduction (17, 18). It has also been reported that demethylation of methylene blue occurs under basic conditions (19, 20); however, the dye was stable below pH 9.5. Demethylation started between pH 9.5 and 9.8. Azure B was found to undergo demethylation at lower pH values than methylene blue.

As can be seen from Table IV, loss of an *N*-methyl group leads to an approximate 10–20-nm shift in the visible light absorption maximum. The identification of azure A as a contaminant in commercially prepared toluidine blue O-^{3}H at λ_{max} 632 nm by Normann and Normann (7) is undoubtedly an error. The identification of toluidine blue O at λ_{max} 616 nm by Normann and Normann (7) was also consistent with the data presented by Patel (5) and Apgar and Patel (6). Ball and Jackson (9) noted that chromatography of commercial samples of toluidine blue O on aluminum oxide yielded material that gave a rather broad absorption maximum from 590 to 625 nm. These investigators eluted the dye from the column and dried the sample on a water bath at 100°. This experimental technique probably produced a mixture of 2-methylthionine (λ_{max} 595 nm), normethyl-toluidine blue (λ_{max} 613 nm), and toluidine blue O (λ_{max} 638 nm).

Due care must be exercised when one is handling these dyes. The conditions of heat (especially at an alkaline pH) and light must be avoided to assure that demethylation is held to a minimum.

The mass spectral studies of toluidine blue O, isolated from commercial sample by chromatography, still exhibit evidence of a higher homolog at M + 14 (Figs. 4 and 5). Since mass spectral analysis of normethyl-toluidine blue O indicates no higher order homologs (Fig. 6), the possibility of intermolecular methyl transfer taking place in the high temperature source of the mass spectrometer probably is remote. Table III indicates that commercial toluidine blue O contains a small amount of, presumably, a tetramethylated derivative. This fraction could not be separated from the band corresponding to toluidine blue O by column chromatography; consequently, higher order homologs are seen in the mass spectrometer.

SUMMARY

Commercial toluidine blue O has been shown to be a mixture of the normethyl derivative and 2-methylthionine. The synthetic environment used to generate the dye is responsible for a small portion of the contaminants. Heat and alkaline conditions can result in rapid degradation of the parent dye molecule into its demethylated derivatives. Observations made in the literature can be explained on the basis of this demethylation phenomenon. Visible light absorption spectroscopy is a convenient device for estimation of the dyes but is prone to misinterpretation if the purity of the dye is unknown and the deviation from the Lambert–Beer relationship is ignored.

A TLC system has been presented which should prove useful in the estimation of the purity of certain phenothiazine dyes.

Inhibition of Synaptosomal Accumulation of *l*-Norepinephrine I: *N*-Arylalkyl and *N*-Aryloxyalkyl *dl*-Amphetamines and Related Compounds

JAMES C. SCHAEFFER, ARTHUR K. CHO [x], GLENN T. NAGAMI, and GLENN S. TAKIMOTO

Abstract □ The ability of a group of systematically modified amphetamines to inhibit the accumulation of *l*-norepinephrine by nonstriatal synaptosomes was investigated. *N*-Substitution by the proper bulky hydrophobic groups can be well tolerated. Structure–activity relationships generate a qualitative picture of the inhibitor–carrier interaction site.

Keyphrases □ *l*-Norepinephrine accumulation by nonstriatal synaptosomes—inhibition by *N*-arylalkyl- and *N*-aryloxyalkyl-substituted amphetamines □ Amphetamines, *N*-substituted—inhibition of synaptosomal accumulation of *l*-norepinephrine □ Structure–activity relationships—*N*-substituted amphetamine inhibition of synaptosomal accumulation of *l*-norepinephrine

A catecholamine recycling mechanism located at the presynaptic neuronal membrane is thought to play a major role in the termination of noradrenergic nerve transmission and in the conservation of catecholamines (1–4). Antidepressant and stimulant drugs, such as desipramine (5), cocaine (6), and amphetamine (7), have been shown to inhibit this carrier-mediated transport process *in vitro*. Thus, at least part of their pharmacological action is believed to be derived from their ability to prolong effective catecholamine concentrations in the synaptic cleft and, therefore, at the postsynaptic receptors.

On the basis of kinetic (8) and differential inhibition (5, 9) data, it has been proposed that there are at least two different, anatomically separable, neuronal transport mechanisms for the catecholamines in the central nervous system (CNS). One is associated with the hypothalamus, cerebral cortex, midbrain, and medulla oblongata-pons, where *l*-norepinephrine is the major catecholamine present; the other is found in the corpus striatum, where dopamine is thought to be the important catecholamine transmitter. A wide range of tricyclic, sympathomimetic, anticholinergic, and antihistamine drugs (5, 9–11) have been shown to inhibit the *in vitro* uptake of catecholamines by both systems. However, few of these compounds exhibited a substantial preference for one of the transport processes. Even when selective inhibition was observed, as with desipramine, the less active nonstriatal process was usually the most susceptable to blockade.

In light of this evidence, a study was initiated to elucidate the differences and similarities of the two catecholamine uptake processes in the CNS by attempting to map the topography of the different carrier sites through the use of a series of amphetamine-related inhibitors. Structural features, which take advantage of the topographical variances thus uncovered, would then be integrated into the design of new inhibitors to increase specificity.

This report describes the effects of a group of amphetamine-related compounds on the uptake of *l*-norepinephrine by a synaptosome-enriched subcellular fraction from nonstriatal rat brain tissue. First,

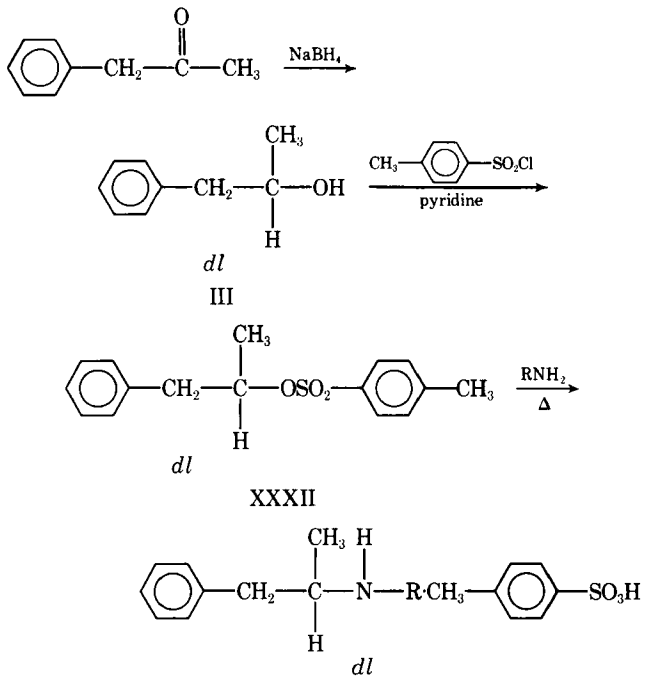
A catecholamine recycling mechanism located at the presynaptic neuronal membrane is thought to play a major role in the termination of noradrenergic nerve transmission and in the conservation of catecholamines (1–4). Antidepressant and stimulant drugs, such as desipramine (5), cocaine (6), and amphetamine (7), have been shown to inhibit this carrier-mediated transport process *in vitro*. Thus, at least part of their pharmacological action is believed to be derived from their ability to prolong effective catecholamine concentrations in the synaptic cleft and, therefore, at the postsynaptic receptors.

On the basis of kinetic (8) and differential inhibition (5, 9) data, it has been proposed that there are at least two different, anatomically separable, neuronal transport mechanisms for the catecholamines in the central nervous system (CNS). One is associated with the hypothalamus, cerebral cortex, midbrain, and medulla oblongata-pons, where *l*-norepinephrine is the major catecholamine present; the other is found in the corpus striatum, where dopamine is thought to be the important catecholamine transmitter. A wide range of tricyclic, sympathomimetic, anticholinergic, and antihistamine drugs (5, 9–11) have been shown to inhibit the *in vitro* uptake of catecholamines by both systems. However, few of these compounds exhibited a substantial preference for one of the transport processes. Even when selective inhibition was observed, as with desipramine, the less active nonstriatal process was usually the most susceptable to blockade.

In light of this evidence, a study was initiated to elucidate the differences and similarities of the two catecholamine uptake processes in the CNS by attempting to map the topography of the different carrier sites through the use of a series of amphetamine-related inhibitors. Structural features, which take advantage of the topographical variances thus uncovered, would then be integrated into the design of new inhibitors to increase specificity.

This report describes the effects of a group of amphetamine-related compounds on the uptake of *l*-norepinephrine by a synaptosome-enriched subcellular fraction from nonstriatal rat brain tissue. First,



Scheme I—Method A

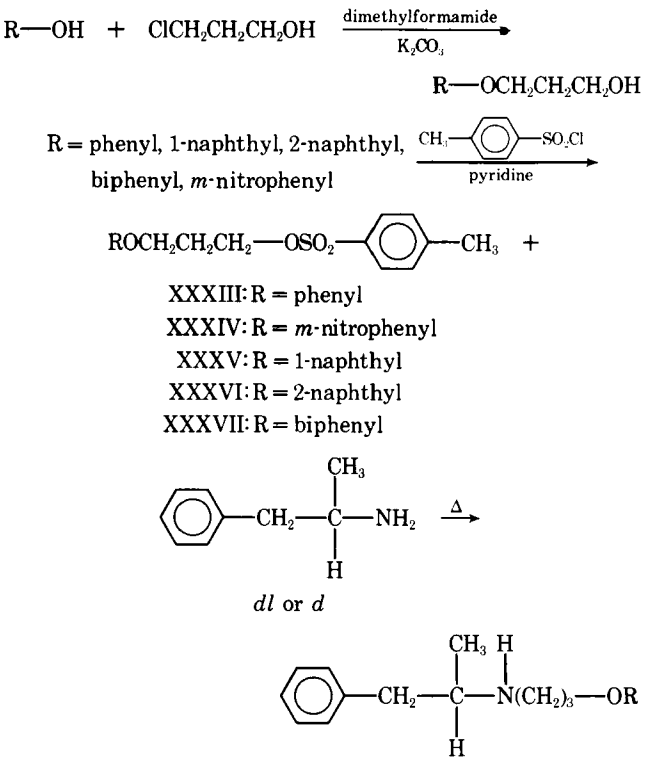
the relative inhibitor potency was investigated in a group of compounds whose structure was systematically modified by small increments to ascertain the important structural and physical–chemical properties connected with the ability of the transport system to recognize its substrate. This series also related the uptake system to previously published results.

Second, following the nonclassical inhibitor rationale of Baker and coworkers (12–14), a series of amphetamines substituted with bulky hydrophobic groups on the nitrogen was synthesized to study possible inhibitor interactions at sites on the carrier adjacent to the normal substrate binding position. The intrinsic affinity of the amphetamine moiety as a substrate mimic was utilized in these compounds to ensure potency, while the bulky substituents provided a means of enhancing selectivity through unique steric effects and/or hydrophobic interactions with adjacent sites on the carrier.

EXPERIMENTAL

Drugs—*S(d)*-Amphetamine[1] (IV), *R(l)*-amphetamine[1] (V), *dl*-amphetamine[1] (II), *dl*-tranylcypromine[1] (IX), *p*-hydroxy-*dl*-amphetamine[1] (VI), *m*-hydroxy-*dl*-amphetamine[1] (VII), phentermine[2] (VIII), *S(d)*-benzphetamine[3] (XVII), *dl*-prenylamine[4] (XXII), and ^{3}H-*l*-norepinephrine[5] (3–8 Ci/mmole) were obtained from commercial sources. The syntheses of other compounds are discussed.

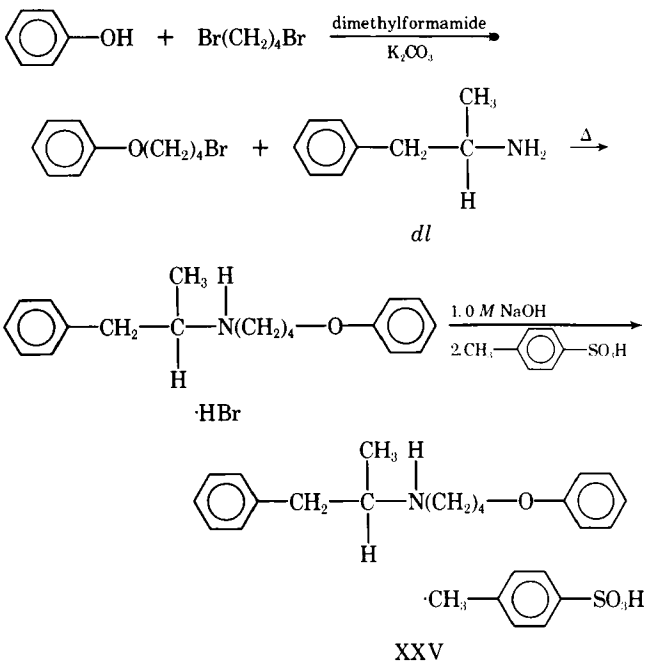
Chemical Methods—The key intermediate in Method A, α-methylphenethyl tosylate (XXXII), was prepared from phenylacetone as shown in Scheme I. This compound was synthesized previously from phenylacetaldehyde (15). Elevated temperatures (100°) and high reactant concentrations (neat conditions) were required to bring about satisfactory tosylate displacement by the



Scheme II—Method B

alkyl- or arylalkylamines employed. Equimolar amounts of tosylate (XXXII) and phenylethylamine in acetone at ambient temperature or reflux, or at 65–70° in dimethylformamide, gave only starting material. The reaction of aniline and XXXII at 100° yielded the aniline *p*-toluenesulfonate as the major product. Thus, elimination is apparently favored over substitution when arylamines are used. Compounds XIX–XXIII (Table I) were obtained *via* Method A.

Method B (Scheme II) was employed to synthesize XIV, XXIV, and XXVI–XXX (Table I). The physical properties of the 3-aryloxypropyl tosylate intermediates (XXXIII–XXXVII) are reported in Table II. Compound XXV was prepared from 4-phenoxybutyl bromide and *dl*-amphetamine according to Method C



Scheme III—Method C

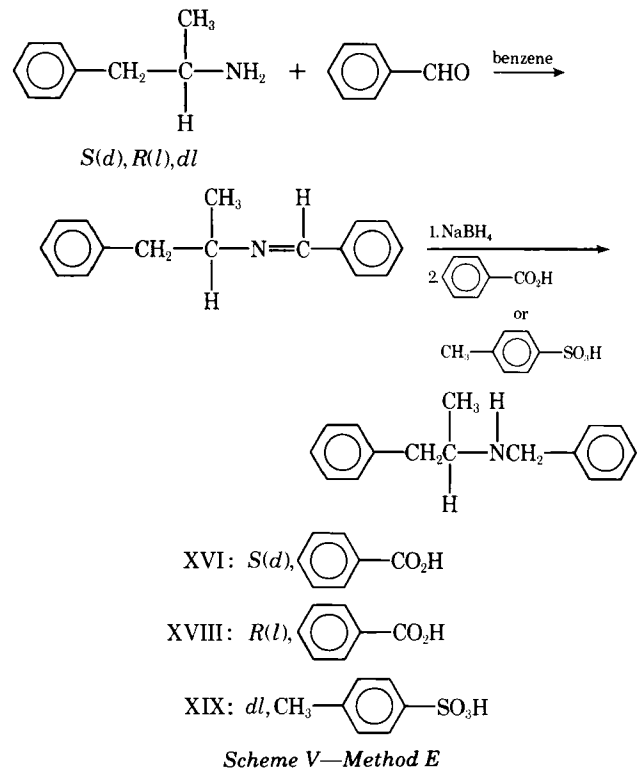
XV

Scheme IV—Method D

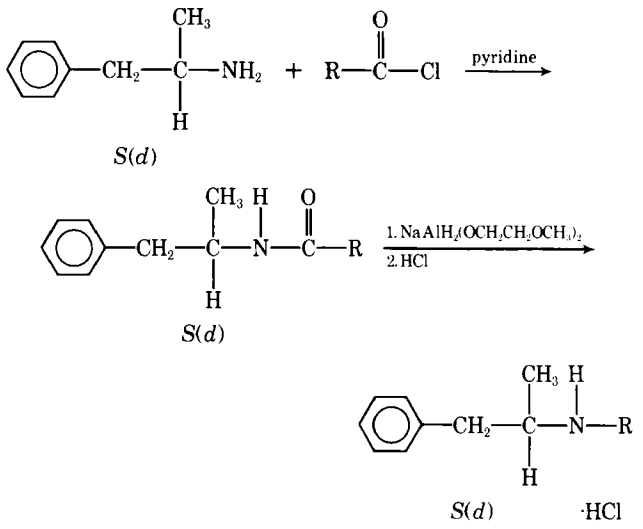
(Scheme III). The reaction of phenylacetone and cyclohexylamine, followed by sodium borohydride reduction, provided XV (Method D, Scheme IV).

To obtain the optical isomers of *N*-benzylamphetamine XVI and XVIII, Method E (Scheme V) was utilized. The benzoic acid salts of these compounds were much more easily recrystallized than the tosylates. The specific rotations of XVI and XVIII were +37.0 and −36.8°, respectively, at 24° (10% w/v, chloroform). The racemic compound, XIX, was also prepared by this method and was identical to that obtained *via* Method A. Method F (Scheme VI) was used to prepare XII and XIII.

Synthetic Procedures[6]—All melting points[7] reported here are uncorrected. The IR spectra were obtained using either neat liquids or mineral oil mulls[8]. At least one compound from each synthetic sequence involving an optically active center was checked on a polarimeter to ensure that the optical outcome of the synthesis was as expected.



Scheme V—Method E



XII: R = $-CH_2CH_3$

XIII: R = $-CH_2CH_2CH_3$

Scheme VI—Method F

General Procedure (Method A)—A mixture of 2 mmoles of *dl*-α-methylphenethyl tosylate (XXXII) and 2 mmoles of the appropriate arylalkylamine was heated at 95–100° for 1–2 hr. After the mixture had cooled to room temperature, the crude tosylate salt was recrystallized from the appropriate solvent and dried under high vacuum over phosphorus pentoxide at 60°. See Table I for additional data.

General Procedure (Method B)—A mixture of 0.1 mole of the appropriate phenolic compound, 0.1 mole of 3-chloro-1-hydroxypropane, 0.11 mole of anhydrous potassium carbonate, and 50 ml of dimethylformamide (dried over 4A molecular sieves) was heated to 85–90° for 18 hr. After the addition of 750 ml of water, the mixture was extracted twice with 150 ml of chloroform. These extracts were combined, backwashed three times with 100 ml of 1 *N* NaOH and three times with 100 ml of water, and dried with magnesium sulfate. The solvent was removed by spin evaporation to give the crude 3-aryloxypropanol. These materials were not rigorously characterized but were sufficiently pure to be used in the next step.

To a solution of 10 mmoles of the appropriate 3-aryloxypropanol in 20 ml of pyridine (dried over potassium hydroxide pellets) was added 2.87 g of freshly recrystallized *p*-toluenesulfonyl chloride (15 mmoles). This mixture was allowed to stand in a refrigerator at 5° for 2 days, during which time pyridine hydrochloride crystallized out. After 400 ml of water was added to the reaction mixture, it was extracted with three 50-ml portions of ether. The ether extract was backwashed with 1 *N* HCl and water, dried with magnesium sulfate, and spin evaporated to the crude tosylate, which was recrystallized from the solvent listed in Table II.

An equimolar mixture of *dl*- or *d*-amphetamine and the appropriate 3-aryloxypropyl tosylate was treated as described in Method A to yield the corresponding *N*-(3-aryloxypropyl)amphetamine. See Table I for further information.

*N-(4-Phenoxybutyl)-*dl*-amphetamine p-Toluenesulfonate (XXV) (Method C)*—A mixture of 9.4 g of phenol (0.1 mole), 100 g of 1,4-dibromobutane (0.46 mole), 15.2 g of potassium carbonate, and 50 ml of dimethylformamide (dried over 4A molecular sieves) was heated at 65° for 6 hr. After the addition of 300 ml of water, the mixture was extracted with 300 ml of heptane. This extract was backwashed once with 100 ml of 1 *N* NaOH and three times with 100 ml of water, dried with magnesium sulfate, and spin evaporated to an oil. This crude mixture was fractionated by high vacuum distillation. The fraction distilling between 113 and 115°/0.5 mm was collected and shown to be 4-phenoxybutyl bromide (5.2 g, 22%) of sufficient purity for use in the next step.

Two hundred and seventy milligrams of *dl*-amphetamine (2

[6] Elemental analyses were performed by H. King, Department of Chemistry, University of California at Los Angeles.

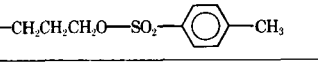
[a] All compounds were uniform by TLC (free base, methanol) and gave satisfactory carbon and hydrogen analyses. [b] Minimum recrystallized yields from last step in synthetic sequence. [c] N. J. Leonard, J. A. Adamick, C. Djerassi, and O. Halpern, *J. Amer. Chem. Soc.*, **80**, 4858 (1958). Apetinil, mp 154–156°. [d] *S(d)*-Isomer. [e] Hydrochloride salt. [f] Hydrochloride salt previously prepared by M. Friefelder and G. R. Stone, U.S. pat. 3,014,966 (1961). [g] Prepared by heating equimolar amounts of *dl*-amphetamine and butyl tosylate at 90–95° for 3 hr. [h] Hydrochloride salt previously prepared by E. H. Woodruff, J. P. Lambody, and W. E. Burt, *J. Amer. Chem. Soc.*, **62**, 922(1940). [i] Hydrochloride salt previously prepared by E. Bumm, British pat. 700,722 (1953). [j] Di-*p*-toluenesulfonate salt. Prepared from the corresponding nitro compound.

mmoles) and 458 mg of 4-phenoxybutyl bromide (2 mmoles) were heated at 95° for 3 hr. After the crude reaction product was cooled to ambient temperature, 25 ml of 1.0 *N* NaOH was added. This mixture was extracted twice with 25 ml of chloroform, and the extract was dried with magnesium sulfate and spin evaporated to an oil. The oil was dissolved in 8 ml of acetone, and a small amount of insolubles was removed by filtration. Then 380 mg of *p*-toluenesulfonic acid hydrate (2 mmoles) was added to the filtrate. After this mixture stood overnight in a refrigerator, a crystalline precipitate formed. This material was filtered, recrystallized twice from acetone, and pumped dry under high vacuum over phosphorus pentoxide. See Table I for additional data.

N-*Cyclohexyl*-dl-*amphetamine* p-*Toluenesulfonate (XV) (Method D)*—A mixture of 6.7 g of phenylacetone (0.05 mole), 5.54 g of cyclohexylamine (0.055 mole), and 100 ml of benzene was distilled until the vapor temperature of the distillate reached 80°. Benzene was added as necessary. After the reaction had gone to completion, the remaining benzene was removed by spin evaporation. To the residual oil were added 100 ml of ethanol and 6.27 g of sodium borohydride (165 mmoles). After the mixture was refluxed for 4 hr, the ethanol was removed under vacuum and 250 ml of 2 *M* NaOH was added to the residue. This mixture was extracted with 150 ml of ether. The extract was dried with magnesium sulfate and spin evaporated to an oil, which was distilled under high vacuum. The fraction distilling at 111–112°/0.3 mm was collected and shown to be *N*-cyclohexyl-*dl*-amphetamine (3.1 g, 29%). It was converted to its analytically pure tosylate salt by treatment with *p*-toluenesulfonic acid hydrate. See Table I for additional information.

General Procedure (Method E)—The benzene–water azeotrope was distilled from a mixture of 6.75 g of the appropriate amphetamine (50 mmoles), 5.83 g of benzaldehyde, and 100 ml of benzene

Table II—3-Aryloxypropyl Tosylates[a]



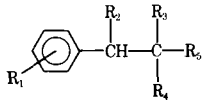
Compound	R	Method	Recrystallization Solvent	Yield, %[b]	Melting Point
XXXIII		B	Ether–hexane (1:1)	57	48–51°
XXXIV		B	Chloroform–ether (1:10)	63	74–75°
XXXV		B	Ether	56	69–71°
XXXVI		B	Ether	55	67–68°
XXXVII		B	Ether	52	96–98°

[a] All compounds moved as single spots on TLC [chloroform–hexane (1:1)] and gave satisfactory carbon and hydrogen analyses. [b] Minimum recrystallized yields.

until the vapor temperature of the distillate reached that of pure benzene. Benzene was added as necessary to maintain a reasonable reaction mixture volume. After the remaining benzene was removed under vacuum, 100 ml of ethanol and 6.27 g of sodium borohydride (165 mmoles) were added. Following a 4-hr reflux, the mixture was spin evaporated to a residue and 250 ml of 2 *M* NaOH was added. The resulting mixture was extracted with 150 ml of ether. The extract was dried with magnesium sulfate and spin evaporated to an oil, which was vacuum distilled.

*N-Benzyl-*d*-amphetamine and N-Benzyl-*l*-amphetamine Benzoates (XVI and XVIII)*—The fraction distilling at 128–130°/0.2 mm was collected (yield of 35–40%). To a solution of 900 mg of either amphetamine isomer (4 mmoles) in 10 ml of acetone was added 488 mg of benzoic acid (4 mmoles). After the solution was cooled overnight, a crystalline precipitate formed; this precipitate was recrystallized from acetone and pumped dry under vacuum over phosphorus pentoxide at 60°. The free bases of both isomers exhibited the same IR spectra, and the benzoate salts both melted at 101–103°. A 10% (w/v) chloroform solution of the free base of the *S(d)*-isomer had a specific rotation of +37.0°, whereas the *R(l)*-isomer had a specific rotation of −36.8°. An elemental analysis of the *R(l)*-isomer gave the following data. Calc. for C, 79.50; H, 7.25. Found: C, 79.29; H, 7.11.

Table III—Inhibition of the Synaptosomal Uptake[a] of *l*-Norepinephrine by Compounds I–IX



Compound	R_1	R_2	R_3	R_4	R_5	Optical Isomer	I_{50}, μM[b]
I	H	H	H	H	NH_2	—	6.0
II	H	H	CH_3	H	NH_2	*dl*	1.3
III[c]	H	H	CH_3	H	OH	*dl*	>>100[d]
IV	H	H	CH_3	H	NH_2	*S(d)*	0.9
V	H	H	CH_3	H	NH_2	*R(l)*	2.3
VI	*p*-OH	H	CH_3	H	NH_2	*dl*	1.1
VII	*m*-OH	H	CH_3	H	NH_2	*dl*	1.8
VIII	H	H	CH_3	CH_3	NH_2	—	1.6
IX	H	—CH_2—		H	NH_2	*dl*	3.7

[a] Substrate concentration was 1 μM *l*-norepinephrine. [b] All values are the average of two or more independent determinations. The variation in each multiple determination was less than 25%. [c] C. Golumbia and D. L. Cottle, *J. Amer. Chem. Soc.*, 61, 996(1939). [d] No inhibition at 100 μM.

*N-Benzyl-*dl*-amphetamine p-Toluenesulfonate (XIX)*—The fraction distilling at 136–137°/0.2 mm was collected (yield of 52%). To a solution of 450 mg of *N*-benzyl-*dl*-amphetamine (2 mmoles) in 40 ml of acetone was added 380 mg of *p*-toluenesulfonic acid hydrate (2 mmoles). After the mixture stood at room temperature overnight, a solid had precipitated. It was filtered, recrystallized from acetone, and dried under high vacuum over phosphorus pentoxide at 60°. The free base of this material did not rotate polarized light. The *p*-toluenesulfonate was identical to that prepared by Method A.

General Procedure (Method F)—To a solution of 6.75 g of *d*-amphetamine (50 mmoles) and 50 ml of pyridine (dried over potassium hydroxide) in an ice bath was added slowly 50 mmoles of the appropriate acid chloride. After this mixture was allowed to stir at room temperature for 25 hr, 750 ml of water was added and the resulting mixture was extracted with three 100-ml portions of chloroform. The extract was backwashed three times with 100 ml of 1 *M* HCl, three times with 100 ml of 2 *M* NaOH, and three times with 100 ml of water; it was then dried with magnesium sulfate and spin evaporated to a residue. The crude amide was dissolved in 50 ml of benzene, and 11.5 g of sodium bis(2-methoxyethoxy) aluminum hydride[9] (40 mmoles) dissolved in 50 ml of benzene was added.

This mixture was refluxed for 27 hr and cooled to 0–4°, and then 300 ml of 1 *N* NaOH was added slowly followed by 100 ml of benzene. The benzene layer was separated, dried with magnesium sulfate, and spin evaporated to an oil. The oil was dissolved in 100 ml of ether, and dry hydrogen chloride gas was bubbled through the solution. The resulting precipitate was filtered, recrystallized, and dried. Further information about XII and XIII, prepared by this method, is presented in Table I.

*N-[3-(3-Aminophenoxy)propyl]-*d*-amphetamine (XXXI)*—A mixture of 974 mg of *N*-[3-(3-nitrophenoxy)propyl]-*d*-amphetamine *p*-toluenesulfonate (XXX) (2 mmoles), 40 ml of ethanol, 5 ml of acetic acid, 5 ml of water, and 1.31 g of zinc powder (20 mmoles) was refluxed for 18 hr. The supernate was decanted from the zinc powder and spin evaporated to a residue. After 150 ml of 1 *N* NaOH was added to the residue, this mixture was extracted with three 50-ml portions of benzene. The extract was dried with magnesium sulfate and evaporated under reduced pressure to an oil. This material was dissolved in 20 ml of ethanol, which contained 760 mg of *p*-toluenesulfonic acid hydrate (4 mmoles). After this solution was cooled, a solid precipitated, which was recrystallized from ethanol and dried under high vacuum over phosphorus pentoxide at 60°. Physical data are provided in Table I.

Filtration Assay Method—*P_2' Preparation*—Male Sprague–Dawley rats, 180–200 g, were killed by decapitation. The brains were immediately removed, and the cerebellum and corpus striatum of each were rapidly dissected and discarded. The remaining brain tissue, henceforth referred to as nonstriatal tissue (1.2 g/brain), was homogenized in nine volumes of ice-cold 0.32 *M* sucrose, using a glass homogenizer with a polytetrafluoroethylene pestle. All subsequent procedures were carried out in ice-cold equipment or at 0–4° in a refrigerated centrifuge[10].

By employing essentially the procedure of Gray and Whittaker (16), a P_2' fraction enriched with synaptosomes was obtained as follows. The brain homogenate was centrifuged for 10 min at 1000×*g* to sediment debris and nuclei. The supernate was carefully separated and centrifuged at 11,000×*g* for 20 min. The resulting pellet (P_2) was uniformly resuspended by hand in 10 ml of 0.32 *M* sucrose/1.2 g of original brain tissue. This suspension was centrifuged for 20 min at 11,000×*g*. The supernate was discarded and the pellet (P_2' or P_2 washed) was resuspended in 2 ml of 0.32 *M* sucrose/1.2 g of original brain weight to give a preparation containing 15–20 mg of protein/ml. All P_2' fractions were used immediately after preparation.

Protein concentrations were measured by the procedure of Lowry *et al.* (17), using bovine serum albumin as the standard.

Assay Procedure—A mixture of 0.53 ml of Krebs–Ringer phosphate buffer (pH 7.4) containing *l*-ascorbate, glucose, and edetic acid, 0.02 ml of 0.19 m*M* nialamide, 0.05 ml of 0.1 *M* NaH_2PO_4–

[a] Substrate concentration was 1 μM *l*-norepinephrine. [b] All values are the average of two or more independent determinations. The variation in each multiple measurement was less than 25%. [c] The I_{50} values listed in this column are corrected for the concentration of the cationic species at pH 7.4. All compounds, except for XVI–XIX, have a pKa of 9.5–10.0; therefore, less than 1% is nonionized under normal assay conditions. [d] Prepared by the Eschweiler–Clarke methylation of *d*-amphetamine. S. Senoh and I. Mita, *J. Pharm. Soc. Jap.*, 72, 1096(1952).

Na_2HPO_4 buffer (pH 7.4) with or without inhibitor, and 0.10 ml of the P_2' preparation was preincubated on a metabolic shaker at 37°. After 5 min, 0.05 ml of 15 μM ^{3}H-*l*-norepinephrine was added to give a 1-μM final concentration. The final concentrations of other components of this incubation medium were 123 mM Na^+, 4.2 mM K^+, 2.5 mM Mg^{+2}, 0.9 mM Ca^{+2}, 8.4 mM *d*-glucose, 1.1 mM *l*-ascorbate, 0.064 mM edetic acid, 42.6 mM sucrose, and 12.5 μM nialamide.

After incubation at 37° for 5 min in the presence of 1 μM substrate, the reaction was quenched by the addition of 5 ml of ice-cold 0.9% NaCl solution, which contained 100 μM unlabeled *l*-norepinephrine. This mixture was rapidly filtered through a 0.8-μm cellulose acetate filter[11] (18). The filter was then washed twice with 5-ml aliquots of quench, dissolved in 10 ml of Bray's counting solution (19) by shaking for 30 min, and counted[12]. Blanks for all inhibitor concentrations were obtained by repeating this procedure for 1 min at 0°.

All points were done in triplicate, and the mean value was used to determine picomoles of *l*-norepinephrine uptake in the fol-

[11] Millipore Corp., Bedford, Mass.
[12] All counting was done on an Amersham-Searle Mark II liquid scintillation counter.

lowing manner. The net counts accumulated for each experimental point, $CPM_{37}-CPM_0$ (CPM_{37} represents the radioactivity accumulated at 37°, and CPM_0 represents the radioactivity accumulated at 0°), were divided by the specific activity (counts per minute per picomole) of the ^3H-*l*-norepinephrine stock solution used for each experiment. The specific activity was determined by counting a mixture of 0.05 ml of the radioactive stock solution, 10 ml of Bray's, and a cellulose acetate filter that had gone through the normal incubation and filtration procedure without [^3H]-*l*-norepinephrine. Quenching was shown to be uniform for all samples in each experiment by the standard channels ratio method.

I_{50} Determinations (20)—The accumulation of 1 μM ^3H-*l*-norepinephrine was determined in the presence of three different inhibitor concentrations that reduced control uptake by 30–70%. The ratio of A_0/A_I, where A_0 represents control accumulation (picomoles per milligram of protein) and A_I represents accumulation with inhibitor, was plotted against [I]. These points were fitted by the method of least squares to give the best line. The point at which $A_0/A_I = 2$ provided the I_{50} values.

RESULTS AND DISCUSSION

The compounds in Table III were used as probes to determine the important substrate–carrier interaction points by measuring the relative potency of their inhibitory power. The simple phenethylamine (I) skeleton of *l*-norepinephrine was a good inhibitor. Introduction of an α-methyl group, the conversion of I to *dl*-amphetamine (II), caused a fivefold increase in inhibitor strength. Similar observations have been made using the perfused rat heart (21) and using a crude synaptosomal preparation (S_1) from rat brain hypothalamus (10). The presence of a monoamine oxidase inhibitor (nialamide) in the incubation mixture ruled out the possibility of this result being more a reflection of metabolism than enhanced inhibitor–carrier association. Thus, the introduction of a small hydrophobic substituent at the α-position has a positive effect. Phentermine (VIII) was as good an inhibitor as *dl*-amphetamine, so that addition of a second α-methyl group can also be tolerated. The inclusion of the α-methyl group of amphetamine in a cyclopropyl ring (tranylcypromine, IX), on the other hand, reduced carrier interaction.

The replacement of the basic and polar amine function of II with a neutral and polar hydroxy group (III) led to complete loss of inhibition. This finding indicates the critical role of the positively charged amine function in substrate recognition and appears to rule out the possibility of a strong interaction through hydrogen bond formation. The carrier molecule appears to contain a negatively charged group at its substrate combining site.

Consistent with recently reported results (22, 23), the *S(d)*-isomer of amphetamine (IV) was twice as potent as the *R(l)*-enantiomer (V). Coyle and Synder (7) previously reported a 10-fold difference in the inhibitor potency of these compounds, but they (7, 9) pretreated their animals with 5–2.5 mg/kg of reserpine to deplete catecholamines and inactivate the vesicular storage mechanism so the tissue sources were different.

The substitution of hydroxy groups on the benzene ring (VI and VII) did not alter inhibitor potency to a great extent, so the phenolic hydroxys of *l*-norepinephrine do not appear to play a major role in substrate–carrier binding. The only case in which ring hydroxylation substantially increases inhibition potency is that of tyramine compared to phenylethylamine (10, 11). However, this result may also reflect the well-known releasing effect of tyramine (23). The general structural feature of the substrate required for carrier binding is the phenethylamine structure. The introduction of one or two α-methyl groups enhances inhibitor strength and if one α-methyl is present, the *S(d)*-optical configuration is optimal.

Table IV summarizes investigations into the effect of *N*-substitution on uptake inhibitor strength to see whether large groups at this position could be tolerated by the carrier. Methamphetamine (X) was essentially as good an inhibitor as *S(d)*-amphetamine (IV). However, the addition of a second methyl group (XI) did result in a sixfold loss in inhibitor strength. There are other examples of the drop in potency with increasing *N*-substitution. Inhibition of *l*-norepinephrine uptake into hypothalamic preparations by desipramine is likewise reduced when the compound is converted to imipramine (5). Furthermore, it is well known that successive methylation of amphetamine causes a marked loss of pressor activity (24). The anionic carrier site does not appear to be able to accommodate a tertiary amine as well as a secondary amine, probably due to increased steric hindrance caused by the third ligand.

Since a secondary amine structure can be tolerated, a homologous series of *N*-alkyl amphetamines (XII–XIV) was investigated. Each successive lengthening of the alkyl substituent by one carbon resulted in a corresponding decrease in binding. The bulky cyclohexyl substituent of XV was no worse than the butyl substituent of XIV in decreasing effective carrier interaction. This finding suggests that only one edge of the ring interacts with the carrier surface. Again, steric factors are probably responsible for the observed reductions in inhibitor strength, because there is no correlation between increased molecular hydrophobicity and inhibitor potency.

The addition of a phenyl ring to methamphetamine (XVI) precipitates an apparent 10-fold loss in effectiveness, which could be the result of unfavorable steric requirements. However, the pKa of *N*-benzylamphetamine is 7.5 (25); thus 44% of this compound is present as the neutral form under the assay conditions employed (pH 7.4) in contrast to methamphetamine, which is 99% ionized at pH 7.4. Since a protonated amine is required for strong carrier interaction (II *versus* III), the substantial decrease in inhibitory power could be partially the result of the decreased concentration of the ionized form. Indeed, after the I_{50} value was corrected for ionization, only a fivefold loss could be attributed to steric factors. Similarly, the corrected I_{50} value for benzphetamine (XVII) cation (pKa = 6.55) (25) is 3.7 μM. Thus, in this case, the methylation of a secondary amine does not greatly change the potency of the ionized form (XVI *versus* XVII).

N-Benzyl substitution also reversed the relative inhibitory potency of the optical isomers. The *R(l)*-isomer (XVIII) was at least twice as potent as the *S(d)*-isomer in blocking *l*-norepinephrine accumulation. The sevenfold loss (corrected I_{50} values) in inhibitory power associated with the conversion of *S(d)*-amphetamine (IV) to *N*-benzyl-*S(d)*-amphetamine (XVI) is reduced to almost none for the corresponding *R(l)*-isomers (V and XVIII). The mode of interaction of the *R(l)*-isomer apparently allows greater steric toleration of the bulky benzyl group or may bring this hydrophobic function into contact with a hydrophobic patch on the transport carrier. The racemic *N*-benzyl-*dl*-amphetamine (XIX) had an intermediate I_{50} value as expected and had half the potency of *dl*-amphetamine (II).

N-Phenethyl-*dl*-amphetamine (XX) was three to four times less potent than *N*-ethyl-*d*-amphetamine (XII). Since the pKa values of these compounds are similar, this loss in inhibitor efficiency can probably be best attributed to steric hindrance. A comparison of the *N*-benzyl (XIX) and *N*-phenethyl (XX) compounds shows that the introduction of a second methylene group causes a twofold decrease in binding after correction for pKa differences. With the substitution of a *N*-phenylpropyl group (XXI), a twofold increase in potency was observed over the simple *N*-propyl derivative. This compound also exhibited twofold greater potency than the phenethyl homolog. Increased chain length and flexibility have apparently brought the phenyl ring into position where positive hydrophobic forces come into operation. The addition of a second phenyl substituent (XXII) slightly decreased inhibitor strength.

The placement of a butyl chain between the terminal phenyl ring and the nitrogen of *dl*-amphetamine (XXIII) slightly decreased the I_{50} value when compared to the corresponding propyl derivative (XXI). This compound was five times as potent as *N*-butyl-*dl*-amphetamine (XIV). Once again, strong hydrophobic interaction of the phenyl ring with the carrier site is the best explanation. Neither the substitution of an ether oxygen for a methylene (XXIV) nor the lengthening of the chain to five atoms (XXV) had much effect on inhibitor strength.

The next series of compounds was synthesized and tested to investigate the dimensions and properties of the proposed hydrophobic site adjacent to the normal substrate-combining region on the *l*-norepinephrine carrier. The substitution of a *p*-phenyl ring on XXIV to form the biphenyl derivative (XXVI) resulted in a fourfold loss in binding. The fusion of an aromatic ring to XXIV at the *meta/para*-position (XXVII) or *meta/ortho*-position (XXVIII) gave inhibitors that were only slightly less effective. Thus, the hydrophobic carrier site can tolerate the planar 2-naphthyl (XXVII) or 1-naphthyl (XXVIII) substituent, whereas a large planar biphenyl appears to exceed the dimensions of the hydrophobic pocket.

The possibility that electronic forces play a significant role in

the interaction of the terminal phenyl ring of the *N*-substituent can be ruled out by XXX and XXXI. The substitution of either a strong electron-withdrawing nitro group (XXX) or a strong electron-donating amino group (XXXI) resulted in only minor fluctuations in inhibitor strength. Additionally, the unaltered inhibitor potency after the addition of a polar amino group to XXIV indicates that only part of the terminal phenyl ring is involved in a hydrophobic interaction with the carrier molecule.

Overall, there appears to be no simple correlation between hydrophobicity and inhibitor strength in this series of compounds as has been reported for primary alcohols (26) and certain psychotropic drugs (27). The introduction of the proper bulky groups on the amphetamine nitrogen can be tolerated with little loss in inhibitor potency. Thus, the preparation of specific nonclassical inhibitors with substitution at the nitrogen seems possible.

Flumizole, a New Nonsteroidal Anti-Inflammatory Agent

E. H. WISEMAN [x], H. M. McILHENNY, and J. W. BETTIS *

Abstract □ Flumizole is a potent anti-inflammatory agent in animal models with an inhibitory activity severalfold that of indomethacin in rat foot edema and prostaglandin synthetase tests. The drug was well absorbed from the GI tract when administered in the solution used in pharmacological assays. However, markedly poorer absorption of the solid form of this poorly water-soluble agent led to the development of a flumizole dispersion with polyethylene glycol 6000. The solid dispersion exhibited an increased dissolution rate in simulated gastric fluid and improved absorption properties in dogs relative to unformulated flumizole. Studies with a capsule formulation of the solid dispersion in human volunteers were indicative of good drug absorption. Plasma levels of flumizole were rapidly achieved and declined with a short half-life (2–7 hr) in rats, dogs, and humans.

Keyphrases □ Flumizole—anti-inflammatory activity, bioavailability, and formulation □ Anti-inflammatory agents—flumizole (nonsteroid) activity, bioavailability, and formulation □ Bioavailability—flumizole, a nonsteroidal anti-inflammatory agent □ Dissolution rates—formulations of flumizole

Flumizole[1] is one of a series of substituted diarylimidazoles with anti-inflammatory activity (1, 2). This compound is distinguished from the general class of acidic agents currently used in the management of inflammatory disease by its very weak acidic character (pKa 10.7). This report describes the potent anti-inflammatory activity of flumizole and biopharmaceutical developments undertaken to opti-

mize drug absorption during pharmacological and toxicological investigations.

EXPERIMENTAL

Charles River strain rats (male), Hartley strain guinea pigs (male), and beagle dogs (both sexes) were used. Adrenalectomy in the rat was performed through a retroperitoneal incision while the animals were anesthetized with ether. The adrenalectomized rats were maintained on 0.9% saline in place of drinking water and were used 5–7 days postoperatively. Oral studies were conducted with an aqueous solution of drug in polyethylene glycol 300 containing 5% polysorbate 80[2] (I; 0.2 ml in 5 ml water/animal).

Anti-Inflammatory Activity—Inhibitory activity toward the formation of edema in response to the subplantar injection of carrageenan in the hindpaw of the rat (mean weight 170 g) was assessed using the technique of Winter *et al.* (3). Carrageenan (0.05 ml of 1% suspension) was injected 1 hr after oral drug administration, and inhibition of edema formation was assessed after a further 3-hr period. Analogous studies were performed in adrenalectomized rats.

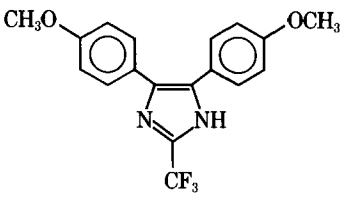
Inhibitory activity toward the formation of granuloma tissue around an implanted irritant was measured by a procedure developed in these laboratories (4). Under ether anesthesia, rats, 140–160 g, were shaved and a 8-cm length of sterile linen string was inserted subcutaneously at the dorsal midline. Drugs were administered orally 4, 24, and 48 hr after implantation. At 72 hr, the animals were sacrificed and weighed and the string together with the granulation tissue was removed and weighed.

Inhibitory activity toward UV irradiation-induced erythema was measured in the guinea pig according to the method of Winder *et al.* (5). Drugs were administered orally in divided doses, 1 hr prior and just subsequent to irradiation. Erythema inhibition was assessed 2 hr after irradiation. Groups of five animals were used, and erythema was scored as follows: no erythema, 0; full circle of erythema 1.0; and intermediate responses, 0.5. Erythema was assessed at three irradiation sites on each animal (maximum possible score = 3.0).

Prostaglandin synthetase was isolated from goat seminal vesicles according to the method of Wlodawer and Samuelsson (6). Labeled (1-^{14}C) and unlabeled arachidonic acid were purified as reported by Flower *et al.* (7). Reaction mixtures contained 1.2 mg/ml of microsomes, 0.36 m*M* arachidonic acid (specific radioactivity 3.45×10^5 cpm/μmole), 10 m*M* L-epinephrine bitartrate, 50 m*M* potassium phosphate buffer (pH 7.2), and 3.0 *M* methanol in a total volume of 1 ml. The range of drug concentrations used were $0.3–4.0 \times 10^{-5}$ *M* indomethacin, $0.2–4.0 \times 10^{-3}$ *M* phenylbutazone, and $0.1–2.0 \times 10^{-6}$ *M* flumizole. The reaction was initiated by the addition of enzyme and was conducted at 37° for 10 min.

Conditions were chosen so that no greater than 30% of the arachidonate was converted to products. The reaction was stopped by the addition of 7 ml of chloroform–methanol (1:1 v/v). Carrier prostaglandin $F_{2\alpha}$ (0.09 μmole), prostaglandin E_2 (0.09 μmole), and arachidonic acid (0.17 μmole) were added. The precipitate was removed by centrifugation, and the radioactive products were extracted and separated by TLC (6). Zones corresponding to prostaglandins $F_{2\alpha}$ and E_2 were visualized with iodine vapors, scraped from the plate, and eluted with 1 ml of methanol. The radioactivity measured was corrected for the amount present in a boiled microsome control. Radiochemical assays were carried out by liquid scintillation[3] with a solvent system of 60 g of naphthalene, 8 g of solute[4], and 100 ml of methanol made to a final volume of 1 liter with dioxane.

Drug Assay in Plasma—To 3–5 ml of plasma was added 2 ml of 1 *M* NaH_2PO_4, and the solution was mechanically extracted for 10 min with freshly distilled benzene (1 × 20 ml). The solvent extract was separated after centrifugation and filtered through a column of silica gel[5], 0.5 g, contained in a 14.6-cm capillary pipet. The filtrate and an additional 3 ml of benzene were rejected. Drug was eluted from the column with 3 ml of benzene–ether (1:1), which was evaporated to 0.2 ml and diluted with 0.5 ml of *n*-hexane. Drug was extracted by mechanical agitation with 1 ml of 1 *M* NaOH; following centrifugation, the aqueous solution was immediately acidified with 1 ml of 2 *M* HCl for spectrophotofluorometric determination[6].



flumizole

Flumizole displayed an excitation maximum at 290 nm with an emission maximum at 460 nm. Response was linear and could be quantitated over a concentration range of 5–1000 ng/ml in plasma. Dilution of the final assay solution permitted quantitative analysis up to 10 μg/ml plasma concentrations. Standardization was achieved by reference to a calibration curve constructed for each assay series by addition of known amounts of flumizole, in duplicate, to untreated animal plasma or normal human serum; these samples were processed in the same manner and at the same time as above. No fluorescent background interferences were present in the plasma of unmedicated rats, dogs, or humans.

Assay precision was determined by repeated analysis, over a 3-week period, of two control samples containing drug. Results showed a reproducibility of 9.5 ± 0.2 ng/ml (seven determinations) and 50.4 ± 4.0 ng/ml (eight determinations). The assay was specific for unchanged drug in plasma as confirmed by fluorescence spectrum, TLC [silica gel GF plates[7], hexane–ethyl acetate–acetic acid (14:6:1)], and GLC (described later) analyses of final assay samples or extracts thereof. Drug recovery from plasma averaged 71 ± 2% over the 10–50-ng/ml concentration range.

Drug Assay in Excreta—Fecal and urinary excretion of flumizole in humans was determined by a GLC procedure. Five milliliters of urine, or 5 ml of 1 *M* NaH_2PO_4 containing 100 mg of lyophilized feces, in a centrifuge tube with 5 ml of pH 4.5 sodium acetate–acetic acid buffer (0.2 *M*) was processed by benzene extraction and silica gel column purification in the manner described for the plasma assay. The urine residue obtained by evaporation of the column eluate to dryness with nitrogen was directly dissolved in 50 μl of methanolic triethylanilinium hydroxide (0.5 *M*) for analysis. The column eluate from the fecal sample was evaporated to 0.2 ml and diluted to 1 ml with *n*-hexane, and drug was extracted into 1 ml of 1 *M* NaOH.

After centrifugation, the aqueous phase was withdrawn, immediately acidified with 1 ml of 2 *M* HCl, and extracted with 10 ml of ethyl acetate. Following centrifugation, the solvent layer was withdrawn, evaporated to dryness, and dissolved in 0.5 *M* triethylanilinium hydroxide, as already described, for analysis. One-microliter aliquots (plus 1 μl of 0.5 *M* triethylanilinium hydroxide solution) were immediately introduced into the injection port (320°) of a gas chromatograph[8] for on-column alkylation to the corresponding N_1-ethylated derivative of flumizole. The derivative was separated on a 0.63 × 183-cm glass column (210°) containing 1% OV-1 on Gas Chrom Q (60–80 mesh) and detected by flame ionization (320°) with a typical retention time, using helium as carrier gas (60 ml/min), of 3.1 min.

Concentration was determined by peak height measurement with reference to a calibration curve constructed from a series of normal human urine or fecal samples fortified with several levels of authentic drug. A linear response over the concentration range of 2.0–10 μg of drug/ml of urine or fecal homogenate permitted quantitative analysis with no background interferences. Recovery of flumizole added to untreated urine or feces was similar to that obtained with plasma, and the derivatization step with triethylanilinium hydroxide was judged 100% complete by GC comparison with the authentic N_1-ethyl analog of flumizole.

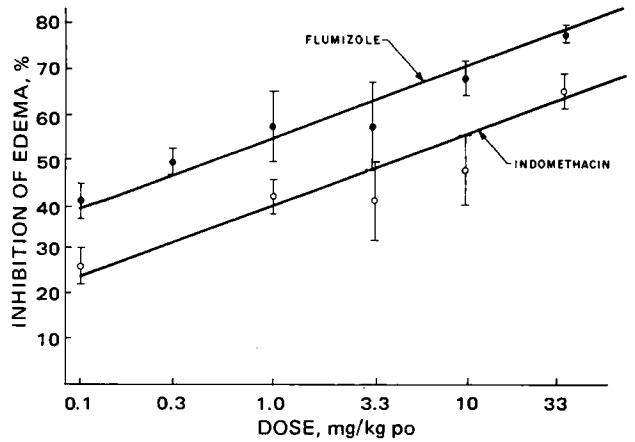

Figure 1—*Dose–response regression lines for the antiedema effects of flumizole and indomethacin in normal rats, six animals at each observation (mean ± SD).*

Estimation of urinary drug excretion in rats and dogs was accomplished by TLC. An aliquot of urine from treated and untreated animals was diluted with an equal volume of 1 *M* NaH_2PO_4, extracted with ethyl acetate (2 × equal volume), and reduced to dryness. The residue obtained directly (or following silica gel column purification as in the plasma assay) was developed on silica gel GF plates[7] with benzene–ethyl acetate–acetic acid (90:5:5) in the presence of authentic flumizole for reference purposes. The presence of drug was revealed by plate exposure to UV light and compared to reference zones of flumizole.

Animal fecal samples were analyzed by fluorometry in aqueous acid (beagles) or by TLC (rats) as already described. Ten percent of administered flumizole would have been detectable in rat feces. Gradual decomposition of flumizole was observed at pH 8 or above in aqueous buffers (the products will be discussed in a forthcoming publication). Drug recoveries averaged 70% (six tests, range of 40–95%) following the incubation of normal dog fecal homogenate with flumizole at concentrations encountered in medicated dog studies. Since a reliable correction factor for potential drug degradation in the gut was not obtainable, fecal assays for flumizole could only be interpreted in a semiquantitative manner and represent, therefore, minimum estimates of actual unabsorbed drug.

Drug Formulation—To prepare the solid dispersion of flumizole for animal bioavailability studies, polyethylene glycol 6000 (II) was melted (approximately 70°) and flumizole was added in small portions with constant stirring. The uniform melt was flash cooled by transferring the beaker to an ice bath. The solidified product was reduced to a fine powder and sieved. Only the powder that passed the 100-mesh but was retained on the 200-mesh sieve was used in the dissolution test.

Analysis was performed by weighing aliquots of the solid dispersions containing approximately 20 mg of flumizole into 100-ml volumetric flasks. After approximately 50 ml of methanol was added, the flasks were shaken mechanically for 30 min and then diluted to volume with methanol. The solutions were filtered[9] to remove undissolved II. A 10-ml aliquot of the filtrate was diluted to 100 ml with methanol. The absorbance of the resulting solution at 267 nm was determined spectrophotometrically[10].

A standard solution was prepared by shaking 20 mg of flumizole and 80 mg of II with methanol, filtering, diluting, and reading as described. A quantity of II equal to that contained in the unknown samples was treated in the same manner as the sample and standard solutions and used as the UV reference solvent. Analysis confirmed drug concentrations in the dispersion within ±5% of theory. Stability of drug in the II melt was established by silica gel GF[7] TLC, using a benzene–5% acetic acid solvent system and UV light irradiation for drug detection.

To determine dissolution rates of the solid dispersion in simulated gastric fluid without pepsin (pH 1.2), an excess of pure flumizole or the solid dispersion beyond its equilibrium solubility was added to 500 ml of simulated gastric fluid maintained at 37 ± 0.5°

Table I—Effects of Flumizole, Indomethacin, and Phenylbutazone on Prostaglandin Synthetase *In Vitro*

Compound	Effective $Dose_{50}$[a] Prostaglandin E_2, μM	Prostaglandin $F_{2\alpha}$, μM	Potency[b]
Flumizole	0.7	0.8	8
Indomethacin	5.6	6.1	1
Phenylbutazone	370	350	0.017

[a] Determined from linear regression analysis of data obtained at arachidonic acid concentrations of 3.6×10^{-4} *M*; a minimum of four concentrations with three replicates was used. [b] Potency relative to indomethacin.

in a 600-ml jacketed beaker. The contents of the dissolution bath were stirred with an overhead T-shaped stirrer rotating at 60 rpm and placed such that the Teflon paddle scraped the bottom of the beaker. Aliquots (10 ml) of the dissolution medium were withdrawn at various times and immediately filtered[11] and diluted to 25 ml with methanolic hydrochloric acid (7 ml of concentrated hydrochloric acid/liter of methanol).

The fluorescence of the resulting solutions was determined[6]. Standard solutions were prepared by dissolving known quantities of flumizole in methanolic hydrochloric acid, adding 10 ml of simulated gastric fluid, and diluting to 25 ml with methanolic hydrochloric acid. There was a linear response over the concentration range studied. The baseline fluorescence of 10 ml of fluid diluted to 25 ml with methanolic hydrochloric acid was subtracted from the readings of all standard and unknown solutions.

For bioavailability studies in animals, the solid dispersion was encapsulated[12]. For clinical investigations, the 100–200-mesh flumizole solid dispersion was mixed with lactose as a bulking agent, followed by the addition of 0.5% fumed silica[13] as a lubricant, to afford a free flowing powder for encapsulation[12]; a 25-mg drug capsule contained 125 mg of solid dispersion and 350 mg of lactose. Dissolution profiles were obtained in simulated gastric fluid according to NF XIII Dissolution Test Method I with minor modifications. Aliquots of the dissolution medium were processed and analyzed spectrophotofluorometrically as previously described.

Biological Availability—Flumizole absorption in the rat was studied after the oral and intraperitoneal routes of administration with the polyethylene glycol 300 vehicle (I) employed in anti-inflammatory tests. Dogs received 10 mg of flumizole/kg, orally as encapsulated unformulated drug or as a solution in I (10 ml) and intravenously in 3 ml of I as a bolus or as a 3-min infusion into a rapid saline drip into the jugular vein.

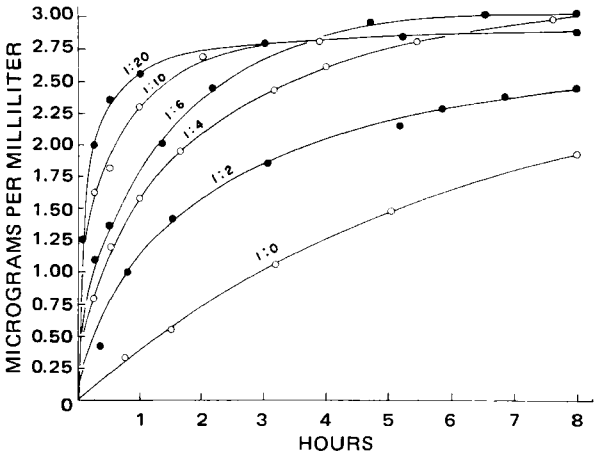

Figure 3—*Dissolution profile of flumizole–polyethylene glycol 6000 (1:x) solid dispersions in simulated gastric fluid (60 rpm, 37 ± 0.5°).*

Comparative dosage form studies with flumizole solid dispersion were conducted in two beagles fasted each night prior to drug administration at weekly intervals. Animals were allowed free access to water after drug ingestion, although food was withheld for an additional 7 hr. Drug analysis was conducted with heparinized whole blood samples drawn at selected intervals from the abdominal aorta of rats maintained under ether anesthesia or from the jugular vein of dogs. Plasma, immediately separated by centrifugation, and total urine and fecal specimens collected in metabolism cages were frozen prior to analysis.

Pharmacokinetic studies were conducted with the solid dispersion capsule formulation in healthy male volunteers during single- (25, 50, and 75 mg administered at weekly intervals) and multiple- (25 mg tid, 10 days) dose tolerance studies. Subjects were fasted overnight prior to single-dose studies and received normal noonday meals 3–4 hr later. During the multiple-dose phase, drug was administered at 4-hr intervals following an initial postprandial morning dose. Serial blood samples were collected into heparinized tubes for plasma drug level determinations.

All samples, including total urine and fecal collections from selected individuals, were frozen upon collection until analysis. Drug level analyses during availability studies were aided by computer-assisted determinations of areas under the plasma concentration–time curves (trapezoidal method). Mean levels based on area ($\bar{c}$) were obtained by dividing area by the number of hours within the time period of interest.

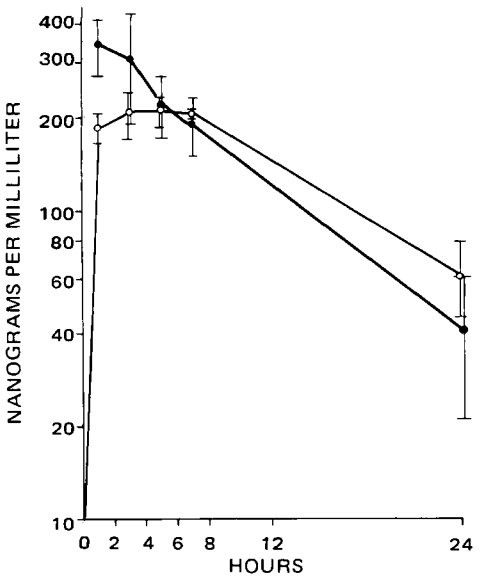

Figure 4—*Mean ± SD plasma levels of flumizole in rats (three per time interval) following intraperitoneal (●) and oral (○) administration of flumizole in polyethylene glycol 300 solution, 3.3 mg/kg.*

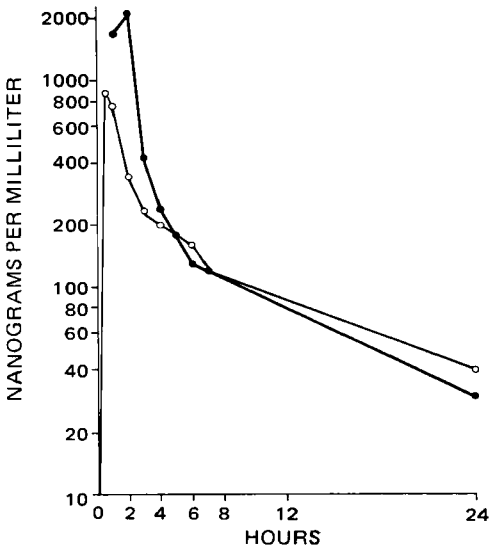

Figure 5—*Plasma levels of flumizole in a female beagle (10.6 kg) following the intravenous bolus (●) and oral (○, 4 weeks later) administration of flumizole in polyethylene glycol 300 solution, 10 mg/kg. Feces (0–48 hr) of this dog contained 43% of the oral dose but none of the intravenous dose as flumizole.*

RESULTS

Antiedema Activity—In the intact Charles River rat, flumizole consistently inhibited edema formation at oral doses of 0.3 mg/kg and above. Some variation was noted, possibly linked to the limited solubility of flumizole, even though administration was performed in the rat in aqueous polyethylene glycol 300 solution. Optimally, however, flumizole was 10 (range of 5–40) times as effective as indomethacin (Fig. 1). The activity of flumizole was not significantly reduced by adrenalectomy; at an oral dose of 1.0 mg/kg, flumizole inhibited edema formation to 54 ± 4% (*cf.*, 57 ± 7% in intact rats).

Antigranuloma Activity—In this test, flumizole possessed 10 times the potency of phenylbutazone (Fig. 2). At the highest doses, both flumizole (18 mg/kg) and phenylbutazone (180 mg/kg) slightly inhibited body weight gain during the 3-day test period.

Antierythema Activity—Flumizole and phenylbutazone both inhibited the erythema caused by UV irradiation in the guinea pig. The largely subjective nature of the evaluation of the end-point of this test (degree of erythema) precluded rigorous estimation of relative potency. Scores for both drugs were 0.8–1.1 at 1.0 mg/kg, 0.5–0.7 at 10 mg/kg, and 0.2–0.4 at 18 mg/kg; concurrently treated control animals scored 3.4–4.0. Therefore, over the 1.0–18-mg/kg dose range, the compounds were approximately equally effective.

Prostaglandin Synthetase Activity—Flumizole inhibited the conversion of arachidonic acid into prostaglandins E_2 and $F_{2\alpha}$ *in vitro* (Table I). The compound was eight times more potent than indomethacin and 470 times more potent than phenylbutazone.

Formulation—Flumizole dissolved in simulated gastric fluid from the solid dispersions containing various amounts of polyethylene glycol 6000 faster than when presented as the compound alone (Fig. 3). Solid dispersions containing increasing amounts of polyethylene glycol 6000 (2, 4, 6, 10, and 20 parts for each part of drug) showed a corresponding increase in the dissolution rate of flumizole.

The addition of lactose and 0.5% fumed silica to the solid dispersion provided a capsule formulation suitable for machine processing. This formulation displayed a dissolution rate profile in simulated gastric fluid comparable to that of the pure solid dispersion. Considerations of capsule size led to the selection of the 1:4 (w/w) formulation for clinical studies.

Biological Availability—Plasma flumizole level determinations in rats following the oral and intraperitoneal administration of flumizole, 3.3 mg/kg in polyethylene glycol 300 solution, indicated that drug was well absorbed at dose levels employed during anti-inflammatory studies (Fig. 4). Peak levels of approximately 200 ng/ml were achieved 3–7 hr after the oral dose. Following in-

[a] Designates levels not determined. [b] Zero levels represent less than 10 ng/ml, minimum assay detectability during this study.

traperitoneal injection, drug levels declined with an apparent half-life of 7 hr within the first 24-hr period. The absence of detectable unchanged drug in the feces and urine of these animals (oral or intraperitoneal dose) indicated the extensive (>90%) metabolism of flumizole by rats prior to excretion[14].

Preliminary studies in beagles suggested poor absorption of solid unformulated flumizole. Plasma concentrations were low, and a major portion of the dose was excreted unchanged in feces. Oral administration of drug as a solution in polyethylene glycol 300 afforded maximum plasma concentrations within 1 hr; these levels were approximately one-half those obtained following intravenous drug injection in the same animal (Fig. 5). An apparent plasma half-life of 2.5 hr during the 3–7-hr postdose period increased with time, a probable consequence of drug redistribution. The recovery of 43% of the oral dose in feces as flumizole and none following intravenous drug administration indicated that absorption was incomplete at this dose level even when drug was administered in solution. With additional evidence that dog urine (intravenous or oral dose) contained no flumizole, it could be established that absorbed flumizole was completely metabolized in this species.

To support the selection of a flumizole dosage form with optimum biological availability properties, comparative blood level studies were conducted in two beagles at successive weekly intervals (Table II). Baseline data were first obtained following the intravenous infusion and oral ingestion of polyethylene glycol 300 solutions of drug. The solid dispersion afforded maximum plasma drug levels of about 100 ng/ml 2–3 hr after the dose. The availability of flumizole from the dispersion was 50–70% that of oral solutions based on area-under-the-curve analyses. Drug levels following administration of capsules containing solid unformulated drug were appreciably lower or undetectable. At 10 mg/kg, drug in the feces of these animals (Table II) supported the incompleteness with which flumizole is orally absorbed in dogs, regardless of dosage form. A fivefold increase in dose to 50 mg/kg only doubled peak plasma levels and elevated areas under the curve 1.4–2-fold in the beagles to indicate further that limits of the drug absorption processes had been reached.

The availability of flumizole from the solid dispersion capsule formulation was assessed in humans by plasma and fecal drug level determinations following the oral administration of single and multiple doses. In 17 volunteers, drug levels peaked after 1–4 hr and averaged 20, 30, and 48 ng/ml of plasma following single doses of 25, 50, and 75 mg, respectively (Table III and Fig. 6); however, appreciable intersubject plasma level variations were evident. The disappearance of drug from plasma proceeded nonexponentially with an increasing half-life in most subjects. A shoulder, plateau, or occasional secondary peak was observed within the first 6 hr in many individuals; at the 75-mg level, 10 of 17 subjects exhibited this phenomenon, which may reflect an irregular drug absorption pattern[15]. A mean half-life of 4.4 hr was apparent during the first 6 hr in all subjects at the maximum 75-mg dose level. Based on measurable 6- and 24-hr levels at this dose in 11 subjects, a longer secondary half-life phase ranging from 4.5 to 20 hr was indicated (mean of 11 hr).

Plasma flumizole levels during a multiple-dose study were maintained without accumulation (Table III). Levels midway through the 10-day trial, 25 mg tid, averaged about 30 ng/ml. On the morning after the last multiple daily dose, drug levels had declined in all subjects to about 10 ng/ml or less. Analysis following a final single dose on Day 11 revealed the usual pattern of drug clearance with levels of less than 10 ng/ml after 24 hr.

The absence of measurable levels of unchanged drug in feces (<20% of dose) and urine (<5% of dose) from selected volunteers at the 75-mg single-dose level supported good drug absorption and indicates the completeness with which flumizole is metabolized prior to excretion by humans.

DISCUSSION

Flumizole demonstrates potent inhibitory activity in classical animal models of inflammation. The erythema formed in response to UV irradiation was inhibited. Flumizole inhibited carrageenan-induced foot edema with a potency greater than that of indomethacin. Some variation in potency was noted, it could be observed from experiment to experiment and was probably a reflection of the very limited aqueous solubility of flumizole. In addition, the potency varied in the strain of rat, flumizole being a somewhat less effective antiedema agent in the Wistar rat than in the Charles River rat (2). Full antiedema activity was retained in adrenalectomized Charles River rats, revealing that anti-inflammatory activity is not dependent upon adrenal gland stimulation. In a model of more chronic inflammation, flumizole inhibited the formation of granulation tissue around an implanted string irritant (sterile string).

Flumizole also inhibits the activity of prostaglandin synthetase *in vitro*. The drug was severalfold more potent than indomethacin and 470 times more active than phenylbutazone in a system examining prostaglandin production. Thus, despite its different physicochemical properties, flumizole resembles the acidic anti-

[14] Analysis of rat urine revealed the presence of *O*-monodemethylated flumizole by mass spectrometric analysis of material isolated from thin-layer plates. Subsequent confirmation of this finding and the detailed elaboration of flumizole metabolism pathways will be the subjects of a forthcoming paper.

[15] Noonday meals were generally taken during a period coincident with the observed drug level fluctuations. Similar blood level patterns reported with the anti-inflammatory agent indoxole (8) may have been related to food intake and consequent gallbladder evacuation of drug. Although double peaking was observed with flumizole in dogs (three of six experiments, intravenous dose), a biliary fistula beagle that received an oral dose of ^{14}C-flumizole secreted very little (by chromatographic estimation) unchanged drug with bile.

Table III—Mean Plasma Levels of Flumizole in Humans during Single- and Multiple-Dose Tolerance Trials following Administration of Flumizole Solid Dispersion Capsule Formulation

Single-Dose Studies, 17 Subjects

Dose, mg (mg/kg, Mean)	Mean Plasma Drug Levels, ng/ml	
	Peak (Range)	$\bar{c}$, 0—6 hr
25 (0.33)	20 ± 11 (7—36)	11 ± 6
50 (0.67)	30 ± 17 (7—66)	17.5 ± 7
75 (1.0)	48 ± 18 (19—87)	28.5 ± 9

Multiple-Dose Studies, Nine Subjects

	Mean Plasma Drug Levels, ng/ml (Range)[a]								
	Day 1			Day 4		Day 11 (Single am Dose)			
Dose	0 hr	4 hr	6 hr	4 hr	6 hr	0 hr	2 hr	6 hr	24 hr
25 mg tid	5 ±3 (0—8)	22 ±21 (6—74)	25 ±20 (3—68)	26 ±12 (11—46)	31 ±16 (6—56)	8 ±3 (4—13)	26 ±14 (9—54)	17 ±14 (3—50)	3 ±3 (0—7)

[a] Hourly intervals designated refer to time period after the first dose of the day; drug was administered at 8:00 am, noon, and 4:00 pm daily. This 10-day study culminated a 25-day trial, in which the dose increased incrementally from 5 mg bid to 15 mg tid through the first 15-day segment.

inflammatory agents in its inhibition of prostaglandin synthetase. The demonstration of anti-inflammatory activity for flumizole in humans[16] is further support for the hypothesized importance of this activity in the mechanism of action of anti-inflammatory agents (9).

Because the aqueous solubility of flumizole is very low, all pharmacological testing was conducted using a solution of the drug in polyethylene glycol 300 containing polysorbate 80. With the development of sensitive fluorometric assay procedures specific for flumizole, measurement of plasma drug concentrations confirmed the absorption of drug from this vehicle in dogs (10 mg/kg) and rats (3.3 mg/kg). For extended studies in animals and humans, a solid dosage form of flumizole was sought with optimum absorption characteristics.

The dissolution of a poorly water-soluble drug in a melt of the water-soluble carrier polyethylene glycol 6000, followed by rapid cooling, affords a solid in which drug particles are finely dispersed, with resultant improvements in wetting properties of the drug (10). The dissolution rates of griseofulvin (11) and indomethacin (12) and the absorption of griseofulvin in dogs (13) and humans (14) have been improved using polyethylene glycol 6000 dispersion systems. The preparation of a solid dispersion of flumizole with polyethylene glycol 6000 (1:4, w/w) by the melting method provided an oral dosage form with an increased dissolution rate in simulated gastric fluid and improved plasma drug concentration patterns in beagles. Plasma levels were higher and were more rapidly and uniformly achieved than from an unformulated dose; solid dispersion drug levels more closely resembled those following the administration of oral solutions of drug. The amounts of unabsorbed drug in feces generally supported these findings. Therefore, the solid dispersion of flumizole was selected as a superior dosage form for further investigation.

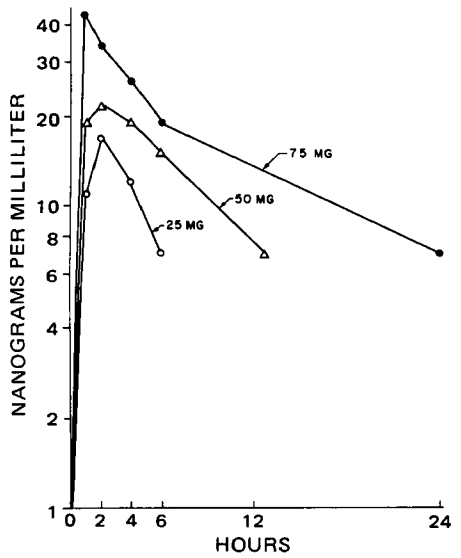

Figure 6—*Mean plasma levels of flumizole in 17 subjects following the administration of single doses of 25 (○), 50 (△), and 75 (●) mg of flumizole solid dispersion capsule formulation.*

Following preclinical safety evaluation in animals[17], bioavailability studies were conducted in humans with the solid dispersion capsule formulation of flumizole. A dose-dependent increase in mean plasma levels of flumizole was observed over the single-dose range of 25–75 mg. Peak plasma levels of flumizole were achieved with 1–4 hr after the dose was received. The magnitude of plasma levels and the absence of appreciable quantities of drug in feces supported good drug absorption during these studies. Similar drug level patterns were observed during multiple-dose regimens of 25 mg tid.

Flumizole was eliminated from the bloodstream of rats (3.3 mg/kg ip) with a plasma half-life of about 7 hr within the first 24-hr period. In dogs (10 mg/kg po and iv) and humans (75 mg po), plasma flumizole levels declined initially with an apparent half-life of 2–4 hr and increased with time, a probable consequence of drug redistribution. Detailed pharmacokinetic properties of flumizole will be discussed in a future publication.

The present studies demonstrate flumizole to be a potent anti-inflammatory agent in standard rodent and prostaglandin synthetase systems. Biological availability of this poorly water-soluble compound is optimized in dogs and humans by administration as a solid dispersion with polyethylene glycol 6000.

Apparent Absorption Kinetics of Micronized Griseofulvin after Its Oral Administration on Single- and Multiple-Dose Regimens to Rats as a Corn Oil-in-Water Emulsion and Aqueous Suspension

THEODORE R. BATES ˣ and PHILIP J. CARRIGAN

Abstract □ This investigation was designed to quantitate and compare in the rat the oral absorption characteristics of micronized griseofulvin from a corn oil-in-water emulsion dosage form containing suspended drug and a control aqueous suspension after single-dose (50 mg/kg) and multiple-dose (50 mg/kg every 12 hr for five doses) administrations. The time course of intact drug in the plasma of all animals was best described by a one-compartment open model with apparent zero-order absorption. In contrast to that observed with the aqueous suspension, the onset of drug absorption after single-dose administration of the corn oil emulsion was significantly delayed. This difference disappeared upon multiple dosing of the two dosage forms, with the mean onset being quite rapid in both cases. Administration of a single dose of the antibiotic as the corn oil emulsion resulted in considerable increases in the maximum plasma levels of griseofulvin and in the duration, relative extent, and uniformity of drug absorption compared to those observed after administration of the control aqueous suspension. The potentiating effects of the lipid on drug absorption persisted on multiple dosing but at a somewhat reduced level.

Keyphrases □ Griseofulvin, micronized, absorption kinetics—corn oil-in-water emulsion compared to aqueous suspension, single and multiple doses, rats □ Absorption kinetics, micronized griseofulvin—corn oil-in-water emulsion compared to aqueous suspension, single and multiple doses, rats □ Corn oil-in-water emulsion, micronized griseofulvin—absorption kinetics compared to aqueous suspension, single and multiple doses, rats

Several investigators (1–3) suggested that the slow rate and low extent of absorption, as well as the appreciable intersubject differences in the amount of micronized griseofulvin absorbed from conventional dosage forms, are the most common reasons for clinical failure with griseofulvin therapy. In a previous report (4), it was demonstrated, using the rat as an animal model, that the maximum plasma levels, the bioavailability, and, of considerable importance, the uniformity of absorption of micronized griseofulvin were markedly enhanced after oral administration of a single dose of the antibiotic dispersed in a corn oil-in-water emulsion dosage form vehicle.

These findings were recently confirmed in a study conducted in humans in which the absorption characteristics of micronized griseofulvin from the same corn oil-in-water emulsion were compared with those from an aqueous suspension and two different commercial tablet dosage forms (5). The results of this study provided evidence that the maximum plasma levels and bioavailability of micronized griseofulvin can be increased approximately three- to fourfold and twofold, respectively, by administering the drug as a corn oil-in-water emulsion.

It is not without precedence for absorption differences, which appear after *single-dose* drug administration, to diminish or even to disappear upon *multiple* oral dosing of a drug or drug product (6). Hence, the purposes of the present investigation were to assess and to compare the absorption profiles of micronized griseofulvin from a corn oil-in-water emulsion and a control aqueous suspension dosage form after single and repetitive administrations to rats. The resultant plasma antibiotic level–time data were subjected to pharmacokinetic analysis with the intent of developing a mechanistic explanation for the

Apparent Absorption Kinetics of Micronized Griseofulvin after Its Oral Administration on Single- and Multiple-Dose Regimens to Rats as a Corn Oil-in-Water Emulsion and Aqueous Suspension

THEODORE R. BATES ˣ and PHILIP J. CARRIGAN

Abstract □ This investigation was designed to quantitate and compare in the rat the oral absorption characteristics of micronized griseofulvin from a corn oil-in-water emulsion dosage form containing suspended drug and a control aqueous suspension after single-dose (50 mg/kg) and multiple-dose (50 mg/kg every 12 hr for five doses) administrations. The time course of intact drug in the plasma of all animals was best described by a one-compartment open model with apparent zero-order absorption. In contrast to that observed with the aqueous suspension, the onset of drug absorption after single-dose administration of the corn oil emulsion was significantly delayed. This difference disappeared upon multiple dosing of the two dosage forms, with the mean onset being quite rapid in both cases. Administration of a single dose of the antibiotic as the corn oil emulsion resulted in considerable increases in the maximum plasma levels of griseofulvin and in the duration, relative extent, and uniformity of drug absorption compared to those observed after administration of the control aqueous suspension. The potentiating effects of the lipid on drug absorption persisted on multiple dosing but at a somewhat reduced level.

Keyphrases □ Griseofulvin, micronized, absorption kinetics—corn oil-in-water emulsion compared to aqueous suspension, single and multiple doses, rats □ Absorption kinetics, micronized griseofulvin—corn oil-in-water emulsion compared to aqueous suspension, single and multiple doses, rats □ Corn oil-in-water emulsion, micronized griseofulvin—absorption kinetics compared to aqueous suspension, single and multiple doses, rats

Several investigators (1–3) suggested that the slow rate and low extent of absorption, as well as the appreciable intersubject differences in the amount of micronized griseofulvin absorbed from conventional dosage forms, are the most common reasons for clinical failure with griseofulvin therapy. In a previous report (4), it was demonstrated, using the rat as an animal model, that the maximum plasma levels, the bioavailability, and, of considerable importance, the uniformity of absorption of micronized griseofulvin were markedly enhanced after oral administration of a single dose of the antibiotic dispersed in a corn oil-in-water emulsion dosage form vehicle.

These findings were recently confirmed in a study conducted in humans in which the absorption characteristics of micronized griseofulvin from the same corn oil-in-water emulsion were compared with those from an aqueous suspension and two different commercial tablet dosage forms (5). The results of this study provided evidence that the maximum plasma levels and bioavailability of micronized griseofulvin can be increased approximately three- to fourfold and twofold, respectively, by administering the drug as a corn oil-in-water emulsion.

It is not without precedence for absorption differences, which appear after *single-dose* drug administration, to diminish or even to disappear upon *multiple* oral dosing of a drug or drug product (6). Hence, the purposes of the present investigation were to assess and to compare the absorption profiles of micronized griseofulvin from a corn oil-in-water emulsion and a control aqueous suspension dosage form after single and repetitive administrations to rats. The resultant plasma antibiotic level–time data were subjected to pharmacokinetic analysis with the intent of developing a mechanistic explanation for the

enhanced absorption of micronized griseofulvin from lipid-in-water emulsion dosage forms.

EXPERIMENTAL

Dosage Forms—The corn oil-in-water emulsion and control aqueous suspension dosage forms employed in these studies were identical in composition and method of preparation to those previously described (4). Both dosage forms contained suspended micronized griseofulvin[1] (specific surface area of 1.32 m^2/g) and the same quantity of the nonionic surfactant polysorbate 60. Prior to use, they were assayed in triplicate for drug content by the spectrophotometric procedure described earlier (4).

Absorption Studies—Adult male Sprague–Dawley rats[2], 250–325 g, were used. All experiments were initiated between 8:00 and 9:00 am.

Single-Dose Oral Studies (Fasting Animals)—The animals were fasted for 20–24 hr prior to, and during, the absorption experiments, but they were allowed free access to water. The aqueous suspension and corn oil-in-water emulsion dosage forms were administered by oral intubation to 11 or 12 lightly anesthetized (ether) rats at a griseofulvin dosage level of 50 mg/kg and a dosing volume of 5.0 ml/kg. After dosing, the animals were placed in restraining cages.

Approximately 0.5-ml blood samples were collected from the tail artery of each rat into heparinized tubes immediately prior to drug administration and at 1, 2, 4, 6, 8, and 12 hr postadministration. Twenty-four-hour samples were obtained *via* decapitation. The blood samples were then centrifuged, and a 0.2–0.3-ml aliquot of the plasma was accurately measured directly into a culture tube extraction vessel. A 2.0-ml plasma sample was obtained at the 24-hr time period. All plasma samples were immediately frozen solid and assayed for griseofulvin within 48 hr of collection.

Single-Dose Oral Studies (Nonfasting Animals)—The *in vivo* protocol employed in studies designed to establish the effect of food on the oral absorption characteristics of griseofulvin from the corn oil-in-water emulsion was similar to that used for fasting animals. The sole exception was that the animals were allowed free access to food[3] prior to, and during, the absorption experiment.

Multiple-Dose Oral Studies—Six animals were fasted for 20–24 hr prior to oral administration of the first 50-mg/kg dose of griseofulvin as the aqueous suspension or corn oil-in-water emulsion. The animals were then allowed free access to food until 20–24 hr prior to the final dose, at which time they were again fasted for the duration of the absorption experiment. Five 50-mg/kg doses of griseofulvin were administered at a constant dosing interval of 12 hr. Blood samples were collected from the tail artery of each animal immediately prior to, and at 1, 2, 4, 6, 8, and 12 hr after, the administration of the last drug dose.

Plasma samples were assayed for intact griseofulvin content by the spectrofluorometric procedure described earlier (4).

RESULTS AND DISCUSSION

Pharmacokinetic Analysis—Previous studies indicated that the plasma levels of griseofulvin decline in a monoexponential fashion with time after intracardiac (i.c.) administration to rats of a single 5- or 10-mg/kg dose of the antibiotic as a solution in polyethylene glycol 400 (7). There was no evidence of a dose dependency in the disposition kinetics of the drug, and the plasma levels attained in the intracardiac studies were comparable to those observed in the present 50-mg/kg dose oral studies.

Therefore, all plasma griseofulvin concentration–time data obtained following single- or multiple-dose oral administration of the dosage forms were fitted to an appropriate linear pharmacokinetic model, using the digital computer, nonlinear regression analysis program (NONLIN) of Metzler (8), and equal weighting of the data points. The goodness of fit of the data to a one-compartment open model with either apparent first-order (Scheme I and Eqs. 1 and 2) or apparent zero-order (Scheme II and Eqs. 3*a*, 3*c*, 4*a*, and 4*c*) absorption was tested (8–10).

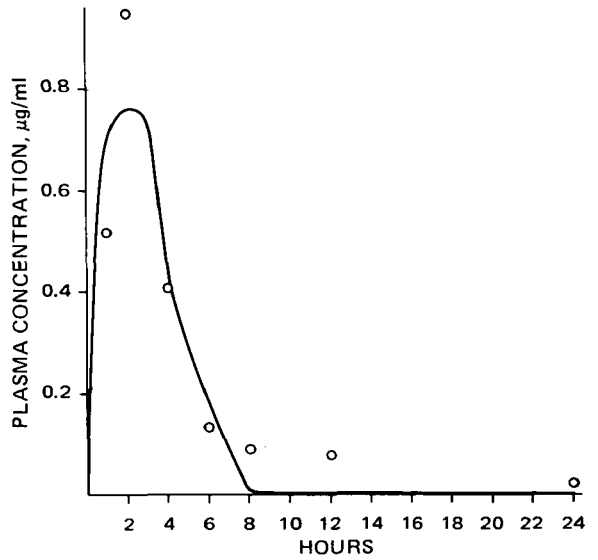

Figure 1—*Plasma concentrations of griseofulvin as a function of time following the oral administration of a 50-mg/kg single dose of micronized griseofulvin as an aqueous suspension to Rat 51. Key:* o, *actual experimental points; and* —, *obtained by computer, nonlinear least-squares regression according to Eq. 1 (CORR = 0.934).*

One-Compartment Open Model with First-Order Absorption—Scheme I shows the simplified model where A_A is the amount of griseofulvin in solution at the absorption site at any time t, k is the apparent first-order absorption rate constant, and K' is the apparent elimination rate constant.

$$A_A \xrightarrow{k} A_B \xrightarrow{K'} A_E$$

Scheme I

For single-dose administration, griseofulvin plasma concentrations (C) at any time t following oral drug administration are given by:

$$C = \left(\frac{FD}{V}\right)\left(\frac{k}{k - K'}\right)[\exp[-K'(t - t_0)] - \exp[-k(t - t_0)]] \quad \text{(Eq. 1)}$$

where F is the fraction of the oral dose absorbed, D is the oral dose, V is the volume of distribution, and t_0 is the lag time before absorption commences or the onset of absorption.

For multiple-dose administration, the plasma concentration of griseofulvin at any time t' following the oral administration of the nth dose (C_n) is given by:

$$C_n = \left(\frac{FD}{V}\right)\left(\frac{k}{k - K'}\right)\left[\left(\frac{1 - \exp - (nK'\tau)}{1 - \exp - (K'\tau)}\right) \times \exp[-K'(t' - t_0)] - \left(\frac{1 - \exp - (nk\tau)}{1 - \exp - (k\tau)}\right) \times \exp[-k(t' - t_0)]\right] \quad \text{(Eq. 2)}$$

where $t' = t - (n - 1)\tau$, n is the number of fixed doses administered, τ is the constant time interval between doses, and C_n is the plasma concentration of griseofulvin at any time t' after the nth dose.

One-Compartment Open Model with Apparent Zero-Order Absorption—Scheme II shows the simplified model where k_0 is the apparent zero-order absorption rate constant.

$$A_A \xrightarrow{k_0} A_B \xrightarrow{K'} A_E$$

Scheme II

[1] Supplied by the Schering Corp., Bloomfield, N.J.
[2] Obtained from Blue Spruce Farms, Altamont, NY 12009
[3] Charles River Rat Formula (low in fat content), Country Foods, Syracuse, N.Y.

For single-dose administration, the plasma concentration of griseofulvin at any time during its absorption over T hours is given by:

$$C = \frac{k_0}{VK'}[1 - \exp[-K'(t - t_0)]] \qquad \text{(Eq. 3a)}$$

with the condition that $t_0 \leq t \leq T$ and where $k_0 = FD/T$, T is the duration of the absorption process, and t is any time after oral administration of griseofulvin.

At the end of the absorption process, the maximum plasma concentration of griseofulvin ($C_{\max,T}$) can be described by the relationship:

$$C_{\max,T} = \frac{k_0}{VK'}[1 - \exp[-K'(T - t_0)]] \qquad \text{(Eq. 3b)}$$

when $t = T$.

After absorption has ceased, the plasma levels of griseofulvin decline monoexponentially with time in accordance with:

$$C = (C_{\max,T})\exp[-K'(t - T)] \qquad \text{(Eq. 3c)}$$

when $t \geq T$.

For multiple-dose administration, at any time t' during the absorption of the nth dose, the plasma levels of griseofulvin are given by:

$$C_n = \frac{k_0}{VK'}\Bigg[1 - \exp - [K'(t' - t_0)] - \left(\frac{1 - \exp - [(n-1)K'\tau]}{1 - \exp - (K'\tau)}\right)(\exp[-K'(t' - t_0 + \tau)] - \exp[-K'(t' - t_0 + \tau - T)])\Bigg] \qquad \text{(Eq. 4a)}$$

with the condition that $t_0 \leq t' \leq T$ and where $t' = t - (n-1)\tau$ = time elapsed after oral administration of the nth dose.

The maximum plasma concentration attained after the nth dose ($C_{n,\max,T}$) is:

$$C_{n,\max,T} = \frac{k_0}{VK'}\Bigg[1 - \exp - [K'(T - t_0)] - \left(\frac{1 - \exp -[(n-1)K'\tau]}{1 - \exp - (K'\tau)}\right) \times (\exp[-K'(T - t_0 + \tau)] - \exp[-K'(\tau - t_0)])\Bigg] \qquad \text{(Eq. 4b)}$$

when $t' = T$.

After the nth dose is absorbed, the plasma concentration decreases with time in accordance with:

$$C_n = (C_{n,\max,T})\exp[-K'(t' - T)] \qquad \text{(Eq. 4c)}$$

when $t' \geq T$.

As can be seen from the representative computer-predicted curves, the use of the apparent first-order absorption model (Scheme I and Eqs. 1 and 2) consistently resulted in poor agreement between the predicted and experimental plasma level–time data obtained from both single- (Figs. 1 and 2) and multiple- (Fig. 3) dose absorption studies. However, when the same experimental data were analyzed by the apparent zero-order absorption model (Scheme II and Eqs. 3a, 3c, 4a, and 4c), excellent computer fits were realized (Figs. 4–6). Therefore, this model was used to interpret the results of all *in vivo* absorption studies performed with griseofulvin.

It is important to note that griseofulvin is *apparently* absorbed in a zero-order fashion from the *test dosage forms* whereas the drug is probably absorbed from *solution* by an apparent first-order process (11, 12). The observed, apparent zero-order absorption profile of griseofulvin can be explained on the basis that a slow, rate-determining dissolution step precedes the true absorption process (13–15). The assumption that the rate-limiting dissolution process is kinetically zero-order appears to be consistent with the unusually low aqueous solubility of griseofulvin (about 15 mg/liter at 37°) and the limited volume of GI fluids available for drug dissolution relative to the oral dose administered to the animals (*i.e.*, 50 mg/kg or approximately 15 mg/animal). A similar hypothesis was proposed (16) to account for the *apparent* zero-order absorption profile of sulfisoxazole from tablet dosage forms in humans.

($AUC_{0-\infty}$) and during the dosing interval after the fifth oral dose (AUC_τ) was determined using the trapezoidal rule (10).

***In Vivo* Absorption Studies**—*Single-Dose Oral Studies (Fasting Animals)*—The mean[4] time course of griseofulvin in the plasma of fasting rats after oral administration of a single 50-mg/kg dose of micronized griseofulvin as the control aqueous suspension or corn oil-in-water emulsion dosage form is presented in Table I. All plasma level–time data were pharmacokinetically interpreted according to a one-compartment open model with apparent zero-order absorption (Eqs. 3*a* and 3*c* and Figs. 4 and 5).

The computer-generated nonlinear least-squares regression estimates of the model parameters[4] are summarized in Table II, together with indications of the goodness of fit of the experimental data to the proposed model. Statistical comparisons of the mean model parameters are presented in Table III. An examination of the mean t_0 values (Table II) reveals that the onset of absorption of griseofulvin from the corn oil emulsion is slightly, but significantly (Table III), delayed relative to that observed from the control aqueous suspension. No statistical difference was noted between the dosage forms with respect to either the relative rate of drug absorption or the apparent elimination rate constant (Table III). However, the duration of absorption of griseofulvin, as reflect-

ed by the magnitude of the mean T values listed in Table II, was significantly increased by 2.7 hr (Table III) when the drug was administered to the fasting animals as a suspension in the emulsified corn oil vehicle as compared to the aqueous suspension.

The maximum plasma levels attained following oral administration of griseofulvin in the two dosage forms to fasting animals were calculated with Eq. 3*b* and the computer-generated model parameters; the mean values are listed in Table II. The estimated values compare favorably with those actually observed (Table II). The mean data show that the maximum plasma level of the antibiotic from the corn oil emulsion was approximately two times higher and less variable (lower coefficient of variation) than from the control aqueous suspension. This difference was highly significant (Table III).

The mean estimated and observed areas under the plasma griseofulvin level–time curves for both dosage forms are also listed in Table II, and excellent agreement exists. A statistical comparison of the mean areas (Table III) reveals that there was a highly significant, threefold increase in the amount of drug absorbed from the corn oil emulsion relative to that absorbed from the control aqueous suspension. As reflected by the magnitude of the coefficients of variation associated with this parameter (Table II), the absorption of micronized griseofulvin appears to be more uniform from the corn oil-in-water emulsion.

Multiple-Dose Oral Studies—It was considered important to determine whether the marked improvement in griseofulvin bioavailability observed with the corn oil emulsion dosage form after single-dose administration also occurred upon multiple dosing. Therefore, animals received orally a 50-mg/kg dose of micronized griseofulvin as the control aqueous suspension or corn oil-in-water emulsion dosage form every 12 hr for a total of five doses. The dosing interval employed was designed to yield an average plasma level at steady state (17) of approximately 1 μg/ml and minimal drug accumulation after repetitive oral dosing with the emulsion dosage form.

The mean[4] plasma griseofulvin concentration–time data fol-

[a] Student t test (20). [b] N.S. = not significant.

However, in contrast to what was observed after repetitive administration of the aqueous suspension, the presence of emulsified corn oil in the GI tract produced approximately a 1.8-hr increase in the duration of the absorption process, a 1.4-fold increase in the maximum plasma levels attained, and a 1.8-fold increase in the bioavailability of griseofulvin (Table V). All of these differences were highly significant (Table VI).

In addition, the drug was more uniformly absorbed from the emulsion dosage form (*i.e.*, the coefficients of variation were lower, Table V) and plasma levels exceeding 1 μg/ml, the minimum effective level in humans (18) and dogs (15), were maintained for appreciably longer periods (Table IV). The fact that the absorption of micronized griseofulvin from the corn oil emulsion is considerably enhanced after both single and repetitive oral administration demonstrates that the effect of emulsified lipid on griseofulvin absorption is not transient.

Effect of Food on Absorption of a Single Dose of Micronized Griseofulvin from a Corn Oil-in-Water Emulsion—In general, food has an inhibitory effect on the GI absorption of most drugs from pharmaceutical dosage forms (19). To determine whether the presence of food in the GI tract could affect the absorption of griseofulvin from the corn oil-in-water emulsion, a single 50-mg/kg dose of this dosage form was administered orally to another group of rats who had been allowed free access to food both before and after drug administration (nonfasting animals). The mean[4] time course of griseofulvin in the plasma of each nonfasting rat is presented in Table I. The pharmacokinetic analysis of the plasma level data is summarized in Table II.

A statistical comparison of the parameters obtained after oral administration of the corn oil emulsion to nonfasting animals with those obtained in fasting animals (Table II) indicated that food did not affect the apparent onset, duration, or rate of drug absorption from the corn oil emulsion (Table III). In addition, the presence of food did not significantly alter the maximum plasma levels, the bioavailability, or the apparent elimination rate constant of the antibiotic from the corn oil emulsion (Table III).

The mechanism underlying the enhanced absorption of micronized griseofulvin after single- and multiple-dose administration to rats as a lipid-in-water emulsion will be the subject of a subsequent report.

Succinylsulfathiazole Crystal Forms II: Effect of Additives on Kinetics of Interconversion

A. R. EBIAN, M. A. MOUSTAFA, SAID A. KHALIL [x], and M. M. MOTAWI [†]

Abstract □ The effect of various additives on the rate of transformation of the metastable anhydrous succinylsulfathiazole Form I to the water-stable dihydrate Form II in aqueous suspensions was studied. Some structurally related compounds, viscosity-imparting agents, surfactants, and coloring agents were used as possible transformation retardants. The effect of including seeds of Form II in the presence and absence of additives is also discussed. Some additives, *e.g.*, methylcellulose and phthalylsulfathiazole, showed significant transformation-retarding effects. Other additives, *e.g.*, sulfanilamide and glycerin, increased the rate of transformation. Coloring agents had only slight effects. Utilization of the results in the formulation of physically stable aqueous suspensions of succinylsulfathiazole is discussed.

Keyphrases □ Succinylsulfathiazole—crystal forms, interconversion, effect of structurally related compounds, viscosity-imparting agents, surfactants, and coloring agents □ Crystal forms—succinylsulfathiazole, effect of additives on interconversion

Succinylsulfathiazole crystal forms, their preparation, characterization, interconversion, and kinetics of transformation under standard conditions, were previously described (1). It was concluded (1) that the formulation of physically stable aqueous suspensions of succinylsulfathiazole may be achieved in one of two ways. The first involves the use of Form II (the water-stable dihydrate), which does not undergo further transformation in suspension and, consequently, does not change in shape or size distribution, thus producing a stable suspension. The second involves the anhydrous Form I (frequently available commercially), provided that adequate measures are taken to prevent the transformation to Form II which results in physical instability. Stabilization of the metastable form (Form I) in aqueous suspension by the use of some formulation additives is the subject of the present report.

The use of various additives to stabilize drug polymorphs has already been reported (2–6). These additives included structurally related compounds, viscosity-imparting materials (hydrocolloids), surfactants, and coloring agents. The present study is concerned with effects of representative examples of these additives, the suspension concentration of Form I, and seeding with Form II on the rate of transformation of the anhydrous succinylsulfathiazole Form I to the dihydrate Form II in aqueous suspension.

EXPERIMENTAL

Materials and Apparatus—Succinylsulfathiazole[1] Forms I and II were obtained as micronized commercial samples. Sulfanilamide, sulfathiazole, phthalylsulfathiazole, methylcellulose, acacia, glycerin, syrup, polysorbate 80, fluorescein sodium, and amaranth, all of USP, BP, or BPC grade, were used. Yellow No. 4[2] and Bordeaux B (BPC 1949) were also used.

IR measurements were made with a double-beam grating spectrophotometer[3].

[a]Corresponding to 10% (w/w) of the total solid succinylsulfathiazole in suspension. [b]Percent v/v.

Methods—Aqueous suspensions of succinylsulfathiazole Form I (1% w/v), each containing a known quantity of one additive, were prepared. The suspensions were kept in a thermostated water bath at 40 ± 0.1°. Samples were withdrawn at various time intervals and filtered, and the concentration of Form I in the solid phase was determined as previously described (1). A temperature of 40° was adopted since, as previously shown (1), transformation was rather slow at room temperature.

Acceleration of the transformation of succinylsulfathiazole Form I, in the presence of phthalylsulfathiazole as an additive, was carried out. For this purpose, 1% (w/v) suspensions of this form, containing 10% (w/w) of phthalylsulfathiazole in succinylsulfathiazole, were kept at 55, 70, and 85 ± 0.1°. The suspensions were assayed periodically for Form I as before.

Seeding experiments were carried out to evaluate the effect of including nuclei of the water-stable succinylsulfathiazole Form II on the rate of transformation of Form I. For this purpose, 5% (w/w) of Form II in Form I was used in place of Form I alone in the presence and absence of some additives.

The effect of the suspension concentration on the rate of transformation of succinylsulfathiazole Form I was studied by measuring the rate in suspensions containing 1, 2, 5, and 10% (w/v) of Form I.

RESULTS AND DISCUSSION

The inhibitory effect of the various additives on the rate of transformation of succinylsulfathiazole Form I, as previously described (6), is manifested by the appearance of a lag period during which the transformation is very slow (almost negligible) and/or obvious rate retardation. The lag period may be interpreted (6) as being a measure of the time needed to produce, through transformation of small particles of Form I, an adequate number of nuclei of the water-stable Form II, which is presumably a prerequisite for the transformation to take place under steady-state conditions (when the various factors affecting the system come to an equilibrium state). Table I summarizes the effect of various additives on the rate of transformation of succinylsulfathiazole Form I in aqueous suspension.

The effect of structurally related compounds on the rate of transformation of succinylsulfathiazole Form I is shown in Fig. 1. Sulfathiazole and phthalylsulfathiazole showed lag periods of 90 and 210 min, respectively. These compounds, being similar in structure to succinylsulfathiazole, are effective transformation retardants in a manner which is probably related to the ease of fit of their molecules to developing nuclei of the water-stable form (Form II).

[a] Determined by extrapolation. [b] Data from Ref. 1.

Unexpectedly, sulfanilamide increased the rate of transformation of Form I to Form II (Fig. 1). This finding may be interpreted by assuming that sulfanilamide molecules, instead of retarding the transformation rate as with other sulfonamides, probably acts as nuclei for the development of crystals of Form II. The smaller and simpler structure of a sulfanilamide molecule would allow for this behavior. The mechanism of action of structurally related compounds probably involves inhibition of the formation of nuclei of the water-stable form by fitting into developing sites of these nuclei, a mechanism that would require the close similarity of the chemical structure as well as a favorable spatial configuration (7).

Acceleration of the transformation of succinylsulfathiazole Form I to Form II in the presence of phthalylsulfathiazole was carried out at several elevated temperatures, and a comparison of the results with those obtained for a standard suspension of Form I containing no additives is shown in Table II. The Arrhenius plots of the data are shown in Fig. 2. It could be observed from Table II that, although the activation energy calculated from the Arrhenius plot (Fig. 2) of the reaction was not significantly affected by the presence of phthalylsulfathiazole, the half-life at 25° was increased about fivefold and the rate constants for the transformation at all temperatures employed were considerably decreased.

Seeding with nuclei of Form II in aqueous suspensions of succinylsulfathiazole Form I containing sulfathiazole or phthalylsulfathiazole eliminated the lag period, indicating that the lag period is really a measure of the time needed to produce an adequate number of nuclei. However, the transformation rate that followed was not significantly affected (Table III).

The effect of viscosity-imparting materials on retarding the transformation of succinylsulfathiazole Form I is shown in Fig. 3. Methylcellulose, in concentrations ranging from 0.05 to 1% (w/v), inhibited the transformation of Form I for periods of over a year at room temperature. Acacia (2% w/v) retarded the rate of transformation only slightly. Simple syrup (50% v/v) had practically no effect on the rate of transformation. Glycerin (20% v/v), on the other hand, accelerated the transformation rate, probably by improving the wetting and solvation of succinylsulfathiazole Form I in aqueous suspension. The transformation-retarding effect of various viscosity-imparting materials could be related to their suppressive effect on both nuclei formation and solvent-mediated growth of the nuclei formed. This effect is, however, less apparent at higher temperatures.

The effect of polysorbate 80 on the rate of transformation of succinylsulfathiazole Form I to Form II varied with temperature (Fig. 4). At room temperature (≃22°), the rate of transformation decreased about 10 times in the presence of polysorbate 80 (1% w/v). Experiments carried out at a higher temperature (40°), using different concentrations of polysorbate 80 (0.05, 0.5, and 1.0% w/v), showed an increase in the rate of transformation of about twofold. The increase in the transformation rate was found to be directly proportional to the concentration of polysorbate 80.

This behavior might be understood if one considers the opposing effects of a temperature increase and the inclusion of polysorbate 80. Polysorbate 80, at low temperatures, may form an interfacial barrier (6, 8) which retards the transformation rate. However, the increase in the rate of transformation at higher temperatures suggests that the retardation effects are either no longer present or being outweighed by other factors such as a solubilization effect (9, 10). Therefore, it would be expected that higher surfactant concentrations could accelerate the transformation rate at higher temperature conditions.

Coloring agents had a slight transformation-accelerating effect on succinylsulfathiazole Form I (Fig. 5). Coloring agents, because of their slight surface activity, probably improve the wetting of the crystal surfaces, thus accelerating the transformation.

Seeding aqueous suspensions of succinylsulfathiazole Form I with nuclei of the water-stable form (Form II) at various temperatures accelerated the rate of transformation of Form I to Form II. Seeding effects (Table IV and Fig. 6) were more pronounced at lower temperatures. It has already been shown (1) that a temperature increase had a marked transformation-accelerating effect. This entails the formation of a large number of nuclei in a relatively short time. Since, under high temperature conditions, an adequate number of nuclei is available, seeding with more nuclei of the water-stable dihydrate form would only have a slight effect, as shown by the present results.

Additive	$K \times 10^4$, min^{-1}	
	Unseeded	Seeded
Standard	40.30	154.44
Sulfathiazole	18.59	18.67
Phthalylsulfathiazole	12.55	13.60

Table IV—Effect of Seeding on the Rate of Transformation of Succinylsulfathiazole Form I to Form II in Aqueous Suspension at Various Temperatures

Suspension	$K \times 10^4$, min^{-1}		
	22°	40°	55°
Standard	6.33	40.30	203.82
Seeded	27.59	154.44	460.60

Seeding effects observed under conditions of the present study are not consistent with those previously reported (6) for sulfameter, where the transformation rate was unaffected by seeding. The discrepancy could be attributed to the rapid rate of transformation of the metastable polymorph of sulfameter ($t_{1/2}$ = 15 min at 25°) relative to the rather slow transformation of succinylsulfathiazole Form I ($t_{1/2}$ = 16 hr at 25°). The rapid rate of transformation in the sulfameter system provides, in a short time, an adequate number of nuclei of the water-stable form, so seeding effects are not apparent. The transformation of succinylsulfathiazole Form I, on the other hand, is accelerated when seeds of Form II are introduced, since the formation of nuclei under standard conditions is rather slow.

The effect of suspension concentration of succinylsulfathiazole Form I on the rate of transformation to Form II is shown in Fig. 7.

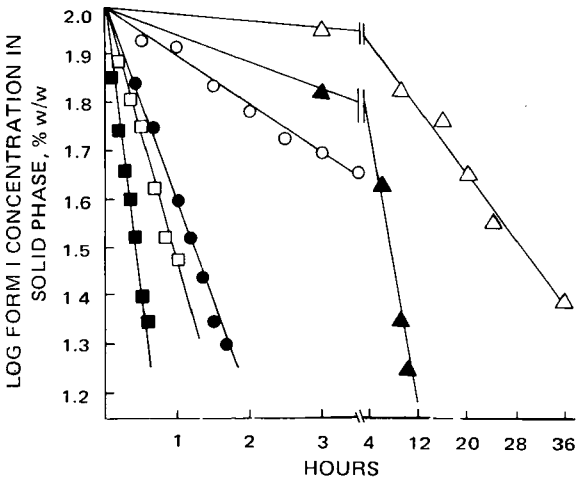

Figure 6—*Effect of seeding with nuclei of Form II on the rate of transformation of succinylsulfathiazole Form I under different temperatures. Key:* □, *55°;* ■, *55° seeded;* ○, *40°;* ●, *40° seeded;* △, *22°; and* ▲, *22° seeded.*

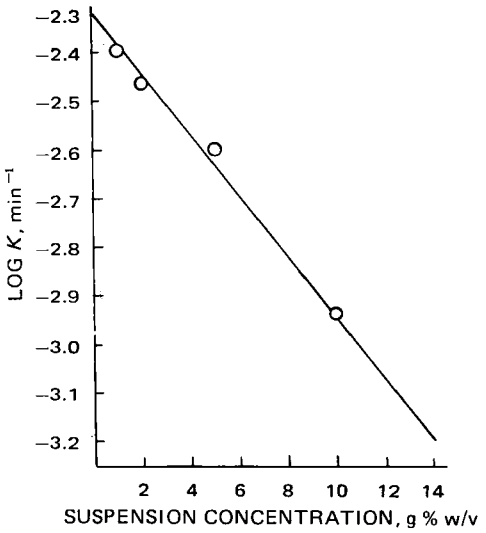

Figure 7—*Effect of suspension concentration of succinylsulfathiazole Form I on the rate of transformation to Form II.*

A linear decrease is observed when the log of the transformation rate constants is plotted against the suspension concentration.

According to the results of the present investigation, assuming the water-stable Form II is not available, the formulation of succinylsulfathiazole Form I in physically stable aqueous pharmaceutical suspensions may be achieved by including a suitable transformation retardant, *e.g.*, methylcellulose. Under these conditions, the suspension would keep its uniformity and ease of resuspension for the expected shelflife of the preparation.

Succinylsulfathiazole Crystal Forms III: Crystal Growth Studies

M. A. MOUSTAFA, A. R. EBIAN, SAID A. KHALIL[x], and M. M. MOTAWI [†]

Abstract □ Crystal growth accompanying the transformation of succinylsulfathiazole crystal forms in aqueous suspensions was studied using a projecting microscope. The effects of increase of temperature, agitation, inclusion of seeds of Form II (the water-stable dihydrate), sulfathiazole, methylcellulose, and polysorbate 80 on the particle-size distribution of anhydrous succinylsulfathiazole Form I were examined. Rates of crystal growth, calculated as increase of diameter per unit time, were given under different experimental conditions. Increase of temperature, agitation, and seeding with nuclei of Form II had significant growth-accelerating effects. Sulfathiazole and polysorbate 80 had growth-retarding effects. Methylcellulose inhibited the crystal growth of Form I for over a year. Aqueous suspensions of Form II did not show any change in particle-size distribution. The crystal growth was shown to be a direct consequence of the transformation of the crystal form. Physical conditions and additives which had accelerating or retarding effects on the rate of transformation of Form I had similar effects on the crystal growth rate of succinylsulfathiazole in aqueous suspensions.

Keyphrases □ Succinylsulfathiazole—crystal growth, effect of temperature, agitation, seeding, methylcellulose, and polysorbate 80, particle-size distributions □ Crystals—succinylsulfathiazole, factors affecting growth, particle-size distributions □ Transformations, crystal—succinylsulfathiazole, various factors affecting growth, particle-size distributions

Succinylsulfathiazole crystal forms, their preparation, characterization, and kinetics of interconversions in the presence and absence of some additives, were described previously (1, 2). These reports noted that crystal growth, caking, and the formation of cement-like precipitates in aqueous suspensions of succinylsulfathiazole were consequences of the transformation of metastable crystal forms to a water-stable form.

Changes in particle-size distribution accompanying transformation of crystal forms of various drugs have been described. Studies on methylprednisolone (3), cholesterol (4, 5), cortisone acetate (6, 7), an experimental antihypertensive compound (8), oxyclozanide (9), theophylline (9), and the antiviral compound SK & F-30097 (10) are some examples.

The present work is concerned with a quantitative study of the changes in particle-size distribution accompanying the transformation of anhydrous succinylsulfathiazole Form I to the dihydrate water-stable Form II in aqueous suspension. The effects of some physical factors, *e.g.*, temperature and agitation, on the crystal growth rate are examined. The effects of including various additives, *e.g.*, seeds of Form II, sulfathiazole, methylcellulose, and polysorbate 80, are also investigated.

A correlation of the results of this study with those of the kinetic studies previously reported (1, 2) would help to evaluate the possible use of metastable crystal forms in aqueous pharmaceutical suspensions and its consequences on the physical stability of the suspensions produced.

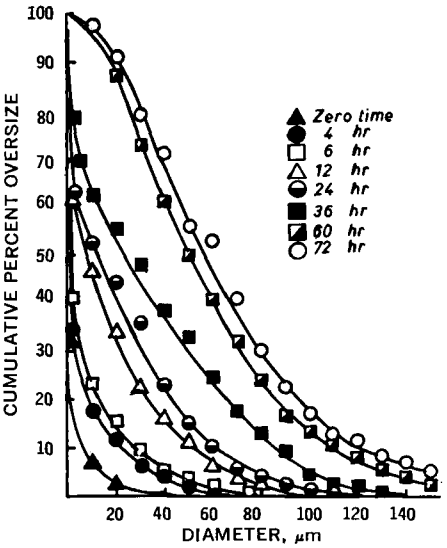

Figure 1—*Change in particle-size distribution with time of aqueous suspension of succinylsulfathiazole Form I at 22°.*

EXPERIMENTAL

Materials and Apparatus—Succinylsulfathiazole Forms I and II were obtained as micronized commercial samples[1], and their identity was checked by IR spectrophotometry (1). Sulfathiazole BPC, methylcellulose, and polysorbate 80 (USP grade) were used.

A projecting microscope[2] was used for particle-size analyses. IR spectra were determined with a double-beam grating spectrophotometer[3].

Methods—Micronized succinylsulfathiazole Form I (0.3 g) was thoroughly mixed with a few drops of distilled water. The smooth paste produced was then gradually diluted with water to produce a 1% (w/v) suspension. The bottle containing the suspension was kept undisturbed in a thermostated water bath maintained at 22 ± 0.1°.

At various time intervals, the suspension was briefly shaken, a drop was transferred to a microscope slide, and the projected diameter was measured for about 100 particles. The particle diameters were classified into 5-μm size range intervals. The procedure was repeated with 5–10 drops of the suspension, taken at the same time. The total counting time varied from 30 to 40 min.

The effect of temperature was examined by repeating this procedure, with the suspension immersed in a thermostated water bath at 37 ± 0.1°.

To investigate the effect of agitation, bottles containing suspensions, prepared as previously described, were rotated at 100 rpm in thermostated water baths at 22 ± 0.1 and 37 ± 0.1° in separate experiments. Sampling was carried out as before.

An experiment was carried out to investigate the effect of seeding aqueous suspensions of succinylsulfathiazole Form I with (10% by weight of the solid phase) Form II on the rate of crystal growth at 22 ± 0.1°.

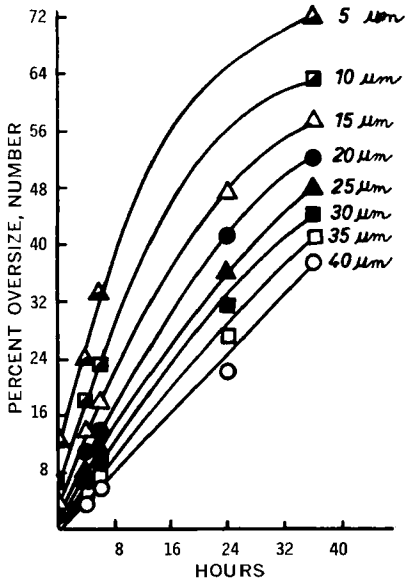

Figure 2—*Change in cumulative count with time of succinylsulfathiazole suspension at 22°.*

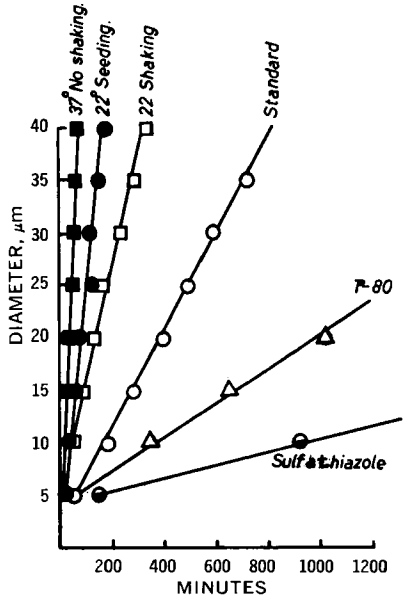

Figure 4—*Comparison of rates of growth above 15% cumulative count.*

The effect of additives, namely sulfathiazole (10% by weight of the solid phase), methylcellulose (0.5% w/v), and polysorbate 80 (1% w/v), on the rate of crystal growth of succinylsulfathiazole Form I in aqueous suspensions at 22 ± 0.1° was examined in separate experiments.

Succinylsulfathiazole Form II was suspended, in place of Form I, in water, and the particle-size distribution was determined as previously described at various time intervals.

IR spectrophotometry (1, 2) was used to follow various stages in the transformation of Form I to Form II in aqueous suspensions under the different experimental conditions adopted.

RESULTS AND DISCUSSION

Particle-size distribution data of anhydrous succinylsulfathiazole Form I in aqueous suspension at 22°, plotted as cumulative oversize frequency percentage *versus* diameter at various time intervals, are shown in Fig. 1. A marked horizontal displacement of the curves to the right with time, indicating crystal growth, was observed. The rate of crystal growth of Form I was derived by following the principles of Edmundson and Lees (11) as applied by Carless *et al.* (6, 7) and Ravin *et al.* (10) in their crystal growth studies.

For this purpose, a plot of the cumulative oversize frequency percentage *versus* time (Fig. 2) was established, from the data in Fig. 1, for various particle diameters. The increase in diameter with time at various cumulative oversize frequency percentages (obtained by following horizontal lines cutting the curves in Fig. 2 at the specified oversize frequency percentages) was then plotted (Fig. 3). The slopes of the lines in Fig. 3 represent the crystal growth rate as the increase of diameter per unit time—*viz.*, in micrometers per hour.

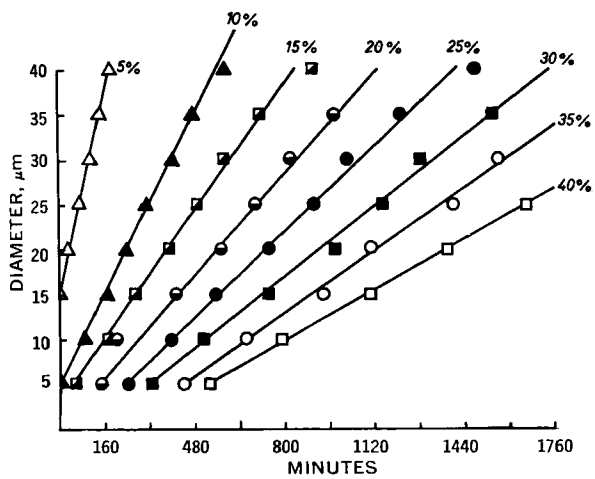

Figure 3—*Rates of growth of aqueous suspension of succinylsulfathiazole Form I at 22°.*

Values of the crystal growth rates at various cumulative oversize frequency percentages are shown in Table I. The rate of crystal growth decreased 5-7 times when the cumulative oversize frequency percentage level at which measurements were made was varied from 5 to 35. IR examination of the solid phase with time showed that a simultaneous transformation of anhydrous succinylsulfathiazole Form I to the dihydrate Form II in aqueous suspension accompanied crystal growth.

Increasing the temperature (37°) was found to increase the rate of crystal growth of succinylsulfathiazole Form I in aqueous suspension about 10 times (Table I). It was previously shown (1, 2) that an increase in temperature increased the rate of transformation of Form I to Form II in aqueous suspension. This would, in turn, lead to the production of the required number of nuclei of Form II necessary for a steady-state transformation (12) in a shorter period.

Since crystal growth was also observed (1) to be a direct consequence of the transformation of crystal form, it is not surprising to find that the rate of crystal growth was increased by an increase of temperature. Furthermore, increased temperature accelerates the diffusion-controlled processes of solution and deposition on the nuclei of the water-stable Form II (13, 14), thus increasing the proportion of large size particles.

Agitation at 100 rpm increased the rate of crystal growth of succinylsulfathiazole Form I in aqueous suspension (Table I). Both nuclei formation and deposition on the nuclei of the water-stable Form II formed involve diffusion-controlled processes (13, 14). Acceleration of the latter processes with agitation is responsible for the crystal growth observed. The effect of agitation becomes negligible at higher temperatures (37°) as the increase in the rate of crystal growth by an increase in temperature largely outweighs the effect of agitation (Table I).

Seeding an aqueous suspension of succinylsulfathiazole Form I with nuclei of the water-stable Form II increased the crystal growth rate (Table I). By increasing the number of nuclei of the water-stable Form II, seeding produced an approximately fourfold increase in the rate of crystal growth.

The presence of sulfathiazole in an aqueous suspension of succinylsulfathiazole Form I decreased the rate of crystal growth approximately 10 times (Table I). This might be explained by the possible fit of sulfathiazole molecules to specific sites in the developing nuclei of succinylsulfathiazole Form II, which results in a re-

Table I—Rate of Crystal Growth as Increase of Diameter per Unit Time at Various Cumulative Oversize Frequency Percentages of Aqueous Suspensions of Succinylsulfathiazole Form I under Different Conditions

	Rate of Growth, μm/hr

Polysorbate 80 (1% w/v, 22°)	3.17	1.60	0.80	—	—	—	—
Sulfathiazole (10%, 22°)	0.78	0.45	0.30	—	—	—	—

duction of their number in addition to a decrease in their growth rate.

Polysorbate 80, by imposing an interfacial barrier (3, 15), reduced the rate of transformation of Form I to Form II in aqueous suspension and, consequently, decreased the crystal growth rate (Table I).

Methylcellulose inhibited the transformation of succinylsulfathiazole Form I to Form II in aqueous suspension for over a year (2). Consequently, little change in particle-size distribution was observed in the presence of methylcellulose.

Succinylsulfathiazole Form II, being stable in aqueous suspension (1), did not exhibit any measurable changes of particle-size distribution with time.

A comparison of the effect of various experimental conditions on the rate of crystal growth of succinylsulfathiazole Form I in aqueous suspension is shown in Fig. 4. An increase in temperature had the greatest growth-accelerating effect. Seeding and agitation also had marked, but weaker, growth-accelerating effects. Greater growth-retarding effects could be observed in the presence of sulfathiazole as compared to polysorbate 80. However, methylcellulose was the most effective growth retardant. In all cases, the rate of growth, calculated as an increase in diameter per unit time, was found to be greater the smaller the cumulative oversize frequency percentage level at which measurement was made.

An attempt was made to correlate the rate of crystal growth to the particle diameter of the growing crystals. The plot in Fig. 2 shows that smaller particles grew to bigger size particles at lower cumulative oversize frequency percentage levels than they did at higher levels; *i.e.*, there would be a greater proportion of large size particles at the lower frequency levels. Since rates of growth were found to be greater at lower frequency levels (where larger particles predominate), it follows that the rate of crystal growth is directly proportional to the particle diameter. This result is in agreement with the findings (6, 7) for cortisone acetate and represents an example of the third case of the crystal growth patterns described by Higuchi and Lau (3), for which they found no simple physical model.

The significance of the change in count of various particle diameters was evaluated by plotting absolute frequency percentage *versus* time curves. This type of plot (Fig. 5) was derived from the cumulative oversize frequency percentage *versus* diameter curves (Fig. 1) following the method of Carless *et al.* (6, 7). Figure 5 shows that there were a decrease in count of smaller particles (3.5 μm) with time, an increase followed by a decrease in count of intermediate-size particles (*e.g.*, 7.5 and 12.5 μm), and a progressive increase in count of larger particles (*e.g.*, 22.5 and 72.5 μm).

The decrease in count with time could be attributed to a predominant dissolution of smaller particles (15), whereas the increase in count represents predominant crystal growth. Thus, small particles are the first to go into solution, and larger particles grow at the expense of the dissolving small ones. Particles of intermediate size grow at first, as a result of the dissolution of smaller particles, until they become relatively the smaller particles in the distribution. Then they start to dissolve to give way for the growth of still larger particles. The point of inflection observed in the curves representing intermediate-size particles (*e.g.*, 12.5 μm) might be taken to mean that the two processes of dissolution and crystal growth reach a state of equilibrium.

A comparison of the curves representing the change in frequency percentage of the 12.5-μm diameter particles under various experimental conditions is shown in Fig. 6. The inflection in these curves took place at different time values. In cases where no growth retardants were present, the point of inflection corresponded to about one-third the transformation of Form I to Form II [as determined by IR analysis (2)]. Since the transformation of a crystal form is known to be a prerequisite for crystal growth, it might be assumed that a transformation of about one-third of Form I to Form II would provide the necessary driving force for the predominant crystal growth in aqueous suspensions of Form I.

The transformation-retarding additives, sulfathiazole and polysorbate 80, by interfering at the interface of dissolving and growing sites of both crystal forms, make it necessary for at least a two-thirds transformation of Form I to take place (as determined by IR analysis) before the inflection indicating predominant crystal growth may be observed (Fig. 6).

Another interesting result of the crystal growth studies of succinylsulfathiazole Form I in aqueous suspension was that the physical conditions and additives employed not only affected the crystal growth rate but also the time at which a fixed proportion of the crystal form had been changed, the time at which equilibrium particle size distribution was attained, and the maximum particle size

Table II—Effect of Various Experimental Conditions on Transformation of Crystal Form and the Time and Extent of Crystal Growth in Aqueous Suspension of Succinylsulfathiazole Form I

Condition	Time at Inflection in Count of 12.5-μm Particles	Time Required to Attain Equilibrium Particle-Size Distribution	Cumulative Oversize Frequency Percentage (100-μm Diameter)
Standard suspension of Form I (22°)	12	72	17
Standard suspension (37°)	1	7	25
Seeding (10% Form II)	4	10	3.5
Agitation (100 rpm)	4	12	2.5
Polysorbate 80 (1% w/v)	48	72	5
Sulfathiazole (10%)	72	96	1

reached. Table II shows that when the additive had an accelerating effect on the transformation of crystal form, a reduction in the time necessary to achieve the equilibrium particle-size distribution and an increase in the number of relatively larger size particles (100 μm) were also observed and vice versa.

Unexpectedly, seeding and agitation, although increasing the crystal growth rate markedly, did not lead to the production of a high proportion of large particles (100 μm). This finding might be attributed to an increase in the number of nuclei of the water-stable Form II under these conditions. Since the amount of solid material in suspension is roughly constant throughout the experiments, distribution of the solid material on the large number of nuclei present results in the production of only fewer numbers of large particles.

An increase in temperature, on the other hand, accelerated the transformation of crystal form and crystal growth and also produced a relatively high proportion of the 100-μm particles (Table II). It could be assumed that, although an increase in temperature accelerated the transformation of crystal form, the number of nuclei required for a steady-state transformation (2, 12) was not increased under these conditions. These nuclei grew, therefore, to larger size particles.

As a result of the foregoing discussion, the mechanism of crystal growth is thought to consist of two stages. The first involves transformation of the metastable crystal form to the water-stable form. The second stage involves growth of formed nuclei of the latter form. Evidence has been accumulating that the rate-controlling step in the crystal growth process is the change of crystal form. When this was inoperative, *e.g.*, when the water-stable form was suspended in water, no growth was observed. When the transformation of crystal form was retarded, crystal growth was also inhibited (*e.g.*, in the presence of methylcellulose, sulfathiazole, and polysorbate 80).

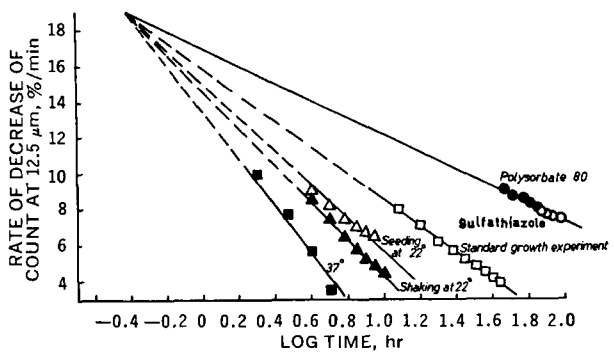

Figure 7—*Comparison of rates of dissolution of succinylsulfathiazole under different conditions.*

Table III—Effect of Experimental Conditions on the Rate of Transformation of Crystal Form and Crystal Growth in Aqueous Suspension of Succinylsulfathiazole Form I

Condition	K[a] Transformation × 10^4, min^{-1}	K Growth (10% Cumulative Oversize Frequency)
Standard suspension (22°)	6.33	3.75
Standard suspension (37°)	33.60	48.00
Seeding (10% Form II)	27.59	17.50
Polysorbate 80 (1% w/v)	4.99	1.60

[a] Data from Ref. 2.

On the other hand, when the transformation of the crystal form was fast or was increased by altering the prevailing physical conditions (*e.g.*, by increasing temperature or agitation), the crystal growth that followed was also quite marked. Seeding effects are also further evidence that the rate-controlling step is the transformation of crystal form. Thus, the inclusion of seeds of the water-stable Form II in aqueous suspensions of Form I increased not only the rate of transformation of crystal form (2) but also the crystal growth rate.

An attempt was made to find out which stage of the growth mechanism is affected by the various experimental conditions and additives employed. For this purpose, the rate of decrease in the count of the 12.5-μm particles, indicating predominant dissolution, *versus* time on a logarithmic scale was plotted (Fig. 7). Figure 7 shows that the rate of decrease in the count (a measure of the dissolution rate) at a very short time after the start of the experiments (about 0.4 hr), obtained by backward extrapolation, was practically the same under various experimental conditions. This finding might be interpreted by assuming that all experimental variables affected the transformation of crystal form and, consequently, the crystal growth of Form II. Form I, existing alone for a very short time, had a high dissolution rate which was not yet affected by the experimental variables. As time went on, transformation of Form I to Form II took place with variable velocities because of the experimental conditions prevailing. Since the developing water-stable Form II is about five times less soluble than Form I (16), the curves in Fig. 7 could be seen to deviate from each other as time progressed.

Table III shows that the rate of crystal growth under different conditions was increased or decreased in the same way as the rate of transformation of crystal form was affected. These arguments are, therefore, supporting evidence of previous conclusions and findings (1, 2) that experimental conditions affect the rate of transformation of Form I to Form II in aqueous suspension and, consequently, the crystal growth rate.

It might be concluded that, in agreement with previous recommendations (1, 2), the formulation of physically stable suspensions of succinylsulfathiazole would best be achieved by using water-stable Form II or, alternatively, including an efficient transformation retardant, *e.g.*, methylcellulose, with Form I. Attention must also be drawn to the incidence of polymorphism among pharmaceuticals as one important factor that could alter the physical stability of pharmaceutical preparations.

Blood Concentration Profiles of Acetaminophen following Oral Administration of Fatty Acid Esters of Acetaminophen with Pancreatic Lipase to Dogs

CARL T. BAUGUESS ˣ, JULIAN H. FINCHER, FARID SADIK, and CHARLES W. HARTMAN †

Abstract □ Fatty acid esters of acetaminophen were administered orally to dogs, and blood concentrations of acetaminophen were determined at various time intervals. Blood concentrations of acetaminophen following oral administration of a short chain ester, *p*-acetamidophenyl acetate, were not significantly different from those found using acetaminophen. Blood concentrations of acetaminophen following oral administration of intermediate hydrocarbon chain-length compounds were less than those of the control at 1 and 3 hr postdosing. There appears to be a direct relationship between the *in vitro* hydrolysis rates and the blood concentration *in vivo*. Concomitant oral administration of acetaminophen derivatives, pancreatic lipase, and calcium salts resulted in an increase in the blood levels of acetaminophen as compared to administration of the esters alone. Calcium carbonate was included as a source of calcium ion to activate the lipase involved in the hydrolysis of the fatty acid esters. A combination of *p*-acetamidophenyl acetate, *p*-acetamidophenyl dodecanoate, pancreatic lipase, and calcium carbonate was shown to achieve a prolonged release of acetaminophen. *p*-Acetamidophenyl acetate was thought to provide the initial release of acetaminophen; *p*-acetamidophenyl dodecanoate, being hydrolyzed more slowly, provided the prolonged release, which maintained therapeutic blood concentrations for 13 hr following a single dose of the combination in dogs.

Keyphrases □ Acetaminophen—blood concentration profiles after oral administration of *p*-acetamidophenyl acetate and dodecanoate with pancreatic lipase, dogs □ Fatty acid esters of acetaminophen—acetaminophen blood concentration after oral administration with pancreatic lipase, dogs □ *p*-Acetamidophenyl acetate and dodecanoate—acetaminophen blood concentration following oral administration with pancreatic lipase, dogs

Timed release, sustained release, and prolonged action are popular terms for describing oral dosage forms that first release an initial dose and then gradually release a remaining quantity of drug sufficient to maintain a uniform therapeutic effect over an extended period (1).

The unique physiological and morphological features in the GI tract present both a challenge and an opportunity in the design of oral dosage forms. Although the physiological environment is an important factor in designing all dosage forms, many dosage forms are designed to operate in a particular set of biochemical conditions. For example, amide and ester derivatives are prepared frequently to alter the physical and chemical properties of a drug molecule to obtain a more acceptable dosage form. These chemical modifications often lead to pharmacologically inactive compounds; however, the presence of autogenous enzyme systems and/or other suitable conditions found in the various segments of the GI tract facilitate the hydrolysis and release of the active form.

Dittert *et al.* (2) found that esters of acetaminophen were substrates for serum lipase. Work in this laboratory indicates that, by controlling the chain length of the esters, it would be theoretically possible to impose a rate-limiting step prior to absorption of the drug from the GI tract, thereby achieving an extended duration of action from acetaminophen (3). Because of the insoluble nature of fatty acid esters of acetaminophen, it was not thought that any appreciable quantity of intact ester would be absorbed.

The objectives of this work were to investigate the feasibility of employing fatty acid ester derivatives of

a drug in an enzyme substrate system to control the rate of absorption following oral administration and to establish a possible role for the concomitant administration of pancreatic lipase to provide a more uniform enzyme activity in the GI tract.

EXPERIMENTAL

Acetaminophen Assay in Blood—A 15.1-mg sample of acetaminophen[1], weighed on an analytical balance, was transferred to a 100-ml volumetric flask, and the flask was filled to the mark with distilled water. Aliquots of 0.5, 0.4, 0.3, 0.2, 0.1, 0.050, and 0.025 ml were diluted to 0.5 ml with distilled water and mixed with 0.5 ml of whole blood from pooled samples of blood drawn before the administration of acetaminophen. The removal of serum proteins and red blood cells was accomplished by a method used in the determination of blood sugar (4).

A 2.0-ml portion of 0.12 *N* barium hydroxide solution[2] was added, and the mixture was stirred[3]. After standing for about 2 min, a deep reddish-brown color developed. A 2.0-ml portion of 2% zinc sulfate solution[2] was added with mixing, resulting in the precipitation of red blood cells and serum protein. The samples were centrifuged at about 4000 rpm for 5 min. After filtration of the aqueous portion through a 0.8-μm filter[4], the absorbance of the clear aqueous filtrate of each sample was determined[5] against a reagent blood blank at 245 nm.

Protocol for *In Vivo* Studies—Groups of six to eight healthy, treated line-bred beagle dogs[6] were selected for the blood concentration studies. All food was withheld from the dogs for 24 hr prior to the beginning and during the experiment. The dogs were about 1 year in age and weighed between 9.1 and 13.6 kg (20 and 30 lb). All doses were calculated on a weight basis equivalent to 40 mg of acetaminophen/kg. This amount is comparable to a dose of 2.8 g for a human weighing 70 kg.

Control blood samples for all experiments were drawn from the cephalic vein of either front leg just prior to the administration of the dose. All doses were administered in hard gelatin capsules followed by 10 ml of water to force dogs to swallow the capsules. Water was available to the animals during the experiment. At 1-, 3-, 5-, 7-, 10-, and 13-hr intervals after drug administration, blood samples of about 2 ml were drawn from the cephalic vein(s) with a 2.5-ml disposable syringe, previously flushed with a heparin solution (10,000 USP units/ml)[7], using a 2.54-cm (1-in.), 22-gauge needle.

Immediately following the withdrawal of each blood sample, the needle was removed from the barrel of the syringe and the contents were delivered to clean glass vials. All blood samples were sealed and stored over ice until analyzed. No samples were stored longer than 24 hr, and most samples were prepared for analysis immediately.

Control studies for acetaminophen absorption were performed at two different dose levels to establish blood concentration–time profiles for the model drug compound. Five dogs were administered a dose of 20 mg of acetaminophen/kg. In this control study, blood samples were drawn at 30-, 90-, 150-, 240-, and 330-min intervals after drug administration. Six dogs were administered 40 mg of acetaminophen/kg, and blood samples were taken at 1-, 3-, 5-, 7-, 10-, and 13-hr intervals.

The short chain ester derivatives of acetaminophen through the octanoate were administered without pancreatic lipase[8] or other additives. The intermediate length and long chain esters were studied both with and without lipase and other additives. When studied with lipase, these esters were mixed with the enzyme preparation and encapsulated in two or three No. 00 hard gelatin capsules. Lipase preparations were assayed prior to each experiment by the method of Lazo-Wasem (5). Capsules containing the long chain esters and lipase were stored in a refrigerator and/or over ice until administered.

Blood samples were analyzed by the procedure previously described. To 0.5 ml of blood, 0.5 ml of distilled water was added. A 2.0-ml portion of 0.12 *N* barium hydroxide solution was added and

mixed with the blood sample. After standing for 2 min, a 2.0-ml portion of a 2% zinc sulfate solution was added and mixed. The samples were centrifuged and filtered. The absorbance of the filtrates was determined against a blood reagent blank.

RESULTS AND DISCUSSION

Control studies for acetaminophen absorption were performed *in vivo* at two dose levels to establish blood concentration–time profiles. The doses of all animal studies were calculated on a weight basis. Five dogs were given an oral dose of 20 mg/kg as noted in Table I. This dose level produced an average blood concentration peak of 20.84 μg/ml after 2.5 hr. However, some individual animals exhibited a peak concentration level after 1 hr, and it was difficult to assess what happened between samples. After 5.5 hr, the concentration decreased to about half that of the peak concentration.

Since prolonged-release medication required a larger dose, a second control study was conducted at 40 mg of free acetaminophen/kg in six dogs; the results are given in Table II. In this study, a maximum concentration was observed after 1 hr and an exponential decay began at 3 hr and continued through a 10-hr period. A plot of the data on a semilogarithmic graph gave a linear decay, beginning at the 3-hr interval and continuing through the 10-hr interval. A half-life for blood concentration was determined graphically from the data in Table II and was found to be in the order of 1 hr and 40 min.

The availability of acetaminophen after oral administration and administration of its ester derivatives was determined by the following equation (6, 7):

$$\frac{A_T}{V_d} = C_T + K_e\,(AUC) \qquad \begin{matrix} t = T \\ t = 0 \end{matrix} \qquad \text{(Eq. 1)}$$

where A_T is the amount of drug absorbed up to time T, V_d is the distribution volume, C_T is the concentration at time T, K_e is the elimination rate constant, and AUC is the area under the curve. When the data in Table II were treated by this method, the half-life for absorption was found to be 40 min, and acetaminophen was more available when administered as the free drug.

Three dogs were given oral doses of *p*-acetamidophenyl acetate equivalent to 40 mg of acetaminophen/kg. A comparison of blood levels of acetaminophen shown in Table III with the control study presented in Table II indicates a slight increase in the half-life for absorption from 40 to 60 min, although there was only a slight change in the availability of acetaminophen with equivalent doses. Treatment of the data in Table II gave an $(A_T/V_d)_{max}$ of 75.3 μg/ml as compared to 71.5 μg/ml for the data in Table III. These estimates of relative availability most likely underestimate the true value.

From observations on the *in vitro* hydrolysis of acetaminophen derivatives, it was anticipated that intermediate and long chain esters would reduce the availability of acetaminophen (3). The study recorded in Table IV illustrates a reduced availability of aceta-

[a] Inactive lipase.

minophen following oral administration of equivalent doses of *p*-acetaminophenyl decanoate. The availability of drug from this ester form was 34% of that produced by acetaminophen. Concomitant administration of *p*-acetamidophenyl decanoate, pancreatic lipase (3 Wilson units/mg), and calcium chloride increased the availability from 34 to 73% as calculated from the data reported in Table V.

To investigate the feasibility of using a combination of ester derivatives with pancreatic lipase and calcium ions to achieve a prolonged release of acetaminophen, *p*-acetamidophenyl acetate and *p*-acetamidophenyl dodecanoate, equivalent to 20 and 40 mg/kg of acetaminophen, respectively, were administered with 59 mg/kg of pancreatic lipase and 10 mg/kg of calcium carbonate. The acetate ester was included to provide the initial release, and the dodecanoate ester was selected because of its slower hydrolysis rate. The amounts of pancreatic lipase and calcium carbonate were determined to be adequate from preliminary studies.

The results of this combination using a short chain ester and an intermediate ester are shown in Table VI and in Fig. 1. At the 1-, 3-, and 5-hr intervals, the blood concentrations were somewhat higher than an average of 21 μg/ml; at 7 and 10 hr, they were slightly below. The control used in this study was identical to the experiment, except that the pancreatic lipase used in the dose was inactivated by moisture and heat. No statistical difference at a 90% confidence level was noted at the 1- and 3-hr intervals; however, at 5-, 7-, 10-, and 13-hr intervals, a significant difference was observed. The hydrolysis and subsequent absorption from *p*-acetamidophenyl dodecanoate were facilitated by the inclusion of lipase in the dose. The availability of acetaminophen was increased by a factor of 1.7 when the combination included the active enzyme preparation.

Correlation of Kinetic Parameters and Thermal Behavior of Segmented Polyurethane Elastomers with Biological Responses

G. W. C. HUNG, L. J. NUNEZ, and J. AUTIAN ˣ

Abstract □ Kinetic studies of thermal degradation of 16 segmented polyether polyurethane samples, containing various amounts of 3,4-diaminotoluene and dibutyltin diacetate as additives, were carried out by thermogravimetry. From a single dynamic thermogravimetric experiment, the temperatures of initiation of degradation, 10, 25, and 50% (w/w) of degradation, as well as the activation energies for degradation, were determined. The activation energies were computed from the thermogravimetric curves using Broido's graphical approximation method, which applies to first-order decomposition kinetics. The results of stepwise multiple linear regression analysis indicate that the biological responses to elastomer samples, such as tissue culture, hemolysis, intramuscular implant, intradermal irritation, systemic toxicity, and histopathological rating, and the cumulative biological response index are highly correlated with thermal stability and kinetic measurements of the materials.

Keyphrases □ Segmented polyurethane elastomers—correlation of kinetic parameters and thermal behavior with biological responses □ Polyurethane elastomers, segmented—correlation of kinetic parameters and thermal behavior with biological responses □ Biomaterials, segmented polyurethane elastomers—correlation of kinetic parameters and thermal behavior with biological responses

Segmented polyether polyurethane elastomers demonstrate superior properties of strength and flex-life (1) and are excellent candidates for biomedical applications (2–9). These polymers consist of at least two major segments in the repeating chain structural unit: a crystalline *hard* segment (urea), melting above 200°, and a *soft* segment (polyether glycol), melting below 50° (10–12). Both segments are polymeric and connected by urethane linkages. The final product is termed a polyether/urethane/urea or a segmented polyurethane.

The chemistry and techniques involved in the production of these polymer materials are well known (13, 14). In addition, several investigations considered the chemical, physical, mechanical, and biological properties (5), the dependence of morphological structure on the chain characteristics and cast conditions (15), the hemolytic activity (16, 17), and the toxicity (18, 19) of the polymeric material relevant to biological applications. However, no systematic studies have been reported that compare and correlate physical properties with biological responses for segmented polyurethane systems containing different kinds and amounts of additives.

The purposes of this paper, therefore, are to consider one system of segmented polyurethanes containing various quantities of additives and to illustrate the correlation between the measured thermal

minophen following oral administration of equivalent doses of *p*-acetaminophenyl decanoate. The availability of drug from this ester form was 34% of that produced by acetaminophen. Concomitant administration of *p*-acetamidophenyl decanoate, pancreatic lipase (3 Wilson units/mg), and calcium chloride increased the availability from 34 to 73% as calculated from the data reported in Table V.

To investigate the feasibility of using a combination of ester derivatives with pancreatic lipase and calcium ions to achieve a prolonged release of acetaminophen, *p*-acetamidophenyl acetate and *p*-acetamidophenyl dodecanoate, equivalent to 20 and 40 mg/kg of acetaminophen, respectively, were administered with 59 mg/kg of pancreatic lipase and 10 mg/kg of calcium carbonate. The acetate ester was included to provide the initial release, and the dodecanoate ester was selected because of its slower hydrolysis rate. The amounts of pancreatic lipase and calcium carbonate were determined to be adequate from preliminary studies.

The results of this combination using a short chain ester and an intermediate ester are shown in Table VI and in Fig. 1. At the 1-, 3-, and 5-hr intervals, the blood concentrations were somewhat higher than an average of 21 μg/ml; at 7 and 10 hr, they were slightly below. The control used in this study was identical to the experiment, except that the pancreatic lipase used in the dose was inactivated by moisture and heat. No statistical difference at a 90% confidence level was noted at the 1- and 3-hr intervals; however, at 5-, 7-, 10-, and 13-hr intervals, a significant difference was observed. The hydrolysis and subsequent absorption from *p*-acetamidophenyl dodecanoate were facilitated by the inclusion of lipase in the dose. The availability of acetaminophen was increased by a factor of 1.7 when the combination included the active enzyme preparation.

Correlation of Kinetic Parameters and Thermal Behavior of Segmented Polyurethane Elastomers with Biological Responses

G. W. C. HUNG, L. J. NUNEZ, and J. AUTIAN ˣ

Abstract □ Kinetic studies of thermal degradation of 16 segmented polyether polyurethane samples, containing various amounts of 3,4-diaminotoluene and dibutyltin diacetate as additives, were carried out by thermogravimetry. From a single dynamic thermogravimetric experiment, the temperatures of initiation of degradation, 10, 25, and 50% (w/w) of degradation, as well as the activation energies for degradation, were determined. The activation energies were computed from the thermogravimetric curves using Broido's graphical approximation method, which applies to first-order decomposition kinetics. The results of stepwise multiple linear regression analysis indicate that the biological responses to elastomer samples, such as tissue culture, hemolysis, intramuscular implant, intradermal irritation, systemic toxicity, and histopathological rating, and the cumulative biological response index are highly correlated with thermal stability and kinetic measurements of the materials.

Keyphrases □ Segmented polyurethane elastomers—correlation of kinetic parameters and thermal behavior with biological responses □ Polyurethane elastomers, segmented—correlation of kinetic parameters and thermal behavior with biological responses □ Biomaterials, segmented polyurethane elastomers—correlation of kinetic parameters and thermal behavior with biological responses

Segmented polyether polyurethane elastomers demonstrate superior properties of strength and flex-life (1) and are excellent candidates for biomedical applications (2–9). These polymers consist of at least two major segments in the repeating chain structural unit: a crystalline *hard* segment (urea), melting above 200°, and a *soft* segment (polyether glycol), melting below 50° (10–12). Both segments are polymeric and connected by urethane linkages. The final product is termed a polyether/urethane/urea or a segmented polyurethane.

The chemistry and techniques involved in the production of these polymer materials are well known (13, 14). In addition, several investigations considered the chemical, physical, mechanical, and biological properties (5), the dependence of morphological structure on the chain characteristics and cast conditions (15), the hemolytic activity (16, 17), and the toxicity (18, 19) of the polymeric material relevant to biological applications. However, no systematic studies have been reported that compare and correlate physical properties with biological responses for segmented polyurethane systems containing different kinds and amounts of additives.

The purposes of this paper, therefore, are to consider one system of segmented polyurethanes containing various quantities of additives and to illustrate the correlation between the measured thermal

stability and kinetic parameters with some biological responses[1]. The sample preparations were designed to give a wide range of biological responses and were not related to specific end-use conditions.

The segmented polyurethane elastomers used were prepared and cured from elastomer solution (1). The additives selected were 3,4-diaminotoluene (I) and dibutyltin diacetate (II). The amounts of I and II added to the polyurethane ranged from 0 to 6% (w/w), and the samples were not analyzed for I and II after preparation. Sixteen polyurethane samples containing various amounts of additives were prepared.

Six principal biological response tests, including tissue culture, hemolysis, intramuscular implant, intradermal irritation, systemic toxicity, and histopathological rating of the intramuscular implant site, were carried out in parallel on each preparation. The thermal stability and kinetic parameters of thermal degradation of the polyurethane samples were measured by thermogravimetry, using a dynamic (nonisothermal) degradation procedure under an inert nitrogen atmosphere. The correlations of the six principal biological responses with the overall activation energies for thermal degradation and other physical properties are discussed.

THEORETICAL

During the past few years, several methods using the nonisothermal approach have been developed to allow kinetic analysis of thermogravimetric data (20). The simple and sensitive approximation method proposed by Broido (21) was used in the present work. Broido's integral method applies only to first-order reactions, including the majority of simple pyrolyses (*i.e.*, for situations where the simple Arrhenius equation is applicable).

Modification of Broido's approach by using suitable assumptions and approximations allows a linear equation to be obtained. This equation is presumed to hold for uniform linear heating rates:

$$\log \log Z = -(E_a/2.303R)\,(1/T) + \text{constant} \qquad \text{(Eq. 1)}$$

where:

$Z = \Delta w_{\text{total}}/(\Delta w_{\text{total}} - \Delta w_t)$
Δw_{total} = total change in weight after completion of degradation
Δw_t = change in weight of active material at time, t

Thus, by applying Eq. 1, a plot of log log Z *versus* $1/T$ should yield a straight line if the reaction is first order. Then E_a can be evaluated from the least-squares slope. The calculations were performed by a computer.

EXPERIMENTAL

Materials—The starting material was a segmented polyether polyurethane polymer[2] offered as a 30% (w/w) solution in dimethylacetamide (III). Some physical properties of the elastomer solution are given in Table I.

Compounds I[3] and II[4] and the solvent III[5] were obtained commercially. All other solvents were reagent grade and were used without further purification. Table II lists some physical properties of I–III.

Apparatus and Conditions—The thermogravimetric instrument[6] consisted of a linear temperature programmer[7], a furnace[8], a thermogravimetric accessory[9], an RG electrobalance[10], and a potentiometric recorder[11]. The function of the systems were described previously (22, 23). Briefly, the experimental conditions set up for these studies were as follows: sample size, 10 ± 0.5 mg; electrobalance sensitivity, 0.01 mg; programming rate, 10°/min; recorder span, 10 mg full scale; chart speed, 20.3 cm (8 in.)/min; dynamic inert atmosphere, nitrogen gas, at a flow rate of 200 ml/min; and operational temperature range, room temperature to the completion of degradation (up to about 750°).

Table I—Physical Properties of Elastomer Solution

Physical Property	Description
Solubility	30% (w/w) solution of segmented polyether polyurethane in dimethylacetamide. The solution can be diluted with secondary solvents such as toluene, chlorobenzene, methylene chloride, chloroform, and tetrahydrofuran.
Viscosity	90,000–150,000 cps at 25°. The solution tends to increase in viscosity on standing. However, this viscosity increase can be reversed by stirring.
Density	0.96 g/cc
Flash point	70°
Hygroscopicity	It is extremely hygroscopic and must be protected from contact with atmospheric moisture.

Preparation of Polyurethane Samples—*Without Additives*—The elastomer solution was poured onto a glass plate, and the solvent was allowed to evaporate over a warming plate at 68° for 22 hr.

With Additive II Only—Compound II was added by pipet to the elastomer solution with continuous stirring. After thorough mixing, the mixture was poured onto a warming plate and the solvent was evaporated for 21 hr at 68°.

With Both I and II Additives—Compound II was added by pipet to the elastomer solution with continuous stirring. Compound I was dissolved in the elastomer solvent III and then added to the mixture with continuous stirring. After thorough mixing, the product was poured onto a warming plate and the solvent was evaporated for 20.5 hr at 68°.

With Additive I Only—Compound I was dissolved in III and then added to the elastomer solution with continuous stirring. After thorough mixing, the solution was poured onto a warming plate and the solvent was evaporated for 20.5 hr at 68°.

In general, an evaporation time of 20–22 hr at 68° was sufficient to obtain a firm nonsticky film product.

Measurement of Density of Elastomer Samples—The density of elastomer films was measured at 25 ± 0.1° by a water-displacement method using a pycnometer. The method of calculation is similar to that presented previously (23).

Methanol Extraction (% RW)—Methanol was selected for the extraction of components from elastomer samples. The samples were cut into small pieces and exposed to 150 ml of methanol for 24 hr at room temperature with continuous stirring. The results are reported as percent residue weight (% RW).

Biological Response Tests—The six biological response tests employed for the evaluation of the formulations follow.

Hemolysis Assay (H)—Hemolytic activity was determined by spectrophotometric estimation of hemoglobin release from rabbit erythrocytes in saline solution in the presence and absence of polymer (5 g of polymer/10 ml of saline) at 37° in 1 hr. Percent hemolysis was calculated relative to the positive control (100% hemolysis).

Tissue Culture (TC)—The method of Guess *et al.* (24) was used. The tissue culture response was evaluated in terms of a re-

Table II—Physical Properties of Solvent and Additives

Compound	Formula Structure	Formula Weight	Melting Point	Boiling Point	Density	Refractive Index (n_d)
Dimethylacetamide (III)	$CH_3CON(CH_3)_2$	87.12	−20.0°	165.0°	0.9366_6^{25}	1.4380^{20}
3,4-Diaminotoluene (I)		122.17	89.0–90.0°	265.0°	—	—
Dibutyltin diacetate (II)	$(C_4H_9)_2Sn(OOCCH_3)_2$	351.00	10.0°	142.–145.0°	1.3200	1.4820

sponse index (RI), reflecting zone size and percent lysis within the zone:

$$RI = ZI/LI \qquad \text{(Eq. 2)}$$

where ZI is the zone index, and LI is the lysis index. The values of ZI and LI are treated as independent values, however, in the calculations that yield the data presented in Table IV. The magnitude of ZI was defined as follows:

0 = no detectable zone around or under the sample
1 = zone limited to area under sample
2 = zone not greater than 0.5 cm in extension from the sample
3 = zone not greater than 1.0 cm in extension from sample
4 = zone greater than 1 cm in extension from sample but not involving the entire plate
5 = zone involving the entire plate

The magnitude of LI was defined as follows:

0 = no observable lysis
1 = less than 20% of zone lysed
2 = less than 40% of zone lysed
3 = less than 60% of zone lysed
4 = less than 80% of zone lysed
5 = greater than 80% lysis within zone

The normalization factors for tissue culture are (ZI + LI) × 10. The numerical values listed in Table III are the sum of four individual tests, including the sample material, cottonseed oil USP extract, polyethylene glycol 400 USP extract, and saline USP extract.

Intradermal Irritation Test (ID)—The USP XVIII method (25) was used. The intensity of gross visible inflammation and necrosis around the implant are primary factors. The intradermal irritation rating scale is as follows:

0 = no detectable irritation
0.5 = minimal irritation detected
1 = very slight but distinct irritation
2, 3, 4, 5 = increasing intensity of inflammation and wheal

A value of 5 represents a response greater than the positive control. A value of 4 for the positive control is normalized to 100%. The intradermal irritation values were calculated by the factor (0–5) × 25. The listed intradermal irritation values are the sum of three individual tests (*i.e.*, extracts of cottonseed oil USP, polyethylene glycol 400 USP, and saline USP).

Intramuscular Implant (IM)—The USP XVIII method (26) was used with the following exceptions: *(a)* the implant period was 7 days, and *(b)* clean, but not necessarily aseptic, technique and samples were employed.

The rating scale for the intramuscular implant test is analogous to that for the intradermal irritation test already presented.

Systemic Toxicity Test (ST)—The USP XVIII method (25) was used. The rating scale (0–5) of the systemic toxicity is the number of deaths after 7 days. The normalization factor is (0–5) × 20. The normalized values reported are the sum of intravenous and intraperitoneal administration.

Histopathological Rating (HR)—The method of Turner *et al.* (27) was used. The histopathological rating values are reported in terms of a 0–4 rating scale and normalized by a factor of (0–4) × 25. The magnitude of histopathological rating was defined as follows:

0 = not different from negative control
1 = minimal response
2, 3, 4 = increasing tissue reaction around implant; degree of necrosis is the primary factor

Cumulative Biological Response Index (CI)—CI values are the sum of the normalized values of response ratings for all tests. CI values represent a broadly based estimate of biological activity.

Molecular Weight Determination—The molecular weight distribution of an elastomer sample containing no additives was determined by gel permeation chromatography[12]. Calibration was based on polystyrene standards, and the sample was run in a dimethylformamide solvent.

Table III—Experimental Results of Biological Response Tests for Elastomer Samples

Sample	Tissue Culture (TC)[a]	Hemolysis (% H)	Intramuscular Implant (IM)	Intradermal Irritation (ID)[b]	Systemic Toxicity (ST)[b]	Histopathological Rating (HR)	Cumulative Biological Index (CI)

[a] Sum of tissue culture response (ZI and LI) for material test samples and saline USP, cottonseed oil, and polyethylene glycol 400 extracts. [b] Sum of biological response to saline USP, cottonseed oil, and polyethylene glycol 400 extracts.

RESULTS AND DISCUSSION

Characterization of Segmented Polyether Polyurethane Elastomer—The samples used were prepared from an elastomer solution[13]. The molecular weight and molecular weight distribution were obtained by means of gel permeation chromatography. The molecular weight (based on polystyrene standards) calculated from the assumed mol. wt./size ratio *(Q)* of 25 are $\bar{M}_w$ (weight average) = 115,000, $\bar{M}_n$ (number average) = 51,200, and $\bar{M}_w/\bar{M}_n$ = 2.24.

Thermal Properties of Elastomer Samples—The thermal stability, as indicated by the amount degraded at specific temperatures, and the E_a values for thermal degradation of the 16 samples determined by the thermogravimetric technique are shown in Table IV. The total amount added listed in Table IV represents

[12] DeBell and Richardson, Inc., Enfield, Conn.
[13] According to the manufacturer, the product is based on the original DuPont formula for Lycra.

the sum of I and II in terms of number of moles/10 mg of sample. The four degradation temperatures are T_i, T_{10}, T_{25}, and T_{50}; T_i is the temperature of initiation of degradation, and T_{10}, T_{25}, and T_{50} represent the temperatures at which 10, 25, and 50% (w/w) of degradation occur.

The E_a values were evaluated from the slope of the plot of log log Z *versus* $1/T$ using Eq. 1. Figure 1 shows some typical examples (Samples 1, 6, 15, and 16) of such plots. The thermal degradation data of the elastomer samples follow the linear form of Eq. 1 very nicely; the average relative precision of the determinations is about 3.5%. The E_a values range from 16 to 25 kcal/mole, depending upon the kinds and quantities of additives in the sample.

For example, the E_a value for Sample 16, which contains the highest amount of I (4.0% added), is the largest (25 kcal/mole), while Sample 15, which consists of the highest quantity of II (6.0% added) and a medium amount of I (2.0% added), is the smallest (16 kcal/mole). Apparently, I and II affect the structural properties that contribute to activation energy but are not simply additive.

Physical Properties of Elastomer Samples—Density *(d)* data and the residue weight of methanol extractable substances (% RW) are also listed in Table IV.

In general, the % RW is directly related to the amounts of I and II added. However, it should be pointed out that the nonzero percent extracts (2.44%) observed for Sample 1 suggest that some unknown components other than the materials added are leached out of the polymers by methanol.

Biological Response Tests on Elastomer Materials—The experimental results of biological response tests are listed in Table III.

The results of no hemolytic activity and no other biological responses for the sample without additives (Sample 1) are consistent with the findings reported by other investigators (6, 16, 17). Generally speaking, % H is higher for those samples containing higher amounts of II added (*e.g.*, Samples 8, 9, 14, and 15). Samples 2, 3, 7, 11, and 12, which have the smallest quantities of either I or II added, have the lowest % H.

Multiple Correlations of Physical Properties and Biological Responses—To determine which variables best predict the biological responses, a stepwise multiple linear regression analysis was carried out. This analysis included 10 properties: percent 3,4-diaminotoluene (I) added, percent dibutyltin diacetate (II) added, total amount of I and II added, E_a, T_i, T_{10}, T_{25}, T_{50}, density *(d)* and residue weight of methanol extractable substance (% RW) as independent variables, and the seven biological responses as dependent variables. The results are given below.

$$(TC) = 31.93\,(RW) + 43.03 \qquad (R = 0.844) \quad \text{(Eq. 3)}$$

$$(\%\ H) = -7.20\,(E_a) + 1.54\,(\text{total added}) - 315.70\,(d) + 483.53 \qquad (R = 0.936) \quad \text{(Eq. 4)}$$

$$(IM) = -7.37\,(E_a) - 1.99\,(T_{10}) + 2.80\,(T_{25}) - 195.90 \qquad (R = 0.975) \quad \text{(Eq. 5)}$$

$$(ID) = 24.54\,(\text{dibutyltin diacetate}) - 13.62\,(E_a) + 376.46 \qquad (R = 0.913) \quad \text{(Eq. 6)}$$

$$(ST) = 24.11\,(\text{dibutyltin diacetate}) + 3.65\,(T_{50}) - 1401.08 \qquad (R = 0.920) \quad \text{(Eq. 7)}$$

$$(HR) = -2.10\,(T_{10}) + 1.79\,(T_{25}) + 47.43 \qquad (R = 0.930) \quad \text{(Eq. 8)}$$

$$(CI) = 54.96\,(\text{dibutyltin diacetate}) - 12.14\,(T_{10}) + 9.68\,(T_{25}) + 606.85 \qquad (R = 0.956) \quad \text{(Eq. 9)}$$

Each coefficient of the independent variables in Eqs. 3–9 is significant at the $\alpha = 0.05$ level or better. Equation 3 indicates that tissue culture response is correlated with the residue weight (percent) of methanol extractable substance. In other words, the data suggest that the tissue culture reaction results directly from leachable materials existing in the polymer matrix. The multiple correlation coefficient is 0.844.

For percent hemolysis, Eq. 4, a multiple correlation coefficient of 0.936 is obtained. Since the percent hemolysis determination is performed at 37° and the total exposure time of the polymer to aqueous solutions is no greater than 90 min, it may be somewhat surprising that E_a is so highly correlated to percent hemolysis assay. However, the E_a value may be considered as a measure of thermal stability; the greater the E_a value, the more stable is the material. A simple correlation coefficient of −0.788 is obtained for the E_a–% H relationship, showing that the easier it is for the plastic to decompose, the greater is the hemolysis. Furthermore, evaporation of additives from the polymer in the process of thermal analysis is not distinguishable from decomposition of the polymer so that the E_a value calculated from the thermogravimetric curve is certainly influenced by the presence of additives.

Correlation of percent hemolysis assay with the total amount of additives is to be expected, since at the conditions of hemolysis it would appear that the additives could be easily leached out and contribute to cellular destruction.

Density appears as the third variable in Eq. 4. The simple correlation coefficient of d–% H is −0.587. There is little or no simple correlation between density and the total amount of additives or between density and E_a ($r = 0.427$).

The multiple correlation coefficient corresponding to Eq. 5 for intramuscular implant is 0.975, the highest value observed for all seven dependent variables analyzed. The simple correlation coefficients for IM–E_a and IM–T_{10} are −0.858 and −0.899, respectively. These results strongly suggest that the intramuscular implant response is highly dependent on the thermal stability of elastomer samples. The easier the material is degraded, the higher is the tissue reaction around the implant.

Equation 6 indicates that intradermal irritation is a function of percent II added and the E_a values. The simple correlation coefficient between the percent II added and the E_a value is −0.736, indicating that E_a is inversely related to the percent II added; the simple correlation coefficients for ID–% II and ID–E_a are 0.873

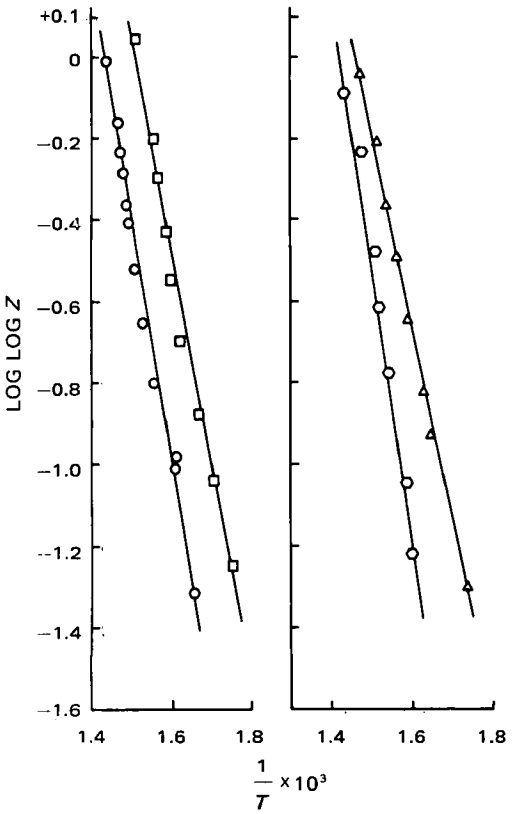

Figure 1—*Typical examples showing the determination of activation energies for thermal degradation of segmented polyether polyurethane elastomers by Broido's (21) method. Key:* ○, *Sample 1, no additives;* □, *Sample 15, 2% 3,4-diaminotoluene and 6% dibutyltin diacetate;* ○, *Sample 16, 4% 3,4-diaminotoluene only; and* △, *Sample 6, 6% dibutyltin diacetate.*

and −0.825, respectively. The higher the percent II added, the lower is the E_a required for degradation (hence the less stable the material) and the higher is the intradermal irritation response. Therefore, it is obvious that intradermal irritation is also directly related to the thermal stability of the elastomer samples. The multiple correlation coefficient is 0.913.

The systemic toxicity is correlated with the percent II added and T_{50} (Eq. 7, R = 0.920). However, the simple correlation coefficient for ST–% II is 0.851; but for ST–T_{50}, it is only 0.358.

The multiple correlation coefficient corresponding to Eq. 8 for histopathological rating is 0.930. But only two variables, T_{10} and T_{25}, are found in Eq. 8. A simple correlation coefficient of −0.866 was obtained for the T_{10}–HR relationship, indicating that T_{10} is negatively correlated to histopathological rating.

In general, T_{10} is considered as a measure of the degradation of active material free from the influence of contamination or sorption of volatile components or solvent on the material. It is, therefore, a better measurement of the thermal stability of the material than T_i (T_i is very sensitive to impurities). The stability of the material may indeed play an important role in the histopathological rating response, since implantation was continued for 1 week. Thus, the lower the value of T_{10}, the easier the material can decompose to products that increase the histopathological rating value.

Furthermore, since the histopathological rating and total amount of additives have a simple correlation coefficient of only 0.254, the additives apparently are relatively ineffective in producing the histopathological response. The data suggest that the additives may strongly influence the thermal stability of the material and thereby indirectly affect the histopathological rating response through the leaching process in the body of the animal.

Equation 9 expresses the multiple correlation of cumulative biological index to the amount of II added, T_{10} and T_{25} (R = 0.956). Since the cumulative biological index is a composite of six major tests, it may be viewed as an overall response. The amount of II added strongly contributes to this overall response. The simple correlation coefficient between II and the cumulative biological index is 0.88. The simple correlation coefficient relating percent I added to the cumulative biological index is only −0.07, a negligible value. Thus, it appears that the amount of II added rather than the amount of I added is largely responsible for the cumulative biological response. However, the average amount of II added for all samples was larger by a factor of two than the amount of I added, and this may in part account for its presence in Eq. 9. The terms T_{10} and T_{25} are related to the cumulative biological response index in a manner similar to the histopathological rating, as already discussed.

Stepwise multiple linear regression analysis has shown that the magnitude of various biological responses is highly correlated to the thermal and physical properties of the polymer system as well as to the amounts of dibutyltin diacetate added to the polymer system in arbitrarily excessive quantities. Since the segmented polyether polyurethane elastomer *per se* showed very low biological response and was present in the same absolute amount in each preparation, it was concluded that its contribution to biological response in the presence of additives was limited to its influence on the leachability of the additives, the biological response being highly correlated with the total amount of additives and the thermal properties of the complex polymer system.

Decomposition of Amitriptyline Hydrochloride in Aqueous Solution: Identification of Decomposition Products

R. P. ENEVER, A. LI WAN PO, B. J. MILLARD, and E. SHOTTON [x]

Abstract □ The decomposition of amitriptyline hydrochloride upon autoclaving in a buffered solution (pH 6.8) was investigated. Three major decomposition products [3-(propa-1,3-dienyl)-1,2:4,5-dibenzocyclohepta-1,4-diene, dibenzosuberone, and 3-(2-oxoethylidene)-1,2:4,5-dibenzocyclohepta-1,4-diene] were detected and identified by chromatographic and spectroscopic techniques. Evidence is presented that the latter two compounds are formed by further oxidation of 3-(propa-1,3-dienyl)-1,2:4,5-dibenzocyclohepta-1,4-diene, and a possible decomposition pathway is outlined.

Keyphrases □ Amitriptyline hydrochloride—identification of decomposition products, aqueous solution, mechanisms □ Decomposition—amitriptyline hydrochloride in aqueous solution, identification of products, mechanisms □ Antidepressants—decomposition of amitriptyline hydrochloride in aqueous solution, identification of products, mechanisms

The antidepressant drug amitriptyline hydrochloride may be formulated as a parenteral solution and sterilized by filtration according to BP 1974. Although Henwood (1) showed that amitriptyline base breaks down into dibenzosuberone and Bouche (2) indicated that anthraquinone was formed when the base was boiled in alkaline potassium permanganate solution, there are little published data concerning the stability of the drug.

A project was initiated to assess the drug's instability in aqueous solution and to identify the decomposition products produced during autoclaving and long-term storage. Preliminary experiments showed that decomposition occurred when solutions of amitriptyline hydrochloride in water or phosphate buffers were autoclaved for 30 min at 115–116° in the presence of excess oxygen. The purpose of this paper is to describe the isolation of the decomposition products by TLC and GLC and their identification using mass spectrometry, NMR, and other spectroscopic techniques.

EXPERIMENTAL

Materials—The following chemicals were used: amitriptyline hydrochloride[1], dibenzosuberone[2], ethyl iodide[3], potassium chloride[4], potassium dihydrogen phosphate[4], ether[4], *n*-propanol[4], carbon tetrachloride[4], ethylene dichloride[4], benzene[4], hexane[4], chloroform[4], ethanol[4], methanol[4], ethyl acetate[4], and acetone[4].

Degradation of Amitriptyline Hydrochloride Solution—A 0.5% (w/v) amitriptyline hydrochloride solution was prepared in 0.2 *M* phosphate buffer solution (pH 6.8); 2-ml quantities were distributed in 10-ml ampuls to ensure excess oxygen and sealed. The ampuls were autoclaved at 115–116° for up to 6 hr to produce sufficiently large quantities of the degradation products for subsequent identification by various physicochemical techniques.

TLC—The plates (20 × 20 cm) were coated with silica gel G[5], 250 μm thick, and activated by heating at 110° for 2 hr. They were stored in a desiccator prior to use.

The contents of a heated ampul were extracted with 200 μl of ether, and 50 μl was spotted on a plate in 10-μl portions. Ascending development was carried out over 15 cm with benzene–carbon tetrachloride (7:3 v/v). The spots were detected visually in transmitted light and also by spraying with 4% (v/v) formaldehyde solution BP in concentrated sulfuric acid and viewing under UV light. Dragendorff reagent and 0.4% (w/v) 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid were also used as spray reagents to detect nitrogen- and carbonyl-containing compounds, respectively. The R_f values were determined for the various degradation products (Table I).

Table I—TLC Data for Amitriptyline Hydrochloride Degradation Products and Reference Compounds

Compound	R_f Value	Color Reaction: 4% Formaldehyde Solution BP in Concentrated Sulfuric Acid, Daylight	Color Reaction: 4% Formaldehyde Solution BP in Concentrated Sulfuric Acid, UV Light	Color Reaction: 2,4-Dinitrophenylhydrazine Reagent, Daylight
A	0.70	Brown	—	—
B	0.33	Yellow[a]	Yellow fluorescence	Light orange
C	0.17	Brown	—	Orange
Synthesized I	0.70	Brown	—	—
Dibenzosuberone	0.33	Yellow[a]	Yellow fluorescence	Light orange

[a]The yellow color was not evident at low concentrations, although even low concentrations fluoresce under UV light.

TLC was also carried out in a similar manner using the solvent systems listed in Table II.

To obtain sufficient quantities of the degradation products, 20 ml of autoclaved solution was extracted with two 5-ml quantities of ether. The volume of ether was reduced by evaporation under nitrogen to 2 ml, and this sample was streaked on five plates and developed with benzene–carbon tetrachloride (7:3 v/v). Subsequently, each plate was partially covered by a screen so that only approximately 1 cm was exposed. This area was sprayed to reveal the position of the degradation products, and the nonsprayed areas were removed and eluted separately with methanol. These solutions were evaporated under nitrogen to obtain the degradation products.

GLC—The contents of a heated ampul were extracted with 1 ml of ether, and 5 μl was analyzed using a chromatograph equipped with a flame-ionization detector[6]. A 1.5-m (5-ft) × 0.6-cm (0.25-in.) i.d. glass column, packed with 3% (w/w) OV-25 on 80–100-mesh Chromosorb W AW/DCMS, was used at 220°. The flow rates of hydrogen, air, and nitrogen were 83, 450, and 28.5 ml/min, respectively. Peak assignment was achieved by injecting ethereal solutions of each degradation product separated by TLC.

Spectroscopic Analysis—The UV spectra[7] of solutions of the isolated degradation products in methanol were obtained using 1-cm path length silica cells.

To obtain IR spectra[8], samples were presented in the form of liquid films or dilute solutions in carbon tetrachloride.

NMR spectra[9] were obtained by preparing solutions of the products in deuterated chloroform containing tetramethylsilane as the internal marker.

Mass spectra[10] were obtained using a beam energy of 70 ev with the sample probe maintained at 210°.

Synthesis of 3-(Propa-1,3-dienyl)-1,2:4,5-dibenzocyclohepta-1,4-diene (I)—Amitriptyline hydrochloride (500 mg) was made alkaline with 1 *N* sodium hydroxide and extracted with ether. The extract was dried over anhydrous sodium sulfate and filtered. The filtrate was evaporated to dryness *in vacuo*, and 10-ml volumes of ethyl iodide and ether were added. The mixture was refluxed on a steam bath for 20 min, and the unreacted reagents were removed by distillation. Then the residue was dried in a stream of dry nitrogen and dissolved in a minimum of methanol, and excess silver oxide was added.

The mixture was shaken and filtered, and the filtrate was sealed in ampuls under nitrogen and autoclaved for 5 hr. The solvent was removed, and the residue was dissolved in 10 ml of ether and extracted with 5 ml of 5 *N* hydrochloric acid. The ethereal layer was washed with a further two 5-ml volumes of acid, dried over anhydrous sodium sulfate, and filtered, and the product was isolated by vacuum evaporation. The purity of the compound was checked by TLC.

The physicochemical data on the compound were as follows: UV (methanol): λ_{max} 268 nm; IR (liquid): 3060 (aromatic CH stretch), 2920 (CH_2 stretch), 1650 (diene), 910 and 990 (—CH=CH_2), and 755 and 765 (aromatic hydrogen) cm^{-1}; NMR: δ 3.2 (unresolved multiplet, protons on seven-membered ring), 5–5.5 (multiplet, methylene protons), 6.2–6.7 (multiplet, methine protons), and 7.2 (multiplet, aromatic protons) ppm.

The mass spectrum showed a molecular ion at *m/e* 232 (100%) corresponding to $C_{18}H_{16}$ and significant peaks at 231 (34), 229 (8), 218 (11), 217 (65), 216 (26), 215 (52), 204 (18), 203 (23), 202 (36), 191 (10), 189 (16), 151 (8), 142 (17), 116 (24), 113 (13), 106 (17), 105 (13), 104 (8), 92 (8), 88 (7), and 49 (7).

Anal.—Calc. for $C_{18}H_{16}$: C, 93.11; H, 6.89. Found: C, 92.85; H, 7.14.

RESULTS AND DISCUSSION

TLC of degraded amitriptyline hydrochloride, using benzene–carbon tetrachloride (7:3 v/v), indicated the presence of three major decomposition products (A, B, and C). Table I gives their R_f values and color reactions. Also included in Table I are the data for the synthesized I and dibenzosuberone (II). The chromatographic behavior of A and B and the two reference compounds in a range of developing solvent systems is shown in Table II.

GLC produced peaks that correspond to amitriptyline, A, and B. Product C could not be detected in the extract, but a peak was obtained when injecting the eluate from thin-layer plates. Table III shows the retention times of these products together with those of the reference compounds.

From the chromatographic results in Tables I–III, it is apparent that Product A was I. This finding was confirmed by the similarity of their UV, IR, NMR, and mass spectra.

When chromatograms of A, produced by development with benzene–carbon tetrachloride (7:3 v/v), were exposed to air for 12 hr and then developed at right angles to the direction of initial development with chloroform–benzene–diethylamine (5:4:1 v/v), the decomposition product was broken down into B and C.

The identity of B was established by comparing its physicochemical data with those of dibenzosuberone. As shown in Tables I–III, their chromatographic data were identical, as were their UV spectra (λ_{max} 270 nm). Final confirmation that B was dibenzosuberone was obtained by comparison of their mass spectra. These spectra were identical, with a molecular ion at *m/e* 208 (100%) corresponding to $C_{15}H_{12}O$ and significant peaks at 207 (43), 192 (7), 181 (7), 180 (45), 179 (48), 178 (36), 177 (5), 166 (7), 165 (24), 151 (7), 150 (5), 90 (7), 88 (24), 77 (7), 76 (2), 75 (17), 62 (10), 50 (7), 49 (5), and 39 (7).

Table II—Chromatographic Behavior of A, B, Dibenzosuberone, and Synthesized I

Solvent System	R_f Value: Product A	Synthesized I	Product B	Dibenzosuberone
Benzene–hexane (3:2 v/v)	0.77	0.77	0.27	0.27
Ethylene dichloride–hexane (1:1 v/v)	0.83	0.83	0.37	0.37
Chloroform–benzene (1:4 v/v)	0.77	0.77	0.48	0.48
Ethyl acetate–carbon tetrachloride (3:2 v/v)	0.73	0.73	0.69	0.69
n-Propyl alcohol–benzene–carbon tetrachloride (3:3:4 v/v)	0.93	0.93	0.91	0.91
Ethanol–water (3:1 v/v)	0.75	0.75	0.75	0.75

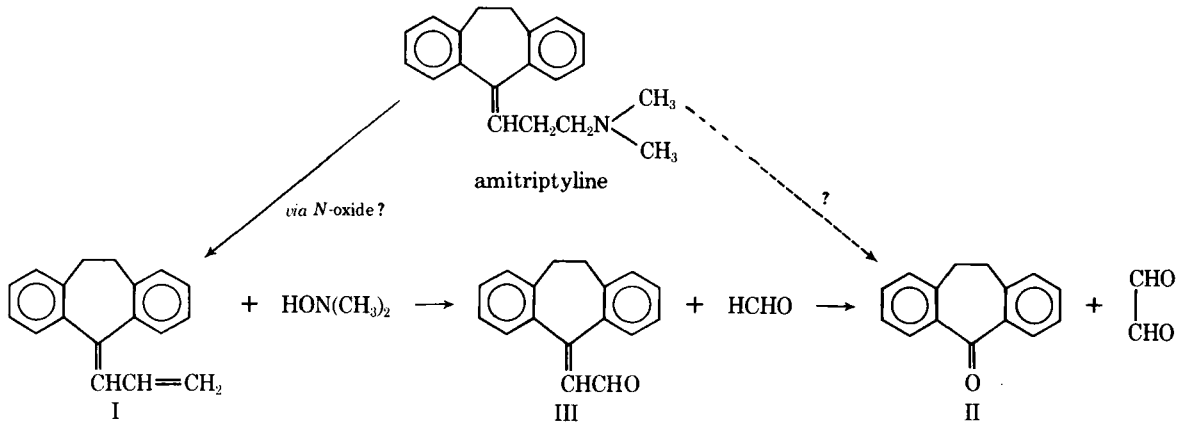

Scheme I—Proposed decomposition pathway for amitriptyline in aqueous solution

Table I shows that C reacted with 2,4-dinitrophenylhydrazine, and this finding indicated the presence of a carbonyl function. The physicochemical data for the compound were as follows: UV (methanol): λ_{max} 280 nm; IR (liquid): 3020 (aromatic CH stretch), 2920 and 2860 (CH_2 stretch), 1675 (—C=O in conjugated system =CH—CHO), and 767 and 757 (aromatic hydrogen) cm^{-1}; NMR: δ 3.3 (unresolved multiplet, protons on seven-membered ring), 4.4–4.6 (triplet, methine protons), 7.3 (multiplet, aromatic protons), and 9.6–9.7 (aldehydic proton) ppm.

The mass spectrum showed a molecular ion at *m/e* 234 (100%) corresponding to $C_{17}H_{14}O$ and significant peaks at 233 (69), 232 (7), 219 (17), 206 (20), 205 (23), 204 (10), 203 (20), 202 (23), 193 (7), 192 (7), 191 (20), 190 (7), 189 (13), 178 (13), 177 (7), 164 (10), 151 (10), 128 (10), 115 (10), 109 (10), 91 (7), 69 (17), 57 (7), 55 (7), 43 (7), and 41 (7).

From these data, it was concluded that C was 3-(2-oxoethylidene)-1,2:4,5-dibenzocyclohepta-1,4-diene (III).

The formation of dibenzosuberone upon autoclaving amitriptyline hydrochloride could be explained by direct oxidation of the olefinic double bond of the drug. However, such a mechanism does not account for the production of I and III, since only portions of the side chain have been lost. Cope *et al.* (3) showed that loss of dialkyl amino function can proceed *via* formation of *N*-oxide. Although it has not yet been possible to isolate an *N*-oxide in the degraded sample, it seems that *N*-oxidation, followed by loss of dimethylhydroxylamine, is the most probable route of decomposition.

Table III—GLC Behavior of Degradation Products of Amitriptyline Hydrochloride and Reference Compounds

Compound	Retention Time, min
A	3.5
B	4.5
C	8.0
Dibenzosuberone	4.5
Synthesized I	3.5
Amitriptyline	7.0

The aldehyde (III) has been shown to result from the further oxidation of I. The formation of formaldehyde was also detected in this step. A quantity of the isolated allylic compound (I) was placed in a conical flask having a sealed vapor trap (containing chromotropic acid in sulfuric acid) connected to the neck. Upon storage, the chromotropic acid solution developed a violet color, indicating the presence of formaldehyde.

During the subsequent oxidation of III to dibenzosuberone, glyoxal was formed. It was detected by adding excess *o*-aminophenol and calcium oxide to an ethanolic solution of aldehyde, which had been allowed to stand overnight. A positive brick-red color, indicative of glyoxal, was produced.

It is evident that oxidation of the olefinic double bond of amitriptyline hydrochloride is not necessarily the first step in the degradation of the drug; Scheme I shows the proposed decomposition pathway.

Effect of Polysorbate 60 on Interphase Transport of Cholesterol

P. B. McNULTY

Abstract □ Interphase cholesterol transport was investigated at 24 ± 1° in a stirred diffusion cell and in various oil-in-water emulsions. Cholesterol uptake by vegetable oil from a cholesterol–surfactant-rich aqueous phase was extremely slow in the stirred cell; no measurable transport had occurred after 500 hr. Cholesterol transport in oil-in-water emulsions following dilution with a cholesterol–surfactant-rich aqueous phase was much faster due to the greatly increased interfacial area available for mass transfer. Equilibration half-lives, $t(50)$, varied from 2.02 to 28.1 hr. Variations in the $t(50)$ were due to: *(a)* differences in the mean oil droplet diameter among various emulsions, and *(b)* differences in cholesterol–polysorbate 60 micelle sizes among various dilution media. When polysorbate 60 was omitted from the dilution medium, transport occurred in a two-stage process. In the first stage, transport was extremely rapid, with the $t(50)$ less than 30 sec; in the second stage, transport was comparable to previous emulsion rates, with the $t(50)$ varying from 7.9 to 8.1 hr. The significance of this two-stage transport to mechanisms of interphase cholesterol transport is briefly discussed.

Keyphrases □ Polysorbate 60—effect on interphase transport of cholesterol, mechanism □ Cholesterol—effect of polysorbate 60 on interphase transport, mechanisms and equations □ Transport, interphase—cholesterol, effect of polysorbate 60, stirred diffusion cell, mechanism □ Emulsions—vegetable oil–surfactant–water, effect of polysorbate 60 on interphase transport of cholesterol

Much research has been devoted to investigating the transport of various solute molecules in aqueous media across biomembranes, using both *in vivo* and *in vitro* techniques. Such studies have enhanced the understanding of the mechanisms of absorption, distribution, and metabolism of biologically important compounds in living systems.

Recent studies (1, 2) attempted to elucidate the mechanism (or mechanisms) of *in vivo* transport of cholesterol and related steroids by investigating interphase transport in liquid hexadecane oil-in-water emulsions stabilized by various surfactants. The results of these studies led to the postulation of two possible mechanisms of transport: "free drug delivery" and "micelle delivery." The term "drug" is used because the investigators regard the steroids as model drug compounds. The term "free drug" denotes a steroid dissolved in monomeric form in aqueous solution in contrast to the aggregated or micellar form consisting of steroid–surfactant micelles dispersed throughout the aqueous medium.

The free drug delivery model is based on that proposed by Sylvén and Borgström (3) for absorption and digestion of fat, in which monomeric or free cholesterol diffuses from an oil droplet into the intestinal aqueous phase, where it associates with the bile salts and the polar split products of the oil phase formed by the action of lipase. This micelle transports cholesterol to the "vicinity" of the cell membrane, where the micelle dissociates and monomeric cholesterol is absorbed by the cell while the bile salts return to the bulk aqueous phase. According to Surpuriya and Higuchi (2), the micelle may not take part in the transfer of solute across the hexadecane–water interface and only the free drug is involved in the rate-determining step.

The micelle delivery model proposes that only the micelle takes part in the transfer of drug across the hexadecane–water interface, although free drug is present in solution. Surpuriya and Higuchi (2) suggested that the micelle: "interacts with the hexadecane–water interface and unloads the solute, which passes into the oil phase, and the micelle returns to the aqueous phase."

The objective of this investigation is to present data from a related study (4), which suggest an alternative interpretation of interphase cholesterol transport.

EXPERIMENTAL

Stirred Diffusion Cell Experiment—Cholesterol[1] uptake by vegetable oil[2] containing 1.5% (w/v) sorbitan monostearate[3] from an aqueous phase containing 5% isopropanol[4] and 1.1% polysorbate 60[5] was studied at 24 ± 1° in a 1-liter aspirator bottle[6]. The initial aqueous cholesterol concentration, C_{wi}, was 500 μg/ml. The water was double distilled and deionized.

The upper oil phase (200 ml) was stirred at 12.5 rpm by an umbrella stirrer[7] driven by a variable speed motor[8]. The lower aqueous phase (200 ml) was stirred at 52 rpm by a 25.4 × 7.9-mm octagonal magnetic stirring bar powered by a stirrer[9]. Both stirrers were hooked to variable autotransformers[10] to provide sensitive stirring speed control.

Transport was measured periodically by withdrawing 0.5 ml of the aqueous phase (through the stirred cell side arm sealed with a serum cap) in a 0.5-ml tuberculin syringe fitted with a 50.8-mm 22G hypodermic needle. The samples were mixed with 2 ml of isopropanol and analyzed by colorimetry[11] at 550 nm using a standard procedure (5). Full experimental details were described elsewhere (4).

Emulsion Experiments—*Emulsion Preparation*—Liquid oil-in-water emulsions were prepared using vegetable oil and the sorbitan monostearate–polysorbate 60 emulsifier system (4). The emulsifier hydrophilic–lipophilic balance (HLB) was 11.8, and the concentration was 2.67% (w/v) of oil plus emulsifier. Emulsification was by the agent-in-oil method (6), and the initial oil volume fraction, ϕ_i, was 0.5.

The oil droplet size was varied by using emulsification treatments of increasing severity: *(a)* propeller mixing in a blender[12] at an autotransformer setting of 30 v, *(b)* propeller mixing in the

blender at an autotransformer setting of 100 v, and *(c)* treatment *(b)* followed by piston homogenization at 140 kg/cm^2 (1 pass) in a single-stage laboratory homogenizer[13]. Particle size, d_{vs}, and distribution, d_m/d_n (*i.e.*, polydispersity), were measured[14] (4), where d_{vs} is the volume to surface mean droplet diameter, and d_m and d_n are the mass and number average diameters, respectively.

Preparation of Aqueous Dilution Media—Cholesterol-rich aqueous phases were prepared using different solvents—*viz.*, ethanol[15], isopropanol, and polysorbate 60 (4) (Table I). The cholesterol–polysorbate 60 micelle size was estimated by filtration through 25-mm diameter filters[16] with pore sizes of 0.025, 0.05, 0.1, 0.22, 0.3, and 0.45 μm. The filters were contained in a microsyringe filter holder[17] attached to a 5-ml hypodermic luer-lok syringe. Samples in the syringe were forced under manual pressure through the filter by the syringe plunger. Approximately 1 ml of filtrate was collected in a 3-ml vial and was analyzed for cholesterol concentration as described previously.

Measurement of Cholesterol Transport—Ninety-five milliliters of the appropriate aqueous dilution medium at 24 ± 1° was weighed into a 125-ml erlenmeyer flask, which was placed on a rotary shaker. Then 5 ml of emulsion (ϕ_i = 0.5) at 24 ± 1° in a 5-ml graduated cylinder was rapidly poured into the dilution medium at zero time. (This procedure gave an emulsion dilution factor, DF_{em}, of 20.) The shaker was immediately switched on at 150 rpm.

The sampling procedure involved: *(a)* withdrawing ~3 ml of diluted emulsion in a 5-ml syringe attached to a 102-mm 15G stainless hypodermic needle, *(b)* inverting the syringe and detaching the needle, *(c)* attaching the syringe to the filter holder, and *(d)* filtering the sample through 0.22-μm pore size filters. The earliest separation time was 30 sec. Aqueous filtrates of unlabeled cholesterol were analyzed as described previously. Cholesterol-4-^{14}C[18] was analyzed by liquid scintillation counting[19] after 0.5 ml of aqueous filtrate was pipetted into 10 ml of scintillation cocktail[20] in a 20-ml scintillation vial.

RESULTS AND DISCUSSION

Stirred Cell Experiment—Transport rate may be evaluated from Eq. 1, which applies to one-dimensional unsteady-state mass transfer across an oil–water interface in cylindrical stirred diffusion cells (4, 7):

$$\ln \frac{C_{we} - C_w}{C_{we} - C_{wi}} = -\frac{K_w A}{V_w}\left[\frac{V_w + V_o K_p}{V_o K_p}\right]t = -S_{sc}t \quad \text{(Eq. 1)}$$

where $(C_{we} - C_w)/(C_{we} - C_{wi})$ = fraction of unattained equilibrium; C_{we} and C_{wi} = equilibrium and initial aqueous concentrations, respectively; K_w = overall mass transfer coefficient accounting for the diffusional resistance in each phase expressed in terms of the aqueous concentration gradient; A = interfacial area; V_o and V_w = oil and aqueous volumes, respectively; S_{sc} = stirred cell transport rate; and t = time. The partition coefficient, K_p, is defined as follows:

$$K_p = C_{oe}/C_{we} \quad \text{(Eq. 2)}$$

where C_{oe} and C_{we} = concentrations in the oil and aqueous phases at equilibrium, respectively.

Figure 1 shows that no perceptible uptake of cholesterol by vegetable oil from an aqueous phase containing 5% isopropanol and 1.1% polysorbate 60 was detected over 500 hr. The extremely slow uptake rate was surprising, particularly since transport rates equivalent to equilibration half-lives of 2.0–13.5 hr were reported for normal alcohols (C_3–C_8) in a similar system (4, 7) and the estimated diffusion coefficients of cholesterol in vegetable oil and water were only slightly less than *n*-octanol diffusivities (4).

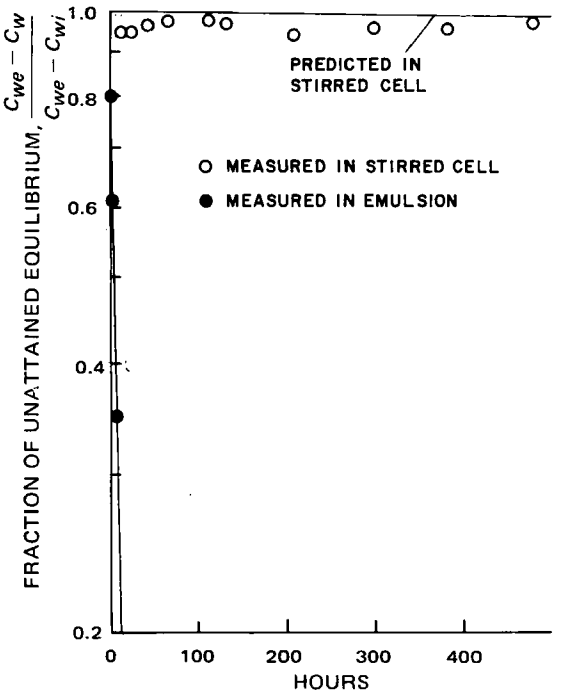

Figure 1—*Comparison of cholesterol transport rates in the stirred diffusion cell (experimental and predicted) and in a vegetable oil-in-water emulsion (Experiment 4) at 24°.*

Prediction of Cholesterol Transport in Emulsions—A scale-up model was developed (4, 8) on the assumption that Eq. 1 also applies to three-dimensional diffusion to spherical oil droplets in oil-in-water emulsions following instantaneous aqueous dilution, *i.e.*:

$$\psi = S_{em}/S_{sc} = t_{sc}(50)/t_{em}(50) \quad \text{(Eq. 3)}$$

where ψ is the scale-up factor (*i.e.*, transport rate ratio) and $t(50)$ is the time for the attainment of 50% equilibration. Equation 1 can be written in a form more suitable for mass transfer in diluted emulsions when the following relationships are used:

$$DF_{em} = \phi_i/\phi \quad \text{(Eq. 4)}$$

$$V_w = (1 - \phi)V_{ow} \quad \text{(Eq. 5)}$$

$$d_{vs} = 6\phi V_{ow}/A \quad \text{(Eq. 6)}$$

where DF_{em} = emulsion dilution factor; ϕ_i and ϕ = initial and diluted oil volume fractions, respectively; and V_{ow} = emulsion volume. Rewriting Eq. 1 gives:

$$\ln \frac{C_{we} - C_w}{C_{we} - C_{wi}} = -\frac{K_w}{d_{vs}}\left[\frac{6\phi_i/DF_{em}}{1 - \phi_i/DF_{em}}\right] \times \left[\frac{K_p - 1 + DF_{em}/\phi_i}{K_p}\right]t = -S_{em}t \quad \text{(Eq. 7)}$$

If $K_{p,em} = K_{p,sc}$ and $K_{w,em} = K_{w,sc}$, an isothermal scale-up factor, ψ, can be expressed in measurable stirred cell and emulsion parameters by substituting Eqs. 1 and 7 into Eq. 3 as follows:

$$\psi = \left[\frac{V_{ow}(1 - \phi)}{A}\right]_{sc}\left[\frac{6\phi_i/DF_{em}}{d_{vs}(1 - \phi_i/DF_{em})}\right]_{em} \times \left[\frac{K_p - 1 + DF_{em}/\phi_i}{K_p - 1 + 1/\phi_{sc}}\right] \quad \text{(Eq. 8)}$$

If 50% equilibration has been attained in the diluted emulsion, Eqs. 3 and 7 can be combined to give:

$$t_{em}(50) = 0.693/\psi S_{sc} = 0.693/S_{em} \quad \text{(Eq. 9)}$$

[a] NM = not measured.

Hence the time for the attainment of 50% equilibration in the emulsion can be predicted from Eq. 9 once ψ is evaluated from Eq. 8, provided K_p and S_{sc} are known. However, due to the slow cholesterol transport in the stirred diffusion cell, S_{sc} and K_p could not be evaluated from Eqs. 1 and 2 because of insufficient data. Therefore, emulsion transport rates could not be predicted.

Emulsion Experiments—Filtration of the aqueous dilution media used in Experiments 1–5 (Table I) revealed that some cholesterol was retained by the filters and that the extent of cholesterol retention increased as both filter pore size and polysorbate 60 concentration decreased (Fig. 2). These results were expected, since micelle size in the micellar solutions increased sharply as the polysorbate 60 concentration decreased, as was indicated by an increase in turbidity. It is clear from Fig. 2 that micelle size in the case of the 0.106% polysorbate 60 (P60) concentration level was extremely large; for example, approximately 485 out of 500 μg/ml cholesterol was retained on a 0.1-μm (1000 Å) filter. When the polysorbate 60 concentration is further reduced, cholesterol precipitates out of solution (4).

The extent of cholesterol uptake by emulsion oil droplets was evaluated using Eq. 10, derived from the model of McNulty and Karel (9):

$$\frac{C_{wd}}{C_{we}} = \frac{\phi_i(K_p - 1) + DF_{em}}{DF_{em} - \phi_i} \qquad \text{(Eq. 10)}$$

where C_{wd} = aqueous concentration immediately after emulsion dilution. If K_p is not known, C_{wd} and C_{we} may be estimated by extrapolating C_w *versus* t plots to zero and infinite times, respectively. Then K_p may be evaluated using Eq. 10.

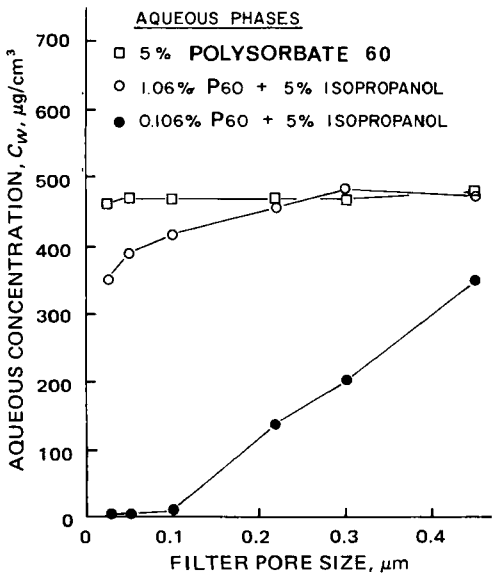

Figure 2—*Effect of aqueous phase composition on the size of cholesterol–polysorbate 60 (P60) micelles* (C_{wi} = *500 μg/ml) at 24°.*

Results of emulsion experiments revealed that the extent of cholesterol transport, C_{wd}/C_{we}, increased as the concentration of polysorbate 60 in the dilution media decreased (Table I). This finding was expected, since the cholesterol equilibrium will increasingly favor the oil phase (*i.e.*, K_p increases) as the aqueous polysorbate 60 concentration decreases.

In Experiment 1, it was difficult to distinguish between the cholesterol retained on the filter and that taken up by the oil due to the large cholesterol–polysorbate 60 micelle size (Table I, Fig. 2). Consequently, the transport rate could not be measured.

In Experiments 2–4, transport rates increased as expected with a decrease in the mean droplet diameter, d_{vs}, due to the increase in interfacial area available for mass transfer. The relative increases in transport rate (1.0:2.6:6.5) were less than the corresponding decreases in d_{vs} (3.7:2.1:1.0), probably due to the corresponding decreases in polydispersity, d_m/d_n. For example, when an emulsion is highly polydisperse (*e.g.*, Experiment 2), a large volume of the dispersed phase exists in a relatively small number of large droplets. Consequently, the transport rate should be slower than that in a less polydisperse emulsion of equivalent d_{vs} due to the relatively slow penetration of diffusing solute into large, as opposed to small, droplets.

Equilibration half-lives for transport of both labeled and unlabeled cholesterol varied from 2.02 to 28.1 hr (Table I). These values are similar to those (*i.e.*, 1.4–4.2 hr) estimated from the data of Bikhazi and Higuchi (10) for cholesterol-4-^{14}C transport in liquid hexadecane oil-in-water emulsions stabilized by polysorbate 80. These rates are extremely slow when compared to equilibration half-lives of normal alcohols (C_3–C_8), $t(50) < 15$ sec, in a similar system (4, 8).

Although emulsion rates could not be predicted, it was possible to use emulsion data and the scale-up model to predict the uptake rate in the stirred cell. Initial experimental results qualitatively confirmed the prediction (Fig. 1).

The effect of surfactant on the uptake rate of cholesterol-4-^{14}C was studied by omitting polysorbate 60 from the dilution medium and using a concentration level in the range of its solubility[21] (*i.e.*, approximately 0.1 μg/ml). The results in Fig. 3 suggest that when polysorbate 60 is omitted, cholesterol transport occurs in a two-stage process, probably due to the following scheme of events:

1. When the emulsion is diluted with aqueous cholesterol, the excess polysorbate 60 in the aqueous phase of the emulsion competes with the oil droplets for the monomeric cholesterol. A fraction of monomeric cholesterol is taken up by the oil droplets very rapidly, as shown in Fig. 3.
2. The remaining cholesterol is rapidly taken up by the polysorbate 60 micelles, and the uptake of surfactant-associated cholesterol is a slow process occurring at approximately the same rate as that in the earlier experiments where polysorbate 60 was included

[21] Aqueous cholesterol solubility was reported as approximately 0.025 μg/ml (11). The approximation in this study is larger, presumably because 0.15% ethanol increases the aqueous solubility.

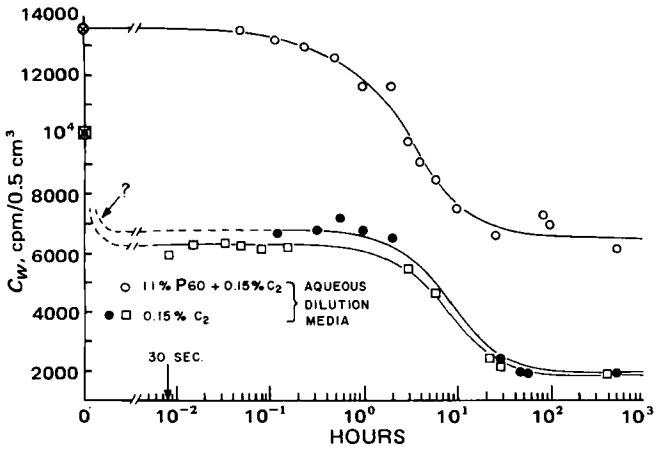

Figure 3—*Effect of the dilution medium composition on the transport rate of cholesterol-4-^{14}C in vegetable oil-in-water emulsions at 24° (Experiments 7 and 8; P60 = polysorbate 60; C_2 = ethanol).*

in the dilution medium. The slow transport is probably due to the opposing driving forces to which cholesterol is subjected, *i.e., (a)* an overall interphase gradient of chemical potential which drives cholesterol out of the micelle, through the water, and into the oil; and *(b)* a local gradient of chemical potential, which maintains the hydrophobic cholesterol in the micelle and out of the water.

It is suggested that, in ternary systems, cholesterol equilibration between oil and water should be rapid as indicated by the rapid monomeric cholesterol transport observed in this study. Furthermore, cholesterol equilibration between water and aqueous surfactant micelles should also be rapid. For example, Nakagawa (12) indicated that "solubilization is a phenomenon proceeding spontaneously." On the other hand, interphase cholesterol transport in quaternary (or multicomponent) emulsion systems proceeds very slowly.

As mentioned previously, the free drug delivery and micelle delivery models (1, 2) describe free drug transfer and micelle association or dissociation as the respective rate-determining steps in interphase cholesterol transport. In the absence of an opposing driving force, as in the described ternary systems, such equilibrations should be rapid. Therefore, the opposing driving force model proposed here appears to be more conceptually consistent.

It is interesting to speculate on the reported transport rates of related steroids (1). For example, in hexadecane oil-in-water emulsions stabilized by polysorbate 80, interfacial permeabilities for cholesterol, demosterol, β-sitosterol, and vitamin D_3 varied from 2.5 to 60 × 10^{-8} cm/sec. For 20α-hydroxycholesterol, progesterone, and testosterone, they varied from 2.0 to 30 × 10^{-5} cm/sec. No explanation was offered for the large difference in permeability between the two groups.

McNulty (4) observed that the steroids of lower permeability are sterols containing one hydroxy group. In contrast, the steroids of higher permeability possess an additional hydrophilic group on the opposite side of the steroid backbone; *i.e.*, 20α-hydroxycholesterol has two hydroxy groups, progesterone has two carbonyl groups, and testosterone has one carbonyl and one hydroxy group. The presence of an additional hydrophilic group will increase aqueous solubility and may produce a more randomly organized steroid–surfactant micelle, since both steroid hydrophilic groups will tend to orient themselves toward the hydrophilic exterior of the micelle. These two effects should reduce the magnitude of the opposing driving forces and thus increase permeability.

In conclusion, the equilibria and kinetics of steroid transport should be quantitatively established in steroid–oil–water and steroid–surfactant–water. [For the latter case, investigators should note the procedure of Short and Rhodes (13) who proposed a thermodynamic description of the effect of surfactants on diffusion of steroids across cellulose acetate membranes.] Characterization of such ternary systems should then permit a more quantitative interpretation of steroid transport in quaternary (or multicomponent) emulsion systems and also help to establish unambiguously the mechanism (or mechanisms) of interphase steroid transport.

Effect of Carbonated Beverages and of an Antiemetic Containing Carbohydrate and Phosphoric Acid on Riboflavin Bioavailability and Salicylamide Biotransformation in Humans

J. BRIAN HOUSTON and GERHARD LEVY ˣ

Abstract □ Two carbohydrate–phosphoric acid solutions, one a widely used beverage (Solution C) and the other a pharmaceutical product used as an antiemetic (Solution E), administered together with riboflavin-5′-phosphate or salicylamide to healthy human adults, significantly increased the bioavailability of riboflavin and appreciably altered the metabolic fate of salicylamide (increased conversion to the sulfate and decreased formation of the glucuronide). A beverage containing phosphoric acid but no carbohydrates (Solution T) also increased the bioavailability of riboflavin but not as much as Solution C. These effects are attributed to a decrease of the gastric emptying rate caused by carbohydrates and phosphoric acid, consistent with the empirical use of Solution C syrup and Solution E as antinauseants and antiemetics. The results demonstrate also that the choice of beverage to be taken with medication can affect the bioavailability and/or metabolic fate of medicinals with saturable absorption and/or biotransformation characteristics.

Keyphrases □ Phosphoric acid and phosphoric acid–carbohydrate solutions—effect on riboflavin bioavailability and salicylamide biotransformation in humans □ Carbohydrate–phosphoric acid solutions—effect on riboflavin bioavailability and salicylamide biotransformation in humans □ Gastric emptying rates—effects of phosphoric acid and phosphoric acid–carbohydrate solutions, riboflavin bioavailability and salicylamide biotransformation in humans □ Antiemetic effect—carbohydrate–phosphoric acid solutions

A recent study in humans showed that caffeine contained in a proprietary carbonated beverage (Solution C[1]) is absorbed much more slowly from this beverage than from coffee or tea (1). Solution C contains sucrose and phosphoric acid, both of which inhibit gastric emptying (2, 3). A proprietary antinauseant and antiemetic product (Solution E[2]) also contains sugars and phosphoric acid (and no other active ingredients) and has been found to reduce the amplitude and rate of contraction of isolated strips of rabbit GI smooth muscle (4). Solution C syrup is widely used as an antiemetic, apparently on an empirical basis. Because of these findings, it was considered likely that Solution C (and other widely used beverages with similar ingredients) can inhibit significantly the rate of gastric emptying in humans and that the antiemetic properties of Solution C syrup and Solution E may be due to an inhibition of gastric motility produced by the carbohydrates and phosphoric acid.

The primary purposes of this investigation were to determine if Solution C can modify the absorption of concomitantly administered medicinal agents and to assess the relative contribution of carbohydrates and phosphoric acid to such an effect. The availability of a carbohydrate-free cola beverage, Solution T[3], otherwise practically identical to Solution C in composition (Table I), facilitated such an assessment. A secondary purpose was to obtain some indication of the mechanism whereby Solutions E and C exert an antiemetic effect; the remarkable similarity in the composition of these products (Table I) suggests that they act by an identical mechanism.

The medicinal agents utilized, riboflavin and salicylamide, were chosen because the bioavailability of the former and the metabolic fate of the latter are strongly affected by their absorption rate. Riboflavin is absorbed by a specialized, saturable process, apparently located in the proximal region of the small intestine (5–7). Large doses are almost completely recovered in the urine following parenteral injection (8, 9) and are only partially absorbed upon oral administration (5–7). Food, viscous solutions, hypothyroidism, and anticholinergic drugs increase the absorption of riboflavin, apparently by decreasing the rate of gastric emptying and thereby prolonging the residence time of riboflavin at specialized absorption sites in the proximal region of the small intestine (10–13).

Salicylamide is eliminated in humans by biotransformation to the sulfate and glucuronide and by formation of gentisamide (14). The formation of the sulfate conjugate is a saturable process of very low capacity; the fraction of a dose of salicylamide converted to salicylamide sulfate increases, therefore, with the decreasing rate of absorption (14). These pronounced nonlinear pharmacokinetic characteristics make riboflavin and salicylamide ideal agents for a safe, noninvasive, and convenient indirect determination of possible changes of the gastric emptying rate in humans. If a beverage such as Solution C can modify the bioavailability of riboflavin and the metabolic fate of salicylamide in humans, it is likely to have a similar effect on other medicinal agents with saturable absorption or biotransformation characteristics.

EXPERIMENTAL

Five healthy male volunteers, 26–38 years old, capable by education and experience to give their informed consent (research assistants and associates), participated in the study. They did not take any vitamins or drugs for 1 week before and during the experiments. They were given 41 mg of riboflavin-5′-phosphate (equivalent to 30 mg of riboflavin) in the morning on an empty stomach and did not eat for the next 4 hr. The vitamin was dissolved in 60 ml of water, 450 ml of water, 60 ml of Solution E, or 450 ml of So-

lution C according to a modified Latin-square experimental design. The solutions were at room temperature and the container was rinsed with 10 ml of water, which was also ingested. Three of the subjects also took riboflavin in 450 ml of Solution T, the sugar-free equivalent of Solution C.

In the second part of this investigation, the five subjects were given 1 g of salicylamide in four hard gelatin capsules with 450 ml of Solution C or water, in crossover fashion, in the morning on an empty stomach. The subjects did not eat for 4 hr and collected urine according to the same protocol as was used in the riboflavin study. All experiments were carried out at 1-week intervals.

Each subject emptied his bladder immediately before vitamin or drug administration and then collected urine every 30 min for 4 hr, every hour for the next 4 hr, every 2 hr until bedtime, and then at desired intervals for up to 36 hr (riboflavin study) or 24 hr (salicylamide study). The subjects were allowed to drink 50–100 ml of water after each urine collection to facilitate urine flow, except during the first 2 hr of the Solution C and T studies and during the 1st hr of the Solution E study when no fluids were permitted.

Urine containing riboflavin was collected in brown polyethylene bottles, and 5 ml of 25% acetic acid was added. All urine samples were stored in a refrigerator. They were assayed fluorometrically for riboflavin (6, 7) and for total salicylamide, salicylamide glucuronide, salicylamide sulfate, and gentisamide as described previously (14). All data were corrected for physiological excretion rates of riboflavin (based on a 12-hr urine collection) and for apparent salicylamide blank values (based on −1 to 0-hr urine samples). A separate experiment with Solution C alone established that ingestion of this beverage did not increase the blank values of urine.

RESULTS

The results of the study of the effects of Solutions C and T on the bioavailability of riboflavin are summarized in Table II. An example of the time course of the urinary excretion rates of riboflavin in the three experiments in an individual subject is presented in Fig. 1. The bioavailability of riboflavin was increased by 110%, from 16.9 to 35.5% of the dose on the average, by administration with Solution C. Solution T caused an average increase in bioavailability of 60%, *i.e.*, from 17.8 to 27.4% of the dose.

The data for Solution E are summarized in Table III, and an individual example of the time course of riboflavin excretion rates with and without Solution E is presented in Fig. 2. The bioavailability of riboflavin was increased by 70%, from 18.0 to 30.7% of the dose. The one subject (O) who did not show an increase in bioavailability with Solution E experienced nausea after taking the solution.

Because of the difference in the volume of Solutions C and E, different controls (riboflavin-5′-phosphate in 60 and 450 ml of water, respectively) were used in the two studies. There was no statistically significant difference in bioavailability of riboflavin from the two aqueous solutions.

There was a strong ($r = -0.938$) and statistically highly significant ($p < 0.001$) negative correlation between the bioavailability of riboflavin in control experiments and the increase in bioavailability obtained with Solutions C and E. Both sets of data could be fitted to the same regression line (Fig. 3). A similar negative relationship was observed for Solution T but with a much different slope,

[a] Riboflavin-5′-phosphate, 41 mg, administered orally in 60 ml of water or Solution E. [b] Paired t test.

consistent with the smaller effect of this carbohydrate-free solution on riboflavin availability.

The results of the study of salicylamide biotransformation are summarized in Table IV. The total recovery of salicylamide metabolites was essentially quantitative and identical in the control and Solution C experiments. Administration of salicylamide with Solution C caused a statistically significant increase in the formation of the sulfate conjugate and a decrease in the glucuronide fraction. The change in the gentisamide fraction was not statistically significant. The maximum urinary excretion rate of salicylamide sulfate increased from 1.25 ± 0.45 mg of salicylamide equivalent/min in the control experiments to 2.11 ± 0.29 mg/min in experiments with Solution C ($p < 0.001$). The time of occurrence of maximum excretion rates of salicylamide sulfate was 1.05 ± 0.27 hr in the controls, and it was 1.65 ● 0.42 hr in experiments with Solution C ($p < 0.05$).

There was a strong ($r = -0.934$) and statistically significant ($p < 0.025$) negative correlation between the maximum excretion rate of salicylamide sulfate in control experiments and the increase in that rate with Solution C (Fig. 4). A similar negative correlation was found with respect to the fraction of the dose excreted as salicylamide sulfate ($r = -0.768$), but it was not statistically significant because of one unusual value. There was no apparent correlation between the relative increase in riboflavin bioavailability and in the fraction of salicylamide sulfate produced by concomitant administration of Solution C in the individual subjects ($r = 0.177$).

DISCUSSION

Gastric emptying can be a major determinant of the drug absorption rate, and individual variations in the rate of drug absorption from any one dosage form may be due largely to differences in the rate of gastric emptying (15). The very slow absorption of caffeine from Solution C, relative to its absorption from coffee and tea (1), suggested that this beverage may have a pronounced inhibitory effect on gastric emptying. This supposition was strengthened by the fact that two major ingredients of Solution C, sugar and phosphoric acid, are known to inhibit gastric emptying in hu-

mans (2, 3). The similarity of the composition of Solutions C and E, an antiemetic product, provided additional indirect support for this theory and suggested that the mechanism of the antiemetic effect of both products is an inhibition of gastric motility.

A change in the gastric emptying rate can, by modifying the rate of absorption, alter the time course of drug concentrations in the body. If drug biotransformation involves one or more saturable processes, changes in drug absorption kinetics can alter the metabolic fate of a drug (16). Examples of such absorption rate-dependent quantitative changes in biotransformation are the conjugation of salicylamide with sulfate (14) and the acetylation of p-aminobenzoic acid (17) and p-aminosalicylic acid (18). It is appropriate, therefore, to assess possible effects of beverages, diseases, drugs, and other modalities on the gastric emptying rate in terms of their pharmacokinetically most relevant aspects: the magnitude of change in the absorption and biotransformation of drugs with saturable absorption or biotransformation characteristics. This purpose was served by riboflavin and salicylamide in this investigation.

The results of this investigation demonstrate that the type of beverage taken with a medicinal agent may modify appreciably its absorption. This can obviously affect the onset, intensity, and time course of drug action. An additional implication, although speculative, is that the beverage taken with drug products in bioavailability studies may affect the results obtained *relative* to the standard product. It is known, for example, that a decrease in GI motility can bring about an increase in the bioavailability of incompletely absorbed digoxin tablets while having no effect on the bioavailability of a digoxin solution (19). Small differences in pH or agitation intensity can have a pronounced effect on the relative dissolution rate of a drug in different tablet formulations (20, 21). Changes in the gastric emptying rate will affect the length of time of exposure of tablets to the low pH and mild agitation conditions of the gastric environment and the much higher pH and more intensive agitation in the small intestine.

Finally, the results of this study show that both Solutions C and E inhibit gastric motility and suggest that this may be the mechanism of their antiemetic effect. The effectiveness of Solution T, which contains phosphoric acid but no sugars, and the greater effectiveness of Solution C show that both sugar and phosphoric acid contribute significantly to the inhibition of gastric emptying observed in this investigation.

Preliminary Investigations of Intrinsic and Extrinsic Optical Activity as Purity Criterion for Human Serum Albumins

J. H. PERRIN * and J. J. VALLNER ‡x

Abstract □ Induced circular dichroism measurements were made to follow the binding of four acidic drugs to two lots of crystalline and two lots of fraction V human serum albumins. The magnitude of the induced circular dichroism varied with all lots of albumin, suggesting a strong sensitivity of the phenomenon to small changes in purity or secondary structure of the albumins. The circular dichroism of the albumins themselves showed much less variation. The more classical analytical techniques of UV absorption, measurement of absorption following methyl orange binding, gel electrophoresis, and ultracentrifugation were also performed on the albumins for comparison.

Keyphrases □ Albumins, human serum—intrinsic and extrinsic optical activity as a purity criterion, circular dichroism compared to other techniques □ Optical activity, intrinsic and extrinsic—purity criterion for human serum albumins, circular dichroism studies □ Circular dichroism—intrinsic and extrinsic optical activity as a purity criterion for human serum albumins, binding of four acidic drugs

Dicumarol has been shown to become optically active on binding to human serum albumin (1, 2). During a quantitative investigation of this binding, it was found that the shape and magnitude of the induced circular dichroism (CD) curves varied with the lot of albumin (2). Therefore, it was decided to investigate the curves generated by four planar and acidic drugs, dicumarol, sulfaethidole, phenylbutazone, and flufenamic acid, following the binding of two new lots of crystalline and two new lots of fraction V human serum albumin to see whether the phenomenon is purity related.

The CD curves of the albumins themselves were also investigated. More classical analytical techniques such as ultracentrifugation, gel electrophoresis, UV absorption, and absorption following methyl orange binding were performed on these albumins for comparison.

EXPERIMENTAL

Materials—Dicumarol[1] USP, flufenamic acid[2], and phenylbutazone[3] were used as supplied. Sulfaethidole[4] was recrystallized twice from water, mp 185–186°. All other materials were reagent grade, and deionized water was used throughout. Two lots of crystalline and two lots of fraction V human serum albumins were obtained from leading manufacturers. They were stored, refrigerated, and desiccated under identical conditions and were used as supplied by the manufacturers.

Methods—All CD spectra were obtained in a 6003 CD attachment to a spectropolarimeter[5] with a slit programmed for a half bandwidth of 15 Å. All measurements were made in 0.054 *M* sodium phosphate buffer, pH 7.4, adjusted to isotonicity with sodium chloride. All solutions were scanned in 10- or 20-mm cells from regions of high wavelength having no ellipticity to the lower limit of the system.

All albumin samples were subjected to sodium lauryl sulfate gel electrophoresis, similar to that described by Weber and Osborn (3). The samples were dissolved in 0.01 *M* sodium phosphate buffer, pH 7.0, containing sodium lauryl sulfate and 1% β-mercaptoethanol, and were heated at 37° for 2 hr. Electrophoresis was carried out at 3 mamp/gel for 18 hr with the anode in the lower chamber. Gels were then stained for 4 hr with 0.25% Coomassie brilliant in 50% methanol and 9.2% acetic acid; destaining was accomplished by diffusion in 5% methanol and 9.2% acetic acid.

Sedimentation velocity experiments were carried out at 20° in an analytical ultracentrifuge[6]. A Kel F cell with a sapphire window was used in these runs, carried out at 68,000 rpm on 0.9% albumin solutions. The schlieren optical system was used to record the rate of change in the refractive index of the sample as a function of distance from the rotor's axis of rotation.

Spectrophotometric[7] measurements were made in silica cells of 10-mm path length. For the determination of the albumins by methyl orange, the original method of Bracken and Klotz (4) was modified in that twice as much methyl orange was used and measurements were made at 535 and 550 nm.

Table I—$E^{1\%}_{1\,cm}$ of pH 7.4 Solutions of the Albumins

Sample	Absorbance, nm	
	279	210
A, fraction V	5.85	157
B, fraction V	6.13	168
C, crystalline	6.36	190
D, crystalline	3.85	136

Table II—Percentage Purity of Albumins Using the Methyl Orange Method of Bracken and Klotz (4), Taking Sample C as the Standard

Sample	Purity, %	
	550 nm	534 nm
A	96	98
B	99	98
C	100	100
D	72	72

RESULTS AND DISCUSSION

UV Characteristics—The absorbances of 1% solutions of the albumins in 1-cm cells at 279 and 210 nm are shown in Table I. Sample D gave a significantly lower absorption than the others, and this crystalline sample repeatedly behaved as if it contained 25% of a nonabsorbing impurity, perhaps an inorganic salt used in the purification procedures. Even if Sample D is omitted, there was still almost a 10% fluctuation in the absorbances at 279 nm.

Most literature reports give a figure of $E^{1\%}_{1\,cm}$ for "pure" serum albumin of 5.30–5.80 (5–7). The absorption in this region is primarily due to the aromatic amino acid residues. Therefore, contamination due to globulins, which contain more aromatic amino

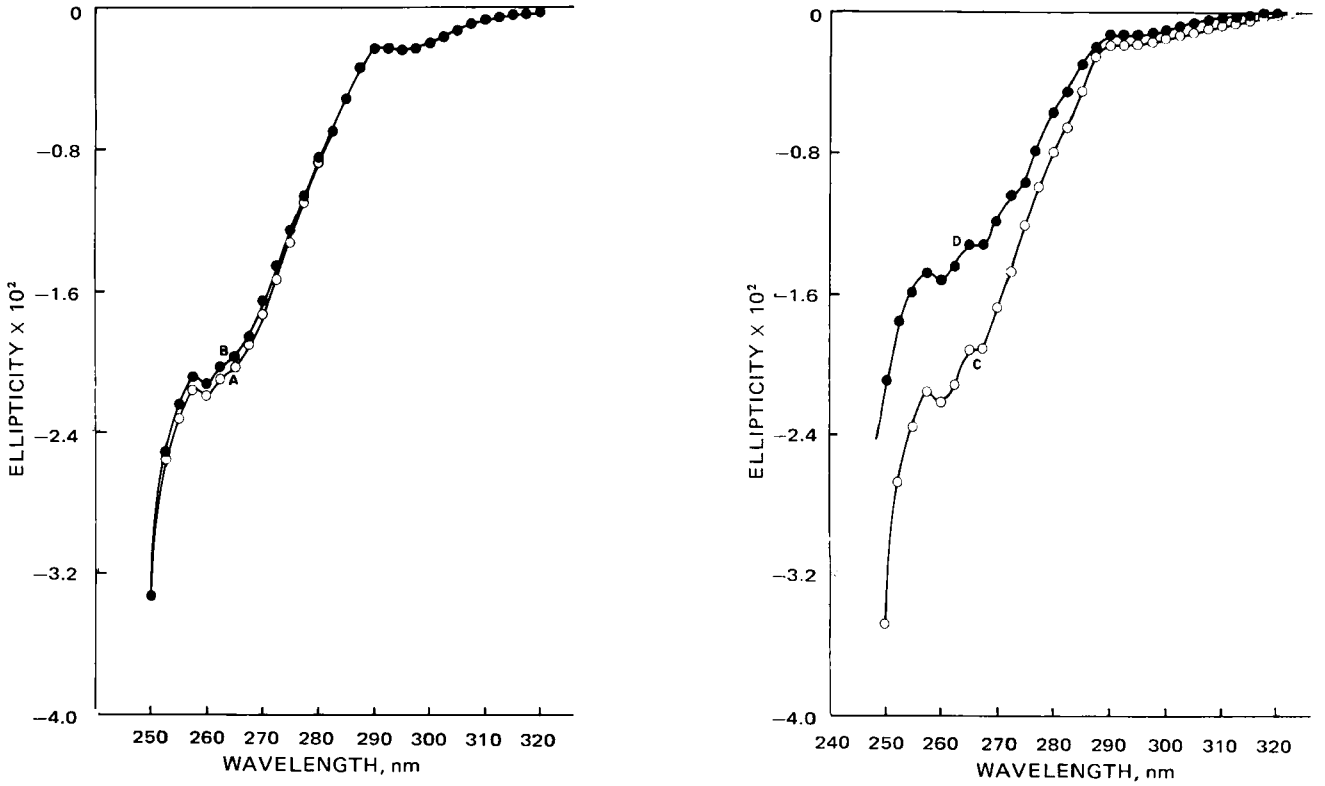

Figure 1—*CD curves of albumin samples alone in the 250–300-nm region. Human serum albumin concentration is 0.2% (2.9 × 10^{-5} M) in 10-mm cells at pH 7.4. (See Table I.)*

acids than do albumins, results in an increased absorbance at this wavelength. Any aromatic impurity acquired during the extraction or purification process or added as a stabilizer also contributes to the absorbance in this region.

Globulins and albumins have been reported to have similar UV absorbances at 210 nm, and a pure sample of albumin was reported to have an $E^{1\%}_{1\,cm}$ of 190 (5). This value was obtained with the crystalline Sample C. The fraction V samples gave significantly lower values than 190. The UV spectrum at 210 nm resulted from aromatic residues and contributions from peptide linkages. The latter contributions are from both the primary and secondary structures of the protein.

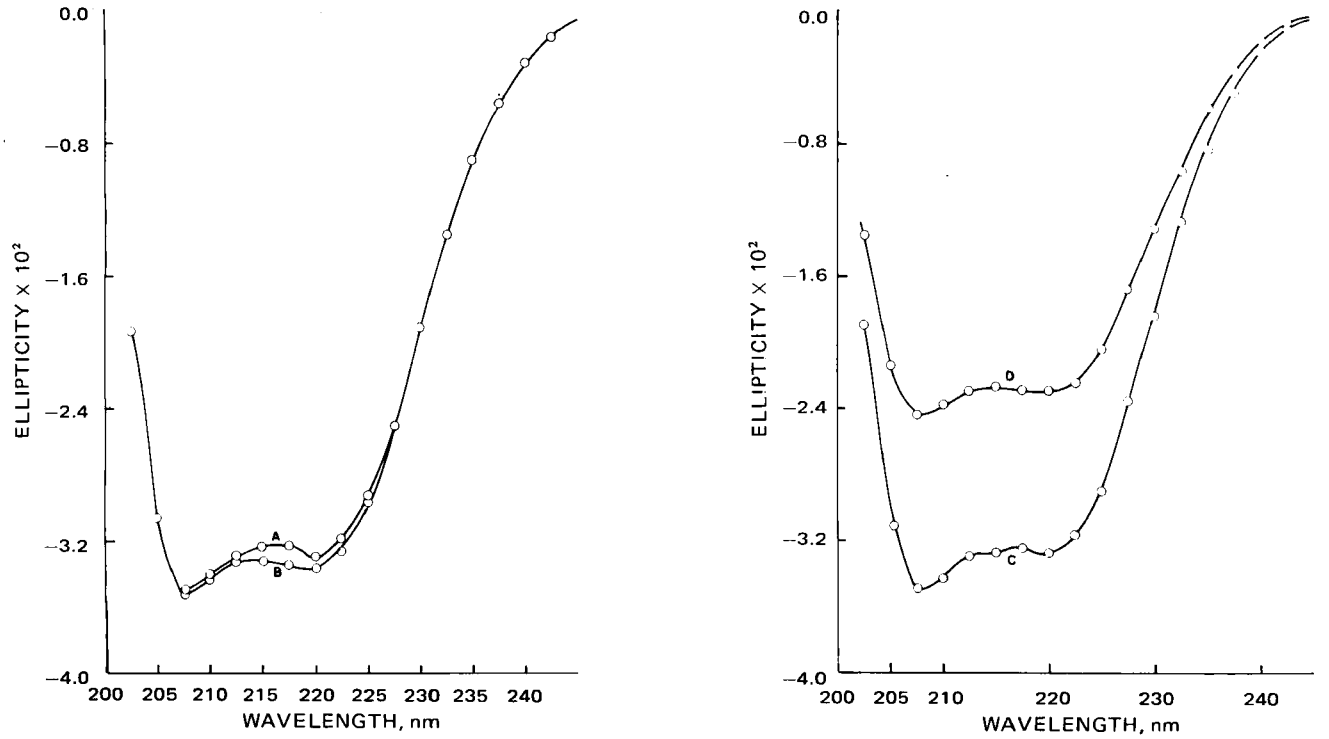

Figure 2—*CD curves for the four albumins in the 200–250-nm region. Human serum albumin concentration is 0.001% (1.45 × 10^{-7} M) in 20-mm cells at pH 7.4. (See Table I.)*

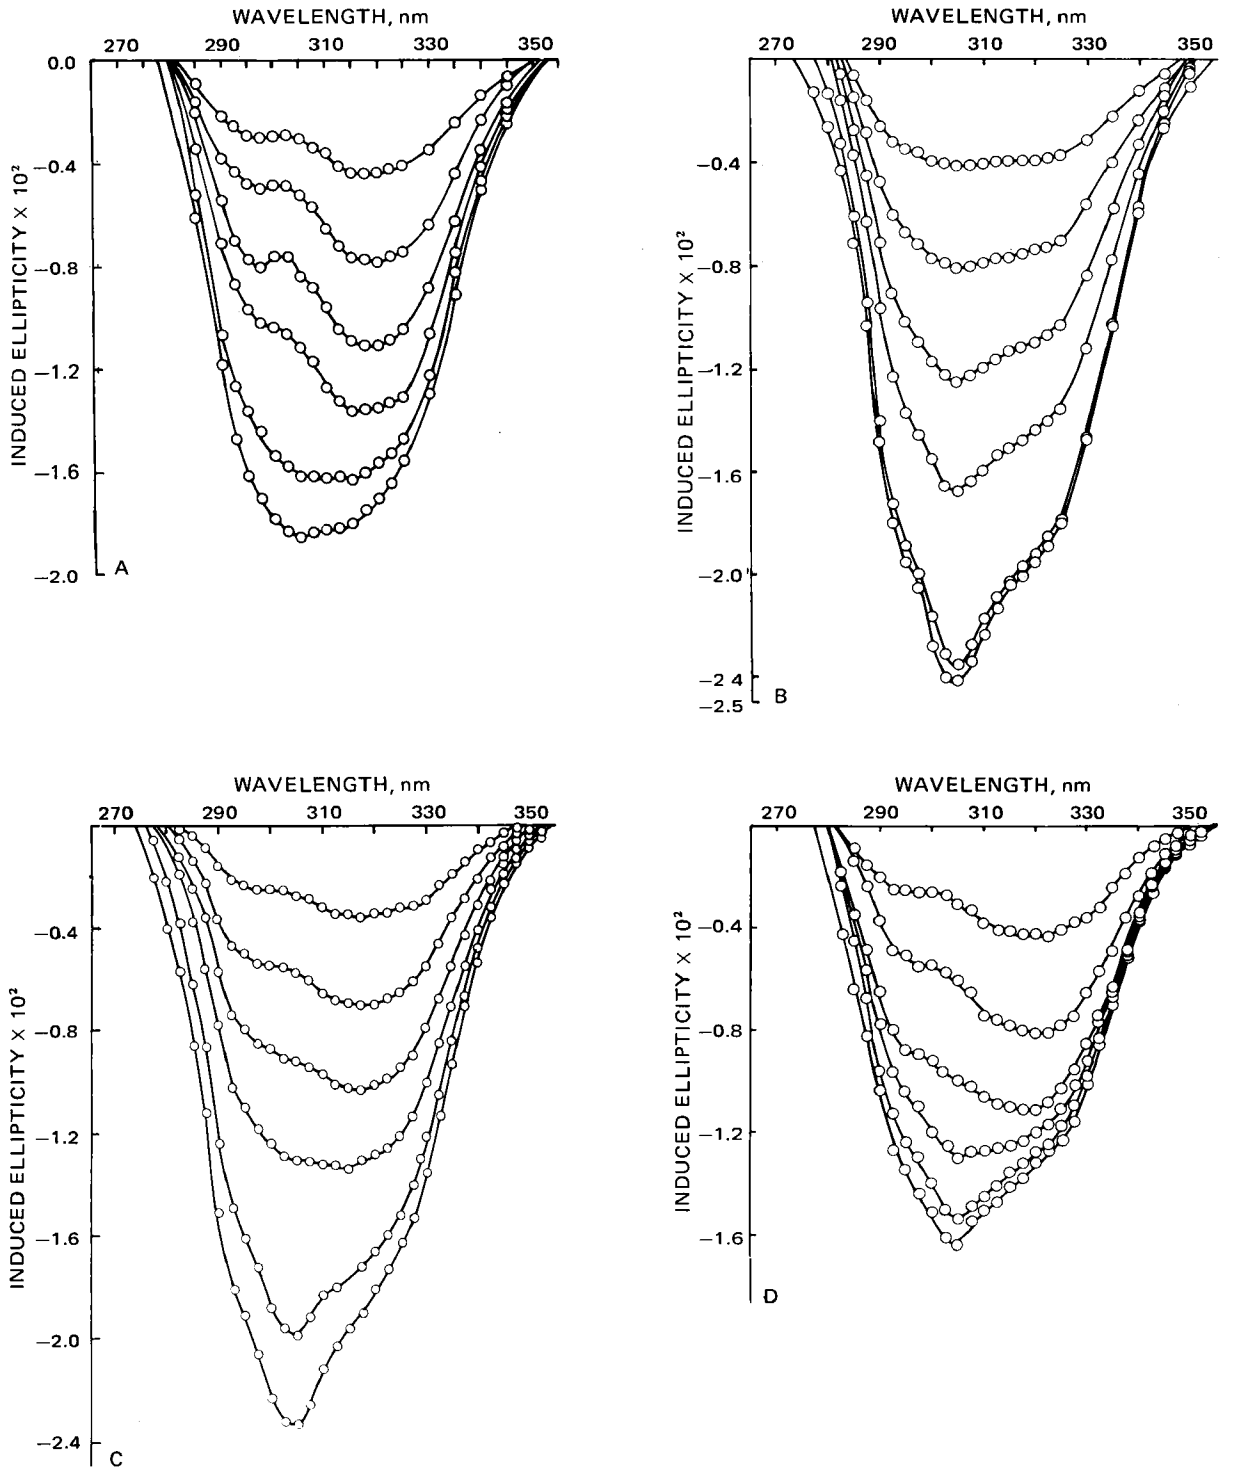

Figure 3—*Induced CD of dicumarol with the four albumin samples. (See Table I.) Human serum albumin concentration is 1.45 × 10⁻⁵ M in 10-mm cells at pH 7.4. Dicumarol concentrations are 0.743, 1.48, 2.23, 2.96, 4.46, and 5.92 × 10⁻⁵ M.*

The decreased absorbance following reaction with methyl orange was measured at 550 and 535 nm. The percentages are expressed taking Sample C as the standard, because this sample gave the largest decrease in absorbance (Table II). Methyl orange does not react with globulins (5). This method, involving the reaction with dyes, is greatly superior to the UV measurement of the albumins, but it demands a correct choice of an albumin standard and it may not be sensitive to changes in the secondary structure of the albumins.

CD Characteristics—CD in the 250–300-nm region is due to the aromatic residues in the primary structure of albumin. As evident from Fig. 1, there is considerable fine structure present in this region due to contributions from various electronic transitions associated with phenylalanine, tryptophan, tyrosine, and histidine residues. Samples A, B, and C were virtually superimposable over this wavelength region, suggesting that they had similar concentrations of albumin. However, Sample D, as expected, showed decreased ellipticity of approximately 30%.

The 200–250-nm region is frequently regarded as being due to the secondary structure of the protein. However, it contains contributions from the aromatic residues as well. The spectra of Samples A, B, and C in this region were again virtually superimposable, having peaks near 220 and 208 nm (Fig. 2). Greenfield and Fasman (8) suggested that the percentage of α-helix in a protein, using

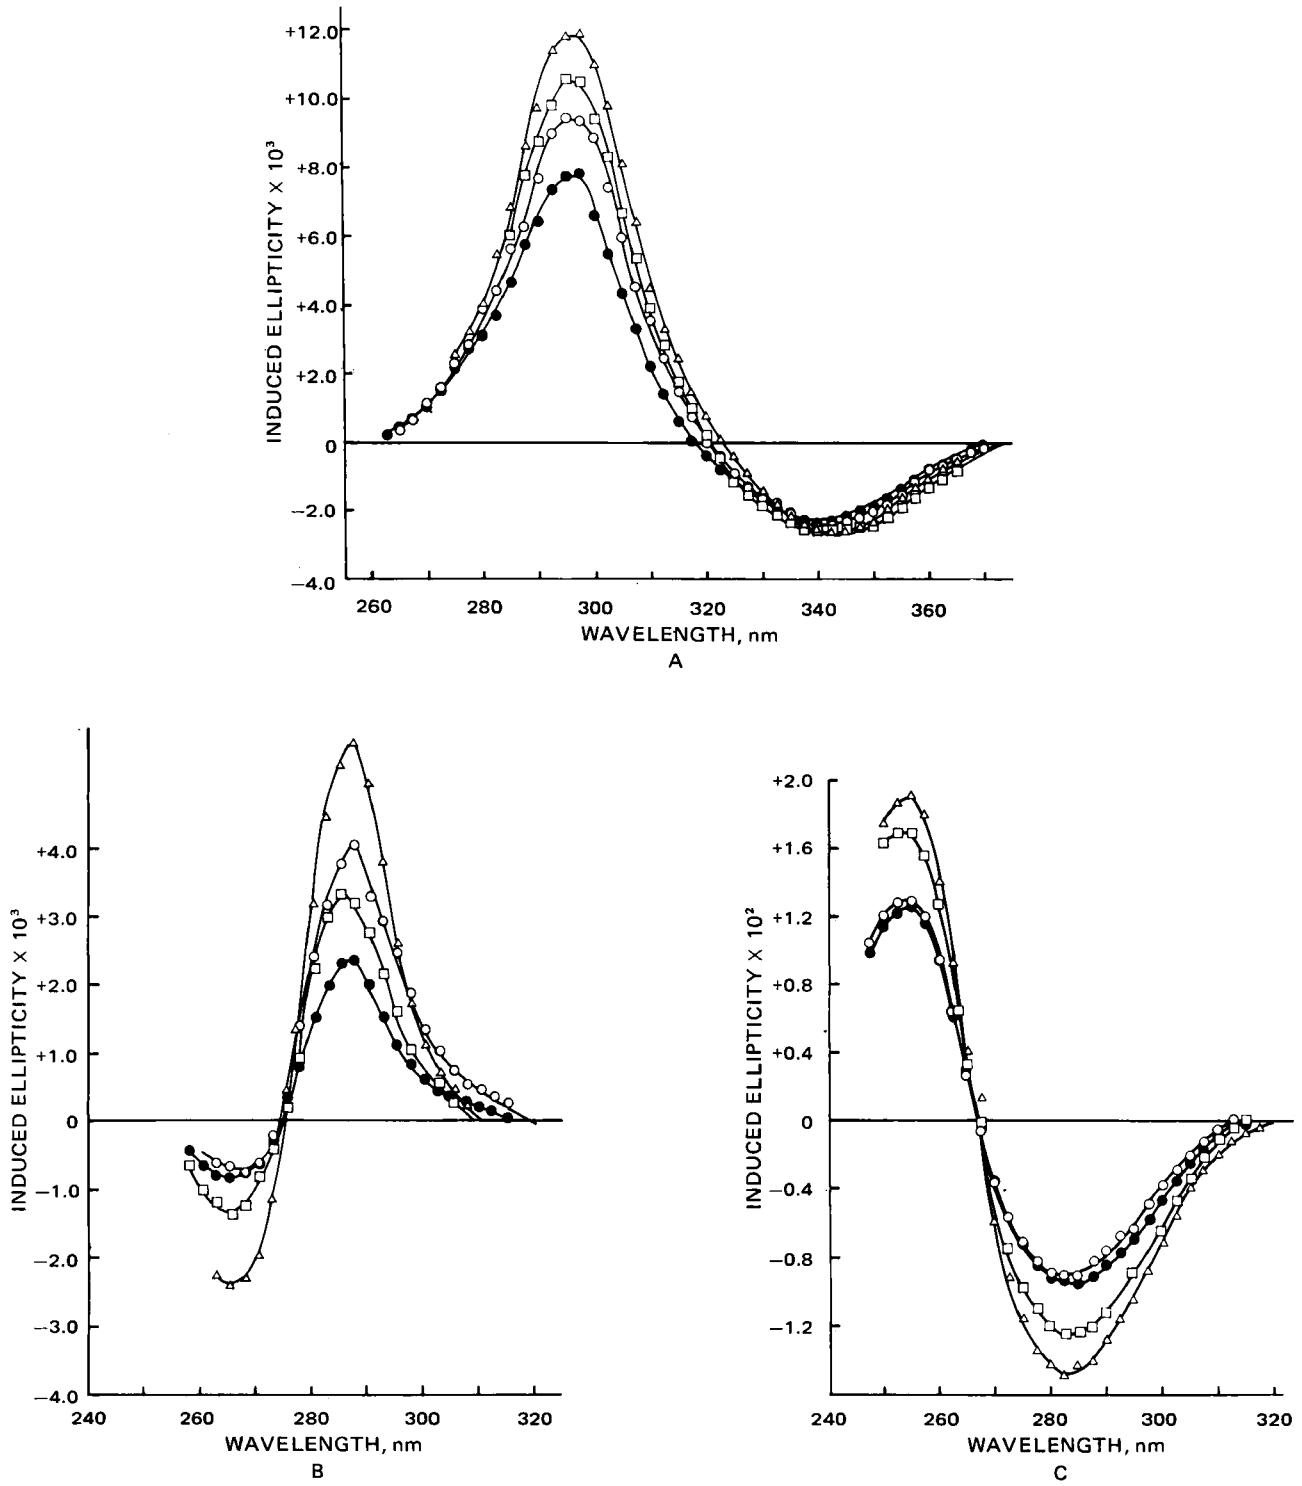

Figure 4—*Induced CD of flufenamic acid (A, 5 × 10^{-5} M), phenylbutazone (B, 2.59 × 10^{-5} M), and sulfaethidole (C, 1.27 × 10^{-5} M) with the four albumin samples. Human serum albumin concentration is 1.45 × 10^{-5} M in 10-mm cells at pH 7.4. Key: ●, albumin A; ○, albumin B; △, albumin C; and □, albumin D.*

poly-L-lysine as a model, is given by:

$$\% \ \alpha\text{-helix} = \frac{-[\theta]_{208} - 4000}{33{,}000 - 4000} \times 100 \qquad \text{(Eq. 1)}$$

Using a mean residue molecular weight of 113 for human serum albumin and substituting in this formula give the data shown in Table III. Samples A, B, and C had essentially the same helical content. The shape of the CD spectra was consistent with the remainder being primarily in the random coil conformation rather than being the β-structure (7). Sample D had the same shape CD curve, but it was of greatly reduced intensity due to the presence of nonabsorbing and nonoptically active impurities. This finding suggests that there had been no macrodenaturation of the albumins during their preparation.

Induced CD—Figures 3 and 4 show the induced CD of the four drugs following their binding to the various albumin samples. The resultant binding curves were apparently sensitive to impurities or a localized denaturation of the albumin. The four sets of dicumarol–albumin curves showed no new peaks; however, the shape of

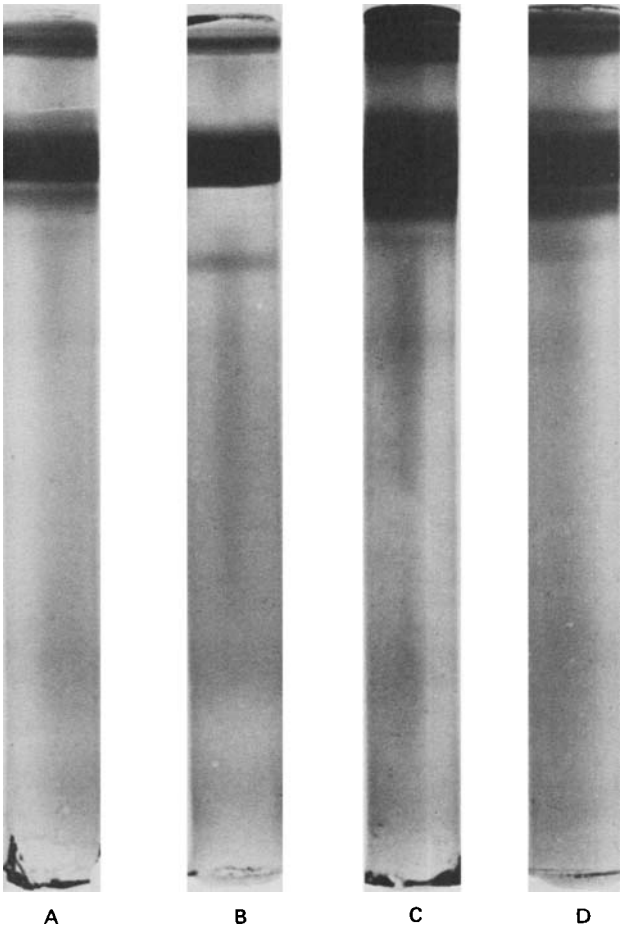

Figure 5—*Sodium lauryl sulfate gel electrophoresis. The letters refer to the albumin samples.*

the induced curves was different, as were their concentration dependencies. The curves of albumin Sample A–dicumarol gave characteristics similar to the fraction V sample used in earlier work (2). The widely different concentration dependence of the peak heights is immediately apparent on comparison of Samples A and B. The two crystalline samples (C and D) gave similar shaped curves when corrections were made for the impurity present in Sample D.

Figure 4 shows the induced CD of flufenamic acid, sulfaethidole, and phenylbutazone when bound to the various albumin samples. Curves obtained with Sample D were continually lower in peak height, and this problem appears to be entirely a concentration effect. The curves obtained with sulfaethidole (Fig. 4C) were similar for both fraction V samples, but the small differences between the two were reproducible; however, both curves were much smaller than the curves seen with the crystalline albumins.

The shape of the sulfaethidole-induced CD was concentration independent, and only one class of site was capable of inducing optical activity[8]. When sulfaethidole was bound to crystalline and fraction V samples of bovine serum albumin, the induced curves were similar in size and the binding parameters were of about equal value (9). The binding curves of flufenamic acid and phenylbutazone, which were very concentration dependent, emphasize the differences in the fraction V samples. Some small conformational change may, by slightly altering the nature of the binding process, account for the observed differences in the curves.

Gel Electrophoresis—The result of the sodium lauryl sulfate gel electrophoresis examination is shown in Fig. 5. The protein became negatively charged by the sodium lauryl sulfate and migrated toward the bottom. The gels were overloaded with protein to make apparent obvious inconsistencies between samples. It was immediately apparent that Sample B, a fraction V albumin, was of higher quality than the others tested. Samples A, C, and D had a small amount of low molecular weight material, probably about 50,000, and all samples contained a higher molecular weight material of molecular weight around 150,000. Since mercaptoethanol treatment in the presence of sodium lauryl sulfate destroys disulfide bonds (10), the dimer probably was eliminated; therefore, this high molecular weight material must have been another protein impurity.

[8] J. H. Perrin, unpublished observations.

Table III—Percentage of α-Helical Content of the Four Albumin Samples[a]

Sample	Observed Ellipticity at 208 nm × 10^2	Calculated α-Helix, %
A	3.51	55
B	3.49	54
C	3.50	54
D	2.41	33

[a] All solutions were 1.45×10^{-5} *M*; measurements were made in 20-mm cells using physiological phosphate buffer of pH 7.4.

Ultracentrifugation—Schlieren patterns developed during ultracentrifugation of the albumin samples are shown in Fig. 6. It can be seen from the areas of the peaks that Sample D contained less total protein than the other samples. Sample B showed a negligible amount of high molecular weight impurity; however, Samples A, C, and D all showed a small peak due to a high molecular weight material, possibly some albumin dimer or γ-globulin (γ-immunoglobulin G). The percentages of this high molecular weight material in the samples are given in Table IV.

CONCLUSION

The samples of albumin were assumed to be essentially free of globulins due to their method of preparation. Nevertheless, gel electrophoresis suggests the presence of a very small quantity of high molecular weight material which should not be albumin polymers. Globulins contain more aromatic residues than albumins,

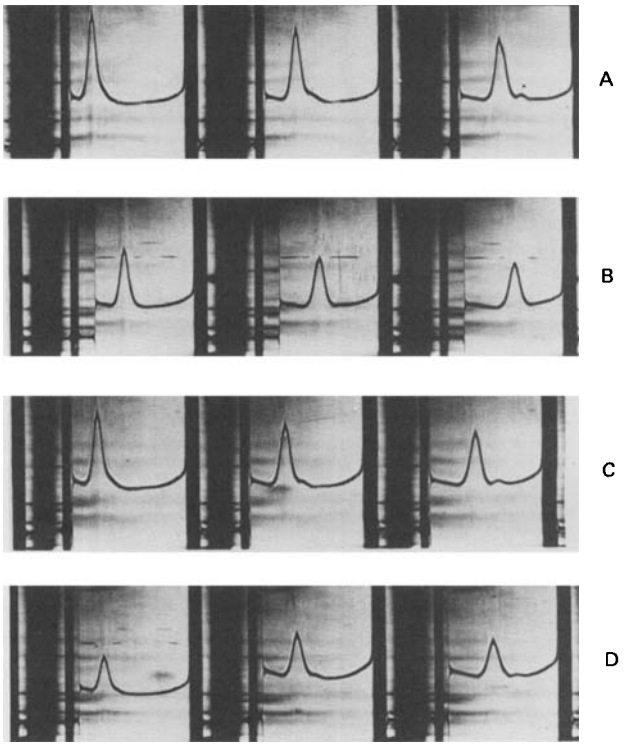

Figure 6—*Results of analytical ultracentrifugation analysis at 68,000 rpm for 2 hr. The letters correspond to the albumin samples.*

Table IV—Analysis of Impurity in Albumin Samples by Ultracentrifugation for Approximately 100 min at 68,000 rpm

Sample	Impurity, %
A	7.6
B	<1.0
C	6.5
D	7.7

and their presence would complicate the UV absorbances, particularly at 280 nm. Aromatic impurities can also arise from stabilizers and fractionating aids or as impurities in extracting solvents. The absorbance at 210 nm, although more difficult to measure, is a better analytical tool for total protein content because the main contribution at this wavelength is from the peptide bond.

There does not appear to be extensive literature on the binding of anionic drugs to other components of human serum such as globulins or lipoproteins. The anionic dye, methyl orange, does not appear to bind to γ-globulin (4, 11), but it has been reported to bind to β-lipoprotein as strongly as it does to albumin (12). It has also been reported that molecular aggregation of albumin in solution has no effect on its methyl orange binding capacity (5) whereas heat denaturation does (13).

The induced CD curves seem to be very sensitive to either impurities (perhaps lipoproteins, globulins, or albumin dimers) or minor changes in conformation. The effect of a high molecular weight impurity can best be seen when curves B and C are compared (Fig. 3). These albumins gave the largest induced CD with dicumarol, but C contained much more impurity than B. Therefore, the difference was probably not due to the impurity. Significant differences in shape and concentration dependence are evident in all CD curves of the dicumarol–albumin complexes. With the other drugs investigated, all albumins gave similarly shaped curves, but they exhibited variations in the magnitude of the induced signals.

CD curves of Samples A, B, and C in the 250–300-nm region were similar and showed considerable fine structure due to aromatic moiety contributions. These findings suggest that these albumin samples are of similar total albumin concentration. In the lower wavelength region, where the induced CD is primarily from secondary structure, the curves were again similar and suggest a helical content of about 55%; however, the small and reproducible differences shown may well be significant.

Small but locally significant conformational changes cannot be easily examined by CD since the technique measures the average contribution over the whole albumin molecule. Such small changes in the binding site region could well explain the differences observed and could be the results of variations in solvent or possibly heat treatment during the albumin extraction process. It is apparent that during any binding study, particularly if of a quantitative nature, a single lot of albumin should be used. Moreover, established analytical techniques such as reaction with biuret (14) or phosphotungstophosphomolybdate (15) or spectrophotometric color determination with bromcresol green (16), bilirubin (5), or methyl orange (4) should be used to check for gross contamination as was found with Sample D.

CD of albumins alone or in conjunction with a molecule giving extrinsic Cotton effects may be an extremely sensitive technique for assessing the quantity and quality of albumin samples. In any quantitative investigations using crystalline or fraction V albumins, an investigator should use a single lot of albumin.

Synthesis of *dl*-4ξ-(4-Carboxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo-[3,4-*d*]imidazol-2-one (*N*-Carbethoxyazabiotin)

HENRY C. WORMSER ˣ and HANLEY N. ABRAMSON

Abstract □ The total synthesis of *dl*-4ξ-(4-carboxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (*N*-carbethoxyazabiotin) by a 16-step sequence, starting from 2-bromo-6-methoxyhexanoic acid, has been accomplished.

Keyphrases □ *dl*-4ξ-(4-Carboxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one—16-step synthesis from 2-bromo-6-methoxyhexanoic acid □ *N*-Carbethoxyazabiotin—16-step synthesis from 2-bromo-6-methoxyhexanoic acid □ Biotin derivatives—16-step synthesis of *N*-carbethoxyazabiotin □ 2-Bromo-6-methoxyhexanoic acid—starting material for 16-step synthesis of *N*-carbethoxyazabiotin

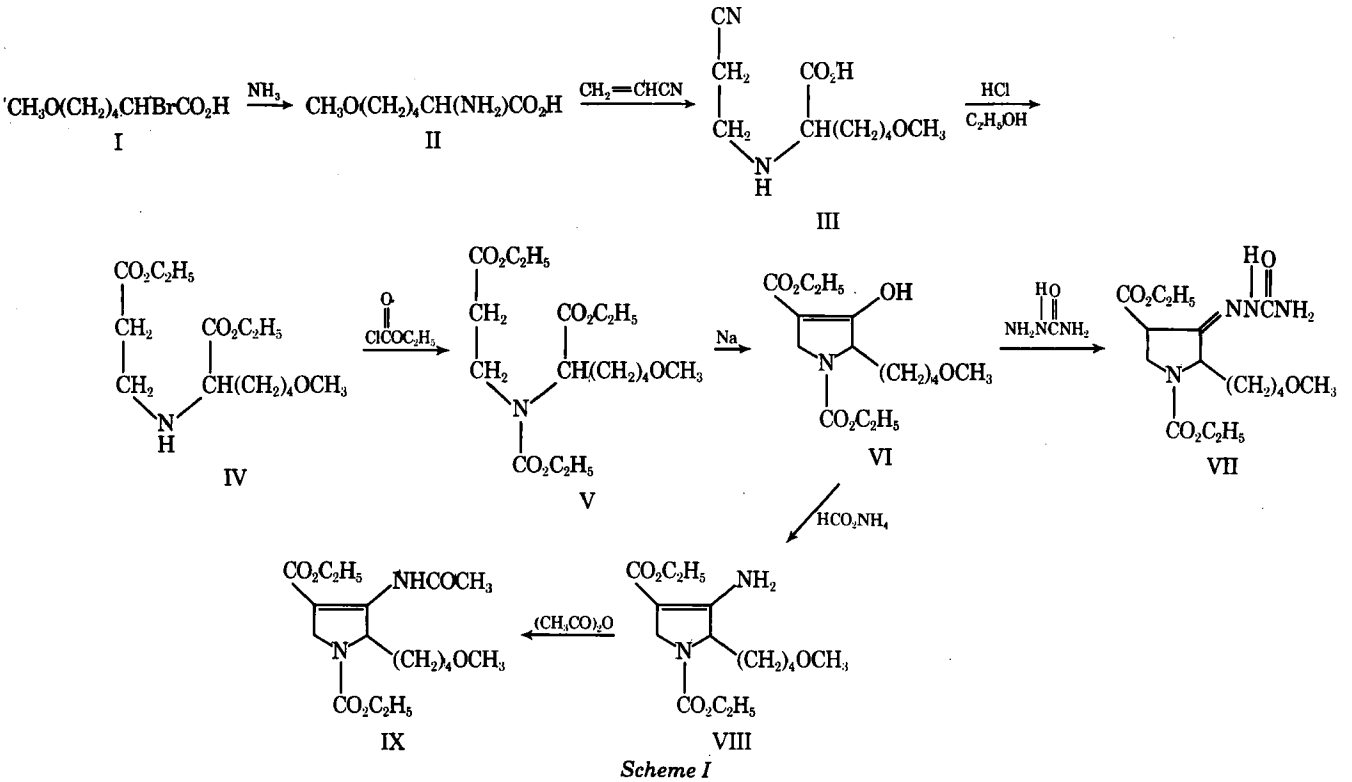
As part of a program for the development of new agonists and antagonists of biotin (1–3), a close analog of the vitamin has been synthesized in which the sulfur atom has been replaced by a nitrogen. It is yet unclear whether the sulfur atom is indeed essential for optimum activity of the cofactor, since compounds such as oxybiotin (4–6), carbobiotin (3), and desthiobiotin (7) exhibit some degree of activity as growth promoters in microorganisms.

In previous articles (1, 2), a scheme was devised for the synthesis of substituted pyrrolo[3,4-*d*]imidazole compounds. The method now has been applied in the synthesis of the title compound, *dl*-4ξ-(4-carboxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*] imidazol-2-one, hereafter referred to as *N*-carbethoxyazabiotin (XIX) (Schemes I–III).

DISCUSSION

The synthesis of XIX starts with 2-bromo-6-methoxyhexanoic acid (I), prepared by the method of Schmid (8) from 1,4-dibromobutane. The α-bromo acid was first converted to the corresponding α-amino acid (II) by treatment with concentrated ammonium hydroxide. Monocyanoethylation with acrylonitrile in aqueous base followed by ethanolysis–esterification gave the aminodiester (IV) in good yield. The amino group was protected with a carbethoxy group by treating IV with ethyl chloroformate, and a Dieckmann condensation afforded an oily pyrroline (VI) in 93% yield.

A crystalline semicarbazone (VII) of the β-keto ester (VI) was prepared to secure an analytical sample since attempts to distill the Dieckmann product only led to decomposition. Condensation of VI with ammonium formate in ethanol afforded a 96% yield of the enamine (VIII). Following acetylation with acetic anhydride at 90°, the oily pyrroline was reduced at 1000 psi of hydrogen over freshly prepared W-2 Raney nickel. Reduction at lower pressures (Parr apparatus) was very slow and incomplete, and reduction utilizing platinum as the catalyst failed completely. A crystalline 3,4-*cis*-pyrrolidine (X) was obtained in 40% yield from the Raney nickel reduction.



Scheme I

Hydrazinolysis of X under relatively mild conditions afforded a mixture of two products, consisting primarily of the 3,4-*cis*-hydrazide (XII*a*) and a small amount of the 3,4-*trans*-epimer (XII*b*). This latter product could also be obtained by first epimerizing X in ethanol containing catalytic amounts of ethoxide and subsequent treatment of the 3,4-*trans*-pyrrolidine (XI) with hydrazine hydrate. Because of the relatively small amount of the 3,4-*trans*-epimer by-product in the crude hydrazide product, no attempt was made to purify the mixture for the next step and it was found suitable as such.

Conversion to the azide, followed by Curtius rearrangement, gave the pyrrolo[3,4-*d*]imidazole (XIII) as a dark oil. Cleavage of the side-chain methoxy group without additional damage to the ring system proved somewhat problematic. Attempts with 48% hydrobromic acid in acetic acid, concentrated hydrochloric acid, and the mixed anhydride acetyl *p*-toluenesulfonate (9) failed to afford a suitable product either by giving unresolvable resinous mixtures or by failing to alter the starting material at all. A solution of XIII in acetic anhydride containing boron trifluoride etherate finally afforded the triacetyl compound (XIV) along with small quantities of the *N,N*-diacetyl ether (XIV*a*).

Room temperature hydrolysis of XIV in 48% hydrobromic acid gave the carbinol (XV), which was converted to the homologous nitrile (XVII) *via* the mesylate (XVI). Ethanolysis of the nitrile to the ester (XVIII) followed by base hydrolysis gave the title compound (XIX). Although XIII–XVIII were obtained as noncrystalline, nondistillable oils, spectroscopic data for these compounds were in agreement with the assigned structures.

EXPERIMENTAL[1]

2-Amino-6-methoxyhexanoic Acid (II)—2-Bromo-6-methoxyhexanoic acid (I) (8) (225 g, 1.0 mole) was treated with 3 liters of concentrated ammonium hydroxide and allowed to stand at room temperature for 24 hr. The solution was concentrated to about one-quarter volume, and the precipitated crystals were collected by suction filtration and gave 125.0 g, mp 269–271°. An additional 21.0 g, mp 269–271°, was obtained from the mother liquor. Recrystallization from ethanol gave 129.5 g (80%), mp 272–274°. IR: λ_{max} (mineral oil) 3.75, 3.87, and 6.05 μm.

Anal.—Calc. for $C_7H_{15}NO_3$: C, 52.17; H, 9.38; N, 8.69. Found: C, 52.29; H, 9.25; N, 8.78.

2-(2-Cyanoethylamino)-6-methoxyhexanoic Acid (III)—Compound II (129.0 g, 0.80 mole) was dissolved in 600 ml of water and treated with a solution of 32.0 g (0.80 mole) of sodium hydroxide in 200 ml of water, followed by 42.5 g (0.80 mole) of acrylonitrile, while stirring magnetically in an ice bath. Dropwise treatment with 46 ml (0.80 mole) of acetic acid gave a white precipitate. The product was filtered and washed with ether–ethanol followed by ether. The mother liquor was concentrated, filtered, and similarly washed. The total yield amounted to 140.0 g (82% yield), mp 218–224°. Two recrystallizations from ethanol–water gave an analytical sample, mp 220–222°; the melt resolidified at 222–223° and remelted at 249–252° dec.; IR: λ_{max} (mineral oil) 4.44 μm.

Anal.—Calc. for $C_{10}H_{18}N_2O_3$: C, 56.05; H, 8.47; N, 13.08. Found: C, 56.11; H, 8.41; N, 13.13.

Ethyl 2-(2-Carbethoxyethylamino)-6-methoxyhexanoate (IV)—A solution of 140.0 g (0.65 mole) of III in 500 ml of absolute ethanol was treated with dry hydrogen chloride gas for 8 hr while stirring in an ice bath. After refluxing the reaction mixture for 1 hr, the ethanol was removed *in vacuo*. The residue was dissolved in water and cooled in an ice bath. The cold solution was treated with 10% ammonium hydroxide to pH 9. The oil was extracted into ether. The ether extract was washed with saturated sodium chloride, dried (sodium sulfate), and concentrated to give 149.0 g (79%) of colorless liquid; IR: λ_{max} (neat) 2.91, 3.00, 5.82, and 8.50 μm. The product was considered suitable for conversion to the carbamate (V).

Ethyl 2-[*N*-(2-Carbethoxyethyl)-*N*-carbethoxy]amino-6-methoxyhexanoate (V)—To a solution of 149.0 g (0.52 mole) of IV in 400 ml of chloroform, cooled in an ice bath, was added dropwise 66.5 g (0.62 mole) of ethyl chloroformate followed by a solution of 28.0 g (0.26 mole) of sodium carbonate in 100 ml of water. After stirring in the cold for 2 hr, the reaction mixture was heated at 60° for 1 hr. The chloroform layer was separated, washed with water, dried (magnesium sulfate), and concentrated. Distillation gave 159.0 g (85%) of a colorless liquid, bp 147–150° (0.12 mm); IR: λ_{max} (neat) 5.81 and 5.92 μm; NMR: δ 1.26 (9H, t, $-OCH_2CH_3$, J = 7 Hz), 2.67 (1H, t, $-CH_2CHN(C{=}O)-$, J = 7 Hz), 3.36 (3H, s, OCH_3), 3.46 (2H, t, $-OCH_2CH_2-$, J = 6 Hz), and 4.20 (9H, q, $-COOCH_2CH_3$, J = 7 Hz).

Anal.—Calc. for $C_{17}H_{31}NO_7$: C, 56.50; H, 8.65; N, 3.88. Found: C, 56.36; H, 8.74; N, 3.96.

1,4-Dicarbethoxy-2-(4-methoxybutyl)-3-hydroxy-3-pyrroline (VI)—A suspension of 12.2 g (0.53 mole) of sodium in 500 ml of toluene was heated at reflux and treated with a solution of 159.0 g (0.44 mole) of V in 600 ml of toluene. When the addition was complete, the reaction mixture was refluxed overnight. While cooling in an ice bath, the mixture was treated dropwise with a solution of 65 ml of acetic acid and 250 ml of water. The mixture was extracted with chloroform. The organic layer was washed with water, dried, and concentrated to yield 129.0 g (93%) of a brown oil; IR: λ_{max} (chloroform) 5.73, 5.85 (sh), 5.90 (sh), 6.00, and 6.15 (sh) μm; UV: λ_{max} (ethanol) 250 and 280 nm; addition of base gave λ_{max} 278 nm. The copper chelate had a melting point of 61–65° after recrystallization from ether.

The pyrroline (VI) was converted to its semicarbazone (VII), mp (analytical sample) 158–161° (from ethanol–water).

Anal.—Calc. for $C_{16}H_{28}N_4O_6$: C, 51.60; H, 7.58; N, 15.04. Found: C, 51.79; H, 7.54; N, 15.01.

1,4-Dicarbethoxy-2-(4-methoxybutyl)-3-amino-3-pyrroline (VIII)—A solution of 125.0 g (0.40 mole) of VI and 50.5 g (0.80 mole) of ammonium formate in 2 liters of absolute ethanol was refluxed for 4 hr. The solvent was removed *in vacuo*, and the residue was partitioned between water and chloroform. The organic layer was washed with water, dried (magnesium sulfate), and concentrated to yield 120.0 g (96%) of an oil; IR: λ_{max} (chloroform) 2.88, 3.00, 5.91, and 6.09 μm; UV: λ_{max} (ethanol) 275.5 nm; NMR: δ 1.30 (6H, t, $-OCH_2CH_3$, J = 7 Hz), 3.32 (1H, s, $-OCH_3$), 3.32 (2H, t, $-OCH_2CH_2$, J = 6 Hz), 4.21 (4H, q, $-OCH_2CH_3$, J = 7 Hz), and 5.78 (2H, s, $-NH_2$).

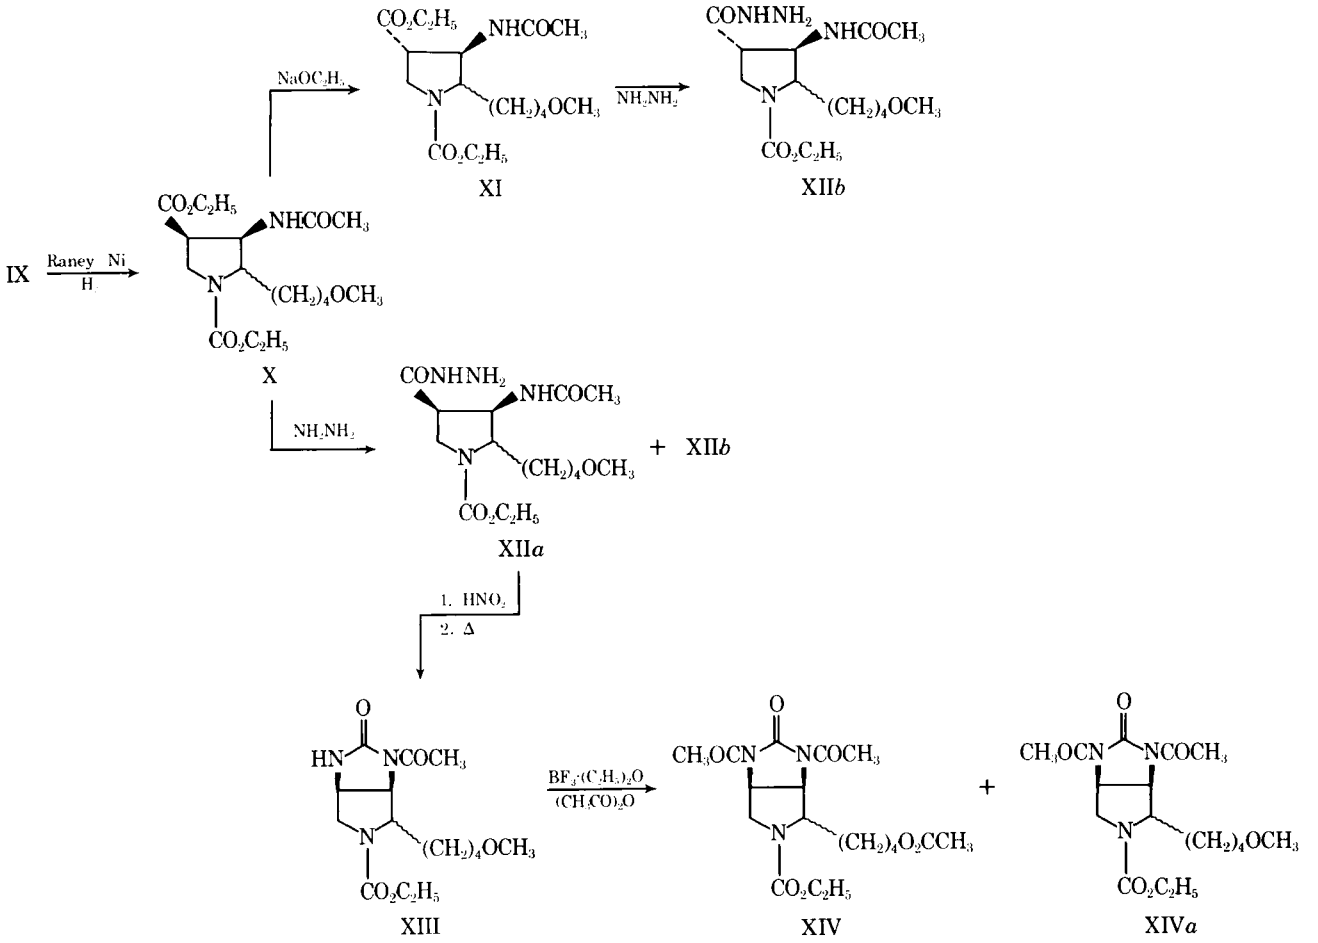
1,4-Dicarbethoxy-2-(4-methoxybutyl)-3-acetamido-3-pyrroline (IX)—A solution of 120.0 g (0.38 mole) of VIII in 300 ml of acetic anhydride was heated on an oil bath at 90–100° for 36 hr. The excess acetic anhydride was removed under high vacuum to give 135.0 g (100%) of a dark-red oil; IR: λ_{max} (chloroform) 3.10, 6.03, and 6.20 μm; UV: λ_{max} (ethanol) 275 nm; NMR: δ 1.30 (6H, t, $-OCH_2CH_3$, J = 7 Hz), 2.17 (3H, s, $-NCOCH_3$), 3.32 (3H, s, $-OCH_3$), 3.32 (2H, t, $-CH_2CH_2O$, J = 6 Hz), 4.24 (4H, q, $-OCH_2CH_3$, J = 7 Hz), and 5.67 (1H, s, —NH).

1,4-Dicarbethoxy- 2ξ- (4-methoxybutyl)-3-acetamido-3,4-*cis*-pyrrolidine (X)—A solution of 45.0 g (0.126 mole) of IX in 150 ml of absolute ethanol was treated with 25 teaspoonsful of W-2 Raney nickel catalyst and hydrogenated at 1000 psi and room temperature for 15 hr. The catalyst was filtered off, and the ethanol was evaporated *in vacuo*. The oily residue was scratched with isopropyl ether. The crystals that appeared were removed by filtration and washed with cold isopropyl ether to yield 18.5 g of 1,4-dicarbethoxy-2ξ-(4-methoxybutyl)-3-acetamido-3,4-*cis*-pyrrolidine (X), mp 95–98°. Two recrystallizations from isopropyl ether gave an analytical sample, mp 98–99°; IR: λ_{max} (chloroform) 2.91, 5.82 (sh), and 5.99 μm; NMR: δ 1.25 (6H, t, $-OCH_2CH_3$, J = 7 Hz), 2.02 (3H, s, $-NCOCH_3$), 3.36 (3H, s, $-OCH_3$), 3.36 (2H, t, OCH_2CH_2-, J = 6 Hz), 4.27 (4H, q, $-OCH_2CH_3$, J = 7 Hz), and 6.90 (1H, d, —NH, J = 5 Hz).

Anal.—Calc. for $C_{17}H_{30}N_2O_6$: C, 56.96; H, 8.44; N, 7.82. Found: C, 56.93; H, 8.40; N, 7.48.

1,4-Dicarbethoxy- 2ξ- (4-methoxybutyl)-3-acetamido-3,4-*trans*-pyrrolidine (XI)—A sample of 358 mg (1.0 mmole) of X was refluxed with 5 ml of a freshly prepared 1% sodium ethoxide

[1] Melting points were taken on a Fisher-Johns melting-point stage and a Thomas-Hoover melting-point apparatus and are uncorrected. UV absorption spectra were determined in 95% ethanol on a Beckman (model DK2A) recording spectrophotometer. IR absorption spectra were recorded on Beckman (models 8 and 33) recording spectrophotometers. NMR spectra were determined in deuterochloroform, using tetramethylsilane as reference standard, on Varian T-60 and Varian EM 360 spectrometers. Microanalyses were carried out by Spang Microanalytical Laboratory, Ann Arbor, Mich. TLC was carried out with silica gel G, silica gel $HF_{254+366}$, and silica gel $PF_{254+366}$.



Scheme II

solution for 30 min. The solvent was evaporated, and the residue was partitioned between chloroform and water. The organic layer was washed with water, dried (magnesium sulfate), and concentrated to give 325 mg (91%) of crystals of XI (the 4-epimer of X), mp 75–79°. Recrystallization from ether gave the analytical sample, mp 78–80°; IR: λ_{max} (chloroform) 2.90, 3.00 (sh), 5.82 (sh), and 5.99 μm; NMR: δ 1.26 (6H, t, $-OCH_2CH_3$, J = 7 Hz), 2.03 (3H, s, $-NCOCH_3$), 3.36 (3H, s, $-OCH_3$), 4.24 (4H, q, $-OCH_2CH_3$, J = 7 Hz), and 6.5 (1 H, broad s, NH).

Anal.—Calc. for $C_{17}H_{30}N_2O_6$: C, 56.96; H, 8.44; N, 7.82. Found: C, 56.88; H, 8.36; N, 7.76.

1-Carbethoxy-2ξ-(4-methoxybutyl)-3-acetamidopyrrolidine-4-carboxylic Acid Hydrazide (XII)—A solution of 25.0 g (0.07 mole) of X in 250 ml of absolute ethanol was treated with 50 ml of hydrazine hydrate. The mixture was heated at 45–50° for 4 hr, when TLC analysis showed the absence of starting material. The alcohol and excess hydrazine hydrate were removed *in vacuo*. The resulting product (actually a mixture of epimers consisting primarily of XII*a* with small amounts of XII*b*) weighed 24.0 g and was used directly in the preparation of XIII.

A 430-mg sample of XII was subjected to preparative TLC, utilizing 25% methanol in chloroform as the eluent. The higher R_f band gave 250 mg of a crystalline substance, mp 137–138°. Three recrystallizations from methanol–ether gave an analytical sample, mp 142–144°; IR: λ_{max} (mineral oil) 2.98, 3.02, 6.00, and 6.14 μm; NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.00 (3H, s, $-NCOCH_3$), 3.33 (3H, s, $-OCH_3$), 3.33 (2H, t, OCH_2CH_2-, J = 6 Hz), 4.15 (2H, q, $-OCH_2CH_3$, J = 7 Hz), and 7.01 (3H, m, —NH). This compound was designated as the *cis*-isomer (XII*a*).

Anal.—Calc. for $C_{15}H_{28}N_4O_5$: C, 52.31; H, 8.19; N, 16.27. Found: C, 52.23; H, 8.07; N, 16.09.

The lower R_f band yielded 72 mg of an oil, which solidified on long standing in a desiccator. The solid was recrystallized from methanol–ether, mp 125–127°; IR: λ_{max} (chloroform) 3.01 and 6.01 μm; NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.01 (3H, s, $-NCOCH_3$), 3.33 (3H, s, $-OCH_3$), 3.33 (2H, t, $-OCH_2CH_2$, J = 6 Hz), and 4.15 (2H, q, $-OCH_2CH_3$, J = 7 Hz).

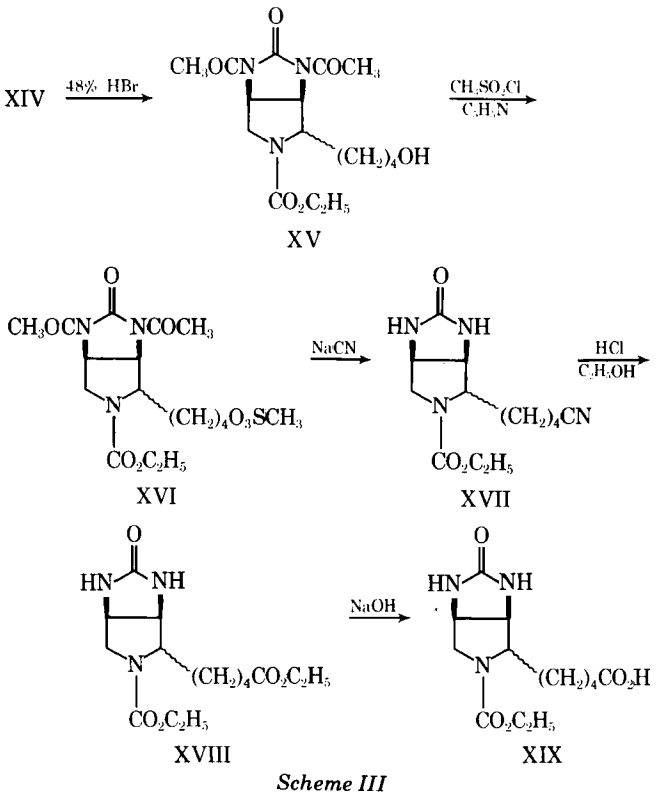
This compound was designated as the *trans*-isomer (XII*b*), since it could be readily prepared by treatment of XI with hydrazine hydrate in ethanol at room temperature.

Anal.—Calc. for $C_{15}H_{28}N_4O_5$: C, 52.31; H, 8.19; N, 16.27. Found: C, 52.13; H, 8.16; N, 16.09.

3-Acetyl-4ξ-(4-methoxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (XIII)—A solution of 24.0 g (0.07 mole) of a mixture of XII*a* and XII*b* in 300 ml of 1 *N* hydrochloric acid was cooled in an ice–salt bath and treated with a solution of 20 g of sodium nitrite in 100 ml of water. Near the end of the addition, a flocculent white precipitate formed in the reaction flask. The product was extracted with ethyl acetate several times. The extract was washed with water, dried (magnesium sulfate), and concentrated to give 20.2 g of solid acyl azide; IR: λ_{max} (chloroform) 4.65 μm. This solid was redissolved in 150 ml of ethyl acetate and refluxed on a steam bath for 3 hr. The solvent was evaporated to give 18.0 g of a dark oil; IR: λ_{max} (chloroform) 2.90, 3.05, and 6.05 μm; NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.57 (3H, s, $-NCOCH_3$), 3.34 (3H, s, $-OCH_3$), 3.34 (2H, t, $-OCH_2CH_2$, J = 6 Hz), 4.18 (2H, q, $-OCH_2CH_3$, J = 7 Hz), and 6.57 (1H, s, NH).

1,3-Diacetyl-4ξ-(4-acetoxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (XIV)—A solution of 29.0 g (0.09 mole) of XIII in 100 ml of acetic anhydride was treated with 15 ml of freshly distilled boron trifluoride etherate. The mixture was heated at 50° for 3.5 hr and then concentrated under high vacuum. The residue was chromatographed on a silica gel column, using increasing concentrations of chloroform in benzene. Elution with chloroform–benzene (3:2) gave 9.4 g of XIV as an uncrystallizable oil; IR: λ_{max} (chloroform) 5.70–5.95 μm (strong, broad); NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.04 (3H, s, $-OCOCH_3$), 2.58 (6H, s, $-NCOCH_3$), and 4.18 (2H, q, $-OCH_2CH_3$, J = 7 Hz).

Further elution of the column with chloroform–benzene (3:2)



Scheme III

gave 1,3-diacetyl-4ξ-(4-methoxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (XIV*a*) as an uncrystallizable oil; IR: λ_{max} (chloroform) 5.70–5.95 μm (strong, broad); NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.58 (6H, s, $-NCOCH_3$), 3.34 (3H, s, $-OCH_3$), and 4.18 (2H, q, $-OCH_2CH_3$, J = 7 Hz).

1,3- Diacetyl- 4ξ- (4-hydroxybutyl) -5 - carbethoxy- *cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (XV)—A solution of 9.4 g (0.024 mole) of XIV in 50 ml of 48% hydrobromic acid was stirred at room temperature for 16 hr. The water and hydrobromic acid were removed under high vacuum. The residue was chromatographed on a silica gel column, using increasing concentrations of ether in benzene. Elution with ether–benzene (1:4) gave 3.3 g of XV as an uncrystallizable oil; IR: λ_{max} (chloroform) 2.80, 2.90, 5.70, and 5.90 μm; NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.58 (6H, s, $-NCOCH_3$), 3.30 (1H, s, CH_2OH), 3.60 (2H, m, CH_2CH_2OH), and 4.15 (2H, q, $-OCH_2CH_3$, J = 7 Hz).

1,3-Diacetyl- 4ξ- (4-methanesulfonylbutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (XVI)—A solution of 1.63 g (0.0046 mole) of XV in 10 ml of pyridine was treated with 3 ml of freshly distilled methanesulfonyl chloride. The solution was allowed to stand in the refrigerator for 16 hr and the pyridine and excess methanesulfonyl chloride were removed under high vacuum. The residue was dissolved in chloroform, washed with water, dried (magnesium sulfate), and concentrated to give 1.90 g (96%) of an uncrystallizable oil; IR: λ_{max} (chloroform) 5.70, 5.92, 7.05, and 8.53 μm; NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.59 (3H, s, $-NCOCH_3$), 3.02 (3H, s, $-SO_3CH_3$), and 4.16 (2H, q, $-OCH_2CH_3$, J = 7 Hz).

4ξ- (4-Cyanobutyl)-5- carbethoxy-*cis*- hexahydropyrrolo-3,4-*d*]imidazol-2-one (XVII)—Compound XVI (1.68 g, 0.0039 mole) was dissolved in 5 ml of methanol. To this solution was added a solution of 1.62 g of sodium cyanide in 5 ml of water. The reaction mixture was diluted with 5 ml of methanol to remove the cloudiness and was then refluxed for 1 hr. After concentration to dryness *in vacuo*, the residue was partitioned between water and ethyl acetate. The ethyl acetate layer was dried (magnesium sulfate) and concentrated to an uncrystallizable oil (620 mg); IR: λ_{max} (chloroform) 2.83, 3.00, 4.40, and 5.70–6.00 μm; NMR: δ 1.26 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 4.18 (2H, q, $-OCH_2CH_3$, J = 7 Hz), 5.98 (1H, broad s, NH), and 6.50 (1H, broad s, NH).

4ξ-(4-Carbethoxybutyl)-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (XVIII)—A cold solution of nitrile XVII (0.985 g, 3.51 mmoles) in 20 ml of absolute ethanol was treated with dry hydrogen chloride gas for 2 hr while keeping the reaction flask in a salt–ice bath. The reaction mixture was allowed to reach room temperature and was refluxed for 1 hr. The precipitated ammonium chloride was filtered, and the filtrate was concentrated to dryness. The residue was dissolved in chloroform, and the extract was washed with water, dried (magnesium sulfate), and concentrated under reduced pressure to give a pale-brown oil (0.920 g, 80%); IR: λ_{max} (chloroform) 2.88, 3.08, and 5.88–6.00 μm; NMR: δ 1.27 (6H, t, $-OCH_2CH_3$, J = 7 Hz), 4.17 (4H, q, $-COOCH_2CH_3$, J = 7 Hz), 6.25 (1H, broad s, NH), and 6.40 (1H, broad s, NH).

4ξ- (4-Carboxybutyl)-5- carbethoxy-*cis*- hexahydropyrrolo[3,4-*d*]imidazol-2-one (XIX)—A 1% solution of sodium hydroxide (2 ml) was added to 100 mg (0.31 mmole) of ester XVIII. After 20 min of stirring at room temperature, dissolution of the oily ester was complete. The cooled yellow solution was acidified with concentrated hydrochloric acid, and the mixture was concentrated to dryness. Two successive recrystallizations from 95% ethanol afforded colorless crystals (35 mg, 38%), mp 192–195°; IR: λ_{max} (mineral oil) 3.07, 5.85, and 6.00 μm.

Anal.—Calc. for $C_{13}H_{21}N_3O_5$: C, 52.17; H, 7.07; N, 14.04. Found: C, 52.19; H, 6.93; N, 14.13.

Evaluation of a Convective Diffusion Drug Dissolution Rate Model

ASHOK C. SHAH [x] **and KENNETH G. NELSON** *

Abstract □ A recently introduced drug dissolution rate model based on convective diffusion was evaluated by experimentally determining dissolution rates. Alkyl *p*-aminobenzoates were used as the test compounds in a dissolution cell which promoted laminar flow of the liquid past the dissolving surface. The parameters evaluated were diffusivity, solubility, rate of shear, dissolving surface shape, and orientation of the surface relative to flow. The agreement between theory and experiment was quite satisfactory with respect to the functional dependence of the rate on these parameters as well as the actual magnitude of the rates.

Keyphrases □ Dissolution—evaluation of a convective diffusion drug dissolution rate model, evaluation of diffusivity, solubility, rate of shear, dissolving surface shape, and orientation of surface relative to flow □ Diffusion—evaluation of a convective diffusion drug dissolution rate model, alkyl *p*-aminobenzoates, discussion of various parameters □ Convective diffusion—drug dissolution rate model, experimental evaluation using dissolution rates of alkyl *p*-aminobenzoates

A convective diffusion model was introduced recently (1) to describe the phenomenon of drug dissolution rate. The equations given for the rate of dissolution, R, were:

$$R = 0.808D^{2/3}C_0\alpha^{1/3}bL^{2/3} \quad \text{(Eq. 1)}$$

for a rectangular surface of width b and length L (in the direction of flow), and:

$$R = 2.157D^{2/3}C_0\alpha^{1/3}r^{5/3} \quad \text{(Eq. 2)}$$

for a circular surface of radius r. In these equations, D is the diffusivity, C_0 is the solubility, and α is the rate of shear over the dissolving surface.

The experimental apparatus used to evaluate the applicability of the model, however, was not ideal with respect to one principle upon which the model was based. In particular, the tangential annular flow system did not facilitate the development of a well-behaved hydrodynamic boundary layer. The present report describes experimental studies on drug dissolution rates utilizing a flow system designed to produce a laminar layer over the dissolving solid. The data are evaluated in terms of the functional dependence of the experimental rate on the various parameters in Eqs. 1 and 2.

EXPERIMENTAL

A schematic diagram of the dissolution cell employed is shown in Fig. 1. It consists of two rectangular transparent plastic[1] plates, which are fastened together by bolts and wing-nuts. The top plate has a liquid entry port on one end, which opens into a rectangular channel cut into the underside of the plate. The bottom plate is recessed to accommodate the die employed in the previous study (1). When installed, the surface of the die is coplanar with the surface of the bottom plate, and the die may be oriented with either the long or short axis of the rectangular dissolving surface parallel t the direction of liquid flow. For exposing circular surfaces, th plastic die employed in the previous study was used. The bottor plate also has a vertical duct, which serves as an outlet for th flowing liquid.

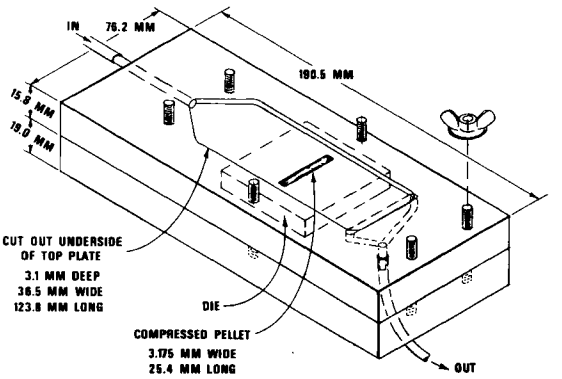

Figure 1—*Schematic diagram of the dissolution cell.*

As in the previous study (1), a compressed pellet of an alky ester of *p*-aminobenzoic acid was prepared in the metal or plasti die. The die was then placed in the recess of the lower plate, an the dissolution cell was assembled. Silicone grease was applied a the points of contact between the plates to ensure a watertigh seal. The cell was positioned on a leveled, vibration-free platform and distilled water (25°) was pumped through the cell at a set flo rate with an infusion syringe pump[2]. The effluent liquid was a sayed spectrophotometrically[3] at 285 nm for the ester. The esti concentration, together with the flow rate, permitted calculation o the experimental dissolution rate.

The solubilities of the methyl through pentyl esters of *p*-amino benzoic acid were determined by equilibrating an excess amount o each with distilled water for 2 days at 25°. After filtration and ap propriate dilution, the concentration was determined spectrophotometrically.

RESULTS AND DISCUSSION

The dissolution cell employed was designed with a relative long liquid flow channel to promote the development of lamin liquid flow in the region of the dissolving solid. To verify that su was the case, the flow visualization technique used before (1), i volving a water-soluble dye dispersed in polyethylene glycol 60C was employed. The dissolved dye displayed a wedge-shaped pa tern, which flowed over the dissolving surface as desired. The li uid flow appeared to be uniform and homogeneous.

The dependence of the experimental dissolution rate on solubi ty was studied by determining the rates for the methyl throu pentyl esters of *p*-aminobenzoic acid. The rates were determin with the long axis of the dissolving surface perpendicular to the d rection of liquid flow and with a flow rate of 5.5 ml/min. The da are shown as a log–log plot of dissolution rate *versus* solubility Fig. 2; this plot yields a least-squares slope of 0.978 and a correl tion coefficient of 0.999. This slope corresponds satisfactorily wi the slope of unity predicted by Eq. 1, assuming the diffusivities be essentially constant.

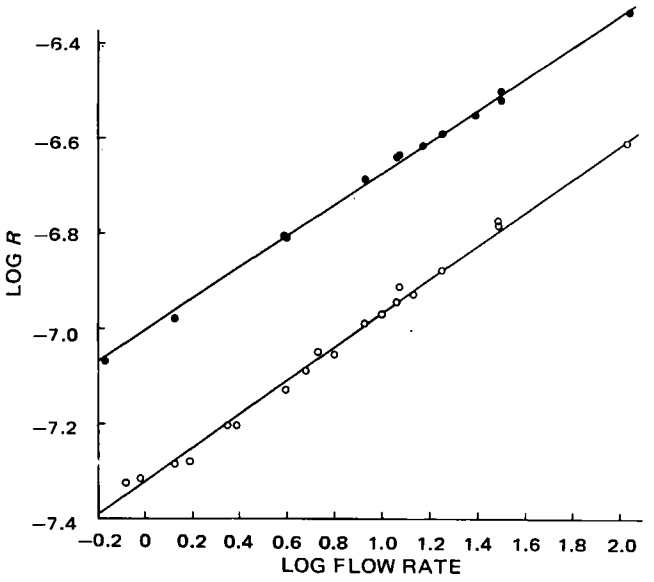

Figure 3—*Log–log plot of dissolution rate as a function of fluid flow rate.*

The effect of the rate of shear can be demonstrated by measuring the dissolution rate at various rates of flow. If the edge and end effects are neglected, the velocity profile for flow in the dissolution cell, *i.e.*, flow between two parallel planes, is parabolic in nature (2). If the limiting slope of the velocity profile at either plane is taken to be the rate of shear, then it can be shown that (see *Appendix*):

$$\alpha = \frac{6Q}{H^2W} \qquad \text{(Eq. 3)}$$

where Q is the volumetric flow rate, and H and W are the height and width, respectively, of the channel in the dissolution cell. Inasmuch as α is directly proportional to Q in Eq. 3, a plot of log R *versus* log Q should give a straight line with a slope of ~0.33 according to Eq. 1. Such a plot is shown in Fig. 3 for ethyl *p*-aminobenzoate with the long axis of the dissolving surface perpendicular to (upper curve) and parallel with (lower curve) the direction of flow. The least-squares slope of the upper curve is 0.336 with a correlation coefficient of 0.999, and the corresponding values for the lower curve are 0.359 and 0.997. The agreement between theory and experiment with respect to the functional dependence of the dissolution rate on the rate of shear is quite satisfactory.

The convective diffusion equations are based on the fluid having a uniform density; *i.e.*, natural convection is not considered. To determine whether density gradients in the vicinity of the dissolving surface might be present and influence the experimental rates in the present studies, the experiments at different flow rates were repeated with the dissolution cell inverted. The data from these experiments are shown in Fig. 4. It can be seen that natural convection has an influence on the dissolution rate at relatively slow flow rates and when the long axis of the dissolving surface is parallel to the direction of flow (lower curve). The slopes and correlation coefficients of the upper and lower lines in Fig. 4 are 0.342 and 0.998 and 0.331 and 0.994, respectively, and are in good agreement with the theoretical slope of 0.333. The first four points from the lower set of data were omitted in the statistical calculations.

The relative position of the two lines in each set of data (Figs. 3 and 4) is due to the orientation of the rectangular dissolving surface with respect to the direction of flow. The die was designed with a length-to-width ratio of the dissolving surface of 8:1. As such, the convective diffusion theory (Eq. 1) would predict a twofold increase in dissolution rate in going from an orientation having the long axis of the dissolving surface parallel to the direction of flow to that having the long axis perpendicular. The distance between the lines at about the midrange of the data (log flow rate = 1.0) is 0.294 in Fig. 3 and 0.272 in Fig. 4. This correlation between theory and experiment is quite satisfactory inasmuch as Eq. 1 predicts the difference between the lines on these plots of 0.301 (*i.e.*, log of 2). This effect emphasizes the importance of including convection along with diffusion when considering drug dissolution phenomena. To consider the dissolution rate simply as proportional to area is inadequate.

A further evaluation of the relationship between the geometry of the dissolving surface and the dissolution rate was accomplished by determining the dissolution rates from the surface of a series of circular disks of ethyl *p*-aminobenzoate. Equation 2 indicates that a log–log plot of dissolution rate *versus* radius would be linear with a slope of ~1.67. Data from this series of experiments with a flow rate of 24 ml/min is shown in Fig. 5; the plot yields a least-squares slope of 1.619 and a correlation coefficient of 0.999. Additional data (not shown) having a flow rate of 14.7 ml/min gave a slope of 1.656 with a correlation coefficient of 0.998. The functional dependence of the dissolution rate on the radius as predicted by Eq. 2 is thus borne out by experiment.

The convective diffusion equations indicate that the dissolution rate is a function of the diffusivity to the two-thirds power. A convenient method of experimentally studying the dependence on the diffusion coefficient is to carry out experiments using a solubilized system (3). In this method, it is assumed that the free and solubilized solutes are in equilibrium in any small volume so that the sol-

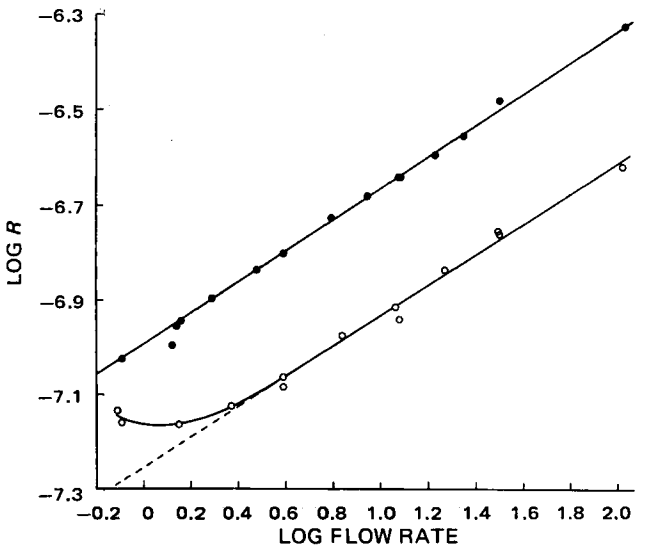

Figure 4—*Log–log plot of dissolution rate as a function of fluid flow rate with the dissolution cell inverted.*

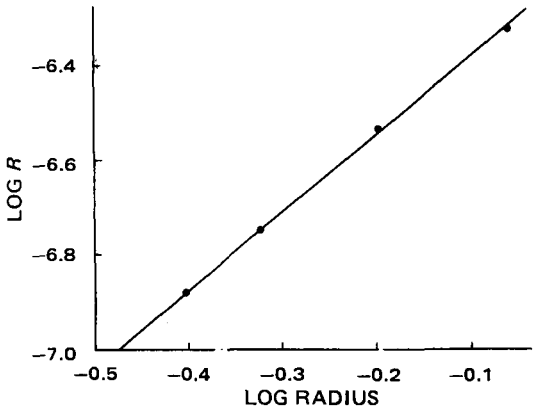

Figure 5—*Log-log plot of dissolution rate as a function of tablet radius.*

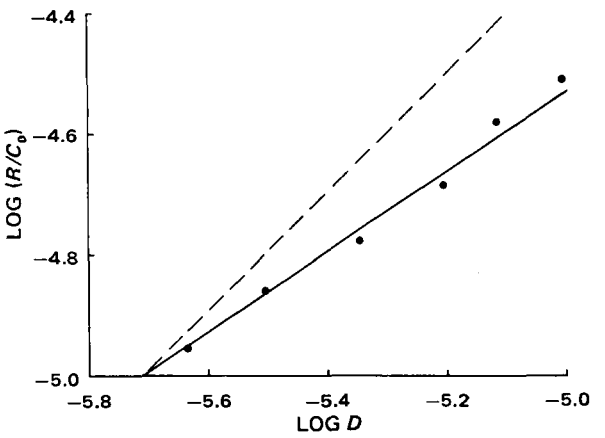

Figure 6—*Log-log plot of (dissolution rate/solubility) as a function of diffusivity.*

ubility and diffusivity measured on a macroscopic level may be employed as the effective parameters in a theoretical treatment.

Dissolution rate experiments were carried out with disks (r = 0.476 cm) of ethyl *p*-aminobenzoate at 37° and a flow rate of 14.9 ml/min. The liquid medium was water containing various concentrations (0–6%) of polysorbate 80, a system for which the effective solubility and effective diffusion coefficient of ethyl *p*-aminobenzoate have been determined (3). The data are shown in Fig. 6 as a plot of log R/C_0 *versus* log D, which yields a least-squares slope of 0.706 and a correlation coefficient of 0.990. These values are in satisfactory agreement with convective diffusion theory in that Eq. 2 indicates a slope of 0.667.

A dashed line of slope 1 is included in Fig. 6 to permit visual comparison of the experimental data with the expected relationship according to the commonly employed stagnant diffusion layer model (1). It is apparent that the convective diffusion model more accurately describes the role of diffusion in the process of dissolution into a moving liquid.

These considerations have focused primarily on the functional dependence of the dissolution rate on solubility, diffusivity, rate of shear, and geometry and orientation of the dissolving surface. To complete this evaluation, the actual value of a dissolution rate is calculated, based on independently determined parameters, and compared with the corresponding experimental dissolution rate. For this purpose, the rate corresponding to the first point (no polysorbate) on Fig. 6 is used. The diffusivity and solubility were reported (3) to be 9.86×10^{-6} cm^2/sec and 7.27×10^{-6} mole/cm^3, respectively. The rate of shear is calculated to be 4.25 sec^{-1} with Eq. 3 by substituting in the dimensions of the dissolution cell and the flow rate (14.9 cm^3/min). These values, together with the dissolving surface radius of 0.476 cm, are substituted into Eq. 2 to give a theoretical dissolution rate of 2.03×10^{-7} mole/min. The experimentally determined dissolution rate for these conditions is 2.25×10^{-7} mole/min. The ability of the model to predict the dissolution rate to within 10% of the actual value inspires considerable confidence in the convective diffusion approach to describing drug dissolution rate.

The convective diffusion approach enables one to describe drug dissolution rates in terms of the fundamental processes of convection and diffusion. As discussed in Ref. 1, the model currently utilized to describe drug dissolution is the Noyes–Whitney equation, which includes the Nernst unstirred diffusion layer. This model is useful, but the general approach cannot account for such factors as agitation and the orientation of the surface relative to flow because convection is not included in the mathematical model.

The convective diffusion model considered in this report is also somewhat limited in that it describes dissolution under rather idealized conditions. Under these conditions, however, the model can quantitatively describe the effects of solubility, diffusivity, rate of shear (agitation), and geometry and orientation of the surface relative to flow. Any inability of the model to describe drug dissolution from tablets or other solid dosage forms will be primarily due to experimental conditions that differ from those assumed in the model, *e.g.*, flow over a curved surface such that the boundary layer leaves the surface. The constant rate of shear was assumed in the model to retain a high degree of generality. It is recognized that the rate of shear over a surface can be more complex because of such conditions as end effects, distance downstream, curved surfaces, and natural convection.

APPENDIX

The flow pattern between two parallel planes a distance H apart (in the Z direction) is described by a parabolic function of Z. If the edge and end effects are ignored, the velocity function, v_x, for flow in a cell of width W and the length l is given by:

$$v_x = \frac{\Delta P H^2}{8 \mu l}\left[1 - \left(\frac{2Z - H}{H}\right)^2\right] \qquad \text{(Eq. A1)}$$

where ΔP is the pressure difference over l, and μ is the viscosity (2). The volumetric flow rate, Q, is given by (2):

$$Q = \frac{\Delta P H^3 W}{12 \mu l} \qquad \text{(Eq. A2)}$$

Differentiating Eq. A1 with respect to Z yields:

$$\frac{dv_x}{dz} = \frac{\Delta P(H - 2Z)}{2 \mu l} \qquad \text{(Eq. A3)}$$

This differential is the rate of shear. In the vicinity of the dissolving surface, the rate of shear, α, may be considered to be constant and is thus obtained by substituting $Z = 0$ into Eq. A3. If this result is combined with Eq. A2, an equation relating α with the volumetric flow rate results:

$$\alpha = \frac{6Q}{H^2 W} \qquad \text{(Eq. A4)}$$

Comparative Bioavailabilities from Truncated Blood Level Curves

E. G. LOVERING ˣ, I. J. McGILVERAY, I. McMILLAN *, and W. TOSTOWARYK

Abstract □ The period of time after administration over which blood level measurements are required to obtain a reliable bioavailability comparison of two or more formulations of the same drug was considered by the analysis of bioavailability data taken from the literature. The drugs examined, selected to represent a range of absorption and elimination half-lives, were acetaminophen, aminosalicylic acid, chloramphenicol, chlordiazepoxide, digoxin, isoniazid, phenylbutazone, sulfamethizole, tetracycline, and warfarin. For most drugs, ratios of areas under the curve changed little between the end of the absorption period and the time when blood sampling was terminated. Reliable bioavailability comparisons among different brands of the drugs apparently could have been made by blood sampling over 24 hr or less.

Keyphrases □ Bioavailability—length of time for blood level measurements, analysis of literature data, 10 drugs considered, truncated blood level curves □ Blood level curves, truncated—comparative bioavailabilities of 10 drugs, analysis of literature data, determination of length of time necessary for blood level measurements □ Sampling, blood—time necessary for bioavailability studies, analysis of literature data, truncated blood level curves

Bioavailability is an important parameter in the comparison of commercial drug formulations. It was defined by Riegelman (1) as the relative rate and extent at which an administered dose reaches the general circulation. However, it is commonly interpreted as only the relative extent of absorption and is expressed as the percent ratio of test to reference formulations absorbed. This ratio is estimated either by the appropriate ratio of total areas under the curves of drug concentration in the blood following administration of the doses (2) or by the ratio of the total cumulative amounts of test and reference drugs excreted in the urine.

Ideally, the areas under the blood concentration curves *(AUC)* should be calculated to infinite time; but in practice, it is usually suggested that areas calculated over three elimination half-lives are sufficient (3). The extrapolation to infinity can frequently be made but often makes no appreciable difference to the final bioavailability estimate. For many commercial formulations, it was observed that the ratios of areas of test to reference formulations approach a limiting value many hours prior to the complete elimination of the drug. In this study, 10 drugs of widely differing kinetic properties were examined to determine how long blood sampling should continue after drug administration to estimate adequately the ultimate test to reference *AUC* ratio.

EXPERIMENTAL

The data used came from both the literature and internal unpublished investigations. Bioavailability studies comparing different formulations of the same drug commonly report blood levels at each sampling time averaged (arithmetic means) over all subjects.

Table I—*AUC* Ratios (Percent) of Acetaminophen Formulations[a]

Formulation	Blood Sampling Time, hr						
	0.33	0.67	1.00	1.50	2.00	4.00	6.00
K_1	120	88	83	86	88	92	93
K_2	139	105	93	87	86	86	87
K_3	110	84	78	78	79	78	79
N	121	81	69	71	76	83	85
O	161	113	97	94	96	97	97
P	153	122	111	108	108	106	102
Q	88	75	74	80	86	93	89
S	197	131	109	101	100	97	97

[a] Calculated from McGilveray *et al.* (5).

By using these average blood levels, the *AUC* at each sampling time was determined by the trapezoidal rule for the test and reference formulations, and *AUC* ratios were calculated at these sampling times.

Occasionally, blood levels are reported for individual subjects. In these cases, areas from the time of administration to each sampling time were calculated by the trapezoidal rule for each subject. Geometric means of the *AUC*'s at each sampling time were determined for each formulation in the study, and *AUC* ratios of test to reference formulations were calculated. Graphs of *AUC* ratios *versus* time were tested for parallelism, height, and slope, using the method of profile analysis (4).

RESULTS

Acetaminophen—*AUC* ratios at each sampling time from 20 min to 6 hr were calculated from the individual blood level data of McGilveray *et al.* (5). Tablet R (5) was used as the reference formulation. The curves constructed from the bioavailability–time data (Table I) were found to be approximately parallel ($p > 0.9$) and at the same level ($p > 0.3$). *AUC* ratios did not change significantly after 2 hr postadministration ($p > 0.2$).

Aminosalicylic Acid—The individual blood level data reported by Schirmer *et al.* (6) were not in a suitable form for profile analysis. Mean blood level curves were used to calculate the *AUC* ratios at 2, 4, 6, 8, and 12 hr postadministration (Table II). This study included uncoated and enteric-coated tablets, and uncoated Tablet A was used as the reference formulation. Plasma levels of the drug from some enteric-coated tablets were low and erratic and were not included in the analysis. There was little change in the *AUC* ratios of uncoated Tablets B, C, and D after 6 hr. Enteric-coated Tablet E1 showed slowly increasing *AUC* ratios to 12 hr.

Wagner *et al.* (7) recently reported blood level curves of aminosalicylic acid obtained from solutions of the sodium salt, suspension, compressed tablets, and enteric-coated tablets. In all cases the absorptive phases were complete within 3 hr.

Chloramphenicol—Mean plasma levels determined colorimetrically by Glazko *et al.* (8) were used to calculate *AUC* ratios of four brands of chloramphenicol capsules (Table III). Formulation A was used as the reference. Six hours after administration, the *AUC* ratios approached a constant value for Capsules B and C. The *AUC* ratio of Capsule D appeared to increase slightly between 6 and 24 hr but remained very low compared to B and C.

Chlordiazepoxide—*AUC* ratios determined in this laboratory[1] are given in Table IV for from 1 to 54 hr. The ratios were calculat-

[1] I. J. McGilveray and G. L. Mattok, unpublished work.

Table II—*AUC* Ratios (Percent) of Aminosalicylic Acid Formulations[a]

Formulation	Blood Sampling Time, hr				
	2	4	6	8	12
B	92	84	78	78	78
C	80	83	85	85	85
D	97	91	85	83	83
E2	—	100	100	100	100
E1	—	78	86	94	98

[a] Calculated from Schirmer *et al.* (6).

Table III—*AUC* Ratios (Percent) of Chloramphenicol Formulations[a]

Formulation	Blood Sampling Time, hr							
	0.5	1.0	2.0	4.0	6.0	8.0	12.0	24.0
B	19	22	32	45	52	54	55	53
C	24	32	45	57	62	63	64	62
D	10	12	16	22	26	29	32	35

[a] Calculated from Glazko *et al.* (8).

ed on the basis of total drug, *i.e.*, free chlordiazepoxide and metabolite. With the exception of Formulation 43, the bioavailabilities calculated at 7 hr were within 12% of those calculated at 54 hr. The bioavailability of Formulation 43 increased from 1 to 54 hr, although the increase after 24 hr was only about 10%. *AUC* ratios calculated from the data of Foldes *et al.* (9) varied erratically between 4 and 24 hr.

Digoxin—Table V gives the *AUC* ratios of a digoxin formulation calculated from the data of Wagner *et al.* (10); Formulation A was used as the reference. The ratios remain unchanged, within a few percent, from 1.5 to 96 hr. More than half the area under the curve to 96 hr was in the 24–96-hr interval.

After 24 hr, the plasma levels were low and their determination was subject to greater error than when the plasma level was high. Thus, measurement of plasma levels over a period of days apparently gives no additional information about relative availability and, in fact, may increase experimental error.

Isoniazid—*AUC* ratios were calculated from the individual blood level data of Gelber *et al.* (11), using Formulation 4 as the reference (Table VI). Results of profile analysis indicated that curves of *AUC* ratios *versus* time were approximately parallel ($p > 0.7$) and at the same level ($p > 0.8$). For each curve, the analysis showed that the slope was not significantly different ($p > 0.1$) from zero in the time interval from 2 to 8 hr.

Phenylbutazone—*AUC* ratios of nine tablet formulations were calculated from the mean plasma level data of Van Petten *et al.* (12), taking a solution of the drug as the reference formulation.

Table IV—*AUC* Ratios (Percent) of Chlordiazepoxide Formulations[a]

6	59	84	91	97	105	107	105	103	102

[a] Calculated from Gelber *et al.* (11).

Van Petten *et al.* divided their study into two groups (Table VII). Except for Formulation D, the ratios varied little after 12 hr but varied considerably before that time. The extended time required to reach constant *AUC* ratios may be due to the fact that many phenylbutazone tablets are coated.

Sulfamethizole—*AUC* ratios were calculated from the individual blood level data of Mattok and McGilveray (13), using Tablet B as the reference (Table VIII). The *AUC* ratio curves were approximately parallel ($p > 0.7$), at the same level ($p > 0.6$), and constant in slope ($p > 0.3$) over the profile.

[a] Calculated from Wagner *et al.* (15).

Tetracycline—Lovering *et al.* (14) reported individual blood level data for nine tablet formulations, and these data were used to calculate *AUC* ratios relative to a reference solution. Results of the profile analysis (Table IX) showed that the *AUC* ratios of Tablets F and G differed significantly ($p > 0.05$) from the other tablets. The mean *AUC* ratio of F and G decreased between 6 and 24 hr, but the mean ratio for the remaining formulations was level from 6 to 9 hr and then decreased to 24 hr. The decrease for both groups was slight.

Warfarin—Individual plasma level data from Wagner *et al.* (15) were analyzed for three 5-mg tablets, using Formulation A as the reference (Table X). Results of profile analysis indicated that curves were approximately parallel ($p > 0.8$) and at approximately the same level ($p > 0.07$). The hypothesis of equal *AUC* ratios across all sampling times was not rejected ($p > 0.6$).

Based on a one-compartment model, approximate first-order absorption and elimination rate constants, k_1 and k_2, respectively, were taken from the papers cited or were calculated from:

$$C_t = \frac{fD}{V}\frac{k_1}{k_1 - k_2}(e^{-k_2 t} - e^{-k_1 t}) \qquad \text{(Eq. 1)}$$

where C_t is the concentration of drug in the blood at time t; f is the fraction of dose, D, absorbed; and V is the apparent volume of distribution (16) (Table XI). Elimination rate constants were calculated using the final points on the mean blood level–time curves. Absorption rate constants were calculated from the first derivative of Eq. 1 and the mean peak blood level time, t^*, when $dC_t/dt = 0$:

$$t^* k_2 - \ln k_2 = k_1 t^* - \ln k_1 \qquad \text{(Eq. 2)}$$

The time to 99% absorption was calculated by assuming the exponential disappearance of drug from the GI tract at a rate controlled by k_1 (Table XI).

DISCUSSION

Ten formulations (Tables I–X) exhibited changes in *AUC* ratios of more than 15% after the estimated absorption period. The *AUC* ratios of an enteric-coated aminosalicylic acid tablet measured against an uncoated reference tablet increased from 78 to 98% between 4 and 12 hr. The increase may be the result of slow drug release from the enteric-coated tablet. The *AUC* ratio of chlordiazepoxide Formulation 43 increased 57% between 5 and 54 hr, but the increase was only 10% after 24 hr. Formulations 44 and 45 showed some increase between 5 and 24 hr but were relatively constant thereafter.

Three phenylbutazone formulations showed *AUC* ratio changes of more than 15% between 6 and 48 hr, but only slight changes occurred after 24 hr. The results may indicate that the time for complete absorption lies between 6 and 24 hr for a number of phenylbutazone formulations. Chloramphenicol Formulations B and D (Table III) and Formulation F (Table IX) showed large changes in the *AUC* ratio in the postabsorption period, but these formulations were of low bioavailability.

The constancy of the *AUC* ratios in these studies, a few hours after administration of the drug, suggests that it may not be necessary to follow blood levels to complete elimination of the drug, or even over two to three elimination half-lives, to obtain *AUC* ratios that are approximately equal to the bioavailability (3). The time over which samples should be taken depends upon the relative values of the test and reference absorption rate constants, k_1 and k_1^*, respectively, and the elimination rate constant, k_2.

The *AUC* ratios also depend upon the time available for absorption. Formulation comparison studies are usually carried out in starved, healthy subjects. Under these conditions, the rate at which the drug, whether in solution or not, flows through those regions of the GI tract that favor dissolution and absorption may be uniform; for certain regions of the GI tract, the rate may be rapid.

Consider a one-compartment model with first-order absorption and elimination, in which absorption is allowed to proceed from time zero to time T, where T is the end of the absorption period. The concentration of drug in the blood at time t is given by Eq. 1 if $t \leq T$. If $t > T$:

$$C_t = C_T e^{-k_2(t-T)} \qquad \text{(Eq. 3)}$$

where C_T is the concentration of drug in the blood at time T. If $t \leq T$ (16), the corresponding *AUC*'s to time t are:

$$A_t = \frac{fD}{V}\frac{1}{k_2(k_1 - k_2)}(k_2 e^{-k_1 t} - k_1 e^{-k_2 t} + k_1 - k_2) \qquad \text{(Eq. 4a)}$$

If $t > T$:

$$A_t = A_T + \frac{C_T}{k_2}(1 - e^{-k_2(t-T)}) \qquad \text{(Eq. 4b)}$$

where A is the *AUC* at time T.

The *AUC* ratios of test to reference formulations follow. Quantities marked by an asterisk refer to the reference formulation. If it

is assumed that k_2, D, and V are the same for the test and reference formulations administered to a given subject, then, if $t \leq T$:

$$\frac{A_t}{A_t^*} = \frac{f}{f^*}\frac{(k_1^* - k_2)(k_2e^{-k_1t} - k_1e^{-k_2t} + k_1 - k_2)}{(k_1 - k_2)(k_2e^{-k_1^*t} - k_1^*e^{-k_2t} + k_1^* - k_2)} \quad \text{(Eq. 5a)}$$

If $t > T$:

$$\frac{A_t}{A_t^*} = \frac{A_T + \frac{C_T}{k_2}(1 - e^{-k_2(t-T)})}{A_T^* + \frac{C_T^*}{k_2}(1 - e^{-k_2(t-T)})} \quad \text{(Eq. 5b)}$$

Tables of *AUC* ratios were constructed from Eqs. 1 and 3, taking typical values of k_1^* and k_2 from Table XI. The value of k_1 was taken as $0.25k_1^*$ throughout to represent formulations from which drug is released slowly. The time to which absorption was allowed to proceed, T, varied from 0.5 to 24 hr, and the *AUC* ratio was calculated over appropriate time periods. The *AUC*'s in Tables XII and XIII at the end of the period available for absorption, $t = T$, are usually within 10–20% of the *AUC* ratio when t is infinite. The *AUC* ratios at $t = 2T$ are, in most cases, within a few percentage points of the *AUC* ratio at infinite time and experimentally indistinguishable from it. Thus, for slowly eliminated drugs, a limited period during which absorption occurs can account for the approach to constant values of *AUC* ratios long before two or three elimination half-lives have elapsed.

The duration of the absorption period may vary considerably among drugs. If a drug dissolves only at gastric pH and is administered with water on an empty stomach, the dissolution period will be fixed by the gastric emptying time and may be less than 1 hr. If absorption occurs only over a short proximal segment of the GI tract, the absorption period also may be very short. In any case, barring adhesion of drug crystals to the intestinal mucus, the absorption period is probably limited by the time required for the intestinal contents to reach solid matter in the lower intestine and certainly by the total intestinal transit time (about 30 hr).

In conclusion, analysis of blood level profiles obtained in several bioavailability studies indicated that "partial" *AUC* ratios at the end of the absorption period often agree with the total area ratios. Careful consideration of the rate constants and the general behavior observed during experimental work, which must precede any bioavailability trial, may permit shorter blood sampling schedules.

Configuration of Dienestrol

THOMAS D. DOYLE *x, JAMES McDONALD STEWART ‡, NICOLAE FILIPESCU §, and WALTER R. BENSON *

Abstract □ Uncertainty concerning the configuration of dienestrol was resolved by a detailed spectrochemical investigation, including single-crystal X-ray diffraction, of the active drug and its stereoisomers. A symmetric structure in which the phenyl and methyl groups are *cis* about each double bond is unambiguously assigned.

Keyphrases □ Dienestrol—determination of configuration, single-crystal X-ray diffraction □ Estrogens—determination of configuration of dienestrol, X-ray diffraction □ X-ray diffraction—determination of dienestrol configuration

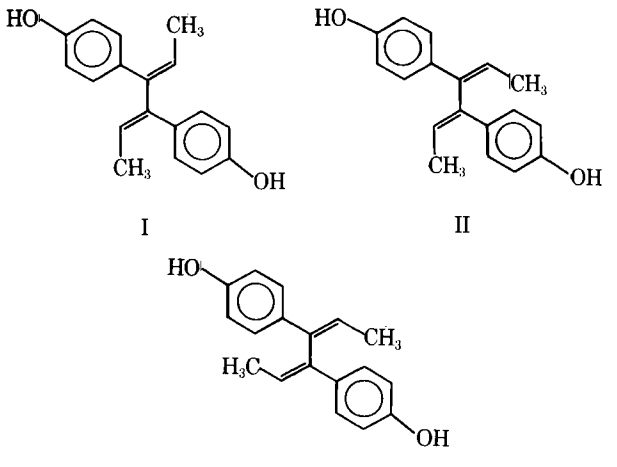
The synthetic estrogen dienestrol [3,4-bis(*p*-hydroxyphenyl)-2,4-hexadiene] was originally prepared in 1939 (1). Its exact structure, however, has remained a controversial subject (2–5); the configuration remains unspecified in NF XIV (6).

Theoretically, there are three possible stereoisomers, I–III. Koch and coworkers (2, 3) suggested configuration I for the isomer available to them. Later, presumed authentic samples of each stereoisomer were synthesized (4, 5); their corresponding diacetates were prepared by dehydration of mixtures of *meso*- and racemic 3,4-bis(*p*-acetoxyphenyl)-3,4-hexanediols. On the basis of the IR absorption of the diacetates, Lane and Spialter (5) concluded that the drug dienestrol has steric configuration III.

In view of the authors' interest in the stereochemistry and photoreactivity of synthetic estrogens (7), the question of the structure of dienestrol was reexamined from five distinct points of view: NMR spectroscopy, UV spectrophotometry, molecular models, chemical reactivity, and X-ray diffraction. Results prove that dienestrol has Structure I.

EXPERIMENTAL

Dienestrol was used as received from the supplier[1] without further purification, except that the specimen for X-ray crystallography was recrystallized from absolute alcohol, mp 227–228°.



[1] K&K Laboratories, Plainview, N.Y.

NMR spectra[2] were obtained in acetone-d_6 with tetramethylsilane internal standard.

Electronic absorption spectra were obtained in 95% ethyl alcohol on a recording spectrophotometer[3]; 1-cm silica cells were used.

X-ray crystallography was performed on an automated single-crystal X-ray diffractometer[4]. Preliminary investigation of the space group and cell dimensions were made by means of oscillation and Weissenberg photographic techniques. The accurate cell dimensions and intensities were collected on the X-ray diffractometer by the θ–2θ scan technique. All calculations for the preliminary data treatment, solution by direct methods, and refinement by full matrix least squares of the structure and the calculations of bond lengths and angles were carried out using XRAY72 (8) on a computer[5]. Figure 1 was produced using the ORTEP (9) crystallographic plotting program.

The structure determination was carried out using the NORMSF, SINGEN, PHASE, and FOURR links of the XRAY72 system of crystallographic programs. The E map produced revealed the molecule, including hydrogen atoms lying on a center of symmetry at ½, ½, ½. The coordinates from the E map were used as input to the LOADAT, CRYLSQ, BONOLA, and LSQPL links of the XRAY72 system. The result of the refinement is displayed in the figures. The final conventional R value ($\Sigma 1\Delta F1/1F_0 1$) is 0.048. The parameters refined were the scale factor, the secondary extinction factor, and the positional and thermal factors. The equation of a least-squares plane through C(1), C(2), C(3), and C(4) (see Fig. 2) is:

$$7.753X - 5.509Y - 4.454Z + 1.138 = 0 \qquad \text{(Eq. 1)}$$

These four atoms are all within 0.01 Å of this plane.

The phenyl ring system, C(4) + C(9), is also planar, with an average deviation of 0.004 Å. These two planes are found to be at an angle of 87.6° to one another[6].

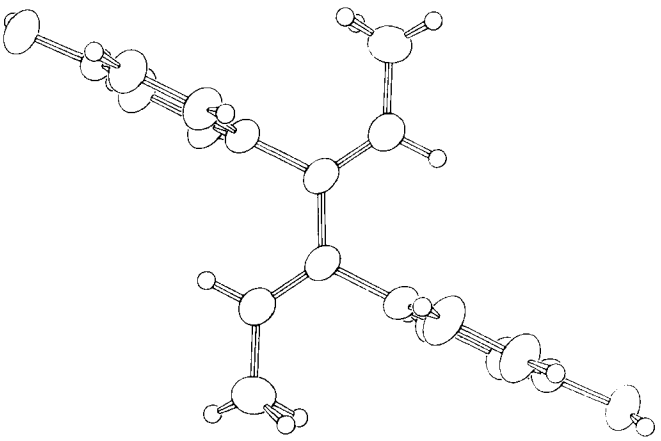


Figure 1—*The ORTEP computer plot of the whole molecule of dienestrol, showing the projection normal to the plane of C(1), C(2), C(3), and C(4).*

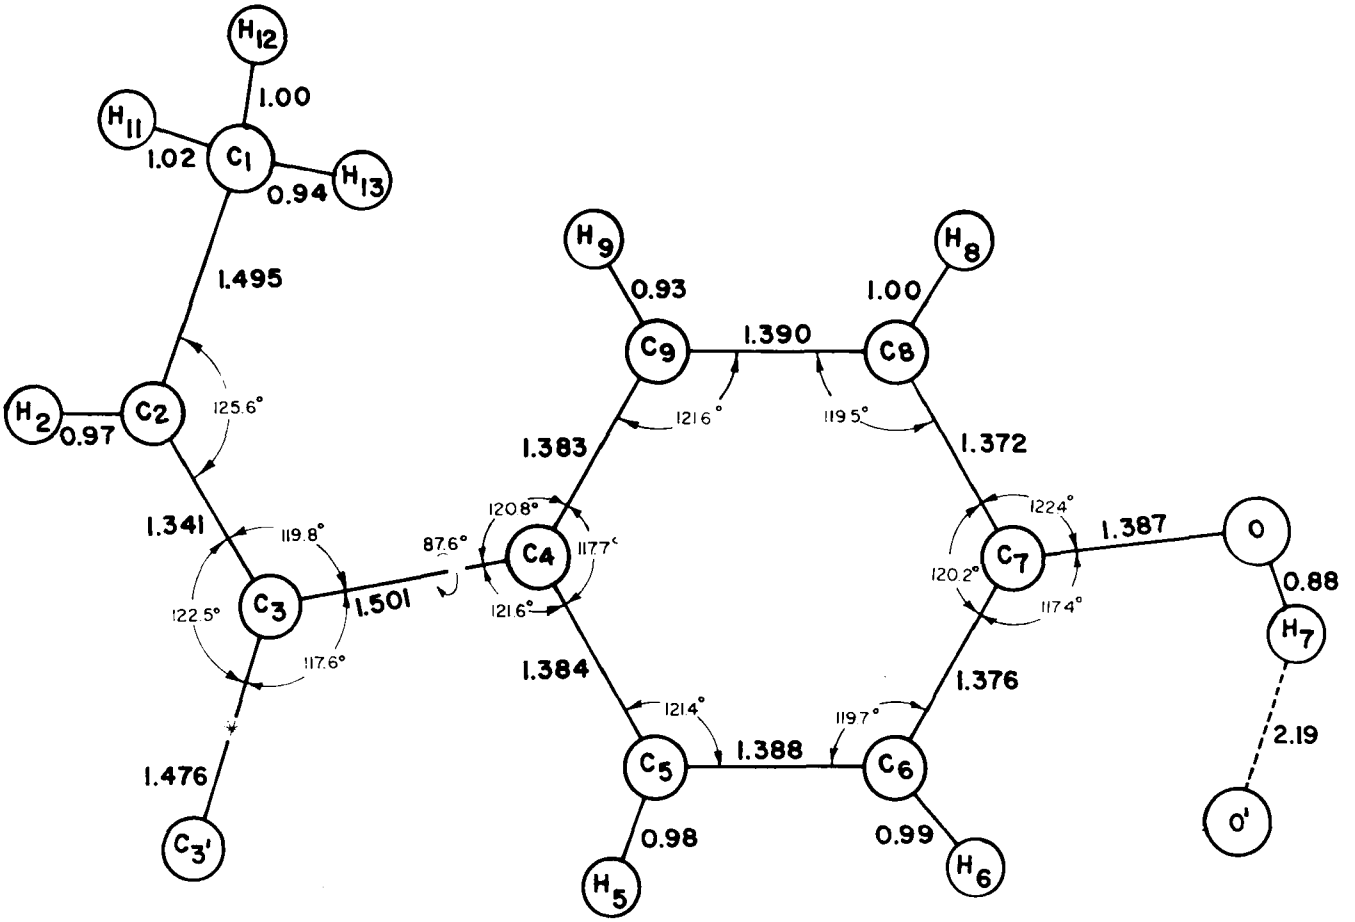

Figure 2—*Bond lengths in angstroms and angles in degrees for the refined structure of dienestrol. Since the molecule has a center of symmetry (denoted by the asterisk), only one-half of it is shown. For clarity, bond angles involving H atoms are omitted. The average estimated error in the bond angles shown is 0.15°.*

RESULTS AND DISCUSSION

The NMR spectrum of the therapeutic agent dienestrol, identical with the substance of Dodds *et al.* (1), showed that the two methyl groups have an equivalent molecular environment and identical chemical shifts, δ 1.50 ppm (doublet, J = 6.5 Hz, =CH—C*H*$_3$, 6H), and that the two vinyl protons are equivalent: δ 5.37 ppm (quartet, J = 6.5 Hz, =C*H*—CH$_3$, 2H). The only other signals in the NMR spectrum were caused by the aromatic protons at δ 6.65–7.30 ppm (multiplet, 8H) and the hydroxylic protons at δ 8.45 ppm (singlet, 2H). These findings eliminate the low symmetry Structure II as a possible dienestrol configuration.

The remaining two alternatives, I and III, could be differentiated by analysis of the UV absorption spectra of dienestrol and diacetoxy derivatives of stereoisomers I–III. Dienestrol diacetate was separately prepared from dienestrol by treatment with acetic anhydride in pyridine and recrystallization from ethanol–water, mp 113–114°. The near-UV absorption of dienestrol and its diacetate is compared to those of the other two isomeric diacetates[7] in Fig. 3. The absorption maxima of the pharmaceutical form, its diacetylated derivative, and the other diacetates are displayed at 228, 221, and 247 and 252 nm, respectively.

Evaluation of these absorption curves in terms of steric interference of substituents with normal styrene chromophore absorption allows configuration I to be assigned to dienestrol. Unsubstituted styrene, simple *trans*-β-alkylstyrenes (IV), and simple α-alkylstyrenes (V) exhibit absorption maxima in the 243–255-nm spectral region (10). On the other hand, *cis*-β-alkylstyrenes (VI) lack the characteristic styrene chromophore absorption because of out-

isotropic temperature factors are of the form:

$$\exp[-8\pi^2 U(\sin\theta/\lambda)^2]$$

anisotropic temperature factors are of the form:

$$\exp[-2\pi^2(h^2a^{*2}U_{11} + \ldots + 2klb^*c^*U_{23})]$$

of-plane distortions of the vinyl group with respect to the aryl π-system brought about by the steric hindrance between the alkyl substituent and the hydrogen at the *ortho*-position (11). Consequently, the λ_{max} at 221 nm displayed by dienestrol diacetate in Fig. 3 is incompatible with structural types IV or V, which leaves by elimination the *cis*-β-alkylstyrenic Structure I, analogous with VI. The fact that the other two stereoisomeric diacetates exhibit near-UV absorption consistent with the preservation of the styrene chromophore confirms their concordance with Structures II and III.

Conclusions consistent with these interpretations were also obtained from examination of scale molecular models[8] of the geometric isomers. The models suggest that the two olefinic bonds in stereoisomer I readily attain coplanarity with each other, without strain, outside the planes of the aryl nuclei, whereas prohibitive tension would be required to reach double bond conjugation in Structures II and III.

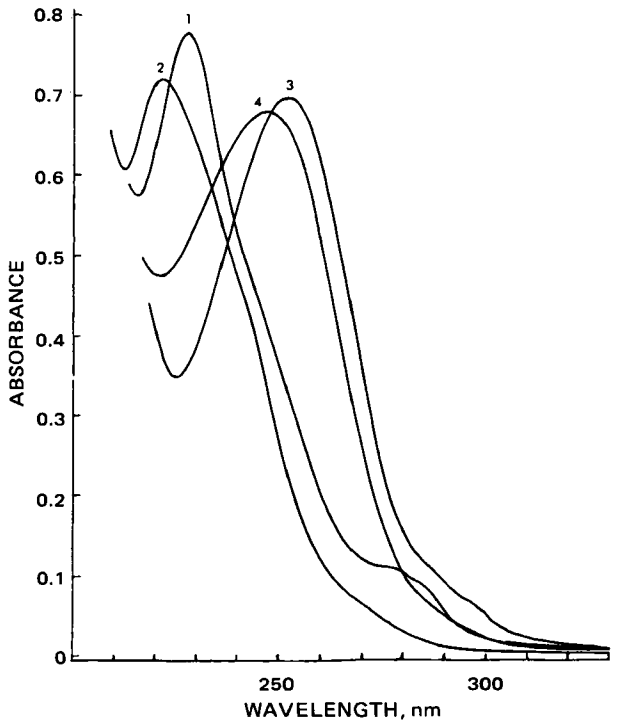

Figure 3—*Electronic absorption spectra of: (1) the active drug dienestrol, (2) the diacetate of I, (3) β-dienestrol diacetate, and (4) γ-dienestrol diacetate. The concentrations are: (1) 2.68 × 10^{-5} M (ε = 29,100), (2) 2.78 × 10^{-5} M (ε = 25,900), (3) 3.11 × 10^{-5} M (ε = 22,600), and (4) 3.50 × 10^{-5} M (ε = 19,600).*

[8] Corey–Pauling–Koltun models, Schwarz BioResearch, Orangeburg, N.Y.

The conjugation of the two vinyl groups in I offers compensatory stabilization energy for the lost styrene π-delocalization and retains a butadiene chromophore characterized by an absorption maximum at 217 nm. This may be interpreted as additional evidence for the assignment of configuration I to dienestrol, since of the four compounds in Fig. 3, only the drug and its diacetate have absorption maxima compatible with the presence of an isolated butadiene chromophore.

These deductions are in accord with the known chemical reactivity of dienestrol and its diacetate toward adduct formation with Diels–Alder dienophiles[9]. This evidence is consistent with configuration I but would not be expected with III, since planarity of the butadiene system is required for this reaction; hindrance from the methyl groups in III would prevent this planar *cis*-conformation.

Although these lines of evidence were compelling, they nevertheless were based on indirect inferences. Unambiguous configurational assignment in complete accord with the preliminary deductions was obtained by single-crystal X-ray diffraction. Table I summarizes the physical constants obtained, and Table II gives the coordinates and temperature parameters of the asymmetric atoms of the unit cell.

Figure 1 is a computer-produced view of the molecule perpendicular to the plane of the hexadiene chain, as determined by the crystallographic analysis. Assignments of bond lengths and bond angles in the crystalline state are shown in Fig. 2. The structure of dienestrol is I, in agreement with the postulation of Koch and coworkers (2, 3) but contrary to the conclusions of Lane and Spialter (5).

A least-squares plane calculated from the coordinates of C(1), C(2), C(3), C(3′), C(2′), and C(1′) shows that these atoms of the hexadiene chain are planar within 0.02 Å. In contrast, the phenyl rings lie virtually perpendicular (87.6°) to the hexadiene system and are thus out of conjugation with the remainder of the molecule. These findings for the crystalline state buttress the interpretation of the electronic spectrum of dienestrol in solution and support arguments based on molecular models and chemical reactivity.

Stabilizing Effect of Inorganic Phosphate Salts on Antibiotic–Steroid Ophthalmic Preparations

JAMES W. McGINITY ˣ and ROBERT L. BROWN

Abstract □ Drocinonide phosphate potassium forms an insoluble complex with neomycin sulfate in aqueous solution. Dibasic sodium phosphate can be employed in an ophthalmic formulation to prevent the formation of this precipitate without affecting the stability of the steroid or the bioactivity of the antibiotic. Other phosphate steroid salts behaved in a like manner.

Keyphrases □ Ophthalmic formulations—antibiotic–steroid preparations, stabilizing effect of inorganic phosphate salts, drocinonide phosphate potassium–neomycin sulfate complex studied □ Steroid–antibiotic ophthalmic preparations—stabilizing effect of inorganic phosphate salts □ Antibiotic–steroid ophthalmic preparations—stabilizing effect of inorganic phosphate salts □ Drocinonide phosphate potassium—complex with neomycin sulfate, prevention of precipitation by use of inorganic phosphate salts □ Inorganic salts—as stabilizers of antibiotic–steroid ophthalmic preparations

Neomycin sulfate is a polybasic antibiotic which ionizes in aqueous solution to give a positively charged species of neomycin. A wide range of anionic compounds were studied to assess their compatibility with the antibiotic (1). Approximately 50% of the high molecular weight anionic compounds tested precipitated with neomycin sulfate as an addition complex of low solubility. The stability of neomycin was investigated in several pharmaceutical preparations, and it was found that the antibiotic was relatively stable in solution over pH 2.0–9.0 (2). All products studied showed a minimum stability of 1 year at room temperature; tablets, troches, and ointment bases were stable for 2 years.

The present report describes a method for overcoming the incompatibility of neomycin sulfate with corticosteroid drugs in aqueous ophthalmic preparations. As a model, the soluble steroid chosen for investigation was drocinonide phosphate potassium[1]. To formulate this steroid with neomycin sulfate in an ophthalmic solution, the incompatibility of the two drugs must be overcome to produce a clear, particle-free solution in which the drug remains stable and active.

EXPERIMENTAL

Materials—The following were used: neomycin sulfate[2], drocinonide phosphate potassium[1], anhydrous disodium hydrogen phospate[3], anhydrous dipotassium hydrogen phosphate[3], sodium borate[3], sodium bisulfite[3], dexamethasone sodium phosphate[4], prednisolone sodium phosphate[4], polyvinylpyrrolidone[5], sodium formaldehyde sulfoxylate[6], sorbitol[7], polymyxin B sulfate[8], and thimerosal[9].

Stability Assay of Drocinonide Phosphate Potassium—A quantitative paper chromatographic method (3) was employed, using the solvent system of 1-butanol–ethanol–2 *N* ammonium hydroxide (5:1:2). Prior to the application of the sample, the paper strips were washed in alcohol and dried (4). The zones of steroid were located by use of a guide-strip spray reagent technique, and the zones on the untreated strips were eluted with water. An aliquot of the eluate was mixed with concentrated sulfuric acid, and the resulting fluorescence was measured spectrophotofluorometrically[10].

Microbiological Assay of Neomycin Sulfate—The microbiological activity of neomycin sulfate was determined by the cylinder-plate method described in USP XVIII (5).

Table I—Composition of Formula I

Ingredient	Amount, mg
Neomycin sulfate	3.26
Drocinonide phosphate potassium	3.4
Disodium hydrogen phosphate	6.0
Polyvinylpyrrolidone[a]	8.0
Sodium formaldehyde sulfoxylate	2.0
Thimerosal	0.02
Sorbitol, 70% (w/v)	0.01 ml
Purified water, *q.s.*	1.0 ml

[a] PVP-C-30.

Preparation of Formulas I–IV—These formulas appear in Tables I and II. The neomycin sulfate was dissolved in 60% of the purified water. The soluble phosphate buffer agent was dissolved in 15% of the water and was then added to the solution of neomycin sulfate. The steroid salt plus other additives was dissolved in 15% of the water and added slowly to the neomycin sulfate–phosphate buffer solution. Then the solution was adjusted to volume.

Stoichiometry of Antibiotic–Steroid Complex—To determine the stoichiometry of the complex, 0–10 ml of a 0.05 *M* solution of neomycin sulfate was pipetted in increments of 0.5 or 1 ml into 20-ml vials. Enough 0.05 *M* steroid solution was added until the volume of each vial totaled 10 ml. The mixtures were swirled and permitted to equilibrate at 25°; after 24 hr, the contents of each container were filtered. The precipitated complex was dried and weighed. The data obtained are plotted in Fig. 1, according to the method of Job (6). Data points represent the average of duplicate experiments.

RESULTS AND DISCUSSION

The ideal agent used to overcome the incompatibility of drocinonide phosphate potassium and neomycin sulfate in an ophthalmic solution should exhibit little or no physiological activity and be effective in very small concentrations. Various materials were studied for their effectiveness in solubilizing the precipitate or in preventing the formation of the low solubility complex.

Preliminary screening studies showed that the solubility of the antibiotic–steroid complex was dependent on pH and that the addition to the mixture of strongly acidic or basic amino acid salts produced clear solutions. However, the addition of amino acid salts closer to neutrality was unsuccessful. Sodium borate, which has been used to solubilize a number of drugs (*e.g.*, riboflavin), proved reasonably effective when used in a great concentration (20 mg/ml) at pH 9.2. However, when the preparation was buffered to a pH range desirable for ophthalmic solutions (pH 6–8.5), a precipitate slowly appeared.

An agent successful in overcoming the incompatibility of drocinonide phosphate potassium and neomycin sulfate was disodium hydrogen phosphate. Singh (7), who studied the interaction of various antibiotics with condensed phosphates, found that neomycin possessed the strongest binding capacity for these higher phosphates. Disodium hydrogen phosphate proved an ideal agent for overcoming the incompatibility of drocinonide phosphate potassium and neomycin sulfate, because it was a good buffer agent and was effective in small concentrations. The pH of a solution of disodium hydrogen phosphate (7.8–8.0) may be lowered by the addition of sodium dihydrogen phosphate or dilute phosphoric acid to produce the monobasic salt *in situ*.

Table I shows the composition of a prototype formulation containing the two active ingredients in therapeutic amounts. This product was packaged in 30-ml amber-glass containers and stored at various temperatures to assess the stability of the steroid. Soluble steroid salts have been shown to undergo hydrolysis in aqueous solution, the process being accelerated at temperatures above room temperature. Saccharin sodium (8), creatinine, and niacinamide (9) have been shown to slow this hydrolytic process.

Preliminary studies[11] of stability had shown that polyvinylpyrrolidone was effective in preventing the hydrolysis of drocinonide phosphate potassium, and it was included in Formula I as a stabilizing agent. The data in Table III show that the stability of the steroid was maintained at 33° after 6 months but had declined at 40° after the same period.

[11] Unpublished data.

Table II—Formula Assayed Microbiologically for Neomycin Activity

Ingredient	Formula II	Formula III	Formula IV
Neomycin sulfate	3.26 mg	—	3.26 mg
Drocinonide phosphate potassium	3.4 mg	3.4 mg	—
Disodium hydrogen phosphate	6.0 mg	6.0 mg	6.0 mg
Purified water, *q.s.*	1.0 ml	1.0 ml	1.0 ml

To assess the influence of the steroid on the bioactivity of neomycin, three formulations were prepared (Table II). To eliminate interference with the neomycin assay, the other additives listed in Table I were omitted from the formulation. The data in Table IV show that the steroid did not interfere with the antimicrobial activity of neomycin and that the steroid itself possessed no antimicrobial activity.

To characterize the complex further, its stoichiometry was determined, as outlined under *Experimental*. From Fig. 1, it can be seen that maximum interaction between the two drugs occurred when the mole fraction of neomycin (X_A) to steroid (X_B) was 1:3. The level of disodium hydrogen phosphate required to maintain a clear solution proved to be dependent on the concentration of neomycin sulfate and not on that of drocinonide phosphate potassium.

For a concentration of neomycin sulfate equivalent to 2.5 mg/ml as neomycin base, the minimum recommended level of disodium hydrogen phosphate was 6 mg/ml. At lesser concentrations of buffer (*e.g.*, 4 mg/ml), it was also possible to obtain a crystal-free solution if both reactants were well diluted. However, when both solutions had been frozen at −20° for 12 hr, the preparation containing disodium hydrogen phosphate at 6 mg/ml produced a clear solution after being shaken at room temperature, whereas the preparation containing buffer at 4 mg/ml contained crystals. These crystals did not dissolve at room temperature, but their solubility increased as the temperature was raised; all crystals were in solution at 50°.

NMR spectroscopy was employed to investigate the system further. The primary amino groups on the neomycin molecule were suspected to be the sites of interaction with the steroid. The buffer agent and the two active ingredients were each lyophilized from deuterated water solutions to ensure the deuteration of the water of hydration. The NMR spectra obtained from deuterated water solutions of neomycin sulfate in the presence of the disodium hydrogen phosphate, with and without the steroid, indicated no interaction among the species. This fact, plus the fact that neomycin was bioactive in the presence of the steroid, suggested that the two active constituents were present as individual moieties and would be bioavailable to exert the desired therapeutic effect, but this assumption has yet to be proven *in vivo*.

Disodium hydrogen phosphate was also investigated for its ability to overcome the incompatibility that occurred when polymyxin

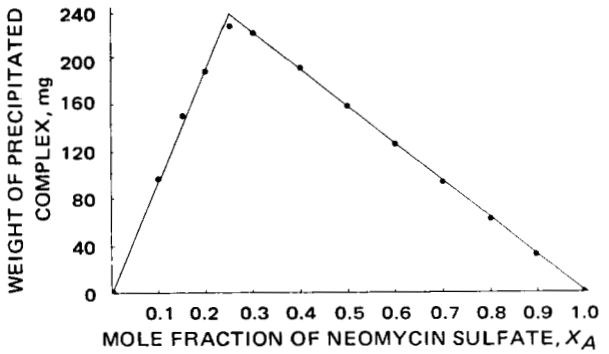

Figure 1—*Job (6) plot showing stoichiometric relationship between neomycin sulfate and drocinonide phosphate potassium. (See text for details.)*

Table III—Stability of Drocinonide Phosphate Potassium in Formula I[a]

Temperature	1 Month	2 Months	3 Months	6 Months
5°	97.0	99.4	97.7	96.4
25°	95.2	96.2	100.3	93.5
33°	94.7	95.3	99.7	97.9
40°	94.1	95.9	95.6	80.0

[a] Expressed as percent undegraded steroid.

B sulfate was added to the drocinonide phosphate potassium–neomycin sulfate system to increase the antibacterial activity of a combination ophthalmic preparation. Increasing the buffer concentration an additional 25% and adding the steroid slowly to the disodium hydrogen phosphate–antibiotic mixture in dilute solution made it possible to prepare a solution of the three drugs in concentrations considered desirable for therapeutic effect.

A very slight haze in the product developed immediately after preparation. Filtration yielded a crystal-clear solution that remained clear. The haze also appeared in the product formulated without neomycin sulfate. (The haze might be due to a small amount of impurity in polymyxin that was not protected by disodium hydrogen phosphate and was, therefore, precipitated by the steroid.) The bioactivity of polymyxin in these systems has not been investigated and certainly warrants further investigation.

The ability of disodium hydrogen phosphate to counteract the incompatibility of neomycin sulfate with other steroids, such as dexamethasone sodium phosphate and prednisolone sodium phosphate, was also investigated. As with drocinonide phosphate potassium, solutions of these steroids in the presence of neomycin sulfate were clear and free of crystals.

A currently marketed ophthalmic solution of dexamethasone sodium phosphate and neomycin sulfate contains sodium bisulfite as an antioxidant to help overcome the incompatibility between the steroid and the antibiotic. Studies in these laboratories have shown sodium bisulfite to be effective in the drocinonide phosphate potassium–neomycin sulfate system; small concentrations of bisulfite produced a crystal-free solution. When this solution was purged with oxygen, the bisulfite was oxidized to bisulfate, and rosette crystals began to grow on the walls of the container. The advantage to using disodium hydrogen phosphate rather than bisulfite was the stability of phosphate in the presence of oxygen, which permitted packaging of the product in a plastic squeeze-bottle container.

Dipotassium hydrogen phosphate exhibited properties similar to those of the disodium salt. No studies have been made of the stability or bioactivity of drocinonide phosphate potassium and neomycin sulfate in the presence of the dipotassium salt, but no marked difference is expected between the two salts.

SUMMARY AND CONCLUSIONS

Dibasic phosphate salts can be satisfactorily utilized to overcome the chemical incompatibility between neomycin sulfate and soluble corticosteroid phosphate salts.

Of the many mechanisms that could play a role in this "salting-in" process, two are: (*a*) phosphate ions from disodium hydrogen phosphate exert a common-ion effect, *via* ion-pair formation, or a cosolute effect (10); and (*b*) phosphate ions from disodium hydrogen phosphate interact with reactive sites on neomycin and sterically hinder the chemical reaction between the antibiotic and the steroid salt. By this latter mechanism, the bonding of phosphate ions to the reactive site(s) on neomycin would probably be *via* weak electrostatic bonds, since NMR spectra suggested that both neomycin sulfate and drocinonide phosphate potassium are present as separate moieties. The stoichiometry of the antibiotic–steroid complex (1:3) seems to indicate that the complex may not be formed by a simple ionic interaction between the two high molecular weight species. Further studies of the salting-in mechanism are currently underway.

The stability and bioactivity of drocinonide phosphate potassium and neomycin sulfate in a disodium hydrogen phosphate solution were not adversely influenced by the presence of the other drug. The use of disodium hydrogen phosphate as a simple and efficient way to overcome the chemical incompatibility between neomycin sulfate and soluble phosphate salts of corticosteroids is strongly recommended for ophthalmic formulations where some combination of these drugs is desirable.

Table IV—Bioactivity[a] of Neomycin in Formulas II, III, and IV Stored at Various Temperatures

GLC Determination of 7-Chloro-5,11-dihydrodibenz[*b,e*][1,4]-oxazepine-5-carboxamide in Serum or Plasma

A. O. NIEDERMAYER ˣ **and R. G. KOSKI**

Abstract □ This report describes the isolation, derivative formation, GLC, and quantitation of unmetabolized 7-chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepine-5-carboxamide (I) in blood serum or plasma. Carbamazepine is used as the internal standard to compensate for losses of I during extraction and handling. Essentially complete recovery (100 ± 6%) was demonstrated over a concentration range of 1–30 μg of I/ml of serum.

Keyphrases □ 7-Chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepine-5-carboxamide—GLC, analysis in serum and plasma as 5-nitrile derivative □ GLC—analysis, 7-chloro-5,11-dihydrodibenz[*b,e*]-[1,4]oxazepine-5-carboxamide in serum and plasma as 5-nitrile derivative

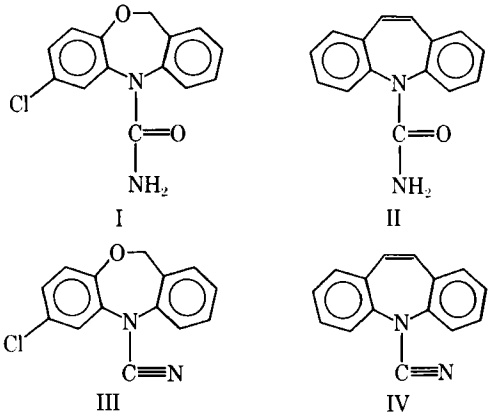
7-Chloro-5,11-dihydrodibenz[*b,e*][1,4]oxazepine-5-carboxamide (I) (1) exhibits antidepressant properties related to those of imipramine and anticonvulsant properties like those of carbamazepine (II). The pharmacological evaluation of I and a comparison of it with carbamazepine both require determination of the blood concentration of I.

The structural similarity of I and II suggested that a procedure for isolating carbamazepine from serum (2) might be useful in isolating I. It also appeared that carbamazepine might be used as an internal standard in any quantitative assay for I. Both premises proved to be correct.

The search for derivatives of I and II that are easier to chromatograph and assay than the parent compounds led to the synthesis of nitriles III and IV of I and II, respectively. These compounds were characterized by mass spectrometry, NMR spectroscopy, and IR spectrophotometry.

The flame-ionization response of the 5-nitrile derivative (III) was used successfully in the GLC determination of unmetabolized I in plasma and serum.

This methodology will prove useful in comparative bioavailability studies[1] in sheep, dogs, and humans, as well as for ascending-dose oral safety and short-term, multiple-dose tolerance studies[1] in humans.



EXPERIMENTAL

Reagents—Chloroform, methanol, *n*-hexane, and benzene, all chromatographic quality, were used without further purification. Trimethylamine[2] (0.2–0.5 *M*) in benzene was prepared by bubbling the amine through chilled benzene (dried for at least 24 hr over molecular sieve) at a slow rate until the desired concentration, as determined by perchloric acid titration, was achieved. The refrigerated reagent was found to deteriorate slowly, and its concentration was checked monthly by titration.

Ammonium hydroxide (5%) was prepared by diluting 17 ml of the concentrated reagent to 100 ml with water. Heptafluorobutyric anhydride[3], obtained in 1-ml ampuls, was stored refrigerated in a glass-stoppered tube after opening and was used for not more than 2 weeks. Compound I[4] and carbamazepine[5] were prepared as methanolic solutions with concentrations near 340 and 240 μg/ml, respectively. Phosphate buffer (pH 7.2) was prepared according to USP XVIII.

Hydrochloric acid (0.25 *N*) was prepared by diluting 21.4 ml of the concentrated reagent to 1 liter with distilled water. Tribasic potassium phosphate (0.2 *M*) was made by dissolving 4.2 g of K_3PO_4 in sufficient distilled water to yield 100 ml of solution. The 1% OV-17 on 80–100-mesh Chromosorb G (HP)[6] was used as purchased.

Apparatus—The gas chromatograph[7] was equipped with a 1.7-m (5.5-ft) × 0.3-cm (0.125-in.) o.d. glass column filled with OV-17 packing and had both flame-ionization and ^{63}Ni electron-capture detectors. A multistation evaporator[8] was used for solvent stripping during isolation and purification. The centrifuge was capable of handling 50-ml tubes and of attaining speeds of at least 1500 rpm. The typical laboratory glassware used included 2.5-, 13-, 15-, and 35-ml centrifuge tubes, Pasteur 14.6-cm (5.75-in.) disposable pipets, and 10-, 50-, and 250-μl syringes[9].

GLC Conditions—Operating temperatures for the inlet, column, and flame-ionization detector were 240, 210, and 270°, respectively. Helium at 30 psig was applied at the column head. The flow of air and hydrogen for the flame detector was optimized. The electrometer input sensitivity was adjusted to $\sim 2 \times 10^{-10}$ Å, and output attenuation was applied as necessary. The samples injected never exceeded 1 μl. Under the stated conditions, the retention times for the nitriles corresponding to carbamazepine and I were ~9 and 12 min, respectively (Fig. 1).

Newly prepared columns were conditioned for at least 16 hr under operating conditions. In this time, a stable baseline was achieved and the subsequent chromatograms appeared completely satisfactory.

The ^{63}Ni electron-capture detector was operated in dc and pulsed modes, using nitrogen and argon with 5% methane as the respective carrier gases.

Standard Preparation—Exactly 40 μl each of internal standard solution (carbamazepine) and standard solution (I) were transferred by syringe into 2.5-ml glass-stoppered centrifuge tubes. The solvent was removed by placing the tube in a 55° water bath[8] and flushing its head space with a gentle stream of nitrogen gas to remove the solvent vapor.

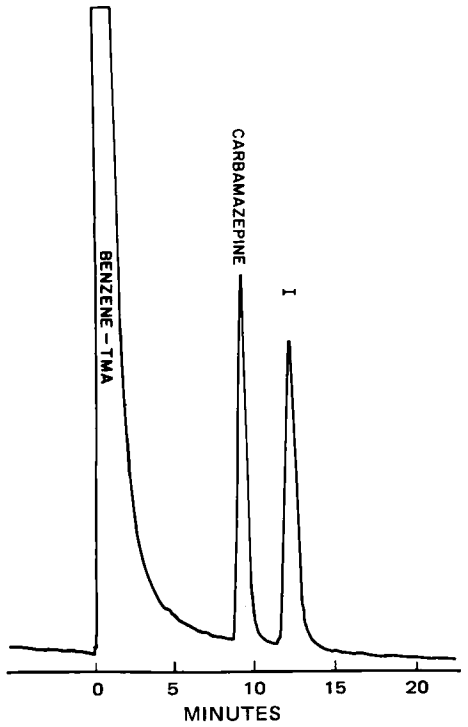

Figure 1—*Chromatogram of nitrile derivatives of I and carbamazepine.*

Sample Preparation (Extraction and Cleanup)—Exactly 5 ml of cell-free serum or plasma, obtained by standard techniques, or fraction thereof diluted to 5 ml with water was pipetted into a 35-ml centrifuge tube. Then 40 μl of internal standard solution was added by microsyringe, followed successively by 1 ml of pH 7.2 phosphate buffer and 13 ml of chloroform. The tube was shaken gently for 15 min but vigorously enough to ensure thorough mixing of the phases and was then centrifuged for 5 min at 1500 rpm. Occasionally, an emulsion formed but it was dispersed by stirring with a glass rod and recentrifugation.

The entire lower solvent phase was transferred by pipet into a 15-ml glass-stoppered centrifuge tube to effect complete removal of solvent (55° water bath and stream of nitrogen). To the resulting residue was added 3 ml of methanol, 2 ml of 0.25 *N* HCl, and 5 ml of *n*-hexane. After 5-min applications of shaking and centrifugation of the tube, the upper solvent phase was discarded. The wash cycle was repeated once with fresh hexane.

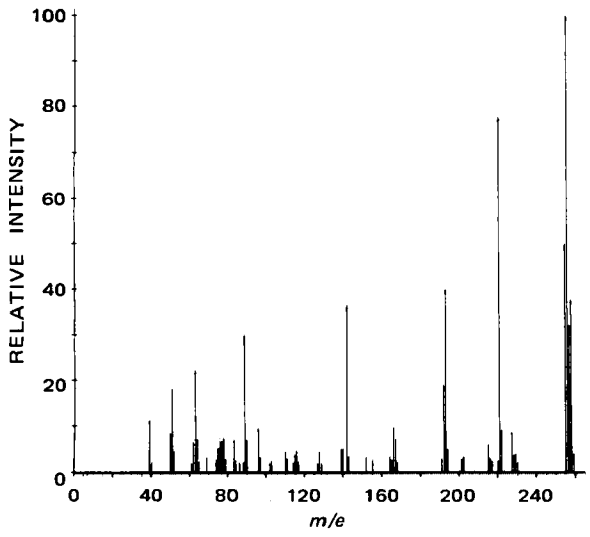

Figure 2—*Mass spectra of III.*

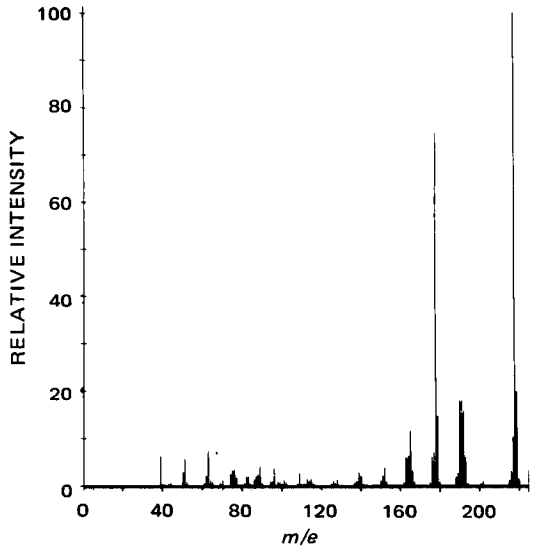

Figure 3—*Mass spectra of carbamazepine reaction product.*

The lower aqueous methanolic hydrochloric acid solution was transferred with a disposable pipet into a clean 13-ml centrifuge tube and extracted with 5 ml of chloroform for 5 min. After 3 min of centrifugation, the upper aqueous phase was discarded. The remaining chloroform solution was washed for 3 min with 5 ml of 0.2 *M* tribasic potassium phosphate and was then centrifuged. After centrifugation, the aqueous phase was discarded.

The washed chloroform extract was transferred in three aliquots into a 2.5-ml glass-stoppered centrifuge tube with intermittent solvent stripping (55° water bath and stream of nitrogen). Finally, the inside of the tube was twice alternately rinsed with a 1-ml aliquot of chloroform and restripped to concentrate the residue in the tube bottom.

Derivative Formation (Standards and Samples)—The residue of standard or sample contained in the 2.5-ml glass-stoppered centrifuge tube was dissolved in 100 μl of trimethylamine–benzene reagent. Five microliters of heptafluorobutyric anhydride was added, and the solutions were thoroughly mixed. The tube was tightly stoppered, and the solutions were allowed to react at 55° for 10 min.

After the reaction mixture had been cooled to room temperature, 0.5 ml of water was added and the two-phase system was thoroughly shaken. Following the addition of 0.5 ml of 5% NH_4OH, the tube was shaken again. After centrifugation, the lower aqueous phase was withdrawn almost completely by means of a capillary pipet; the upper solvent phase was lowered into the constricted part of the tube to facilitate sampling for chromatography.

Quantitation—After the peaks attributed to carbamazepine and I were identified by their retention times, baselines were interpolated and either peak height or area under the peak was measured. Then:

$$R_s = \frac{H_s}{H_{is}} \text{ and } R_u = \frac{H_u}{H_{is}} \qquad \text{(Eq. 1)}$$

where R_s is the ratio of standard peak height (H_s) to internal standard peak height (H_{is}), and R_u is the ratio of unknown peak height (H_u) to internal standard peak height (H_{is}). Finally:

$$\begin{matrix}\text{micrograms of I}\\ \text{per milliliter of}\\ \text{serum}\end{matrix} = \frac{R_u}{R_s} \times \frac{\text{micrograms of I in standard}}{\text{milliliters of serum taken}} \qquad \text{(Eq. 2)}$$

RESULTS AND DISCUSSION

Selection of Extraction and Cleanup Procedure—The structural similarity of carbamazepine and I made Kupferberg's extraction methodology (2) appear to be applicable to the extraction of I from serum. When ^{14}C-labeled I was added to human serum and its recovery from various stages of Kupferberg's extraction pro-

Table I—Recovery of I from Spiked Serum

I Added, μg	I Recovered, μg	Recovery, %
5	4.5	90
13.9	13.9	100
20.1	19.1	95
26.0	25.4	98
39.0	37.1	95
40.2	39.3	98
52.0	51.3	99
93.8	82.2	98
157.5	159.4	101

cedure was monitored by scintillation counting, the recovery of I was essentially quantitative.

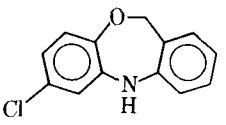
Selection of Internal Standard—The structural similarity of carbamazepine and I is the prime reason for the choice of carbamazepine as the internal standard. The comparable chemical and physical properties of the two compounds ensured similar behavior during isolation. When added to the serum early in the assay, the internal standard compensates for I losses due to partitioning and handling. As a result, the need for accuracy in measuring aliquots for chromatographic injection is reduced. The chromatographic system chosen produced an adequate separation of the pertinent components. The cleanup procedure removed all interferences.

Derivative Formation—Several chromatographic procedures were studied and rejected. Chromatography of underivatized I suffered from problems observed (3) with carbamazepine—*viz.*, absorption, decomposition, and chromatographic peaks unsuitable for quantitation. Formation of the trimethylsilyl derivative by standard techniques was rapid, but the derivatives exhibited poor stability. Furthermore, conflicting peaks were evident in serum extracts, precluding quantitation of I.

The anticipated need for high sensitivity led to consideration of electron-capture detection and the feasibility of preparing an electron-capturing derivative of I. Heptafluorobutyramides exhibit great electron affinity and have been used as amine derivatives (4). Reaction of heptafluorobutyric anhydride with amides was unreported.

The unanticipated reaction products produced by the attempted heptafluorobutyrylation of I and carbamazepine chromatographed well (Fig. 1). However, it was quickly established that they had little electron-capturing capability. Neither dc nor pulsed-mode operation of the detector yielded responses comparable in sensitivity to those of flame ionization. Mass spectrometry of the I derivative (Fig. 2) failed to reveal the expected molecular ion at *m/e* 470. This failure is consistent with the lack of electron-capturing capability of the compound. The molecular ion at *m/e* 256 is 18 mass units less than the molecular weight of I, possibly the result of dehydration. As expected for a chlorine-containing molecule, a second ion was evident at *m/e* 258 with one-third the intensity. The analogous derivative of carbamazepine revealed a molecular ion at *m/e* 218, also indicative of the corresponding 5-nitrile (Fig. 3).

Both derivatives exhibited IR absorption at 2220 cm^{-1}, indicative of a nitrile, probably the result of dehydration. NMR indicated the absence of exchangeable NH protons, along with a methylene singlet at δ 5.25 and an aromatic proton multiplet between δ 6.80 and 7.60 to support the formation of the 5-nitrile. The use of acetic anhydride as a substitute for heptafluorobutyric anhydride in the dehydration reaction failed to produce the expected products. Trifluoroacetic anhydride, however, produced the nitriles in yields comparable to those obtained with heptafluorobutyric anhydride, but the use of heptafluorobutyric anhydride was continued for consistency.



V

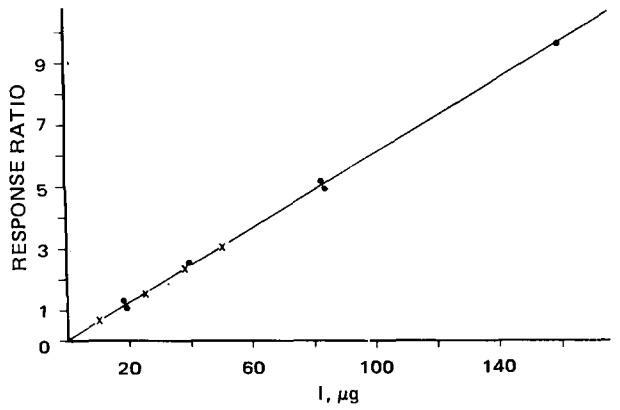


Figure 4—*Calibration curve of I.*

Linearity and Sensitivity—The linearity of the assay was first demonstrated for concentrations of I from 0 to 60 μg and then extended through 160 μg. The composite calibration curve is shown in Fig. 4. The extended linear range permits the assay of higher concentrations of I through signal attenuation rather than by rerunning a reduced size sample.

The response ratio (Fig. 4) represents the corrected I peak height response, for attenuation through ×8, related to the peak height of the internal standard. The concentrations are expressed as micrograms of I per sample (1–5 ml) of serum. The curve slope is ~16.5 (response per microgram of I), and deviation from the origin is negligible. A change in the concentration of internal standard obviously yields a different slope. In practice, the same internal standard solution is used for both standard and sample, and rigid control of its concentration is not necessary.

The limit of detection can be visualized on the calibration curve as 1–2 μg of I. When using 5 ml of serum, 0.2–0.4 μg/ml should be quantifiable. In practice, 0.2 μg/ml was readily achieved, since the sample background was negligible.

Specificity and Interference—Serum and plasma, known to be free of I or carbamazepine, were carried through the entire analytical procedure to demonstrate the absence of any normally occurring interference.

The precursor for I, 2-chloro-6,11-dihydrobenz[*b,e*][1,4]oxazepine (V), was tested for possible chromatographic interference during the quantitation of I. The nitrile derivative of I was unaffected by V. There was, however, chromatographic interference with the derivative of the internal standard, carbamazepine, since V is situated on its tail. The degree of interference was related to the condition and efficiency of the chromatographic column. The presence of V inflates the response of the carbamazepine, thus depressing the response ratio for I and leading to low biased assays. It is unlikely that significant quantities of the precursor V will ever be present during therapy, since it apparently is not a degradation product of I.

The anticoagulants potassium oxalate and edetic acid were examined for their effects on the assay of I. Both substances are commonly used to prevent coagulation of blood samples drawn by vein. At anticoagulant concentrations up to 2 mg/ml of whole blood (the concentration of anticoagulant usually employed), the recovery of I was essentially quantitative. There was no chromatographic evidence of either anticoagulant.

Recovery from Serum—The validity of any assay method for the blood level of a substance is the recovery of such material from fortified serum. This validation procedure was applied to the entire analytical range (Table I).

Stability of I in Frozen Serum—When 5-ml serum samples, containing 12.7 μg of I each, were stored frozen for 1, 3, 8, and 102 weeks, recoveries were 102, 106, 104, and 97%, respectively. Storage of serum for more than 8 weeks is not anticipated. The data for the 102-week period demonstrate that I can be recovered from serum stored that long.

Recoverability of I from Urine—The described methodology was also applied to urine spiked with I. The recovery of I from frozen urine stored for 8 weeks was 97%. No drug could be found in the urine of several subjects given I orally, suggesting that I had been excreted as a metabolite or conjugate.

Molecular Arrangement in Monolayers Containing Cholesterol and Dipalmitoyl Lecithin

JOEL L. ZATZ [x] and GARY W. CLEARY [*]

Abstract □ The molecular arrangement of dipalmitoyl lecithin and cholesterol in mixed monolayers was investigated with the aid of a physical model. The two lipids are miscible at the surface, but there is no indication of a specific interaction. In equimolar mixed monolayers at 25 and 37°, the lipids are in tail contact. Lecithin molecules are able to remain hydrated in the mixed monolayers at high values of surface pressure.

Keyphrases □ Monolayers—cholesterol and dipalmitoyl lecithin, molecular arrangement, force–area isotherms, model □ Cholesterol–dipalmitoyl lecithin monolayers—molecular arrangement, force–area isotherms, model □ Dipalmitoyl lecithin–cholesterol monolayers—molecular arrangement, force–area isotherms, model □ Films—molecular arrangement in cholesterol–dipalmitoyl lecithin mixed monolayers, model

The notion that monomolecular films might serve as a physical model for cellular membranes was first suggested by Langmuir (1) in 1917. Like a natural membrane, the monolayer is a coherent, organized, interfacial structure. Consequently, it is a particularly useful model system for obtaining information on the orientation and arrangement of membrane components.

Special significance has been ascribed to the behavior of monolayers containing both cholesterol and a phospholipid, such as lecithin, since these materials are known to be important constituents of biological membranes. Usually, investigators have reported the mean area per molecule (at constant surface pressure) for the mixture as a function of monolayer composition (2–7). In some cases, the mean molecular area has been a linear function of composition, indicating that each component occupied essentially the same molecular area in the mixed system as in a monolayer of the pure material.

However, deviation from linearity has been observed. The mean molecular area in such systems is less than that expected on the basis of the monolayer properties of the pure materials (2–7). These deviations have been interpreted in various ways. One view is that they are evidence of a significant interaction between the two lipids as a result of van der Waals' forces, configurational entropy effects, and alteration in water structure (3), leading to the conclusion that cholesterol must strengthen or stabilize the monolayer. The implication is that cholesterol also stabilizes biological membranes.

Another explanation of the reduction in mean area per molecule was put forth by Shah and Schulman (4), who attributed the effect to the formation of cavities between phospholipid molecules as a result of thermal motion of the fatty acyl chains. Cholesterol molecules were believed to be accommodated in the cavities. These authors noted that monolayers of pure dipalmitoyl lecithin at a surface pressure of 35 dynes/cm underwent a transition to the gel state and that compression to 40 dynes/cm resulted in the formation of a two-dimensional solid. The transitions were not observed in mixed monolayers containing cholesterol, which remained fluid at all values of surface pressure. It was concluded that cholesterol decreases monolayer cohesion and, by inference, that it acts as a "biological plasticizer" in natural membranes (4).

Gershfeld and Pagano (8) reviewed these theories and, based on the results of adsorption experiments, concluded that dipalmitoyl lecithin is immiscible with cholesterol at the surface and that a rational interpretation of the mixed monolayer experiments is not possible.

A physical model (the "heads-or-tails" model), which should help clarify the role of cholesterol, was recently suggested (9). It is based on the assumptions that lipids with long hydrocarbon chains are essentially vertically oriented and that the surface area of each molecule in a coherent monolayer conforms either to the area of the hydrocarbon tails (tail contact) or the hydrated polar head (head contact). According to this model, phospholipids in tail contact (*i.e.*, in a condensed surface state) do not exhibit a reduction in the mean molecular area in the presence of cholesterol, a result in accord with published findings (4, 5). But if the phospholipid molecules are extensively hydrated, cholesterol molecules may find free space between the hydrocarbon tails and thus require little

Molecular Arrangement in Monolayers Containing Cholesterol and Dipalmitoyl Lecithin

JOEL L. ZATZ [x] and GARY W. CLEARY [*]

Abstract □ The molecular arrangement of dipalmitoyl lecithin and cholesterol in mixed monolayers was investigated with the aid of a physical model. The two lipids are miscible at the surface, but there is no indication of a specific interaction. In equimolar mixed monolayers at 25 and 37°, the lipids are in tail contact. Lecithin molecules are able to remain hydrated in the mixed monolayers at high values of surface pressure.

Keyphrases □ Monolayers—cholesterol and dipalmitoyl lecithin, molecular arrangement, force–area isotherms, model □ Cholesterol–dipalmitoyl lecithin monolayers—molecular arrangement, force–area isotherms, model □ Dipalmitoyl lecithin–cholesterol monolayers—molecular arrangement, force–area isotherms, model □ Films—molecular arrangement in cholesterol–dipalmitoyl lecithin mixed monolayers, model

The notion that monomolecular films might serve as a physical model for cellular membranes was first suggested by Langmuir (1) in 1917. Like a natural membrane, the monolayer is a coherent, organized, interfacial structure. Consequently, it is a particularly useful model system for obtaining information on the orientation and arrangement of membrane components.

Special significance has been ascribed to the behavior of monolayers containing both cholesterol and a phospholipid, such as lecithin, since these materials are known to be important constituents of biological membranes. Usually, investigators have reported the mean area per molecule (at constant surface pressure) for the mixture as a function of monolayer composition (2–7). In some cases, the mean molecular area has been a linear function of composition, indicating that each component occupied essentially the same molecular area in the mixed system as in a monolayer of the pure material.

However, deviation from linearity has been observed. The mean molecular area in such systems is less than that expected on the basis of the monolayer properties of the pure materials (2–7). These deviations have been interpreted in various ways. One view is that they are evidence of a significant interaction between the two lipids as a result of van der Waals' forces, configurational entropy effects, and alteration in water structure (3), leading to the conclusion that cholesterol must strengthen or stabilize the monolayer. The implication is that cholesterol also stabilizes biological membranes.

Another explanation of the reduction in mean area per molecule was put forth by Shah and Schulman (4), who attributed the effect to the formation of cavities between phospholipid molecules as a result of thermal motion of the fatty acyl chains. Cholesterol molecules were believed to be accommodated in the cavities. These authors noted that monolayers of pure dipalmitoyl lecithin at a surface pressure of 35 dynes/cm underwent a transition to the gel state and that compression to 40 dynes/cm resulted in the formation of a two-dimensional solid. The transitions were not observed in mixed monolayers containing cholesterol, which remained fluid at all values of surface pressure. It was concluded that cholesterol decreases monolayer cohesion and, by inference, that it acts as a "biological plasticizer" in natural membranes (4).

Gershfeld and Pagano (8) reviewed these theories and, based on the results of adsorption experiments, concluded that dipalmitoyl lecithin is immiscible with cholesterol at the surface and that a rational interpretation of the mixed monolayer experiments is not possible.

A physical model (the "heads-or-tails" model), which should help clarify the role of cholesterol, was recently suggested (9). It is based on the assumptions that lipids with long hydrocarbon chains are essentially vertically oriented and that the surface area of each molecule in a coherent monolayer conforms either to the area of the hydrocarbon tails (tail contact) or the hydrated polar head (head contact). According to this model, phospholipids in tail contact (*i.e.*, in a condensed surface state) do not exhibit a reduction in the mean molecular area in the presence of cholesterol, a result in accord with published findings (4, 5). But if the phospholipid molecules are extensively hydrated, cholesterol molecules may find free space between the hydrocarbon tails and thus require little

Table I—Calculation of Mean Molecular Area in Mixed Monolayers of Cholesterol and Dipalmitoyl Lecithin Using the Heads-or-Tails Model[a]

Case	Criterion	A_m =		
1	$(A_2 - A_{HC}) \approx 0$	$A_1X_1 + A_{HC}X_2$		
		for $X_2 \leq 0.5$		for $X_2 \geq 0.5$
2	$A_1 > (A_2 - A_{HC}) > 0$	$A_1X_1 + A_{HC}X_2$		$(A_1 + A_{HC})X_1 + A_2(X_2 - X_1)$
3	$(A_2 - A_{HC}) = A_1$	$A_1X_1 + A_{HC}X_2$		A_2X_2
		for $X_2 \leq 0.333$	for $X_2 \geq 0.333$	
4	$2A_1 > (A_2 - A_{HC}) > A_1$	$A_1X_1 + A_{HC}X_2$	$A_2(2X_2 - X_1) + (2A_1 + A_{HC}) \cdot (X_1 - X_2)$	A_2X_2

[a] A_m = mean per area per molecule, X_1 = mole fraction of cholesterol, A_1 = area per molecule in cholesterol monolayer, X_2 = mole fraction of lecithin, A_{HC} = area per molecule of lecithin hydrocarbon tail, and A_2 = area per molecule in lecithin monolayer.

additional area. Therefore, in the presence of cholesterol, the effective area of a phospholipid molecule is the area of its hydrophobic tail rather than that of the bulkier polar portion, provided that the monolayer components are miscible.

An advantage of the proposed model is that it permits the derivation of quantitative relations for the mean area per molecule in a mixed monolayer as a function of the surface properties of the pure components, the composition of the mixed monolayer, and the area of the hydrocarbon tail of the phospholipid. This report deals with results obtained with mixtures of cholesterol and dipalmitoyl lecithin at two temperatures.

EXPERIMENTAL

Cholesterol[1] and dipalmitoyl lecithin[1] were reportedly 99% pure. Organic solvents were spectrograde, and sodium chloride was reagent grade. Water was double distilled; the final distillation took place in an all-glass still. The apparatus used was described previously (10).

The subphase contained 0.9% sodium chloride. Dipalmitoyl lecithin and lecithin–cholesterol mixtures were spread from solution in hexane–ethanol (4:1), and cholesterol was spread from solution in hexane. A thermostat[2] was used to maintain the subphase temperature constant within 0.1°. Surface pressure (π) was measured by the Wilhelmy plate method.

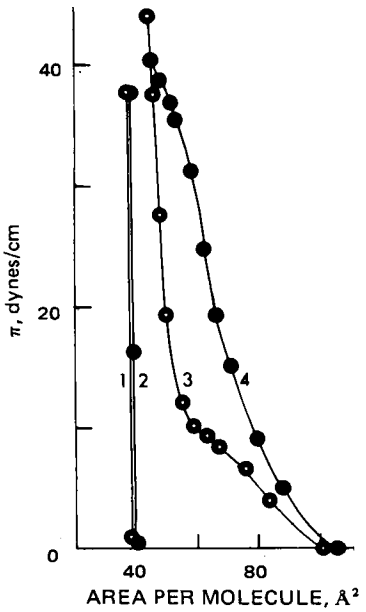

Figure 1—*Surface pressure as a function of available surface area of pure lipids. Key: curve 1, cholesterol at 25°; curve 2, cholesterol at 37°; curve 3, dipalmitoyl lecithin at 25°; and curve 4, dipalmitoyl lecithin at 37°.*

RESULTS AND DISCUSSION

Force–area isotherms for cholesterol and dipalmitoyl lecithin monolayers at 25 and 37° are plotted in Fig. 1. The cholesterol monolayer at 25° is in a highly condensed state at surface pressure values above 1 dyne/cm. An increase in the subphase temperature to 37° has no effect on the state of the monolayer. The entire isotherm is displaced to slightly higher values of surface area per molecule. Based on its low compressibility and the correspondence of the experimental surface area per molecule with the cross-sectional area of the hydrocarbon portion of cholesterol (11), it was concluded that the hydrocarbon tail determines the surface area required for each cholesterol molecule (9).

The π–A curve for dipalmitoyl lecithin at 25° (Fig. 1) is of the expanded type below a surface pressure of about 20 dynes/cm. In terms of the model, the molecules are described as being in head contact. In other words, the area occupied by each molecule is that of the hydrated polar portion. With increasing surface pressure, a change of state takes place and the area per molecule approaches that of the hydrocarbon tails (11). In contrast to the behavior of cholesterol, dipalmitoyl lecithin monolayers undergo marked changes in surface state as a function of temperature. At 37° (Fig. 1), the monolayer is considerably more expanded than at 25°. A state of tail contact is not realized until the surface pressure reaches 40 dynes/cm.

The equations previously derived (9) permit calculation of A_m, the mean area per molecule at a given surface pressure of the

mixed monolayer, from the surface properties of the pure components. These relations are summarized in Table I. The only parameter needed for the calculation that may not be obtained directly from experiment is A_{HC}, the area of the hydrocarbon tail of the phospholipid. It is possible to estimate A_{HC} from molecular models and data from π–A curves of simple lipids. However, to obtain a more accurate approximation and also to see the effect of surface pressure on A_{HC}, another method was chosen.

The 1:1 mixed monolayer at 25° represents a Case 2 situation (above a surface pressure of about 5 dynes/cm), so Eq. 1 applied:

$$A_m = A_1X_1 + A_{HC}X_2 \qquad \text{(Eq. 1)}$$

where X_1 and X_2 are the mole fractions of cholesterol and lecithin, respectively; and A_1 is the area per molecule in a monolayer of pure cholesterol at the same surface pressure. This equation may be rearranged to:

$$A_{HC} = \frac{A_m - A_1X_1}{X_2} \qquad \text{(Eq. 2)}$$

where A_1, X_1, and X_2 are known. By using the experimental values of A_m at each surface pressure for the 1:1 mixed monolayer, A_{HC} can be calculated. As shown in Fig. 2, A_{HC} is a linear function of π, obeying the relationship:

$$A_{HC} = 45.2 - 0.2\pi \qquad \text{(Eq. 3)}$$

The compressibility of the hydrocarbon tails corresponds to what one would expect for a liquid condensed monolayer (12) and thus supports the notion that the tails are vertically oriented.

The π–A data for the pure monolayers at 25° and values of A_{HC} from Eq. 3 were used to calculate A_m at various values of surface pressure for each mixed monolayer at that temperature. For each system, the theoretical points were joined to produce a continuous curve. These curves and the corresponding experimental data are presented in Figs. 3–5. It is not surprising that the fit to experimental data is so good for the 1:1 monolayer (Fig. 3), since the values for A_{HC} were derived from this system. However, the correspondence between theory and experiment is also quite good for the other mixtures (Figs. 4 and 5).

The values of A_m for a 1:1 mixed monolayer at 37° were also calculated. However, since A_{HC} is expected to vary with temperature, the values at 25° from Eq. 3 could not be used directly at the higher temperature. The effect of temperature on A_{HC} was estimated

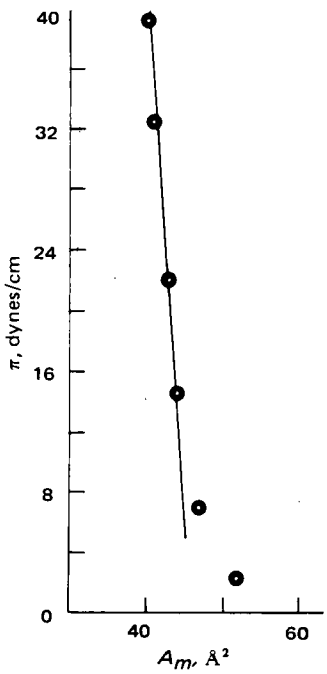

Figure 6—*The π–A curve for mixed monolayers of cholesterol–dipalmitoyl lecithin (1:1) at 37°. Key: —, calculated from heads-or-tails model; and O, experimental points.*

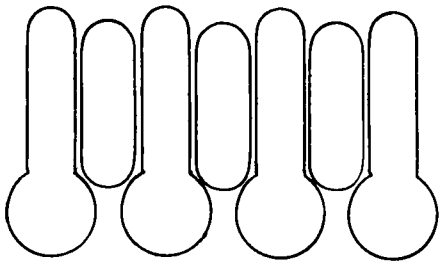

Figure 7—*Representation of molecular arrangement in equimolar mixed monolayers of cholesterol (short rod) and dipalmitoyl lecithin at surface pressure values above 5 dynes/cm.*

from the surface properties of palmitic acid, since its hydrocarbon chain is saturated and contains 16 carbon atoms, as do each of the hydrocarbon chains of our lecithin. An adjustment was made based on the observation that a comparable increase in temperature causes an expansion of 2.8 Å^2/molecule of palmitic acid in the condensed state (13).

Therefore, A_{HC} of dipalmitoyl lecithin at 37° was assumed to be 2.8 Å^2/hydrocarbon chain, or 5.6 Å^2/molecule, higher than at 25° at the same surface pressure. The values of A_m were calculated for various surface pressures, and the theoretical points were joined to produce a continuous curve. The curve and corresponding experimental data are compared in Fig. 6.

The good agreement found in these experiments between calculations based on the heads-or-tails model and the experimental results strongly supports the validity of the assumptions of the model, at least with respect to mixtures of dipalmitoyl lecithin and cholesterol. Therefore, it is concluded that these substances are miscible in monomolecular films (and presumably in biological membranes). Furthermore, there is no indication of a specific interaction between the two lipids. Shah and Schulman (4) arrived at the same conclusion, based on surface potential measurements.

In the mixed monolayers, lecithin molecules are in tail contact with cholesterol molecules (Fig. 7). Since the hydrocarbon portions of the molecules are area determining, lecithin molecules in the mixed monolayers may remain hydrated even at high values of surface pressure. In contrast, compression of pure lecithin monolayers to surface pressures above 20 dynes/cm severely restricts the space available to the molecules (Fig. 1), thereby limiting the ability of the polar groups to surround themselves with water molecules. This difference in the extent of hydration may explain the liquefaction of monolayers of dipalmitoyl lecithin by cholesterol.

The mechanical properties of surface films depend not only on the size and shape of the hydrocarbon chains but also on interactions among polar groups and between polar groups and the subphase (14). In fact, the high values of surface viscosity found for monolayers of long chain alcohols and amides have been ascribed to the existence of two-dimensional networks as a result of intermolecular hydrogen bonding (15). If the formation of similar networks is responsible for the rheological changes that occur in monolayers of dipalmitoyl lecithin at 25° (4), then the effect of cholesterol in permitting interactions of lecithin molecules with the subphase rather than with each other can account for the lower viscosity of monolayers containing cholesterol.

The force–area isotherms for the equimolar mixed monolayers at the two temperatures studied are quite similar (Figs. 3 and 6) and, as shown, differences between them are accounted for by the dependence of the hydrocarbon tail area on temperature. The arrangement of the lipids in the 1:1 mixed monolayers is practically independent of temperature, while the packing of dipalmitoyl lecithin in monolayers of the pure material is a function of temperature. This observation may have some significance in the extrapolation of work with model membranes containing dipalmitoyl lecithin at room temperature to a biological system at some other temperature.

Fluorocarbon Aerosol Propellants VI: Interspecies Differences in Solubilities in Blood and Plasma and Their Possible Implications in Toxicity Studies

SARFARAZ NIAZI and WIN L. CHIOU ˣ

Abstract □ Solubilities of the three most commonly used fluorocarbon aerosol propellants were determined in the blood and plasma of humans, monkeys, dogs, rats, and mice. Differences as large as ~fourfold in blood and more than 33-fold in plasma were found in different species. The partitioning of fluorocarbons between blood cells and plasma showed even greater differences between species. An indirect method was suggested for the calculation of plasma concentrations from total blood concentrations. A comparative evaluation was reported for the nonprotein bound fractions of fluorocarbons in the blood samples of various species. A correlation was drawn for the pharmacokinetic properties of the fluorocarbons within and between species, and a rationale was provided for the extrapolation of toxicity data from animals to humans.

Keyphrases □ Fluorocarbon aerosol propellants—interspecies differences in blood and plasma solubilities, toxicity implications □ Aerosol fluorocarbon propellants—interspecies differences in blood and plasma solubilities, toxicity implications □ Trichloromonofluoromethane—interspecies differences in blood and plasma solubilities, toxicity implications □ Dichlorodifluoromethane—interspecies differences in blood and plasma solubilities, toxicity implications □ Dichlorotetrafluoroethane—interspecies differences in blood and plasma solubilities, toxicity implications

Due to the wide use of fluorocarbon aerosol propellants in various household, cosmetic, and pharmaceutical pressurized packages, the possible adverse effects or toxicities of these compounds have been extensively studied in recent years. These studies have concerned the effects on the cardiovascular system (1–10), enzyme activities (7, 11–13), mutation (14), and ozone concentrations in the stratosphere (15, 16).

The prediction of acute toxicity of the propellants in humans has often been made by extrapolating the toxicity data from various animal species to humans (2, 10, 17, 18). However, the possibility of interspecies differences may render such extrapolations less important. One means of evaluating such differences is the study of absorption, distribution, metabolism, and elimination of these compounds in various species and of possible differences in the acute and chronic accumulation following accidental or normal exposures to these compounds.

The three most commonly used fluorocarbon aerosol propellants, trichloromonofluoromethane, dichlorodifluoromethane, and dichlorotetrafluoroethane, exist in gaseous form at 37°. Therefore, the absorption, distribution, elimination, and accumulation of these compounds are likely to be subjected to parameters that have been shown to be important for gaseous anesthetics (19, 20). Two such parameters are the solubilities of the gaseous compound in the blood and plasma of various species.

For gaseous or volatile compounds, the term "solubility" is commonly defined as the ratio of concentration of the compound between the liquid phase and the gaseous phase at the equilibrium state (19, 20). Such a ratio is, in fact, identical to the partition coefficient, P, between the two phases, as used conventionally for nonvolatile compounds between organic and aqueous phases. The purpose of this paper is to report the results of a study on the solubilities of the three most commonly used fluorocarbon propellants in the blood and plasma of various species. The possible correlation between the solubilities and the pharmacokinetic properties and a rationale for extrapolation of animal toxicity data to humans also will be discussed.

EXPERIMENTAL

Propellants and GC Analyses—The three pure propellants were supplied by the manufacturer[1]. These compounds were analyzed using a dual-column gas chromatograph equipped with a tritium electron-capture detector. The exact procedure followed was reported previously (21).

Blood and Plasma—Blood samples were freshly drawn and were used within 2 hr. Plasma samples were prepared by centrifuging either pooled or individual blood samples for 20 min in a clinical centrifuge and were also used within 2 hr after the withdrawal of blood samples. Blood samples were collected in 7.0-ml vacuum tubes[2], each containing 60 mg of ethylenediaminetetraacetate (humans, monkeys, dogs, and rats) or heparin (mice) as the anticoagulant.

Humans—About 15 ml of blood was collected from each of four healthy male volunteers, 24–35 years of age and weighing 50–70 kg.

Dogs—About 15 ml of blood was collected from four male German pointer dogs, weighing 12–16 kg.

Monkeys—About 20 ml of blood was collected from each of four rhesus monkeys, weighing 6–8 kg.

Rats—Four Sprague–Dawley-strain male rats, weighing ~300 g, were anesthetized with 65 mg/kg ip of pentobarbital sodium. The chest was opened with a quick incision, and blood samples were drawn directly from the ventricles of the heart.

Mice—Twenty BDF_1-strain male mice, weighing ~25 g, were given a deep incision in the throat, and the oozing blood was collected in a tube containing heparin. Only initial samples were collected, however, to avoid contamination with clotting factors. From 0.5 to 1 ml of blood was obtained from each mouse, and all blood samples were pooled together. There was no visible precipitation or coagulation in the pooled blood sample.

All plasma prepared from each individual was pooled, although the blood samples were studied individually except in the case of mice.

Partition Coefficient Determination—The partition coefficient or solubility, S, was determined based on the head-space method (21, 22) and can be expressed as:

$$S = \frac{A_t - C_h(V_t - V_l)}{V_l C_h} \qquad \text{(Eq. 1)}$$

where A_t = total amount of fluorocarbon added to a sealed serum bottle, V_h = volume of the head space, C_h = concentration of fluo-

Rat	16.714 (28.28)	14.555 (255.35)	4.405 (4.25)

[a] Values in parentheses are for comparison purposes; the partition coefficient in humans was considered unity. [b] Hematocrit values used in calculations were: human, 47%; dog, 45.5%; monkey, 42%; mouse, 41.5%; and rat, 46%.

rocarbon in the head space, V_t = internal volume of the sealed bottle, and V_l = volume of liquid phase in the sealed bottle.

The partition coefficients were determined at two concentrations, and the equilibrium concentration in the liquid phase, C_l, was determined using the following mass balance equation:

$$C_l = \frac{A_t}{V_l + V_h/S} \qquad \text{(Eq. 2)}$$

The effect of ethylenediaminetetraacetate and heparin on the partition coefficient was studied by comparing the solubility of the three fluorocarbon propellants in normal saline with or without heparin (1%) or ethylenediaminetetraacetate (1%).

RESULTS

The solubility values of the three fluorocarbon propellants in blood and plasma of five species are summarized in Table I. The solubility in human blood and plasma is also compared to that in other species.

The partition coefficient between blood cells and plasma ($P_{bc/plasma}$) was calculated using the information in Table I through the following mass balance equations:

$$P_{blood/air} = (\text{hematocrit})(P_{bc/air}) + (1 - \text{hematocrit})(P_{plasma/air}) \qquad \text{(Eq. 3)}$$

Rearranging Eq. 3 gives:

$$P_{bc/air} = \frac{[P_{blood/air} - (1 - \text{hematocrit})(P_{plasma/air})]}{\text{hematocrit}} \qquad \text{(Eq. 4)}$$

The partition coefficient between blood cells and plasma can be expressed as:

$$P_{bc/plasma} = \frac{P_{bc/air}}{P_{plasma/air}} \qquad \text{(Eq. 5)}$$

Substituting Eq. 4 into Eq. 5 gives:

$$P_{bc/plasma} = \frac{P_{blood/air}}{(\text{hematocrit})(P_{plasma/air})} - \frac{(1 - \text{hematocrit})}{\text{hematocrit}} \qquad \text{(Eq. 6)}$$

Table II shows the partition coefficient values of the three fluorocarbon propellants between blood cells and plasma along with the comparison of the values in humans to other species. The hematocrit values for various species were obtained from the literature (23).

The concentration of fluorocarbons in the plasma could be calculated using the following relationship:

$$\frac{C_{plasma}}{C_{blood}} = \frac{C_{plasma}/C_{air}}{C_{blood}/C_{air}} = \frac{P_{plasma/air}}{P_{blood/air}} = \text{constant} \qquad \text{(Eq. 7)}$$

and, hence:

$$C_{plasma} = (C_{blood})(\text{constant}) \qquad \text{(Eq. 8)}$$

Table III shows the comparative concentrations in the plasma for an arbitrary concentration of 10 μg/ml in the blood of the five species. Table IV shows the head-space concentration if the plasma obtained from a 10-μg/ml blood sample is equilibrated to obtain estimates of nonprotein bound fractions as discussed later.

The solubility values determined at two concentration levels (50 and 100 ng/ml for dichlorodifluoromethane and 30 and 60 ng/ml for trichloromonofluoromethane and dichlorotetrafluoroethane) did not show any dependence on the equilibrium concentration. Similarly, no effect was observed due to the presence of heparin and ethylenediaminetetraacetate.

DISCUSSION

Table I shows the solubilities of the three fluorocarbons in the blood and plasma of five species. These values are higher than the solubilities of these fluorocarbons in water (22), but the order of the solubility is the same as that found in water, *i.e.*, trichloromonofluoromethane > dichlorodifluoromethane > dichlorotetrafluoroethane. Marked differences were seen, however, in the solubilities in the blood and plasma of the five species studied. For example, an almost fourfold difference was seen in the solubility of trichloromonofluoromethane in the blood of five species (Table I). Similarly, an almost 30-fold difference was noted for the solubility of dichlorotetrafluoroethane in the plasma of the five species. Such large differences can only be attributed to differences in the interaction of these fluorocarbons with the components of the blood. In general, the higher solubility of fluorocarbons in the plasma compared to water can be attributed to binding to plasma proteins.

Table III—Concentrations (Micrograms per Milliliter) of Fluorocarbon Propellants in Plasma for an Arbitrary Propellant Concentration of 10 μg/ml in Whole Blood[a]

Species	Dichlorodifluoromethane	Dichlorotetrafluoroethane	Trichloromonofluoromethane
Human	12.37 (1.00)	17.95 (1.00)	9.82 (1.00)
Dog	2.80 (0.23)	6.03 (0.33)	3.76 (0.38)
Monkey	4.77 (0.38)	10.71 (0.60)	7.75 (0.79)
Mouse	2.57 (0.21)	3.99 (0.22)	1.71 (0.17)
Rat	1.21 (0.10)	1.38 (0.08)	3.89 (0.40)

[a] Values in parentheses are for comparison purposes; the concentration in human plasma was considered unity.

Table IV—Gas Phase Concentrations[a] (Micrograms per Milliliter) of Equilibrated Plasma Obtained from Blood Samples with an Arbitrary Concentration of 10 μg/ml[b]

Species	Dichlorodifluoromethane	Dichlorotetrafluoroethane	Trichloromonofluoromethane
Human	35.44 (1.00)	37.87 (1.00)	10.63 (1.00)
Dog	22.22 (0.63)	35.06 (0.92)	4.29 (0.40)
Monkey	29.44 (0.83)	71.40 (1.88)	10.06 (0.95)
Mouse	15.12 (0.43)	32.97 (0.87)	2.84 (0.27)
Rat	34.57 (0.97)	81.18 (2.14)	9.75 (0.92)

[a] These values are proportional to nonprotein bound fractions in the blood. [b] Values in parentheses are for comparison purposes; the concentration for humans was considered unity.

This observation recently was confirmed in several reports (24–27) where the binding of these fluorocarbons with human and bovine albumins was demonstrated. Not all proteins show specific interactions resulting in an increase in the solubility, and it was recently demonstrated in this laboratory that bovine globulin in fact caused a decrease in the solubility of fluorocarbons compared to water. The net solubility in the plasma, therefore, reflects the effect of the presence of several proteins showing varying degrees of interactions with the fluorocarbons.

The solubility of fluorocarbons in the blood is contributed to not only by specific interactions with plasma proteins but also to blood cells as shown in Table II, where the partition coefficients between blood cells and plasma were calculated based on Eq. 6. Differences much larger than those reported for the solubility in blood and plasma (Table I) were found for partitioning between blood cells and plasma. A 255-fold difference was seen for dichlorotetrafluoroethane between human and rat blood, the latter showing a greater degree of partitioning.

In general, dichlorotetrafluoroethane showed greater partitioning into blood cells compared to the other two fluorocarbons in all species studied. In all cases, however, the blood cells possessed a higher concentration than in the plasma, indicating the possibility of specific interactions of fluorocarbons with various structures of the blood cells. It is obvious, however, that the blood cells show a higher magnitude of interaction than the net interaction of fluorocarbons in the plasma. The postulation of the interaction of fluorocarbons with cellular components, as already mentioned, was demonstrated recently (12); trichloromonofluoromethane was shown to bind with the phospholipid of a microsomal preparation and also to another site that appeared to be similar to the carbon monoxide binding site.

The solubility values reported here form an important basis for a comparative evaluation of the absorption, distribution, elimination, and toxicity of the fluorocarbon in various species.

The effect of solubility of volatile compounds in blood on their uptake and distribution has been emphasized (20, 28, 29). The elimination of fluorocarbon propellants takes place mainly through the lungs. In a recent study (30), almost 97% of a single dose of trichloromonofluoromethane was expired unchanged from Wistar rats. The possibility of the metabolism of trichloromonofluoromethane was also studied. No possible metabolites were, however, detected following incubation with microsomal preparations from chickens, rats, mice, guinea pigs, and hamsters pretreated with phenobarbital. The resistance of fluorocarbon propellants against metabolism is mainly due to the higher stability of C—F bonds as compared to C—Cl bonds (31). Since the elimination of fluorocarbon takes place mainly through the lungs, it is believed that the observations that have been made regarding the uptake and elimination of many volatile anesthetics also eliminated through the lungs could be applied to the fluorocarbon propellants.

Stoelting and Eger (32) studied the effect of solubility on recovery from anesthesia from various gaseous anesthetics. They showed that the solubility in blood of the three anesthetics, methoxyflurane, halothane, and nitrous oxide, was directly proportional to their recovery time. Recovery time was defined as the time required for the alveolar concentration to drop to a certain fraction following various degrees of equilibration of these anesthetics with body tissues. They also showed that compounds with high solubility such as methoxyflurane (solubility = 13) and halothane (solubility = 2.3) showed a significant distribution to the tissues, which was reflected in the longer recovery times following equilibration for longer periods as compared to nitrous oxide (solubility = 0.47). Consequently, higher solubility compounds also will have larger uptakes and longer biological half-lives if they are absorbed and eliminated primarily from the lungs.

For example, it was shown (33) that upon inhalation in humans of a mixture of four fluorocarbons, including the three in this report, the most soluble, trichloromonofluoromethane, was absorbed in the blood to a greater extent than dichloromonofluoromethane and dichlorotetrafluoroethane, which have lower solubility in the blood (Table I). Trichloromonofluoromethane also showed a comparatively slower elimination from the body.

Detailed pharmacokinetics of these fluorocarbons recently were studied (34, 35) in dogs following intravenous dosing, and it was found that the biological half-lives of dichlorotetrafluoroethane and dichlorodifluoromethane ranged from 40 to 60 min but the half-life of trichloromonofluoromethane was significantly longer (90–100 min). This difference corresponds very well to the differences in solubility values (Table I) in the dog blood. The differences in the solubility of the three fluorocarbons in the dog blood were very well represented in their elimination behavior. For example, the pulmonary clearance of the high solubility fluorocarbon trichloromonofluoromethane was 0.9 liter/min compared to 2.05 and 2.53 liters/min for dichloromonofluoromethane and dichlorotetrafluoroethane, respectively (34).

The distribution of these fluorocarbons from the central (blood) compartment to the tissue compartments followed the general principle that compounds having low solubility in the blood are distributed faster to the tissue. For example, it took 5 min to obtain peak concentration in one tissue compartment and 10 min for the other tissue compartment for both dichloromonofluoromethane and dichlorotetrafluoroethane, but the corresponding time periods were 10 and 30 min for the two compartments for trichloromonofluoromethane in dogs (34).

These observations suggest that solubility values indeed offer an important index for the evaluation of absorption, distribution, and elimination and can be used to study toxicity correlations and differences between species. Since these fluorocarbons are primarily eliminated from the lungs, interspecies variations of several properties can be anticipated. For example, an almost fourfold difference in the blood solubility of trichloromonofluoromethane be-

tween humans and mice is most likely to result in a significant difference in the uptake and disposition characteristics between the two species; any extrapolation of possible toxicity based on these properties is probably less justified than between monkeys and humans where the solubility of this fluorocarbon is in good agreement. On the other hand, placing great confidence in solubility values to anticipate uptake and disposition patterns is also not justified in view of the differences in the pulmonary ventilation and cardiac output both within and between species (23) since these factors can seriously affect the uptake and disposition patterns.

It is generally agreed that the plasma concentrations of the drugs correlate better with various pharmacological and toxicological properties than the dose administered. In some instances, the nonprotein bound fraction of the drug in a blood sample correlates even better. However, it is not very practical to measure directly the plasma concentrations of fluorocarbon propellants by first centrifuging the blood samples, since the high volatility of these compounds can result in a significant loss to the atmosphere, especially at room temperature during handling. An indirect method can be easily employed if the partition coefficients between blood cells and plasma are available, as described earlier (Eq. 6). The plasma concentration can then simply be calculated using Eq. 8.

Table III shows the plasma concentrations of the three fluorocarbons in the five species for an arbitrary whole blood concentration equal to 10 μg/ml. Differences as large as 13-fold existed in the plasma concentrations between various species; in all instances, the human plasma showed the highest concentration at equal blood concentrations. These differences are attributable to the differences in the partitioning between blood cells and plasma. This observation can have an important bearing on comparative evaluations of toxic blood concentrations in various species if the plasma concentrations correlate better with the possible toxic manifestations. Nevertheless, this conclusion can be misleading if due consideration is not given to the nonprotein bound fraction in the plasma. Although no such measurements were made directly, an indirect comparison can be made easily by dividing the plasma concentration by the partition coefficient between plasma and air to obtain the concentration in the gaseous phase equilibrating with the plasma. In such a hypothetical equilibration, the concentration in the gaseous phase will be directly proportional to the unbound fraction in the plasma. These values are shown in Table IV.

Although the relative nonprotein bound concentration was generally higher for humans, except for dichlorotetrafluoroethane, the maximum difference decreased to about 3.5-fold compared to a 13-fold difference in the plasma (Table III).

In conclusion, the large differences in the solubilities of fluorocarbon aerosol propellants can result in significant differences in the pharmacokinetics of these fluorocarbons. Thus, any interspecies extrapolation of toxicity data based on parameters such as dose, toxic blood concentration, accumulation, and uptake should take into account the various solubility parameters described here.

High-Performance Liquid Chromatographic Analysis of Ampicillin

KIYOSHI TSUJI ˣ and JOHN H. ROBERTSON

Abstract □ A high-pressure liquid chromatographic method for the analysis of ampicillin is described. The method uses a 1-m long stainless steel column packed with anionic exchange resin, with a mobile phase of 0.02 *M* $NaNO_3$ in 0.01 *M* pH 9.15 borate buffer at a flow rate of 0.45 ml/min. The degradation products of ampicillin, penicillenic and penicilloic acids of ampicillin, can be separated and quantitated in less than 12 min of chromatographic time. The relative standard deviation for the analysis of ampicillin is less than 1%, and the method is sensitive to approximately 20 ng of ampicillin/sample injected. The method was applied to the analysis of various pharmaceutical preparations of ampicillin. It is also applicable, with a slight modification, for the analysis of penicillins G and V.

Keyphrases □ Ampicillin—high-pressure liquid chromatographic analysis □ Penicillins G and V—high-pressure liquid chromatographic analysis □ High-pressure liquid chromatography—analysis, ampicillin and penicillins G and V

Numerous chemical and physical methods and several automated methods are available for the determination of penicillins (1–13). Of these methods, the iodometric and hydroxylamine methods have been officially recognized by the Food and Drug Administration for "potency" determination (1). Although the speed of the automated iodometric and hydroxylamine methods (9–13) is fast, 20–60 determinations/hr, they are incapable of differentiating the intact penicillin molecules from the degradation compounds, since they determine the degraded penicillins, penicillanic and penicilloic acids.

Several GLC methods for penicillin have been reported (14–17); however, the methods determine penicillanic acid and have not been used for the analysis of ampicillin due mostly to difficulties in solubilization and derivatization of ampicillin. Chromatographic separation using a cross-linked dextran gel[1] column (18, 19) is slow and, to the knowledge of the authors, no high-performance liquid chromatographic (HPLC) method has been used to quantitate ampicillin, although an HPLC method was reported for the detection of ampicillin in nitrofurantoin (20) and for the determination of cephalosporin C (21).

EXPERIMENTAL

Apparatus—A modular liquid chromatograph equipped with a 254-nm UV monitor[2], a minipump[3], and a pulse dampener[4] were used.

An empty stainless steel column[5], 2.1 × 1000 mm, was first rinsed with tetrahydrofuran. Then the inside of the tubing was vigorously cleaned with a cotton string, presoaked with tetrahydrofuran, to remove loose metal particles. Chloroform was then drawn through the column, and the column was dried under a stream of dry nitrogen.

A 10-μm pore size stainless steel frit was fitted into the inlet end of the column, and a hex nut[6] with a stainless steel front, back lock ferrules, and cap[7] were attached to the column. Anionic exchange resin[8] was dry packed into the open end of the column by adding a small amount of the resin at a time and lightly tapping on the floor. After the column was tightly packed, a 2-μm pore size stainless steel frit was inserted into the outlet end of the column. The packed column was attached to a septumless injector valve[9] and the 254-nm UV monitor. The theoretical plates of the column, thus prepared, were approximately 555/m for the ampicillin peak.

Reagents—For the mobile phase, 0.02 *M* sodium nitrate in 0.01 *M* sodium borate, pH 9.15, was used.

Preparation of Ampicillin Standard Solution—The USP ampicillin reference standard was used "as is" at 867 μg/mg. Approximately 10 mg of the reference standard was accurately weighed[10] and placed in a 10-ml volumetric flask.

Prior to analysis, the standard was dissolved and diluted to the volume with the mobile phase.

Preparation of Samples—*Ampicillin Bulk Powder*—Approximately 10 mg of ampicillin bulk powder was accurately weighed and placed in a 10-ml volumetric flask. Prior to analysis, the sample was dissolved and diluted to volume with the mobile phase.

Hard-Filled Capsule—To minimize capsule weight variation, 10 capsules were emptied and their contents were accurately weighed. A portion of the powder equivalent to 1000 mg ampicillin was accurately weighed and placed in a 1000-ml volumetric flask. The contents were then diluted to volume with double-distilled water and shaken for 5 min to dissolve the ampicillin. About 25 ml of the suspension was placed into a 50-ml conical bottom centrifuge tube and then centrifuged at 2000 rpm for 20 min.

Sterile Injectables—Each vial containing 250 mg, 500 mg, or 1 g of product was reconstituted with the recommended volume of double-distilled water. An ultrasonicator[11] was used to dissolve each sample quickly.

From each of four 250-mg vials, 0.1 ml was removed with a 100-μl micropipet[12] with a disposable tip and placed in a 100-ml volumetric flask. The sample was then diluted to volume with the mobile phase.

From each of two 500-mg vials, 0.1 ml was removed and placed in a 100-ml volumetric flask. The sample was then diluted to volume with the mobile phase.

From one 1-g vial, 0.1 ml was removed and placed in a 100-ml volumetric flask. The sample was then diluted to volume with the mobile phase.

Oral Formulation—Each bottle containing 125 or 250 mg of oral preparation was reconstituted with the recommended volume of double-distilled water. From one 125-mg bottle, 5 ml was pipetted into a 50-ml round-bottom centrifuge tube. Then 0.1 ml of concentrated hydrochloric acid was added and mixed, followed by 30 ml of chloroform. The centrifuge tube was capped and shaken vigorously for 5 min, using a reciprocal shaker[13], and then centrifuged for 2 min at 2000 rpm. Four milliliters of the upper aqueous layer was pipetted into a 100-ml volumetric flask and diluted to volume with 0.02 *M* pH 6.0 phosphate buffer.

10.036	280.4	27.94	25.65	2.556
10.120	285.7	28.23	25.65	2.535
	RSD	3.40%	*RSD*	0.98%

Chromatographic Conditions—The flow rate of the mobile phase was 0.45 ml/min, with a column pressure of about 34 atm (500 psi). The column temperature was ambient, and the chart speed was 0.6 cm (0.25 in.)/min. A 2.0-μl quantity of sample was quantitatively injected into the column, using a septumless injector valve at an electrometer range setting of 0.02 full scale.

RESULTS AND DISCUSSION

A typical chromatogram of ampicillin is shown in Fig. 1. The HPLC method takes less than 12 min of chromatographic time to analyze one sample.

Penicillins G and V can also be separated and quantitated by the HPLC method (Fig. 2). For the quantitation of penicillin G samples, a slight increase in the amount of sodium nitrate in the mobile phase to 0.03 *M* optimizes the retention time of penicillin G and speeds up the analysis. The relationship between the concentration of sodium nitrate and the retention time of various compounds was described by Nelson (22). Since procaine elutes much slower than penicillin G (relative retention of 11) and interferes with subsequent, multiple analysis of samples, procaine must be removed prior to analysis. For the quantitative analysis of penicillin V, the addition of methanol to 10% in the mobile phase speeds up the analysis.

Detection of Degradation Compounds—Commercially produced ampicillin powder was degraded in an alkaline solution for 1 week, and the degraded ampicillin sample was then chromatographed. As shown in Fig. 3, the HPLC method is capable of dif-

ferentiating penicillenic and penicilloic acids of ampicillin from ampicillin. The presence of a small amount of penicillin G was also detected in this sample. These peaks were identified by matching the relative retention times with those of relatively pure penicillenic and penicilloic acids of ampicillin. Penicillenic acid was prepared by forming a mercuric mercaptide of ampicillin followed by decomposition with hydrogen sulfide (23). The purity of penicillenic acid thus prepared was approximately 84%. The penicilloic acid sample was obtained from a commercial source[14]. Since penicillanic acid has no UV absorption, its presence may not be detected by this method.

Since a slight degradation, less than 5%, can occur when ampicillin is left in the mobile phase for more than 1 hr, the ampicillin sample should be diluted in the mobile phase just prior to the analysis.

The minimum quantity of ampicillin detection was approximately 20 ng/sample when injected at an electrometer range setting of 0.01 full scale. Since the method is capable of detecting degradation compounds and since penicillenic acid, a degradation compound, was reported to have "allergenic equivalence" with penicillin G (24, 25), the HPLC method is of value for penicillin cross-contamination studies.

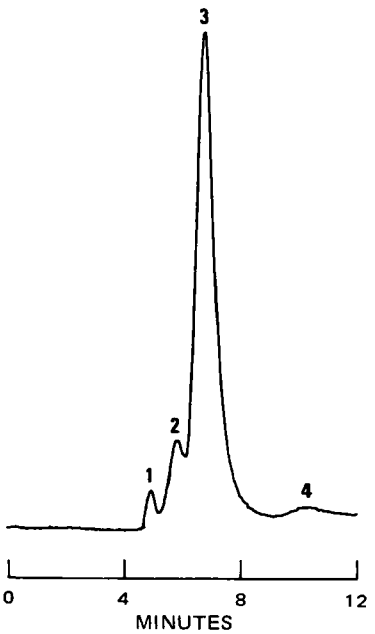

Figure 3—*HPLC analysis of ampicillin degraded in an alkaline solution indicating separation of (1) penicillenic acid, (2) penicilloic acid of ampicillin, (3) ampicillin, and (4) penicillin G.*

2	842	863	825, 894	770	840	777, 808
3	849	847	—	743	818	732, 757

Quantitative Determination of Ampicillin—Various amounts of the USP ampicillin reference standard, ranging from 0.1 to 15 mg/ml, were prepared, and a 2.0-μl quantity of each was quantitatively injected into the column using a septumless injector valve. The calibration curve was linear (correlation coefficient of 1.000) over the entire range, with a linear regression of $y = 3.33x - 0.036$.

The precision of the HPLC method was determined by comparing 12 replicate preparations of the USP ampicillin reference standard at approximately 1.0 mg/ml. Table I indicates that the relative standard deviation of the method is 3.4% when the peak area to weight ratio is used for the calculation and less than 1% when the peak height to weight ratio is used. Thus, good precision can be obtained by use of the septumless injector valve without an internal standard.

Ten current lots of ampicillin trihydrate bulk powder were analyzed (Table II). The potency was calculated using the ampicillin reference standard at 867 μg/mg. The drug contents thus calculated were compared to those of the iodometric method. The values obtained by the HPLC method showed no statistically significant difference from those of the iodometric assay method.

Table III shows the results of analysis of pharmaceutical products containing ampicillin. The potencies calculated from the HPLC method showed no statistical difference from those of the iodometric method.

Three lots of ampicillin trihydrate powder were aged for 1 month at 55°. Data obtained by the HPLC method showed 6.8–12.5% reductions in potencies, indicating that the powders underwent degradation by the heat treatment (Table IV). As expected, no loss in potencies was detected by the iodometric method. Microbiological assay (1) values of these samples indicated degradation and agreed very well with those of the HPLC method.

Determination of Major Impurity in Chlordiazepoxide Formulations and Drug Substance

W. N. FRENCH, F. F. MATSUI, and S. J. SMITH [x]

Abstract □ Procedures for quantitating the lactam impurity, 7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one 4-oxide, which can be present in chlordiazepoxide formulations, is presented. The method consists of trapping chlordiazepoxide in sulfuric acid in kieselguhr, eluting the impurity with ether, and quantitating by UV spectrophotometry in absolute alcohol at 312 nm.

Keyphrases □ Chlordiazepoxide and chlordiazepoxide hydrochloride—UV analysis for lactam impurity (7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one 4-oxide) □ 7-Chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one 4-oxide—UV analysis in chlordiazepoxide and chlordiazepoxide hydrochloride □ UV spectrophotometry—analysis, 7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one 4-oxide in chlordiazepoxide formulations

Pharmacopeial monographs for the widely used tranquilizer chlordiazepoxide [7-chloro-2-(methylamino)-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide] and the hydrochloride salt include limit tests for the lactam (7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one 4-oxide, I) and phenone (2-amino-5-chlorobenzophenone, II) impurities (1–3). These specifications allow a maximum of 0.1% of I and 0.01 (1, 2) or 0.05% (3) of II in the chlordiazepoxide drug substance. Monographs for capsules prepared with the hydrochloride salt permit a maximum of 3.0 and 0.1% of the two impurities (1, 3), respectively, while tablets prepared with chlordiazepoxide base may contain a maximum of 4% of I and 0.1% of II (2).

While limit tests are effective in monitoring impurities in chlordiazepoxide drug compounds and formulations, quality assurance procedures often require that the levels of impurities present in a drug substance or formulation be known precisely. This article describes methodology employing a "trap" column suitable for the quantitation of the impurity I present in the drug substance and formulations.

EXPERIMENTAL

Apparatus and Materials—Glass columns (2.5 × 20 cm), 0.2 *N* sulfuric acid, water-washed ether (ethyl), and absolute ethanol were used.

For purified kieselguhr, soxhlet extract kieselguhr[1] with methanol (ACS grade) for 24 hr. Thoroughly dry the support material and store in a well-closed bottle.

For purified absorbent cotton, soxhlet extract absorbent cotton with methanol (ACS grade) for 24 hr. Dry thoroughly and store in well-stoppered bottles.

For the standard solution of I, dissolve sufficient I in ether so that each milliliter contains 150 μg.

Procedure—Place a pledget of purified absorbent cotton at the bottom of the column. Then place purified kieselguhr (3 g), which has been triturated with 0.2 *N* sulfuric acid (3 ml), over the cotton. Tamp the layer lightly but evenly. Triturate a second 3-g portion of purified kieselguhr with 3 ml of 0.2 *N* sulfuric acid, add an accurately weighed portion of powdered tablet or capsule material or drug substance equivalent to about 25 mg of chlordiazepoxide (base or salt) or 5.0 ml of standard solution of I, and mix thoroughly. Transfer this material to the prepared column and tamp into a uniform second layer. Wipe the beaker and mixing rod with purified absorbent cotton and place the cotton on top of the prepared kieselguhr column.

Elute the column with water-washed ether. Collect at least 25 ml of eluate in a 50-ml volumetric flask and evaporate the eluate to dryness, employing a stream of dry nitrogen. Dissolve the resultant residue in ethanol and make to volume with this solvent. Measure the absorbances of standard and sample solutions at 312 nm against a similarly prepared blank containing no sample or standard.

Calculate the percent of I as follows:

$$\%\,\mathrm{I} = \frac{\text{weight of I in standard } (\mu g)}{} \times \frac{A_{spl}}{A_{std}} \times \frac{100}{\text{weight of chlordiazepoxide taken } (\mu g)} \quad \text{(Eq. 1)}$$

Table I—Trap Chromatography of Chlordiazepoxide and Compound I

Sample	Chlordiazepoxide Hydrochloride Introduced to Column[a], mg	Compound I Introduced to Column[b], μg	Absorbance of Eluant at 312 nm
1	25.60	—	0.002
2	30.73	—	0.009
3	50.00	264	0.160
4	40.62	264	0.164
5	30.88	264	0.161
6	—	264	0.158
7	—	264	0.158
8	—	264	0.160

[a] Actual quantities of chlordiazepoxide weighed and added to acidic kieselguhr layer. [b] Where indicated, an ethereal solution containing 264 μg of I was added to the acidic kieselguhr layer.

where A_{spl} is the absorbance at 312 nm of the sample solution, and A_{std} is the absorbance at 312 nm of the standard solution.

DISCUSSION

When I is present in chlordiazepoxide, it cannot be quantitated by direct UV spectrophotometry because of the similar maxima exhibited by the two compounds. GLC also is unsuitable since preliminary studies indicated, as reported previously (4), that chlordiazepoxide decomposed during chromatography. Thus it was decided to take advantage of the basic nature of chlordiazepoxide and the acidic character of I and to separate the compounds by employing a trap chromatography procedure (5–7).

Since the procedure was required specifically for the quantitation of I, experimental conditions were chosen so that chlordiazepoxide would be retained on the column, thus allowing the isolation and subsequent quantitation of the I present. Sulfuric acid in the trap layer was used to ensure that all parent drug was converted to the salt form, which is insoluble in ether. The presence of the acid also ensured that no basic material, which might be present in the sample, could cause retention of I. Ether was chosen as the eluant because of its known poor solvolytic power for chlordiazepoxide and salts but good affinity for I. In addition, this solvent did not elute sulfuric acid from the trap layer under the experimental conditions.

Samples of chlordiazepoxide, of I, and of mixtures were chromatographed through trap columns, employing the procedure described. Results (Table I) indicated that chlordiazepoxide was quantitatively retained while I was recovered from eluates. Weak absorbances observed with chlordiazepoxide samples (Samples 1 and 2) and slightly higher absorbances observed with drug–I mixtures (Samples 3–5) compared to pure I (Samples 6–9) were probably due to a combination of traces of I present in the drug compound, solvent residues (discussed later), and instrumental variation. High-pressure liquid chromatography (HPLC) of trap column eluates from the mixtures (Samples 3–5) did not detect the presence of chlordiazepoxide.

Table II—Recovery of Lactam Impurity I through the Trap Column

Theoretical Concentration in Final Ethanol Solution, g/ml	Absorptivity at 312 nm Obtained with No Column Trap	Absorptivity at 312 nm after Trap Chromatography	Recovery through Column, %
30.76	36.4	35.5	97.5
21.53	35.2	35.4	100.5
15.38	35.8	35.3	98.6
6.152	35.7	36.0	100.8
4.306	34.8	35.0	100.5
3.076	35.1	34.4	98.0
Mean value	35.5[a]	35.3	99.6
Coefficient of variation	1.6	1.5	1.2

[a] Absorptivity of ethanolic solutions of impurity I measured at 312 nm was 35.6 (two determinations).

Table III—Trap Column Analysis of I in a Triturate and a Commercial Capsule Formulation

Triturate[a]			
Triturate Taken, mg	I Determined, %	Recovery, %	Capsule Composite[b], I Found, %
42.47	1.58	103.9	2.93
49.64	1.55	101.9	2.91
61.02	1.47	96.9	2.85
81.41	1.44	94.7	2.88
50.64	1.59	104.3	2.83
51.11	1.55	101.8	—
Mean recovery		100.6	2.88
Coefficient of variation		3.9	1.5

[a] Content of I, 1.52%, was determined by tumbling seven weighed aliquots of triturate with ether (25 ml) for 1 hr, filtering the mixture, washing the filter and residue with ether (3 × 5 ml), evaporating the ether solution to dryness with dry nitrogen, dissolving the residue in 50.0 ml ethanol, and measuring the absorbance of the final solution. [b] Various weights of the composite were taken for analysis.

To determine whether any I was retained by the trap chromatography column, 5-ml aliquots of various concentrations of I in ether were treated as described in *Procedure* and the absorptivities of eluants were determined. These data were compared with absorptivities obtained when similar aliquots of I were diluted to 25 ml with ether, the ether solution was evaporated to dryness with dry nitrogen, and the residue was made to 50.0 ml with ethanol. The data (Table II) indicate that I was not retained on the trap column.

The data also show that the absorbance of solutions of I is linear over the range indicated with a mean recovery of 99.68% [coeffi-

Table IV—Comparative Analysis of Compound I in Chlordiazepoxide Formulations

Sample and Form of Chlordiazepoxide	Percent I Relative to Chlordiazepoxide Found by: Trap Chromatography Method	TLC[a]	HPLC[b]
A, capsule, hydrochloride salt	5.52	5	—
B, capsule, hydrochloride salt	0.31	<0.3	0.24
C, capsule, hydrochloride salt	4.25	4	4.01
D, capsule, hydrochloride salt	4.55	5.5	—
E, capsule, hydrochloride salt	2.56	2–2.5	—
F, capsule, hydrochloride salt	3.15	3.5	—
G, capsule, hydrochloride salt	5.92	5	5.57
H, tablet, free base	0.45	0.4	0.38
I, tablet, free base[c]	8.56	8	8.49

[a] TLC was carried out on silica gel F60-precoated layers (Merck) in ethyl acetate–ethanol (9:1) (8). Visualization was effected by spraying with Bratton–Marshall reagent (1), and estimation was made by comparison with standard spots. [b] HPLC was performed in a 5-μm microparticulate silica gel column with 5% ammoniacal ethanol (3% v/v), 30% tetrahydrofuran, and 65% *n*-hexane as solvent in a Varian model 4100 HLSL liquid chromatograph with a 254-nm UV detector. The internal standard was nitrazepam. [c] A pink material in the tablet coating interfered with the trap column method. Consequently, powdered tablet containing an equivalent of 25 mg of drug was extracted with acetone, the extract was taken to dryness, the residue was taken up in the kieselguhr containing sulfuric acid, and the analysis was concluded in the manner described.

cient of variation (*CV*) 1.2%]. Manipulation of samples does not lead to the loss of material, since absorptivity measurements of a directly prepared 5.1-μg/ml solution of I in ethanol afforded an absorptivity of 35.6.

The similar absorptivity values obtained between solutions of I prepared directly in ethanol and those prepared through an ether stage indicate that any residue from ether that could be present does not appear to make a significant absorbance contribution at 312 nm. To confirm this finding, 25-ml portions of ether were evaporated to dryness with a stream of dry nitrogen, any residue present was dissolved in 50.0 ml of ethanol, and the absorbance was measured. Values of 0.01 or lower were obtained.

Results from TLC examination of chlordiazepoxide formulations carried out over an extended period showed that all formulations contained well under 0.1% 2-amino-5-chlorobenzophenone (II). Thus, normally encountered levels of II in chlordiazepoxide formulations, while present in column eluates, do not interfere significantly with the absorbance of I at 312 nm. The absorbance maximums of a solution of I in ethanol (equivalent to 3% I using procedures described under *Experimental*) and a I–II mixture (equivalent to 3 and 1%, respectively) were nearly the same, 0.531 and 0.538, respectively. The level of II utilized was 10 times higher than pharmacopeial specifications (1–3) and was present in a much greater proportion relative to I than is ever encountered in the practical situation. Thus, it can be concluded that the absorbance contribution due to II, if present, will be well within experimental variation.

The accuracy of the proposed method for quantitating I in chlordiazepoxide was determined by analyzing aliquots of lactose triturate of I. The data obtained from this study (Table III) indicated a through-column recovery of 100.58% I (*CV* 3.9%). The precision of the proposed method was determined by analyzing replicate samples of a commerical capsule formulation, which indicated a coefficient of variation of 1.5% (Table III). This coefficient of variation of 1.5% compared very closely with coefficient of variation values obtained from ethereal solutions of I measured directly (1.6) and put through the trap column (1.5) (Table II) and with results obtained when mixtures of chlordiazepoxide and I were passed through the trap column (Table I, Samples 3–5, coefficient of variation of absorbance at 312 nm, 1.28%). In comparison, it would appear that the higher coefficient of variation values obtained from I–lactose triturate samples (Table III) reflect problems encountered in attempting to obtain a homogeneous triturate of a low level of I rather than the imprecision of the method.

Nine samples of chlordiazepoxide tablets and capsules, from a number of suppliers, were analyzed for I, employing the trap column method. The results from duplicate analyses were compared with values for I obtained from TLC and/or HPLC. Data obtained (Table IV) confirm the accuracy of the method of analysis and underline the suitability of the trap column procedure for the quantitation of decomposition product I in chlordiazepoxide.

Spectrophotometric Determination of Acetaminophen and Dichloralantipyrine in Capsules

FOTIOS M. PLAKOGIANNIS [x] and AHMED M. SAAD

Abstract □ A rapid method for the routine determination of acetaminophen and dichloralantipyrine in capsules is reported. The determination of acetaminophen is based on the ability of its hydrolytic product, *p*-aminophenol, to produce an intensive yellow color with vanillin. The determination of dichloralantipyrine is based on the fact that it, as well as its major metabolite chloral hydrate, produces a blue color with quinaldine ethiodide. No interferences were encountered, and good recovery and precision data were obtained.

Keyphrases □ Acetaminophen–dichloralantipyrine—spectrophotometric analysis of capsule formulation □ Dichloralantipyrine–acetaminophen—spectrophotometric analysis of capsule formulation □ UV spectrophotometry—analysis, acetaminophen and dichloralantipyrine in capsules

Several methods for the quantitative determination of acetaminophen in pharmaceutical preparations are available. Most of them are colorimetric and require the hydrolysis of acetaminophen to *p*-aminophenol (1–6). A significant contribution was provided by Vaughn (6), who capitalized on the fact that acetaminophen is readily hydrolyzed to *p*-aminophenol, which produces a stable yellow color with vanillin.

Archer and Haugar (7) found out that the addition compound, dichloralantipyrine, produces, upon the addition of quinaldine ethiodide, a blue color in proportion to its chloral hydrate content.

cient of variation (*CV*) 1.2%]. Manipulation of samples does not lead to the loss of material, since absorptivity measurements of a directly prepared 5.1-μg/ml solution of I in ethanol afforded an absorptivity of 35.6.

The similar absorptivity values obtained between solutions of I prepared directly in ethanol and those prepared through an ether stage indicate that any residue from ether that could be present does not appear to make a significant absorbance contribution at 312 nm. This report describes a quantitative UV spectrophotometric technique for the determination of acetaminophen and dichloralantipyrine in capsules containing 325 mg of acetaminophen, 100 mg of dichloralantipyrine, and 65 mg of isometheptene mucate.

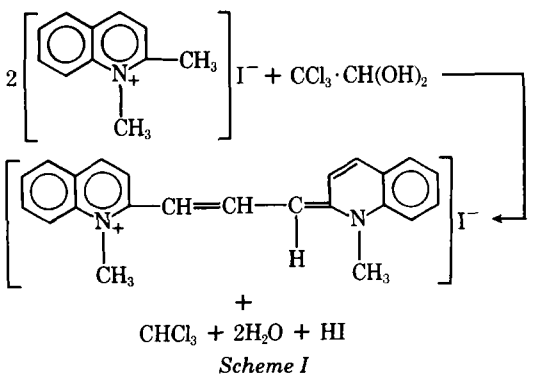
EXPERIMENTAL[1]

Materials and Reagents—The following were used (all of analytical grade): acetaminophen–dichloralantipyrine–isometheptene mucate capsules[2], 5% vanillin[3] in isopropanol, acetaminophen[4], dichloralantipyrine[5], 1.5% (w/v) quinaldine ethiodide[6] solution (dissolve 1.5 g of quinaldine ethiodide in 100 ml of water and filter if necessary), and 0.1 *N* ethanolamine[3] (dissolve 6.1 g of ethanolamine in water and dilute to 1 liter).

Acetaminophen Assay—The colorimetric curve is prepared as follows. Accurately weigh about 120 mg of acetaminophen in 100 ml of 4 *N* HCl. Transfer by pipet 0.5, 1.0, 1.5, 2.0, and 2.5 ml of the standard solution to five test tubes. Add 5 ml of 4 *N* HCl and place the tubes in a beaker of boiling water for 1 hr. Allow the tubes to cool and transfer the contents quantitatively to 50-ml volumetric flasks.

Add 10 ml of vanillin reagent to each flask and dilute to volume. Mix well and measure the absorption, after appropriate dilution, at 395 nm against a blank (6 ml of 4 *N* HCl, 10 ml of vanillin reagent, and enough water to make 50 ml). The absorbances obtained plot into a straight line.

Acetaminophen Sample Preparation and Assay—Weigh and finely powder the sample to correspond to 120 mg of acetaminophen based on label claim. Transfer it to a suitable container and add about 50 ml of 4 *N* HCl. Agitate with mechanical shaker for 20 min, filter through paper into a 100-ml volumetric flask, and dilute to volume with 4 *N* HCl. Mix well and transfer 1 ml to a test tube. Add 5 ml of 4 *N* HCl and heat for 1 hr in boiling water. Then proceed as directed under *Acetaminophen Assay* beginning with: "Allow the tubes to cool and . . . ." Calculate the amount of *p*-aminophenol from the calibration curve and multiply it by the factor 1.385 and the dilutions used.



Scheme I

Dichloralantipyrine Assay—The calibration curve is prepared as follows. Dissolve 250 mg of chloral hydrate in water and dilute to 500 ml. Dilute 10 ml of this solution to 100 ml with water, so that the standard chloral hydrate solution contains 50 μg/ml. Transfer by pipet 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, and 1.6 ml of the standard solution to seven test tubes and pipet 1 ml of water into an eighth test tube to serve as a blank. Add to each tube 1 ml of quinaldine ethiodide solution and 6 ml of isopropanol, mix well, add 0.5 ml of 0.1 *N* ethanolamine, dilute to 10 ml with water, and mix. Then place the tubes in a water bath at 60° for 1 hr. Remove the tubes from the water bath, cool, and measure the absorption at 605 nm after appropriate dilutions. The absorbances obtained plot into a straight line.

Dichloralantipyrine Sample Preparation and Assay—Weigh an aliquot from the previously finely powdered capsules to correspond to 75 mg of dichloralantipyrine based on label claim. Transfer it to a suitable container so that it can be diluted with water to contain 60 μg/ml. Transfer by pipet 1 ml to a test tube and proceed as described under *Dichloralantipyrine Assay*, beginning with: "Add to each tube 1 ml of quinaldine ethiodide solution . . . ." Calculate the amount of chloral hydrate from the calibration curve and multiply it by the factor 1.63 and the dilutions used.

Table II—Arithmetic Mean of Determination of an Accurately Weighed Capsule Mixture

Acetaminophen			Dichloralantipyrine		
Reported, mg	Found, mg	%	Reported, mg	Found, mg	%
120	120.0	100.0	60	58.8	99.7
	119.5	99.6		59.7	99.5
	118.8	99.0		60.3	100.5
	120.7	100.6		59.3	98.8
	119.6	99.7		59.0	98.3
	119.9	99.9		58.5	99.2
Mean	119.7	99.8		59.6	99.3

RESULTS AND DISCUSSION

Vaughn (6) reported that complete hydrolysis of acetaminophen with 1 *N* HCl is not attained even after 45 min, so he chose 10 min in boiling water for convenience. The present assay uses 4 *N* HCl and 1 hr in boiling water to obtain as complete an hydrolysis as possible. However, studies in which the duration of time in boiling water was reduced to 20 min gave identical results. The hydrolytic product, *p*-aminophenol, produced a stable, intense yellow color upon the addition of vanillin reagent, with a maximum absorption peak at 395 nm. The amount of acetaminophen in each capsule was determined by taking into account that the ratio of acetaminophen to *p*-aminophenol is 1:1.385.

Archer and Haugar (7) showed that quinaldine ethiodide reacts with the addition compound, dichloralantipyrine, to produce a blue color in proportion to its chloral hydrate content (Scheme I). This reaction is specific for dichloralantipyrine and chloral hydrate, and substances such as trichloroacetic acid, acetic acid, chloroform, bromoform, and glucose do not produce a blue color.

The quantity of dichloralantipyrine was based on the fact that each mole of dichloralantipyrine produces 2 moles of chloral hydrate, so the ratio of dichloralantipyrine to chloral hydrate is 1:1.63. Isometheptene mucate did not interfere with either assay, and the results of adding known amounts of acetaminophen and dichloralantipyrine are shown in Table I. The assay of the capsules is reported in Table II.

High-Speed Liquid Chromatographic Analysis of Sulfasalazine (Salicylazosulfapyridine)

LYLE D. BIGHLEY *x and J. PATRICK McDONNELL ‡

Abstract □ A high-speed liquid chromatographic method for analysis of sulfasalazine (salicylazosulfapyridine) in bulk powder and tablet dosage form is presented. Analysis is accomplished with a reverse-phase partition column and 10% 2-propanol in pH 7.7 phosphate buffer as the mobile phase. The method of analysis utilizes a simple, one-step, solubilization procedure with dimethylformamide, addition of an internal standard, and chromatography. The method is specific for sulfasalazine in the presence of starting materials, degradation products, or by-products from its manufacture.

Keyphrases □ Sulfasalazine—high-speed liquid chromatographic analysis, bulk powder and tablet dosage form □ Salicylazosulfapyridine—high-speed liquid chromatographic analysis, bulk powder and tablet dosage form □ High-speed liquid chromatography—analysis, sulfasalazine bulk and tablet forms

Several analytical methods have been reported for the determination of sulfasalazine {salicylazosulfapyridine, 5-[*p*-(2-pyridylsulfamoyl)phenylazo]salicylic acid} (I). These methods include spectrophotometry (1), titration with titanium trichloride (1), polarography (2), and nonaqueous potentiometric titration (2). However, most of these methods fail to determine this compound selectively in the presence of its by-products of synthesis or degradation products. Conversely, a chromatographic method would be expected to provide simple, rapid, and specific separation and quantitation of this compound in the presence of its impurities.

Although GC has not been investigated, its use for the underivatized I probably would be unsuccessful since this compound was thermally labile when subjected to differential thermal analysis[1]. TLC, although specific, has the disadvantage of potentially long analysis times and requires a number of manipulative steps which may adversely affect precision. For example, a relative standard deviation of 2–6% resulted just from spotting and chromatography (3). (Quantitation in these experiments was effected directly on the plate with a densitometer.) Consequently, even larger errors would be expected in the overall assay if the compound is removed from the TLC plate and eluted from the adsorbent prior to quantitation.

Table I—Column Packing Materials

Column	Packing	Column Dimensions
a	Neutral alumina[a], 100–200 mesh	1 m × 0.3 cm o.d.
b	Ether stationary phase chemically bonded on a controlled porous surface[b]	1 m × 0.3 cm o.d.
c	Strong anion-exchange resin coated on a controlled porous surface[c]	0.6 m × 0.3 cm o.d.
d	Spherical siliceous particles with a controlled porous surface[d]	0.6 m × 0.3 cm o.d.
e	Diphenyldichlorosilane stationary phase chemically bonded on a controlled porous surface[e]	0.6 m × 0.3 cm o.d.
f	Octadecyltrichlorosilane stationary phase chemically bonded on a controlled porous surface[f]	1.2 m × 0.3 cm o.d.

f	5% CH_3OH in water	>23.4[c]	1.0

[a] See Table I. [b] Times measured from the leading edge of solvent peak to the peak maximum. [c] Retention times were greater than these values, but the exact times were not determined.

were dry packed using the tap fill method of Kirkland (5). All columns were operated at ambient room temperature.

Mobile Phases—The mobile phases employed are listed in Table II. The phosphate and citrate buffers were prepared by the addition of 2.5 *N* sodium hydroxide to 0.01 *M* monobasic sodium phosphate and citric acid (monohydrate), respectively. The pH 9.2 borate buffer (0.01 *M*) was prepared by dissolving sodium tetraborate decahydrate in distilled water.

Materials—The following were used: sulfasalazine[3], salicylic acid[3], sulfapyridine[3], propylparaben[4], monobasic sodium phosphate[5], heptane[5], *n*-butyl alcohol[5], methanol[6], acetonitrile[6], sodium nitrate[6], sodium tetraborate decahydrate[6], ammonium carbonate[6], 2-propanol[6], sulfanilic acid[7], dimethylformamide[7], chloroform[7], 2-aminopyridine[8], citric acid USP (monohydrate)[9], and commercially available I tablets[10,11].

Analysis of Bulk Chemical—*Internal Standard Solution*—Weigh accurately approximately 125 mg of propylparaben and quantitatively transfer to a 25-ml volumetric flask with the aid of dimethylformamide. Dilute to volume with dimethylformamide and mix well.

Sample Solution—Accurately weigh approximately 50 mg of I and quantitatively transfer to a 50-ml volumetric flask with the aid of dimethylformamide. Add 10 ml of the internal standard solution, dilute to volume with dimethylformamide, and mix well.

Standard Solution—Prepare concurrently a standard solution, containing an amount of internal standard identical to the sample solution, and a reference lot of I in approximately the same quantity as the sample solution.

Table III—Individual Retention Times for Several Possible Impurities of Sulfasalazine

Compound	Adjusted Retention Time[a], min
Impurity 1[b]	0.0
Impurity 2[b]	0.0
2-Aminopyridine	1.8
Sulfapyridine	0.0
Impurity 3[b]	8.9
Sulfanilic acid	0.0
Impurity 4[b]	4.7
Salicylic acid	0.0

[a] Time measured from the leading edge of solvent peak to the peak maximum. [b] Isolated but unidentified compounds.

Liquid Chromatography—Inject alternately 5 μl of the sample and standard solutions with a 10-μl syringe[12], using the stop-flow technique. Operational parameters for the liquid chromatographic separations are listed with the appropriate figures.

Quantitation—Quantitation was accomplished either by measurement of peak heights or of peak areas with a planimeter. The

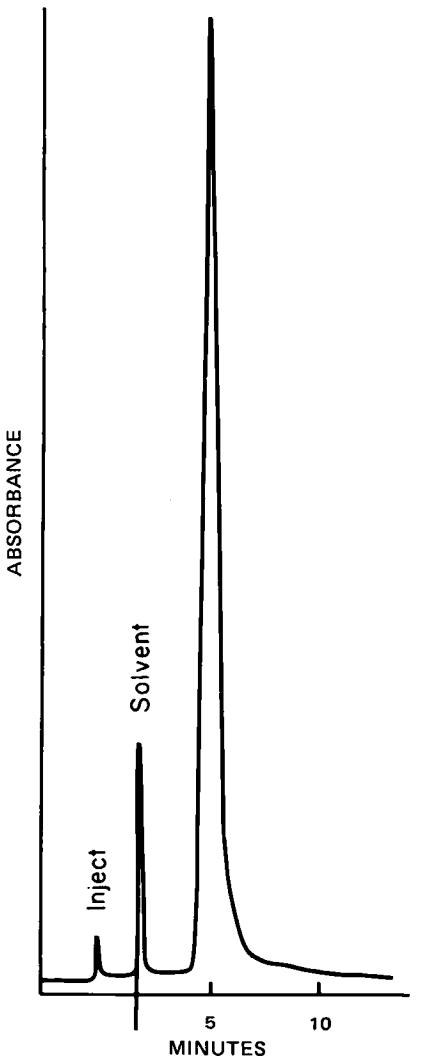

Figure 1—*Typical chromatogram of sulfasalazine. Chromatography conditions were: Column f; solvent, 10% 2-propanol in pH 7.7 phosphate buffer; chart speed, 30.48 cm (12 in.)/hr; flow, 1.5 ml/min; detector sensitivity, 0.16 aufs; and sample size, 5 μl.*

[12] Hamilton 701 NWG.

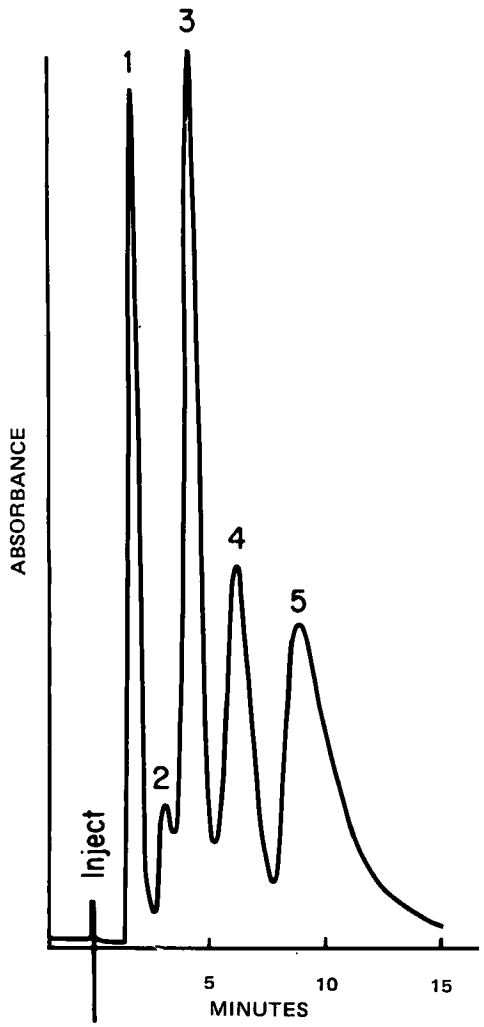

Figure 2—*Separation of a synthetic mixture containing sulfasalazine and some possible impurities. Key: peak 1, impurities 1 and 2, sulfapyridine, sulfanilic acid, and salicylic acid; peak 2, 2-aminopyridine; peak 3, sulfasalazine; peak 4, impurity 4; and peak 5, impurity 3. Chromatography conditions were the same as in Fig. 1.*

percentage of I in the sample was determined by:

$$\% \text{ I in sample} = \frac{(P_1W_2)/(P_2W_1)}{(P_3W_4)/(P_4W_3)} \times 100 \qquad \text{(Eq. 1)}$$

where P = peak height or peak area, W = weight, subscript 1 = I in sample, subscript 2 = internal standard in sample, subscript 3 = I in standard, and subscript 4 = internal standard in standard.

Since the weight of the internal standard is identical in the sample and standard solutions, this term can be deleted from Eq. 1. In addition, this equation can be simplified by using the ratio of the peak area (or peak height) of I/peak area (or peak height) of propylparaben for both standard and sample, $R_{sample} = P_1/P_2$ and $R_{std} = P_3/P_4$. Then it can be shown that:

$$\% \text{ I in sample} = \frac{R_{sample}W_3}{R_{std}W_1} \times 100 \qquad \text{(Eq. 2)}$$

Analysis of Tablets—Place one tablet (label claim 500 mg of I) in a beaker, add approximately 20 ml of dimethylformamide, and crush the tablet with a stirring rod. Quantitatively transfer the contents of the beaker to a 100-ml volumetric flask and rinse the beaker with three additional portions of dimethylformamide. Dilute to volume with dimethylformamide and mix well.

Pipet 10 ml of this solution into a 50-ml volumetric flask, add 10 ml of the internal standard solution previously described, and dilute to volume with dimethylformamide. Alternate 5-μl injections of the standard solution with the tablet formulation solution. The standard solution is prepared as described under *Analysis of Bulk Chemical.*

Quantitation is done as described under *Analysis of Bulk Chemical.* Since the weight of internal standard is identical for the tablet formulation and the standard solution, the equation is:

$$\text{I in tablet} = \frac{R_{sample}W_3D}{R_{std}} \qquad \text{(Eq. 3)}$$

where D = dilution factor, *i.e.*, 10 with this dilution; subscript 1 = I in tablet; subscript 2 = internal standard in tablet solution; subscript 3 = I in standard; subscript 4 = internal standard in standard; $R_{sample} = P_1/P_2$; $R_{std} = P_3/P_4$; and the other symbols have the same meaning as before.

RESULTS AND DISCUSSION

Initially, the chromatographic behavior of I was studied as a function of several column packing and mobile phase combinations; the adjusted retention times relative to the dimethylformamide peak for these systems are presented in Table II. Studies were not continued with those packing and mobile phase combinations giving long retention times. With the other systems, it became evident that an adjusted retention time for I of approximate-

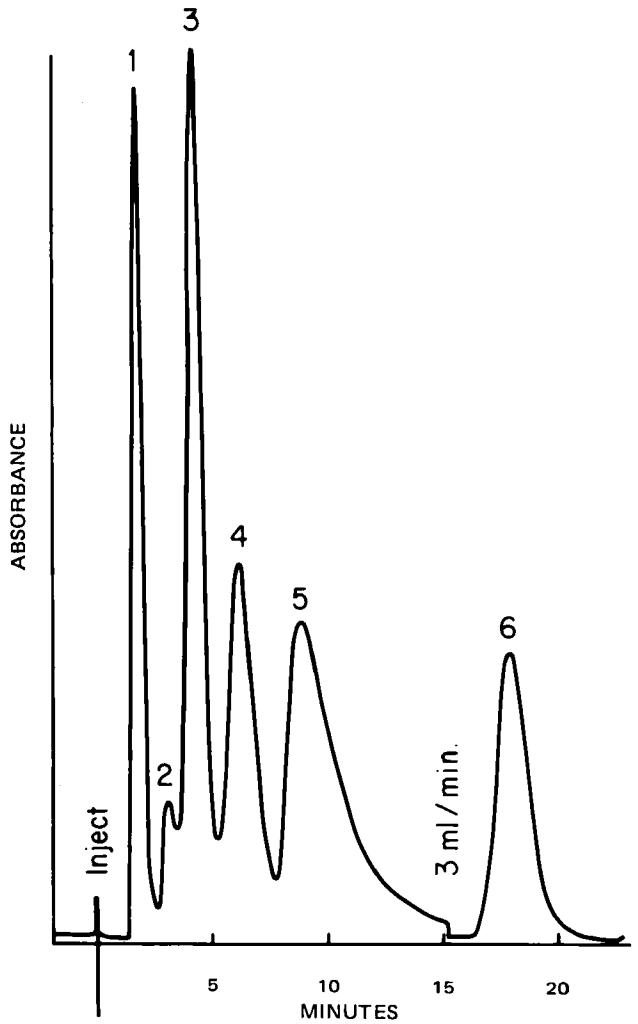

Figure 3—*Separation of a synthetic mixture containing sulfasalazine, some possible impurities, and an internal standard. Key: peak 1, impurities 1 and 2, sulfapyridine, sulfanilic acid, and salicylic acid; peak 2, 2-aminopyridine; peak 3, sulfasalazine; peak 4, impurity 4; peak 5, impurity 3; and peak 6, propylparaben. Figure 4—*Linearity of detector response to sulfasalazine.*

ly 3 min was necessary, since certain known impurities which may be present in I elute at, or immediately after, the solvent front. Consequently, only four column packing and mobile phase combinations met this requirement: Column e or f with 10% 2-propanol in pH 7.7 phosphate buffer, and Column f with either 10% acetonitrile in water or 10% 2-propanol in pH 6.5 phosphate buffer (Table I).

Of these four systems, only Column f with 10% 2-propanol in pH 7.7 phosphate buffer was satisfactory. When this system was used with the conditions shown in Fig. 1, I has an adjusted retention time of approximately 3.2 min. The other three systems were undesirable for various reasons. For example, Column f with 10% acetonitrile in water was unacceptable because certain by-products from synthesis had the same retention time as I or were not eluted. When 10% 2-propanol in pH 6.5 phosphate buffer was used with this packing, the peak width broadened slightly. Similarly, Column e in combination with 10% 2-propanol in pH 7.7 phosphate buffer resulted in a broadening of the I peak.

Further studies were undertaken with Column f and 10% 2-propanol in pH 7.7 phosphate buffer to determine if this system would resolve I from various structurally related compounds which could be present as impurities under normal circumstances. Adjusted individual retention times for several possible degradation products, starting materials, and by-products of synthesis were found to be sufficiently different from the retention time of I (Table III). Consequently, a synthetic mixture was prepared by dissolving approximately equal amounts of I and these compounds

[a] Label claim: 500 mg of sulfasalazine.

in dimethylformamide. A chromatogram of this mixture is shown in Fig. 2. Although baseline separation was not achieved, separation of I was adequate to permit quantitation even in the presence of these large amounts of impurities.

The specificity of this HSLC system was further confirmed by repeatedly injecting a sample of approximately 85% pure I and collecting the effluent when the peak with an adjusted retention time of 3.2 min appeared. When this effluent was subjected to TLC, using the solvent system of Kiger and Kiger (6), only I was found in the trapped samples. Plates that were sprayed with a solution containing 4-dimethylaminocinnamaldehyde and titanium trichloride (7) also only showed one spot.

Quantitative analysis of I samples was accomplished by the internal standard technique, using propylparaben as the internal standard. This compound was selected because it could be separated from the impurities shown in Fig. 2. Since these impurities elute immediately before and after the I peak, the compound selected as the internal standard had to have a relatively long retention time; and propylparaben was the only compound tested that met this requirement. Figure 3 shows the synthetic mixture containing propylparaben. The flow rate was increased from 1.5 to 3 ml/min after 15 min to hasten the elution of the propylparaben. The change in flow rate at this time permits elution of the impurities without overlapping either the I or propylparaben.

The UV detector response to I and propylparaben is linear over the concentration ranges used in this study. Plots of absorbance peak heights or areas *versus* concentration are shown in Figs. 4 and 5.

The precision of the HSLC method was determined by comparing the results obtained on six subsamples of I taken from one lot of bulk chemical. Peak heights are shown in Table IV, and peak areas are shown in Table V. Values for each injection and the average of duplicate injections are shown for each analysis. The standard deviation and relative standard deviation were calculated for individual and duplicate injections and are consistent with values reported for the liquid chromatographic analysis of other compounds (8–11).

The precision of measurement of peak areas probably could have been further improved in this study if integration were done with either a mechanical or electronic integrator. However, since a planimeter was used, precision of area measurements was maximized by increasing the recorder chart speed so that the peak area could be determined more precisely.

It is evident from the precision studies that either peak height or area can be used for quantitative analysis. However, if peak heights are used, the time at which the flow rate is increased from 1.5 to 3 ml/min must be closely regulated to prevent band spreading, which results from increased retention time. Use of peak areas would not require such close attention with respect to the time at which the flow rate was changed because the area of the propylparaben should remain the same even if some band spreading does occur, provided resolution remains adequate for accurate quantitation. Since the propylparaben is well resolved from I and other possible impurities, slight band spreading would not be a problem.

Two commercially available tablet formulations were examined for their I content to determine the feasibility of this method for tablet dosage forms. Preliminary results (Table VI) indicate that this procedure is applicable. Tablet excipients did not interfere with the analysis and need not be separated from I prior to liquid chromatography.

Since dimethylformamide was used as the solvent for I in the assay procedure and since solutions were occasionally prepared several hours prior to injection, it was desirable to determine whether this solvent degrades I. Therefore, a sample of I was dissolved in dimethylformamide and subjected to thermal stress at 80° for 196 hr. No degradation was observed when this solution was analyzed by TLC and HSLC.

Effect of Surface Roughness and Coating Solvent on Film Adhesion to Tablets

PRAKASH D. NADKARNI *, DANE O. KILDSIG ×, PAUL A. KRAMER, and GILBERT S. BANKER

Abstract □ The adhesion of a polymer film to selected tablet substrates was studied. The effect of tablet surface roughness and film-coating solvent on the adhesion of the film to the tablet was determined. A film-coating solvent having a solubility parameter close to that of the polymer was found to produce a stronger adhesional bond than a solvent having a lower surface tension. An increase in tablet surface roughness also increased film adhesion to the tablet. The adhesion was measured as the force required to peel a section of film from the tablet with a stress–strain analyzer.

Keyphrases □ Films—adhesion to tablets, effect of surface roughness and coating solvent □ Tablets—effect of surface roughness and coating solvent on film adhesion □ Adhesion—polymer films to tablet substrates, peel strength, effect of surface roughness and coating solvent □ Solvents, coating—effect on polymer film adhesion to tablet substrates

Adhesion to their substrates is a major prerequisite of pharmaceutical film coatings. Assessment of coating adhesion in fundamental terms is very difficult and is undoubtedly a factor that has limited the research in this field. The method of choice for studying coat bonding to substrates appears to be the measurement of the force required to peel the film from the substrate.

In a recent adhesion study involving pharmaceutical systems (1), the adhesion of film coating to tablets was quantified by measuring the force required to pull films from tablet surfaces. A correlation was found between peeling force and the critical surface tension of the tablet surface but not between surface tension of the coating solution and peeling force. As pointed out by Wood and Harder (1), this latter finding was contrary to theory.

The solvent from which a polymer film is cast can significantly affect the film's adhesion to the substrate (2). Engel and Fitzwater (3) found that the nature of the solvent used in film formation significantly affected the peel strength of methyl methacrylate films. They also observed a good correlation between the peel strength and the cohesive energy density of the solvents employed using a tin substrate. Peel strengths of film prepared from polymer solutions containing 25% solvent showed an increase in numerical value with an increase in solvent cohesive energy density. The solvent showing the maximum peel strength was considered the most efficient for a particular polymeric system.

While studying the effect of fillers on peel strength, Brantley (4) noticed that the addition of higher concentrations of talc decreased the peel strength. He attributed this effect to embedded filler particles between the polymer film and the substrate, which interfered with the polar groups of the film or shielded them from the substrate.

The effect of polymer molecular weight on adhesion has been studied (5, 6), and the peel strength was observed to be independent of molecular weight in one case (5). Vakula *et al.* (6), studying the adhesion of copolymers of acrylonitrile and butadiene, found an initial increase in adhesion with an increase in molecular weight up to 350,000. Beyond this point, the adhesion was independent of molecular weight. The work was carried out on a polyamide substrate.

The effect of the percentage of polar groups of cellulosics on adhesion to nonferrous metals was studied, and an increase in adhesion with increased nitration in cellulose and increased ethoxy content in ethylcellulose was found (7). McLaren (8) demonstrated the increase in adhesion of poly(alkyl methacrylate) as the alkyl group was changed from ethyl through *n*-butyl. This increase in peel strength was thought to be due to a change in crystallinity of the film material resulting in an increase in adhesion.

The objective of this research was to investigate the effect of the coating solvent on film adhesion to tablet substrates; in addition, the effect of surface roughness on film adhesion is also reported.

EXPERIMENTAL

Preparation of Substrates—Three tablet substrates (Table I) were prepared by compressing the powder mixtures into disks with a laboratory press[1]. Each 2.54-cm (1-in.) diameter, flat-face disk weighed approximately 2 g and was prepared at a compressional load of 9091 kg (20,000 lb), held for 15 sec. For surface roughness studies, disks were also compressed at 4545 kg (10,000 lb) and 6818 kg (15,000 lb). The compressed disks were stored in a desiccator prior to use.

Preparation of Polymeric Coating Solutions—The polymer used was poly(methyl vinyl ether/maleic anhydride), molecular weight 250,000[2]. Eight percent (w/v) solutions of the polymer were prepared in acetone, methyl acetate, methyl ethyl ketone, and tetrahydrofuran. Each solution also contained 6% glyceryl triacetate[3]. All solvents were reagent grade.

Coating of Compressed Substrate Disks—To facilitate film coating, maintain individual tablet identity, control coating thickness, and facilitate subsequent quantitative testing, compressed substrate disks were coated using an immersion coating method.

Table I—Tablets Employed in Film Adhesion Studies

Formula for 50 Tablets	Tablet Substrate I[a], g	Tablet Substrate II[a], g	Tablet Substrate III[b], g
Microcrystalline cellulose[c]	100	—	—
Acacia	—	100	—
Magnesium oxide granulation	—	—	100
Talc	0.5	1.0	0.25
Magnesium stearate	1.0	2.0	0.25

[a] Substrates I and II were prepared by hand sieving all ingredients through a 40-mesh sieve, mixing for 20 min in a planetary mixer, and compressing. [b] Substrate III was prepared by wet massing the magnesium oxide with 7.5% starch paste followed by hand granulating through a 30-mesh sieve. The resulting granules were dried overnight at 48.8° (120°F), sized through a 16-mesh sieve, and compressed. [c] Avicel.

Each compressed substrate disk was brushed with a camel-hair brush to remove dust and was measured for thickness with a micrometer gauge[4]. A penciled rectangle of 0.5 × 0.75 cm was marked on the substrate disks to provide a reference for subsequent film peeling in evaluating adhesion properties of polymeric films.

The tablets were coated individually by maintaining the disk at the end of a small glass tube with suction applied by a vacuum pump. One side of the flat tablet was coated by immersing it into the coating solution 12 times. The resulting film thickness varied from 0.12 to 0.16 mm as measured by a micrometer[4]. Each coat was allowed to air dry for 3–5 min before the next coat was applied. Coated disks were stored at 40° and 52% relative humidity for 12 hr before testing in the peeling studies.

Contact Angle Measurements of Polymeric Solutions on Compressed Substrate Disks—The environmental chamber of a goniometer[5] was saturated for 24 hr with vapors of the solvent used in the coating solution prior to the contact angle measurements. This operation was carried out to minimize the recession of the contact angle during the measurement. The substrate disks were individually placed on the platform of the goniometer chamber. One small drop of the polymeric coating solution was then placed on the disks with a capillary pipet and the chamber was covered immediately. Measurement of the wetting angles was taken within 60 sec.

Surface Tension Measurement—The surface tension of the polymer solutions and of the pure solvents was determined[6] at 25°. Correction factors were calculated according to the procedure in the manufacturer's instruction manual. Density determinations necessary for the correction factor calculation were determined using a 25.00-ml pycnometer.

Surface Roughness Measurements of Compressed Substrate Disks—To evaluate the effect of substrate surface morphology upon polymeric film peeling strength, surface roughness characteristics of the substrates were determined. The surface profile measurements were made using a surface analyzer[7]. This instrument is used in the measurement of the surface profiles of thin films and roughness characteristics of solid substrates. The specifications used in the experimental studies were as follows: sensitivity, 500,000 and 100,000 Å full scale; minimum detectable step, 5000 and 1000 Å; scan speed, 0.1–10 cm/min; stylus diameter, 0.0005 cm; and stylus tracking force (preset), 15 mg.

Surface roughness measurements were carried out by the method described by Schwartz and Brown (9). The surface peak-to-valley distance was used to characterize surface roughness, and an average of six such readings was reported as the average peak-to-valley distance.

Peel Strength Determination—The peel adhesion of applied polymeric films was evaluated using a stress analyzer[8]. The tension load cell was calibrated at the lowest range of 10 g for full-chart deflection. This calibration enabled the use of all ranges of amplification (1–50). The cross-head speed of 1.27 cm/min (0.5 in./min) was chosen to take into account a gradual and slow peeling of the film and reduce elastic deformation of the film. A preset chart speed of 50.8 cm/min (20 in./min) gave a total amplification of deflection by 40×. The gauge and return dials were set to reproduce a predetermined distance of 2.54 cm (1 in.) of peeling of the film from the substrate.

The samples of coated substrate disks previously marked (rectangle of 0.5 × 0.75 cm) were tightly clamped to the platform. One end of the rectangular outline of the film, representing 25% or less of the total gauge length, was cut with a small razor knife and pulled free for insertion into the jaws of the grip. The dimensions of the peeled film was such that when the sample was clamped and inserted into the jaws of the grip, a small initial distance was allowed for weakening of the film contact to the substrate surface. This distance was taken into account prior to recording the actual peeling by zero adjustment. All measurements were carried out using 20× amplifier sensitivity to enable the load cell to record to a maximum of 200 g of force.

The angle of peel was almost constant (90°) during the peeling of films. Due to the very small distance over which the peel adhesion was studied, no attempt was made to slide the platform to maintain a constant angle of peel. Measurements were carried out at 25° and 52% relative humidity.

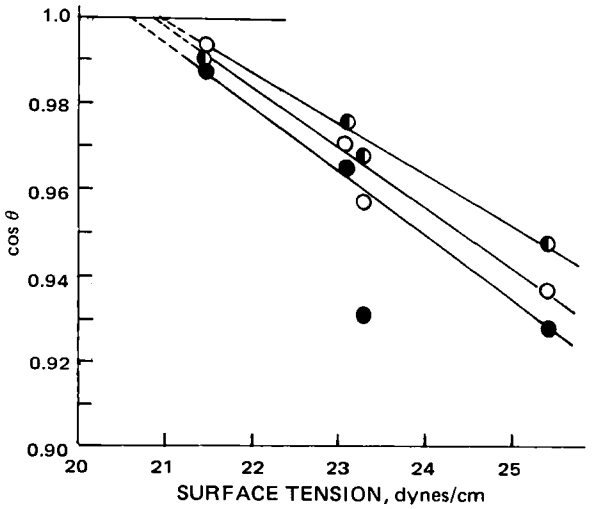

Figure 1—*Zisman plot of cos θ versus surface tension. The intercept at cos θ = 1 represents the critical surface tension of the solid. Key: ◐, Tablet I; ○, Tablet II; and ●, Tablet III.*

RESULTS AND DISCUSSION

Relationship between Contact Angles and Film Adhesion—Contact angle measurements of film-coating solutions on the three tablet formulations were made, and the adhesion of the corresponding polymer film to the three tablets was measured as the peel strength of the films from the tablets (Table II). As expected, the film adhesion, as reflected by the force required to peel the film from the tablet, increased with a decrease in the contact angle. Thus, the better the wetting of the tablet by the film solution, the better was the film adhesion.

However, an unusual phenomenon, previously reported (1), was observed with respect to the relationship between film adhesion and the surface tension of the film solution. Instead of an increase in adhesional force with a decrease in solution surface tension, an increase in adhesional force was observed with an increase in solution surface tension. In other words, the contact angle of the solution on the tablet increased as the surface tension of the film solution decreased.

To try to discover the reasons for the observed deviations from theory, the contact angles of the pure solvents used to make the film solutions were determined on the three tablet formulations. The data are given in Table III and are shown in Fig. 1 as a Zisman plot, with the extrapolation intercept at cos θ = 1 (θ = 0) pro-

Table II—Contact Angle and Peel Strength Data for Films Applied to the Tablets as Affected by Film-Coating Solvent

Tablet	Solvent[a]	Contact Angle ± 1°	Surface Tension of Polymer Solution, dynes/cm	Peel Strength, g/cm	Solubility Parameter of Solvent
I	Acetone	21	22.7	12.7	9.9
	Methyl acetate	18	23.1	19.4	9.6
	Methyl ethyl ketone	18	23.3	24.1	9.3
	Tetrahydrofuran	15	26.1	32.5	9.1
II	Acetone	28	22.7	11.4	9.9
	Methyl acetate	25	23.1	17.0	9.6
	Methyl ethyl ketone	22	23.3	22.0	9.3
	Tetrahydrofuran	19	26.1	29.5	9.1
III	Acetone	32	22.7	8.1	9.9
	Methyl acetate	28	23.1	15.4	9.6
	Methyl ethyl ketone	28	23.3	22.0	9.3
	Tetrahydrofuran	25	26.1	24.5	9.1

[a] Each solution contained 8% poly(methyl vinyl ether/maleic anhydride), molecular weight 250,000, and 6% glyceryl triacetate.

viding the apparent critical surface tension of the solid. The contact angle–surface tension relationship for the pure solvent–tablet system is as the Zisman theory would predict. Thus, the theory does hold when considering the pure solvent, which was used to prepare each of the four coating solutions, in contact with the tablet.

To better understand the observed adhesional phenomenon, the polymer solution must be considered further. Since it is the polymer that is adhering to the tablet and not the solvent, it is the wetting of the tablet by the polymer that is important. The adhesional bond that forms between polymer and tablet depends on both the duration of the polymer solution–tablet contact and the intimacy of the contact between the polymer, while in solution, and the tablet. The length of polymer solution contact with the tablet is usually very short because the solvent evaporates very rapidly, producing an immobilized polymer in a viscoelastic film. Yet the wetting of the tablet by the polymer must occur in that short time period while the polymer is in solution and prior to the formation of the viscoelastic film. Therefore, it is important that the polymer solution provide for maximum polymer tablet interaction immediately on contact. It would be expected that for a given polymer the greater the extent of polymer solvation by the solvent, the greater the polymer tablet interaction as the solvent initially contacts and penetrates the tablet surface.

One way of approaching the problem is to use the solubility parameter of the solvent as a qualitative measure of the extent of polymer solvation and to analyze its relationship to the observed contact angles. Table II shows the relationship between the solubility parameters of the four solvents and the observed contact angles. Tetrahydrofuran (δ = 9.1) would be expected to be the most efficient solvent for the polymer (δ = 8.7) since its solubility parameter is closest to that of the polymer. The tetrahydrofuran solvent did produce the lowest contact angle and highest adhesional strength, although it had the highest surface tension. It is certainly apparent that the choice of a film-coating solvent having a solubility parameter close to that of the polymer is important in achieving good film adhesion, and it is even more important than selecting a solvent solely on the basis of surface tension considerations.

Table III—Contact Angles of Pure Solvents on Tablet Substrates

Tablet	Solvent	Surface Tension, dynes/cm	Contact Angle ± 1°	cos θ
I	Acetone	21.5	8.0	0.9903
	Methyl acetate	23.1	12.5	0.9763
	Methyl ethyl ketone	23.3	15.0	0.9659
	Tetrahydrofuran	25.4	17.5	0.9537
II	Acetone	21.5	7.0	0.9925
	Methyl acetate	23.1	14.0	0.9700
	Methyl ethyl ketone	23.3	17.0	0.9563
	Tetrahydrofuran	25.4	20.5	0.9367
III	Acetone	21.5	9.0	0.9877
	Methyl acetate	23.1	15.0	0.9659
	Methyl ethyl ketone	23.3	21.5	0.9304
	Tetrahydrofuran	25.4	22.0	0.9272

The nature of the polymer itself may influence the adhesional bond formed between the film and the tablet substrate. Additional studies are in progress to determine the effect of alkyl ether substitution on the film–tablet adhesional bond.

Wetting and Adhesion as Related to Tablet Surface Roughness—Two of the tablet formulations were compressed at various compressional loads to obtain different surface roughness characteristics. The tablets were compressed at 4545, 6818, and 9091 kg, and the surface roughness characteristics of these tablets were measured (Table IV). For both formulations, the average peak-to-valley height was the greatest for the tablets compressed at 4545 kg and decreased with increasing compressional load; the tablets were becoming smoother with increasing compressional load.

The adhesion of a polymer film to the tablets with differing surface roughness characteristics was determined as the peel strength of the film from the tablet (Table IV). Only one solvent, acetone, was used to deposit the polymer on the tablet formulations, so the surface tension of the coating solution remained constant. From Table IV it is apparent that the peel strength correlates with the roughness data; the rougher the tablet, the higher the peel strength. The differences in peel strength are quite significant and must result from the increased surface area of the rougher tablet which provides for greater interfacial contact between polymer solution and tablet.

A relationship between the contact angle and surface roughness was proposed by Wenzel (10):

$$r = \frac{\cos\theta'}{\cos\theta} \qquad \text{(Eq. 1)}$$

where θ' is the apparent contact angle on a rough surface, θ is the contact angle on an ideal smooth surface, and r is the roughness factor and is defined as:

$$r = \frac{\text{true surface area}}{\text{apparent plane area}} \qquad \text{(Eq. 2)}$$

Since r is always greater than unity, the apparent contact angle, θ', is less than the true contact angle θ when θ is less than 90°. Thus, the effect of roughening the tablet surface is to make the apparent contact angle between the coating solution and the tablet less than the true contact angle. In other words, the polymer solu-

Table IV—Wetting Angle and Adhesion Peel Strength of Films Applied to Substrates as Related to Substrate Surface Roughness

Tablet	Compressional Load, kg	Roughness, Average Peak-to-Valley Distance, A	Wetting Angle	Peel Strength, g/cm
I	4545	17,330	14°	29.1
	6818	16,000	19°	17.7
	9091	7,666	22°	12.7
II	4545	12,400	17°	24.1
	6818	12,000	21°	16.5
	9091	6,833	28°	11.4

tion appears to spread more when the the tablet surface is rough, making the exact determination of the critical surface tension, γc, of a compressed tablet very difficult.

In most cases ($\theta \leq 90°$), the true critical surface tension is greater than that determined experimentally. However, from a film-coating standpoint, the influence of surface effects on film adhesion may well be minimal, with the correlation of solvent–polymer solubility parameters being the major factor in determining film adhesion. Regardless of the tablet surface characteristics, the adhesional bond between tablet and polymer must form at a faster rate than the cohesional forces in the polymer film. When this occurs, a strong adhesional bond is established between the tablet and the film.

Laboratory Automation of High-Pressure Liquid Chromatography

WILLIAM F. BEYER *‡ and DAVID D. GLEASON ‡

Abstract □ An automated system for high-pressure liquid chromatography was developed. The system is built around commercial modules wherever possible, modified to varying degrees. An automatic sampler, a sample pump, a high-pressure sampling valve, a recorder with an integrator, and a high-pressure liquid chromatograph comprise the commercial instruments. Relays, solenoid valves, and timers control chromatographic events, *i.e.*, duration of sampling and rinse, mobile phase pump refill, sample injection, and chromatographic time. The automated system is dependable over long periods of unattended operation. With the 40-sample capacity of the sample tray and the last sample stop capability, the automated system produces, for example, 40 20-min chromatograms in approximately 13 hr of unattended operation. Data demonstrate the reliability and utility of the system.

Keyphrases □ High-pressure liquid chromatography—automated equipment developed and discussed □ Automated analysis—high-pressure liquid chromatographic equipment developed and discussed

High-pressure liquid chromatography (HPLC), with its widespread use over the last 5 years, has undergone dramatic growth from the standpoint of methodology and instrumentation. Michaelis *et al.* (1) made it apparent that HPLC is of major importance in quantitative analysis and identification of various pharmaceutical agents. An HPLC equipment review (2) covers a large number of domestic and foreign manufacturers.

The application of HPLC for stability-indicating assays because of specificity, sensitivity, and relative ease of sample preparation is clearly indicated, particularly for labile compounds. Specific applications of HPLC were reported for various pharmaceutical products containing various active compounds (3) and for steroid formulations (4–7). The increased use of HPLC for stability-indicating assays of steroid formulations, for example, has produced the need for an automated HPLC system. Specific applications of the automation of particular aspects of HPLC have been reported. Among these are the use of short columns and low pressures (8) and the determination of the antibiotic tetracycline (9). More recent work (10) covers the use of a dedicated small computer to study the precision in HPLC.

Although automated HPLC systems are obtainable from commercial manufacturers[1,2], they are not readily available. A symposium presentation (11) covered an automated HPLC system developed at Lederle Laboratories. To increase the output of HPLC assays, an automated HPLC system (patent applied for) was developed from commercially available instruments, relays, solenoid valves, and timers and is the subject of this report.

EXPERIMENTAL

Keyphrases □ High-pressure liquid chromatography—automated equipment developed and discussed □ Automated analysis—high-pressure liquid chromatographic equipment developed and discussed

High-pressure liquid chromatography (HPLC), with its widespread use over the last 5 years, has undergone dramatic growth from the standpoint of methodology and instrumentation. Michaelis *et al.* (1) made it apparent that HPLC is of major importance in quantitative analysis and identification of various pharmaceutical agents. An HPLC equipment review (2) covers a large number of domestic and foreign manufacturers.

The application of HPLC for stability-indicating assays because of specificity, sensitivity, and relative ease of sample preparation is clearly indicated, particularly for labile compounds. Specific applications of HPLC were reported for various pharmaceutical products containing various active compounds (3) and for steroid formulations (4–7). The increased use of HPLC for stability-indicating assays of steroid formulations, for example, has produced the need for an automated HPLC system. Specific applications of the automation of particular aspects of HPLC have been reported. Among these are the use of short columns and low pressures (8) and the determination of the antibiotic tetracycline (9). More recent work (10) covers the use of a dedicated small computer to study the precision in HPLC.

Although automated HPLC systems are obtainable from commercial manufacturers[1,2], they are not readily available. A symposium presentation (11) covered an automated HPLC system developed at Lederle Laboratories. To increase the output of HPLC assays, an automated HPLC system (patent applied for) was developed from commercially available instruments, relays, solenoid valves, and timers and is the subject of this report.

EXPERIMENTAL

The commercial instruments comprising a portion of the automated HPLC system, modified to varying degrees, follow.

Instruments and Modifications—A liquid chromatograph[3]

[3] Model 820, DuPont.

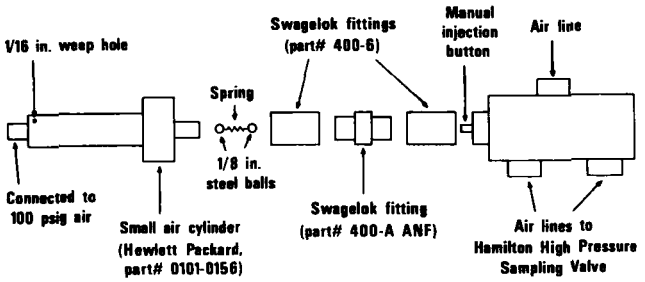

Figure 1—*Schematic drawing showing the modification of the high-pressure sampling valve to make it operate automatically.*

with 316 stainless steel columns, 100 cm long × 2.1 mm i.d., and permanently bonded, reverse-phase column packings[4,5] were used. The chromatograph was equipped with a 254-nm UV detector set at a sensitivity of 0.04 absorbance unit full scale.

A 1-mv recorder[6] was equipped with an integrator[7]. Chart speeds were 0.25 and 0.51 cm/min.

The high-pressure sampling valve[8] provides plug injection of sample at liquid pressures up to 5000 psig. It is mounted in the column oven and is actuated by 30–100 psig of air, supplied from the pneumatic section of the mobile phase pumping system of the chromatograph. A 5.0-μl sample valve was used. The manual injection switch of the high-pressure sampling valve was modified to operate automatically from the 30–100-psig air *via* an air cylinder[9] and a solenoid valve[10]. Figure 1 gives a schematic drawing of the details.

The holdup volume of the sample pump[11] was reduced with Teflon inserts in the entrance and exit chambers. The inserts have openings approximately 0.13 cm (0.050 in.) in diameter for fluid transport. The power plug was changed to a pin type, dedicating it to the automated system.

The standard timing cams were eliminated in the automatic sampler[12]. Sampling time is controlled by an automatic timer[13] located in a separate unit. A metal disk was constructed and placed under the sample tray to act as a support for 45 × 14-mm o.d. glass vials holding approximately 3 ml. A glass cover plate replaced the plastic one provided by the manufacturer. Retaining clips were added to the glass plate and to the sample tray to orient and anchor the cover plate.

Approximately 0.10-cm (0.040-in.) i.d. polyethylene tubing connects the automatic sampler and the sample pump. Stainless steel tubing, 0.03 cm (0.010 in.) i.d., connects this pump to the sampling valve. The same dimension tubing connects the high-pressure sampling valve to the column.

Wiring and Functions of Electronic Components—To control and to coordinate the sequence of events necessary for the flexible operation of the automated HPLC sampling system, appropriate timers, relays, and solenoid valves were installed. Timers were contained in a separate control unit; relays and solenoids were mounted in the chromatograph.

As shown in Fig. 2, three separate timers[13] establish sample, rinse, and chromatographic times. The pump timer (A) is wired for momentary start and resets by the time delay relay (D) contact opening (adjustable 3–30 sec, normally set to 4 sec). The chromatographic timer (B) is wired for momentary start and automatic reset. Depression of the start switch located in the control unit causes the sample pump timer (A) to start timing. This allows the sample pump (F) to run for the preset time.

At the end of the sampling time, No. 8 contacts open, stopping the sample pump; No. 13 contacts close and apply power to the time relay (D), the automatic sampler (G), and the standard 115 v ac relay (H). The sampler (G) starts, and the sample probe is allowed to cycle to the wash position. The time delay relay (D) then times out to keep the sample probe from coming out of the rinse solution. When in the rinse position, the sample pump (F) is re-

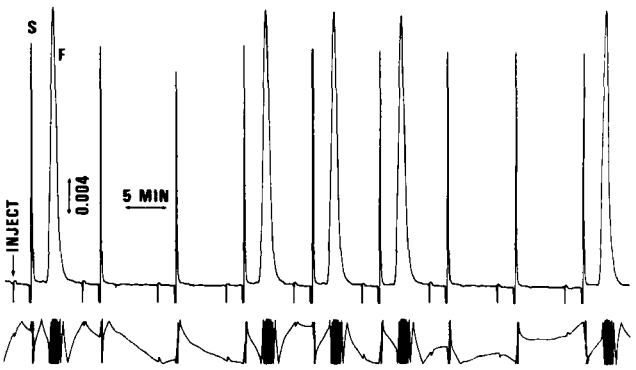

Figure 3—*Eight-minute chromatography from the automated HPLC sampling system showing the absence of carryover from fluorometholone, 0.15 mg/ml (F), or 75% 3A alcohol (S). The sequence of injections, from left to right, was F, S, S, F, F, F, S, S, and F. Chromatographic conditions were: ODS column packing, 6% aqueous acetonitrile with 0.0075 M borate buffer at pH 11.0 as the mobile phase, 500 psig column pressure (0.67 ml/min), and column temperature at 35°.*

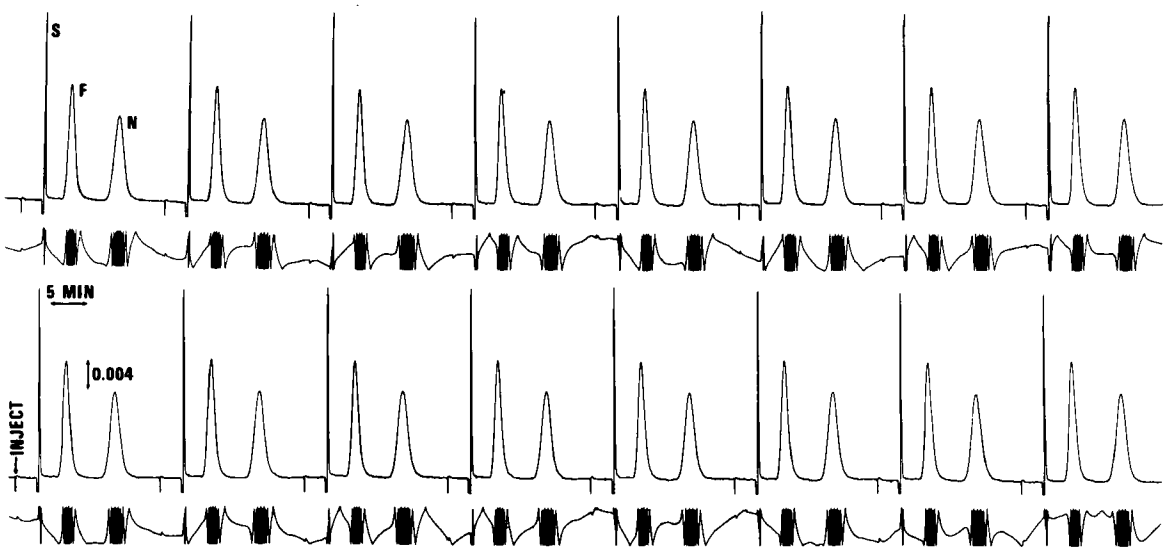

Figure 4—*Twenty-minute chromatograms of automatically sampled fluorometholone, 0.075 mg/ml (F), and internal standard norethindrone, 0.050 mg/ml (N), in 75% 3A alcohol (S). Chromatographic conditions were: ODS column packing, 6% aqueous acetonitrile with 0.0075 M borate buffer at pH 11.0 as the mobile phase, 300 psig column pressure (0.4 ml/min), and column temperature at 35°.*

started *via* a standard 115 v ac relay (E), mounted in the sampler and energized by the rinse timer (C). The timer (C), started by the sampler, operates for the programmed rinse time. After timing out, the sampler probe moves to the sampling position and rests until the next sampling and injection cycle.

The 115 v ac relay (H) closing allows the 24 v dc supply to pull in the mobile phase pump refill relay (J_1) and the sample injection relay (J_2) which, in turn, supplies 24 v ac current to two solenoid valves[10] (K_1 and K_2). K_2 supplies air to refill the mobile phase pump, and K_1 supplies air to the air cylinder, which pulses the injector valve and causes the sample from the flowing stream to be injected. The spring, steel balls, and weep hole ensure return of the plunger after injection to the normally off position.

The two solenoid valves can also be activated *via* front panel push button switches in the manner provided by the chromatograph manufacturer. The time delay relay (D) times out, resets sample pump timer (A), which, in turn, removes 115 v ac from contact 13, removing power from the solenoid valve *via* the relay (H). The chromatograph timer (B), on timing out, restarts the sample pump timer (A) *via* contact 3. The chromatograph time can be stopped at any desired time by manually pushing a reset button or by an automatic stop activated by the last sample in the sample tray. The last sample stop also removes power from the recorder and the mobile phase pump. The UV detector remains on to ensure its stability.

Each of the four functions—control of sample pump, control of automatic sampler, mobile phase pump refill, and sample injection—has a separate relay (J), which can be activated by a 24 v dc signal. This system was used so that the automated HPLC sampling system can be computer operated, independent of the three timers now used. The three timers were wired in the following manner: pump timer, wired for momentary start and separate reset switch; rinse timer, wired for sustained start; and chromatograph timer, wired for momentary start and automatic reset at end of programmed time.

Procedure—The sample probe is placed in a vial of liquid (preferably sample solvent), and the sample pump is primed. The sampling rate is selected from the vernier of the sample pump; sampling and rinse times are set on their appropriate timers. The length of chromatographic time is set, with the exact time determined from a test chromatogram. This time is calculated as the elapsed time from one sample injection to the next sample injection. Sampling time occurs for a preset period prior to injection. Sampling, therefore, can be programmed to begin during the elution of the last peak, depending on what effect, if any, the initiation of sampling signal has on the chromatogram.

The glass sample vials or plastic sample cups can be closed with aluminum foil, if necessary, to prevent solvent evaporation prior to placement in the sample tray. For many applications, however, the glass cover plate is satisfactory, particularly if internal standards are used.

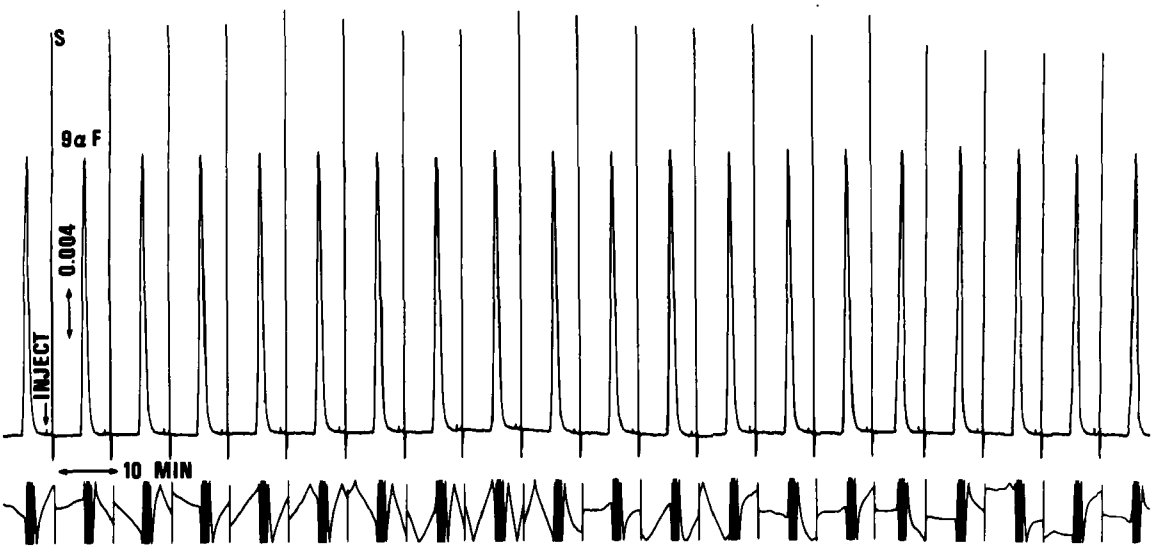

Figure 5—*Ten-minute chromatograms of automatically sampled 9α-fluoroprednisolone acetate, 0.25 mg/ml (9αF), in 75% 3A alcohol (S). Chromatographic conditions were: C-18 column packing, 24% aqueous acetonitrile mobile phase at 1000 psig (1.5 ml/min), and column at ambient temperature.*

volume desired to flush the automated injection system. The volume of sample available for injection was usually 10 ml or more; therefore, volume was no problem. Approximately 3 ml of sample and 3 ml of rinse were used routinely. Settings of 50 on the sample pump vernier and of 2 min on sampling and rinse timers gave these volumes. Figure 3 gives chromatograms showing the absence of carryover when going from a steroid sample, producing a peak approximately 77% of full scale, to 75% 3A alcohol solvent. For these chromatograms, an ODS column at 35° was used with a 6% aqueous acetonitrile mobile phase containing 0.0075 *M* borate buffer at pH 11.0. The flow rate was 0.67 ml/min, and pressure was 500 psig.

These conditions are similar to those used for the assay of fluorometholone in a topical steroid cream[14]. Either 5 μl of fluorometholone at 0.15 mg/ml in 75% 3A alcohol or 75% 3A alcohol was automatically injected. Chromatographic time was set for 8 min. Under the same chromatographic conditions, except for a pressure of 300 psig (0.4 ml/min), fluorometholone (0.075 mg/ml) and norethindrone internal standard (0.05 mg/ml) were automatically injected over approximately 11.5 hr, yielding 34 separate chromatograms, each of 20-min duration. The peak height ratios with a relative standard deviation of 0.61% are shown in Table I. A number of the chromatograms are shown in Fig. 4.

Additional data using the automated HPLC sampling system were obtained using a C-18 column with a mobile phase of 24% aqueous acetonitrile. Column pressure was 1000 psig with a flow rate of 1.5 ml/min at ambient temperature. The compound chromatographed was 9α-fluoroprednisolone acetate in a veterinary product[15] at approximately 0.24 mg/ml in 75% 3A alcohol. The relative standard deviation for 20 separate sample injections was 1.0% (Table II). A reproduction of 20 chromatograms, each of 10 min duration, is given in Fig. 5.

HPLC assays of 9α-fluoroprednisolone acetate, prepared for assay with and without the internal standard, were made using the automated HPLC sampling system. Twelve separate samples were prepared for assay using 2.0 ml of the steroid product and 15.0 ml of the internal standard solution (norethindrone at 0.20 mg/ml in 75% 3A alcohol). These samples were assayed against a 9α-fluoroprednisolone acetate standard (0.25 mg/ml) dissolved in the internal standard solution. Assay samples without the internal standard were prepared by adding 2.0 ml of the steroid formulation to 15.0 ml of 75% 3A alcohol. These samples were assayed against 9α-fluoroprednisolone acetate standard with a placebo vehicle. The standard solution was prepared by adding 2.0 ml of placebo vehicle to 15.0 ml of a 0.25-mg/ml 9α-fluoroprednisolone acetate solution in 75% 3A alcohol. The placebo vehicle was added to the standard solution to compensate for the volume change of the sample preparation. Table III shows that nearly identical results were obtained, with the steroid content of the 12 samples near the labeled amount (2.0 mg/ml).

The data show that the automated HPLC system described is capable of supplying uniform data over a long, unattended period. The data also suggest that the application of automated HPLC assays without the use of internal standards is possible, thus reducing analysis time as well as development time. Peak areas were also available for the data of this report; however, peak heights gave better precision and, therefore, were used in the calculations.

Relationship of *In Vitro* Hydrolysis of 17-Chloroacetylajmaline and 17-Acetylajmaline in Different Animal Species

MARIO SALMONA ˣ, KATERINA LAKSZNER *, ROBERTO FANELLI, CARLO SARONIO, ROBERTO BIANCHI, and EMILIO MUSSINI

Abstract □ 17-Chloroacetylajmaline and 17-acetylajmaline are reported to have *in vivo* antiarrhythmic activity and are metabolized by hydrolysis. Since the hydrolysis product, ajmaline, may be the actual antiarrhythmic agent, the hydrolysis of these derivatives by various tissues of the guinea pig, rat, and mouse was determined *in vitro* by a titrimetric method and compared to hydrolysis by α-naphthylacetate. The heart is the most active tissue in the guinea pig for hydrolyzing 17-chloroacetylajmaline. The hydrolyzing activity is greater in the guinea pig than in rat or mouse heart, corresponding with the more significant pharmacological activity in the guinea pig. 17-Chloroacetylajmaline has a significantly lower K_m value than 17-acetylajmaline, which is in agreement with the *in vivo* activity.

Keyphrases □ 17-Chloroacetylajmaline—*in vitro* hydrolysis, relationship to hydrolysis of 17-acetylajmaline, different animal species □ 17-Acetylajmaline—*in vitro* hydrolysis, relationship to hydrolysis of 17-chloroacetylajmaline, different animal species □ Antiarrhythmic activity—*in vitro* hydrolysis of 17-chloroacetylajmaline and 17-acetylajmaline, different animal species

The presence of several esterases in the blood and body tissues may be important in the distribution and metabolism of drugs possessing an ester bond (1). The pharmacological effects also may be influenced, depending upon whether an active or an inactive moiety of the particular drug is released with this esterase activity.

This problem should be considered not only for the blood but also for the tissues, with particular reference to the target organ of drug action. Recently, a new ester of ajmaline (2–4), 17-chloroacetylajmaline, was proposed as a therapeutic agent for the treatment of arrhythmias[1]. Preliminary data showed that this new compound is more effective in guinea pigs than in other animal species such as rats and mice. Therefore, it was of interest to investigate comparatively the capacity of blood and tissues, with particular reference to the heart, of these animal species to hydrolyze 17-chloroacetylajmaline.

This study may show whether 17-chloroacetylajmaline is active *per se* or through formation of ajmaline. It may also give an explanation of the outstanding action seen in guinea pigs.

EXPERIMENTAL

Animals—Male Sprague–Dawley rats (200–250 g), male albino Swiss mice (20–25 g), and male albino guinea pigs (300–350 g) were used in all experiments and were fed *ad libitum*.

Substrates—17-Chloroacetylajmaline[2] (I) and 17-acetylajmaline[2] (II) are odorless, white, microcrystalline powders. They do not have a significant melting point but begin decomposing above 220 and 230°, respectively. Their purity was checked by TLC utilizing silica gel[3] precoated aluminum sheets with a layer thickness of 0.25 mm and F_{254} UV indicator.

The plates were activated at 60° for 1 hr. After the application of about 20 ng of each compound, the plates were developed with

[a] Each figure represents the mean ± *SE* of the enzymatic activity of three enzyme preparations from different animals.

methanol. Compounds I and II presented one spot each with R_f values of 0.63 and 0.55, respectively.

α-Naphthylacetate (III) was synthesized as previously described (5).

Preparation of Biological Samples—Tissue and plasma samples were prepared as previously described (5) and were immediately assayed for their enzymatic activity.

Protein Analysis—Protein concentration in plasma and tissues was determined according to Lowry *et al.* (6).

Determination of Esterase Activity—The esterase activity of tissues were determined by a titrimetric method[4] according to Schwark and Ecobichon (7). All substrates were dissolved in 0.05 *M* phosphate buffer at the desired pH value. The volume of the reaction mixture was always 16 ml. A volume of 0.020 ml of appropriate supernate was added to the reaction vessel. The final concentration of the substrates in the vessel was 10^{-3} *M*.

Sodium hydroxide, at a concentration of 0.01 *M*, was used for the titrations, which were carried out at 37° for 6 min. In fact, the reaction was linear for at least 20 min. The pH of the reaction was 7.0 instead of 7.6, which is described to be the optimum for many esterases, because I and II are highly unstable at pH values above 7.2. However, with these experimental conditions in the absence of the enzymatic preparations, the spontaneous hydrolysis of I and II was negligible.

The initial rate of hydrolysis was determined from the titration curves as micromoles of sodium hydroxide utilized per minute per milligram of protein of extract (eu).

RESULTS AND DISCUSSION

Enzyme Distribution in Tissue—To determine the distribution of the enzyme hydrolyzing I and II, a substrate of reference α-naphthylacetate was used; this ester is known to be hydrolyzed, although at a different rate, by all esterases (8–10). Tables I, II, and III show the enzyme distribution in plasma and tissues of the guinea pig, mouse, and rat, respectively.

Compound I was hydrolyzed more rapidly in the heart than in other tissues of the guinea pig, and I was hydrolyzed fourfold faster than II. In rat and mouse hearts, I and II were hydrolyzed at equal rates but this activity was less than in the brain and liver. Since work performed *in vivo* (2) showed that I was much more active than II in the guinea pig only, this finding may suggest that the antiarrhythmic activity is due to the hydrolysis product ajmaline, at the site of action, namely the heart muscle.

It was evident from the high hydrolysis of I in the guinea pig that a large amount of ajmaline was released. Even though ajmaline was reported to be an active compound, if ajmaline itself was administered, it was less effective than 17-chloroacetylajmaline. The reported esterase activity for I present in the heart could have therapeutic significance because it may permit sustained release of ajmaline, the active moiety, at the effected site. It is remarkable that the hydrolysis of 17-chloroacetylajmaline was several fold higher in the guinea pig than in the rat and mouse, in agreement with the more significant pharmacological activity in the former animal species as compared to the two latter species (2).

Kinetic Parameters—Since I acts on the heart, it was of interest to determine the kinetic parameters of the esterase activity in the atria and ventricles of the guinea pig. This species was selected because it showed the highest esterase activity with respect to I among the three species tested.

Figures 1–3 show Woolf plots for I in comparison to II and III in the guinea pig heart. The K_m values in the atria are, for the three substrates, 4.5×10^{-4}, 4.3×10^{-3}, and 5.0×10^{-5} *M*; the V_{max} values are 10.00, 6.14, and 17.09 eu, respectively. In ventricles, the K_m values are calculated to be 9.8×10^{-4}, 7.8×10^{-3}, and 5.0×10^{-5} *M*; the V_{max} values are 9.70, 8.00, and 17.09 eu, respectively.

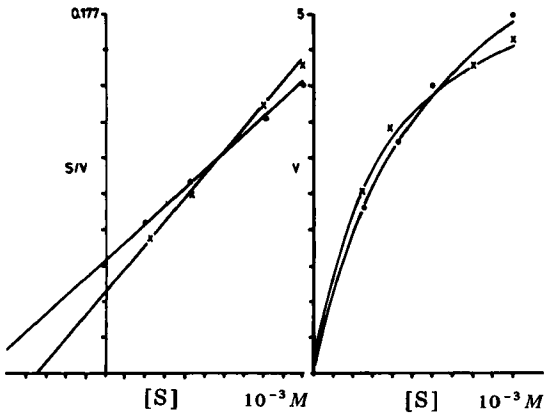

Figure 2—*Woolf plot for the hydrolysis of acetylajmaline in the guinea pig heart. The* K_m *and* V_{max} *values in the atria (×—×) are 4.3 × 10⁻³ M and 6.14 eu, respectively. The* K_m *and* V_{max} *values in the ventricles (●—●) are 7.8 × 10⁻³ M and 8.0 eu, respectively. V = initial velocity expressed as micromoles per minute per milligram of protein; S = substrate concentration (molar).*

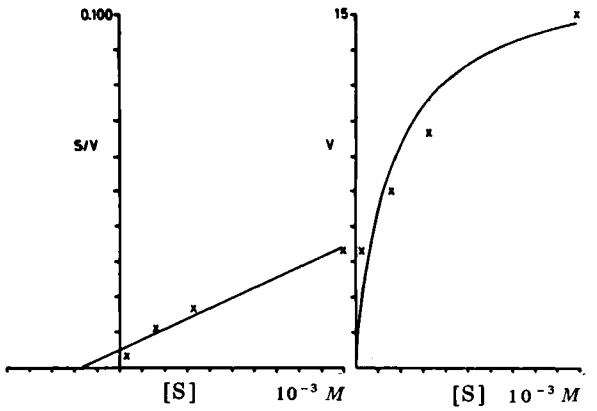

Figure 3—*Woolf plot for the hydrolysis of α-naphthylacetate in the guinea pig heart. The atria and ventricles show the same* K_m *and* V_{max} *values, 5 × 10⁻⁵ M and 17.09 eu, respectively. V = initial velocity expressed as micromoles per minute per milligram of protein; S = substrate concentration (molar).*

[4] pH-Stat, TTT lc Apparatus, Radiometer, Copenhagen, Denmark.

From these results, it is evident that the chloroacetyl ester of ajmaline (I) is more effectively hydrolyzed than the acetyl ester (II) by both the atria and ventricles. Also, the apparent affinity for the enzyme is at least 10 times higher for the chloroacetyl than for the acetyl ester, thus substantiating its *in vivo* effect. Further *in vivo* work is being conducted to determine: *(a)* the levels of ajmaline produced at the site of action after administration of I and II and *(b)* the levels reaching the site of action after administration of ajmaline itself.

Synthesis and *In Vitro* Evaluation of 8-Hydroxyquinolines as Dental Plaque Inhibitors

VICTOR D. WARNER *ˣ, JOSEPH D. MUSTO *, SAMUEL S. TURESKY ‡, and BARBARA SOLOWAY ‡

Abstract □ Some 4- and 5-substituted 8-hydroxyquinolines, with predicted log *P* values in the range of 1.48–2.90, were synthesized by modified Skraup reactions or thermal cyclization. These hydroxyquinolines include the 5-methyl, 4,5-dimethyl, 4-methyl, 5-hydroxy-4-methyl, 5-methoxy, 5-methoxy-4-methyl, 4-hydroxy, 4-chloro, 4-amino, and 5-amino analogs. Partition coefficients, antibacterial activity, and antiplaque activity were determined. Four analogs showed *in vitro* antiplaque activity. None of the derivatives with ionizable functions was active.

Keyphrases □ 8-Hydroxyquinoline analogs—synthesis and antibacterial and antiplaque activities □ Antibacterial activity—8-hydroxyquinoline analogs □ Antiplaque activity—8-hydroxyquinoline analogs

If dental plaque is to be controlled, it must be actively removed or its formation must be prevented. Mechanical cleansing is the principal means of removing plaque and its effectiveness is limited. Since dental plaque consists primarily of bacteria and their metabolites, consideration has been given to controlling plaque formation by use of antibacterial agents administered in dentifrices, mouthwashes, troches, or other appropriate vehicles. The present level of knowledge indicates that bacterial plaque is the direct cause of gingivitis and marginal periodontal disease and that without bacterial plaque there will be a great reduction in the occurrence of caries and peridontitis.

Previous research (1) showed that 8-hydroxyquinoline and some of its analogs inhibit *in vitro* plaque formation. It has been suggested that the antibacterial activity of the 8-hydroxyquinolines and their ability to chelate with trace ions on the surface of teeth, with subsequent slow release, should result in good long-term inhibition of dental plaque. Plaque inhibition by 8-hydroxyquinoline has been correlated favorably with the lipid–water partition coefficients. Analogs with log *P* values in the 1–4 range have been shown to have good antiplaque activity.

In an attempt to optimize antiplaque activity and to investigate other physicochemical factors that influence activity in addition to the partition coefficient, the following compounds with calculated log *P* values in the 1–4 range were synthesized and tested: 5-methyl- (I), 4,5-dimethyl- (II), 4-methyl- (III), 5-hydroxy-4-methyl- (IV), 5-methoxy- (VIII), 5-methoxy-4-methyl- (IX), 4-hydroxy- (XIV), 4-chloro- (XV), 4-amino- (XVII), and 5-amino-8-hydroxyquinoline (XVIII).

Compounds I–III, XV, XVII, and XVIII were prepared by standard methods (Table I). Compounds IV, VIII, and IX are unreported derivatives of 8-hydroxyquinoline, while XIV was previously prepared (10) but by a different method than is presented here. Intermediates VI and VII are known compounds (11, 12), but a different method for their preparation is presented in Scheme I.

Antiplaque activity as displayed by 8-hydroxyquinoline requires that a compound be an antibacterial agent. Therefore, the analogs were first evaluated for their *in vitro* antibacterial activity against *Streptococcus mutans* (No. 6715), a pure strain of plaque-forming bacteria. The antiplaque activity of the analogs was evaluated using an *in vitro* screening procedure (2).

From these results, it is evident that the chloroacetyl ester of ajmaline (I) is more effectively hydrolyzed than the acetyl ester (II) by both the atria and ventricles. Also, the apparent affinity for the enzyme is at least 10 times higher for the chloroacetyl than for the acetyl ester, thus substantiating its *in vivo* effect. Further *in vivo* work is being conducted to determine: *(a)* the levels of ajmaline produced at the site of action after administration of I and II and *(b)* the levels reaching the site of action after administration of ajmaline itself.

Keyphrases □ 8-Hydroxyquinoline analogs—synthesis and antibacterial and antiplaque activities □ Antibacterial activity—8-hydroxyquinoline analogs □ Antiplaque activity—8-hydroxyquinoline analogs

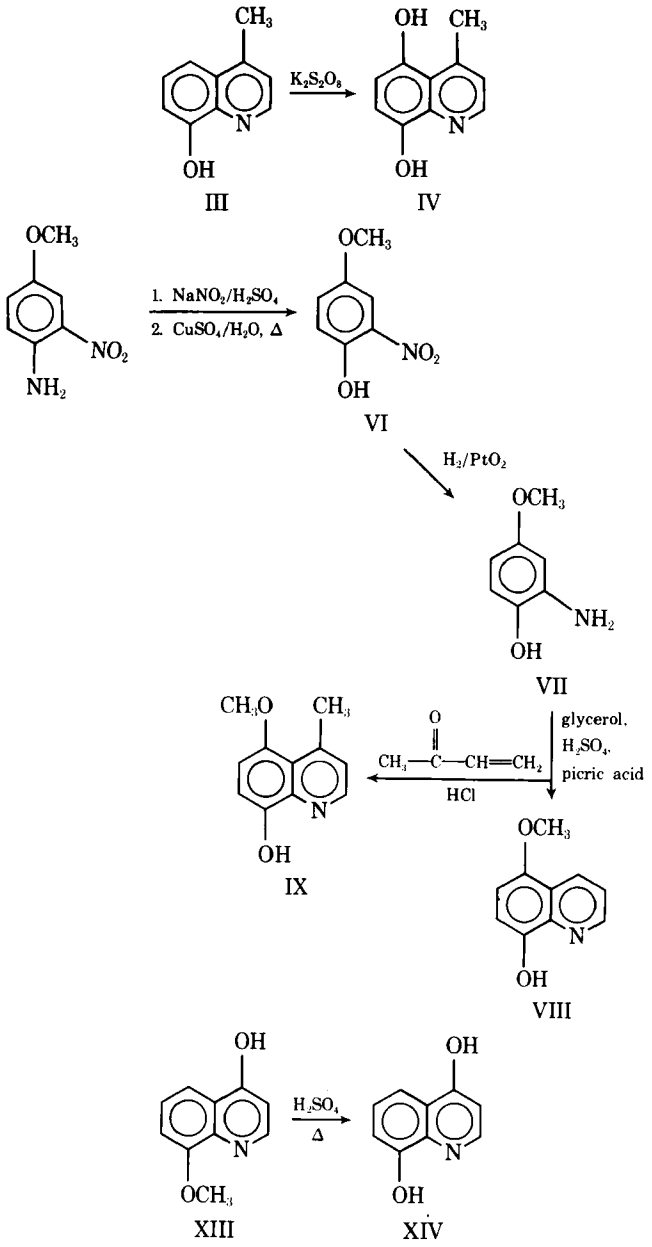
If dental plaque is to be controlled, it must be actively removed or its formation must be prevented. Mechanical cleansing is the principal means of removing plaque and its effectiveness is limited. Since dental plaque consists primarily of bacteria and their metabolites, consideration has been given to controlling plaque formation by use of antibacterial agents administered in dentifrices, mouthwashes, troches, or other appropriate vehicles. The present level of knowledge indicates that bacterial plaque is the direct cause of gingivitis and marginal periodontal disease and that without bacterial plaque there will be a great reduction in the occurrence of caries and peridontitis.

Previous research (1) showed that 8-hydroxyquinoline and some of its analogs inhibit *in vitro* plaque formation. It has been suggested that the antibacterial activity of the 8-hydroxyquinolines and their ability to chelate with trace ions on the surface of teeth, with subsequent slow release, should result in good long-term inhibition of dental plaque. Plaque inhibition by 8-hydroxyquinoline has been correlated favorably with the lipid–water partition coefficients. Analogs with log *P* values in the 1–4 range have been shown to have good antiplaque activity.

In an attempt to optimize antiplaque activity and to investigate other physicochemical factors that influence activity in addition to the partition coefficient, the following compounds with calculated log *P* values in the 1–4 range were synthesized and tested: 5-methyl- (I), 4,5-dimethyl- (II), 4-methyl- (III), 5-hydroxy-4-methyl- (IV), 5-methoxy- (VIII), 5-methoxy-4-methyl- (IX), 4-hydroxy- (XIV), 4-chloro- (XV), 4-amino- (XVII), and 5-amino-8-hydroxyquinoline (XVIII).

Compounds I–III, XV, XVII, and XVIII were prepared by standard methods (Table I). Compounds IV, VIII, and IX are unreported derivatives of 8-hydroxyquinoline, while XIV was previously prepared (10) but by a different method than is presented here. Intermediates VI and VII are known compounds (11, 12), but a different method for their preparation is presented in Scheme I.

Antiplaque activity as displayed by 8-hydroxyquinoline requires that a compound be an antibacterial agent. Therefore, the analogs were first evaluated for their *in vitro* antibacterial activity against *Streptococcus mutans* (No. 6715), a pure strain of plaque-forming bacteria. The antiplaque activity of the analogs was evaluated using an *in vitro* screening procedure (2).



Scheme I

EXPERIMENTAL[1]

5,8-Dihydroxy-4-methylquinoline (IV)—4-Methyl-8-hydroxyquinoline (3.18 g, 0.02 mole), sodium hydroxide (4.00 g), and water (120 ml) were stirred and treated dropwise with a solution of potassium persulfate (5.40 g, 0.02 mole) in 100 ml of water. The temperature was maintained between 5 and 10° during the addition. The reaction mixture was stirred for 30 min, refrigerated for 4 days, adjusted to pH 6 with 10% HCl, and filtered. After filtration, the filtrate was extracted with ether (3 × 30 ml).

The aqueous solution was treated with 50 ml of concentrated hydrochloric acid and allowed to stand refrigerated for 4 days. The red crystals which formed were filtered and heated with 30 ml of concentrated hydrochloric acid on a steam bath for 1 hr and then cooled to give 0.4 g (9.5%) of the IV-HCl. Isolation of the free base (neutralization with 20% NaOH) and crystallization from benzene gave the pure compound (IV), mp 294–296°.

4-Methoxy-2-nitrophenol (VI)—A suspension of 22.00 g (0.13 mole) of 4-methoxy-2-nitroaniline in 150 ml of 50% H_2SO_4 was cooled, and 150 ml of ice was added. After a homogeneous mixture and a temperature between 0 and 5° were obtained, a solution of sodium nitrite (26 g + 60 ml of water) was added to the bottom of the mixture while the temperature was maintained. The presence of excess nitrous acid was determined using starch iodide paper. Stirring was continued for 10 min after the completion of the reaction, and the product (V) was used immediately.

A solution containing 350 g of cupric sulfate pentahydrate in 1 liter of water was heated to boiling. The diazonium solution (V) was added slowly as the phenolic product was removed *via* steam distillation. The distillate was filtered, and the precipitate was dissolved in 5% NaOH, filtered, and extracted with ether. The aqueous layer was then acidified with 5% HCl, and the precipitate was recrystallized from petroleum ether, yielding 4.88 g (22.1%) (VI), mp 81–82° [lit. (11) mp 80°].

4-Methoxy-2-aminophenol (VII)—A solution of 5.00 g (0.03 mole) of VI in 150 ml of 95% ethanol and 150 mg of platinum oxide were hydrogenated (120 psi of H_2) for 30 min. The catalyst was filtered off, and the solvent was evaporated to give 3.60 g (95%) of a dark crystalline material (VII), mp 129–132° [lit. (12) mp 135°]. This compound was used without further purification.

5-Methoxy-8-hydroxyquinoline (VIII)—To 4.30 g (0.046 mole) of glycerol were added 2.0 g (0.01 mole) of VII and 0.45 g (0.002 mole) of picric acid. The temperature was raised to 110–120° as 3.50 g (0.04 mole) of concentrated sulfuric acid was added dropwise. The reaction mixture was then stirred and heated to 120–140° for 4 hr. After cooling, 72 ml of water was added and the pH was adjusted to 3 with 5% NaOH.

The product was obtained by steam distillation of the reaction mixture, followed by neutralization with 5 *N* ammonium hydroxide and extraction with ether. Recrystallization from hexane yielded 0.70 g (28%) of VIII, mp 83–85°.

4-Methyl-5-methoxy-8-hydroxyquinoline (IX)—To 100 ml (3.33 mole) of concentrated hydrochloric acid was added 28.0 g (0.20 mole) of VII. The temperature was raised to 100°, and 35.0 g (0.50 mole) of methyl vinyl ketone was added slowly. The reaction mixture was then stirred and heated for 5 hr at 100–120°. After cooling, the pH was made slightly alkaline with 10% NaOH and the mixture was steam distilled. The product was recrystallized from hexane to yield 5.40 g (14.3%) of IX, mp 130–132°.

4,8-Dihydroxyquinoline (XIV)—A solution of 4-hydroxy-8-methoxyquinoline (XIII) (1.50 g, 0.009 mole), 9.80 ml of concentrated sulfuric acid, and 5.8 ml of water was refluxed for 5.5 hr. Then the solution was poured over crushed ice and neutralized with concentrated ammonium hydroxide to precipitate the product. Recrystallization from water yielded 0.80 g (58%) of XIV, mp 316–318° [lit. (10) mp 315–319°].

Partition Coefficients[2]—The compounds were partitioned between 1-octanol saturated with water and distilled water saturated with octanol. Usually 50–150-ml portions of octanol and water were used. In partitioning these compounds, gentle shaking for 90 min was carried out at room temperature (25 ± 5°). The volume ratio of the two phases and the amount of sample were chosen so that the absorbance of the sample from the water layer after partitioning usually had a value between 0.2 and 0.9 using a 1-cm cell. Only the concentration of the sample in the water layer was determined; that in the octanol was obtained by difference.

Analyses of the concentrations of the partitioned substances were made by spectrophotometry[3]. The partition coefficient was calculated as $P = C_{octanol}/C_{water}$. Each determination was done in at least triplicate, using different amounts of sample; the average value for log P has been reported. The partition coefficient of XVIII could not be determined since the free base was not stable.

Antibacterial Activity—To 7.85 ml of sterile trypticase broth, 1 ml of an aqueous solution of the hydrochloride salt of the test compound and 1 ml of 50% sterile sucrose solution were added. The medium was inoculated with 0.15 ml of a 24-hr culture of *S. mutans*[4] (No. 6715), a pure strain of plaque-forming bacteria. This

[1] Melting points were determined on a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Microanalyses were performed by Midwest Microlab Ltd., Indianapolis, Ind. Where analyses are indicated only by symbols of the elements, analytical results obtained for those elements were within ±0.4% of the theoretical values.

[2] In calculating partition coefficients, a least-squares computer program was used both to produce the equation for the standards and to determine concentrations from experimental values.

[a] All compounds were evaluated in triplicate. [b] All compounds were evaluated as their hydrochloride salts in aqueous solutions. [c] All compounds were evaluated as free bases (except XVIII) in dimethyl sulfoxide solution on five teeth. Values show percentage of teeth that did not show plaque formation after stated incubation period. [d] All determinations were done in triplicate; values in parentheses indicate standard deviations.

mixture was incubated under anaerobic conditions[5] at 37°. Bacterial growth was determined after 24 and 48 hr.

Assay for *In Vitro* Antiplaque Activity—Sterilized extracted human teeth were immersed in dimethyl sulfoxide solutions of the test compounds for two 1-min periods, each of which was followed by a 1-min exposure to air. These treated teeth were washed with 250 ml of distilled water for 5 min and then incubated at 37° under anaerobic conditions in a 5% sucrose-containing trypticase broth with *S. mutans*. The teeth were suspended in test tubes on orthodontic wire[6] (0.71 mm in diameter) threaded through a hole in the root so that the entire tooth was completely immersed.

After 24 and 48 hr, subjective estimates were made of adherent microbial growth on the test tube walls, wire, and teeth and of nonadherent growth in the broth using a scale of 0 (no growth) to 4 (maximum growth). The total microbial accumulation was considered as *in vitro* plaque. For the results, growth ratings of 0 or 1

[5] BBL-Gaspak, Division of Bioquest, Cockeyville, Md.

[6] Rocky Mount.

were scored as plaque inhibition. Each compound was evaluated on five teeth, with percent inhibition values being reported. This method indicates the percentage of teeth that did not show plaque formation after the stated incubation period. The solvent served as the control.

RESULTS AND CONCLUSIONS

In the group of compounds tested, I–III and VIII showed maximal activity at 10^{-4} *M* after 24 and 48 hr while IX showed a shorter duration of activity. Only III showed equivalent activity to that of 8-hydroxyquinoline at 10^{-5} *M* after 24 hr. At 10^{-5} *M*, all of the active, new agents showed decreased duration of action or decreased activity. The antiplaque studies showed that II and IX had 24-hr activity equal to 8-hydroxyquinoline at 10^{-1} *M* while I and III had only 80% of the activity of the parent compound. Compounds IV, XIV, XVI, XVII, and XVIII showed neither antibacterial nor antiplaque activity.

Analogs with ionizable functions in the 4- or 5-position of 8-hydroxyquinoline showed no antibacterial or antiplaque activity. The inactivity may be due to either the test compounds inability to cross the bacterial membrane or their inability to chelate properly as required for biological activity. These data, as well as previous studies in this laboratory (1), indicate that a single parameter such as log *P* is not adequate to predict antiplaque activity accurately.

Influence of Monovalent and Divalent Electrolytes on Sorption of Neomycin Sulfate to Attapulgite and Montmorillonite Clays

JAMES W. McGINITY ˣ and JOHN A. HILL

Abstract □ Langmuir isotherms for the adsorption of neomycin sulfate to clays such as attapulgite, bentonite, and magnesium aluminum silicate were constructed. Monovalent and divalent cations were investigated for their influence on the formation of neomycin–clay adsorbates and the resulting equilibrium concentration in a neomycin solution. Divalent magnesium ions were more effective in displacing the antibiotic from each clay than were monovalent sodium ions. Ions present in the GI fluid might increase the bioavailability of neomycin from such neomycin–clay adsorbates.

Keyphrases □ Neomycin sulfate—sorption to attapulgite and montmorillonite clays, influence of monovalent and divalent electrolytes, Langmuir isotherms □ Attapulgite clay—sorption of neomycin sulfate, influence of monovalent and divalent electrolytes, Langmuir isotherms □ Montmorillonite clay—sorption of neomycin sulfate, influence of monovalent and divalent electrolytes, Langmuir isotherms

The adsorptive capacities of magnesium aluminum silicate (1–3), bentonite (2–4), and attapulgite (5–8) for various medicinals have been studied. The ionic incompatibility of neomycin sulfate with these clays was well documented in studies that demonstrated the strong affinity of this cationic antibiotic for the negatively charged clays, with a resultant reduction in the bioactivity of neomycin *in vitro* (2, 3, 9).

Wai and Banker (10) studied the adsorption of cationic drugs to montmorillonite clays and concluded that the mechanism of binding was ion exchange. This mechanism was verified in a recent investigation[1]. These studies, which also encompassed the influence of mono- and divalent electrolytes on the adsorption of amphetamine sulfate to montmorillonite, showed that the electrolytic cations had a significant effect on displacing the drug from the clay.

One objective of the present studies was to evaluate the influence of sodium and magnesium ions on the desorption of neomycin from attapulgite and montmorillonite clays. Another objective was to pro-

were scored as plaque inhibition. Each compound was evaluated on five teeth, with percent inhibition values being reported. This method indicates the percentage of teeth that did not show plaque formation after the stated incubation period. The solvent served as the control.

RESULTS AND CONCLUSIONS

In the group of compounds tested, I–III and VIII showed maximal activity at 10^{-4} *M* after 24 and 48 hr while IX showed a shorter duration of activity. Only III showed equivalent activity to that of 8-hydroxyquinoline at 10^{-5} *M* after 24 hr. At 10^{-5} *M*, all of the active, new agents showed decreased duration of action or decreased activity. The antiplaque studies showed that II and IX had 24-hr activity equal to 8-hydroxyquinoline at 10^{-1} *M* while I and III had only 80% of the activity of the parent compound. Compounds IV, XIV, XVI, XVII, and XVIII showed neither antibacterial nor antiplaque activity.

Analogs with ionizable functions in the 4- or 5-position of 8-hydroxyquinoline showed no antibacterial or antiplaque activity. The inactivity may be due to either the test compounds inability to cross the bacterial membrane or their inability to chelate properly as required for biological activity. These data, as well as previous studies in this laboratory (1), indicate that a single parameter such as log *P* is not adequate to predict antiplaque activity accurately.

Influence of Monovalent and Divalent Electrolytes on Sorption of Neomycin Sulfate to Attapulgite and Montmorillonite Clays

JAMES W. McGINITY ˣ and JOHN A. HILL

Abstract □ Langmuir isotherms for the adsorption of neomycin sulfate to clays such as attapulgite, bentonite, and magnesium aluminum silicate were constructed. Monovalent and divalent cations were investigated for their influence on the formation of neomycin–clay adsorbates and the resulting equilibrium concentration in a neomycin solution. Divalent magnesium ions were more effective in displacing the antibiotic from each clay than were monovalent sodium ions. Ions present in the GI fluid might increase the bioavailability of neomycin from such neomycin–clay adsorbates.

Keyphrases □ Neomycin sulfate—sorption to attapulgite and montmorillonite clays, influence of monovalent and divalent electrolytes, Langmuir isotherms □ Attapulgite clay—sorption of neomycin sulfate, influence of monovalent and divalent electrolytes, Langmuir isotherms □ Montmorillonite clay—sorption of neomycin sulfate, influence of monovalent and divalent electrolytes, Langmuir isotherms

The adsorptive capacities of magnesium aluminum silicate (1–3), bentonite (2–4), and attapulgite (5–8) for various medicinals have been studied. The ionic incompatibility of neomycin sulfate with these clays was well documented in studies that demonstrated the strong affinity of this cationic antibiotic for the negatively charged clays, with a resultant reduction in the bioactivity of neomycin *in vitro* (2, 3, 9).

Wai and Banker (10) studied the adsorption of cationic drugs to montmorillonite clays and concluded that the mechanism of binding was ion exchange. This mechanism was verified in a recent investigation[1]. These studies, which also encompassed the influence of mono- and divalent electrolytes on the adsorption of amphetamine sulfate to montmorillonite, showed that the electrolytic cations had a significant effect on displacing the drug from the clay.

One objective of the present studies was to evaluate the influence of sodium and magnesium ions on the desorption of neomycin from attapulgite and montmorillonite clays. Another objective was to pro-

[1] Unpublished data.

vide data as a basis for speculating on the probable bioavailability of neomycin sulfate in antidiarrheal suspensions containing these clays.

EXPERIMENTAL

Reagents—The following were used: magnesium aluminum silicate[2], bentonite[3], attapulgite[4], amaranth[5], potassium hydrogen phthalate[6], neomycin sulfate[7], sodium chloride[6], and magnesium chloride[6].

Neomycin Sulfate Assay—The assay[8] for the antibiotic is based on a colorimetric reaction between amaranth and neomycin sulfate, buffered to pH 4.0 with potassium hydrogen phthalate. The absorbance of the uncomplexed dye was read spectrophotometrically[9] at 520 nm. A linear relationship existed between the absorbance of the dye and the concentration of the antibiotic; the amount of free amaranth was inversely related to the concentration of neomycin sulfate present. Excellent agreement exists between the results of this chemical assay and those obtained by an assay of microbiological activity.

Sample Preparation for Langmuir Studies—Neomycin sulfate, 200 mg, was dissolved in 10 ml of purified water and added to weighed amounts of each clay. Clay samples had previously been passed through a 100-mesh screen and hydrated in 80 ml of 60° water. Each suspension was adjusted to 100 ml with room temperature purified water and then agitated in a constant-temperature water bath. After centrifugation, the supernatant liquid was assayed colorimetrically for neomycin content.

Sample Preparation for Electrolyte Studies—The quantity of each clay to adsorb 80% of the neomycin was calculated from the Langmuir studies. These concentrations (w/v) were: magnesium aluminum silicate, 0.8%; bentonite, 1.2%; and attapulgite, 3.2%. Neomycin sulfate, 200 mg, was dissolved in 10 ml of purified water and added to the hydrated clay (prepared as described) with stirring.

After agitation and equilibration for 24 hr at 24°, the electrolyte solution was added with stirring and the resulting mixture was adjusted to 100 ml. After an additional 4 hr of equilibration, the mixture was centrifuged and the supernatant liquid was assayed for neomycin.

Table I—Adsorptive Capacities of Attapulgite and Montmorillonite Clays for Neomycin Sulfate

Clay	Limiting Adsorptive Capacity, b^a, mg/g
Attapulgite	215
Bentonite	604
Magnesium aluminum silicate	772

[a] b appears in the Langmuir equation and denotes the theoretical maximum adsorptive capacity of an adsorbent for a particular drug.

RESULTS AND DISCUSSION

Data obtained from adsorption experiments fit the linear form of the Langmuir equation (11):

$$\frac{C}{x/m} = \frac{1}{ab} + \frac{1}{b}(C) \qquad \text{(Eq. 1)}$$

where x/m is the weight of neomycin in milligrams adsorbed per gram of adsorbent, C is the concentration of neomycin in milligrams per milliliter at equilibrium, and a and b are constants. Constant a is related to the forces involved in binding the drug to the clay, and constant b is the maximum amount of neomycin that can be adsorbed per gram of clay.

Langmuir isotherms for the adsorption of neomycin sulfate to magnesium aluminum silicate, bentonite, and attapulgite appear in Fig. 1. From the reciprocal of the slope for each linear curve, the limiting adsorptive capacity of each clay for neomycin was calculated (Table I). These experimental values were calculated from the regression lines in Fig. 1, using the method of least squares. The b values, particularly for the montmorillonite clays, demonstrated the strong binding capacity of these clays for neomycin.

The influence of sodium chloride and magnesium chloride on the adsorption of neomycin to magnesium aluminum silicate, bentonite, and attapulgite is demonstrated in Figs. 2–4. These studies showed that divalent magnesium cations were more efficient than

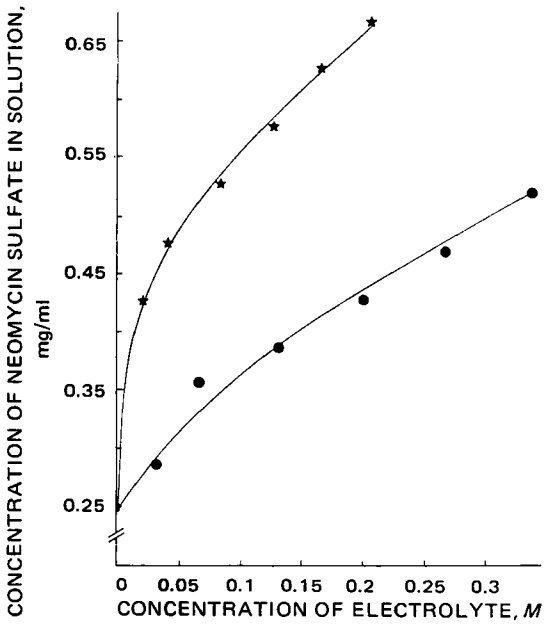

Figure 2—*Effect of electrolyte concentration and valency on the desorption of neomycin from a neomycin–magnesium aluminum silicate adsorbate. Key: ●, sodium chloride; and ★, magnesium chloride.*

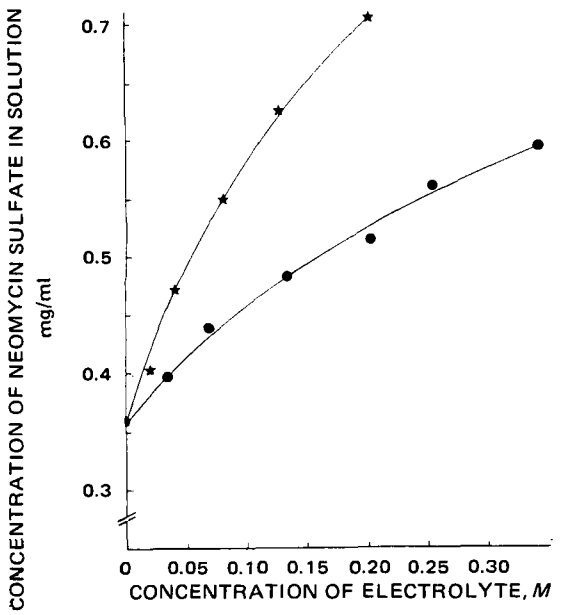

Figure 3—*Effect of electrolyte concentration and valency on the desorption of neomycin from a neomycin–bentonite adsorbate. Key: ●, sodium chloride; and ★, magnesium chloride.*

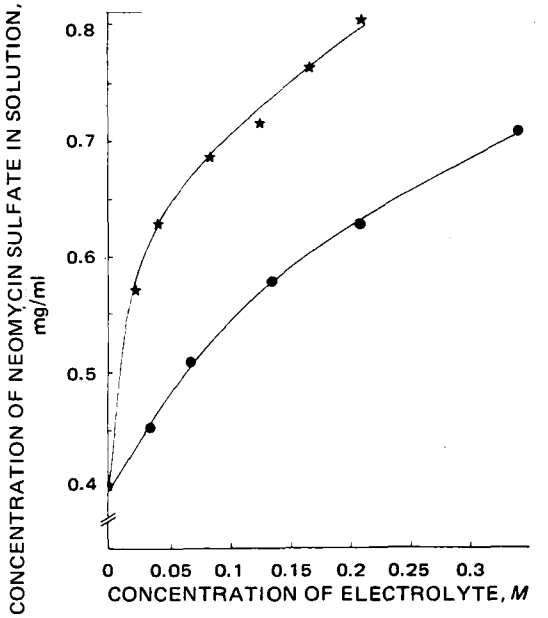

Figure 4—*Effect of electrolyte concentration and valency on the desorption of neomycin from a neomycin–attapulgite adsorbate. Key: ●, sodium chloride; and ★, magnesium chloride.*

monovalent sodium ions in displacing neomycin from negatively charged clays. These data suggest that any cations secreted in the GI fluids could influence the displacement of the antibiotic from these clays.

Sorby (5) suggested earlier that the presence of electrolytes and dilution by various fluids within the GI tract could hasten the release of promazine from activated attapulgite. The test doses that Sorby administered to human subjects had 75% of the drug adsorbed to the clay. However, under the conditions of the Sorby study, the clay slowed the rate of adsorption but had no significant effect on the total availability of promazine.

The average concentrations for sodium ions and potassium ions in GI fluids were reported (12) as 140 and 15 mEq/liter, respectively, but the concentrations of these ions are greater in the lower portion of the intestinal tract, precisely where the local action of neomycin is desired. On the other hand, divalent calcium and magnesium ions appear in negligible quantities in the luminal fluids. However, calcium from an external source (*e.g.*, milk), administered along with the antidiarrheal suspension, may act synergistically with secreted monovalent cations in releasing more free neomycin from the adsorbate. Supplemental oral therapy to replace sodium or potassium ions lost by the patient suffering diarrhea should also increase the desorption of neomycin and, consequently, improve the bioavailability of the antibiotic. During passage through the GI tract, the neomycin–clay adsorbate is continually exposed to freshly secreted fluids, so the desorption process is continuous.

Data presented in Figs. 2–4 were generated in a closed system in an attempt to establish rapidly an equilibrium between adsorbed drug and drug in solution. This equilibrium prevented excessive desorption of neomycin by the electrolyte *in vitro*. However, since equilibrium conditions are never established in the body, it can be argued that electrolytes would exert a greater influence *in vivo* than is suggested by the present *in vitro* studies.

Results of these studies also imply that the poor bioavailability of neomycin from similar adsorbates seen in *in vitro* studies (2, 3, 9) may not have accurately reflected the actual concentration of drug in the luminal fluids under the sink conditions of the body. Besides the electrolytic effect, other factors, such as the presence of bile salts, may influence the process of desorption, making it more difficult still to extrapolate from data for these neomycin–clay systems obtained *in vitro* to the actual situation *in vivo*.

Deviation of Dielectric Constant from Ideality for Certain Binary Solvent Systems

A. K. AMIRJAHED ˣ and MARTIN I. BLAKE

Abstract □ An equation was derived which relates the dielectric constant of mixtures of a binary solvent system to the mole fraction of the polar and nonpolar components of the system. The coefficients of the formula are readily calculated from the dielectric constant and the molar volume of the pure components of the binary solvent system. These calculated values are employed in graphical representations of the theoretical relationship of the dielectric constant of the binary solvent system and the mole fraction of the polar component of the solvent system. Experimental measurements are employed to demonstrate deviations from ideality.

Keyphrases □ Dielectric constant—binary solvent systems, deviation from ideality, equation developed □ Binary solvent systems—deviation of dielectric constant from ideality, equation developed □ Solvents—binary systems, deviations from ideality, equation developed relating the dielectric constant to mole fraction

For solutions of polar solutes in nonpolar solvents, the following equation applies (1):

$$P_M = [(D - 1)/(D + 2)](M/\rho) \qquad \text{(Eq. 1)}$$

By using this equation, the dielectric constant of a binary solvent mixture (D_m) was related to the mole fractions of the nonpolar solvent (X_1) and the polar solvent (X_2):

$$D_m = (aX_1 + bX_2)/(cX_1 + dX_2) \qquad \text{(Eq. 2)}$$

The coefficients a and b are summations of the molar volume and molar polarization of pure nonpolar and polar solvents, respectively; c and d represent the difference between the molar volume and molar polarization of the nonpolar and the polar solvents, respectively (2). These coefficients can be derived and represented as:

$$a = \bar{V}_1 + 2[(D_1 - 1)/(D_1 + 2)]\bar{V}_1 = \bar{V}_1[(3D_1)/(D_1 + 2)] \qquad \text{(Eq. 3)}$$

$$b = \bar{V}_2 + 2[(D_2 - 1)/(D_2 + 2)]\bar{V}_2 = \bar{V}_2[(3D_2)/(D_2 + 2)] \qquad \text{(Eq. 4)}$$

$$c = \bar{V}_1 - [(D_1 - 1)/(D_1 + 2)]\bar{V}_1 = \bar{V}_1[(3)/(D_1 + 2)] \qquad \text{(Eq. 5)}$$

$$d = \bar{V}_2 - [(D_2 - 1)/(D_2 + 2)]\bar{V}_2 = \bar{V}_2[(3)/(D_2 + 2)] \qquad \text{(Eq. 6)}$$

where $\bar{V}_1$ and $\bar{V}_2$ are the molar volumes and D_1 and D_2 are the dielectric constants of the nonpolar and polar components of the binary solvent system, respectively.

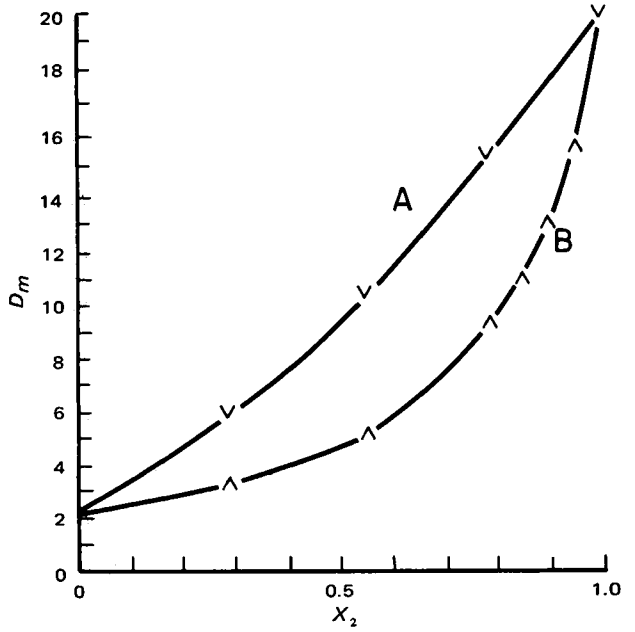

Figure 1—*Relationship of the dielectric constant* (D_m) *and the mole fraction of acetone* (X_2) *for the benzene–acetone binary solvent system. A is the experimental curve, and B is the theoretical curve.*

Table I—Theoretical Values of a, b, c, and d for Benzene–Acetone and Benzene–Methyl Isobutyl Ketone Binary Solvent Systems

Coefficient	Benzene–Acetone	Benzene–Methyl Isobutyl Ketone
a	142.40	142.40
b	201.80	325.50
c	61.90	61.90
d	9.64	25.25

EXPERIMENTAL

Benzene was selected as the nonpolar component of the nonaqueous binary solvent system. The polar component was methyl isobutyl ketone in one system and acetone in the other. These reagents, of the highest purity grades available, were used without further purification.

The benzene–methyl isobutyl ketone solvent system had a dielectric constant range of 2.29 for pure benzene to 12.80 for pure methyl isobutyl ketone (3). The dielectric constant range for the benzene–acetone solvent system was 2.29 for pure benzene to 20.97 for pure acetone. The Heterodyne-Beat apparatus and procedure (2) were employed in determining the dielectric constants of the different mixtures of the two binary solvent systems. All measurements were performed at 25°.

RESULTS AND DISCUSSION

The theoretical values for the coefficients of Eq. 2 are calculated from the molar volumes ($\bar{V}_1$ and $\bar{V}_2$) and dielectric constants (D_1 and D_2) of the pure solvents. The $\bar{V}_1$ and $\bar{V}_2$ values are readily determined from the molecular weight and the density of the pure solvents. The D_1 and D_2 values were determined experimentally and approximated those reported in the literature (3).

The theoretical values of a, b, c, and d for benzene–acetone and benzene–methyl isobutyl ketone are reported in Table I. By using these values and Eq. 2, the theoretical dielectric constant of any mixture at any given mole fraction of the two components can be calculated. These values are reported in Table II.

Mixtures of definite composition were prepared, and their dielectric constants were measured. The results for benzene–acetone and benzene–methyl isobutyl ketone are also reported in Table II. The theoretical and experimental values for the benzene–acetone binary solvent system are plotted in Fig. 1. The experimental curve shows definite deviations from the theoretical (the same is observed when the results for the benzene–methyl isobutyl ketone

Table II—Theoretical, Experimental, and Computer-Calculated Values of D_m for Benzene–Acetone and Benzene–Methyl Isobutyl Ketone Binary Systems

	Benzene–Acetone D_m				Benzene–Methyl Isobutyl Ketone D_m

[a] Based on computer-determined values of the coefficients. (See Ref. 2.)

system are plotted), because the ideal conditions under which the relationship was derived were not satisfied in real mixtures.

For example, the molar volumes of the two solvents change upon mixing. The electrical forces of the surrounding molecules exert an appreciable effect on each other. Consequently, the molar polarizations of the solvents also change upon mixing. Hence, the D_m values calculated from theoretical values of a, b, c, and d are significantly different from the experimentally determined D_m values. Therefore, it becomes necessary to measure the D_m values experimentally and subject them, along with the X_1 and X_2 values, to computer analysis to determine the values of the coefficients that will produce the best fit of the relationship to the experimental data.

The best values of the a, b, c, and d coefficients were determined by computer analysis (2) based on a series of laboratory experiments. The dielectric constant for any mixture of the benzene–acetone or the benzene–methyl isobutyl ketone binary solvent system can thus be predicted with the use of these values and Eq. 2. As reported in Table II, the predicted values (computer calculated) for D_m compare favorably with the experimentally determined values. This finding supports the usefulness of Eq. 2 for predicting D_m values of the binary solvent systems of the type studied here.

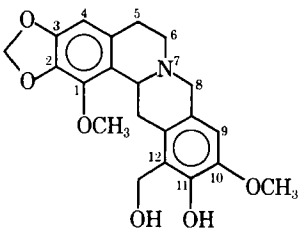
Alkaloids of *Papaver orientale* and *Papaver pseudo-orientale*

A. SHAFIEE [x], I. LALEZARI, P. NASSERI-NOURI *, and R. ASGHARIAN *

Abstract □ Dry latex of *Papaver orientale* was shown to contain 20% oripavine and 9% thebaine. Dry latex of *Papaver pseudo-orientale* contained two major alkaloids, isothebaine (11.7%) and orientalidine (0.5%), and the minor alkaloids bracteolin, salutaridine, Or_1, Or_2, PO-4, alborine (PO-5), and a novel alkaloid aryapavine.

Keyphrases □ *Papaver* alkaloids—isolation and identification from *P. orientale* and *P. pseudo-orientale* □ Aryapavine—isolation, identification from *Papaver pseudo-orientale*

As part of a broad study of the *Papaver* genus in Iran (1–3), the chemotaxonomy of *Papaver bracteatum*[1], *Papaver orientale*[1], and *Papaver pseudo-orientale*[1] has been studied.



I

Contradictory results exist in the literature with regard to the alkaloids of *P. bracteatum* and *P. orientale*. In addition to thebaine, other alkaloids have been reported in *P. bracteatum* (4–7). However, the present authors and others have demonstrated the existence of only thebaine (1, 3, 8) or a small amount of alpinigenine in addition to thebaine (2, 9–11) in *P. bracteatum*. Similar contradictory results have been reported for *P. orientale*. In addition to isothebaine,

[1] The plants were identified by P. Goldblat, Missouri Botanical Garden, St. Louis, Mo. Herbarium samples have been deposited in the Missouri Botanical Garden.

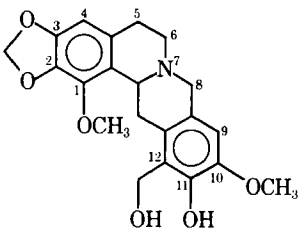
Keyphrases □ *Papaver* alkaloids—isolation and identification from *P. orientale* and *P. pseudo-orientale* □ Aryapavine—isolation, identification from *Papaver pseudo-orientale*

As part of a broad study of the *Papaver* genus in Iran (1–3), the chemotaxonomy of *Papaver bracteatum*[1], *Papaver orientale*[1], and *Papaver pseudo-orientale*[1] has been studied.



I

Contradictory results exist in the literature with regard to the alkaloids of *P. bracteatum* and *P. orientale*. In addition to thebaine, other alkaloids have been reported in *P. bracteatum* (4–7). However, the present authors and others have demonstrated the existence of only thebaine (1, 3, 8) or a small amount of alpinigenine in addition to thebaine (2, 9–11) in *P. bracteatum*. Similar contradictory results have been reported for *P. orientale*. In addition to isothebaine,

[1] The plants were identified by P. Goldblat, Missouri Botanical Garden, St. Louis, Mo. Herbarium samples have been deposited in the Missouri Botanical Garden.

thebaine has been reported to exist in *P. orientale* (12). Some workers found oripavine in *P. orientale* (13, 14), while others reported the same alkaloid in *P. bracteatum* (4). These results suggest that the previous alkaloid accounts are unreliable with respect to species determination.

With the objective of clarifying present uncertainties, the authors undertook the study of the alkaloids of these species, keeping in mind the taxonomic studies of these plants.

Three species of section oxytona were classified according to their haploid chromosome number: *P. bracteatum*, $n = 7$; *P. orientale*, $n = 14$; and *P. pseudo-orientale*, $n = 21$[2].

In the present work, the alkaloid content of the dry latex of *P. orientale* and *P. pseudo-orientale* is reported. These wild plants grow in the mountains in north and northwest Iran.

EXPERIMENTAL[3]

Extraction of Alkaloids from *P. orientale*.—Dried latex (2 g), obtained by incision of the capsules of the plant growing in Takab (northwest Iran), was treated with dilute ammonia to obtain a soft paste and extracted by trituration with chloroform (3 × 20 ml). The extract was filtered and evaporated under reduced pressure. The residue (0.64 g) was chromatographed (TLC, silica gel), using ethyl acetate–methanol–ammonia (85:10:5) as the eluting solvent. The fractions were worked up and crystallized from appropriate solvents.

Extraction of Alkaloids from *P. pseudo-orientale*.—Dried latex (100 g), naturally excreted (as flakes) from capsules during maturation, was worked up as described for *P. orientale*. The residue obtained from the evaporation of chloroform was subjected to column chromatography on silica gel using chloroform–petroleum ether (50:50) as the eluting solvent at first and then gradually increasing the chloroform proportion. Finally, a mixture of chloroform–methanol (95:5) was used, and the proportion of methanol was gradually increased up to 50%. The fractions were further purified by TLC [ether–acetone–diethylamine (85:8:7)] and crystallized.

RESULTS AND DISCUSSION

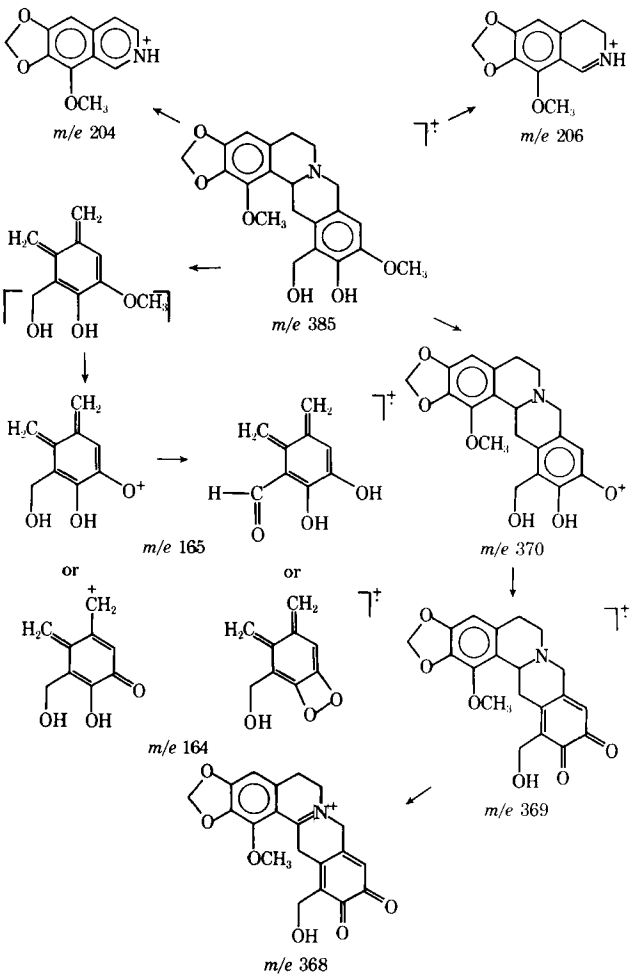
Alkaloids of *P. orientale*.—Two alkaloids were isolated and crystallized:

1. Oripavine (0.45 g, 20%), mp 201–203° (ethanol) [lit. (14) mp 200–201°]. The UV, IR, and NMR spectral properties of the separated alkaloid were identical with those of the authentic sample.
2. Thebaine (0.18 g, 9%), mp 193° (ethanol) [lit. (1–3) mp 193°].

Other samples of the plants collected from different regions of northwest Iran also had oripavine and thebaine; however, in one case, plants collected from Khalkhal (northwest Iran) had trace amounts of isothebaine in addition to oripavine and thebaine.

Alkaloids of *P. pseudo-orientale*.—The following alkaloids were characterized from the extensive studies of the dried latex:

1. Orientalidine, crystallized from ether (0.5 g, 0.5%), mp 192–195° [lit. (15, 16) mp 192–195°].
2. Isothebaine, crystallized from ethanol (11.7 g, 11.7%), mp 203–205° [lit. (15) mp 203–204°].
3. Bracteolin, crystallized from ether, mp 228–230° [lit. (15) mp 226–229°].
4. Salutaridine, crystallized from ether, mp 197–199° [lit. (15) mp 196–198°].
5. Or_1, crystallized from petroleum ether, mp 106–107° [lit. (15) mp 109°].



Scheme I

6. Or_2, crystallized from petroleum ether, mp 120–121° [lit. (15) mp 124–127°]; UV λ_{max} (ethanol): 285 (log ϵ 3.27) and 226 (log ϵ 3.12) nm; NMR ($CDCl_3$): δ 6.63 (s, 1H, aromatic), 3.98 (s, 3H, OCH_3), 3.43 (s, 3H, OCH_3), and 2.47 (s, 3H, NCH_3) ppm. The mass spectrum had a molecular ion at 333.
7. PO-4 (16), crystallized from acetone–ether, mp 300° [lit. (17) mp 300°].
8. Alborine (PO-5) (16), crystallized from methanol–ether, mp 300° [lit. (17) mp 300°].

The spectral data (UV, IR, NMR, and mass) of these alkaloids were identical with those reported in the literature (1–3, 15–17).

In addition to these alkaloids, a new alkaloid was also isolated, 11-demethylmecambridine (aryapavine) (I), mp 156–157° (acetone); UV λ_{max} (ethanol): 287 nm (log ϵ 3.87); NMR ($CDCl_3$): δ 6.62 (s, 1H, H_4), 6.43 (s, 1H, H_9), 5.97 (s, 2H, OCH_2O), 4.80 (s, 2H, CH_2O), 4.07 (s, 3H, OCH_3), 3.93 (s, 3H, OCH_3), and 3.90–2.20 (m, 9H, aliphatic) ppm; IR (KBr): 3400 cm^{-1} (broad, hydrogen bonded hydroxy). The mass spectrum had peaks at *m/e* (%) 385 (M, 70), 370 (77), 369 (85), 368 (63), 206 (100), 204 (77), 165 (55), and 164 (77). Its empirical formula was $C_{21}H_{23}NO_6$. These data were in agreement with Structure I for this alkaloid.

Anal.—Calc. for $C_{21}H_{23}NO_6$: C, 65.45; H, 5.97; N, 3.64. Found: C, 65.58; H, 6.02; N, 3.78.

The electron fragmentation pattern of this compound (Scheme I) was in agreement with the suggested structure. This pattern was similar to that of mecambridine (18). The spectral data of this alkaloid (I) were identical with those of demethylmecambridine as synthesized recently (19).

[2] P. Goldblat, Missouri Botanical Garden, St. Louis, Mo., personal communication.

[3] Melting points were taken with a Koffler hot-stage microscope and are uncorrected. UV spectra were recorded on a Varian Techtron 635 instrument. NMR spectra were taken with a Varian A60A instrument, using tetramethylsilane as the internal standard. Mass spectra were recorded on a CH5 spectrometer. IR spectra were obtained with a Leitz model III spectrograph.

Antitumor Agents XV: Deoxyelephantopin, an Antitumor Principle from *Elephantopus carolinianus* Willd.

KUO-HSIUNG LEE ˣ, CAROLE M. COWHERD *, and MacARTHUR T. WOLO

Abstract □ The active principle responsible for the significant inhibitory activity against the Walker 256 carcinosarcoma (ascites) in rats, isolated from the chloroform extract of the whole plant of *Elephantopus carolinianus* Willd., was characterized as deoxyelephantopin, a sesquiterpene lactone.

Keyphrases □ *Elephantopus carolinianus* Willd.—isolation and structure identification of deoxyelephantopin, antitumor activity □ Deoxyelephantopin—isolation from *Elephantopus carolinianus* Willd., structure identification, antitumor activity □ Antitumor agents, potential—deoxyelephantopin, major constituent of *Elephantopus carolinianus* Willd. □ Structure–activity relationships—sesquiterpene lactones (deoxyelephantopin) as antitumor agents

As a result of the continuing search for *Elephantopus* principles having new and novel potential antitumor agents (1, 2)[1], the chloroform extract of the whole plant of *Elephantopus carolinianus* Willd. (Compositae) was found to show significant inhibitory activity against the Walker 256 carcinosarcoma (ascites) in rats[2]. The extraction of the active principles was carried out according to an exact procedure described in the literature (4). A preliminary examination of the chloroform extract revealed that the antitumor activity was associated with the presence of the terpene-like constituents. Fractionation, characterization, and screening[2] of the isolated compound led to the conclusion that this major active principle was the germacranolide dilactone, deoxyelephantopin (I).

DISCUSSION

Deoxyelephantopin (I), the antitumor principle, was isolated in 0.15% yield as colorless needles from the chloroform eluate. Deoxyelephantopin, mp >320° (sintered at 198–200°)[3], has the empirical formula $C_{19}H_{20}O_6$ as determined by high-resolution mass spectrometry[4]. It shows IR bands in chloroform[5] at 1760 (double strength) and 1650 cm^{-1} and a pair of low field doublets in the NMR spectrum ($CDCl_3$)[6] at δ 6.22 (1H, d, J = 3.5 Hz, H-13) and 5.64 (1H, d, J = 3.5 Hz, H-13)[7], characteristic of an α-methylene-γ-lactone ring system.

An IR band at 1710 cm^{-1} and a characteristic base peak in the mass spectrum of I at m/e 69 suggested the presence of a methacrylate ester side chain, and the NMR signals at δ 1.93 (3H, t, J = 1.0 Hz, H-18), 5.66 (1H, t, J = 1.0 Hz, H-19)[7], and 6.14 (1H, t, J = 1.0 Hz, H-19), which are comparable with those found in molephantin (1) and phantomolin (2), established the presence of this structural feature. The NMR spectrum of I showed, in addition to the well-defined one-proton doublet of doublets (δ 5.13, J = 10.0

[1] See K. H. Lee, T. Ibuka, H. C. Huang, and D. L. Harris, *J. Pharm. Sci.*, **64**, 1077(1975).

[2] *In vivo* antitumor activity was assayed by Dr. I. H. Hall, Department of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, using a literature method (3). Deoxyelephantopin showed significant inhibitory activity against the Walker 256 (ascites) carcinosarcoma in rats at 226% T/C at the 2.5-mg/kg level. A compound is active if it exhibits a T/C of ≥125% (3).

[4] The authors thank Dr. David Rosenthal and Mr. Fred Williams of the Research Triangle Center for Mass Spectrometry for mass spectral data.

[5] This IR absorption band shifted to 1755 and 1738 cm^{-1} in mineral oil. Reference 5 reported 1766 and 1747 cm^{-1} in KBr.

[6] The authors thank Dr. David L. Harris of the Department of Chemistry, University of North Carolina at Chapel Hill, for NMR measurements. The model XL-100 used for the NMR measurements was purchased from grants from the National Science Foundation and the National Institutes of Health to the Department of Chemistry, University of North Carolina at Chapel Hill.

[7] Partially overlapped with H-19. Reference 5 reported H-13 and H-19 as a multiplet at δ 5.64.

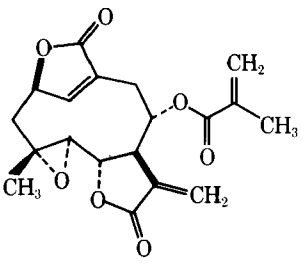
I: deoxyelephantopin



II: elephantopin

and 8.0 Hz) for the proton at C-6 (showing the *trans*-disposition of the lactone fusion) (6), a second vinyl methyl group, seen as a doublet, slightly split by allylic coupling (J = 1.0 Hz) at δ 1.93 (3H). These observations are indicative of the relationship of the protons at C-15, C-5, C-6, and C-7 of I.

The absence of the hydroxy groups and the presence of a strong carbonyl absorption band at 1760 cm^{-1} in the IR spectrum, coupled with the fact that the NMR spectrum of I showed a broad, low field, one-proton singlet at δ 7.13 corresponding to a vinyl proton beta to carbonyl, indicates that the remaining two oxygens must form a second α,β-unsaturated γ-lactone ring.

After treatment with *m*-chloroperbenzoic acid in chloroform, deoxyelephantopin gave a 4,5-epoxide (II: $C_{19}H_{20}O_7$; mp 263–265°[8]) whose spectral data were all in accord with the assigned Structure II. The identity of this compound with elephantopin, a tumor inhibitor isolated from *Elephantopus elatus* (7), was established by comparative TLC and NMR (dimethyl sulfoxide-d_6) spectral analyses[9].

The foregoing evidence led to the conclusion that I was deoxyelephantopin, a germacranolide dilactone which had been isolated from *Elephantopus scaber* (5). To establish the identity of the germacranolide beyond doubt[10], the IR (KBr), NMR, and mass spectra of I were compared with those of deoxyelephantopin. Studies on the structure–activity relationships among deoxyelephantopin-related sesquiterpene lactones are currently in progress.

EXPERIMENTAL[11]

Extraction of *E. carolinianus* Willd.—The *E. carolinianus* (Compositae) used was from a collection made on Oct. 13, 1972, along Flat River at Rt. 1005 in Durham County, N.C.[12]. The ground, air-dried, whole plant material (735 g) was exhaustively extracted with chloroform and worked up in the usual manner (4, 8), affording 18.4 g of a dark-brown syrup.

Isolation of Deoxyelephantopin (I)—The syrup was chromatographed on silica gel (4 × 65 cm) with elution with benzene, chloroform, and acetone. Twenty-four fractions of about 100 ml each were collected and examined by TLC. The first benzene eluate (fractions 1–6) contained only traces of low melting waxes. The subsequent chloroform eluate (fractions 8–16) contained mainly material giving a single spot on TLC. Upon removal of the chloroform solvent, these fractions gave an oily residue which crystallized upon addition of anhydrous ether. One recrystallization from chloroform yielded 974 mg of I as colorless needles, mp > 320° (sintered at 198–200°)[3]. The identity of this compound with deoxyelephantopin was established by their equivalent IR, NMR, and mass spectral data as already described.

Anal.—Calc. for $C_{19}H_{20}O_6$: m/e 344.1260. Found: m/e 344.1256.

The acetone eluate (372 mg) obtained from fractions 17–24 afforded a mixture which, upon rechromatography on silica gel[13] (70–325 mesh, 1.5 × 15 cm, eluted with chloroform), yielded mainly additional deoxyelephantopin (100 mg) (total yield 0.15%) and very small amounts of polar substances whose structures are now under investigation.

Epoxidation of Deoxyelephantopin (I) to Yield Elephantopin (II)—A solution of I (40 mg) in chloroform (1 ml) was treated with a solution of *m*-chloroperbenzoic acid (50 mg) in chloroform (1 ml), and the mixture was allowed to stand at room temperature overnight. Then the solution was washed with 10% sodium sulfite, 5% sodium bicarbonate, and water, dried, and evaporated *in vacuo* to give a crystalline residue. Silica gel column chromatography (0.6 × 10 cm, eluted with chloroform), followed by recrystallization from methylene chloride–absolute ethanol, yielded II as colorless needle tufts, mp 263–265°[14]. The identity of this compound with an authentic sample of elephantopin was confirmed by TLC and superimposable NMR spectra (in dimethyl sulfoxide-d_6).

Anal.—Calc. for $C_{19}H_{20}O_7$: m/e 360.1209. Found: m/e 360.1200.

Reduction of Doxorubicin (Adriamycin) Bone Marrow Toxicity

PHILLIP A. HARRIS ˣ, AGNES S. GARAI, and MARIA A. VALENZUELA

Abstract □ Doxorubicin (adriamycin), an antineoplastic antibiotic, is a potent suppressant of bone marrow. Previous studies on doxorubicin disposition indicated that its diversion from bone marrow in the first few minutes after administration should result in a marked decrease in total exposure to the drug (concentration × time) with a concomitant reduction in concentration–time-dependent toxicity. To test this hypothesis, the descending aorta of rabbits was occluded just proximal to the iliac bifurcation for 30 min to deprive bone marrow of blood flow. Both these rabbits and the control rabbits were given 5 mg/kg of doxorubicin intravenously, and the total white cell count in peripheral blood was monitored periodically for 15 days. The decrease in toxicity produced by the occlusion was quite evident by comparison of white cell counts and deaths in all groups. A possible mechanism of this effect was shown to be a decreased doxorubicin exposure of bone marrow tissue in the occluded animals as judged by relative doxorubicin concentration–time curves in rabbits with and without the aortic occlusion.

Keyphrases □ Doxorubicin (adriamycin)—reduction of bone marrow toxicity, aortic occlusion, rabbits □ Adriamycin—reduction of bone marrow toxicity, aortic occlusion, rabbits □ Toxicity, bone marrow—doxorubicin, reduction by aortic occlusion technique, rabbits □ Antineoplastic agents—reduction of doxorubicin bone marrow toxicity, aortic occlusion, rabbits

Doxorubicin (adriamycin) is a valuable chemotherapeutic drug in the treatment of solid neoplasms (1, 2). The serious toxicity of doxorubicin includes depression of proliferative elements of bone marrow as well as a mucositis and a cumulative dose-dependent delayed myocardiopathy (1–3). In short-term therapy with doxorubicin, the bone marrow suppression with the resultant leukopenia is the major dose-limiting toxicity. Recent pharmacokinetic investigations in these laboratories[1] led to the conclusion that the bone marrow toxicity of doxorubicin may be decreased by a clinically feasible method, albeit not yet proven acceptable or desirable.

This paper concerns the reduction of doxorubicin bone marrow toxicity and its probable mechanism by a temporary restriction of bone marrow blood flow.

EXPERIMENTAL

Female New Zealand white rabbits, 2.0–3.0 kg, were anesthetized with pentobarbital sodium USP[2], 25 mg/kg iv. A lower midline laparotomy was performed, and the aorta was occluded just proximal to the iliac bifurcation with a bulldog clamp. Doxorubicin hydrochloride[3] was administered in a dose of 5 mg/kg into the marginal ear vein immediately after the aorta was occluded. The clamp was removed after 30 min, and the incision was closed. Three hundred thousand units of penicillin G benzathine suspension[4] was administered intramuscularly to prevent possible infection due to surgery.

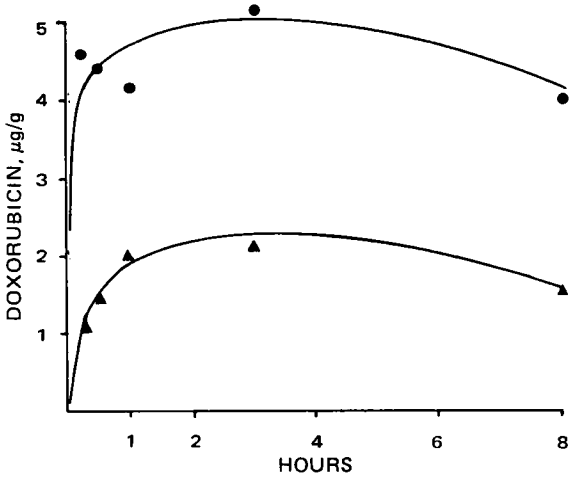

Figure 1—*Femur bone marrow concentrations after doxorubicin given intravenously, 3 mg/kg, in rabbits with (▲) and without (●) aortic occlusion. Each point represents the mean of duplicate determinations in one rabbit.*

Two control groups of animals were treated in the following manner. One group underwent surgery as described with aortic occlusion and penicillin therapy, but doxorubicin was not administered. The second group underwent the surgery, identical handling, trauma, and penicillin therapy as before and received 5 mg/kg of doxorubicin but the aorta was not occluded.

Blood samples were taken from all rabbits prior to and periodically after surgery, and the total white blood cell count was monitored until death or up to 15 days after surgery. The blood counts were performed[5] on a blind basis.

For studies of doxorubicin uptake into bone marrow, the aorta of each of five rabbits was occluded for 30 min as already described and doxorubicin was given intravenously into the marginal ear vein in a dose of 3 mg/kg immediately after the clamp was applied. Rabbits were killed at 15, 30, 60, 180, and 480 min after injection; bone marrow was removed from the femur and analyzed for doxorubicin levels according to a previously published method (4). Five control rabbits were treated similarly, except the aorta was not occluded.

RESULTS AND DISCUSSION

The effect of temporary reduction of blood flow to a major blood cell-producing tissue on doxorubicin toxicity was tested. Occlusion of all blood flow through the aorta at the level of the iliac bifurcation for 30 min was performed to accomplish a reduction or a near complete halt in blood flow to the pelvis and hindlimbs.

A group of five rabbits received 5 mg/kg of doxorubicin immediately after the aorta was occluded. For controls, three rabbits underwent aortic occlusion without administration of doxorubicin and another five rabbits that had no aortic occlusion received 5 mg/kg of doxorubicin. The total white cell count was monitored in all animals (Table I).

Aortic occlusion with no doxorubicin administration had no significant effect on the white blood cell count of the rabbits. When doxorubicin was administered in a dose of 5 mg/kg with no aortic occlusion, four out of the five rabbits died. As can be seen from the

total white cell count, death was probably due to severe bone marrow depression. The fifth rabbit experienced a moderate depression in white cell count. The rabbits that underwent aortic occlusion and received 5 mg/kg of doxorubicin had only mild or moderate bone marrow depression. None of these animals died.

The rabbits were all in excellent health when experiments were commenced. A transient body weight loss of 100–200 g was observed after surgery. No other changes in their clinical condition were observed except for the sudden death of four out of the five rabbits without aortic occlusion. Although the exact cause of death was not determined, a fatal septicemia was strongly suspected because of the leukopenic pattern noted before death.

The results of experiments to determine the effect of 30 min of occlusion on femur marrow uptake of doxorubicin are shown in Fig. 1. Data from rabbits without occlusion that received 3 mg/kg of doxorubicin are also shown. The rabbits with occlusion had an area under the concentration–time curve up to 8 hr of 923 μg min/ml compared to 2235 μg min/ml for those without occlusion. Both areas correlate to the respective smooth curves that were estimated by sight.

Doxorubicin uptake into tissues occurs rapidly (5–8), and the binding to tissues is extremely tenacious[1]. The pelvic and hindlimb bone marrow which normally receive blood flow distal to the occlusion do not receive a normal supply of doxorubicin for 30 min after injection because of blood flow reduction. During this time the doxorubicin becomes "fixed" to other tissues.

When the clamp is released and more normal blood flow resumes, the doxorubicin plasma concentration is very low. Hence, the marrow concentrations of doxorubicin do not reach values encountered without occlusion up to 8 hr after drug administration. The exposure of the marrow based on relative concentration–time areas is only 41% that without occlusion. There is little reason to expect this relationship to change significantly after 8 hr since the marrow concentrations are well past their maximums and the drug should decay from this tissue at similar rates in both cases.

Close examination of marrow levels in the occluded animals indicates that blood flow to the femur marrow was not completely halted during occlusion. The 15- and 30-min points had significant doxorubicin concentrations. There would not, of course, be any doxorubicin in this tissue at these times if flow were stopped completely. Perhaps the clamp on the aorta was not well placed, thus allowing some aortic flow to proceed distally to the femur marrow. It is also possible that some collateral blood vessels supply the femur marrow and receive flow from a point higher than the clamp was placed.

The dose levels selected were based on experiments in this laboratory. A 3-mg/kg doxorubicin dose in rabbits may be given every 7–10 days generally without fatality. The white cell counts are variably depressed at this dose. This level and frequency of doxorubicin would be a likely treatment regimen in rabbits. Therefore, this dose was selected for the uptake studies.

A single 5-mg/kg dose produces a much more profound and less variable drop in white cell count than does a 3-mg/kg dose. For this reason, a 5-mg/kg dose was used for studying the effect of aortic occlusion on white cell count.

Occlusion of the abdominal aorta in humans was used previously to increase tumor exposure to nitrogen mustard (mechlorethamine hydrochloride) (9, 10). The bone marrow of the lower part of the body of rats and rabbits was demonstrated to be protected by temporary occlusions of the abdominal aorta after nitrogen mustard administration (11). Nitrogen mustard has a very short $T_{1/2}$ in the body since it is so reactive. A significant proportion of nitrogen mustard was irreversibly eliminated from the blood during the period the occlusion was applied. Hence, the tissues distal to the occlusion receive protection.

Temporary occlusion of the abdominal aorta is used to control hemorrhage in emergency treatment or during elective aortic surgery. The occlusion may be accomplished by directly clamping the aorta after entering the abdominal cavity or by using external abdominal tourniquets or compression. The use of catheters equipped with inflatable sleeves or balloons for obstructing the aorta was described and evaluated (12–14). These catheters may be introduced by peripheral arterial catheterization.

The metabolic and hemodynamic sequel to abdominal aortic occlusion and declamping also was described (15–17). The main problems appear to be the frequent occurrence of acidosis and severe hypotension and occasionally ventricular fibrillation or cardiac arrest after release of the aortic blood flow. The control and prevention of the shock may be accomplished by fluid therapy (17, 18) or use of vasopressor drugs regionally (19).

Clearly, the results of the total white cell count and doxorubicin bone marrow uptake experiments reported here demonstrate that a significant reduction in the drug exposure of bone marrow and in leukopenic response after doxorubicin administration may be accomplished by only 30 min of aortic occlusion at the iliac bifurcation. These results may have clinical significance in the use of doxorubicin since leukopenia often delays doxorubicin therapy. Also, combination therapy with other marrow toxic drugs or radiation may be more flexible using this approach.

A more complete study should be performed to determine the clinical feasibility, safety, and mechanism of the reduction of doxorubicin toxicity by temporary blood flow restriction.

Relative Bioavailability of Cyclobarbital Calcium from Aqueous Solution Compared to Tablets

Keyphrases □ Cyclobarbital calcium—relative bioavailability from aqueous solution and tablets □ Bioavailability—cyclobarbital calcium, aqueous solution and tablets

To the Editor:

For biopharmaceutical studies, the aqueous drug solution is generally recommended as the reference dosage form if no comparison can be made with intravenous data (1). The highest relative bioavailability of a drug is expected from the solution since dissolution of the drug in the GI tract seems to be bypassed. The present report on cyclobarbital calcium shows that this supposition is not always true.

The pharmacokinetics and relative bioavailability of cyclobarbital calcium were studied in six healthy volunteers (21–26 years of age). Three preparations were used:

1. Tablets[1], containing 200 mg of cyclobarbital calcium, 60 mg of potato starch, 27 mg of lactose, 7 mg of talc, 3 mg of magnesium stearate, and gelatin *q.s.*
2. Tablets[2], containing 200 mg of cyclobarbital calcium.
3. Aqueous solution of cyclobarbital calcium (300 mg/150 ml), which was prepared within 15 min prior to administration.

After fasting overnight, at 9 am the volunteers were given 300 mg of cyclobarbital calcium incorporated in one of the preparations together with 150 ml of water. Additional water was not supplied when cyclobarbital calcium was given in solution. The volunteers remained in an upright position for 15 min after intake of the drug and then rested supine for at least 3.5 hr.

Blood samples were taken at 0.15 or 0.33, 0.66, 1.0, 1.5, 2.0, 2.5, 3.0, 5.0, 8.0, 12, 24, and 32 hr following drug administration. Each volunteer received the three preparations in a random sequence, with an interval of at least 1 week. Cyclobarbital plasma concentrations were determined after a single extraction step by GC with nitrogen selective detection, following on-column methylation with trimethylanilinium hydroxide. The use of a nitrogen detector for the sensitive assay of barbiturates in biological fluids was described previously for hexobarbital (3).

In Table I the cyclobarbital plasma peak concentrations and times (mean values) are given, as well as the bioavailability relative to Preparation 1. Relative bioavailability was estimated for each individual by comparing the areas under the experimental plasma concentration curves and correcting for the undetermined area to infinity. The elimination of cyclobarbital followed first-order kinetics with an average half-life of 11.6 hr (range of 8–17 hr). The half-lives were fairly constant within the individuals during the three trials.

The elimination of cyclobarbital followed first-order kinetics with an average half-life of 11.6 hr (range of 8–17 hr). The half-lives were fairly constant within the individuals during the three trials.

[1] Prepared by the Dutch Pharmacist's Laboratory, The Hague (2).
[2] Commercially obtained as Phanodorm, Merck/Bayer.

Table I—Plasma Peak Concentrations and Relative Bioavailability of Cyclobarbital following Oral Administration of the Three Cyclobarbital Calcium Preparations

Preparation	Mean t_{max} (Range), hr	Mean C_{max} (Range), mg/liter	Mean F_{rel} (Range), %
1. Tablets	1.2 (0.33—3.0)	8.3 (7.3—10.8)	100
2. Tablets	1.2 (0.66—2.5)	8.7 (7.4—10.3)	101 (89—136)
3. Aqueous solution	0.7 (0.25—1.5)	8.3 (5.8—11.7)	78 (64—100)

Although substantial variations in absorption rate and relative bioavailability were observed between individuals (see range values), the rank order of these values for the three preparations was generally the same for each volunteer. For one subject, absorption was comparatively slow (t_{max} of 3.0, 2.5, and 1.5 hr for Preparations 1, 2, and 3, respectively), but still the drug was absorbed more rapidly and to a lesser extent when given in aqueous solution.

The present findings clearly indicate that the extent of bioavailability of cyclobarbital in humans is lower when its calcium salt is administered in aqueous solution. This finding is unexpected, whereas the highest absorption rate is in accordance with the usual behavior of an oral aqueous drug solution. It may be argued that after oral administration of barbiturate salts, precipitation of the poorly soluble free acid will occur as soon as the acidic medium of the stomach is reached. This precipitation, however, will also occur for the calcium salt incorporated in the tablets. The precipitate formed after administration of the aqueous solution may have unfavorable redissolution properties in comparison to the precipitate formed after tablet administration. If so, this situation only holds for part of the precipitate, since the rapid absorption of cyclobarbital calcium solution also suggests that rapid (re)dissolution occurs.

A similar observation was made in a separate study when comparing absorption of heptabarbital as free acid with heptabarbital sodium, both from solid dosage forms. The salt showed the highest absorption rate; however, bioavailability relative to the free acid was approximately 20% lower (4). Higuchi *et al.* (5) showed that, in general, salts show higher dissolution rates than the corresponding nonionic drug at any pH, even though the final equilibrium solubility of the drug and its salt is the same. Additional *in vitro* experiments with cyclobarbital calcium are required to study the influence of precipitate formation on the redissolution characteristics of cyclobarbital under acid and weak alkaline conditions.

Although barbiturates are weak acids, their major site of absorption is the intestine (6, 7); therefore, another factor involved in the present findings may be the rate of drug transfer from the stomach to the intestine. However, it is hard to see how this factor could explain the discrepancy between the rate and the extent of cyclobarbital calcium bioavailability from the aqueous solution. Its rapid rate of absorption suggests that rapid drug transfer takes place, which, in principle, favors high bioavailability.

Fluorocarbon Aerosol Propellants VII: Interaction Studies with Human and Bovine Globulins Using Partition Coefficient Method

Keyphrases □ Fluorocarbon aerosol propellants—interaction with human and bovine globulins, partition coefficient method □ Globulins, human and bovine—interaction with fluorocarbon aerosol propellants, partition coefficient method □ Plasma protein binding—interaction of fluorocarbon aerosol propellants with human and bovine globulins, partition coefficient method

To the Editor:

The partition coefficients of some commonly employed propellants between the aqueous phase and the head space have been shown to be higher in plasma–air systems for humans (1, 2) and other species (2) than in the water (or normal saline)–air system. This finding was postulated to be due to the binding or complexation of these propellants to certain constituent(s) in plasma, as was subsequently confirmed by the partition coefficient method using purified human and bovine albumins (3, 4).

The ability of trichloromonofluoromethane to bind to bovine albumin also was recently demonstrated using a fluorescent probe technique, and these results will be published later. The binding or complexation with other tissue components was also hypothesized to account partially for the high apparent volume of distribution of these neutral propellants in dogs (5).

Table I—Plasma Peak Concentrations and Relative Bioavailability of Cyclobarbital following Oral Administration of the Three Cyclobarbital Calcium Preparations

Preparation	Mean t_{max} (Range), hr	Mean C_{max} (Range), mg/liter	Mean F_{rel} (Range), %
1. Tablets	1.2 (0.33—3.0)	8.3 (7.3—10.8)	100
2. Tablets	1.2 (0.66—2.5)	8.7 (7.4—10.3)	101 (89—136)
3. Aqueous solution	0.7 (0.25—1.5)	8.3 (5.8—11.7)	78 (64—100)

Although substantial variations in absorption rate and relative bioavailability were observed between individuals (see range values), the rank order of these values for the three preparations was generally the same for each volunteer. For one subject, absorption was comparatively slow (t_{max} of 3.0, 2.5, and 1.5 hr for Preparations 1, 2, and 3, respectively), but still the drug was absorbed more rapidly and to a lesser extent when given in aqueous solution.

The present findings clearly indicate that the extent of bioavailability of cyclobarbital in humans is lower when its calcium salt is administered in aqueous solution. This finding is unexpected, whereas the highest absorption rate is in accordance with the usual behavior of an oral aqueous drug solution. It may be argued that after oral administration of barbiturate salts, precipitation of the poorly soluble free acid will occur as soon as the acidic medium of the stomach is reached. This precipitation, however, will also occur for the calcium salt incorporated in the tablets. The precipitate formed after administration of the aqueous solution may have unfavorable redissolution properties in comparison to the precipitate formed after tablet administration. If so, this situation only holds for part of the precipitate, since the rapid absorption of cyclobarbital calcium solution also suggests that rapid (re)dissolution occurs.

A similar observation was made in a separate study when comparing absorption of heptabarbital as free acid with heptabarbital sodium, both from solid dosage forms. The salt showed the highest absorption rate; however, bioavailability relative to the free acid was approximately 20% lower (4). Higuchi *et al.* (5) showed that, in general, salts show higher dissolution rates than the corresponding nonionic drug at any pH, even though the final equilibrium solubility of the drug and its salt is the same. Additional *in vitro* experiments with cyclobarbital calcium are required to study the influence of precipitate formation on the redissolution characteristics of cyclobarbital under acid and weak alkaline conditions.

Although barbiturates are weak acids, their major site of absorption is the intestine (6, 7); therefore, another factor involved in the present findings may be the rate of drug transfer from the stomach to the intestine. However, it is hard to see how this factor could explain the discrepancy between the rate and the extent of cyclobarbital calcium bioavailability from the aqueous solution. Its rapid rate of absorption suggests that rapid drug transfer takes place, which, in principle, favors high bioavailability.

Fluorocarbon Aerosol Propellants VII: Interaction Studies with Human and Bovine Globulins Using Partition Coefficient Method

Keyphrases □ Fluorocarbon aerosol propellants—interaction with human and bovine globulins, partition coefficient method □ Globulins, human and bovine—interaction with fluorocarbon aerosol propellants, partition coefficient method □ Plasma protein binding—interaction of fluorocarbon aerosol propellants with human and bovine globulins, partition coefficient method

To the Editor:

The partition coefficients of some commonly employed propellants between the aqueous phase and the head space have been shown to be higher in plasma–air systems for humans (1, 2) and other species (2) than in the water (or normal saline)–air system. This finding was postulated to be due to the binding or complexation of these propellants to certain constituent(s) in plasma, as was subsequently confirmed by the partition coefficient method using purified human and bovine albumins (3, 4).

The ability of trichloromonofluoromethane to bind to bovine albumin also was recently demonstrated using a fluorescent probe technique, and these results will be published later. The binding or complexation with other tissue components was also hypothesized to account partially for the high apparent volume of distribution of these neutral propellants in dogs (5).

Table I—Average Partition Coefficients ± *SD* of the Three Propellants in Solutions of Plain Buffer and 5% (w/v) Bovine and Human γ-Globulins

Propellant	Plain Buffer	Bovine γ-Globulin	Human γ-Globulin
Trichloromonofluoromethane	0.298 ± 0.0084	0.273 ± 0.0053 ($p < 0.01$)	0.308 ± 0.0085 ($p < 0.1$)
Dichlorodifluoromethane	0.0916 ± 0.0008	0.0887 ± 0.0017 ($p < 0.05$)	0.0882 ± 0.0013 ($p < 0.02$)
Dichlorotetrafluoroethane	0.0296 ± 0.0009	0.0294 ± 0.0013 ($p < 0.8$)	0.0275 ± 0.0010 ($p < 0.05$)

Since it is important to identify various components of plasma that may interact with these propellants and since γ-globulin has the second highest concentration among various plasma proteins, a preliminary study was conducted on the possible interaction between the three most widely used propellants and human and bovine globulins using the partition coefficient method (3, 4).

The crystallized and lyophilized bovine and human γ-globulins were obtained commercially[1] and were used without further purification. Protein solutions (5% w/v) were freshly prepared in pH 7.4 phosphate buffer (3). The equilibrium study was conducted in a water bath maintained at 21.5–22°. The equilibrium concentrations of the propellants in the aqueous phase were about 0.05, 0.08, and 0.015 mg/ml for trichloromonofluoromethane, dichlorodifluoromethane, and dichlorotetrafluoroethane, respectively.

All propellants were studied individually, and at least four runs were performed on each propellant. The propellant concentrations in both the aqueous phase and the head space in sealed serum bottles were analyzed by a GC method using an electron-capture detector (6). The enhancing effect of *n*-hexane used in the extraction on peak heights in the GC analysis for each propellant was corrected in the calculations (7).

The results of this preliminary study are summarized in Table I. Contrary to the albumin study, all of the partition coefficients in globulin–air systems are only slightly different from those in the plain buffer–air system, indicating an insignificant degree of interaction in spite of statistically significant differences in some systems. The slight decrease of the partition coefficients of some propellants in the globulin solutions is most likely due to the salting-out effect of globulin.

Novel, Low Cost Approach to Digitizing Tablet Hardness Values

Keyphrases □ Tablet hardness tester—modified to give digitized values □ Digitized tablet hardness values—equipment described

To the Editor:

When formulating tablets with deliberately low hardness values, *i.e.*, <2 kg, it is difficult to determine these values repeatedly and accurately to 0.1 kg on the meter scale of a hardness tester[1]. Shown in Fig. 1 is an inexpensive addition to the hardness tester which will give a digitized reading of these hardness values and print them on an optional printer if desired.

The transducer used for sensing the force applied to break the tablet is a Hall generator[2]. The output signal from a Hall generator is a voltage that is proportional to the current flowing through it and the magnetic flux density (1).

As shown in Fig. 1, a Hall generator is attached to the movable counterweight shaft and a small magnet is attached to the case of the instrument approximately 5 mm from the Hall device. As force is applied to the tablet, the shaft moves, causing the Hall device to move away from the magnet. This change in magnetic flux density is sensed by the Hall generator; its

output voltage, which is proportional to force, is amplified, scaled, and displayed on a digital voltmeter calibrated directly in kilograms. The display on the digital panel meter is held at the maximum force value by utilizing the tablet breakage point sensing circuitry in the hardness tester.

Calibration and linearity of the digital readings can be checked by displacing the anvil on the hardness tester in small increments while noting the reading on the meter incorporated in the hardness tester. Magnet placement, Hall device power supply voltage, and scaling amplifiers are adjusted for the proper reading.

A method for calibrating the hardness tester was mentioned previously (2).

Advantages of the digital approach include: *(a)* accuracy, *(b)* low cost of the transducer and system, *(c)* ease of construction, *(d)* no change in operating procedures, *(e)* automatic printout if desired, and *(f)* hardness tester not affected by operation of the transducer.

Drug–Nitrite Interactions: Formation of *N*-Nitroso, C-Nitroso, and Nitro Compounds from Sodium Nitrite and Various Drugs under Physiological Conditions

Keyphrases □ Nitrite–drug interactions—formation of *N*-nitroso, C-nitroso, and nitro compounds from sodium nitrite and 20 drugs under physiological conditions □ Nitroso compounds—formation from sodium nitrite and 20 orally administered drugs under physiological conditions □ Interactions—20 orally administered drugs with sodium nitrite, formation of *N*-nitroso, C-nitroso, and nitro compounds under physiological conditions

To the Editor:

Many alkyl, aryl, and cyclic *N*-nitroso compounds are known to be carcinogenic (1, 2). Recently, several drugs containing secondary and tertiary amino groups were found to react with sodium nitrite *in vitro* and *in vivo* to yield *N*-nitroso compounds (3–8). Coadministration of aminopyrine and sodium nitrite by the oral route produced liver tumors in rats identical to those produced by *N*-nitrosodimethylamine, a product of drug–nitrite interaction in the stomach (9, 10). Similarly, concurrent administration of piperazine and sodium nitrite to mice induced lung adenomas attributable to *N*-nitrosopiperazine formed *in vivo* (11).

Since many orally administered drugs contain secondary and tertiary amino groups which could form potentially toxic *N*-nitroso compounds in the stomach, where suitable acidic conditions and significant concentrations of nitrite through dietary intake may prevail, the drug–nitrite interaction has been implicated in the etiology of human cancer (2, 12–15).

In the present communication, the isolation and mass spectrometric identification of *N*-nitroso, C-nitroso, and nitro compounds that arise from the reaction of sodium nitrite with 20 drugs (Table I) are described. These drugs were selected because they are commonly administered by the oral route and represent a wide variety of chemical structures. These studies were initiated to gain a better understanding of drug–nitrite interactions and to delineate the structural features of the drugs most likely to yield potentially toxic nitroso compounds.

The nitrosative cleavage of tertiary amines was studied previously (16–18). We observed that, depending upon the structure of drugs, five types of nitroso compounds may be formed as a result of drug–nitrite interactions (Table I). For the reactions at pH 1–2, 100 mg of drug was incubated with 200 mg of sodium nitrite in 10 ml of 10% hydrochloric acid at 37° for 4 hr; the reactions at pH 3–4 were carried out in 10 ml of 10% acetic acid. The reaction mixtures were adjusted to pH 11 with solid sodium hydroxide and extracted twice with 8 ml of methylene chloride and twice with 8 ml of ethyl acetate.

The volatile *N*-nitroso compounds in the methylene chloride extracts were identified by GC–mass spectrometry and quantitated by GC (19). The nonvolatile nitroso and nitro compounds in the ethyl acetate extract were purified by TLC on silica gel, using a solvent system of ethyl acetate–methanol (1:1), and characterized by mass spectrometry. The yields were calculated on the basis of the isolation of homogeneous products (8, 20). The methylene chloride extracts contained the products listed in Groups 1 and 2, while the ethyl acetate extracts contained the products in Groups 3–5.

The mass spectra of all *N*-nitroso compounds in Groups 1 and 2 (Table I) were consistent with those reported in the literature (19, 21). The *N*-nitroso derivatives in Groups 3 and 4 exhibited fragmentation patterns typical of *N*-nitroso compounds (the characteristic loss of NO from the parent ion) as well as those consistent with the drug structure (8, 20). The mass spectra of synthetic 4-nitrosoantipyrine and 4-nitroantipyrine (22) were identical to the spectra of the respective products from the reaction of antipyrine (XX) with nitrite.

The following comments may be made regarding the formation of nitroso and nitro compounds from drug–nitrite interactions.

Group 1 Products (*N*-Nitrosodialkylamines)—

The following comments may be made regarding the formation of nitroso and nitro compounds from drug–nitrite interactions.

Group 1 Products (*N*-Nitrosodialkylamines)—

Table I—Nitroso and Nitro Compounds from the Reaction of Sodium Nitrite with Orally Administered Drugs

Number	Drug	Nitroso or Nitro Compound Formed	Yield[a], % Reaction at pH 1–2	Yield[a], % Reaction at pH 3–4
		Group 1 Products		
I	Aminopyrine[b]	*N*-Nitrosodimethylamine	31.4	71.4
II	Captodiame	*N*-Nitrosodimethylamine	0	0.7
III	Chlophedianol	*N*-Nitrosodimethylamine	0	0.3
IV	Chlorpromazine[b]	*N*-Nitrosodimethylamine	0	0.6
V	Fonazine	*N*-Nitrosodimethylamine	0	0.8
VI	Oxytetracycline[b]	*N*-Nitrosodimethylamine	0.6	63.2
VII	Diethazine	*N*-Nitrosodiethylamine	0	0.4
VIII	Lucanthone[b]	*N*-Nitrosodiethylamine	0	0.5
IX	Thiphenamil	*N*-Nitrosodiethylamine	0	0.3
		Group 2 Products		
X	Clemizole	*N*-Nitrosopyrrolidine	0	1.4
XI	Cycrimine	*N*-Nitrosopiperidine	0	1.8
XII	Hexadiphane	*N*-Nitrosohexamethyleneimine	0	2.1
XIII	Phenadoxone	*N*-Nitrosomorpholine	0	2.5
XIV	Butaperazine	*N*,*N*′-Dinitrosopiperazine	0	2.8
		Group 3 Products		
IV	Chlorpromazine	*N*-Nitrosodesmethylchlorpromazine	0.4	1.7
XV	Imipramine	*N*-Nitrosodesipramine	0.3	1.2
XVI	Tripelennamine	*N*-Nitrosodesmethyltripelennamine[c]	0.7	5.8
		Group 4 Products		
XVII	Desipramine	*N*-Nitrosodesipramine	10.9	2.8
XVIII	Piperazine[b]	*N*-Nitrosopiperazine	35.0[d]	54.6[d]
		N,*N*′-Dinitrosopiperazine	78.4	84.6
XIX	Protriptyline	*N*-Nitrosoprotriptyline	11.6	3.4
		Group 5 Products[e]		
XX	Antipyrine	4-Nitrosoantipyrine	0[f]	60.8[f]
		4-Nitroantipyrine	89.3	83.7

[a] Percentage of theoretical yield from the reaction of drug with sodium nitrite at 37° for 4 hr. [b] Reaction of this drug with nitrite was reported earlier (3, 5, 24, 31). [c] Formation of this *N*-nitroso derivative was described recently (8). [d] Yield of the mononitroso derivative when the reaction was run for 15 min. [e] Aromatic mononitro and dinitro derivatives of IV, XV, XVII, and XIX were formed (yield of 1–5%) during the reaction of these drugs with nitrite at pH 1–2. Studies are in progress to deduce the structure of these nitro compounds. [f] Yield of the nitroso compound from the reaction at room temperature. Nearly quantitative yield of 4-nitrosoantipyrine can be achieved if the reaction is run in 10% HCl at 0° (22).

The nitrosative cleavage of tertiary amino groups from the dialkylaminoalkyl side chain in Compounds II–V and VII–IX appeared to be the least favored reaction and was completely inhibited at pH 1–2. However, such cleavage of tertiary amino groups attached to ring structures (I and VI) occurred quite readily; indeed the yield of *N*-nitrosodimethylamine formed from aminopyrine was quite high (31.4%) even at pH 1–2.

Group 2 Products (*N*-Nitroso Cyclic Amines)—The yield of cyclic *N*-nitroso compounds from the drug–nitrite reaction at pH 3–4 was between 1.4 and 2.8% with Compounds X–XIV, which contain pyrrolidine, piperidine, hexamethyleneimine, morpholine, and piperazine moieties. Group 2 products were not found when the reactions were carried out at pH 1–2.

Group 3 Products (*N*-Nitroso Derivatives of *N*-Dealkylated Drugs)—Between the two pH ranges examined, higher yields of *N*-nitroso derivatives were obtained at pH 3–4 with all three drugs (IV, XV, and XVI) that gave Group 3 products with nitrite.

Group 4 Products (*N*-Nitroso Derivatives of Drugs)—The reaction of nitrite with drugs containing secondary amino groups yielded substantial quantities of *N*-nitroso derivatives at both pH ranges examined.

Group 5 Products (C-Nitroso and Nitro Derivatives of Drugs)—The highly reactive antipyrine (XX) formed the 4-nitro derivative quite readily in both pH ranges studied. The formation of the C-nitroso derivative of XX was observed only when the reaction was run in 10% acetic acid at room temperature. Aromatic mononitro and dinitro derivatives of drugs containing aromatic rings (IV, XV, XVII, and XIX) were present (yield of 1–5%) in the ethyl acetate extracts of the drug–nitrite reaction mixtures (pH 1–2) as determined from their mass spectra. The location of the nitro groups in the aromatic rings remains to be assigned.

All *N*-nitroso compounds listed under Groups 1 and 2 are known carcinogens (1, 2, 12–14), but the toxicity of the products listed in Groups 3–5 remains unknown. In preliminary studies with tripelennamine (XVI), *N*-nitrosation did not enhance the toxic potential of the drug in rats and the *N*-nitroso derivative was devoid of both central nervous system and antihistaminic activities of the parent drug (8). There is evidence that nitrite has a short half-life in the stomach (14, 23) and that ascorbic acid and other dietary constituents are inhibitors of drug–nitrite reactions (24–27). Nevertheless, the formation of *N*-nitrosamines in the human stomach has been demonstrated (28–30).

Further studies are needed to assess the potentially adverse effects of drug–nitrite interactions in humans, especially those on chronic medication where readily nitrosatable drugs and high dietary intake of nitrite may be involved.

Application of Mixed Electron-Impact–Chemical Ionization High-Resolution Mass Spectrometry to a Medicinal Agent

Keyphrases □ Structure determination—application of mixed electron-impact–chemical ionization high-resolution mass spectrometry □ Mass spectrometry, mixed electron impact–chemical ionization—structure determination

To the Editor:

Chemical ionization mass spectrometry has proven to be a useful technique for molecular structure determination of various classes of medicinal agents, especially for compounds that contain no molecular ion in the electron-impact spectra. Successful identification of drug metabolites and multicomponent drug mixtures, such as those received by forensic laboratories, is an excellent example of the utility of chemical ionization mass spectrometry. Several comprehensive listings of chemical ionization and electron-impact mass spectra are available for comparison with spectra of unknown drugs (1–3). Therefore, it is useful to obtain both types of spectra for structure elucidation of medicinal agents.

Chemical ionization mass spectra are produced *via* gaseous ion–molecule reactions occurring in the ion source of the mass spectrometer. For an ion–molecule reaction to take place, it is necessary to raise the low pressure (10^{-6} torr) which is characteristic of the conventional electron-impact source. "Closing" the source allows the pressure to increase to approximately 0.5 torr when a reagent gas such as isobutane is added. However, this modification, which facilitates ion–molecule reactions in the chemical ionization mode, may precipitate reactions in the source between sample ions and sample molecules in the electron-impact mode (*i.e.*, self-ionization).

Many investigators have noted the occurrence of collision-induced ions in the electron-impact spectra obtained from closed source instruments (4), particularly MH^+ and fragments generally associated with chemical ionization spectra. Collision-induced ions together with those ions resulting directly from electron impact constitute what is referred to here as a mixed electron-impact–chemical ionization spectra. The ratio of collision ions to electron-impact ions contained in a mixed electron-impact–chemical ion-

Table I—Mixed Electron-Impact–Chemical Ionization High-Resolution Mass Spectral Data of Meprobamate

Elemental Composition	Theoretical	Found	Relative Intensity, %
$C_9H_{19}N_2O_4$	219.1344	219.1335	79

C_4H_7	55.0546	55.0550	68
CH_2NO	44.0136	44.0125	51

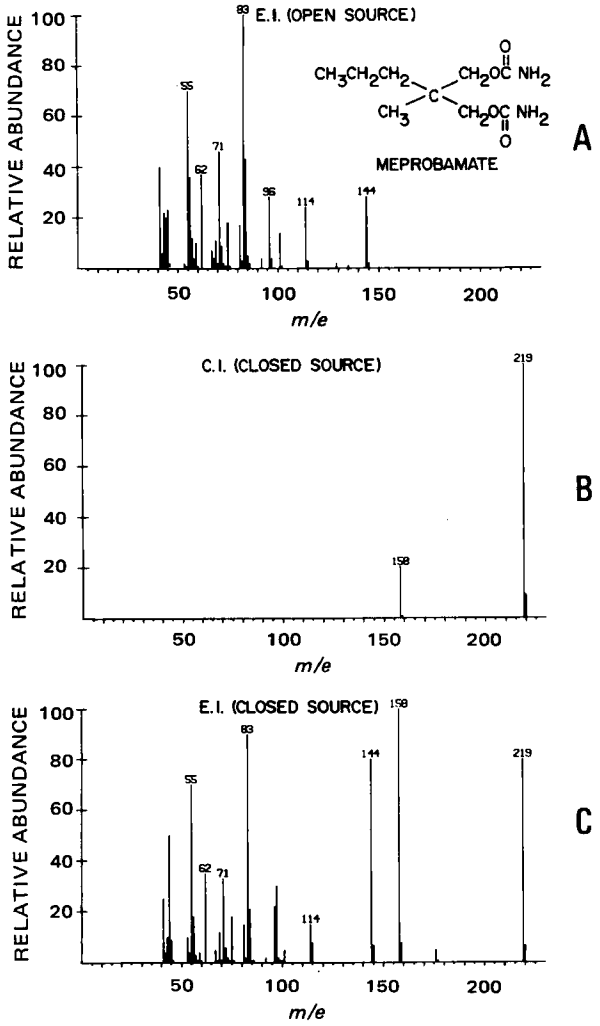

Figure 1—*(A) Mass spectrum of meprobamate obtained prior to chemical ionization modification of the instrument. (B) Chemical ionization (CI) spectrum of meprobamate after installation of a dual electron-impact (EI)–chemical ionization source. (C) Mixed electron-impact–chemical ionization spectrum of meprobamate.*

ization spectra can be altered by varying the pressure in the closed ion source. Higher pressure can easily be attained by either increasing the sample size or reducing the dimensions of the electron entrance and ion exit slit.

Mixed electron-impact–chemical ionization spectra have been particularly useful for compounds, such as meprobamate, that show no molecular ion in the electron-impact spectra (open source). Dicarbamates and many other classes of medicinal agents readily give mixed electron-impact–chemical ionization spectra because of their large cross section for proton capture (5).

All of the mass spectra shown here were obtained on the same high-resolution mass spectrometer coupled with a data processor[1]. Samples were introduced into the source *via* a direct insertion probe. Spectra were obtained at a source temperature of 90°. Figure 1A is a mass spectrum of meprobamate obtained prior to chemical ionization modification of the instrument (open source). Figure 1B shows the chemical ionization spectrum of the same compound after installation of a dual electron-impact–chemical ionization source (closed source). Isobutane was used as the reagent gas. Figure 1C is an illustration of a mixed electron-impact–chemical ionization spectrum obtained from a dual electron-impact–chemical ionization source instrument. This closed source spectrum was obtained in the electron-impact mode by merely increasing the sample pressure. No reagent gas was added.

By adding perfluorokerosene and carefully adjusting the pressure in the source, it is possible to obtain a mixed electron-impact–chemical ionization spectrum suitable for high-resolution mass measurements. While fast scanning the mixed electron-impact–chemical ionization high-resolution spectrum, we were able to measure both electron-impact and collision-induced ions.

Meprobamate shows no molecular ion in the electron-impact spectrum of an unmodified instrument (6, 7). However, additional information was available in the mixed electron-impact–chemical ionization spectra. An MH^+ ion was observed at *m/e* 219, and high-resolution mass spectrometry established its elemental composition as $C_9H_{19}N_2O_4$. The base peak at *m/e* 158 was derived from the MH^+ ion through the loss of carbamic acid. In addition, high-resolution printout data were obtained on all abundant fragment ions usually contained in the electron-impact spectra. In Table I, the exact measured mass values of several major ions are listed and compared with the theoretical mass values.

Simple inspection of the electron-impact spectra obtained from a dual electron-impact–chemical ionization source is usually sufficient to distinguish ions produced by electron impact from collision-induced ions. Mixed electron-impact–chemical ionization spectra cannot be compared with standard electron-impact spectra due to the presence of collision-induced ions. If comparison is desired, however, electron-impact spectra corresponding to a standard can be readily obtained by a simple reduction of the sample pressure in the source.

In conclusion, the mixed electron-impact–chemical ionization high-resolution operation is a simple technique and provides both electron-impact and chemical ionization information on the same spectrum. This technique has proven very useful for the structure determination of medicinal agents in our laboratory.

Methodological Differences in Correlating Digoxin Dissolution with Bioavailability

Keyphrases □ Digoxin—correlating dissolution and bioavailability, differences in methods, paddle-water method and rotating-basket apparatus □ Dissolution—digoxin, methods of determination, correlation with bioavailability □ Bioavailability—digoxin, correlation with dissolution, methods of dissolution determination

To the Editor:

A recent report by Klink *et al.* (1) indicated that the "paddle-water" method for determining dissolution rates for digoxin tablets failed to reflect the comparative bioavailability properties of two commercially available digoxin products. Specifically, large differences in dissolution rates were observed which failed to reflect the similar bioavailabilities of the two brands studied.

A number of reports have appeared indicating successful *in vivo–in vitro* correlation employing different methods (2–8), including the method recently adopted by the USP (9). Thus, the purpose of this communication is to report the results of recent dissolution rate studies carried out on the same batches of tablets employed by Klink *et al.* (1) using the USP dissolution rate test method.

The dissolution properties of six tablets each from Treatment I[1] and Treatment II[2] tablets were determined using the USP rotating-basket apparatus and employing the conditions specified in the USP (9). Samples were withdrawn and assayed by a fluorometric method (10) at 15, 30, 60, and 120 min after commencement of the studies.

The results of these studies are summarized in Table I, which lists the amount of digoxin in solution at various times for both the USP method and the paddle-water method (1). As indicated by these results, the two brands showed fairly similar dissolution properties, especially at the 60- and 120-min sampling times, when the USP method was employed. This finding is in contrast to the large differences observed at all sampling times when the paddle-water method was employed; Treatment I tablets dissolved much more rapidly than did Treatment II tablets.

These results are of significance when the *in vivo* performance of the two brands is considered. As reported by Klink *et al.* (1), the bioavailabilities of Treatment I and Treatment II tablets, as determined by the area under the serum level–time curves from 0 to 48 hr relative to similar areas obtained from digoxin in elixir data, were 106.38 ± 10.27 and 100.75 ± 24.09%, respectively. Similar relationships between the two brands were observed when the 0–5-, 0–12-, and 0–24-hr areas were compared.

Thus, from the dissolution data presented, it appears that, in the case of the specific lots of the two brands of digoxin tablets studied, the USP method for determining dissolution rates is of greater reliability than is the paddle-water method in predicting bioavailability. Based on these findings and the findings of others (2–8), it appears that much work remains to be done before the acceptance of a single *in vitro* dissolution test for the prediction of digoxin bioavailability from compressed tablets.

Table I—Mean Percent (±Standard Error) of Labeled Digoxin in Solution at Various Times following *In Vitro* Dissolution by Two Different Methods

BOOKS

REVIEWS

Quality Control in the Pharmaceutical Industry, Vol. 2. Edited by M. S. COOPER. Academic, 111 Fifth Ave., New York, NY 10003, 1973. 332 pp. 15.5 × 23.5 cm. Price $22.00.

This volume is composed of six chapters covering quality control of aerosol products and veterinary biologicals, the quality control test program of the National Center for Drug Analysis for drug products, pyrogen testing, stability, and sterilization. As in any multiauthor book, certain chapters stand out in comparison with others.

The chapter on Pyrogen Testing of Parenteral Pharmaceuticals by G. R. Personeus provides an excellent comprehensive in-depth discussion of the variables that can influence pyrogen test results and provides the scientist concerned or interested in pyrogen testing with information of how to best use this test. This chapter best fulfills the aim of the editor of the book in dealing in depth with a distinct aspect of the subject of quality control of pharmaceuticals.

The chapter on Pharmaceutical Product Stability by C. J. Lintner provides a general condensed review on stability of pharmaceuticals. Information is provided in this chapter on regulations applicable to stability, types of degradation (hydrolysis, oxidation–reduction, *etc.*,) physical stability of different dosage forms, preservatives, antioxidants, chelating agents, isothermal *versus* nonisothermal reactions, containers and closures, and computer programs for treating and storing stability data; there are also short synopses on stability attributes of specific drug compounds. Because of the considerable amount of information the author provides, no one area of his presentation could be given in depth. The author of this chapter has provided an excellent comprehensive bibliography on his subject.

The chapter on Quality Control of Veterinary Biologics by G. R. Sharpless is concerned for the most part with potency testing of bacterial, viral, sera, toxoid and bacterin–toxoid, and diagnostic products. It also provides a brief review of the tests and procedures outlined by the Animal and Plant Health Inspection Service of the U.S. Department of Agriculture, Veterinary Services Branch, which is responsible for the government regulation of veterinary biologics.

The chapter on the Control of Sterilization Procedures by R. R. Ernst does not discuss sterility tests or testing methods, but instead gives an in-depth presentation of the various factors involved in steam and gaseous sterilization and the types of equipment utilizing these two methods of sterilization. Sterilization by radiation, filtration, and dry heat is treated superficially.

The chapter on Quality Control for Pharmaceutical and Cosmetic Aerosol Products by J. J. Sciarra has only a minor portion related to the quality control of aerosol products and components. The major portion of the chapter is concerned with the general philosophy and principles of quality control and assurance in the pharmaceutical industry.

The chapter on The Test Program of the National Center for Drug Analysis on the Quality Control of Drug Products by A. W. Steers discusses the FDA regulations pertaining to drug quality, the organization of the National Center for Drug Analysis (NCDA), the Retail-Based Drug Monitoring Program, and the Formulator-Oriented Rx Drug Studies (FORDS) Program. Data are presented on the drug products evaluated from the retail-based and formulator-based studies at the NCDA.

Certain chapters of this volume provide the pharmaceutical scientist, quality control chemist, and biologist with pertinent information not readily found in other books which should be of use in their daily work.

Analytical Profiles of Drug Substances, Vol. 4. Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003, 1975. 16 × 23.5 cm. 526 pp. Price $26.50.

Volume 4 of this unique series provides coverage of 20 additional drugs including cefazolin, estradiol valerate, methaqualone, norethindrone, and tybamate. Utilizing a monograph format, these volumes provide frequently difficult to locate information on physical and chemical data, methods of synthesis, pathways of physical and biological degradation, metabolism, and methods of analysis.

Each monograph is amply illustrated and well referenced. Considerable information concerning the drugs is compiled and presented in an easy-to-use format. These volumes should be available to everyone working in pharmaceutical research.

The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N.W., Washington, DC 20037. Printing Offices: 20th & Northampton Streets, Easton, PA 18042

Annual Subscriptions—United States and foreign, industrial and government institutions $50, educational institutions $50, individuals *for personal use only* $30; single copies $5. All foreign subscriptions add $5 for postage. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $55 (foreign $60) APhA membership dues.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N.W., Washington, DC 20037, of any change of address.

HARMLESS, BUT INEFFECTIVE, REMEDIES

Once they disappear, problems are quickly forgotten. If they are not completely forgotten, certainly our once strong feelings concerning their seriousness are greatly dulled and dampened.

Communicable diseases constitute a classic example of this changing pattern of interest on the part of society. Another striking example is that of quack medicines.

It is only within the last few years that we have reached the point that physicians, pharmacists, and patients could rely upon drug products to be effective for the uses, conditions, and treatments claimed for them in their labeling and advertising. But it was not always so.

A century ago, quackery was blatant, with medicine men traveling by horse-drawn wagons across the country hawking the latest concoction. These "cure-alls" generally either tasted terrible or were heavily laced with alcohol. Neither of these considerations made the product harmful but added considerably to the perceived effectiveness—what we today refer to as the "placebo" factor.

Quackery became more sophisticated during the last generation or so—but there still was a lively market for liver pills, Hadacol, honey and vinegar, copper bracelets, electronic devices, and a myriad of other products of highly dubious therapeutic value.

The medical and pharmacy professions campaigned vigorously in an effort to stamp out such quackery, but it wasn't until the Kefauver–Harris Drug Amendments of 1962 were enacted that the Food and Drug Administration finally had an effective weapon to employ in the battle to rid the market of such products. This was because the 1962 amendments, for the first time, required that an article must be demonstrated as *effective* if it is to be promoted as having some therapeutic or medicinal usefulness.

The quack medicines were generally all harmless and nontoxic; safety *per se* was not a problem. However, the health professions—and the public through their elected representatives—decided this was not enough. If a drug is to be on the market, it must have more than just a placebo effect. Skilled health care practitioners must be able to rely upon their therapeutic tools. Moreover, the public must not be bilked by slick con-artists who are eager to take advantage of the hopes and desperation of sick persons and their families by selling useless products for hard-earned money.

If public protection is needed by any group, it is the victims of cancer, arthritis, and similar diseases where hope is little and despair is great. It is this unfortunate group which is most vulnerable to the siren-song of the quacks.

Normally we think of the *New York Times* as a model newspaper in that its editorial views and opinions are well-considered and show care and judgment in their formulation. We were disappointed, therefore, by an editorial appearing this summer entitled "Illegal Laetrile."

The *Times* editorial correctly explained that current law prohibits the marketing of any new drug until it is proven to be both effective and safe. The editorial further explained that there appears to be no concern regarding the safety of laetrile (amygdalin), but that no evidence has been presented to FDA that the drug is useful in the treatment of cancer. In fact, the editorial admits that even animal experiments have been almost uniformly negative except for some curious initial results at one institution which that same institution now regards as spurious.
