The *Times* then concludes by saying: *"While laetrile may in fact be totally ineffective against cancer, it apparently is harmless; and so long as it is prohibited by law, it will have an inevitable fascination for those who have no other hope. It cannot injure those unfortunates; it might help them, at least psychologically. Why should the law deny them such help?"*

In our view, the same argument can be made—and in many cases, has been made—for every quack medicine ever offered to the public. Indeed, some of these at least had some indication of value, if not proven evidence. Based upon present information, there is no more justification for the FDA to permit the marketing of laetrile than there would be for FDA to permit the bottling of sugar water by some huckster who would then sell it at a fancy price as a guaranteed safe cancer cure!

HARMLESS, BUT INEFFECTIVE, REMEDIES

Once they disappear, problems are quickly forgotten. If they are not completely forgotten, certainly our once strong feelings concerning their seriousness are greatly dulled and dampened.

Communicable diseases constitute a classic example of this changing pattern of interest on the part of society. Another striking example is that of quack medicines.

It is only within the last few years that we have reached the point that physicians, pharmacists, and patients could rely upon drug products to be effective for the uses, conditions, and treatments claimed for them in their labeling and advertising. But it was not always so.

A century ago, quackery was blatant, with medicine men traveling by horse-drawn wagons across the country hawking the latest concoction. These "cure-alls" generally either tasted terrible or were heavily laced with alcohol. Neither of these considerations made the product harmful but added considerably to the perceived effectiveness—what we today refer to as the "placebo" factor.

Quackery became more sophisticated during the last generation or so—but there still was a lively market for liver pills, Hadacol, honey and vinegar, copper bracelets, electronic devices, and a myriad of other products of highly dubious therapeutic value.

The medical and pharmacy professions campaigned vigorously in an effort to stamp out such quackery, but it wasn't until the Kefauver–Harris Drug Amendments of 1962 were enacted that the Food and Drug Administration finally had an effective weapon to employ in the battle to rid the market of such products. This was because the 1962 amendments, for the first time, required that an article must be demonstrated as *effective* if it is to be promoted as having some therapeutic or medicinal usefulness.

The quack medicines were generally all harmless and nontoxic; safety *per se* was not a problem. However, the health professions—and the public through their elected representatives—decided this was not enough. If a drug is to be on the market, it must have more than just a placebo effect. Skilled health care practitioners must be able to rely upon their therapeutic tools. Moreover, the public must not be bilked by slick con-artists who are eager to take advantage of the hopes and desperation of sick persons and their families by selling useless products for hard-earned money.

If public protection is needed by any group, it is the victims of cancer, arthritis, and similar diseases where hope is little and despair is great. It is this unfortunate group which is most vulnerable to the siren-song of the quacks.

Normally we think of the *New York Times* as a model newspaper in that its editorial views and opinions are well-considered and show care and judgment in their formulation. We were disappointed, therefore, by an editorial appearing this summer entitled "Illegal Laetrile."

The *Times* editorial correctly explained that current law prohibits the marketing of any new drug until it is proven to be both effective and safe. The editorial further explained that there appears to be no concern regarding the safety of laetrile (amygdalin), but that no evidence has been presented to FDA that the drug is useful in the treatment of cancer. In fact, the editorial admits that even animal experiments have been almost uniformly negative except for some curious initial results at one institution which that same institution now regards as spurious.

The *Times* then concludes by saying: *"While laetrile may in fact be totally ineffective against cancer, it apparently is harmless; and so long as it is prohibited by law, it will have an inevitable fascination for those who have no other hope. It cannot injure those unfortunates; it might help them, at least psychologically. Why should the law deny them such help?"*

In our view, the same argument can be made—and in many cases, has been made—for every quack medicine ever offered to the public. Indeed, some of these at least had some indication of value, if not proven evidence. Based upon present information, there is no more justification for the FDA to permit the marketing of laetrile than there would be for FDA to permit the bottling of sugar water by some huckster who would then sell it at a fancy price as a guaranteed safe cancer cure!

An inclusion compound is a unique form of chemical complex in which one molecule is enclosed within another molecule or structure of molecules. This combination is characterized by the absence of ordinary chemical bonds; the essential criterion is simply that the enclosed molecule or "guest" be of a suitable size and shape to fit into a cavity within a solid structure formed by "host" molecules (1–13). The hollow space formed by the host may be in the form of a channel, cage, or layer.

The stereochemistry and, possibly, the polarity of both the host and the guest molecules determine whether inclusion can occur. The resulting close fit of the two components produces a combination of significant strength due to the total dispersion forces between the interacting components. This type of spatial complex formation does not occur by means of ionic, covalent, or coordinate covalent bonds but rather is dependent upon dispersion forces and, possibly, highly oriented dipoles for stability, contrasting markedly with the usual concept of chemical complexation (14).

Inclusion compounds were first observed by Mylius (15) in 1886 as unusual complexations occurring between hydroquinone and several volatile com-

pounds. He proposed that the two components were interacting without chemical bonding and suggested that one molecule was enclosing the other. These observations were confirmed many years later by X-ray analysis; it was determined that one molecule of gas or liquid formed an insoluble inclusion compound with three molecules of hydroquinone, the host component, which formed a cage-like structure around the guest molecule (16). The presence of the guest component in inclusion compounds of this type could not be detected by odor; however, when the inclusion compound was heated or dissolved in water, the guest molecule was released.

The general title for this class of complexes, "inclusion compounds," was first used by Schlenk (17). Other terms that have been used to describe these complexes are "occlusion compounds," "adducts," and "clathrates" (18). Barrer (19) divided inclusion compounds into three categories, based on the varying concept of the host crystal, as *(a)* those that are stable both in the presence and in the absence of the guest molecule; *(b)* those in which the amount of guest may be changed but which have a critical concentration of guest molecules, below which the host structure becomes metastable and recrystallizes; and *(c)* those in which the host framework continuously readjusts itself as the content of guest molecules fluctuates.

A more convenient and workable classification, utilized in this review, is based upon the organization of inclusion compounds by their structure and properties as follows:

1. Polymolecular inclusion compounds
   —Channel-like spaces
   —Cage-like spaces
2. Monomolecular inclusion compounds
3. Products of the blue-iodine reaction
4. Macromolecular inclusion compounds

This classification differs from that of Baron (20), in that the products of the blue-iodine reaction follow the monomolecular inclusion compounds instead of appearing as the last category. This modification allows them to follow the classification to which they are more closely related.

Polymolecular inclusion compounds consist of a host structure composed of several molecules oriented in a loosely arranged lattice. The individual molecules of the host lattice are joined by hydrogen bonds to form a channel- or cage-like structure enclosing the guest molecule. However, they are not arranged in a whole number ratio to guest molecules as would be expected by the coordination theory (21). The inclusion cavity of specific dimensions forms only in the presence of the guest molecule but not necessarily using the guest as a template. In the absence of a guest molecule, compounds in this category form denser crystal structures without cavities.

As will be pointed out subsequently, similar molecules belonging to the same chemical class will crystallize to form cavities of different sizes and shape, depending on their atomic structure. Polymolecular inclusion compounds that form channel-like spaces include urea, thiourea, and various choleic acids; the latter complexes are among the earliest documented inclusion compounds (22).

A special category of the channel-like inclusion compounds consists of those formed by diphenyl derivatives in which the host molecules are "stacked" on one another in such a way as to leave channels in which an appropriate sized guest can be accommodated (23, 24). The interesting aspect of this arrangement is that no localized bonding is thought to exist.

The term "clathrate," derived from the Latin "clathratus," meaning "enclosed by the bars of a grating," (18) has been used to describe the cage-like structure of the hydroquinone inclusion compounds. The clathrates make up the second group of polymolecular inclusion compounds. In addition to hydroquinone, this group consists of: water or gas hydrates; tetraethylammonium hydrates; phenols; Dianin's compound, a product of the condensation of phenol and mesityl oxide; cycloveratril; and a number of complexes in which the cage-like structure is inorganic and the guest is organic (10). Although *Chemical Abstracts* and several other reference sources use the term "clathrates" as a general descriptor for inclusion compounds, this term more appropriately describes only the cage-like polymolecular inclusion compounds.

Probably the most versatile of the polymolecular inclusion compounds is tri-*o*-thymotide, which can form either channel- or cage-like void spaces, depending on the size and shape of the guest molecule (25).

The second major classification of inclusion compounds includes the monomolecular inclusion compounds. Although the polymolecular inclusion compounds constitute the largest group of inclusion compounds, the monomolecular inclusion compounds are of increasing interest and utility, particularly with reference to biological and pharmaceutical systems. Monomolecular inclusion compounds interact generally on a 1:1 basis with the guest molecule, which is enclosed within a cavity in the host molecule. The cyclodextrins, bis-*N,N'*-alkylenebenzidine compounds, antibiotics, and certain proteins are included in this category. The conclusion that certain proteins may behave as monomolecular inclusion compounds appears to offer a viable explanation for understanding antigen–antibody interactions, enzymatic reactions, and other shape-dependent processes.

Related to both the polymolecular and the monomolecular inclusion compounds are the products of the blue-iodine reaction. Iodine interacts with starch, cyclodextrins, flavones, coumarin, benzophenone, benzamide, cellulose, and barbituric acids to give a blue addition compound. This phenomenon has been attributed to the polymerization of iodine within unique channels formed by these compounds (26, 27).

The terms macromolecular inclusion compounds and "molecular sieves" have been used to characterize the fourth group of complexes. These compounds have been investigated extensively and have wide use in industrial and laboratory processes (19, 28, 29). Of

this group, the numerous zeolites are the most commonly known; however, the modified dextrans, polyacrylamide and agarose gels, silica gels, and other substances are also included.

The basic structure of the zeolites is a crystalline framework of silicon–oxygen or aluminum–oxygen tetrahedra which form a three-dimensional array with many cavities and interconnecting channels. Depending on the size and shape of these void spaces, various guest molecules can enter and be enclosed within the network. Although some macromolecular inclusion compounds occur naturally, it is also possible to custom tailor them to accept a specific guest by using the guest as a template during crystallization of the host.

Graphite is also generally classified as a macromolecular inclusion compound. However, it is more accurately classified as an intercalation compound, in which the guest is entrapped between layers of the graphite crystal (30, 31).

Inclusion compounds have been studied by a variety of conventional analytical methods including microscopy, IR and UV spectrophotometry, differential thermal analysis, NMR, and X-ray analysis[1].

Although a wide range of inclusion compounds is discussed here, emphasis is placed on those areas most apropos to the pharmaceutical sciences. Other areas are mentioned to present a comprehensive overview of this class of complexes. Previous reviews provided more extensive treatment of these latter areas (1–13).

POLYMOLECULAR INCLUSION COMPOUNDS

Compounds Forming Channel-Like Void Spaces—These inclusion compounds are classified as channel or canal complexes. Urea, thiourea, deoxycholic acid, and several other substances form long, tube-shaped cavities in which the guest molecules are oriented end to end.

Urea and Thiourea—Urea inclusion compounds were first reported by Bengen (32) from experiments on the effect of the addition of urea to pasteurized milk. Bengen was able to separate quantitatively the butterfat; however, in an attempt to control the formation of an emulsion at the oil–water interface, he added a small amount of *n*-octanol. After a short period, crystals were observed at the interface. These crystals later proved to be a urea–*n*-octanol inclusion compound. Bengen and Schlenk (21) were then prompted to study inclusion compound formation by urea and many aliphatic straight-chain hydrocarbons, leading eventually to the development of the use of urea inclusion compound formation as a method for separating hydrocarbons (33, 34).

In the presence of straight-chain hydrocarbons, urea generally forms a hexagonal structure surrounding a channel-like void space (Fig. 1) (17, 35–37), although the formation of a rhombohedral structure has been reported for some long chain hydrocarbons

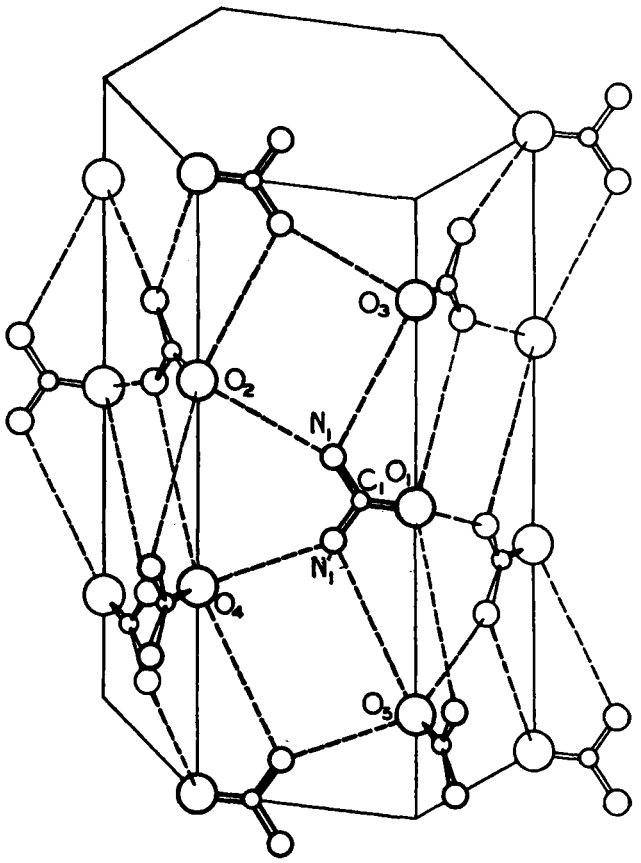

Figure 1—*Arrangement of hydrogen bonding in urea–n-hydrocarbon complexes. (Reprinted, with permission from Van Nostrand Reinhold Co., from M. Hagan, "Clathrate Inclusion Compounds," Litton Educational Publishing, 1962, and, with permission, from Ref. 36.)*

(38). The overall structure of the crystal is that of parallel tubes in which the hydrocarbon molecules are enclosed. The molecules of urea are held together in a loose network of hydrogen bonds between the nitrogen and oxygen atoms (36). The cavities have a diameter of approximately 5 Å, which is sufficient to accommodate straight-chain hydrocarbons and fatty acids or their derivatives. Nonwhole number molal ratios of urea to guest are found such as 6.3 moles of urea/mole of *n*-octane, 3.78 moles of urea/mole of methyl ethyl ketone, and 12.2 moles of urea/mole of oleic acid (39).

At room temperature, substances of a chain length of six or more carbon atoms form complexes with urea, while certain shorter chain-length compounds form urea inclusion compounds only at lower temperatures. In the absence of a guest component, urea crystallizes in a tetragonal arrangement. The structure is relatively open with low van der Waals interactions between the molecules (36). In the presence of a suitable size guest molecule, urea assumes the hexagonal arrangement around the guest, the combination producing a denser structure than that of the tetragonal arrangement. The inclusion compound is thus energetically favored. Schlenk (40) indicated an energy of formation of about 2.8 kcal/methylene group of the guest.

Several studies (34, 41) provided evidence for the

[1] These techniques were discussed in the review article by J. K. Haleblian, *J. Pharm. Sci.*, 64, 1269(1975).

solubilization of cetane, stearic acid, and *n*-valeric acid in saturated solutions of urea; this solubilization was not found for molecules that did not form urea inclusion compounds. The isomer of *n*-valeric acid, α-methylbutyric acid, does not form an inclusion compound and is soluble to the same extent in saturated urea solution as in water. The limited solubility of the isomer also indicates that the carboxyl group does not interact with the urea.

Many other substances form inclusion compounds with urea, including amino acids (42), epoxyesters (42), trioxane (43), aliphatic dinitriles (44), acrylic acid (45), and 1,2-bromotricosane (46). Urea inclusion compounds also have been used to separate racemic mixtures into optical antipodes (42, 47); the guest molecule may be collected by thermal or solvent decomposition of the inclusion compound (10, 42, 48). Fetterly (41) suggested that fatty acids dimerize in a urea inclusion compound, increasing the effective bonding by replacing a van der Waals bond by two hydrogen bonds. Thus, fatty acid–urea inclusion compounds are more stable in water solutions than the corresponding *n*-aliphatic hydrocarbon–urea complex.

As indicated earlier, the urea channel has a diameter of approximately 5 Å, limiting entrance to unbranched hydrocarbons. However, the sulfur analog of urea, thiourea, which also forms channel-like complexes, has a channel diameter of approximately 7 Å due to the larger size of the sulfur atom (36). A broad range of compounds can enter the larger thiourea cavity, including cyclic paraffins and polymethylated and polychlorinated hydrocarbons (49–51). Straight-chain hydrocarbons cannot form inclusion compounds with thiourea because the host framework is not stable and collapses. Since thiourea inclusion compounds do not give continuous layer lines in an X-ray pattern, it has been concluded that the guest molecule is fixed preferentially at certain planes in the channel.

The ability of urea and thiourea to differentiate between unbranched and branched molecules has led to significant industrial applications of these inclusion compounds (52–56). Numerous patents have been issued on processes utilizing the ability of the urea and thiourea inclusion compounds to separate mixtures effectively by removing molecules of a particular size and shape. Most of these applications are in the petroleum industry and involve the separation of hydrocarbon mixtures.

An example of such a process is the removal of high melting-point paraffins, which tend to solidify at low temperatures, from various oils. The straight-chain hydrocarbons are removed from the petroleum fraction by mixing the oil with urea and allowing the formation of the urea channel compounds. The inclusion compound is filtered or allowed to settle, and the supernate is decanted. Similar improvements can be made in other petroleum fractions where it is desired to remove naphthenes, terpenes, or other cyclic hydrocarbons. Both batch and fluidized-bed methods have been developed for these processes (34). The rate of inclusion compound formation is subject to the presence of inhibitors or activators (49, 57, 58).

The free fatty acids in acid-cracked lanolin can be removed as urea complexes, leaving neutral lanolin (59). The fatty acids can be collected by thermally decomposing the inclusion compound and then utilized for other purposes. The selective affinities of urea and thiourea can be used to improve ozokerites and other hydrocarbons of cosmetic and pharmaceutical interest (60).

One interesting aspect of urea and thiourea inclusion compounds is their use to increase the stability of easily oxidized substances. Vitamin A (61), unsaturated fatty acids (62), *d-trans*-oxocamphor (63), turmerone (63), decalin (64), and terpenes of orange oil and lemon oil and related compounds (65) have been stored as channel complexes. As long as the guest remains within the channel, it is protected from attack by atmospheric oxygen or from hydrolysis.

A novel solution to the handling of viscous, adhesive materials and potent or dangerous compounds is the formation of a urea or thiourea inclusion compound with appropriate substances in these categories. Liquid nonionic polyoxyethylene surfactants have been complexed with urea to form a solid powder which is easily handled (66–68). Straight-chain alkyl ethers, esters, and fatty acid derivatives of the polyoxyethylene surfactants form inclusion compounds, whereas sorbitan alkylate and alkyl aryl ethers of the polyoxyethylene series do not due to the large size of the sorbitan moiety and of the benzene ring. Likewise, the handling of potent insecticides such as chlordane is facilitated if the chlordane is in the form of a solid thiourea–chlordane inclusion complex (69, 70).

Cadwallader and Islam (71) prepared tablets of a dry, solid urea–benzalkonium chloride inclusion compound by direct compression.

Polymerization within inclusion compounds was first reported by Clasen (72) in 1956, who carried out stereospecific polymerization reactions of guest molecules within urea and thiourea host crystals. Brown and White (73) and White (74) irradiated monomers such as vinyl chloride and butadiene within their urea hosts and 2,3-dimethylbutadiene, 2,3-dichlorobutadiene, and 1,3-cyclohexadiene in a thiourea complex to form their respective polymers. The channels acted as smooth, straight templates holding the guest monomers, producing 1,4-*trans* addition polymers. The polymers obtained were crystalline and had higher melting points than polymers obtained by irradiation of the liquid monomers. Ivanov *et al.* (75) polymerized piperylene in the channels of urea and reported that the channel polymer had a higher degree of unsaturation (95–98%) than did polymers formed by other means (88%).

The formation of radicals during γ-irradiation of hydrocarbons (76), alkyl halides (77), and fatty acids (78) was recently reported.

The major limitation to this polymerization process is the limited number of molecules of proper size and shape able to reside in the urea or thiourea channels. The use of the channel as the template for the polymerization requires a reasonably precise fit of

the monomer within the channel.

Choleic Acids—The second group of polymolecular inclusion compounds forming channel-like void spaces are the choleic acids. Deoxycholic acid, a bile acid, forms channel-like inclusion compounds with numerous compounds including carboxylic acids, esters, alcohols, ethers, phenols, and hydrocarbons (79, 80). Apocholic acid (8,14-dehydrodeoxycholic acid) also forms similar inclusion compounds; however, the other naturally occurring bile acids are not known to form these complexes, apparently due to the absence of hydroxy groups at C-3 and C-12 (81).

Wieland and Sorge (22) first reported the composition of a choleic acid. Two products were evolved by thermal decomposition of the choleic acid *in vacuo:* deoxycholic acid (92–94%) and a waxy mixture of stearic and palmitic acids (6–8%). Excess palmitic, stearic, and oleic acids can be added to hot alcoholic solutions of deoxycholic acid to precipitate choleic acids of the same solubility and melting point, which can be distinguished only by crystallographic analysis (82). Fourier analysis of the structure of the deoxycholic acid–palmitic acid inclusion compound indicated that the deoxycholic acid molecules formed a framework around the axis of the guest molecules in which the host molecules were linked by hydrogen bonds (82); the host and guest molecules interacted *via* van der Waals forces. Similar results were found by Fourier analyses of choleic acids formed with other fatty acids. Since the choleic acids of C_4–C_{26} normal fatty acids had identical unit cells, they could not be coordination compounds.

Cramer (83) later indicated that a choleic acid is an inclusion compound with fatty acid guest molecules oriented in an end-to-end arrangement within the open channels of the deoxycholic acid crystal. An interesting aspect of the combination of these two unreactive components is that the nature of the molar ratio of the components differs from that in the urea–hydrocarbon inclusion compounds. Nonwhole number ratios were determined for the latter complexes, whereas the choleic acids are characterized by whole number ratios such as four molecules of deoxycholic acid to one of C_4–C_8 acid, six to one of C_9–C_{14} acid, and eight to one of C_{15}–C_{29} acid.

The preparation of choleic acids is not a difficult process. Both host and guest are dissolved in an appropriate hot solvent, *e.g.,* absolute methanol or ethanol, and then slowly cooled to permit crystallization of the choleic acid. The crystals can then be collected and washed, using small amounts of solvent to avoid dissociating the complex. It must be kept in mind that the choleic acids are readily dissociated in water.

The properties of certain substances are modified when they form choleic acids (81). Not only is the resistance to degradation increased, but other properties are influenced as well. For example, ethyl acetoacetate in liquid form or in solution contains 8–13% of the enol form, whereas it is 100% enolized in its choleic acid form. Likewise, acetylacetone is 70% enol in solution and 100% when complexed with deoxycholic acid. When the choleic acid crystals are dissolved, they dissociate and the liberated enol is ketonized at a measurable rate until tautomeric equilibrium is achieved. Racemic mixtures also have been separated by selective choleic acid formation; partial separations have also been accomplished for camphor, *sec*-butylpicramide, methylethylacetic acid, and α-terpineol (84, 85).

The stabilization of autoxidizable compounds by formation of a choleic acid has proved to be a fruitful area, producing inclusion compounds that are highly resistant to degradation not only by oxidation but also by heat and by chemical attack. Choleic acids of vitamins K_1 and K_3 were prepared (86), and complexes of vitamins D_2 and D_3 with deoxycholic acid and apocholic acid were patented (87). Crystalline choleic acids were formed that had vitamin activity equal to that of the uncomplexed vitamins but were significantly more stable with time. Likewise, stable choleic acids with high vitamin activity were prepared from vitamin A and vitamin A palmitate (66, 88–90).

One such crystalline choleic acid, "gallesterol," prepared by treating an egg-yolk preparation with deoxycholic acid, contained approximately 16.8% of highly stable vitamin A (91). The stoichiometry of the vitamin A choleic acids has been variously reported as one molecule of vitamin A to five (91) or eight (92) molecules of deoxycholic acid. By contrast, choleic acids of β-carotene, a precursor to vitamin A, have been reported (93) to be four molecules of deoxycholic acid per molecule of β-carotene. Other stable choleic acids include those prepared from deoxycholic acid and linoleic acid (88), linolenic acid (88), methyl linolenate (88), cinnamaldehyde (88), pentaerythritol tetranitrate (94), 2-methyl-1,4-naphthoquinone (95), and various aromatic solvents (96).

The earliest pharmaceutical use of choleic acid complexes was the preparation of stable choleic acid inclusion compounds of camphor with deoxycholic acid ("codechol") and apocholic acid ("camphochol") (97). The complexes were determined to have a guest–host ratio of either 1:1 or 1:2. "Cholosulin," the choleic acid of insulin and deoxycholic acid, was prepared and investigated (98); the absence of a pharmacological effect of the orally administered complex was reported. There is no direct evidence of the bioavailability of the choleic acids, although it has been indicated that choleic acids of streptomycin sulfate and of dihydrostreptomycin sulfate and its base could be formulated in solution, parenteral, emulsion, powder, tablet, and ointment dosage forms (99). One does not necessarily question the stability of the complex and of the guest molecule in the including structure; however, in the absence of evidence to the contrary, the bioavailability of the drug from such preparations must remain questionable and would be contingent upon the rate of dissociability of the complex and the site and conditions under which it occurred.

Indeed, such evidence was provided on the retardation of salicylic acid excretion after the oral administration to humans of a suspension of a deoxycholic acid–salicylic acid inclusion compound (100). The bioavailability of salicylic acid from the choleic acid

was less than that of salicylic acid from the administration of an equivalent dose of salicylic acid in solution. The difference in bioavailability was presumably due to the acid stability of the choleic acid. Micronization of the choleic acid increased the bioavailability of the salicylic acid. The stability of choleic acids also was studied under tablet manufacturing conditions (101).

Deoxycholic acid is limited in aqueous solubility, but its salts are highly water soluble. The salts are surface active, and micellar solubilization of lipids by these compounds is considered to be part of the mechanism by which fats are absorbed from the GI tract. It would be expected that a choleic acid would be reasonably stable at gastric pH but unstable as pH increased. The guest molecule would then be released in the intestine at a pH-dependent rate. Depending upon the site at which this release occurs, the guest may or may not be well absorbed, if it is absorbed at all. Since the bile salts, including deoxycholate salts, are believed to form cylindrical (channel-like) micelles containing solubilized lipids (102), in the broadest sense, micellar solubilization may be considered to be a form of polymolecular inclusion in solution, albeit that the nature of the interaction of the solubilizate, the guest component, with the surfactant host molecules does not necessarily fit the generalized "no bond" mechanism of the host–guest interaction characteristic of inclusion compounds.

Except for lamellar structures, micelles do reach a limiting size and shape, dependent upon the nature of the solubilizate, surfactant, and solvent. The surfactant monomers within the micelle are joined by van der Waals forces and by electrostatic bonds to form an essentially two-dimensional liquid crystalline structure enclosing (enclathrating?) the solubilizate. Thus, in the case of the choleic acids, one form of an inclusion compound may be exchanged for another, depending on pH and other conditions.

Several other steroids are thought to form inclusion compounds. Mesley (103) reported the inclusion of chloroform within lattices formed by hydrocortisone, dexamethasone acetate, and prednisone.

4,4′-Dinitrobiphenyl—These polymolecular inclusion compounds are formed by 4,4′-dinitrobiphenyl with certain 4,4′-substituted biphenyl derivatives (104). 4,4′-Dinitrobiphenyl molecules were described as being stacked in a face-centered arrangement so as to form channels that enclose the guest molecule (105, 106) (Fig. 2). The abundance of π-electrons electrostatically influences the guest molecules, which are generally nucleophilic and include benzidine, biphenyl, 4-bromobiphenyl, 4-iodobiphenyl, 4-hydroxybiphenyl, 4-aminobiphenyl, *N,N,N′,N′*-tetramethylbenzidine, 4,4′-dimethoxybiphenyl, 4-acetoxybiphenyl, and 4,4′-diacetoxybiphenyl.

Compounds Forming Cage-Like Void Spaces—Inclusion complexes formed by compounds in this category consist of a cage-like structure entrapping a guest molecule. The individual host molecules link together to form a cage or a cup-shaped structure, the open end of which joins with the open end of a second similar structure to form the cage. Because of the characteristic structure of these inclusion compounds, Powell (18) named them clathrates.

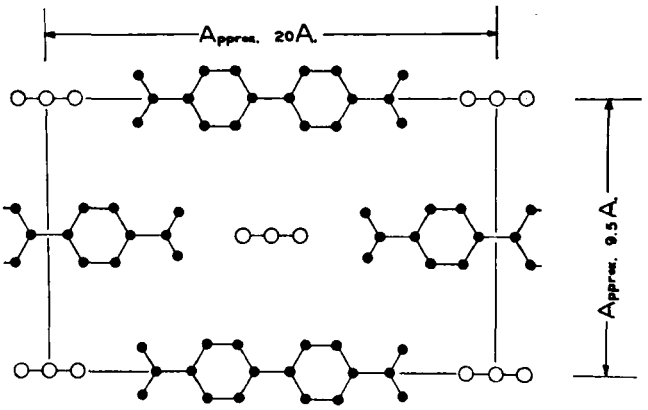

Figure 2—*Cross section of an idealized structure of the dinitrobiphenyl adducts. (Reprinted, with permission from the Eastman Kodak Co., from Ref. 24.)*

Hydroquinone—The hydroquinone–hydrogen sulfide complex was first described in 1849 (107). Mylius (15) later determined that whatever bonding was occurring in the hydroquinone–formic acid complexes he was investigating, it was not of the conventional types. He concluded that one molecule was enclosing another in a relatively stable structure. Examples of this class of inclusion compounds are those formed between hydroquinone and methanol, sulfur dioxide, hydrogen sulfide, hydrogen chloride, or other substances of a suitable size and shape.

Powell (18, 108–112) extensively studied the formation and properties of these complexes. He determined that six hydroquinone molecules are linked by hydrogen bonding to form a large open structure, which may be visualized as consisting of two interpenetrating "cups," each cup formed by three hydroquinone molecules. The hydroquinone molecules in each cup are hydrogen bonded at one end, with the molecules tilted at an angle outward from a plane perpendicular to the hexagonal plane of the hydrogen-bonded hydroxy groups (Fig. 3). The open ends of two such cups interpenetrate to form the cage. Alternate hydroquinone molecules incline upward or downward from a plane hexagon formed by the six oxygen atoms of the six hydroquinone molecules.

Hagan (10) and Brown (11) published excellent diagrams of these structures. The individual hydroquinone structures are not chemically bonded to each other but form an infinite framework. The cage-like framework encloses void spaces approximately 4 Å in diameter, from which the guest molecules cannot escape. Hydroquinone clathrates are formed only by molecules that can fit inside the cavity; molecules small enough to slip out of the cage do not form a clathrate.

Hydroquinone and similar clathrates are prepared by saturating a solution of the host component with the guest. The framework gradually develops and the clathrate forms as a crystalline solid. Some systems are more difficult to prepare and require high gas pressures and/or temperature adjustments to ensure

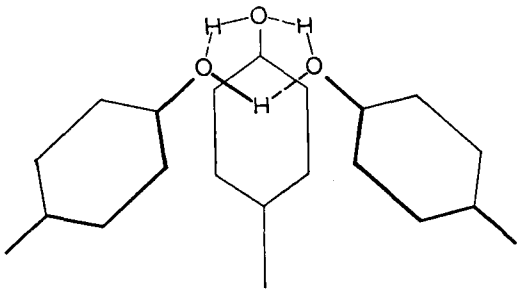

Figure 3—*"Cup" of three quinol molecules formed by hydrogen bonds. (Reprinted, with permission, from Ref. 6.)*

the desired ratio of host to guest to initiate crystallization. A less than stoichiometric ratio may result, indicating that not all of the void spaces are occupied. For a clathrate to form, the guest must be in place when the host framework forms. It is also possible that the solvent may be included if of a suitable molecular size. Solvent clathrates form in the absence of any other guest compound or, alternatively, the solvent molecule may compete with a suitable guest for inclusion.

The crystals that form are very stable; odors, if any, of guest gas molecules cannot be detected. However, the clathrate may be dissociated by heating, by dissolution in water, or by crushing or grinding the crystals (113–115).

Numerous compounds form clathrates with hydroquinone including gases, thiophene, benzene, furan, pyrroles, phenol, hydrochloric acid, and methane (6, 10, 12). The important criterion is the magnitude of the molecular volume of the guest component relative to the volume of the cage; that is, the clathration process is essentially physical in nature, not chemical.

Studies of the thermodynamics of the formation of hydroquinone clathrates of methanol and sulfur dioxide have indicated that the heat of formation of these clathrates is zero and that the free energy differences between the clathrates and the pure components is entropic in nature (116). Aside from crystal lattice interactions, the interactions of the guest and host molecule in hydroquinone clathrates are the only significant forces (117). Evans and Richards (118) suggested that such clathrates thermodynamically resemble dilute solutions.

Van der Waals and Platteeuw (119) proposed a statistical mechanical treatment for the clathrate system, consisting of three phases in equilibrium: clathrate, nonclathrate modification of host (polymorphic changes), and pure nonpolar gas, assuming only one guest molecule per host void space. The guest molecule can move within the cage, but the potential energy of the guest does not entirely depend on the sum of the two terms depending on the potential and orientation coordinates but also on the vibrational state of the molecule moving in its cage. The rotational contribution to the free energy depends on the vibrational state; the molecule loses orientational freedom when enclathrated, and this effect is greater for polyatomic molecules than for nonatomic gases.

Hydroquinone clathrates have found use in extractive crystallization by selective clathration. Rare gases are good examples. Argon may be separated from neon by adjustment of the conditions under which the clathrate forms to conditions specific for one gas or the other, and krypton may be separated from xenon (120). Selective clathration offers great potential for the removal of suitable solutes from solution and for the recovery of impurities or trace compounds.

The good storage capability and ease of handling of the hydroquinone clathrate crystals were utilized in a novel method for the handling of radioactive krypton, ^{85}Kr (121). The dry, crystalline hydroquinone–^{85}Kr clathrate was easy to handle when compared to the use of the heavy, bulky cylinders normally used to store this gas under pressure. The clathrate crystals produced radiation approximately 25 times as intense as that of an equal volume of gas at atmospheric pressure. The clathrate forms an almost leakproof container for the ^{85}Kr gas, which can be powdered and compacted with a minimal loss of radioactivity. These stable radioactive sources find a number of applications wherever ^{85}Kr is used to eliminate static and measure thickness and in other uses of β-radiation such as those of Schuler *et al.* (122) who measured acute changes in regional blood flow by intramuscular administration of ^{85}Kr clathrate.

Water—Under certain circumstances, water molecules form a crystalline clathrate framework containing cavities in which gases or low boiling-point liquids can be entrapped. Such clathrates are termed "gas hydrates" or "liquid hydrates." Compounds with chemically bound water of crystallization are also called hydrates but differ from clathrates in the nature of the bonds holding the water and in the structural arrangement of associated water molecules.

Davy first reported the chlorine hydrate in 1811. Subsequently, Faraday, Lowing, and others analyzed this complex and others, but much controversy raged concerning the exact nature of the inclusion complexes (123). It was not until X-ray diffraction studies of the gas hydrates that the water clathrates were determined to be solid solutions of a gas or a gas contained in a metastable water lattice.

The water clathrate framework resembles the ice lattice in that each oxygen atom is hydrogen bonded to four other oxygen atoms. The hydrogen bonds in ice have a length of 2.76 Å, virtually the same as in the clathrate (2.75 Å). X-ray diffraction studies have shown that water molecules in the clathrate framework are joined mostly in rings of five molecules rather than of six as in ice (124–134). The pentagons are oriented to form dodecahedrons, which are the "building blocks" of the clathrate structure. Since the dodecahedrons cannot be perfectly packed, void spaces are formed; it is in these spaces that the guest molecules are held (Fig. 4). Ordinary ice also has void spaces, but they are not of sufficient capacity to hold molecules larger than helium or hydrogen.

There are three classes of water clathrates, but the first two are most often referred to in the literature

Table I—Polyhedral Hydrates[a]

Class I	Class II	Class III

(Table I). Water clathrates consisting of 46 water molecules associated with eight guest molecules in each unit cell are in the first classification. The unit cell has eight cavities; two are dodecahedrons with a diameter of 5 Å, while the remaining six are tetrakaidecahedrons with a diameter of 6 Å (Fig. 4). As indicated in Table I, many small molecules can form clathrates with water. If only the larger cavities are occupied, the stoichiometry is $M_6\cdot46H_2O$ (where M is an inert gas molecule); however, mixed hydrates are possible, with the stoichiometric formula of $M_2\cdot M_6\cdot46H_2O$ (135).

The second class of water clathrates forms with larger guest molecules (Table I). The unit cell consists of 136 water molecules oriented as dodecahedra enclosing 24 interstitial spaces, 16 5 Å in diameter and eight 7 Å in diameter (Fig. 5). The molecules listed in Table I would occupy the larger cavities, although mixed hydrates form with smaller molecules occupying the 16 smaller cavities. In the third class of water hydrates, the cage may be formed of portions of the simpler polyhedra (136, 137). There is no specified unit cell to describe the third class of clathrates, because each guest molecule requires a specific surrounding cage.

The water clathrates are stabilized by the energy of the hydrogen bonds of the water framework, al-

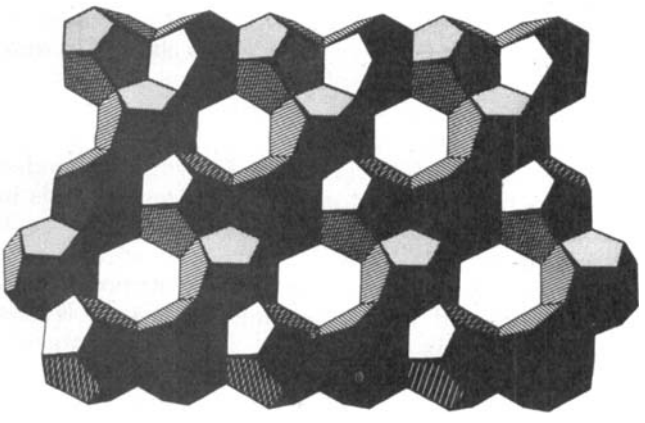

Figure 4—*Structure of the type I hydrate. The tetrakaidecahedral cavities (12 pentagonal plus two hexagonal faces) are formed when layers of dodecahedra, arranged as shown, are stacked on top of each other so that the hexagonal openings line up perpendicular to the plane of the drawing. Figure 5—*Two drawings of a folded-paper model of the hexakaidecahedral cavity of the type II hydrate structure. The 16-sided cavities are formed between 16 dodecahedra framing four hexagonal faces. The plane of each hexagonal face lies on the side of a regular tetrahedron. Each hexagonal face is shared by two hexakaidecahedra. (Reprinted, with permission, from J. F. Catchpool, in "Structural Chemistry and Molecular Biology," A. Rich and N. Davidson, Eds., Freeman, San Francisco, Calif., 1968, p. 345.)*

though the hydrogen bond stabilization of the clathrate is less than that in ice due to the more open clathrate structure (138). Van der Waals interactions between the guest and host molecules contribute, however, to the high degree of the overall stability of the clathrate.

A statistical mechanical model for several gas hydrates based on the Lennard–Jones and Devonshire model has been described (139) and the dissociation pressures, compositions, and heats of dissociation were calculated. Daee *et al.* (140) determined that the Helmholtz free energy of formation of the water clathrate was not a smoothly increasing function of the number of molecules but instead showed a minimum corresponding to closed cages. Phase diagrams for several water clathrate systems have been reported (141–143). Calculations of water vapor pressure over a crystalline gas hydrate indicated the formation of the clathrate structure (144). Phase equilibrium studies indicated the existence of mixed hydrates and of multiple hydrates where more than one guest can occupy a cavity (145). Multiple occupancy is limited to small guest molecules such as neon.

The stable clathrate crystals form when water and a gas or volatile liquid are brought together under high pressures and low temperatures. This process can be used, under proper conditions, for the separation of gas (146) or liquid (147) mixtures. Argon can be separated from krypton, krypton from xenon, and short chain (C_3 and C_4) aliphatic olefinic hydrocarbons from mixtures of higher molecular weight compounds. One interesting and novel approach to the desalination of water depends upon the formation of a propane or halogenated propane clathrate in sea water under reduced pressure and temperature (148). The water clathrate that forms can be separated from the salt water and decomposed by heating to 7.2° (45° F) under pressure to give propane and salt-free water. However, water clathrates do not form in highly concentrated salt solutions (149). The melting temperature of clathrates with a high proportion of empty cavities decreases with increasing pressure while the reverse holds for clathrates with a small proportion of empty cavities (150).

Clathrates are formed not only by inert gases but by hydrocarbons and their derivatives (151, 152), inorganic gases, and a number of polar compounds (Table I). Some guests interact with, or are joined to, the water lattice while others rotate freely (153, 154). Pauling (138) proposed an intriguing mechanism for the action of anesthetic gases based upon the formation of minute water clathrate crystals in the brain. He suggested that the anesthetic actions of certain gases of low chemical reactivity (*e.g.*, chloroform and cyclopropane) may result from clathrate formation in the encephalonic fluid. According to this theory, the clathrates would trap ions and electrically charged side chains of protein molecules in such a way as to decrease the energy of electric oscillations in the brain. (Figure 6 shows a diagram of a similar system.) This process would tend to produce a loss of consciousness due to increased electrical impedence of the neural network to electrical waves.

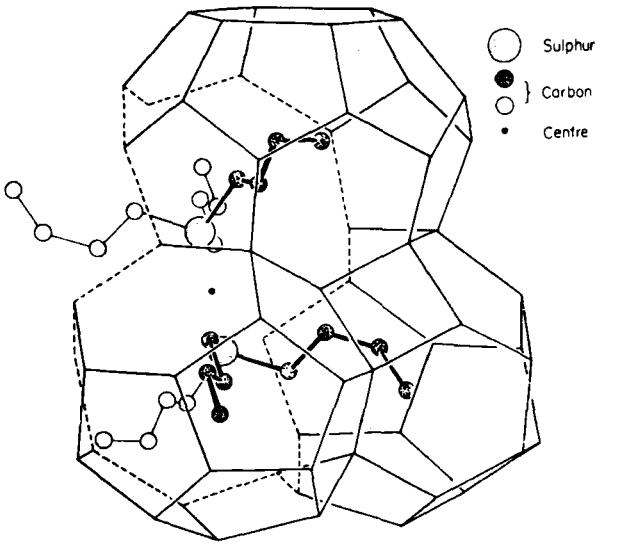

Figure 6—*Projection of clathrate cavity containing a pair of $(C_4H_9)_3S^+$ ions. Only one-half of the cavity is shown, that into which the shaded carbon chains project. The second half surrounds the open-circle carbon chains. The complete polyhedron is constituted of 60 faces. (Reprinted, with permission, from Ref. 135, p. 111.)*

In support of his theory, Pauling determined that a correlation exists between the narcotizing partial pressure of the anesthetic gases and the partial pressure necessary to cause the formation of hydrate crystals. As Pauling indicated, however, approximately the same correlation would be found between the anesthetizing partial pressure of the nonhydrogen-bonding anesthetic agents and any property based upon the van der Waals attraction of the agents for other molecules, *e.g.*, the lipid solubility of the anesthetic gases or the oil–water partition coefficient. The energy of the intermolecular interactions is nearly proportional to the molecular polarizability of the anesthetic agents. If water clathrates do indeed form in the brain and do have a biological function, then it would be a logical extension of this phenomenon to expect their occurrence in other body fluids. This interesting prospect is worthy of further investigation.

Abundant information attests to the formation of hydrate "icebergs" around many ions and proteins in aqueous systems. Included in this category are the trialkylsulfonium and tetraalkylammonium salts. Although the trialkylsulfonium salts and tetraalkylammonium salts are univalent electrolytes, they show a behavior similar to that of the water clathrates (11, 155). Typical formulas for each of these compounds are $2(n\text{-}C_4H_9)_3S^+F^-\cdot 40H_2O$ and $2(\text{iso-}C_5H_{11})_4N^+F^-\cdot 76H_2O$, respectively.

Dyadin *et al.* studied the influence of cation size on clathrate formation in water–quaternary ammonium salt systems (156) and determined the phase diagram for the water–tetra-*n*-butylammonium bromide system (157). Wen (158) reviewed the formation of clathrates of tetraalkylammonium salts.

The crystal lattice of the tri-*n*-butylsulfonium compound resembles the Class I water clathrate with

46 water molecules in the unit cell, except that six of the water molecules are replaced by the two sulfur ions and by the two fluorine ions. The remaining 40 water molecules form the clathrate framework. The interstitial cavities are occupied by the six *n*-butyl hydrocarbon chains rather than by gas molecules. The tri-*n*-butylsulfonium compound is considered to be structurally similar to the chlorine hydrate. McMullan and Jeffrey (155) established the structural arrangement of tetraalkylammonium salts to be similar to the water clathrates. An interesting aspect of the clathrate is that it is highly stable. Although the inclusion complex is 68% water, it remains stable as an ice up to 31.1° (88° F).

The proteins are also highly hydrated crystals with thousands of water molecules per molecule of protein, comprising as much as 90% of the crystal; as such, a water clathrate structure may be expected to exist around the protein molecule. The presence or absence of the water clathrate surrounding the protein molecules may influence the biological function (or lack of function) of the protein. In addition, protein molecules themselves appear to resemble host compounds in that the disulfide bridges between protein layers create spaces between the layers that are capable of enclosing certain hydrocarbons (159).

Phenol—Investigation of the solubility of components of petroleum in liquid hydrogen sulfide led to the discovery of the phenol–hydrogen sulfide clathrate (160). Phenol forms a clathrate with various compounds, including xenon; hydrogen selenide, chloride, bromide, iodide, and sulfide; carbon dioxide, carbon disulfide, and carbon disulfide plus air; carbonyl sulfide; methyl bromide; methylene chloride; tetrafluoroethylene; and 1,1-difluoroethane (161, 162). Lahr and Williams (163) also reported the formation of phenol clathrates with argon and krypton. Some derivatives of phenol also formed clathrates (12, 164). The phenol clathrates were prepared by dissolving phenol in solutions of the guest component or, in the case of gases, dissolution of the gas under pressure. The phenol clathrates separated readily from the solution and were stable at room temperature, but there may be a slight diffusional loss of gas with time.

As described by Mandelcorn (9), the structure of the phenol clathrate depends upon hydrogen-bonded O—O linkages formed by hydroxy groups of six phenol molecules, the linked molecules forming a planar hexagon with the phenyl nuclei oriented alternately above and below the hexagon. A cage is formed when a pair of the six-membered groups are oriented with the hexagons opposite and parallel to one another. The unit cell is rhombohedral, with each corner occupied by the cage arrangement of the 12 phenol molecules, giving an elongated, rather large cage. The unit cell of the phenol clathrate consists of 12 phenol molecules, one large cavity, and a small cavity. Mandelcorn also described the maximum stoichiometry of the phenol clathrates as a function of the size of the guest component.

Dianin's Compound—Dianin's compound (4-*p*-hydroxyphenyl-2,2,4-trimethylchroman) is the condensation product of two molecules of phenol and one of mesityl oxide; upon alkaline fusion, it gives salicylic acid as a product. Dianin (165) observed that this compound retained fixed amounts of the solvent from which it was recrystallized. Several studies showed that Dianin's compound formed clathrates with sulfur dioxide, iodine, argon, and nearly 40 other organic compounds (166, 167). Other guest compounds include heptanol (168), di-*tert*-butyl nitroxide (169), and carbohydrates (170).

A complex structure was proposed in which six molecules of Dianin's compound formed a clathrate cavity (166). The structure has been described as being similar in shape to an hourglass from which the globes have been cut off in the middle. A hexagon of hydrogen-bonded hydroxy groups forms the constriction at the midpoint, and six molecules of Dianin's compound alternately point up or down to form the cups above and below the planar hexagons. These structures are stacked linearly upon each other in the crystal with their hexagons parallel to and above each other. The open end of two cups face each other to form a cavity when the adjacent molecules are held together by strong van der Waals attractions.

Detailed structural analysis by X-ray diffraction has been reported for crystalline inclusion compounds of Dianin's compound with ethanol or chloroform (171). Only one hydroxy group in Dianin's compound is available for hydrogen bonding, so an infinite network of cages does not occur. However, the stacking arrangement in the crystal gives separate columns of individual cages. The hourglass-shaped cage of Dianin's compound is large, approximately 11 Å long and 6.2 Å at its point of maximum width, or about twice as long as the hydroquinone cage.

Mandelcorn (9) compiled a list of the three maximum composition formulas for the Dianin's compound clathrates, depending upon the size of the guest component. Although there are no reported pharmaceutical uses of Dianin's compound clathrates, many simple synthetic precursors and solvents form complexes with Dianin's compound, suggesting that these inclusion compounds might be useful in drug synthesis or purification (172).

Cycloveratril—Formaldehyde and 1,2-dimethoxybenzene (veratrole) combine to form cycloveratril (Fig. 7), which forms numerous clathrates with organic compounds. Caglioti *et al.* (173) prepared clathrates of cycloveratril and benzene, chlorobenzene, chloroform, toluene, acetone, thiophene, carbon disulfide, butyric acid, acetic acid, and decalin. These workers proposed that the benzene rings of the cycloveratril molecule are tilted, giving a nonplanar configuration to the molecule. Strong repulsions between hydrogen atoms of adjacent benzene rings, through rotations of the aliphatic to aromatic carbons, are responsible for the tilting of the benzene rings. Packing of the nonplanar molecules in the crystal leaves small cavities in which guests of small molecular volume can be accommodated.

Miscellaneous Compounds—Over 75 years ago, Hofmann and Küspert (174) reported that a crystalline precipitate formed when benzene was added to a

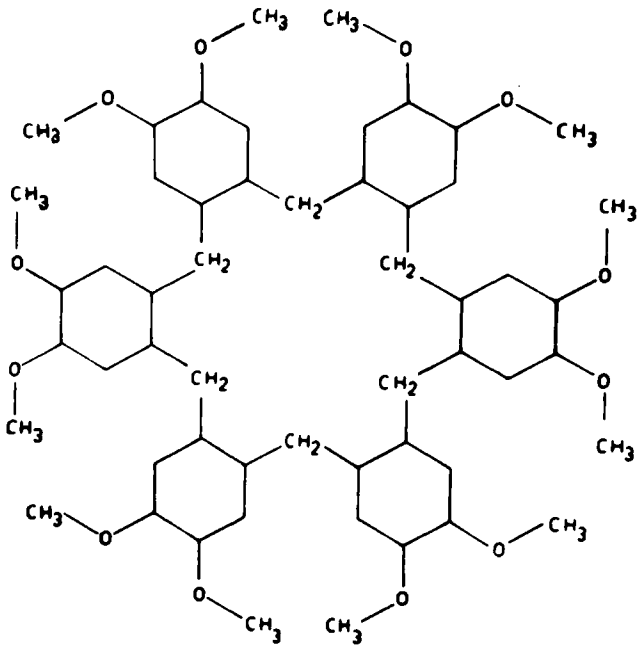

Figure 7—*Structural formula of cycloveratril. (Reprinted, with permission from Pergamon Press, from Ref. 173.)*

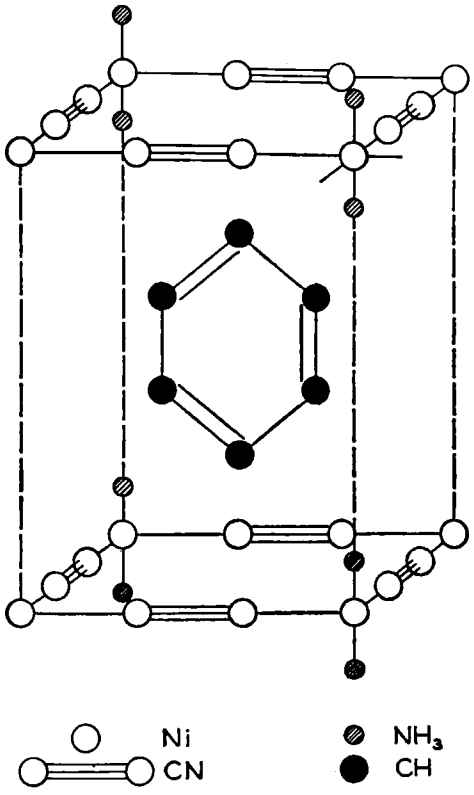

Figure 8—*Schematic representation of the clathrate compound, $Ni(CN)_2NH_3$–C_6H_6. (Reprinted, with permission, from Ref. 175.)*

solution of nickel cyanide in aqueous ammonia solution containing acetic acid. This report was the first on the formation of a clathrate of an organic molecule in an inorganic cage. Numerous organic compounds form clathrates with the nickel cyanide–ammonia complex (12), whose maximum composition formula is $Ni(NH_3)^{+2}2CN^-$·M, where M is the guest molecule. The guest molecules are enclosed in a cavity formed horizontally by two planes of nickel cyanide and vertically by parallel pairs of ammonia molecules. The ammonia molecules are bonded to the nickel atoms and project above and below each plane, giving rise to the cavity when the complex crystallizes (175) (Fig. 8).

The nickel cyanide–ammonia clathrates and similar clathrates are used for the separation of benzene from hydrocarbon mixtures by selective clathration (176). High purity benzene can be recovered from the clathrate under vacuum or by steam decomposition. Clathrates of this type are frequently called "Hofmann's benzene clathrate" if benzene is the guest component or "Hofmann-type clathrates" for other enclathrated guests.

Related to the monoamminonickel (II) cyanide clathrates are clathrates where certain Werner complexes or hexamethylisocyanidoferrous chloride act as the host component. The Werner complexes differ from the nickel cyanide–ammonia complex in that there are usually four neutral molecules and some anions coordinated with the metal ion. An example of a Werner complex forming clathrate compounds is tetra(4-methylpyridine)nickel (II) dithiocyanate. A number of transition elements forming Werner complexes also form clathrates including cobalt, manganese, iron, copper, and zinc. The basic nitrogen compound and the anion also may be varied; the latter may be mono- or polyatomic.

The clathrate compounds of Werner complexes are used industrially for separating and resolving organic mixtures (177–179) and for separating aromatic isomers in liquid phase chromatography (180).

The last of the cage-forming compounds is hexamethylisocyanidoferrous chloride. Water is the guest component in the clathrate, and the overall formula is $Fe(CNCH_3)_6^{+2}2Cl^-·3H_2O$. The $CNCH_3$ groups project octahedrally around each ferrous ion, the unit cell being composed of two hexagonal layers of the ferrous ion (181). No other clathrates of this compound are known.

Bhatnagar (12) discussed these clathrates extensively and there are numerous references in the literature.

Compounds Forming Either Channel or Cage Void Spaces—Tri-*o*-thymotide (182), a versatile host molecule, forms clathrate complexes with many organic compounds (25). The clathrates of tri-*o*-thymotide are unique in that they are arranged in trigonal spirals. The spirals can enlarge in all directions without any constraints, unlike those formed in the hydrogen-bonded hydroquinone framework in which an increase in size in one direction causes a decrease in size in the other.

The general formula is $2C_{33}H_{36}O_6$·M, when the guest molecule (M) has a length not exceeding 9.5 Å. However, very small molecules (*e.g.*, carbon dioxide) have a low probability of clathration. The structure of the clathrate is that of an elongated cage. For molecules longer than 9.5 Å, a channel-like structure is produced and the formula becomes $C_{33}H_{36}O_6$·*x*M,

where x decreases as the chain length of the guest increases.

The tri-*o*-thymotide clathrates are stable; certain complexes can be heated to 100° above the boiling point of the guest compound without loss of the guest. In addition, Lawton and Powell (25) observed spontaneous optical resolution with tri-*o*-thymotide clathrates. If tri-*o*-thymotide is crystallized from a racemic solvent, the cavities of any one crystal will enclose either the dextro- or levo-form of the solvent molecule. If the two different crystals are separated, the solvent can be likewise separated.

MONOMOLECULAR INCLUSION COMPOUNDS

By definition, monomolecular inclusion compounds represent the complexation of a single host molecule and a single guest molecule. The host molecule is characterized by the presence of a cavity or hole into which the guest molecule is inserted.

Cyclodextrins—The most thoroughly investigated monomolecular inclusion compounds are those formed by the cyclodextrins, which are also known as cycloamyloses and as Schardinger dextrins.

The cyclodextrins are water-soluble, nonreducing, macrocyclic polymers, containing glucose molecules joined by α-1,4-linkages (Fig. 9). The most common of these compounds are the α-, β-, and γ-cyclodextrins formed by six, seven, and eight glucose units, respectively. The ring-shaped molecule encloses a cavity of about 6, 8, and 10 Å in diameter for the α-, β-, and γ-cyclodextrins, respectively.

The cyclodextrins are produced by the degradation and cyclization of starch by an enzyme produced by *Bacillus macerans*. The biosynthesis and properties of the cyclodextrins have been discussed in detail (183–188).

Molecules of a suitable size and shape can be held within the cavity of a particular cyclodextrin by van der Waals forces. Advantage of this property is taken in the selective precipitation of the α-, β-, and γ-cyclodextrins from the crude mixture of cyclodextrins produced by the enzymatic process. Cyclohexane or trichloroethylene forms an insoluble inclusion compound with α-cyclodextrin, fluorobenzene or toluene forms an insoluble inclusion compound with β-cyclodextrin, and bromobenzene or anthracene forms one with the γ-cyclodextrin (184). The cyclodextrins readily form inclusion compounds with a great number of organic compounds, including many derivatives of benzene.

The inclusion compounds formed with apolar molecules are only slightly soluble in water (184), whereas those formed with polar molecules are moderately soluble (189, 190). As indicated by Lammers *et al.* (191), the structures of the cyclodextrin inclusion compound in solution and in the crystal differ significantly. In solution, the guest molecule occupies the cavity in the cyclodextrin host and the entire complex is surrounded and solvated by water molecules. In the crystal, however, the guest may be enclosed in a void space of a lattice and not necessarily by individual cyclodextrin molecules. This arrangement may result in the formation of nonstoichiometric inclusion compounds. Exceptions to this behavior are certain cyclodextrin derivatives that do not form lattice-structured inclusion compounds, *e.g.*, cyclodextrin–epichlorohydrin resins (192).

The cyclodextrin cavity was described in the earlier literature as being hydrocarbon in nature, based upon the assumption of a boat configuration of the glucose monomers. Later NMR and X-ray studies confirmed the C-1 chair conformation for the glucose molecules (193). The cyclodextrin molecule would then be arranged with primary and secondary hydroxy groups around the opening of the cavity on opposite ends of the torus with H-3, H-5, and H-6 located within the cavity and H-1, H-2, and H-4 located on the exterior. Cramer and Dietsche (194) proposed that the interior of the cavity behaves as a Lewis base due to its high electron density. Broser and Lautsch (195) suggested that the cyclodextrin was electrophilic due to the increased stability of an inclusion compound in solution with increased basicity of the guest component.

Inclusion of a guest molecule within the cyclodextrin cavity can be utilized to increase the solubility or stability of the guest species. As indicated earlier, many organic compounds form inclusion compounds with the cyclodextrins, including various molecules of pharmaceutical interest. Vitamin A and several unsaturated fatty acids have been stabilized by cyclodextrin inclusion, protecting them from exposure to oxygen and thereby retarding oxidation (88). Cohen and Lach (196) found that α- and β-cyclodextrins formed complexes with the hydroxybenzoic acids and *p*-hydroxybenzoates. Hydrogen bonding was determined to play a role in the formation of the complex, particularly with the hydroxybenzoic acid complex in aqueous solution.

These studies were later extended to include various other drug molecules including sulfadiazine, tetracycline, morphine, aspirin, benzocaine, ephedrine, and sorbic acid (197). In general, the smallest drug molecules showed the greatest complexing activity with the cyclodextrins, and those compounds with the lowest water solubility showed the greatest percent increase in solubility as a function of the concentration of cyclodextrin. Most compounds investigated were too large to fit in the cyclodextrin cavity, leading to the conclusion that the observed interaction was a combination of attractive forces (hydrogen bonding) and inclusion formation.

Pauli and Lach (198) reported that unsaturated phenyl-substituted carboxylic acids were less reactive with β-cyclodextrin than were the corresponding saturated acids. As the chain length of the saturated acids increased, giving greater separation of the phenyl ring and the carboxyl group, the interaction became stronger.

A large number of drug molecules such as reserpine, cortisone acetate, adiphenine, tripelennamine, and testosterone form inclusion compounds with β-cyclodextrin, even though they are too large to be completely included within the cyclodextrin cavity (199). The smaller the guest molecule, the greater is

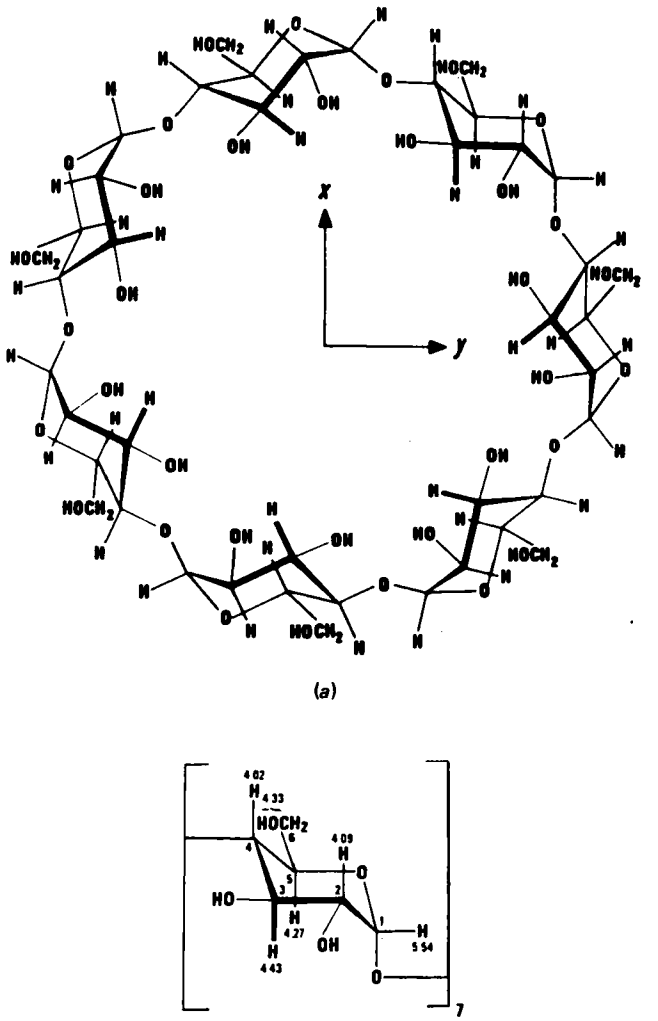

Figure 9—*(a) Cycloheptaamylose molecule. The z-axis is parallel to the cycloheptaamylose cavity, i.e., normal to plane of the page. (b) Recorded chemical shifts in parts per million for various cycloheptaamylose protons. (Reprinted, with permission, from Ref. 203.)*

its complexing activity. Likewise, the degree of activity for the large molecules is dependent on the presence of a suitable group or ring capable of entering the cavity. The ratio of the drug to β-cyclodextrin in the inclusion compounds was 1:1 (adiphenine and tripelennamine) or 2:1 (cortisone acetate and testosterone). The formation constants were relatively high, indicating stable complexes.

The interactions of β-cyclodextrin with barbiturates (200), copper II (201), and several prostaglandins (202) also have been reported. The insoluble inclusion compound of the prostaglandins was collected, dried, and reported to be formulated into suspension, capsule, tablet, suppository, topical, and parenteral dosage forms (202).

Investigations of the apparent formation of inclusion compounds between cyclodextrins and various drug molecules have made significant contributions toward resolving the stoichiometry and mechanism of formation of these complexes. But these studies did not provide conclusive, direct proof of the formation of an inclusion compound. Such evidence has resulted from proton magnetic resonance studies of the inclusion compounds formed between β-cyclodextrin and substituted benzoic acids, aspirin, tetracycline, *d*-phenylalanine, substituted phenols, and other compounds (203). Protons H-3 and H-5, located in the interior of the β-cyclodextrin torus, were shielded by guest protons upon the formation of an inclusion compound; increasingly larger chemical shifts of H-3 and H-5 were detected with increasing concentrations of *p*-hydroxybenzoic acid up to saturation concentration. This study and a subsequent study (204) demonstrated that large molecules can form inclusion compounds if an aromatic moiety or other group of a suitable size and shape can fit into the β-cyclodextrin cavity.

Thakkar *et al.* (205) reported correlation between the formation constants measured by phase solubility analysis for β-cyclodextrin–barbiturate complexes with those obtained by quantitative treatment of induced Cotton effects in the circular dichroism spectra of these inclusion compounds. Circular dichroism was used earlier to study the interaction of α- and β-cyclodextrins with azo dyes (206) and similar complexes with methyl orange and benzoic acid (207).

Cramer *et al.* (208) described the formation of α-cyclodextrin inclusion compounds with azo dyes as consisting of six steps:

1. Approach of the guest or substrate molecule to the cyclodextrin molecule.
2. Loss of the water structure within the cyclodextrin cavity with removal of some water molecules.
3. Breakdown of the water structure around the portion of the substrate that will be included and transport of some water molecules into the solution.
4. Interaction of substituent groups of the substrate with groups on the rim or inside the cyclodextrin ring.
5. Possible formation of hydrogen bonds between the substrate and the cyclodextrin.
6. Reestablishment of the water structure around the exposed parts of the substrate after inclusion has occurred.

These authors (208) pointed out that the rate of formation of the complex should be dependent on the steric factors of Steps 1, 4, and 5. Within the same class of guest molecules, Steps 1, 2, and 6 should not be rate determining. If kinetic specificity with regard to substituent groups is found, Step 3 or 4 and, possibly, Step 5 must be considered. The influence of the breakdown of the water structure and the removal of water molecules from within the ring must also be considered, particularly for the azo dyes. It was determined that the rates of recombination of nitrophenol, its anion, and an azo dye were diffusion controlled; Step 1 was the rate-determining step.

Hoffman and Bock (209) studied the interaction of cyclodextrins with nucleic acids. They determined that only adenosine and inosine compounds (adenosine monophosphate and inosine monophosphate) interacted with β-cyclodextrin and that none interacted with α-cyclodextrin. The primary factors determining the formation of the inclusion complex in ad-

dition to the degree and position of phosphorylation, pH, and polymerization of the nucleotide were the size of the base and its ability to be accommodated in the cyclodextrin cavity. Bases in single-stranded stacked conformation interact to form a complex. Formoso (210) reported the binding constant of 5′-adenosine monophosphate to β-cyclodextrin as well as the interaction of β-cyclodextrin with other nucleic acid monomer units. Hydrophobic interactions did not apparently contribute significantly to the stability of the complexes.

The spatial requirements for the formation of a cyclodextrin inclusion compound in part mimic the "lock and key" mechanism of enzyme catalysis which occurs if the substrate or guest molecule is oriented properly with respect to the active centers of the host (211). It is also possible to use the cyclodextrin ring to include or hold a molecule partially, blocking some reactive sites on the guest but exposing others. Breslow and Campbell (212) produced *p*-chloroanisole by forming the α-cyclodextrin–anisole inclusion compound in which the hydroxy groups rimming the cyclodextrin cavity were converted to intracomplex hypochlorite groups by reaction with hypochlorous acid. The hypochlorite groups react catalytically to chlorinate the exposed *para*-position of the partially included anisole molecule.

Lach and Chin (213) reported the inhibitory effect of β-cyclodextrin on the hydrolysis of ethyl *p*-aminobenzoate (benzocaine). They attributed this effect to the complete inclusion of the ester in the β-cyclodextrin cavity, protecting the ester linkage from attack. Their results indicated that the degradation of benzocaine was dependent on the uncomplexed drug in solution and not on the total amount present.

The results of this work, however, differed from those reported by Bender *et al.* (214, 215) and Van Etten *et al.* (216, 217), which indicated that the cyclodextrins accelerated ester hydrolysis, primarily by nucleophilic attack of the alkoxide ion of the cyclodextrin on the ester within the cyclodextrin cavity. Chin *et al.* (218) explained the apparent difference by observing that the compounds that form an inclusion compound in which the entire molecule (*e.g.*, benzocaine) or the susceptible portion are located in the cyclodextrin cavity (*e.g.*, atropine) exhibited a deceleration in the rate of hydrolysis; the rate of hydrolysis was dependent on the free ester in solution. Conversely, compounds that undergo partial inclusion but leave the active center fixed in close proximity to the hydroxy group of the cyclodextrin (*e.g.*, aspirin) underwent acceleration of hydrolysis. In this case, the rate of hydrolysis is dependent not only on the free ester in solution from dissociation of the complex but also on the nucleophilic attack of the alkoxide ion of the cyclodextrin on the ester linkage. An ester linkage that could be included within the β-cyclodextrin cavity, but only partially within the α-cyclodextrin cavity, would show deceleration of hydrolysis in the former and acceleration in the latter.

Cramer and Kampe (219) reported catalysis of the decarboxylation of methylphenylcyanoacetic acids with α- and β-cyclodextrins in aqueous solution. The rate of reaction was accelerated up to a factor of 14.8, depending on the size of the substituent groups and the nature of the inclusion compound formed. Additional information concerning the relationship between enzyme and inclusion catalysis was reported by Hennrich and Cramer (220), who studied the stereospecific catalysis of the fission of pyrophosphates by cyclodextrin. Cyclodextrins accelerated the cleavage of symmetrical diesters of pyrophosphate with phenols, which are stable in neutral or alkaline solution. β-Cyclodextrin was the most efficient catalyst and the assumption was made that a single phenyl group entered the cyclodextrin cavity, enclosing the pyrophosphate on one side only. Reaction mechanisms were proposed in which the cyclodextrin functions as a neighboring group and/or acts by a push–pull polarization of the pyrophosphate, the result being that the internal phosphate residue of the guest is transferred to the cyclodextrin host.

The cyclodextrins have been used to carry out many other stereospecific catalyses (194, 211). In one case, α-hydroxy ketones were converted from their keto to enol forms upon inclusion in the α-cyclodextrin cavity. The cyclodextrin catalyzed the reaction, which occurs only when the compound is in the enol form.

Cramer and Mackensen (221) synthesized amorphous, nonstoichiometric cyclodextrin–imidazole compounds by reacting cyclodextrins and cyclodextrin derivatives with 4(5)-chloromethylimidazole or 4(5)-aminoalkyl imidazoles. These compounds accelerated the hydrolysis of *p*-nitrophenol acetate about 300-fold. The cyclodextrin–imidazole compounds appear to be models for the complexation of a hydroxy group of the amino acid serine and an imidazole residue of histidine in the active site of chymotrypsin.

Solms and Egli (222, 223) prepared insoluble cyclodextrin–epichlorohydrin resins from mixed cyclodextrins. These compounds were useful in gel chromatographic separations of *o*- and *p*-nitrophenol and of phenylalanine and tryptophan. Wiedenhof and coworkers (192, 224, 225) prepared the α- and β-cyclodextrin–epichlorohydrin resins and determined that they have affinity for aromatic compounds. The isothermal inclusion of undissociated benzoic acid could be described by a Langmuir isotherm; however, the inclusion of *m*-chlorobenzoic acid could be described only by a Freundlich isotherm. Lammers *et al.* (191) also prepared soluble epichlorohydrin resins of α- and β-cyclodextrins. The water-soluble derivatives of α- and β-cyclodextrins form soluble inclusion compounds with nonpolar guest molecules, in contrast to the very slightly soluble complexes the same guests form with the cyclodextrins themselves. These derivatives should prove useful in studying the nature of the cyclodextrin inclusion compounds in solution.

Hoffman (226) separated various nucleotide and nucleoside mixtures, particularly those containing adenine, on stable, cross-linked β-cyclodextrin gels, similar to the mixed cyclodextrin gels described by Solms and Egli (222). The column chromatographic separations were believed to occur by the formation of an inclusion compound. A process for using cyclo-

dextrin gels was patented for the separation of vitamins, perfumes, and aromatic amino acids (227).

The partial resolution of racemic mixtures has been accomplished with modest success by selective inclusion with α- and β-cyclodextrins. β-Cyclodextrin has been particularly effective in differentiating between *d*- and *l*-forms; Cramer (83) partially resolved a number of esters using this host molecule. The resulting resolutions ranged from 0.84 to 11.33%. Mikolajczyk *et al.* (228) partially resolved sulfoxides with β-cyclodextrin, achieving resolutions ranging from 4.4 to 14.5%.

Miscellaneous Compounds—Aside from the cyclodextrins, other substances appear to fit into the classification of monomolecular inclusion compounds. Many large molecules have cavities or other structural arrangements capable of partially or completely enclosing a guest molecule (6). Examples of such compounds are the bis-*N,N'*-alkylenebenzidines which, when crystallized, can enclose a molecule of benzene or of dioxane in an intramolecular ring (229).

Cramer (6) suggested that proteins, minerals, cellulose, and graphite form monomolecular inclusion compounds. The specificity of reactions between various proteins and guest molecules such as those of dyes and other compounds with serum albumin, chromoproteins, and hemoglobin suggests a possible inclusion process; however, normal salt formation could account for this complexation and may negate this concept. Another strong possibility for the consideration of proteins as monomolecular inclusion compounds are the highly specific antigen–antibody interactions, which are dependent upon shape-matching factors. The hapten or nonproteineous portion of the antigen fits closely and specifically within the antibody and actually determines the antigen-to-antibody specificity. Hydrogen bonds and electrostatic attractions play a role in leading to a stable, tightly bound complex, in addition to van der Waals forces resulting from the close spatial proximity of the two interacting species.

Further biological ramifications come from suggestions that deoxyribonucleic acid (DNA) may have a function analogous to that of a host molecule (6). Protamines combine with DNA by fitting into a groove running through the helical macromolecule in a screw line (230). The biological activity of the nucleic acids may therefore be related to an inclusion process. The template function of ribonucleic acid (RNA) may also be a specific inclusion process as well as the interaction of gene mutations with DNA.

The antibiotic gramicidin A has a channel along its helix axis which forms a transmembrane channel through the lipid portion of a membrane when gramicidin A interacts with the membrane (231, 232). Although this does not represent an inclusion process *per se*, the presence of a cavity or channel in this compound and in another antibiotic, valinomycin (233), suggests that these compounds may act as host structures. A specific inclusion possibly could occur that might block the transmembrane channel or otherwise alter the biological activity of these compounds, perhaps leading to the synthesis of molecules with channels specific for a particular guest. The concept of inclusion compound formation as a component of the complex biochemistry of the living organism is exciting and should open new vistas in research for a complete understanding of those vital processes in health and disease.

PRODUCTS OF THE BLUE-IODINE REACTION

The blue-black color resulting from the reaction between iodine and starch has intrigued scientists for over a century and a half. In 1939, Freudenberg *et al.* (234) proposed that this behavior was the result of inclusion compound formation. Subsequent work by Cramer (6, 235, 236) indicated that a soluble, channel-like inclusion compound was formed by the polymerization of iodine atoms into a linear "template" around which the starch molecules formed a helix. This type of helical structure enclosing the iodine polymer was stable only as the inclusion compound. Instead of the characteristic red-brown color of iodine solutions, the inclusion compound was blue-black; hence the common name for this phenomenon is the "blue-iodine reaction."

The blue-black color of the cyclodextrin–iodine inclusion compound occurs by a similar process to that of starch (6). When the cyclodextrin–iodine complex crystallizes from solution, the individual cyclodextrin molecules align themselves to form a long, channel-like structure with the cyclodextrin rings lying side by side and the polyiodide chain occupying the now continuous channel. One turn of the starch helix contains six glucose molecules, the same as that of α-cyclodextrin. Both α- and β-cyclodextrins form inclusion compounds with iodine; α-cyclodextrin can also complex with chlorine and bromine. However, the β-compound can complex only with bromine, because the chlorine molecule is too small to stay in the cavity (6). γ-Cyclodextrin forms a loose complex only with iodine.

The linear iodine polymers are also stabilized by inclusion compound formation with many other compounds including benzonitrile, coumarins, cholic acid, cortisone, flavones, benzamide, barbituric acid, quinine and other alkaloids, and benzophenone (6).

The most likely mechanism to explain the nature of the polyiodide chain is that the host molecule acts as an electron donor, forming a loose charge-transfer complex with the iodine (237, 238) (Scheme I). This mechanism is substantiated by the fact that all host molecules forming blue-iodine compounds have such donor groups, *e.g.*, the electron pairs of the oxygen atoms of the cyclodextrins and the carbonyl groups of the flavones and coumarins.

$$\text{donor} + I_2 \rightleftharpoons (\text{donor}, I)^+ + I^-$$

Scheme I

Two other examples of the blue-iodine reaction should be mentioned. The first example is that of swollen cellulose which interacts with iodine to give a blue-black color (6), leading to the concept that the process of dyeing cellulose and other materials is an inclusion process. The second example is the polariz-

ing filter (239). These filters are prepared by treating a sheet of polyvinyl alcohol polymer with iodine, followed by stretching the sheet to orient the linear polyiodide chains within the polyvinyl alcohol hosts. The electrons along the polyiodide chain resemble those of a metal because they can move along the chain. However, they cannot move perpendicular to it, accounting for the very high extinction coefficient of the polyiodide chains in the inclusion compounds. This property of the electrons of the chain allows the absorbance of light polarized parallel to the direction of the stretched orientation of the polyvinyl alcohol–iodine complex, and only the light polarized at right angles passes through. Bolewski and Uchman (240) reported that the clathrating ability of polyvinyl alcohol decreased with an increase in the degree of branching.

MACROMOLECULAR INCLUSION COMPOUNDS

The last category of inclusion compounds includes those of a macromolecular size. In many cases the differentiation between monomolecular and macromolecular inclusion compounds is not clearly defined so considerable overlap results. Some large molecules such as certain minerals, cellulose, and proteins can be discussed in either category.

A detailed discussion of the macromolecular inclusion compounds is unfortunately beyond the scope of this review. Well over a 100 or more publications appear annually concerned with the preparation, properties, and applications of these useful compounds.

Zeolites—The major category of macromolecular inclusion compounds is commonly known as molecular sieves which are widely used in pharmaceutical processes and other chemical and biological applications due to their unique ability to fractionate molecules according to size. Molecular sieves are three-dimensional inorganic crystalline lattices with a myriad of interconnected cavities, capable of retaining or sorbing water or other molecules, depending on the size of the channels and cavities within the crystal. Of the molecular sieves, the most widely used are the many zeolites which occur naturally and are also synthesized for specific purposes.

The zeolites are hydrated aluminum silicates and may contain sodium, potassium, calcium, and barium (241–244). The void spaces of the zeolites normally contain water, but the water can be removed by heating to give a uniformly porous lattice with empty spaces which can be refilled with gases, vapors, or molecules from solution. Although the zeolites give off water vapor when heated, unlike most other water-bearing crystals, they do not then collapse or disintegrate. After cooling, the lost water vapor is replaced or another gas is adsorbed.

X-ray diffraction studies have indicated that the zeolites contain a precise arrangement of cavities linked by channels (242). Water and exchangeable ions can pass through the interconnecting channels and occupy the cavities, facilitating the reversible processes of water removal and ion exchange. The structure of any zeolite crystal is based on a tetrahedral arrangement of oxygen atoms around a silicon or aluminum ion. Barrer and Meier (241) and Barrer and Stuart (242) described the structure of the common zeolite, chabazite, as consisting of two tight hexagons, each with six silicon and aluminum atoms, along with their associated oxygen atoms, facing each other and forming a flat prism. Eight such prisms are joined together to form an oval cavity of approximately 11.0 Å. The cavities are linked by six channels about 3.9 Å in diameter. Twenty-four water molecules and four calcium ions can occupy each chabazite cavity, of which there are 5×10^{21} cavities/in.^{3} of crystal (245). By contrast, the feldspars have the same silicon–oxygen and aluminum–oxygen tetrahedra, but they are arranged in a way that does not allow free spaces capable of enclosing guest molecules.

The zeolites are capable of sorbing, separating, or exchanging similar molecules (243–245). The molecule to be sorbed or exchanged must have a shortest dimension less than the shortest distance between chains in the zeolite lattice. The zeolites sorb only those molecules that are small enough to enter the channels of the dehydrated mineral lattice. Kipling (246) described the selective separation of mixtures of various organic compounds strictly by molecular size. For example, a particular molecular sieve adsorbs hexane while rejecting benzene, but the larger pore size molecular sieves accept benzene. Mixtures of compounds of a suitable size can be sorbed simultaneously; if the zeolite is sequentially exposed to the individual components, the first substance sorbed will be difficult to displace, resulting in very low sorption of a subsequent component (247).

The zeolites are also capable of ion exchange (243, 244); zeolites containing sodium exchange cations with a solution containing calcium ions, a property utilized commercially in the removal of calcium from hard water. The structure of the zeolites is essentially a silicate tetrahedra with partial replacement by aluminum, requiring additional exchangeable cations for electrical neutrality.

Benson and King (248) indicated that the molecular discrimination in adsorption by zeolites is largely due to differences in the polarizability of the adsorbate. Large molecules would be expected to undergo weak adsorption due to their bulkiness, which prevents strong interaction with adsorption sites. There appears to be a good correlation between the strength of adsorption and the polarizability of the adsorbate. Electrostatic bonding rather than dispersion forces is indicated as the mechanism of bonding by the function of certain zeolites which can discriminate between *ortho*- and *para*-hydrogen. Adsorption isotherms are approximately Langmuir in type, and multilayer adsorption does not generally occur above the critical temperature of the adsorbate. Below the critical temperature, multilayer adsorption generally occurs, and capillary condensation may result from the pores or channels limiting the extent of multilayer formation.

Synthetic zeolites can be prepared for specific separations by crystallization under controlled condi-

tions of temperature and the presence of specific ions to determine the channel size (243, 245, 249, 250). Adjustment of temperature affects the vibrations of the atoms in the zeolite crystal, which, in turn, affect the effective diameter of the channels. The essential criterion in the function of these molecular sieves is that the guest molecule be able to pass through the channel. An example of a synthetic zeolite is a sodium-bearing zeolite that will not sieve *n*-octane from isooctane. In fact, neither compound can enter its channels. However, a calcium-bearing zeolite has channels sufficiently large for only the *n*-octane to enter, giving rise to industrial processes used to improve gasolines. Recently synthesized zeolites specifically adsorb cyclohexane, carbon tetrachloride, *n*-hexane, or water (249).

A major use of the zeolites is in the dehydration of solvents or other materials due to their high affinity for water. The sorption capacity of the zeolites also makes them useful for gas storage, for storage and recovery of radioactive material, as carriers for catalysts in chemical reactions, and for many other applications in adsorption separations, hydrocarbon catalysis, and purifications (249).

Dextrans—Other materials capable of selective inclusion include the modified dextrans and certain support media that are used in column chromatography.

The modified dextrans are cross-linked dextran macromolecules that form a three-dimensional network of polysaccharide chains capable of functioning as a molecular sieve and of fractionating molecules according to size (251). Most modified dextrans are hydrophilic and swell in water or electrolyte solution to form a gel, hence the name "gel filtration" for the fractionating ability of these dextrans. There is also a chemical modification of dextran that is lipophilic and swells in many polar organic solvents as well as in water.

The dextran gel matrix has a porosity determined by the degree of cross-linkage in the polysaccharide network. Molecules larger than the maximum pore size of a particular modified dextran do not enter the matrix, whereas smaller molecules diffuse into the matrix to different degrees, depending on their size. Aqueous mixtures separate as a solution is passed through the gel column, the smallest molecules being the last to be eluted from the column. In addition to their molecular sieve capabilities, the modified dextrans are also used as gel matrixes for ion exchange in a manner similar to that of the zeolites. Other related materials used for affinity chromatography include agarose and the polyacrylamide gels.

Silica Gels—The last group of macromolecular inclusion compounds to be discussed is the silica gels. Like the zeolites and modified dextrans, the silica gels are molecular sieves with a high sorptive capacity. The silica gels are also capable of very high selectivity, perhaps greater than that of the other macromolecular inclusion compounds.

Silica gels are composed of an irregular three-dimensional network of silicon atoms connected by oxygen atoms in the same spatial relationship as the hydrogen-bonded oxygen atoms of water. The silica gels are formed by crystallization of the silicon–oxygen network around a guest molecule. After the inclusion structure has formed, the guest can be removed by heating or degassing. Since the guest acts as a template, the silica gel has strong sorptive properties for that particular molecular species. For example, a silica gel made in the presence of butyl orange as the guest will sorb that molecule to a greater extent than it will adsorb propyl orange (243), although it will accept other molecules of a suitable size and shape. The tailoring of silica gel adsorptive properties is a most unique capability that can be of significant importance when it is necessary to have such a highly specific separation.

Metabolism of 8-(Methylthio)cyclic 3′,5′-Adenosine Monophosphate by Rats and Dogs after Oral or Intravenous Dosing and *In Vitro* by Subcellular Preparations of Dog Liver

JACQUES DREYFUSS ˣ, JAMES M. SHAW, KEITH K. WONG, and ERIC C. SCHREIBER

Abstract □ 8-(Methylthio-^{14}C or -^{35}S)cyclic 3′,5′-adenosine monophosphate (I) was given intravenously to rats (5 mg/kg) and orally and intravenously to dogs (0.25, 2.5, or 50 mg/kg). Oral doses were absorbed well but slowly. Plasma half-lives in dogs were about 3 hr after oral or intravenous doses of 0.25 or 2.5 mg/kg and ranged from 5 to 12 hr after oral or intravenous doses of 50 mg/kg. Plasma glucose and insulin concentrations in dogs were increased by oral or intravenous doses of the compound. Regardless of the route, excretion of radioactivity by rats and dogs at all doses was chiefly in the urine (74–87% of the dose); the remainder was excreted in the feces or bile. Compound I was rapidly distributed to most tissues of dogs but entered the brain and certain portions of the eye slowly and to a limited extent. Urine and plasma of dogs and urine of rats contained I, 8-(methylthio)adenosine, and at least two other unidentified metabolites. Compound I and cyclic 3′,5′-adenosine monophosphate were metabolized *in vitro* by the soluble fraction of dog liver to form 8-(methylthio)adenosine-5′-monophosphate and adenosine-5′-monophosphate, respectively. These compounds were further converted to 8-(methylthio)adenosine and adenosine, respectively. Compound I was metabolized *in vitro* more slowly than cyclic 3′,5′-adenosine monophosphate.

Keyphrases □ 8-(Methylthio)cyclic 3′,5′-adenosine monophosphate—metabolism, dogs and rats after oral and intravenous doses, *in vitro* metabolism by subcellular dog liver preparations □ Adenosine monophosphate—activity mimicked by 8-(methylthio)cyclic 3′,5′-adenosine monophosphate, metabolism of analog *in vivo* and *in vitro* □ Metabolism—8-(methylthio)cyclic 3′,5′-adenosine monophosphate in dogs and rats after oral and intravenous doses and *in vitro* by subcellular dog liver preparations

Metabolism of 8-(Methylthio)cyclic 3′,5′-Adenosine Monophosphate by Rats and Dogs after Oral or Intravenous Dosing and *In Vitro* by Subcellular Preparations of Dog Liver

JACQUES DREYFUSS ˣ, JAMES M. SHAW, KEITH K. WONG, and ERIC C. SCHREIBER

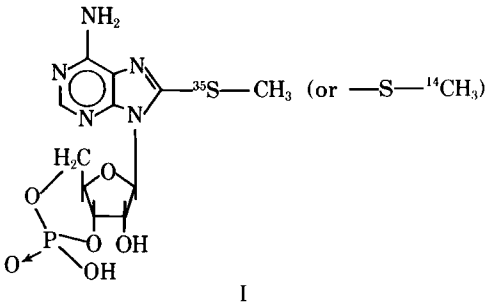
Abstract □ 8-(Methylthio-^{14}C or -^{35}S)cyclic 3′,5′-adenosine monophosphate (I) was given intravenously to rats (5 mg/kg) and orally and intravenously to dogs (0.25, 2.5, or 50 mg/kg). Oral doses were absorbed well but slowly. Plasma half-lives in dogs were about 3 hr after oral or intravenous doses of 0.25 or 2.5 mg/kg and ranged from 5 to 12 hr after oral or intravenous doses of 50 mg/kg. Plasma glucose and insulin concentrations in dogs were increased by oral or intravenous doses of the compound. Regardless of the route, excretion of radioactivity by rats and dogs at all doses was chiefly in the urine (74–87% of the dose); the remainder was excreted in the feces or bile. Compound I was rapidly distributed to most tissues of dogs but entered the brain and certain portions of the eye slowly and to a limited extent. Urine and plasma of dogs and urine of rats contained I, 8-(methylthio)adenosine, and at least two other unidentified metabolites. Compound I and cyclic 3′,5′-adenosine monophosphate were metabolized *in vitro* by the soluble fraction of dog liver to form 8-(methylthio)adenosine-5′-monophosphate and adenosine-5′-monophosphate, respectively. These compounds were further converted to 8-(methylthio)adenosine and adenosine, respectively. Compound I was metabolized *in vitro* more slowly than cyclic 3′,5′-adenosine monophosphate.

Keyphrases □ 8-(Methylthio)cyclic 3′,5′-adenosine monophosphate—metabolism, dogs and rats after oral and intravenous doses, *in vitro* metabolism by subcellular dog liver preparations □ Adenosine monophosphate—activity mimicked by 8-(methylthio)cyclic 3′,5′-adenosine monophosphate, metabolism of analog *in vivo* and *in vitro* □ Metabolism—8-(methylthio)cyclic 3′,5′-adenosine monophosphate in dogs and rats after oral and intravenous doses and *in vitro* by subcellular dog liver preparations

Ample documentation now exists that the biological effects of cyclic 3′,5′-adenosine monophosphate can be mimicked by certain of its analogs (1, 2). Such biologically active analogs might exhibit greater po-

tency, penetrability, tissue specificity, or stability than is the case with cyclic 3′,5′-adenosine monophosphate (2). 8-(Methylthio)cyclic 3′,5′-adenosine monophosphate (I) is one such analog that has exhibited activity in the stimulation of a purified cyclic 3′,5′-adenosine monophosphate-dependent protein kinase (3), the inhibition of cyclic nucleotide phosphodiesterase from cat heart and rat brain (4, 5), and the activation of tyrosine transaminase from hepatoma cells grown in culture (6).

The metabolism of I given to rats and dogs by oral and intravenous routes was studied to determine whether the 8-(methylthio) substituent altered its disposition as compared with that of cyclic 3′,5′-adenosine monophosphate. The results show that I was converted to 8-(methylthio)adenosine and other unidentified metabolites. In addition, I was metabolized *in vitro* more slowly than cyclic 3′,5′-adenosine monophosphate.



I

EXPERIMENTAL

Animals—Albino rats (Sprague–Dawley or Charles River CD) and purebred beagles were used. Animals were fasted overnight before the administration of drug and were housed in metabolism cages which permitted the separate collection of urine and feces.

Purity and Specific Activity—Compound I-^{35}S had an initial specific activity of 12.1 μCi/mg; no radiochemical impurities were detectable. Compound I-^{14}C had a specific activity of 2.76 μCi/mg; no radiochemical impurities were detectable.

Surgical Preparation of Dogs—Dogs were anesthetized with 30 mg/kg of pentobarbital sodium administered intravenously. A catheter was inserted into the bladder for the collection of urine. The radial vein was cannulated and infusion of the following solution, at the rate of 3 ml/min, was begun: mannitol, 100 g; KH_2PO_4, 200 mg; K_2HPO_4, 900 mg; pentobarbital sodium, 25.5 mg/kg; and sufficient water to make 2 liters. Mannitol was given to ensure an adequate flow of urine.

A midline incision was made, and the entrance to the gallbladder was clamped just above its point of entry into the common bile duct. A polyethylene catheter (No. 100) was then inserted about 1.3 cm (0.5 in.) into the common bile duct. The catheter was tied in place, and the midline incision was closed with wound clips.

Analysis of Urine and Bile—Samples of urine and bile were counted directly in 15 ml of Bray's scintillation fluid (7).

Analysis of Blood for ^{35}S—A 0.2-ml sample of heparinized blood was digested in 0.5 ml of 1.0 *N* NaOH by heating overnight at 80°. The sample was then bleached with 30% hydrogen peroxide, followed by neutralization with 0.2 ml of 2-ethylhexanoic acid. The sample was counted with 15 ml of Bray's scintillation fluid.

Analysis of Blood for ^{14}C—Samples of blood (0.2 ml) were combusted with a biological material oxidizer[1].

Analysis of Plasma—A 0.4-ml sample of plasma was dissolved in 2 ml of solubilizer[2]. The sample was counted with 15 ml of Bray's or toluene scintillation fluid. The toluene scintillation fluid contained, per liter, 5 g of 2,5-diphenyloxazole and 300 mg of 1,4-bis[2-(4-methyl-5-phenyloxazolyl)]benzene.

Analysis of Feces for ^{35}S—Fecal samples were homogenized in about three volumes of methanol. A 100-mg sample of the homogenate was digested in 1 ml of solubilizer for 16 hr with shaking and then bleached with 30% hydrogen peroxide. The sample was counted with 15 ml of Bray's scintillation fluid.

Analysis of Feces for ^{14}C—Samples of feces were homogenized with two to three volumes of methanol. About 400 mg of homogenate was combusted with the biological material oxidizer.

Analysis of Tissue for ^{35}S—Samples of brain were homogenized in water, using an all-glass homogenizer[3]; about 200 mg of homogenate was digested in 2 ml of solubilizer. Certain portions (about 200 mg) of the eye (lens, cornea, aqueous and vitreous humors, and combined retina, choroid, and sclera) or representative portions of the pancreas, renal and omental fat, skin (without hair), adrenal, thyroid and pituitary glands, and ovary were each placed in 2 ml of solubilizer. Samples of tissue from the heart, kidneys, liver, lungs, thigh muscle, and testes or the entire rat carcass were analyzed by first grinding the tissue in a meat grinder and then digesting about 200 mg of the well-mixed sample in 2 ml of solubilizer. All samples were counted in 15 ml of Bray's scintillation fluid.

Analysis of Tissue for ^{14}C—Samples of brain were homogenized in water, using an all-glass homogenizer; about 400 mg of homogenate was combusted with the biological material oxidizer. Certain portions of the eye (lens, cornea, aqueous and vitreous humors, and combined retina, choroid, and sclera) and representative portions of the pancreas, renal and omental fat, skin (without hair), adrenal, thyroid and pituitary glands, and ovary were combusted. Samples of tissue from the heart, kidneys, liver, lungs, thigh muscle, and testes or the entire rat carcass were analyzed by first grinding the tissue in a meat grinder and then combusting about 400 mg of the well-mixed sample.

Measurement of ^{14}C-Carbon Dioxide—To measure the $^{14}CO_2$ evolved, each rat was placed in a plastic metabolism cage[4] enclosed in a plastic bag. Air was drawn from the cages through two carbon dioxide-absorbing traps, connected in series with a vacuum line and containing monoethanolamine–2-methoxyethanol (1:3). The amount of radioactivity in the expired air was measured by adding a 0.5-ml sample of the absorbing solution to 2.0 ml of solubilizer, followed by 15 ml of toluene scintillation fluid.

Binding of Drug to Plasma Proteins—Binding measurements were made on 3-ml samples of plasma which were transferred to ultrafiltration membrane filter cones[5]; they were centrifuged at 25–30° for 30 min at 2000 rpm. After centrifugation, an aliquot of the ultrafiltrate and the plasma sample prior to centrifugation were solubilized in 2.0 ml of solubilizer and counted with 15 ml of toluene scintillation fluid.

Extraction Procedure for Feces—Samples of feces were homogenized with two to three volumes of methanol and then centrifuged; the supernatant fluid was recovered and saved. Chloroform–methanol (1:1), equal in volume to the supernatant fluid recovered, was added to the fecal residue, and the mixture was shaken for 30 min and centrifuged; the supernatant fluid was saved. This last step was repeated one more time. The supernates were combined and spotted directly for chromatography or were first concentrated to a suitable volume at 40–50° under reduced pressure. This extraction procedure removed an average of 59.8% of the radioactivity present in the fecal homogenates of dogs.

Chromatography—Samples of urine, bile, and extracts of feces and plasma were spotted on cellulose Q2-F[6] plates and developed in one or more of the following solvent systems: 1, isopropanol–28% ammonia–water (7:1:2); 2, *n*-butanol–pyridine–acetic acid–water (30:20:6:24); and 3, 95% ethanol–buffer (70:30). (The buffer was prepared by mixing 1 *M* ammonium acetate and 3×10^{-3} *M* ethylenediaminetetraacetate and adjusting the pH to 5.0 with acetic acid.)

Counting of Samples—The radioactivity in each sample was

Q2-198	F	Oral	2.5	4	2.8	4–12
Q3-10	M	Oral	50	8	9.6	8–48
Q2-198	F	Oral	50	4	11.9	12–48

[a] The type of radioactivity given to these dogs is indicated in Table V. [b] Intravenous doses were dissolved in 0.1 *M* Na_2CO_3. [c] Oral doses were administered in capsules. Tepid water (100 ml) was given to each dog immediately after the capsule.

determined with a liquid scintillation spectrometer[7]. Counting efficiency was determined with automatic external standardization and the use of previously prepared quench curves. Chromatograms were scanned for the presence of radioactivity with a scanner[8]. Areas of the various radioactive peaks were integrated by the use of a planimeter.

Calculation of Biological Half-Lives and Absorption and Elimination Rate Constants—Biological half-lives in the plasma were estimated graphically from linear portions of the appropriate semilogarithmic plots. Absorption rate constants were calculated as described by Rescigno and Segre (8).

Determination of Glucose Concentrations in Plasma—These analyses were performed automatically[9] by the method of Kornberg and Horecker (9).

Determination of Insulin Concentrations in Plasma—These analyses were performed employing an insulin radioimmunoassay kit[10]. The results were calculated from standard curves prepared from standardized human insulin.

Preparation of Subcellular Fractions from Dog Liver—Male beagle dogs (10–12 kg) were anesthetized intravenously (thiopental sodium, 30 mg/kg) and killed by exsanguination; the livers were removed. Samples of liver from different lobes were homogenized immediately in three volumes of 1.15% KCl, using a homogenizer[3]. The whole homogenate was centrifuged at 9000×*g* for 20 min, and the supernatant fraction was decanted through a single layer of gauze to remove some fat droplets; this fraction was designated the "postmitochondrial supernate."

The postmitochondrial supernate was centrifuged at 105,000×*g* for 60 min. The supernatant material, filtered through a single layer of gauze, was designated the "soluble fraction," and the pellet was resuspended in 6 ml of 1.15% KCl. This suspension was designated the "microsomal fraction," which was centrifuged again at 105,000×*g* for 60 min. After removal of the supernatant fluid, the pellet was resuspended again in 6 ml of 1.15% KCl and was designated the "washed microsomal fraction."

As controls, the postmitochondrial supernate or the soluble fraction was inactivated in a boiling water bath for 10 min. The coagulated protein was removed by filtration through a thin plug of glass wool, and the clear filtrate was designated the "boiled postmitochondrial supernate" or the "boiled soluble fraction."

Incubation of I and Cyclic 3′,5′-Adenosine Monophosphate *In Vitro*—Each incubation contained 0.2 ml of I, 5 m*M*; 0.2 ml of tromethamine buffer, 0.35 *M*, pH 7.4; 0.02 ml of $MgCl_2$, 250 m*M*; 0.02 ml of glucose-6-phosphate, 500 m*M*; 0.02 ml of NADP, 15 m*M*; and 0.02 ml of glucose-6-phosphate dehydrogenase[11] (two units). To each incubation was added 0.2 ml of the whole homogenate, postmitochondrial supernate, microsomal, washed microsomal, soluble, or boiled postmitochondrial supernatant fraction. Distilled water (0.32 ml) was added to provide a final volume of 1.0 ml. The incubation was carried out, with shaking, at 37° for 60 min; then the tubes were frozen immediately in an acetone–dry ice bath and stored in the freezer.

For the study of the metabolism of I-^{14}C (1 m*M*) or cyclic 3′,5′-adenosine-8-^{14}C monophosphate[12] (1 m*M*) as a function of time, the incubation mixtures were scaled up by increasing the amount of each ingredient by 3.5. Only the soluble fraction was used as the enzyme preparation, and the boiled soluble fraction served as the control. Aliquots (0.5 ml) were removed at different time intervals, as indicated in each experiment. Each aliquot was frozen immediately in an acetone–dry ice bath and then stored in the freezer. Each sample was chromatographed, as described under *Chromatography*. For the studies with cyclic 3′,5′-adenosine monophosphate, nonradioactive cyclic 3′,5′-adenosine monophosphate, adenosine-5′-monophosphate, and adenosine were used as reference compounds.

RESULTS

Absorption—In separate experiments, two dogs were given the ^{35}S-labeled compound, either 0.25 or 2.5 mg/kg iv, or the ^{14}C-labeled compound, 50 mg/kg iv. The concentrations of radioactivity found in the plasma of dogs after each dose during the first 12 hr are shown in Fig. 1. Shortly after dosing, concentrations of radioactivity in plasma reflected the amount of compound administered. After the distribution of radioactivity into tissues, the plasma concentrations of radioactivity decreased according to first-order kinetics.

Four dogs were given 2.5-mg/kg doses of I as a finely divided powder in capsules. Figure 2 shows the average concentrations of radioactivity in the plasma of these dogs during the first 12 hr after dosing. The compound was absorbed slowly, attaining an average maximum plasma concentration 3 hr after dosing, which was similar (about 1–2 μg/ml) to that found after a comparable intravenous dose. An average of 16.9 ± 6.4% (±*SE*) of the radioactivity was bound to the plasma proteins of these dogs 2 hr after they had been dosed.

Figure 3 shows similar data for two dogs that received an oral dose of 50 mg/kg. Plasma concentrations found at this higher dose reflect: *(a)* the greater dose administered, *(b)* the greater time required to absorb this larger dose, and *(c)* the greater persistence of radioactivity in the plasma, since the time scale for these two dogs extends to 48 hr.

Table I summarizes plasma half-lives for each dog after the oral and intravenous administration of I. The plasma half-lives were determined by a linear regression analysis for as long as the curves were linear and still significantly above background. Plasma half-lives after intravenous doses were about 3 hr with either the small-

[a] Average glucose concentration in the plasma of these dogs at zero time was 84 ± 1 mg %. [b] Average glucose concentration in the plasma of these dogs at zero time was 83 ± 4 mg %. [c] Average glucose concentration in the plasma of these dogs at zero time was 76 ± 4 mg %.

est or the intermediate dose and about 5 hr with the largest dose. After oral doses of 2.5 mg/kg, it took 2–4 hr to attain maximum plasma concentrations of radioactivity; after oral doses of 50 mg/kg, 4–8 hr was required.

Plasma half-lives after oral doses of 2.5 mg/kg ranged from 2.3–3.0 hr for the indicated time intervals, which were essentially the same as those found after a comparable intravenous dose. After oral doses of 50 mg/kg, plasma half-lives ranged from 9.6 to 11.9 hr and were about twice as long as those cited previously for the same intravenous doses. Absorption half-times, which were 1.1 hr with the smaller dose and 3.2 hr with the larger dose, support the slower absorption of the compound at the larger dose.

Studies of Glucose and Insulin—Compound I, like cyclic 3′,5′-adenosine monophosphate, is capable of producing a hyperglycemic effect. The data of Table II show plasma glucose concentrations as a function of time after intravenous doses of 0.25 or 2.5 mg/kg; they are expressed as the percent change from control values for each individual dog. Within 5 min, intravenous doses of 0.25 or 2.5 mg/kg of I produced significant elevations of plasma glucose; these levels returned to control values within 30–60 min after dosing. In these particular dogs, the larger intravenous dose did not produce a greater elevation of glucose concentration than did the smaller dose.

After an intravenous dose of 50 mg/kg, a marked elevation in glucose concentrations was seen within 5 min; these levels persisted for 1–2 hr and then returned toward control values. The elevations in plasma glucose seen after an intravenous dose of 50 mg/kg were considerably greater than after either of the two smaller doses. In fact, the response was so marked that both dogs seemed to exhibit an overshoot phenomenon in which plasma glucose concentrations were transiently depressed to approximately one-half the control values.

Changes in plasma glucose concentrations as a function of time after oral doses of 2.5 or 50 mg/kg are shown in Table III. At the smaller dose, average elevations of glucose were slight because one dog showed a good response, one dog showed a mild response, and two dogs showed no response. However, with the larger dose, both dogs showed hyperglycemic responses, beginning between 30 and 60 min in one case and between 1 and 1.5 hr in the other. This response was more delayed than that seen after intravenous dosing and correlated with the slow absorption of the compound. The extent of the response after oral dosing was also much less than that seen after comparable intravenous doses.

Plasma insulin concentrations were measured as a function of time in dogs that had received intravenous doses of 0.25 or 2.5 mg/kg of I (Table IV). Insulin concentrations in plasma generally followed a time course similar to that observed for glucose concentrations; they were steeply elevated within 5 min after dosing and returned to control values within 30–60 min. However, the elevations found for insulin concentrations, rising more than an order of magnitude for two dogs, were generally much greater than those found for glucose.

Excretion Studies—Excretion of radioactivity by rats after in-

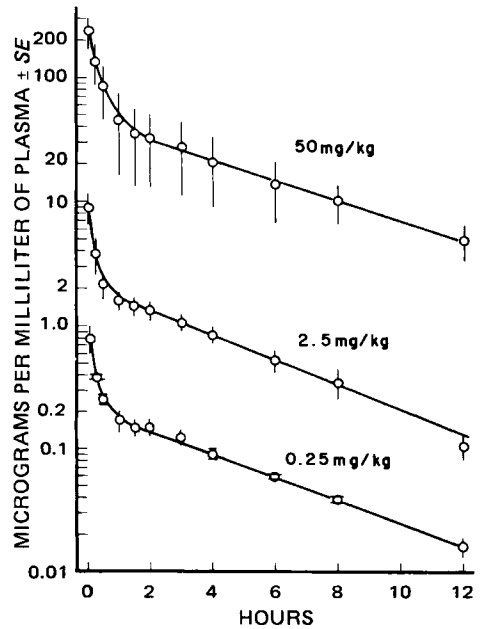

Figure 1—*Concentrations of radioactivity in the plasma of dogs after the intravenous administration of I. A male and a female dog were given the compound at each dose.*

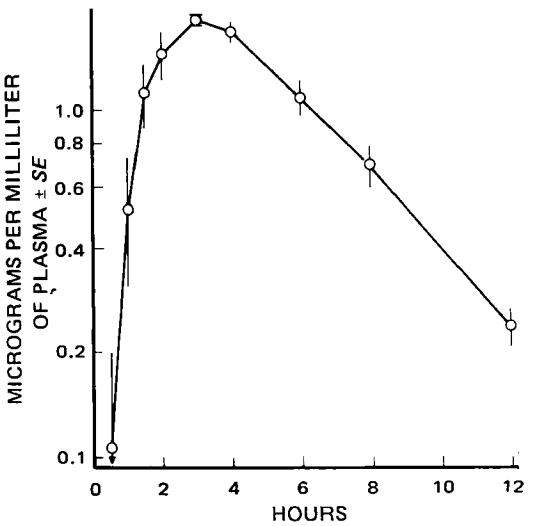

Figure 2—*Concentrations of radioactivity in the plasma of dogs after the oral administration of 2.5 mg/kg of I. Two male and two female dogs were given the compound in capsules.*

Table III—Concentrations of Glucose in the Plasma of Dogs as a Function of Time after the Oral Administration of I

Hours	2.5 mg/kg[a]	50 mg/kg[b] Dog Q3-10	50 mg/kg[b] Dog Q2-198
	Percent Change		
0	(0)	(0)	(0)
0.5	2 ± 6[c]	−1	15
1	5 ± 3	4	51
1.5	12 ± 14	40	80
2	21 ± 15	61	61
3	5 ± 10	4	27
4	4 ± 6	1	28
6	5 ± 6	22	30

[a] Four dogs, two of each sex, were used. Average glucose concentration in the plasma of these dogs at zero time was 110 ± 6 mg %. [b] Average glucose concentration in the plasma of these dogs at zero time was 80 ± 6 mg %. [c] Standard error.

travenous doses of 5 mg/kg of I bearing either the ^{35}S or ^{14}C label is shown in Table V. After administration of either radioactive compound, 74–87% of the dose was excreted in the urine and 8–14% in the feces. Dogs given intravenous doses of the ^{35}S-labeled compound at 0.25 and 2.5 mg/kg excreted radioactivity in a manner quantitatively similar to that seen for rats.

A single dog, prepared surgically for the collection of bile and given a 2.5-mg/kg dose of I intravenously, excreted 64% of the dose in the urine and 19% in the bile in 7 hr. One hour after it had been dosed, this dog had 8.8% of the radioactivity in the plasma bound to the plasma proteins. After an intravenous dose of 50 mg/kg, excretion of the ^{14}C-labeled compound was quantitatively similar to that of the ^{35}S-labeled compound when the latter had been given at 0.25 and 2.5 mg/kg.

After oral doses of 2.5 mg/kg, the excretion of radioactivity by dogs over a 5-day period was similar to that found after 50 mg/kg (Table V). From 76 to 82% of the dose was excreted in the urine and the remainder was excreted in the feces. Most of this radioactivity was excreted during the first 24 hr. These data are very similar to those found after comparable intravenous doses and indicate that at least four-fifths of an oral dose of I was absorbed by dogs.

Table VI shows the rate of excretion by rats of a 5-mg/kg iv dose of I-^{14}C. Of the 89% of the dose recovered in 4 days, 81% was excreted during the 1st day. Only 0.22% of the dose was excreted by these rats as $^{14}CO_2$, indicating that the methylthio side chain is not removed from the molecule to any appreciable extent.

Tissue Distribution—The distribution of radioactivity was studied in dogs 5 and 60 min after receiving 2.5 mg/kg iv of I (Table VII). One dog of each sex was studied at each time. Five minutes after dosing, when compared with the values found in the blood, radioactivity was highly localized in the excretory organs and widely distributed to most of the other tissues including the skin, pancreas, and other endocrine structures. Radioactivity was present in much smaller concentrations in the portions of the brain

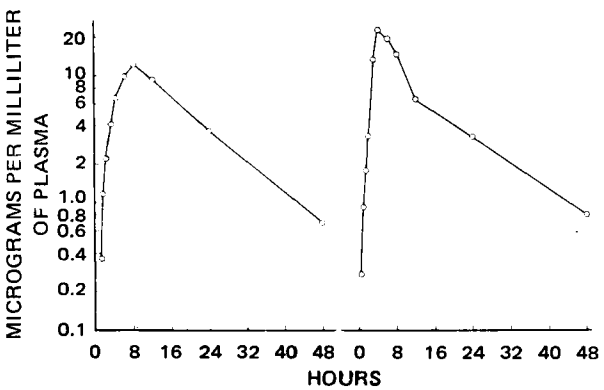

Figure 3—*Concentrations of radioactivity in the plasma of dogs after the oral administration of 50 mg/kg of I. A male (left) and a female (right) dog were given the compound in capsules.*

Table IV—Concentrations (Microunits per Milliliter) of Insulin in the Plasma of Dogs as a Function of Time after the Intravenous Administration of I

0	Lost	17	15	22
5	58	145	135	214
15	96	90	278	235
30	17	18	30	95
60	27	14	13	18

examined and in the various portions of the eye. Sixty minutes after dosing, the distribution of radioactivity in the various organs was much more uniform, but the amounts present in the brain were still only about one-tenth those present in the blood.

Biotransformation *In Vivo*—Urine that had been collected from rats and dogs during the first 24 hr after dosing with either 5 or 2.5 mg/kg, respectively, was chromatographed on thin-layer plates coated with cellulose and developed in Solvent System 1. The chromatographic reference compounds used were the parent compound, I, 8-(methylthio)adenosine-5′-monophosphate, 8-(methylthio)adenine, and 8-(methylthio)adenosine.

Four radioactive components were present in the urine of both rats and dogs (not shown), although the amounts varied between the species, particularly for the slowest moving component. Chromatography in System 1, as well as in the other two systems, indicated that the fastest moving component corresponded to 8-(methylthio)adenosine. No 8-(methylthio)adenosine-5′-monophosphate appeared to be present in these samples. Solvent System 2 clearly separates 8-(methylthio)adenosine from its adenine analog, and none of the latter was found in these samples of urine.

Figure 4 illustrates clearly the time-dependent transformation of I. These chromatograms are of urine from a dog in which the bile duct had been externalized; the urine was collected at hourly intervals. The sample collected during the 1st hr showed the presence primarily of unchanged I and of some 8-(methylthio)-

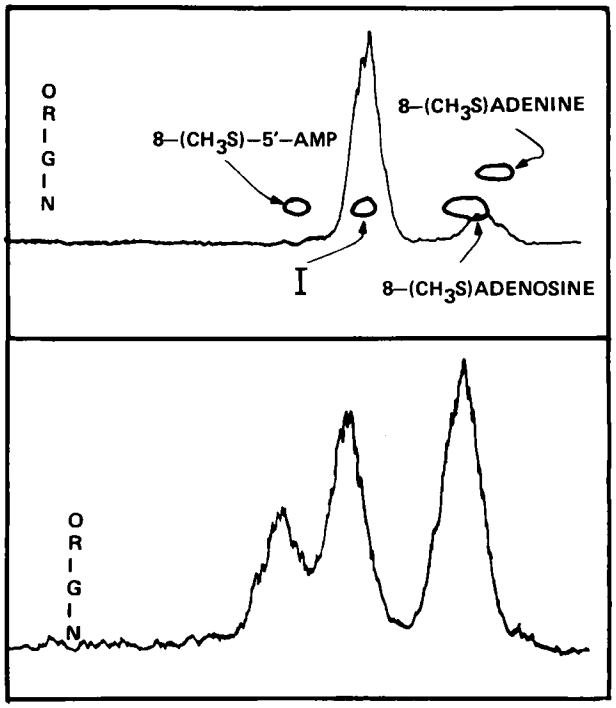

Figure 4—*Chromatograms of urine collected during the 1st (upper) and 3rd (lower) hr after the intravenous administration to a dog of 2.5 mg/kg of I. Urine was collected continuously from this dog for 7 hr. Solvent System 3 was employed. 8-(CH$_3$S)-5′-AMP is 8-(methylthio)adenosine-5′-monophosphate.*

Table V—Excretion of Radioactivity by Rats and Dogs after the Oral or Intravenous Administration of I

Species	Radio-activity	Route[a, b]	Dose, mg/kg	Average Percent of Dose ± SE: Urine	Feces or (Bile)	Total
4 Rats	^{35}S	Intravenous	5	86.66 ± 5.89	8.31 ± 2.00	94.97 ± 4.27[c]

	74.16 ± 8.82	14.29 ± 5.75	0.22 ± 0.02	88.66 ± 7.41

[a] Using 5 mg/kg. [b] After 4 days, the carcasses contained an average of 0.083 ± 0.044% (±*SE*) of the dose.

adenosine, based on chromatography in the three solvent systems. A sample of urine similarly analyzed during the 3rd hr after dosing showed the formation of an additional metabolite that traveled more slowly than I but was not 8-(methylthio)adenosine-5′-monophosphate and the increasing prominence of 8-(methylthio)adenosine. Studies with bile from this same animal (not shown) showed a similar time-dependent metabolic transformation.

Figure 5 shows chromatograms of urine collected from dogs during the first 24 hr after oral or intravenous doses of 50 mg/kg. Based on chromatography in the three solvent systems, these samples contained some I[13] and a good deal of 8-(methylthio)adenosine but no 8-(methylthio)adenosine-5′-monophosphate or 8-(methylthio)adenine. 8-(Methylthio)adenosine was also the principal metabolite in the feces of dogs that had been dosed orally with 2.5 mg/kg of I, as well as in the plasma of dogs that had been dosed intravenously with 2.5 or 50 mg/kg.

Table VIII shows some of these aspects quantitatively for the individual dogs. Chromatograms of urine of a dog shown in Fig. 5 indicate that only about 27% of the parent compound was present 5 hr after dosing, whereas 43% was then accounted for as 8-(methylthio)adenosine. In the urine of other dogs that had been given 50 mg/kg, from 33 to 59% was present as I in a 24-hr collection, and a large portion of the balance was accounted for as 8-(methylthio)-adenosine. After oral doses of 2.5 mg/kg, about 30% of the radioactivity in urine was I, with a good deal of the remainder being represented by the adenosine metabolite. After 50 mg/kg po, somewhat less of the radioactivity on the average was the parent compound, with a correspondingly greater amount as the adenosine metabolite.

Biotransformation *In Vitro*—The metabolism of I *in vitro* was studied with subcellular fractions of dog liver for two reasons: *(a)* to determine whether the cleavage of the 3′-bond occurred, since no 8-(methylthio)adenosine-5′-monophosphate was detectable *in vivo;* and *(b)* to determine the comparative rates of metabolism of I and cyclic 3′,5′-adenosine monophosphate *in vitro* under identical conditions. Incubation of I and appropriate cofactors with the whole liver homogenate, postmitochondrial supernate, and the soluble or microsomal fractions indicated that the soluble fraction contained all of the enzymatic activities involved in converting I to its metabolites.

[13] Presence of I was confirmed by mass spectrometry; unpublished data.

Figure 6 shows the results obtained by incubating I with the soluble fraction of dog liver. When the samples were developed in the three solvent systems, three components were consistently obtained. The slowest one corresponded in each case to 8-(methylthio)adenosine-5′-monophosphate, the component consistently found in the middle represented the unchanged parent compound, and the fastest moving component consistently corresponded to 8-(methylthio)adenosine.

[a] Urine was collected continuously.

Table IX shows the conversion of I to the adenosine-5′-monophosphate and adenosine metabolites as a function of time. 8-(Methylthio)adenosine-5′-monophosphate appeared to be formed first from I, since little of the adenosine metabolite was present after 20 min. After 3 hr, there were approximately equal amounts of I and 8-(methylthio)adenosine-5′-monophosphate and about 14% of the adenosine metabolite.

Table X shows the results of having incubated I-^{14}C and cyclic 3′,5′-adenosine monophosphate with the soluble fraction of dog liver as a function of time. Cyclic 3′,5′-adenosine monophosphate was converted very rapidly to adenosine-5′-monophosphate. After 30 min, only 20% of the original amount of cyclic 3′,5′-adenosine monophosphate remained, whereas 80% of the original amount of I was still present. Two hours after incubation with the soluble fraction of dog liver, 67% of the I still remained, but *none* of the cyclic 3′,5′-adenosine monophosphate was found at this time.

DISCUSSION

The metabolism of cyclic 3′,5′-adenosine monophosphate has been studied in a number of laboratories. Verbert and Cacan (10) showed the formation of cyclic 3′,5′-adenosine monophosphate, adenosine-5′-monophosphate, adenosine, and a trace of adenine after adenosine-5′-triphosphate-^{3}H had been incubated with rat liver plasma membranes containing adenyl cyclase. Pull and McIlwain (11) studied the metabolism of adenine-^{14}C by superfused and electrically stimulated cerebral tissues of guinea pigs. The compounds released from brain tissue to superfusion fluids included adenine, adenosine, inosine, and hypoxanthine and small amounts of cyclic 3′,5′-adenosine monophosphate, adenosine-5′-monophosphate, adenosine-5′-diphosphate, and adenosine-5′-triphosphate. The output of all these compounds, except adenine, increased upon electrical stimulation. When adenosine-5′-triphosphate-^{14}C was added at low concentrations to fluids superfusing the cerebral tissue, adenosine-^{14}C was the main product.

Rutten *et al.* (12), employing homogenates of rat pancreas to study the assay of cyclic 3′,5′-adenosine monophosphate phospho-

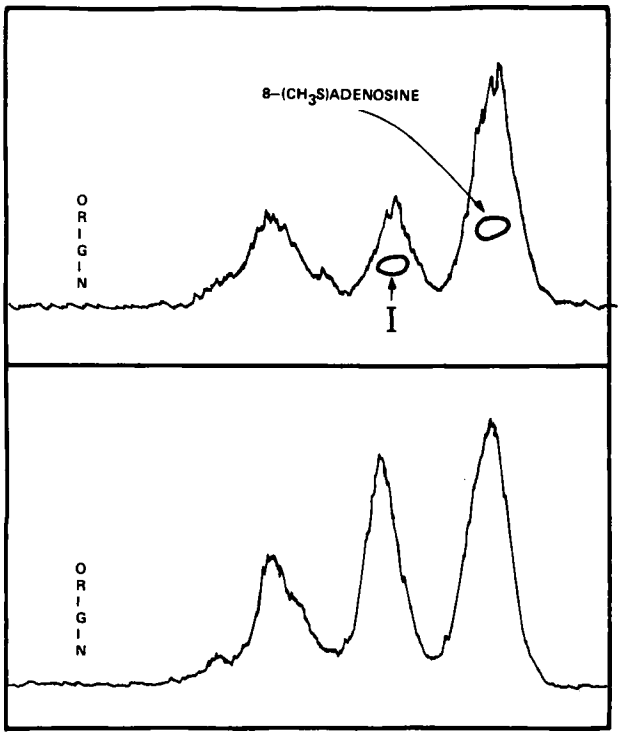

Figure 5—*Chromatograms of urine collected during the first 24 hr after the oral (upper) and intravenous (lower) administration to dogs of 50 mg/kg of I. Solvent System 2 was employed.*

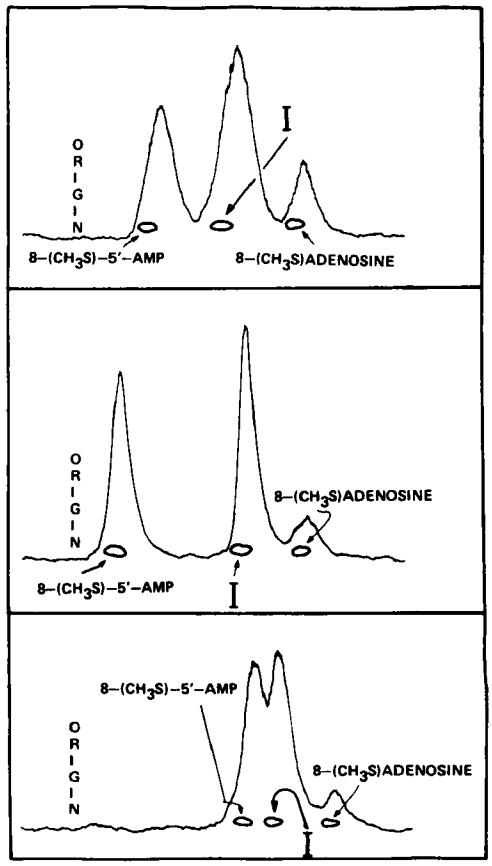

Figure 6—*Chromatograms of the incubation of I with the soluble fraction of dog liver. The samples were incubated at 37° for 150 min and developed in Solvent Systems 3 (upper), 1 (middle), and 2 (lower). 8-(CH_3S)-5′-AMP is 8-(methylthio)adenosine-5′-monophosphate.*

diesterase, concluded that the hydrolysis of cyclic 3′,5′-adenosine monophosphate to adenosine *via* adenosine-5′-monophosphate was the predominant pathway but that the conversion of cyclic 3′,5′-adenosine monophosphate to cyclic 3′,5′-inosine monophosphate also occurred to some extent. In another study, Lee and Dubos (13) examined the metabolism of cyclic 3′,5′-adenosine monophosphate in mice. Nine hours after the injection of cyclic 3′,5′-adenosine-8-^{14}C monophosphate into mice, the plasma contained some adenosine-5′-monophosphate, large amounts of adenosine, small amounts of adenine, and a small amount of an unidentified metabolite.

Compound I appears to be metabolized in a manner similar to that of cyclic 3′,5′-adenosine monophosphate. After incubation with the soluble fraction of dog liver *in vitro*, both cyclic 3′,5′-adenosine monophosphate and I are metabolized by the action of a phosphodiesterase to adenosine-5′-monophosphate or its 8-(methylthio) derivative and, subsequently, by the action of a nucleotidase to adenosine or its 8-(methylthio) derivative. *In vivo*, I appears to be excreted primarily as 8-(methylthio)adenosine, but other metabolites, which have not yet been identified, are also excreted.

The hyperglycemic response found after oral or intravenous doses of I would seem to be mediated by I, rather than by some of its potential metabolites, since neither 8-(methylthio)adenosine nor 8-(methylthio)adenine produced any increases in serum glucose after intravenous administration to dogs. Comparable studies with 8-(methylthio)adenosine-5′-monophosphate resulted in only marginal increases in serum glucose[14]. Compound I appears to be absorbed at least partly as such after oral dosing, since increases in glucose concentrations in the plasma were found in each of two dogs after 50 mg/kg and in one of four dogs after 2.5 mg/kg.

In these studies, 8-(methylthio)adenosine was found to be the major metabolite of I. Adenosine, the corresponding metabolite of cyclic 3′,5′-adenosine monophosphate, has been reported to have biological activity *in vitro* in a variety of tests. McKenzie and Bar (14) studied the mechanism of the inhibition of adenylate cyclase by adenosine. They found that adenylate cyclase activities from various sources were inhibited by adenosine but not by inosine. The inhibition of cyclic 3′,5′-adenosine monophosphate-dependent protein kinases by adenosine also has been reported (15, 16). Melnykovych and Bishop (17) studied glycogen concentrations in cultured HeLa cells. In this system, the presence of adenosine decreased the degradation of glycogen, thereby resulting in an increase of the glycogen concentrations.

In an unrelated study, Ortiz *et al.* (18) found that adenosine produced morphological alterations of iris epithelial cells *in vitro*. Adenosine has also been proposed as a regulator of lipolysis in isolated fat cells. Thus, Ebert and Schwabe (19) reported that lipolysis was increased by adenosine in a dose-dependent manner, and Fain (20) reported that the accumulation of cyclic 3′,5′-adenosine monophosphate in fat cells was inhibited by adenosine.

Adenine is toxic when administered intravenously to dogs for 3 weeks because of the formation and deposition of 2,8-dihydroxyadenine in the kidneys (21). Earlier studies (22, 23) with rats and mice that had been given adenine orally and intraperitoneally demonstrated its oxidation *in vivo* to 2,8-dihydroxyadenine and the deposition of the latter in the renal tubules. In the present studies on the metabolism of I in rats and dogs, the formation of 8-(methylthio)adenine did not appear to be a significant pathway, if it occurred at all. Moreover, the 8-position of the purine ring of I could not have been hydroxylated, since it already had a methylthio substituent.

Recently, Merits and Anderson (24) reported on the metabolic fate of the noncyclic nucleoside derivative, adenosine-5′-carboxylic acid ethyl ester-8-^{14}C, in rats, mice, and dogs. Their studies indicated that at least 94% of an oral dose of the compound was absorbed by dogs and that the compound did not traverse the blood–brain barrier to any great degree. Adenosine-5′-carboxylic acid ethyl ester was metabolized by rats, mice, and dogs, predominantly to adenosine-5′-carboxylic acid and, to a much smaller extent, inosine-5′-carboxylic acid. However, the dog eliminated only 71–82% of an oral dose of the radioactive compound within 3 days; most of the remainder was excreted slowly in the urine over the next 21 days. More detailed studies by Merits (25) of this phenomenon of prolonged elimination revealed that radioactivity from a dose of adenosine-5′-carboxylic acid ethyl ester was incorporated into the nucleic acids of mice and dogs. Most of the radioactivity seemed to be associated with ribosomal ribonucleic acid rather than with soluble ribonucleic acid or deoxyribonucleic acid. Merits (25) attributed the greater incorporation of radioactivity into the nucleic acids of dogs than those of mice to the more efficient mechanism of adenine "salvage" in dogs. The present studies of the metabolism of I in dogs indicate that there was no significant incorporation, if any, of radioactivity into nucleic acids, since the type of delayed excretion reported by Merits and Anderson (24) for adenosine-5′-carboxylic acid ethyl ester was not observed.

Microbial Kinetics of Drug Action against Gram-Positive and Gram-Negative Organisms II: Effect of Clindamycin on *Staphylococcus aureus* and *Escherichia coli*

SAMUEL M. HEMAN-ACKAH

Abstract □ Clindamycin-affected *Staphylococcus aureus* cultures show biphasic steady-state generation curves. An initial (phase I) generation of the clindamycin-affected *Staph. aureus* is followed by an ultimate (phase II) generation at the same dose level. The phase I apparent generation rate constant is greater than the phase II apparent generation rate constant and suggests the development of resistant *Staph. aureus* mutants to clindamycin action after a finite period of drug–bacteria contact at any subcompletely inhibitory concentration level. It is rationalized that the increased resistance to drug action in mutant strains is due to a comparatively reduced ribosomal binding affinity for clindamycin. In contrast, clindamycin-affected *Escherichia coli* cultures show monophasic steady-state generation curves at all concentration levels; *E. coli* cultures do not develop resistance to clindamycin action. The dependence of the apparent generation rate constant on drug concentration yields a sigmoidal curve, which is coincident by a potency factor for the phase I and phase II generations of clindamycin-affected *Staph. aureus* and suggests a common mechanism of action for both generation phases. That of clindamycin-affected *E. coli* yields an asymptote curve, which indicates a different mechanism of action. Clindamycin possesses both a bacteriostatic and a bactericidal action on initial and mutant resistant strains of *Staph. aureus*, whereas its action on *E. coli* is only bacteriostatic. Consequently, clindamycin has a minimum inhibitory concentration (MIC) against *E. coli* that is about 1000 times the MIC value against *Staph. aureus* at 37.5°. The effect of pH changes in broth media on generation inhibition of both *Staph. aureus* and *E. coli* by clindamycin action indicates that the unprotonated fraction of drug concentration contributes to the activity, possibly because of its ready penetration through cell membranes.

Keyphrases □ Microbial kinetics—drug action on Gram-positive and Gram-negative organisms, comparison of clindamycin action on *Staphylococcus aureus* and *Escherichia coli* □ Clindamycin—comparison of effects on *Staphylococcus aureus* and *Escherichia coli*, microbial kinetics □ *Staphylococcus aureus*—effects of clindamycin, compared to *Escherichia coli* □ *Escherichia coli*—effects of clindamycin, compared to *Staphylococcus aureus* □ Antimicrobial activity—comparison of clindamycin on *Staphylococcus aureus* and *Escherichia coli*

Clindamycin is one of the 7*(S)*-chloro analogs of lincomycin (1, 2) that is claimed to be more than four times as active as the parent antibiotic against a variety of Gram-positive and Gram-negative organisms (3). Like lincomycin, it interferes with ribosomal functioning in the synthesis of cell proteins (4, 5) to inhibit microbial growth and generation.

Comparative studies on the action of lincomycin and its 7*(S)*-chloro analogs against *Escherichia coli* by microbial kinetics (6) confirmed the enhanced potency of clindamycin action relative to that of lincomycin. These studies also revealed that clindamycin has only one of two mechanisms of lincomycin action against *E. coli*. Recently, it was shown (7) that lincomycin also possesses one mechanism of action against *Staphylococcus aureus*. However, *Staph. aureus* cultures, unlike *E. coli*. cultures, develop resistence to lincomycin after a finite period of organism contact with subcompletely inhibitory concentrations of the drug.

It was of interest to study the kinetics and dependencies related to modes of clindamycin action

Microbial Kinetics of Drug Action against Gram-Positive and Gram-Negative Organisms II: Effect of Clindamycin on *Staphylococcus aureus* and *Escherichia coli*

SAMUEL M. HEMAN-ACKAH

Abstract □ Clindamycin-affected *Staphylococcus aureus* cultures show biphasic steady-state generation curves. An initial (phase I) generation of the clindamycin-affected *Staph. aureus* is followed by an ultimate (phase II) generation at the same dose level. The phase I apparent generation rate constant is greater than the phase II apparent generation rate constant and suggests the development of resistant *Staph. aureus* mutants to clindamycin action after a finite period of drug–bacteria contact at any subcompletely inhibitory concentration level. It is rationalized that the increased resistance to drug action in mutant strains is due to a comparatively reduced ribosomal binding affinity for clindamycin. In contrast, clindamycin-affected *Escherichia coli* cultures show monophasic steady-state generation curves at all concentration levels; *E. coli* cultures do not develop resistance to clindamycin action. The dependence of the apparent generation rate constant on drug concentration yields a sigmoidal curve, which is coincident by a potency factor for the phase I and phase II generations of clindamycin-affected *Staph. aureus* and suggests a common mechanism of action for both generation phases. That of clindamycin-affected *E. coli* yields an asymptote curve, which indicates a different mechanism of action. Clindamycin possesses both a bacteriostatic and a bactericidal action on initial and mutant resistant strains of *Staph. aureus*, whereas its action on *E. coli* is only bacteriostatic. Consequently, clindamycin has a minimum inhibitory concentration (MIC) against *E. coli* that is about 1000 times the MIC value against *Staph. aureus* at 37.5°. The effect of pH changes in broth media on generation inhibition of both *Staph. aureus* and *E. coli* by clindamycin action indicates that the unprotonated fraction of drug concentration contributes to the activity, possibly because of its ready penetration through cell membranes.

Keyphrases □ Microbial kinetics—drug action on Gram-positive and Gram-negative organisms, comparison of clindamycin action on *Staphylococcus aureus* and *Escherichia coli* □ Clindamycin—comparison of effects on *Staphylococcus aureus* and *Escherichia coli*, microbial kinetics □ *Staphylococcus aureus*—effects of clindamycin, compared to *Escherichia coli* □ *Escherichia coli*—effects of clindamycin, compared to *Staphylococcus aureus* □ Antimicrobial activity—comparison of clindamycin on *Staphylococcus aureus* and *Escherichia coli*

Clindamycin is one of the 7*(S)*-chloro analogs of lincomycin (1, 2) that is claimed to be more than four times as active as the parent antibiotic against a variety of Gram-positive and Gram-negative organisms (3). Like lincomycin, it interferes with ribosomal functioning in the synthesis of cell proteins (4, 5) to inhibit microbial growth and generation.

Comparative studies on the action of lincomycin and its 7*(S)*-chloro analogs against *Escherichia coli* by microbial kinetics (6) confirmed the enhanced potency of clindamycin action relative to that of lincomycin. These studies also revealed that clindamycin has only one of two mechanisms of lincomycin action against *E. coli*. Recently, it was shown (7) that lincomycin also possesses one mechanism of action against *Staphylococcus aureus*. However, *Staph. aureus* cultures, unlike *E. coli*. cultures, develop resistence to lincomycin after a finite period of organism contact with subcompletely inhibitory concentrations of the drug.

It was of interest to study the kinetics and dependencies related to modes of clindamycin action

against *Staph. aureus* and to compare the data with those obtained for *E. coli*. The results of such studies are presented in this paper.

EXPERIMENTAL

Materials and Methods—*Staph. aureus* (ATCC 6538) and *E. coli* (ATCC 12407) were used in all of the experiments. They were cultivated in broth medium[1] and used for determining antibiotic–bacteria reaction in the same manner as previously described (7). The antibiotic was an assayed sample of clindamycin hydrochloride[2] (860 μg base equivalent/mg). A particle-size counter[3] and the poured plate method, using sandwiched agar plates, were employed in the determination of total and viable counts, respectively, on drug-free and drug-affected *Staph. aureus* cultures as previously described (7).

Effect of Antibiotic Concentrations on Generation Rates—Aliquots (0.5 ml) of aqueous solutions of clindamycin were aseptically added to replicate 50-ml samples of cultures to yield the desired antibiotic concentrations. The solutions were added to the cultures in an exponential phase of generation at 37.5°. The cell concentration at the time of drug addition was 2.0×10^6/ml. Culture samples were withdrawn every 30 min, and the organism population was determined by the appropriate method.

Generation curves were obtained by the total count method for *Staph. aureus* and *E. coli* cultures affected with a range of clindamycin concentrations (0–0.1 and 0–120 μg/ml, respectively). Generation curves for *Staph. aureus* cultures affected with selected clindamycin concentrations (0, 0.04, 0.05, 0.07, 0.08, 0.16, and 0.32 μg/ml) and for *E. coli* cultures affected with selected clindamycin concentrations (0, 25, 50, 100, and 200 μg/ml) were also obtained by both total and viable count methods.

Effect of Broth Composition on Drug-Affected Generation Rates—Three different types of broth, containing half, single, and double concentrations of the ingredients as specified by the manufacturer, were prepared and adjusted to pH 7.05 ± 0.05 where necessary. They were used for determining the generation curves at 37.5° of replicate *Staph. aureus* cultures affected with clindamycin concentrations of 0, 0.03, 0.05, 0.07, and 0.09 μg/ml. The organism concentration at the time of drug addition was 2×10^6 cells/ml. Total counts were obtained on samples withdrawn every 30 min.

Effect of Organism Population on Drug-Affected Generation Rates—Three sets of single strength broth were prepared and used for determining the generation curves of replicate *Staph. aureus* cultures affected with clindamycin concentrations of 0, 0.03, 0.05, 0.07, and 0.09 μg/ml. The organism concentrations at the time of drug addition were 5.0×10^5, 2.0×10^6, and 2.0×10^7 cells/ml in the respective sets of broth. Total counts were obtained on samples withdrawn every 30 min.

Reversibility of Drug Action—An aliquot (0.5 ml) of an aqueous solution of clindamycin was aseptically added to a 50-ml sample of *Staph. aureus* culture in the exponential phase of generation at 37.5° to yield a final concentration of 0.03 μg/ml of clindamycin. The cell concentration at the time of drug addition was 2.0×10^6 cells/ml. When the drug-affected culture settled to a steady-state generation phase I, an aliquot (0.5 ml) was added to 49.5 ml of fresh broth so that both the organism and drug concentrations were diluted 100-fold. At the same time, an aliquot (0.5 ml) of the culture was diluted 100-fold in broth containing enough clindamycin so that the drug concentration was restored to 0.03 μg/ml.

A drug-free culture was likewise diluted 100-fold as a control. When the sample of the drug-affected culture, which was diluted in fresh broth, emerged from a lag phase into steady-state generation, an aliquot (0.5 ml) of clindamycin solution was added to its replicate culture to reestablish the drug concentration at 0.03 μg/ml.

The entire dilution steps were repeated on the initial drug-affected culture when it entered into a steady-state generation phase II. Total counts were obtained on samples withdrawn every 30 min.

The experiment then was performed on another 50-ml sample of *Staph. aureus* culture affected with a higher concentration of the drug, *i.e.*, 0.06 μg/ml of clindamycin.

Effect of pH on Drug-Affected Generation Rates—Sufficient amounts of 2.0 *N* HCl and 2.0 *N* NaOH were added to the broth media to obtain pH values of 5.9, 6.3, 6.5, 7.0, 7.3, 7.6, 7.8, and 8.2. Six replicate 50-ml volumes of each broth, inoculated with *Staph. aureus*, were maintained at 37.5° until the organism population reached 2.0×10^6 cells/ml. Aliquots (0.5 ml) of clindamycin solutions were added to five replicates to achieve the desired concentrations of antibiotic. The sixth replicate in each set contained no drug. Total counts were obtained from samples withdrawn every 30 min.

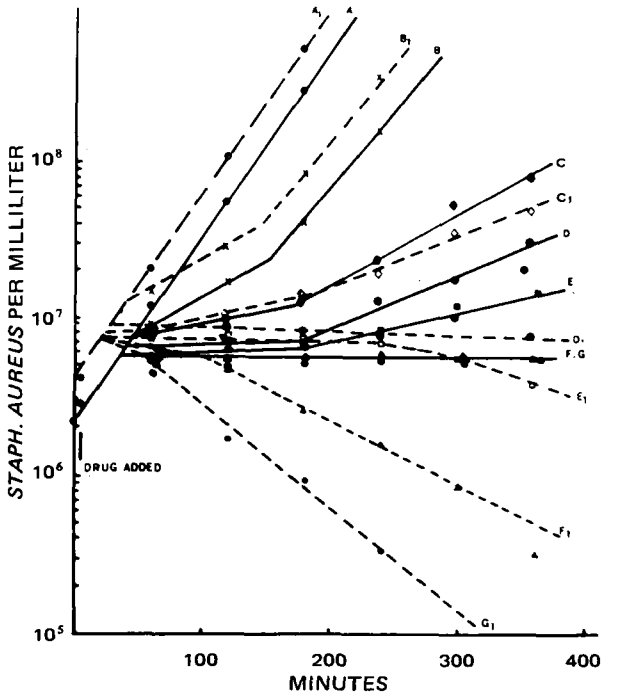

Figure 1—*Generation curves of* Staph. aureus *at pH 7.05 and 37.5° in the absence and presence of clindamycin obtained by total (——) and viable (- - -) counts. The curves and respective drug concentrations (micrograms per milliliter) are: A and A_1, 0.0; B and B_1, 0.04; C and C_1, 0.05; D and D_1, 0.07; E and E_1, 0.08; F and F_1, 0.16; and G and G_1, 0.32.*

RESULTS

Shape of Generation Curves for Drug-Affected Cultures—Semilogarithmic plots of total and viable counts *versus* time are shown in Fig. 1 for the action of selected clindamycin concentrations of 0, 0.04, 0.05, 0.07, 0.08, 0.16, and 0.32 μg/ml on *Staph. aureus*. Figure 2 shows these plots for the action of clindamycin concentrations of 0, 25, 50, 100, and 200 μg/ml on *E. coli*. The addition of graded concentrations of clindamycin to balanced cultures of *Staph. aureus* (Fig. 1) and *E. coli.* (Fig. 2) in the exponential phase of generation at 37.5° and pH 7.05 decreased the generation rates after a lag period approximating 20 min. With the *Staph. aureus* cultures, a newly established steady-state phase of generation (phase 1) was followed after one to two generations by an ultimate steady-state phase of generation (phase II). Clindamycin-affected *E. coli* cultures exhibited one steady-state phase of generation.

Apparent generation rate constants of the drug-affected cultures are obtained from the slopes of the linear portions of semilogarithmic plots of the counts *versus* time in accordance with the expression:

$$\ln N = \ln N_0 + k_{app}t \qquad \text{(Eq. 1)}$$

where N is the number of organisms per unit volume of broth medium of any time, t; N_0 is the number of organisms per unit volume of broth medium at some initial time, 0, in the generation phase; and k_{app} (in seconds^{-1}) is the apparent generation rate con-

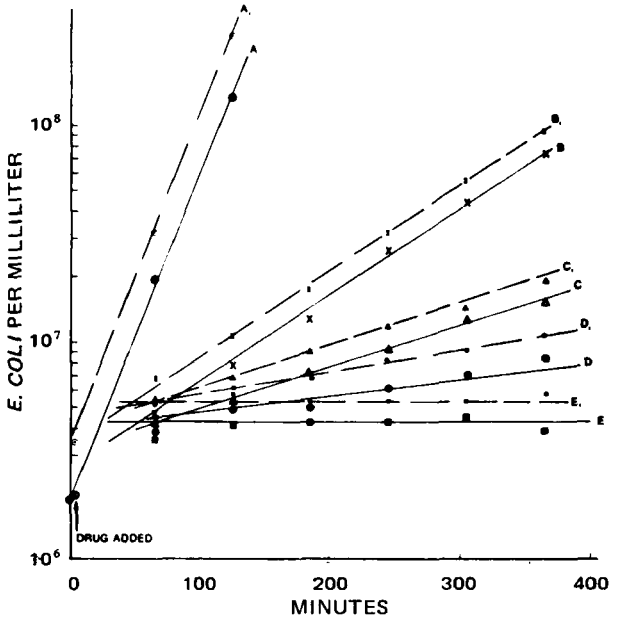

Figure 2—*Generation curves of* E. coli *at pH 7.05 and 37.5° in the absence and presence of clindamycin obtained by total (——) and viable (- - -) counts. The curves and respective drug concentrations (micrograms per milliliter) are: A and A_1, 0.0; B and B_1, 25.0; C and C_1, 50.0; D and D_1, 100.0; and E and E_1, 200.0.*

stant. In the absence of drug, $k_{app} = k_0$, which is the generation rate constant for the drug-free or control culture.

The k_{app} for phase I and phase II generations of clindamycin-affected *Staph. aureus* is designated k_{app_I} and $k_{app_{II}}$, respectively. The k_{app_I} value is less than the $k_{app_{II}}$ value for the action of subcompletely inhibitory concentrations of clindamycin determined by the total count method.

Generation Curves of Drug-Affected Cultures Determined by Total and Viable Count Methods—Parallel generation curves are obtained from plots of the total and viable counts for *Staph. aureus* cultures (Fig. 1) affected with clindamycin in the 0–0.04-μg/ml concentration range. The total count was 50% of the viable count at each concentration level (curves A_1, A and B_1, B). The cultures affected with 0.05–0.08 μg/ml of clindamycin showed

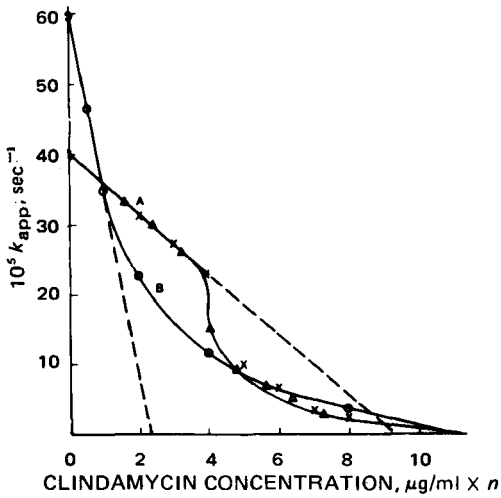

Figure 3—*Functional dependency of apparent generation rate constants,* k_{app} *in seconds*$^{-1}$*, for drug-affected* Staph. aureus *and drug-affected* E. coli *on concentrations of clindamycin (micrograms per milliliter) at pH 7.05 and 37.5°. Actual concentrations are multiplied by a factor,* n, *where* n = *100 in curve A for* Staph. aureus *phase I generation (×),* n = *80 in coincident curve for* Staph. aureus *phase II generation (▲), and* n = *0.1 in curve B for* E. coli *(○).*

complete generation inhibition for 200 min when the total count also remained 80–90% of the viable count. Thereafter, there was a drop in the viable count whereas there was a progressively small increase in the total count with time (curves C_1, C, D_1, D, and E_1, E).

Cultures affected with concentrations of clindamycin greater than 0.08 μg/ml showed coincidence of plots for the total counts, which remained constant for the entire experiment (curves F and G). The corresponding plots for the viables showed a rapid drop of the count with time as a function of the drug concentration (curves F_1 and G_1). This finding clearly indicates that a bactericidal or lytic phenomenon is superimposed on generation inhibition by the action of clindamycin at concentrations of 0.04 μg/ml.

Parallel generation curves are obtained from plots of the total and viable counts for *E. coli* cultures (Fig. 2) affected with clindamycin in the subcompletely inhibitory concentration range (curves A_1, A, B_1, B, C_1, C, and D_1, D) and also above the bacteriostatic concentration (curves E_1 and E). The total count was 50–80% of the viable count at each concentration level. There was no evidence of a bactericidal or lytic phenomenon superimposed on generation inhibition by the action of clindamycin in the concentration range studied.

Functional Dependency of Generation Rates on Drug Concentrations—Figure 3 shows the plot of k_{app} *versus* clindamycin concentration for *Staph. aureus*-affected cultures (curve A) and for *E. coli*-affected cultures (curve B). Coincidence of plots was obtained when the actual concentrations for the phase I and phase II clindamycin action on *Staph. aureus* were multiplied by a factor of 1.0 and 0.80, respectively (curve A). The extent of generation inhibition was directly proportional to the clindamycin concentration, C, in the 0–0.04-μg/ml range for the phase I action and in the 0–0.05-μg/ml range for the phase II action on *Staph. aureus* or in the 0–10.0-μg/ml range for the action on *E. coli*, in accordance with the expression:

$$k_{app} = k_0 - k_c C \qquad \text{(Eq. 2)}$$

where k_c is the specific inhibitory rate constant.

At higher drug concentrations, the k_{app} was not a linear function of increasing drug concentrations, but it asymptotically approached zero. There was a striking difference between the k_{app} dependency on drug concentration for *Staph. aureus* cultures affected with clindamycin at concentrations greater than 0.04 μg/ml and that for *E. coli* cultures affected with clindamycin at concentrations greater than 10.0 μg/ml. The rate of decrease of k_{app} with an increase in drug concentration was greater than would be obtained by extrapolation of the initial linear portion of the regression for the *Staph. aureus* cultures (curve A) but was less than would be predicted by such an extrapolation for *E. coli* cultures (curve B). Consequently, sigmoidal curves were obtained from plots of the data for *Staph. aureus* cultures. This finding may indicate that there is a change in the bioavailability or binding affinity of the clindamycin for bioreceptors which permits enhanced inhibition and/or kill of the *Staph. aureus* cultures but reduces the extent of generation inhibition of *E. coli* cultures.

Applicability of Saturation Kinetics to Action of Clindamycin on *Staph. aureus* and *E. coli*—The plot of $C/(k_0 - k_{app})$ *versus* C is given in Fig. 4. The plot is in accordance with a previously (8) derived, saturable receptor site model:

$$C/(k_0 - k_{app}) = C(k_b/k_a) + 1/k_a \qquad \text{(Eq. 3)}$$

where $k_b = K_1K_2$ and $k_a = qK_1K_2$. The term K_1 is the drug partition constant through cell membranes, K_2 is the drug affinity constant for bioreceptors, and q is a constant of proportionality related to the metabolic activity of the microbial cell.

Adherence to Eq. 3 is observed from linear plots obtained for concentrations of clindamycin greater than 0.04 μg/ml in phase I action (curve A) and greater than 0.05 μg/ml in phase II action (curve B) against *Staph. aureus* or greater than 10.00 μg/ml (curve C) against *E. coli*. Deviations from linearity of the plot occurred at concentrations of clindamycin less than 10.00 μg/ml against *E. coli* or less than 0.04 μg/ml in phase I and less than 0.05 μg/ml in phase II against *Staph. aureus*. These findings demonstrate a nonadherence to a saturable process at the lower concentration ranges. Additionally, the plots for *Staph. aureus* show a complete break and displacement of the saturable from the nonsaturable level, which may indicate a change in drug partitioning and/or binding properties in the biophase.

Table I—Kinetic Parameters of Clindamycin Action on *Staph. aureus* and *E. coli*

Kinetic Parameter[a]	*Staph. aureus* Phase I	*Staph. aureus* Phase II	*E. coli*
$10^5 k_c$, ml/μg sec[b]	416.67	322.50	2.56
$10^5 k_a$, ml/μg sec[c]	1333.33	1111.11	3.70
$10^5 k_a/k_b$, sec^{-1}[c]	54.17	54.17	70.00
$(k_a/k_b)/k_0$[c]	1.35	1.35	1.11
$10^2 k_b$, ml/μg[c]	2461.53	2051.27	5.28
MIC, μg/ml[d]	0.11	0.14	113.20

[a] Derived from data of Fig. 3. [b] Calculated from the slope of the plot of k_{app} *versus* concentration from 0 to 0.04 μg/ml of clindamycin in phase I action and from 0 to 0.25 μg/ml of clindamycin in phase II action on *Staph. aureus* or from 0 to 10 μg/ml of clindamycin action on *E. coli*, in accordance with Eq. 2. [c] The k_a, k_a/k_b, $(k_a/k_b)/k_0$, and k_b values are estimated from the slopes and intercepts of plots of C $(k_0 - k_{app})$ *versus* C from Eq. 3 for clindamycin concentrations greater than 0.04 μg/ml in phase I action and greater than 0.05 μg/ml in phase II action on *Staph. aureus* or greater than 10 μg/ml on *E. coli*. [d] Calculated from Eq. 4, where clindamycin is at the MIC.

The values of k_a and k_b calculated from the slopes and intercepts of such plots are given in Table I. The minimum inhibitory concentration (MIC) of clindamycin in Table I is calculated from the expression (7):

$$C_m = k_0/(k_a - k_0 k_b) \qquad \text{(Eq. 4)}$$

where C_m is the MIC. It is estimated that clindamycin has an MIC value against *E. coli* that is about 1000 times the MIC value against *Staph. aureus*.

Effect of Broth Media of Different Compositions—Table II gives the apparent generation rate constants of drug-free and drug-affected *Staph. aureus* cultures in three broth media of different compositions. Variations in generation rate constants among the different media at each concentration level of clindamycin were not significantly different from those observed in the daily variations observed in organism generation rates, as previously was found for *E. coli* (6).

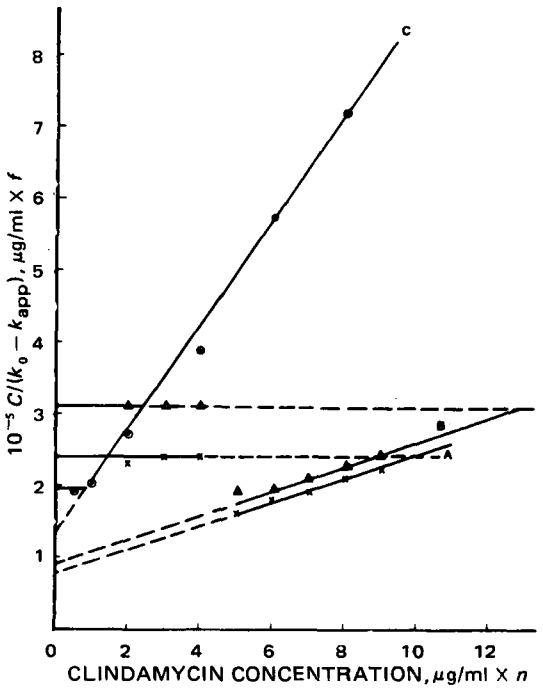

Figure 4—*Applicability of saturation kinetics to the action of clindamycin on* Staph. aureus *and* E. coli *at pH 7.05 and 37.5°. Curve A is for clindamycin-affected* Staph. aureus *in phase I generation (×), curve B is for clindamycin-affected* Staph. aureus *in phase II (▲), and curve C is for clindamycin-affected* E. coli *(⊙). Curves are plotted in accordance with Eq. 3. Actual values of* $C/(k_0 - k_{app})$ *are multiplied by a factor,* f, *where* f = *1000 for curves A and B and* f = *5 for curve C. Actual clindamycin concentrations are also multiplied by a factor,* n, *where* n = *100 for curves A and B and* n = *0.1 for curve C.*

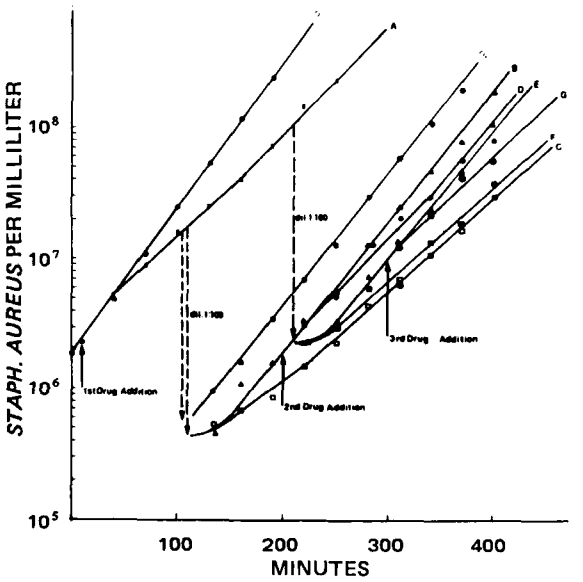

Figure 5—*Semilogarithmic plots of reversibility studies of* Staph. aureus *with time of addition of clindamycin and dilution of the cultures with broth. Curve O is without drug. Curve A is after addition of clindamycin to the culture of curve O to a final concentration of 0.03 μg/ml; curve O_1 is for the drug-free culture of curve O diluted 100-fold with broth. Curves B and E are for the drug-affected culture of curve A diluted 100-fold with broth during phase I and phase II generations, respectively, so that the final clindamycin concentration is reduced to 0.0003 μg/ml. Curves C and F are for the drug-affected culture of curve A diluted 100-fold with broth containing a sufficient amount of clindamycin during phase I and phase II generations, respectively, so that the final clindamycin concentration is reestablished at 0.03 μg/ml. Curve D is for the diluted culture of curve B that has emerged from lag phase and clindamycin has been added to restore the concentration to 0.03 μg/ml. Curve G is for the diluted culture of curve E that has similarly emerged from lag phase and clindamycin has been added to restore the concentration to 0.03 μg/ml.*

Effect of Inoculum Size at Time of Drug Addition—The apparent generation rate constants of drug-free and drug-affected *Staph. aureus* cultures, which varied in organism population at the time of drug addition, are also given in Table II.

There were no significant variations among the generation rate constants for the different organism populations at each concentration level of the clindamycin studied, as previously was found for *E. coli* (6).

Reversibility of Clindamycin Action—The results obtained for reversibility of clindamycin action on *Staph. aureus* at concentration levels of 0.03 and 0.06 μg/ml are shown in Figs. 5 and 6, respectively.

The equilibration of clindamycin between the broth medium and the biophase in *Staph. aureus* was readily achieved. It took 20–25 min after drug addition for cultures affected with 0.03 μg/ml (curve A in Fig. 5) and 0.06 μg/ml (curve A in Fig. 6) to attain a new steady-state phase of generation.

The steady-state generation of drug-free culture (curve O in Figs. 5 and 6), when diluted 100-fold, reverted to a new steady state with a predictable rate constant (curve O_1 in Figs. 5 and 6). The diluted culture showed an apparent initial lag phase period of 5–10 min before reverting to the new steady state. This lag may be attributed to a possible need for cell rejuvenation before reestablishment of the new steady state or to a consequence of the shock of dilution.

Table II—Effect of Variations in Broth Composition and Inoculum Size on Phase I and Phase II Generation Rates of Clindamycin-Affected *Staph. aureus*

Clindamycin Concentration, μg/ml	$k_{app} \times 10^{-5}$ sec^{-1}

The generation pattern of drug-affected *Staph. aureus*, when diluted 100-fold, depended on the concentration level of the clindamycin employed. For the culture affected with the 0.03-μg/ml clindamycin concentration, dilution of the culture in phase I (curve B in Fig. 5) or phase II (curve E in Fig. 5) generation resulted in a short lag phase of approximately 20–25 min. Thereafter, a new steady generation was established at a rate similar to that of the control culture (curve O in Fig. 5). This finding shows that the drug action is nullified by high dilution in broth. It also indicates that the rate of dissociation of the drug–receptor complex in the biophase is the same as the rate of formation of complex and/or the rate of diffusion of drug from the broth medium into the biophase through cell membranes.

The addition of clindamycin to the diluted cultures of curves B and E (Fig. 5), which had emerged from the lag phase, to restore the concentration to 0.03 μg/ml resulted in a short period of equilibration, *i.e.*, 5–10 min, followed by a new steady-state generation (curves D and G, respectively) with predictable rate constants. Likewise, a 1:100 dilution of the drug-affected culture of curve A (Fig. 5) during phase I (curve C in Fig. 5) or phase II (curve F in Fig. 5) so as to reestablish the concentration to 0.03 μg/ml resulted in a new steady-state generation with predictable rate constants. The new steady-state generations were preceded by a short lag period of 20–25 min. These observations indicate that clindamycin action on *Staph. aureus* at a concentration level of 0.03 μg/ml is rapidly reversible and is similar to that reported (6) for *E. coli* at a

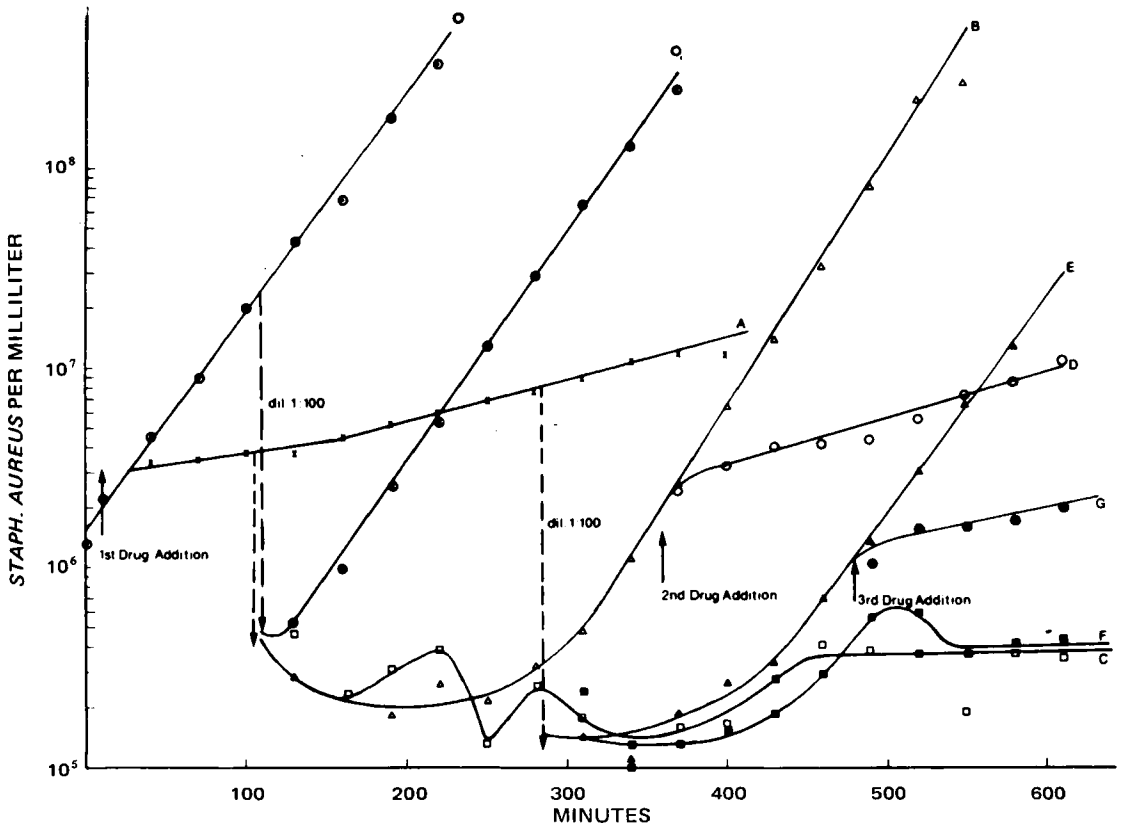

Figure 6—*Semilogarithmic plots of reversibility studies of* Staph. aureus *with time of addition of clindamycin and dilution of the cultures with broth. Curve O is without drug. Curve A is after addition of clindamycin to the culture of curve O to a final concentration of 0.06 μg/ml; curve O_1 is for the drug-free culture of curve O diluted 100-fold with broth. Curves B and E are for the drug-affected culture of curve A diluted 100-fold with broth during phase I and phase II generations, respectively, so that the final clindamycin concentration is reduced to 0.0006 μg/ml. Curves C and F are for the drug-affected culture of curve A diluted 100-fold with broth containing a sufficient amount of clindamycin during phase I and phase II generations, respectively, so that the final clindamycin concentration is reestablished at 0.06 μg/ml. Curve D is for the diluted culture of curve B that has emerged from lag phase and clindamycin has been added to restore the concentration to 0.06 μg/ml. Curve G is for the diluted culture of curve E that has similarly emerged from lag phase and clindamycin has been added to restore the concentration to 0.06 μg/ml.*

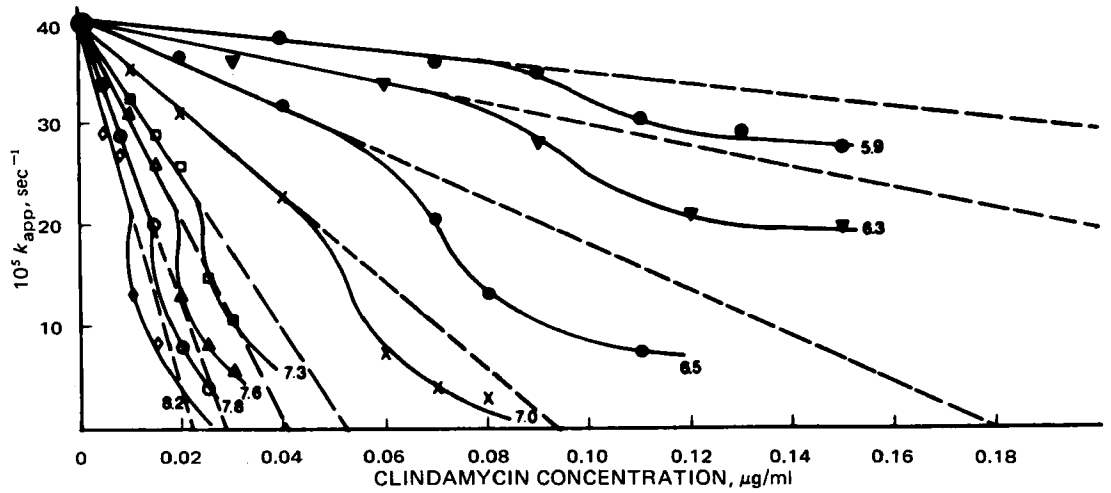

Figure 7—*Dependence of apparent generation rate constant,* k_{app} *in seconds*$^{-1}$*, of clindamycin-affected* Staph. aureus *cultures in phase I generation on the pH of the broth medium. Curves are labeled with the pH values.*

concentration level of 33.34 μg/ml (6).

On the other hand, a 1:100 dilution of the culture affected with clindamycin at a concentration of 0.06 μg/ml during phase I (curve B in Fig. 6) or phase II (curve E in Fig. 6) generation resulted in a prolonged lag period of approximately 150–200 min. Subsequently, a new steady-state generation was established at a rate similar to that of the control culture (curve O in Fig. 6). This finding indicates that the drug action is nullified by the high dilution of the culture. However, even if the time for rejuvenation of the cells or the consequence of shock on dilution is considered, the prolonged lag period observed for the diluted culture to attain a new steady-state generation suggests that the rate of dissociation of the drug–receptor complex in the biophase is less than the rate of drug diffusion from the broth medium into the biophase through cell membranes. Alternatively, it may suggest that there is a kill of the greater proportion of cells by a bactericidal or lytic phenomenon, which leaves relatively few survivors whose lag phase becomes unduly prolonged.

The addition of clindamycin to the diluted cultures of curves B and E (Fig. 6), which had emerged from the lag phase, to restore the concentration to 0.06 μg/ml resulted in a short period of equilibration, *i.e.*, 20–25 min. Subsequently, a new steady-state generation was established with predictable rate constants (curves D and G in Fig. 6). However, a 1:100 dilution of the drug-affected culture of curve A (Fig. 6) during phase I (curve C in Fig. 6) or phase II (curve F in Fig. 6) generation to reestablish the concentration of clindamycin in the broth to 0.06 μg/ml produced an initial phase of erratic generation curves followed by a stationary phase. This finding may indicate a type of generation inhibition in which an increase in the number of survivor cells is offset by a decrease in the number of cells killed by a bactericidal or lytic phenomenon. Since the dilution did not result in changes in thermal or osmotic conditions of the environment, it is concluded that lysis of the cells could occur from permanent damage or injury of cell membranes and/or cell walls resulting in leakage of cell contents or as a consequence of autolysis of cells killed by bactericidal action of clindamycin at a concentration level of 0.06 μg/ml.

The action of clindamycin at the high concentration level (0.06 μg/ml) clearly was not as readily and rapidly reversible as at the low concentration level (0.03 μg/ml). Furthermore, a bactericidal or lytic phenomenon could be superimposed on normal generation inhibition at the high concentration level.

Effect of pH on Drug-Affected Generation Rates—Apparent generation rate constants obtained for *Staph. aureus* in broth at pH 5.9–8.2, in the absence and presence of graded concentrations of clindamycin, are plotted in Fig. 7. The generation rate constants for drug-free cultures were invariant with pH, but those for drug-affected cultures were significantly decreased as the pH was increased at the same clindamycin concentration. The sigmoidal shape of the curve obtained from plots of the generation rate constant *versus* drug concentration at pH 7.05 (Fig. 3) was reproduced at all other pH values studied.

The calculated values of k_c, obtained from slopes of plots of k_{app_I} *versus* clindamycin concentration, *C*, in accordance with Eq. 2, are plotted as a function of pH (curve C) in Fig. 8. The calculated values k_a, obtained from intercepts of plots of $C/(k_0 - k_{app_I})$ *versus C* in accordance with Eq. 3, are also plotted as a function of pH (curve B in Fig. 8). The values for k_c and k_a increased about 10-fold per unit increase in pH over the 5.9–7.0 range, but the slopes of the plots tended to lessen, in both cases, as the pH approached the pKa value of clindamycin. The plots of k_a *versus* pH obtained from the data (6) of clindamycin action on *E. coli* (curve A in Fig. 8) show similar evidence.

DISCUSSION

The suitability of a particle-size counter for monitoring the organism population in an estimate of apparent generation rate constants of drug-affected *E. coli* cultures has been well established (8). Its applicability for similar determinations on drug-affected *Staph. aureus* cultures recently was reported (7). The present work also confirms that the method is applicable for determining

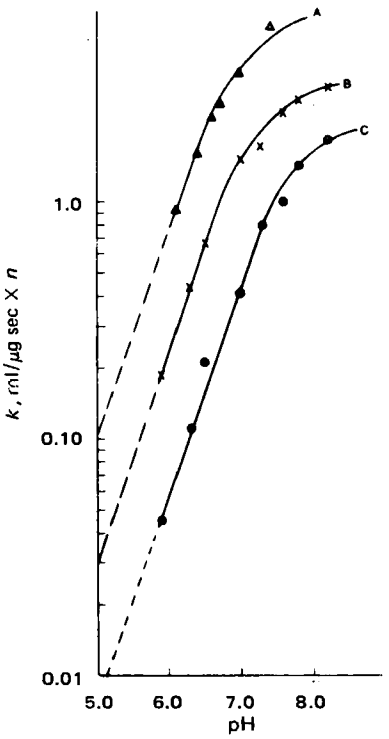

Figure 8—*Semilogarithmic plots of apparent inhibitory rate constant,* k *(in milliliters per microgram seconds), for the action of clindamycin on* E. coli *(curve A) and* Staph. aureus *(curves B and C). In curves A and B,* k *values are the* k_a *values derived from the intercepts of plots of* $C/(k_0 - k_{app})$ versus C *in accordance with Eq. 3; k values in curve C are the* k_c *values derived from the slopes of plots of* k_{app} versus C *in accordance with Eq. 2.*

the generation rates of *Staph. aureus* and *E. coli* cultures affected with subcompletely inhibitory concentrations of clindamycin.

At the low clindamycin concentration level (0–0.04 μg/ml), the total count on *Staph. aureus*-affected cultures was 50% of the viable count (Fig. 1). This finding is attributed (7) to the dissociation of cell aggregates by the high dilution steps and/or subsequent generation of the culture samples withdrawn for the viable count procedure, which result in relatively high colony counts. However, the generation curves obtained from the total count remained parallel to those of the viable count. Reversibility studies (Fig. 5) demonstrated a rapidly reversible action of the clindamycin on *Staph. aureus* cells. The conclusion is that there is no kill or death of the organisms superimposed on normal generation inhibition by the action of clindamycin in this low concentration range.

At the high clindamycin concentration level (> 0.04 < 0.1 μg/ml), the total count on the drug-affected *Staph. aureus* in phase I generation was increased to 80–90% of the viable count (Fig. 1). This finding suggests a condition of "dynamic bacteriostasis" (9), in which the rate of kill of the organisms is balanced by the rate of generation of survivor cells in the culture. Consequently, the total count remains virtually the same as the viable count. During the phase II generation of the cultures, however, there was an apparent increase in the rate of generation obtained by the total count. This result may be attributed to an increased rate of generation of mutant-resistant survivor cells that are counted indiscriminately with dead cells by the particle counter. The corresponding viable counts, on the other hand, showed that the rate of generation was: *(a)* increased to a relatively less extent than the increase obtained by total count for the culture affected with a subcompletely inhibitory clindamycin concentration of 0.05 μg/ml, *(b)* unchanged for the culture affected with an inhibitory clindamycin concentration of 0.07 μg/ml, or *(c)* slightly decreased for the culture affected with the clindamycin concentration of 0.08 μg/ml.

These observations indicate that there is a kill and/or poor recovery of a large percentage of cells damaged or injured by a bactericidal or lytic phenomenon as a function of drug concentration and drug–bacteria contact time. Furthermore, the clindamycin action in this subcompletely inhibitory concentration range is not readily and rapidly reversible (Fig. 6). The inference is that a bactericidal or lytic phenomenon may be superimposed on generation inhibition of the *Staph. aureus* cultures by the action of clindamycin. At very high clindamycin concentrations (> 0.1 μg/ml), there was a rapid drop in the viable count with time as a function of drug concentration whereas the total count remained constant with time and was invariant with drug concentration.

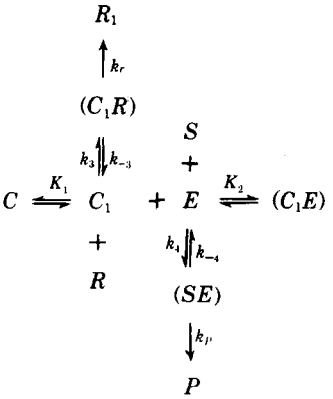
These findings demonstrate unequivocally that clindamycin exerts a bactericidal effect on the cultures in this concentration range. In contrast, the viable count of clindamycin-affected *E. coli* was 50–80% of the total count (Fig. 2), and the generation curves obtained from the viable count remained parallel to those obtained from the total count at any concentration level. There was no evidence of a bactericidal or lytic phenomenon superimposed on generation inhibition by the action of clindamycin on *E. coli* in the subcompletely inhibitory concentration range of 0–100 μg/ml or above the inhibitory concentration levels, *e.g.*, 200 μg/ml. It is, therefore, quite evident that clindamycin exerts a "true" bacteriostatic action (9) on *E. coli*.

Staph. aureus cultures affected with subcompletely inhibitory concentrations of clindamycin exhibited biphasic steady-state generation curves (Fig. 1). The apparent generation rate constant (k_{app_I}) of the initial (phase I) generation was less than the apparent generation rate constant ($k_{app_{II}}$) of the subsequent (phase II) generation of the clindamycin-affected *Staph. aureus*, suggesting organism adaptation or development of resistance to drug action after a finite period of drug–bacteria contact. On the other hand, *E. coli* cultures affected with subcompletely inhibitory concentrations of clindamycin exhibited monophasic steady-state generation curves (Fig. 2). There was no evidence of organism adaptation or development of resistance to drug action.

The functional dependency of the apparent generation rate constant, k_{app}, on drug concentration for clindamycin-affected *Staph. aureus* in phase I was the same as that of the phase II generation (Fig. 3), suggesting a common mechanism of action in both generation phases. Therefore, the plots of k_{app} *versus* drug concentration for phase I and phase II generations are superimposable by a potency factor of 0.80 over the entire concentration range studied. This finding indicates that only 80% of the available drug concentration in broth is effective against the resistant mutants of *Staph. aureus* in phase II generation.

The curve for the dependence of the k_{app} on drug concentration for the clindamycin-affected *Staph. aureus* has a sigmoidal shape similar to that recently reported for the action of fusidate sodium (10) and quinacrine (11) on *E. coli*. It has been shown from theoretical considerations (10) that this shape can be attributed to either: *(a)* a saturable enzymatic degradation of the drug in the biophase of the microorganism or *(b)* drug binding to saturable binding sites in the medium. Table II shows no evidence of interference in clindamycin action on *Staph. aureus* to suggest that degradation of the drug occurs from microbial metabolic activities as a function of organism numbers or that a depletion of free or unbound drug in the broth medium is produced by binding, absorption, or inactivation processes as a result of variations in broth composition. On the other hand, there is demonstrated evidence of a bactericidal phenomenon which operates concurrently with generation inhibition at subcompletely inhibitory concentrations of clindamycin (>0.04 μg/ml). It is possible, therefore, that perturbations in the kinetics of the drug inhibitory action produced by the onset of a bactericidal action may account for the sigmoidal shape of the curve for the dependence of k_{app} on drug concentration.

A model consistent with the dual mechanism of clindamycin action on *Staph. aureus* is shown in Scheme I.



Scheme I

In this model, C is the clindamycin concentration in the broth medium, which is in equilibrium with C_1, the clindamycin concentration within the cell or biophase that reversibly binds with enzyme, E, to form the drug–enzyme complex, C_1E; S is the normal substrate (or metabolite) synthesized by the enzyme into the protein product, P, from the substrate–enzyme complex, SE, and is utilized in cell development and generation. The clindamycin concentration in the biophase also reacts irreversibly with a "target" site (or vital structure), R, to form a damaged (or injured) site or a toxic product, R_1, from a reaction complex, C_1R. The target site may be a sensitive compound of the cytoplasmic membrane, protoplasmic or nuclear material, or a metabolic or transport agent, which is essential for organism survival (12–16). The following equations apply if it is postulated that:

1. The rate of increase in microbial numbers, dN/dt, is proportional to the net rate of microbial generation, dG/dt, above microbial death, dD/dt, and to the number, N, of organisms present.
2. The rate of microbial generation, dG/dt, is proportional to the net rate of protein synthesis, dP_1/dt, above a certain minimum, Δp, required for life-sustaining processes and to the number, N, of organisms present.
3. The rate of microbial death, dD/dt, is proportional to the rate of formation of the damaged (or injured) site or the toxic product and to the number, N, of organisms present.

The equations are:

$$dN/dt = k_n(dG/dt - dD/dt)N = k_{app}N \qquad \text{(Eq. 5)}$$

where k_n is a constant of proportionality and k_{app} is the apparent generation rate constant of the drug-affected culture, and:

$$dG/dt = k_g(dP_1/dt)N = k_g(dP/dt - \Delta p)N \qquad \text{(Eq. 6)}$$

where k_g is a constant of proportionality and dP/dt is the overall

rate of protein synthesis. Moreover:

$$dD/dt = k_d(dR_1/dt)N \quad \text{(Eq. 7)}$$

Combination of Eqs. 5–7 yields:

$$k_{app} = k_n\{k_g(dP/dt - \Delta p) - k_d(dR_1/dt)\} \quad \text{(Eq. 8)}$$

On the basis of Scheme I, it can be stated that:

$$dP/dt = (k_pk_4/k_p + k_{-4})(S)(E) = k_p{}^1E = k_p{}^1(1 - \theta)E_t \quad \text{(Eq. 9)}$$

where $k_p{}^1 = (k_pk_4/k_p + k_{-4})S$, S is assumed invariant, and $\theta = C_1E/E_T$ is a fraction of total enzyme, E_t, bound to the drug.

The value of θ is explicitly defined by a previously derived equation (1, 6) as follows:

$$\theta = K_1K_2C/(1 + K_1K_2C) \quad \text{(Eq. 10)}$$

where K_1 is the drug partition constant through cell membranes and K_2 is the drug affinity constant for the enzyme, E.

Combination of Eqs. 9 and 10 yields:

$$dP/dt = k_m\{1 - [K_1K_2C/(1 + K_1K_2C)]\} \quad \text{(Eq. 11)}$$

where $k_m = k_p{}^1E_t$.

Also, under steady-state conditions:

$$dR_1/dt = (k_rk_3/k_r + k_{-3})(C_1)(R) \quad \text{(Eq. 12)}$$

and:

$$C_1 = K_1C \quad \text{(Eq. 13)}$$

where K_1 is as defined in Eq. 10.

Combination of Eqs. 12 and 13 yields:

$$dR_1/dt = (k_rk_3/k_r + k_{-3})(K_1)(C)(R) \quad \text{(Eq. 14}a\text{)}$$

$$dR_1/dt = k_eC \quad \text{(Eq. 14}b\text{)}$$

where $k_e = (k_rk_3/k_r + k_{-3})(K_1)(R)$, and R is assumed to be comprised of an infinitely large number of molecules (12) so that the rate of formation of R_1 becomes only dependent on drug concentration. Substitution of Eq. 14*b* into Eq. 7 yields:

$$dD/dt = (k_dk_eC)N = (k_uC)N = -dN/dt \quad \text{(Eq. 15)}$$

where $k_u = k_dk_e$ is the death rate constant, and $-dN/dt$ is the rate of decrease in microbial numbers. Equation 15 is the typical equation of the "mechanistic theory" that attempts to explain the bactericidal process of many compounds (12–20).

Combining Eqs. 8, 11, and 14*b* and simplifying give:

$$k_{app} = k_nk_g(k_m - \Delta p) - [k_nk_gk_mK_1K_2C/(1 + K_1K_2C) + k_dk_eC] \quad \text{(Eq. 16}a\text{)}$$

$$k_{app} = k_0 - \{[k_{a_1}C/(1 + k_bC)] + k_uC\} \quad \text{(Eq. 16}b\text{)}$$

where k_0 is the generation rate constant of the drug-free culture, $k_b = K_1K_2$, $k_{a_1} = k_nk_gk_mK_1K_2$, and k_u is as defined in Eq. 15. Therefore:

$$k_a/k_b = k_nk_gk_m > k_0 \quad \text{(Eq. 17)}$$

Equation 16*b* describes the functional dependencies of k_{app} on the drug concentrations for clindamycin-affected *Staph. aureus* in phase I and phase II generations (Fig. 3). At low clindamycin concentrations in phase I action (0–0.04 μg/ml) or in phase II action (0–0.05 μg/ml), when the death rate is exceedingly small so that $k_uC \rightarrow 0$ and when few enzyme sites are possibly interacted with drug to inhibit protein synthesis so that $k_bC \ll 1$, Eq. 16 simplifies to Eq. 2, which is the expression for the observed linear dependence of k_{app} on drug concentration in these concentration ranges (Fig. 3).

At high drug concentrations, it is possible that the extent of generation inhibition is decreased with an increase in drug concentration because of the saturation of enzyme sites by the drug, *i.e.*, $k_bC > 1$. Under such conditions, the k_{app} should decrease asymptotically to zero with an increase in drug concentration similar to that observed for lincomycin action on *Staph. aureus* (7). However, an onset of a bactericidal action, when $k_uC \gg 0 < 1$, causes a reduction in the numbers of viable cells in the active phase of multiplication to alter the functional dependency of the k_{app}. The overall interaction of bacterial death from a bactericidal action, with generation inhibition as a consequence of decreased rate of protein synthesis by the clindamycin action, results ultimately in a sigmoidal shape of the curve for the dependence of k_{app} on drug concentrations, which is described by Eq. 16*b*.

Transformation of Eq. 16*b* yields:

$$C/(k_0 - k_{app}) = Ck_b/[(k_{a_1} + k_u) + k_bk_uC] + 1/[(k_{a_1} + k_u) + k_bk_uC] \quad \text{(Eq. 18)}$$

If k_uk_bC values are extremely small compared to exceedingly large $k_{a_1} + k_u$ values, then Eq. 18 simplifies to Eq. 3 as follows:

$$C/(k_0 - k_{app}) = k_bC/(k_{a_1} + k_u) + 1/(k_{a_1} + k_u) = k_bC/k_a + 1/k_a \quad \text{(Eq. 19)}$$

where $k_a = k_{a_1} + k_u$.

Equation 19 is adhered to by the data of Fig. 3 from linear plots of $C/(k_0 - k_{app})$ *versus* C for clindamycin concentrations greater than 0.04 μg/ml in phase I action (curve A in Fig. 4) or greater than 0.05 μg/ml in phase II action (curve B in Fig. 4) and may indicate a saturable mechanism of the clindamycin action at high concentration levels. The plots are, however, completely displaced from those of clindamycin action in the low concentration range, *i.e.*, 0–0.04 μg/ml in phase I or 0–0.05 μg/ml in phase II action, which do not adhere to the saturable receptor site model. This finding confirms that a different mechanism of action (*i.e.*, the bactericidal action) is superimposed on generation inhibition at the saturable level.

Table II shows kinetic parameters derived from plots of the data of Fig. 3 in accordance with Eqs. 12 and 19. The k_a/k_b value for *Staph. aureus* is 1.35 times the k_0 value, which is in agreement with theoretical predictions of Eq. 17. The calculated value of k_b in Eq. 19 for the phase I generation is 1.20 times the value for the phase II generation. Since k_b is derived from K_1 and K_2 as defined in Eq. 10, it can be rationalized for clindamycin–*Staph. aureus* interactions, as in the case of lincomycin–*Staph. aureus* interactions (7), that K_2 is decreased in the phase II generation of the drug-affected cultures. The resistant mutant strains in the phase II generation may have ribosomal components whose binding affinity for clindamycin is less than that of the initial strains in the phase I generation. Therefore, the observation that 80% of the total drug concentration in broth is kinetically active against the drug-affected organism in phase II generation is attributed to this phenomenon.

The dependence of the generation rate constant, k_{app}, on drug concentration, C, for clindamycin-affected *E. coli* is linear at low drug concentrations (0–10 μg/ml) but is curvilinear at high drug concentrations (>10 μg/ml) when it also decreases asymptotically to zero with an increase in drug concentration (Fig. 3). An operative kinetic model (6), which defined the action of lincomycin and its 7(*S*)-chloro analogs, is applicable. Clindamycin action on *E. coli* is explained as competitive binding of a saturable receptor site, which is also the binding locus for a metabolite normally utilized by the receptor site in the synthesis of protein for microbial generation. The functional dependency of k_{app} on clindamycin (curve B in Fig. 3) is explicitly defined by the equation:

$$k_{app} = k_0 - k_aC/(1 + k_bC) \quad \text{(Eq. 20)}$$

where k_0, k_a, and k_b are as defined in Eq. 10. Adherence to a saturable receptor site model is observed from linear plots of $C/(k_0 - k_{app})$ *versus* C (Fig. 4), obtained from the data of Fig. 3 in accordance with the expression in Eq. 3 for clindamycin concentrations greater than 10 μg/ml. Deviations occur at low concentrations (0–10 μg/ml), when only few receptors can possibly be interacted with drug.

The calculated value of k_b (Table II) for clindamycin-affected *E. coli* is 0.21% of the value for clindamycin-affected *Staph. aureus* in phase I or 0.25% of the value for clindamycin-affected *Staph. aureus* in phase II generation. Since $k_b = K_1K_2$ as defined in Eq. 10, it is inferred that clindamycin is far more readily partitioned through cell membranes into the biophase and/or has exceedingly higher affinity for receptors in *Staph. aureus* than in *E. coli*, due possibly to differences in gross morphology and physiology of the organisms.

At the MIC, C_m, when $k_{app} = 0$, Eq. 3 simplifies to Eq. 7 and the calculated values of C_m (Table II) for clindamycin action against

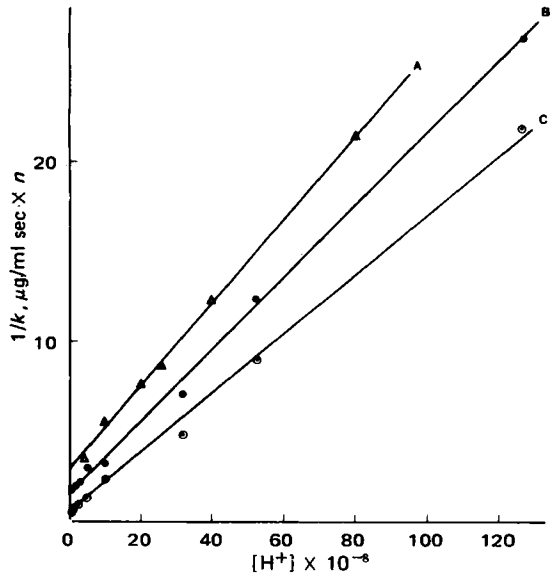


Figure 9—*Linearity of plots for 1/k (micrograms per milliliter second)* versus *[H+] in accordance with Eq. 22 for the action of clindamycin on* E. coli *(curve A) and* Staph. aureus *(curves B and C). In curves A and B,* k *values are the* k_a *values derived from the intercepts of plots of* $C/(k_0 - k_{app})$ versus C *in accordance with Eq. 3;* k *values in curve C are the* k_c *values derived from the slopes of plots of* k_{app} versus C *in accordance with Eq. 2.*

E. coli are 1000 times that against *Staph. aureus*, which is attributed to differences in the modes of clindamycin action and the nature of the respective organisms.

The pH of the broth medium influences the activity of clindamycin on *Staph. aureus* (Fig. 7) in a manner similar to what was observed for its action on *E. coli* (6). The k_{app} values of drug-affected cultures decrease with an increase in the pH at any specified concentration. Therefore, progressively larger quantities of the drug are needed to produce the same generation inhibition as the pH is decreased. The sigmoidal shape of curve for the k_{app} dependence on drug concentration is observed at all other pH values studied. The constant k_c (milliliters per microgram second), as defined in Eq. 2, and the constant k_a (milliliters per microgram second), as defined in Eq. 3, for various pH values from the data of drug-affected *Staph. aureus* in Fig. 7, or the constant k_a (milliliters per microgram second), as defined in Eq. 3, for various pH values obtained from previous data (6) of drug-affected *E. coli* adhere to the expression:

$$k = k^* f K_a/(K_a + [H^+]) \qquad \text{(Eq. 21)}$$

where k is either k_c or k_a, k^* is the intrinsic value of k for the unprotonated drug molecule, f is the fraction of the unprotonated drug, K_a is the dissociation constant of the unprotonated base, and $[H^+]$ is the hydrogen-ion concentration. The plots of log k *versus* pH (Fig. 8) approach a slope of unity when $[H^+] > K_a$ but have a null slope when $K_a > [H^+]$, suggesting that the unprotonated drug molecule is the active species. The linear plots of $1/k$ *versus* $[H^+]$ in Fig. 9 are obtained from the data of Fig. 8 in accordance with an expression derived from Eq. 21:

$$1/k = [H^+]/(k^* K_a) + 1/k^* \qquad \text{(Eq. 22)}$$

The pKa and k^* values of clindamycin, derived from the slopes and intercepts of the plots for drug-affected *Staph. aureus* (curves B and C in Fig. 9) and *E. coli* (curve A in Fig. 9) are given in Table III. The kinetically derived pKa values are in reasonably good agreement with the 7.0 value (6) obtained by potentiometric titration. It is concluded that Eq. 21 holds and that the unprotonated form of the clindamycin molecule contributes to activity because of its ready penetrability through cell membranes of Gram-positive and Gram-negative organisms.

Table III—Values of pKa and Intrinsic Inhibitory Rate Constants (k^*) for Clindamycin Action on *Staph. aureus* and *E. coli*

Organism	$10^5 k_c^{*a}$	$10^5 k_a^{*b}$	Kinetically[c] Determined pKa	Potentiometrically[d] Determined pKa
Staph. aureus	—	3333.34	7.2	7.0

Microbial Kinetics of Drug Action against Gram-Positive and Gram-Negative Organisms III: Effect of Lincomycin and Clindamycin Combinations on *Staphylococcus aureus* and *Escherichia coli*

SAMUEL M. HEMAN-ACKAH

Abstract □ The functional dependencies of apparent first-order generation rate constants, k_{app}, of drug-affected cultures on drug concentrations indicate that lincomycin and clindamycin possess the same mechanism of action, which is bacteriostatic, against *Staphylococcus aureus*. Clindamycin also possesses another mechanism of action, which is bactericidal, at high concentration levels. However, clindamycin possesses only one of the two mechanisms of lincomycin action, which is bacteriostatic, against *Escherichia coli*. The relative potency of action of a clindamycin–lincomycin combination against *Staph. aureus* is variable, and the effective ratio ranges between 5:1 and 9:1; the effective ratio against *E. coli* is fixed at 6:1 over a wide concentration range. This difference is attributed to differences in bioavailability and/or binding characteristics of the drugs for bioreceptors, as a consequence of structural modifications in the drug molecules, and to differences in modes of action in the respective organisms. Mixtures containing equipotent fractions of clindamycin and lincomycin show "equivalence" or "indifference" of effects on *Staph. aureus*. The combined action of the mixtures can be quantitatively predicted from the separate dose–response curves of either component drug alone. Therefore, it is concluded that clindamycin and lincomycin may bind to the same receptor site that is engaged in microbial protein synthesis to inhibit the generation of *Staph. aureus*. However, combinations of clindamycin and lincomycin are less active than the *a priori* equipotent concentration of either drug alone in their action against *E. coli*, demonstrating unequivocally an antagonism of effects. Furthermore, the degree of antagonism is dependent on the order of addition of the drugs, which is attributed to the possibility that clindamycin and lincomycin bind differently on active and allosteric loci of the same receptor site functionally engaged in protein synthesis in *E. coli*. A rational approach to the quantification and prediction of combined antibiotic action must, therefore, be based not only on the kinetics and mechanisms of action as well as on the dose–response relationship over a wide concentration range for the separate antibiotics but also on the strain and species of the test organism.

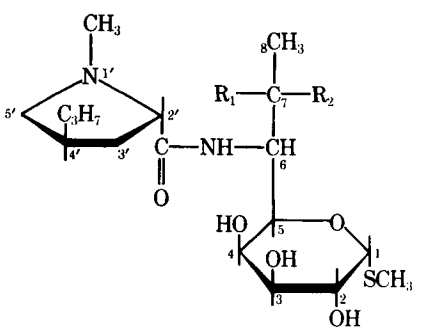
Since the discovery of lincomycin (I), an antibiotic produced by *Streptomyces lincolnensis* (1, 2), different structurally modified analogs have been prepared with a view to understanding structure–activity relationships (3). Halogen substitution at the 7(*S*)-configuration of the lincomycin molecule is claimed to potentiate antibacterial effects. Clindamycin (II), which is the 7-deoxy-7(*S*)-chloro analog of lincomycin, is reported to be more than four times more active than the parent antibiotic against a variety of Gram-positive and Gram-negative organisms (4). The similarity in chemical structure would imply that clindamycin should have the same mechanism of action as lincomycin but possess different intrinsic biological activities, so the combined action of clindamycin with lincomycin should produce "additive" or "synergistic" effects (5) on microorganisms.

Comparative studies on the action of lincomycin and its 7(*S*)-chloro analogs, such as the 7-deoxy-7(*S*)-chloro-*N*-demethyl-4-pentyl analog (III) and clindamycin, against *Escherichia coli* by microbial kinetics (6) revealed that combinations of II and III yielded "indifference" of effects (5) but that combinations of I and II or I and III yielded "antagonism" of effects (5). The latter evidence indicates incompatibility in the use of combinations of lincomycin and clindamycin as recommended in current chemotherapy. However, these antibiotics are normally employed for the treatment of Gram-positive infections, which are highly sensitive to the action of the antibiotics (7), and not for Gram-negative infections, which show little or no sensitivity. Therefore, data obtained for *E. coli*, a typical Gram-negative organism, may not be readily extrapolated to Gram-positive organisms without experimental evidence.

Recently, microbial kinetic studies were applied to the action of lincomycin (8) and clindamycin (9) against *Staphylococcus aureus*, a representative Gram-positive coccus, and relative differences in their modes of action against *E. coli* were established. However, the effects of lincomycin and clindamycin combinations on *Staph. aureus* remain to be evaluated and quantified experimentally. These were the objectives of the study reported here.



I: R_1 = OH, R_2 = H
II: R_1 = H, R_2 = Cl

EXPERIMENTAL

Antibiotics—The antibiotics[1] were assayed samples of lincomycin hydrochloride (860 μg of base equivalent/mg) and clindamycin (860 μg of base equivalent/mg). Stock solutions of the antibiotics were prepared by membrane filtration and stored at 4°.

Bacteria and Growth Conditions—*Staph. aureus* (ATCC 6538) and *E. coli* (ATCC 12407) were cultivated in broth medium[2] and used for the experiments. An overnight (12–18 hr) culture of the respective organism was grown aerobically at 37.5° in a shaker water bath[3] to a cell density of 2.0×10^7 cells/ml. It was diluted 100-fold into 50-ml replicates of fresh broth medium and brought to the exponential phase of generation. Aliquots (0.5 ml) of the suitably diluted antibiotic solutions or mixtures were then added to the replicate exponential cultures at a cell density of about 10^6 cells/ml.

Total Count Method—Total counts of drug-free and drug-affected cultures were determined by a particle-size counter[4] as previously described (10). The suitability of the total count method for determining the generation rates of drug-affected cultures previously was established by a demonstrated correlation between the total count and viable (colony) count for lincomycin-affected *Staph. aureus* (8) and *E. coli* (11) and for clindamycin-affected *Staph. aureus* (9) and *E. coli* (9).

RESULTS

Effect of Drug Concentrations on Generation Rates—Semilogarithmic plots of the total count *versus* time yield generation curves of the drug-affected cultures as previously described (8). Lincomycin-affected or clindamycin-affected *Staph. aureus* cultures show two phases of steady-state generation. An initial (phase I) generation expressed as:

$$\ln N = \ln N_0 + k_{app_I} t \qquad \text{(Eq. 1)}$$

is followed by an ultimate (phase II) generation:

$$\ln N = \ln N_0 + k_{app_{II}} t \qquad \text{(Eq. 2)}$$

where k_{app_I} and $k_{app_{II}}$ are the apparent generation rate constants of the respective generation phases, N_0 is the number of organisms at some initial time (0), and N is the number of organisms at any time (t). The $k_{app_{II}}$ is greater than k_{app_I} due to *Staph. aureus* adaptation or development of resistance to lincomycin (8) or clindamycin (9) action after a finite period of drug–bacteria contact.

Lincomycin-affected *E. coli* cultures also show two phases of steady-state generation whose characteristics are different from those of lincomycin-affected and clindamycin-affected *Staph. aureus* cultures. The k_{app_I} is greater than $k_{app_{II}}$, which is attributed (6) to dual mechanisms of the lincomycin action which become "synergistic" (5) in the subsequent generation phase of the culture. On the other hand, clindamycin-affected *E. coli* cultures show one phase of steady-state generation (6):

$$\ln N = \ln N_0 + k_{app} t \qquad \text{(Eq. 3)}$$

where k_{app} is the apparent generation rate constant.

Figure 1 shows the plots of k_{app} *versus* drug concentration for the lincomycin-affected *Staph. aureus* cultures (curve A), in which the phase I and phase II generation curves are superimposable by a potency factor. Likewise, curve B shows superimposable curves of the k_{app} dependence on drug concentration for phase I and phase II generations of clindamycin-affected *Staph. aureus*. The curve for lincomycin-affected *Staph. aureus* (curve A) is linear at low drug concentrations: 0–0.35 μg/ml (in the phase I action) or 0–0.55 μg/ml (in the phase II action). At concentrations greater than 0.35 μg/ml in the phase I action or greater than 0.55 μg/ml in the phase II action, the k_{app} is not a linear function of the increasing drug concentration. The plot for clindamycin-affected *Staph. aureus* (curve B) is a complex function of the drug concentration and yields a sigmoidal shape of curve for the phase I and phase II generations, which are also superimposable by a potency factor.

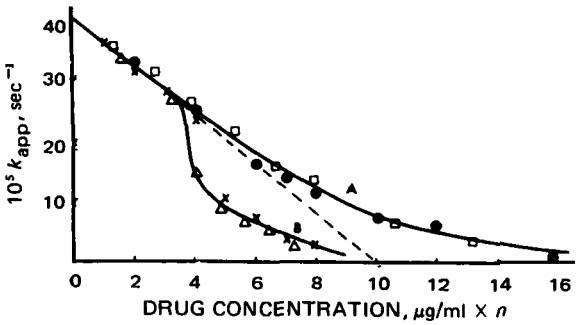

Figure 1—*Dependence of apparent generation rate constants,* k_{app} *in seconds*$^{-1}$*, for drug-affected* Staph. aureus *on drug concentrations (micrograms per milliliter) at pH 7.05 and 37.5°. Actual concentrations are multiplied by a factor,* n, *where* n = *20 for lincomycin phase I action (●) and* n = *13.20 for lincomycin phase II action (□) on* Staph. aureus *in curve A and* n = *100 for clindamycin phase I action (×) and* n = *80 for clindamycin phase II action (△) on* Staph. aureus *in curve B.*

Figure 2 shows plots of k_{app} *versus* drug concentration for the phase I lincomycin action on *E. coli* (curve A), which is coincident with that of clindamycin action on *E. coli* when normalized by a potency factor. The curve for the phase II lincomycin action on *E. coli* (curve B) is different from that of its phase I action (curve A) and is, therefore, not superimposable.

Effect of Order of Addition of Antibiotics on Microbial Generation—*Action of Equipotent Lincomycin Added to Clindamycin-Affected* Staph. aureus—The generation curves for the drug-free *Staph. aureus* cultures are shown as curves A in Figs. 3 and 4. In Fig. 3, the resultant generation curve for the action of 0.04 μg/ml of clindamycin on the *Staph. aureus* culture of curve A is shown as curve B; the generation curve for the culture affected with a mixture of equipotent concentrations of clindamycin (0.04 μg/ml) and lincomycin (0.3 μg/ml) is shown as curve E and is coincident with the curve for the culture affected with an *a priori* equipotent concentration of clindamycin (0.07 μg/ml).

Furthermore, Fig. 3 shows that equipotency of action is demonstrated by coincident or parallel generation curves of the drug-affected cultures having the same generation rate constant, k_{app}. The addition of an equipotent concentration of lincomycin (0.3 μg/ml) to the steady-state phase I generation of the clindamycin-affected culture of curve B produces an ultimate generation curve D, which shows two generation phases parallel to the respective phase I and phase II generations of the drug-affected cultures of curve E. Likewise, the addition of an equipotent concentration of

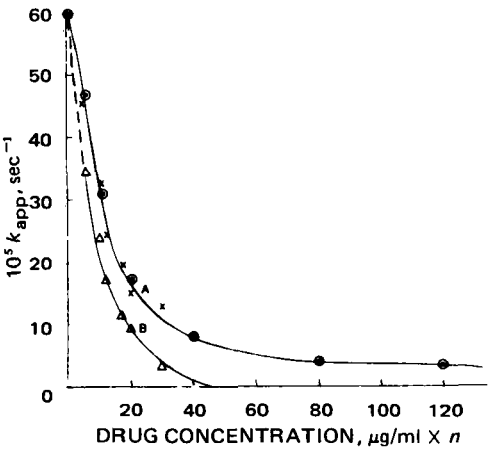

Figure 2—*Dependence of apparent generation rate constants,* k_{app} *in seconds*$^{-1}$*, for drug-affected* E. coli *on drug concentrations (micrograms per milliliter) at pH 7.05 and 37.5°. Actual concentrations are multiplied by a factor,* n, *where* n = *0.15 for lincomycin phase I action (×) and* n = *1.0 for clindamycin action (⊙) on* E. coli *in curve A and* n = *0.15 for lincomycin phase II action (△) on* E. coli *in curve B.*

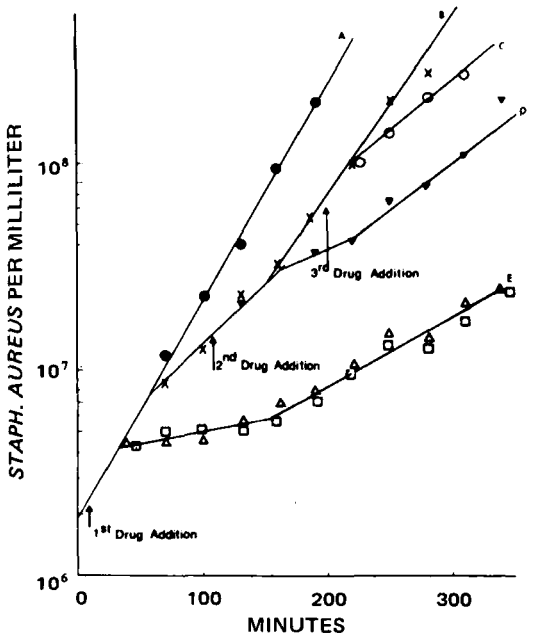

Figure 3—*Effects of addition of an equipotent concentration of lincomycin to clindamycin-affected* Staph. aureus. *Curve A is for the generation of drug-free culture (⊙). Curve B is for the generation of culture affected with 0.04 μg/ml of clindamycin (×). Curve E is for the generation of culture affected with either 0.07 μg/ml of clindamycin (△) or a mixture of equipotent 0.04 μg/ml of clindamycin and 0.3 μg/ml of lincomycin (□). Curve D is generated when an equipotent concentration of lincomycin (0.3 μg/ml) is added to the phase I clindamycin-affected culture of curve B (▼), and curve C is generated when an equipotent concentration of lincomycin (0.3 μg/ml) is added to the phase II clindamycin-affected culture of curve B (○).*

lincomycin (0.3 μg/ml) to the phase II generation of the clindamycin-affected culture of curve B yields a generation curve C, which is parallel only to the phase II generation of the drug-affected cultures of curve E.

Action of Equipotent Clindamycin Added to Lincomycin-Affected Staph. aureus—In Fig. 4, the generation curve produced by the action of 0.3 μg/ml of lincomycin on the *Staph. aureus* culture of curve A is shown as curve B; the generation curve for the culture of curve A affected with a mixture of equipotent concentrations of lincomycin (0.3 μg/ml) and clindamycin (0.04 μg/ml) is shown as curve E and is coincident with the curve obtained from the culture affected with an *a priori* equipotent concentration of lincomycin (0.6 μg/ml).

Furthermore, Fig. 4 shows that the addition of an equipotent concentration of clindamycin (0.04 μg/ml) to the steady-state phase I generation of the lincomycin-affected culture of curve B produces an ultimate generation curve D, which is parallel to that for the culture of curve E and shows typical phase I and phase II generations. The addition of an equipotent concentration of clindamycin (0.04 μg/ml) to the phase II generation of the lincomycin-affected culture of curve B results in a generation curve C, which is parallel only to the phase II generation curve of the drug-affected cultures of curve E.

These observations indicate that the order of addition of equipotent concentrations of lincomycin and clindamycin on *Staph. aureus* produces an ultimate generation inhibition that is not significantly different from that of the *a priori* equipotent concentration of either antibiotic alone.

Effect of Order of Addition of Clindamycin and Lincomycin on Generation of E. coli—In Fig. 5, the generation curve for the drug-free *E. coli* culture is shown as curve A; the generation curve for the action of clindamycin (15 μg/ml) on the *E. coli* culture of curve A is shown as curve B and is coincident with the phase I action of lincomycin (100 μg/ml) in curve C, which indicates equipotency of action. The generation curve produced by the action of clindamycin (30 μg/ml) in curve G is also coincident with the phase I action of lincomycin (200 μg/ml) in curve H.

The addition of a mixture of equipotent concentrations of clindamycin (15 μg/ml) and lincomycin (100 μg/ml) to the *E. coli* culture of curve A yields an ultimate generation phase (curve F), which has a slope higher than the curve for the action of the *a priori* equipotent concentration of clindamycin (30 μg/ml) in curve G or the phase I lincomycin (200 μg/ml) in curve H. This finding indicates decreased effectiveness or "antagonism" (5) of effects for the clindamycin and lincomycin mixture. The addition of an equipotent amount of lincomycin (100 μg/ml) to the steady-state phase generation of the clindamycin-affected *E. coli* culture of curve B results in an ultimate generation curve that is coincident with that of the phase II generation of the lincomycin-affected culture of curve C. This finding suggests that the added equipotent amount of lincomycin virtually nullifies the initial action of clindamycin on the culture.

However, the addition of an equipotent amount of clindamycin (15 μg/ml) to the steady-state phase I and phase II generations of the lincomycin-affected *E. coli* culture of curve C produces generation curves E and D, respectively, whose slopes are the same as that of the drug-affected culture of curve F. This finding indicates that the added equipotent amount of the clindamycin does not have an effect on the initial action of lincomycin on the culture but that clindamycin yields a relatively reduced effect on the ultimate generation inhibition.

These observations demonstrate that the order of addition of clindamycin and lincomycin to *E. coli* cultures produces significant effects on the ultimate generation inhibition and suggests antagonism of effects as observed previously (6).

Effect of Equipotent Mixtures of Different Fractions of Lincomycin and Clindamycin on Generation Rates—The gen-

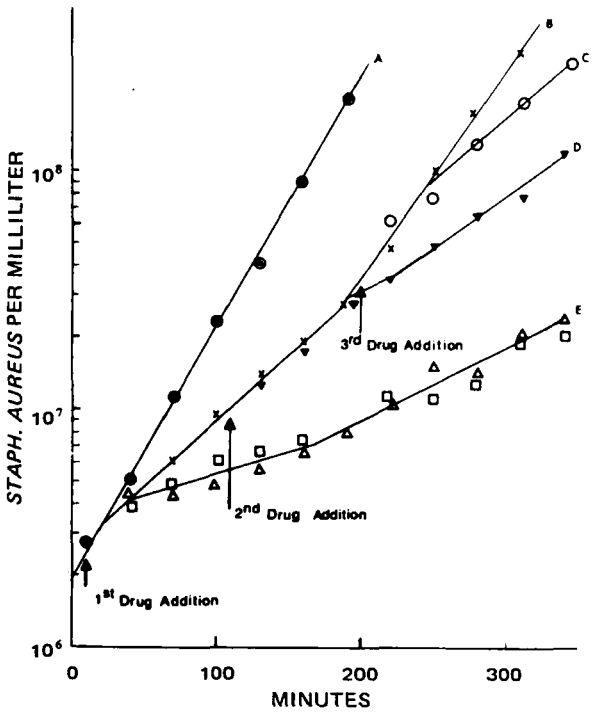

Figure 4—*Effects of addition of an equipotent concentration of clindamycin to lincomycin-affected* Staph. aureus. *Curve A is for the generation of drug-free culture (⊙). Curve B is for the generation of culture affected with 0.3 μg/ml of lincomycin (×). Curve E is for the generation of a culture affected with either 0.6 μg/ml of lincomycin (△) or a mixture of equipotent 0.3 μg/ml of lincomycin and 0.04 μg/ml of clindamycin (□). Curve D is generated when an equipotent concentration of clindamycin (0.04 μg/ml) is added to the phase I lincomycin-affected culture of curve B (▼), and curve C is generated when an equipotent concentration of clindamycin (0.04 μg/ml) is added to the phase II lincomycin-affected culture of curve B (○).*

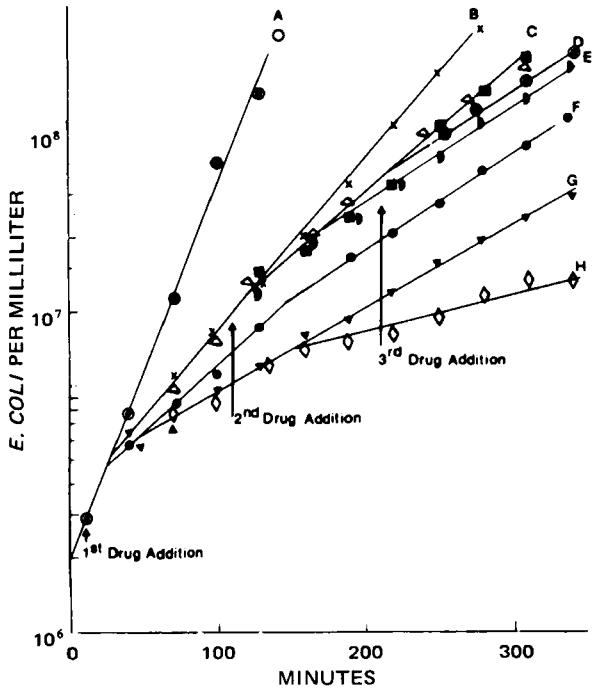

Figure 5—*Effects of the order of addition of equipotent concentrations of clindamycin and lincomycin on the generation rates of* E. coli. *Curve A is for the generation of drug-free culture. Curve B is for the generation of culture affected with 15.0 μg/ml of clindamycin (×). Curve C is generated by a culture affected with an equipotent 100-μg/ml concentration of lincomycin (△), and its coincident curve is generated when an equipotent 100-μg/ml concentration of lincomycin is added to the clindamycin-affected culture of curve B (■). Curve E is generated when an equipotent 15-μg/ml concentration of clindamycin is added to the phase I lincomycin-affected culture of curve C (◗). Curve D is generated when an equipotent 15-μg/ml concentration of clindamycin is added to the phase II lincomycin-affected culture of curve C (⊙). Curve F is generated when a mixture of equipotent concentrations of clindamycin (15 μg/ml) and lincomycin (100 μg/ml) is added to the culture of curve A (●). Curve G is generated when 30 μg/ml of clindamycin is added to the culture of curve A (▼), and curve H is generated when an equipotent 200-μg/ml concentration of lincomycin is added to the culture of curve A (◇).*

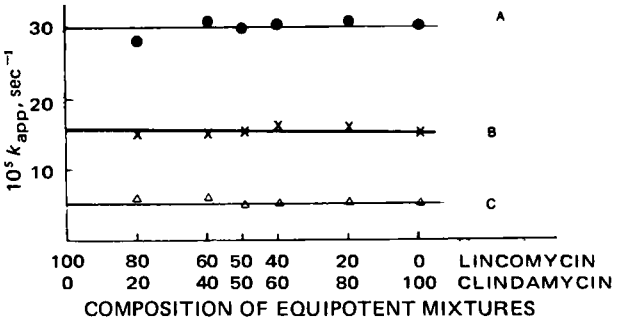

Figure 6—*Effect of varied clindamycin and lincomycin fractions in equipotent mixtures at three different levels of activity on the apparent generation rate constants,* k_{app} *in seconds*$^{-1}$, *of* Staph. aureus *at pH 7.05 and 37.5°. A, B, and C indicate the activities of* a priori *equipotent concentrations: 0.02 μg/ml of clindamycin = 0.11 μg/ml of lincomycin, 0.04 μg/ml of clindamycin = 0.36 μg/ml of lincomycin, and 0.05 μg/ml of clindamycin = 0.50 μg/ml of lincomycin, respectively.*

eration rate constant, k_{app}, for the steady-state phase I generation of *Staph. aureus* cultures affected with equipotent mixtures of clindamycin and lincomycin are shown in Fig. 6. The mixtures consisted of 100, 80, 60, 50, 40, 20, and 0% lincomycin and the residual percentage of an equipotent concentration of clindamycin. The mixtures were prepared so as to be *a priori* equipotent in their combined action on *Staph. aureus* generation in accordance with the dependence of k_{app} on drug concentration (Fig. 1). The null slopes for the plots of k_{app} for all the *a priori* equipotent mixtures at three different levels of activity demonstrate "indifference" or "equivalence" of effects (5).

The k_{app} values of *E. coli* cultures similarly affected with equipotent mixtures of clindamycin and lincomycin are shown in Fig. 7. The equipotent mixtures show lessened activity, as indicated by higher k_{app} values than when the *a priori* equipotent antibiotic was used alone at all levels of activity. These values demonstrate unequivocally an antagonism of effects for the combined action of clindamycin and lincomycin on *E. coli* cultures and confirm previous observations (6).

DISCUSSION

The data reported in this paper show (Fig. 1) that phase I and phase II generations of lincomycin-affected *Staph. aureus* (curve A) or clindamycin-affected *Staph. aureus* (curve B) have similar functional dependencies of generation rate constants, k_{app}, on drug concentrations. This finding suggests the same mechanism of drug action for phase I and phase II generations of drug-affected cultures. The ratio of biological potency for the lincomycin action on phase I and phase II generations of *Staph. aureus* is 1:0.67. The corresponding ratio for the clindamycin action is 1:0.80. These apparent differences are attributable to adaptation or development of initial strains of *Staph. aureus* in phase I generation into resistant mutants in phase II generation whose ribosomal components have reduced binding affinity for the drugs (8).

The dependence of k_{app} on drug concentration for the lincomycin-affected *Staph. aureus* is similar to that of clindamycin-affected *Staph. aureus* in the low concentration range and indicates a common mechanism (9) of action. However, the dependencies are different at the high concentration levels, which may indicate variations in modes of action. It has been explained that both lincomycin (8) and clindamycin (9) inhibit microbial generation by competitive binding on a receptor site, which is also the binding site for a substrate (or metabolite) utilized in microbial protein synthesis. At low drug concentrations, when possibly few receptors are interacted with drug, there is a linear dependence of the k_{app} on drug concentration, as shown by the coincident portion of the regression for lincomycin-affected *Staph. aureus* and clindamycin-affected *Staph. aureus* (Fig. 1). At high drug concentrations, the already complexed receptor sites reduce the availability of remaining sites by steric effects, protective colloid action, or other mechanisms (11). Therefore, it takes progressively greater drug concentrations to bind the remaining sites, and the k_{app} is a nonlinear function of drug concentration but follows saturation kinetics (6, 8, 11).

In the case of clindamycin, it has been demonstrated (9) that a bactericidal phenomenon is also superimposed on generation inhibition by the action of clindamycin at the saturable level. Therefore, perturbations in the kinetics of generation inhibition result in a complex function for the dependence of the k_{app} on drug concentration. The overall effect yields a sigmoidal shape for curves of plots of k_{app} *versus* clindamycin concentration. The potency ratio for the action of lincomycin and clindamycin on *Staph. aureus* was not constant over the concentration range studied (Table I). Equipotent lincomycin and clindamycin concentrations are, therefore, estimated from the separate dose–response curves of either drug alone.

Equipotent mixtures comprised of different fractions of lincomycin and clindamycin are quantifiable as kinetically "equivalent" or "indifferent" (5) to the *a priori* equipotent concentration of either drug alone in the inhibition of *Staph. aureus* phase I generation at different levels of activity (Fig. 6). This is not inconsistent with the same mechanism (10) of action for the drugs. Furthermore, the order of addition of equipotent amounts of the drugs (Figs. 3 and 4) does not affect the ultimate generation inhibition of *Staph. aureus* cultures, which indicates a common locus of action (6).

There is an observable difference in the potency of action for

Table I—Potency Ratio for the Action of Clindamycin and Lincomycin against *Staph. aureus*[a]

Clindamycin Concentration, μg/ml	Lincomycin Concentration, μg/ml	k_{app} for Phase I of Drug-Affected Cultures, sec^{-1}	Potency Ratio of Clindamycin–Lincomycin
0.020	0.10	32.5	5.0
0.038	0.20	24.5	5.6
0.040	0.30	17.5	7.5
0.044	0.40	12.0	9.1
0.055	0.50	7.5	9.1
0.070	0.60	5.0	8.6

[a] Obtained from the data of Fig. 1.

lincomycin and clindamycin, but this difference can be attributed to relative differences in the drug partition through cell membranes and/or affinity for bioreceptors. Another factor is the bactericidal action of clindamycin, which causes a reduction in the number of survivor cells in the active state of growth and multiplication with a consequent decrease in the apparent generation rate of the drug-affected cultures. Of course, the high activity of clindamycin may be related to halogen substitution at the 7(*S*)-configuration. An increase in the lipophilicity of the molecule in the order I > Br > Cl, which correlates with enhanced antimicrobial activity, was reported for the 7(*S*)-halogen analogs of lincomycin (3). The enhanced activity may be the result of an increased drug availability in the biophase and/or modification of drug–receptor interactions. Additionally, halogen substitution in a homologous series of compounds was reported (12, 13) to alter antibacterial properties of compounds toward bactericidal activities.

The k_{app} dependence on drug concentration for clindamycin-affected *E. coli* is the same as for lincomycin-affected *E. coli* in phase I generation (Fig. 2) and suggests the same mechanism (10) of action, which is different from that for lincomycin-affected *E. coli* in phase II generation. On this presumption, the ratio of 1:6 for the biological potencies of lincomycin (phase I)–clindamycin confirms previous observations (6). However, equipotent mixtures of lincomycin (phase I) and clindamycin demonstrate unequivocally an antagonism (5) of effects (Fig. 7). The mixtures are less effective on the generation of *E. coli* cultures than the *a priori* equipotent concentrations of either drug alone at different levels of activity. This observation confirms a previous report (6) and suggests the possibility that lincomycin (phase I) and clindamycin do not have a common locus of action. Therefore, the similarity in the functional dependency of the k_{app} on drug concentration can be attributed to the binding of clindamycin and lincomycin at different loci of a receptor site that are functionally linked.

Steric configuration possibly plays an important role in the selective binding of the drugs at the sites, as was found for a number of compounds (14). In the case of lincomycin analogs, it was observed (3) that replacement of the 7(*R*)-hydroxy group by a 7(*R*)-halogen substituent has little or no effect on *in vitro* antibacterial activity. However, a 7(*S*)-halogen substituent increases the activity 4–32-fold. This type of evidence suggests that the 7(*R*)- and 7(*S*)-epimers bind differently on the same receptor site. On this premise, it was postulated (6) that two binding sites—a "catalytically active" site and an "allosterically modifying site" (14–16)—possibly exist on the same receptor surface in *E. coli* for the lincosaminide antibiotics. This conceivably may not be the case for *Staph. aureus*, which is different in gross morphology and physiology from *E. coli* (17).

The high activity of clindamycin relative to lincomycin phase I action against *E. coli* suggests that the former binds to the active site while the latter binds to the allosteric site. The binding of lincomycin (phase I) to the allosteric site possibly produces an extensive conformational change (15) which reduces the binding affinity of the active site for clindamycin (or the normal substrate) as a consequence of an unfavorable configuration. The effects of the order of addition of the drugs (Fig. 5) on the ultimate generation inhibition of *E. coli* cultures provide evidence in support of this hypothesis. Pretreatment of the cultures with lincomycin reduces the effect of an added equipotent concentration of clindamycin but not vice versa. It was also implied that, in this type of allosteric

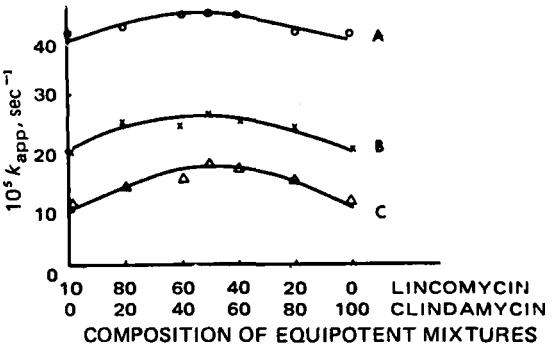

Figure 7—*Effect of varied clindamycin and lincomycin fractions in equipotent mixtures of three different levels of activity on the apparent generation rate constants, k_{app} in seconds^{-1}, of* E. coli *at pH 7.05 and 37.5°. A, B, and C indicate the activities of* a priori *equipotent concentrations: 10.0 μg/ml of clindamycin = 67.0 μg/ml of lincomycin, 20.0 μg/ml of clindamycin = 130.0 μg/ml of lincomycin, and 40.0 μg/ml of clindamycin = 260.0 μg/ml of lincomycin, respectively.*

interaction, only a noncompetitive type of antagonism (18), which is insurmountable by the addition of an excessive amount of one drug in the presence of the other, can result from the combined action of the drugs, as shown by the effects of mixtures of equipotent concentrations of lincomycin and clindamycin (Fig. 7).

The lincomycin phase II action on *E. coli* was attributed (6, 11, 19, 20) to a different mechanism, which is interdependent with the lincomycin phase I action but becomes rate limiting on microbial protein synthesis to enhance generation inhibition after a finite period of drug–bacteria contact. The lincomycin phase II action is the result of lincomycin binding at a receptor site that is different from the binding receptor site for the lincomycin phase I or clindamycin action. The separate sites are engaged in "sequential" metabolic pathways (21) leading to protein synthesis. Therefore, the sequential blocking (22) of the metabolic pathway by lincomycin results in "synergism" (5) of the phase I action by the onset of the phase II action, as evidenced by the effects of lincomycin alone or in combination with clindamycin on *E. coli* (Fig. 5). Although clindamycin action is antagonized by the lincomycin phase I action, it is kinetically equivalent (5) to the lincomycin phase II action, as was observed (20) for erythromycin and the lincomycin phase II action on *E. coli*.

The present work confirms earlier observations (6, 19, 20) that the kinetics and mechanisms of action, as well as the dose–response relationship, of the separate antibiotics must be considered in the quantification and prediction of combined antibiotic action. Moreover, the effect of antibiotic combinations is dependent on the strain and species of the test organism.

Synthesis of Cyclopropyl Analogs of Stilbene and Stilbenediol as Possible Antiestrogens

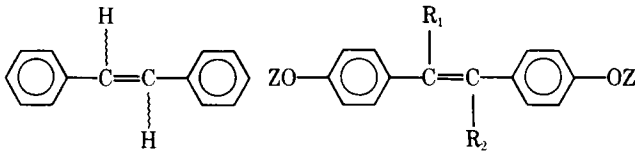
ROBERT A. MAGARIAN ˣ **and ERIC JOEL BENJAMIN** *

Abstract □ Conformationally rigid analogs of stilbene and stilbenediol were prepared *via gem*-dichlorocyclopropyl precursors utilizing two different synthetic methods: a two-phase catalytic method and an organomercurial method. These precursors were reduced to the corresponding cyclopropyl analogs using sodium and methanol. All compounds are being tested to discriminate between estrogenic and antiestrogenic activity, to determine estrogen binding ability, and to evaluate tissue culture anticancer activity.

Keyphrases □ Cyclopropyl analogs of stilbene and stilbenediol—synthesis as potential antiestrogens □ Stilbene and stilbenediol cyclopropyl analogs—synthesis as potential antiestrogens □ Antiestrogens, potential—synthesis of cyclopropyl analogs of stilbene and stilbenediol

A previous publication (1) discussed the cyclopropane moiety in connection with work on estrogen receptor elucidation. The preparation of *gem*-dichlorocyclopropyl analogs of the stilbene (I) and stilbenediol (II) series (Table I), using two different synthetic methods, and their subsequent reduction to the corresponding cyclopropyl analogs (Table II) are reported here.

Antiestrogens that arrest epithelial proliferation caused by estrogens in the uterus or vagina could have some utility in a particular uterine or vaginal cancer. Furthermore, certain antiestrogens may prove effective against other hormonal-dependent cancers such as breast cancer. Effective chemotherapeutic agents against such solid, hormone-sensitive tumors have not been fully developed and the duration of chemotherapeutic remissions is not as long lasting as those induced by endocrine manipulation.



I II

Currently, the compounds reported in Tables I and II are being tested to discriminate between their estrogenic and antiestrogenic activities and for their estrogen binding ability, and they are being evaluated in a tissue culture anticancer assay[1].

DISCUSSION

A two-phase catalytic method (2) and an organomercurial method (3–7) have proven effective as applied to olefins of low reactivity (*e.g.*, *trans*-stilbene) toward dichlorocarbenes generated by other procedures. Of practical significance is the fact that yields are usually high by these two routes.

The *gem*-dichlorocyclopropyl analogs of stilbene were prepared according to both methods, while the stilbenediols were subjected only to the latter mercurial method since the phenolic groups were sensitive to strong base and some stilbenediols were poorly soluble in chloroform. The *gem*-dichlorocyclopropane precursors listed in Table I were subsequently reduced with sodium metal and methanol (8, 9).

The general reaction developed by Simmons and coworkers (10–12) for the stereospecific synthesis of cyclopropane derivatives involves the treatment of olefins with diiodomethane and zinc–copper couple. This convenient method could have allowed omission of the reductive step; however, in spite of various modifications (13–17), this method does not consistently produce respectable yields when the olefins are weak nucleophiles. Olefins in which the nucleophilic character of the double bond has been reduced by electron-withdrawing groups should react less readily with carbenes than those in which the nucleophilic character has been increased by electron-donating groups (18–20).

Method A—All reports of the syntheses of *gem*-dihalocyclopropane derivatives have stressed the necessity of operating under strictly anhydrous conditions because of the rapid hydrolysis of dichlorocarbene. On the other hand, the method established by Makosza and Wawrzyniewicz (2) and improved by Dehmlow and Schonefeld (21, 22) (Scheme I) generates dichlorocarbene in the reaction among chloroform, a concentrated solution (50%) of sodium hydroxide, and a catalytic amount of triethylbenzylammonium chloride, thus allowing the preparation of *gem*-dichlorocyclopro-

pane derivatives with retention of configuration by the addition of dichlorocarbene to olefins.

Although the reaction is carried out in an aqueous medium, only a small fraction of the generated dichlorocarbene is hydrolyzed. This result may be explained by the catalytic mode of action of the quaternary ammonium compound (2). In concentrated sodium hydroxide solution, triethylbenzylammonium chloride is transformed into the hydroxide, which is insoluble in the reaction medium. Thus, the quaternary ammonium hydroxide migrates to the boundary between the aqueous and organic phases, where it reacts with chloroform to yield the quaternary ammonium derivative of the trichloromethyl anion. After diffusion into the organic phase, the derivative is transformed into dichlorocarbene and the ammonium chloride (Scheme II).

The dichlorocarbene reacts rapidly with the olefin present in the organic layer, whereas the quaternary ammonium chloride passes to the phase boundary and reenters the transformation cycle. Thus, dichlorocarbene is only slightly hydrolyzed. On the other hand, the high degree of dichlorocarbene utilization, despite the use of stoichiometric amounts of olefin and chloroform, is due to the fact that the quantity of dichlorocarbene that can be formed at one time is small and does not exceed the amount of the catalyst, *i.e.*, 1%. Consequently, dichlorocarbene is always confronted with a large excess of olefin.

This catalytic method seems to be the simplest procedure used so far, and the isolation of the resulting products appears to present no difficulties. The yields of the products obtained by this method are high, and no excess of the olefin is required; the ratio of olefin to chloroform is 2:1 to 1:2, depending on the availability of the olefin.

Excellent yields were obtained by this method for olefins that gave either no product or poor yields by other methods (8, 23–26). For example, the *gem*-dichlorocyclopropyl analog of *trans*-stilbene was not isolated using the Doering and Hoffman procedure (8); it was produced in 90% yield by the Seyferth *et al.* method (5, 6) and in 96% yield by the Dehmlow and Schonefeld method (21, 22). In most cases, high yields (74–86%) were obtained by this method when commercially available olefins were used.

This basic method, however, was not suited for diphenolic olefins such as diethylstilbestrol (II, $R_1 = R_2 = CH_2CH_3$, Z = H) due to salt formation from the concentrated sodium hydroxide solution. The enormous decrease in solubility of diethylstilbestrol in chloroform posed a problem. The diacetate ester of diethylstilbestrol, which was soluble in chloroform, was tried at room temperature, but it too was hydrolyzed to the salt and thrown out of organic phase and thus was unavailable for reaction with the dichlorocarbene.

Method B—Seyferth and coworkers (3–7) reported that phenyl(trihalomethyl)mercury compounds were very useful and versatile reagents as sources for dihalocarbenes; they reacted with olefins to give *gem*-dihalocyclopropanes in high yields. It was found that phenyl(bromodichloromethyl)mercury is far superior to phenyl(trichloromethyl)mercury in its reaction with olefins to produce exclusively 1,1-dichlorocyclopropanes (3). This mercurial route does not involve basic reaction conditions and does not proceed *via* nucleophilic intermediates (such as trichloroacetate or trichloro-

methide ion); high yields at lower temperatures are obtained. The conversion of *cis*- and *trans*-olefins to *gem*-dichlorocyclopropanes proceeds with retention of configuration, as illustrated in the preparation of 1,1-dichloro-*trans*-2,3-diphenylcyclopropane in 90% yield from *trans*-stilbene (Scheme III).

The preparation of the Seyferth reagent, phenyl(bromodichloromethyl)mercury, is time consuming and tedious, involving anhydrous conditions. A special high-speed stirring apparatus is needed since both the phenylmercuric halide and the potassium *tert*-butoxide (in the form of its monosolvate) have very low solubility in the solvent system, and a large excess of the haloform (bromodichloromethane) is needed (3, 4). The monosolvate was found to produce high yields. Seyferth and Lambert (4) succeeded in eliminating the need for preparing potassium *tert*-butoxide–*tert*-butyl alcohol monosolvate by modifying the original procedure so that commercial potassium *tert*-butoxide could be substituted; however, the modified procedure resulted in 5% yields in this laboratory. Consequently, freshly prepared potassium *tert*-butoxide as the monosolvate with *tert*-butyl alcohol was used and yields increased to 69%. During the crystallization of this reagent, the first crop of crystals was contaminated with unchanged phenylmercuric chloride. Hence, the procedure was modified in this laboratory to prevent the contamination.

This was the method of choice in preparing the *gem*-dichlorocyclopropane derivatives of 4,4′-dimethoxystilbene (II, $R_1 = R_2 = H$, $Z = CH_3$), dimestrol (II, $R_1 = R_2 = CH_2CH_3$, $Z = CH_3$), and diethylstilbestrol diacetate (II, $R_1 = R_2 = CH_2CH_3$, $Z = COCH_3$). In the reactions using dimestrol or diethylstilbestrol diacetate, the PMR spectrum of the product indicated the presence of a considerable amount of unchanged olefin. Despite a twofold quantity of reagent, the yield did not improve. Since all attempts to separate the mixture failed, it was necessary to remove the precipitated phenylmercuric bromide and rerun the reaction using the original mixture (unused olefin and product) with additional amounts of the Seyferth reagent to induce the reaction to go to completion. Using this variation, Compounds VI and VII were obtained in 59 and 72% yields, respectively.

Minor limitations in the Seyferth method were reported (27). Phenyl(bromodichloromethyl)mercury reacted with carboxylic acids in benzene at 60–80° to give dichloromethyl esters in high yields, and the mercurial reagent reacted with alcohols to form dichloromethyl ethers and a mixture of products. Refluxing diethylstilbestrol with phenyl(bromodichloromethyl)mercury in benzene at 80° yielded a dark liquid from which no product was isolated. This promoted the use of dimestrol and diethylstilbestrol diacetate as substrates (Scheme IV).

$$CHCl_3 + (CH_3CH_2)_3\overset{+}{N}CH_2C_6H_5\ \overset{-}{O}H \rightleftharpoons \overset{-}{C}Cl_3(CH_3CH_2)_3\overset{+}{N}CH_2C_6H_5 + H_2O$$

$$\overset{-}{C}Cl_3(CH_3CH_2)_3\overset{+}{N}CH_2C_6H_5 \longrightarrow :CCl_2 + (CH_3CH_2)_3\overset{+}{N}CH_2C_6H_5\overset{-}{C}l$$

Scheme II

Reduction of aliphatic *gem*-dihalocyclopropyl compounds by sodium in wet methanol was originated by Doering and Hoffman (8). All *gem*-dichlorocyclopropanes involved in this study were reduced by this method (Scheme V) except VII and VIII. The 2,3-dialkyl derivatives were difficult to reduce, but increasing the equivalent amount of sodium metal and the quantity of methanol brought about good yields (Table II).

Being unable to reduce VII and VIII completely to the corresponding cyclopropyl analogs because of hydrolysis, it was of interest to search for a method that would bring about demethylation of XII to the analog X. Demethylation of aryl methyl ethers can be effected by a variety of reagents (28, 29), but usually it is necessary to employ high temperatures and acidic reagents. These conditions are too drastic for the cyclopropyl ring. Aromatic ethers have been cleaved at room temperature or lower using boron tribromide (30–32) (Scheme VI). The reactants are mixed in methylene chloride or *n*-pentane at −80°, and the mixture is allowed to warm to room temperature with continuous stirring for 15–20 hr. Methylene chloride is reported to have the most powerful solvent action and is preferred.

Even though cyclopropanes are sensitive to Lewis acids, boron tribromide was used successfully as a demethylating agent on XII.

EXPERIMENTAL[2]

Phenyl(bromodichloromethyl)mercury—The procedure described by Seyferth and Lambert (4) was modified. Phenylmercuric chloride[3] (31.25 g, 0.1 mole) and bromodichloromethane[3] (25 g, 0.15 mole) were dissolved in 600 ml of tetrahydrofuran (dried with calcium hydride and distilled from lithium aluminum hydride[4]) in a flame-dried, 1-liter, three-necked flask. The flask was equipped with a mechanical stirrer, a nitrogen inlet tube, and an air condenser fitted with a mercury trap. The mixture was stirred and cooled in a dry ice–acetone bath. To a 500-ml conical flask in a dry box under anhydrous nitrogen was added 24 g (0.13 mole) of potassium *tert*-butoxide–*tert*-butyl alcohol monosolvate (33).

[2] Methods A and B are representative for the preparation of most compounds listed in Table I. Analyses and physical properties for all compounds are reported in Tables I and II. All IR spectra were recorded on a Beckman IR-20A, using polystyrene film as a standard to ascertain reproducibility. The NMR spectroscopic analyses were performed on a Varian T-60 MHz instrument. Most spectra were reported in either $CDCl_3$ or CD_3OD with tetramethylsilane as the internal standard. Mass spectra were taken with a Hitachi-RMU-6E mass spectrometer. Melting points were taken on a Hoover capillary melting-point apparatus and are uncorrected. Yields are based on pure samples. Research chemicals were of the purest grade and, in all cases, were used without further purification. Solvents were reagent grade and most were purchased from Eastman Chemical Co., Rochester, NY 14650

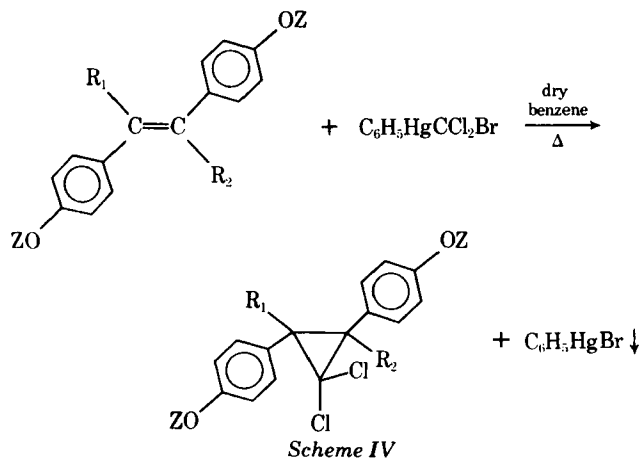
The conical flask was connected to the 1-liter three-necked flask by 2.54-cm (1-in.) Tygon tubing, and the contents were transferred to the reaction mixture slowly over 30 min. After addition, the mixture was stirred for 15 min at −55° and transferred to a 2-liter single-necked flask. The solvent was removed *in vacuo* (3 mm) through a dry ice–acetone trap without heating the flask until most of the solvent had evaporated. The remaining solvent was removed on a water bath at 20°, yielding a gray solid to which was added 500 ml of benzene.

The mixture was agitated until a partial solution was effected. Then 100 ml of water was added, the mixture was shaken vigorously, and 8.0 g of gray solid was collected. The layers were separated, and the aqueous phase was extracted with three 100-ml portions of benzene. All of the organic layers were collected, and benzene was removed *in vacuo*. To the white solid was added 500 ml of hot hexane–chloroform (3:1) solution in small portions with swirling and occasional heating on a steam bath until most of the solid dissolved. The flask was then placed at 0°, and 4.0 g of unreacted phenylmercuric chloride was collected on filter paper.

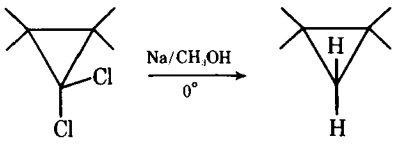
The clear filtrate was placed in the refrigerator at 0°. Crystals formed and were collected, yielding 22.74 g of white needles, mp 108–110° dec. Concentrating the mother liquor and placing the residue into the refrigerator yielded another 7.4 g of the mercurial reagent; the total yield was 30.14 g (68.5%).

1,1-Dichloro-*trans*-2,3-diphenylcyclopropane (III) (Method A)—Following the method reported (21, 22), 16.0 g (0.09 mole) of *trans*-stilbene[3] and 2.0 g (0.008 mole) of triethylbenzylammonium chloride[3] were dissolved in 300 g of chloroform contained in a 1-liter three-necked flask fitted with a mechanical stirrer, condenser, and dropping funnel. The flask was cooled in an ice water bath, and 200 g of ice-cold 50% sodium hydroxide solution was added dropwise. The mixture was stirred at 10–20° for 6 hr and then at room temperature for 2 days. The dark-brown mixture was diluted with 100 ml of water and filtered. Two layers were separated, and the aqueous layer was washed with three 50-ml portions of methylene chloride.

All organic extracts were combined, washed with water, and dried over anhydrous magnesium sulfate. The drying agent was filtered, and the chloroform was evaporated under reduced pressure,



Scheme IV



Scheme V

yielding 28 g of a dark-brown oil. Distillation of the crude oil at 140° (0.5 mm) gave 20 g (86%) of a light-yellow liquid, which solidified after several days at 5°, mp 38–40° [lit. (5, 6) mp 39–40.5°]. In subsequent reactions the distilled compound was passed through neutral alumina (activity I)[5], using petroleum ether (bp 30–60°) as the eluent to remove a small amount of the decomposed products; ν_{max} (mineral oil mull): 3095 (weak), 3060 (medium), 3025 (medium), 1610 (medium), 1503 (strong), 1220 (weak), 1175 (medium), 1108 (weak), 1095 (strong), 1060 (medium), 1035 (medium), 915 (weak), 865 (strong), 755 (strong), 743 (weak), and 695 (strong) cm^{-1}; $\delta_{60\ MHz}$ ($CDCl_3$): 3.15 (s, 2H) and 7.37 (s, 10H).

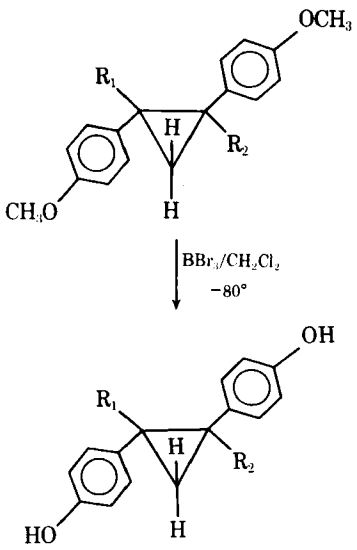
1,1-Dichloro-*cis*-2,3-diphenylcyclopropane (IV)—*Method A*—To a cold solution of 0.50 g (0.002 mole) of triethylbenzylammonium chloride and 110 g of chloroform in a three-necked flask was added 6.0 g (0.33 mole) of *cis*-stilbene[3], and the solution was stirred to dissolve the stilbene. A 50% sodium hydroxide solution (75 g) was added carefully through a dropping funnel; it was stirred at 10–20° for 6 hr and then at room temperature for 24 hr by means of a magnetic stirrer. The mixture was diluted with 100 ml of water, and a dark-brown chloroform layer separated. The aqueous phase was extracted with three 50-ml portions of methylene chloride, and the organic layers were collected and dried over anhydrous magnesium sulfate. Evaporation of the solvent *in vacuo* yielded 7.5 g of dark-brown oil.

The crude oil was purified by placing it on a 1.3 × 33-cm column of alumina (activity I)[5] and eluting with purified petroleum ether (bp 30–60°). A cream-colored oil, 6.0 g (69%), solidified at 0°, mp 48–49°.

The IR and NMR spectra were identical to those obtained using Method B.

Method B—According to the literature method (5, 6), 3.6 g (0.02 mole) of *cis*-stilbene[3] was added to 10.0 g (0.022 mole) of phenyl(bromodichloromethyl)mercury in benzene. After the resulting solution was refluxed with stirring under dry nitrogen and maintained at 82–88° in an oil bath for 1.5 hr with stirring, phenyl mercuric bromide precipitated (7.2 g, 92%) and the reaction mixture turned yellow. The relative proton absorption in the NMR spectrum showed small quantities of the unchanged olefin.

The mixture then was refluxed with stirring for an additional hour. The NMR spectrum of this mixture indicated that the olefin



Scheme VI

[5] E. Merck ag Darmstadt.

had reacted. Benzene was removed on a flash evaporator, yielding 6.5 g of crude product, which was dissolved in petroleum ether (bp 30–60°) and filtered to remove a small amount of white precipitate, mp 175° dec. The crude product was purified through a 2 × 18-cm column of neutral alumina (activity I)[5] using purified petroleum ether (bp 30–60°). A cream-colored oil was eluted, which solidified after standing in a refrigerator overnight. The solid had a melting-point range of 49–51° and weighed 4.5 g (86%).

An analytical sample was obtained by sublimation. The sublimator was kept at 45° (0.03 mm) in an oil bath while the inner cold finger was maintained at −5° by a cold water pump. The white needles melted at 50–51.5°; ν_{max} (neat): 3065 (medium), 3050 (strong), 1960 (weak), 1890 (weak), 1810 (weak), 1609 (medium), 1587 (weak), 1500 (strong), 1453 (strong), 1386 (weak), 1250 (weak), 1160 (weak), 1080 (medium), 1050 (medium), 1035 (medium), 1005 (weak), 958 (weak), 927 (medium), 840 (weak), 813 (strong), 754 (strong), 721 (weak), 700 (strong), 648 (weak), and 626 (weak) cm^{-1}; $\delta_{60\ MHz}$ ($CDCl_3$): 3.28 (s, 2H) and 7.18 (m, 10H).

1,1-Dichloro-*trans*-2,3-diethyl-2,3-(4,4′-dimethoxyphenyl)-cyclopropane (VI)—*Method A*—In 150 g of chloroform were dissolved 9.0 g (0.03 mole) of dimestrol[3] (34) and 0.75 g (0.0032 mole) of triethylbenzylammonium chloride in a three-necked flask, fitted with a condenser and a dropping funnel. The mixture was cooled in an ice water bath, and 75 g of a 50% sodium hydroxide solution was added dropwise while the mixture was agitated with a magnetic stirrer. Then the mixture was stirred at 10–20° for 6 hr and at room temperature for an additional 40 hr.

To the dark mixture was added 100 ml of water, and the solution was transferred to a separator. A dark-brown chloroform layer was separated after the phases were allowed to separate. The aqueous layer was neutralized with dilute hydrochloric acid and extracted with two 50-ml portions of chloroform. The chloroform extracts were combined and dried over anhydrous magnesium sulfate, and the drying agent was filtered. Evaporation of chloroform at reduced pressure gave 13.0 g of a dark-brown oil, which solidified on cooling.

This dark-brown solid was refluxed with 200 ml of petroleum ether (bp 30–60°) for 15–20 min, and the hot mixture was filtered from 2.5 g of a dark-brown solid, mp 170° dec. The light-brown solution was concentrated to about 40 ml at reduced pressure until crystallization occurred. After cooling and stirring, 8.0 g of a yellow solid was collected, mp 109–110°. Another 2.0 g was isolated from further concentration of the filtrate, bringing the total yield to 10 g.

This crude product was crystallized from 200 ml of hot methanol, yielding 8.5 g (74.7%) of light-yellow crystals, mp 110–111°. In a subsequent reaction, the product was purified using a neutral alumina column (activity I)[5] and *n*-hexane as the eluent.

Repeated crystallization from hot methanol gave an analytical sample, mp 111–112°; ν_{max} (CCl_4): 3038 (weak), 2975 (strong), 2940 (strong), 2920 (weak), 2880 (weak), 2835 (medium), 1613 (strong), 1580 (weak), 1508 (strong), 1463 (strong), 1445 (medium), 1415 (weak), 1375 (medium), 1333 (weak), 1293 (strong), 1245 (strong), 1175 (strong), 1110 (medium), 1090 (weak), 1035 (strong), 960 (weak), 925 (weak), 885 (weak), 845 (strong), 830 (strong), and 655 (medium) cm^{-1}; $\delta_{60\ MHz}$ ($CDCl_3$): 0.8 (t, 6H), 1.5 (m, 4H), 3.8 (s, 6H), and 7.12 (m, 8H).

Method B—A mixture of 3.4 g (0.011 mole) of dimestrol (34) and 5.5 g (0.013 mole) of phenyl(bromodichloromethyl)mercury in 35 ml of dry benzene was stirred and refluxed at 85–87° (oil bath) under dry nitrogen for 2.0 hr. During refluxing, phenylmercuric bromide precipitated and the reaction mixture turned yellow. The NMR spectrum showed a considerable amount of unchanged olefin. The mixture was stirred and refluxed for an additional 2 hr, but a considerable amount of unchanged olefin was still present as ascertained by NMR spectroscopy.

From the mixture was filtered 3.8 g (87%) of phenylmercuric bromide. Benzene was evaporated under reduced pressure, and a cream-colored solid (3.0 g) was stirred and refluxed under dry nitrogen with 3.0 g of phenyl(bromodichloromethyl)mercury in benzene for 2.0 hr. At this time no unchanged olefin was present in the NMR spectrum. The cream-colored solid (2.8 g) was dissolved in cold chloroform and filtered to remove a small amount of white precipitate. Evaporation of the chloroform and recrystallization of the cream-colored solid from hot methanol gave 2.5 g (59%) of white crystals, mp 110–112°. The NMR and IR spectra were identical to those obtained using Method A.

1,1-Dichloro-*trans*-2,3-diethyl-2,3-(4,4′-diacetoxyphenyl)-cyclopropane (VII) (Method B)—A mixture of 6.0 g (0.016 mole) of diethylstilbestrol[6] diacetate (35, 36) and phenyl(bromodichloromethyl)mercury (8.8 g, 0.02 mole) in 30 ml of dry benzene was refluxed for 5 hr (oil bath) with stirring, using a magnetic stirrer under dry nitrogen. The solution turned yellow and phenylmercuric bromide (6.65 g, 93%) precipitated. An NMR spectrum of the mixture indicated the presence of a small amount of unreacted olefin.

The benzene was evaporated *in vacuo*, and the solid collected was dissolved in 30 ml of dry benzene and refluxed with 4.4 g of phenyl(bromodichloromethyl)mercury under dry nitrogen at 87–90° for 3 hr. At this time, the NMR spectrum showed no unchanged olefin, and the mixture was warmed; 3.65 g (91%) of phenylmercuric bromide was collected. The solvent was removed under vacuum, yielding 6.5 g of a yellow solid.

The crude yellow compound was stirred with cold ethanol to dissolve the unreacted mercurial reagent. A light-yellow solid (5.5 g) was collected, mp 134–180° (melted with partial decomposition at 134° and another melt at 180°). Recrystallization from hot ethanol yielded 5.0 g (72%) of cream-colored crystals, mp 135–137°.

An analytical sample, mp 137–137.5°, was obtained from additional recrystallizations from hot ethanol; ν_{max} (CCl_4): 3050 (weak), 2290 (strong), 2948 (medium), 2795 (weak), 1775 (very strong), 1610 (weak), 1508 (strong), 1465 (medium), 1448 (weak), 1418 (weak), 1377 (strong), 1340 (weak), 1312 (weak), 1205 (very strong), 1170 (strong), 1115 (weak), 1092 (weak), 1022 (strong), 948 (medium), 915 (strong), 852 (strong), 705 (weak), 658 (weak), 618 (medium), and 565 (weak) cm^{-1}; $\delta_{60\ MHz}$ ($CDCl_3$): 0.8 (t, 6H), 1.53 (m, 4H), 2.3 (s, 6H), and 7.28 (q, 8H).

1,1-Dichloro-*trans*-2,3-diethyl-2,3-(4,4′-dihydroxyphenyl)-cyclopropane (VIII)—In 50 ml of methanol on a steam bath was dissolved 4.35 g (0.01 mole) of VII with stirring. After complete solution was obtained, 10 g of 15% sodium hydroxide solution was added dropwise to the warm solution with stirring for 10 min. Then the solution was poured over an ice water bath with vigorous stirring. This mixture was neutralized carefully with 7 ml of 36% HCl. The gum which appeared was collected on a filter paper, dissolved in 80 ml of hot benzene, and left at 37° for crystallization. White needles, mp[7] 143–145° dec, 2.95 g (84%), were obtained.

An analytically pure sample, mp 147.5–148° dec.[7] (with melting) was obtained by a second recrystallization from hot benzene; ν_{max} (KBr): 3400 (strong and broad), 3040 (weak), 2980 (medium), 2940 (weak), 2880 (weak), 1610 (strong), 1600 (strong), 1505 (strong), 1435 (strong), 1380 (strong), 1333 (strong), 1295 (weak), 1230 (strong), 1170 (strong), 1110 (medium), 1088 (weak), 1030 (weak), 1015 (medium), 965 (weak), 934 (medium), 895 (weak), 835 (strong), 789 (weak), 750 (weak), 670 (medium), 630 (weak), 560 (medium), and 498 (weak) cm^{-1}; $\delta_{60\ MHz}$ ($CDCl_3$ + CD_3OD): 0.80 (t, 6H), 1.50 (q, 4H), 3.80 (s, 2H), and 7.03 (m, 8H).

1,1-Dichloro-*trans*-2,3-(4,4′-dimethoxyphenyl)cyclopropane (V) (Method B)—To 150 ml of dry benzene (distilled with calcium hydride) under nitrogen was dissolved 2.4 g (0.01 mole) of 4,4′-dimethoxystilbene (light brown in color, mp 210°) with stirring (magnetic bar). The solution was refluxed using an oil bath and cooled to 85°. Then 6.0 g (0.014 mole) of phenyl(bromodichloromethyl)mercury was added, and the mixture was refluxed with stirring under nitrogen for 2.5 hr. The mixture turned yellow-brown with a large quantity of precipitate.

From the warm solution was filtered 3.3 g (68%) of light-brown phenylmercuric bromide. Benzene was removed under vacuum, yielding a waxy, dark-blue substance, which solidified on standing. The solid was stirred with 20 ml of chloroform to effect a partial solution, which was allowed to stand at 0° for 3 hr. The starting olefin was collected, 1.0 g (41%), and the filtrate was transferred to a 100-ml flask. The chloroform was evaporated *in vacuo*, leaving a yellow oil, which solidified.

To the solid was added 50 ml of hot ethanol; this mixture was heated on a steam bath to effect a partial solution and was filtered. The yellow filtrate was cooled slowly, and 1.7 g (52%) of light-yellow crystals, mp 86–88°, was collected. The crystals were dissolved in hot ethanol and treated with activated charcoal. After filtering

[6] Nutritional Biochemical Corp., Cleveland, OH 44128

[7] To obtain an accurate melting point, the bath was first heated to 135° and the capillary was introduced.

and cooling, 1.5 g (45%) of cream-colored needles, mp 88–89.5°, was obtained. An analytical sample was prepared from hot ethanol; ν_{max} (CCl_4): 3045 (weak), 3000 (medium), 2960 (medium), 2940 (weak), 2910 (weak), 2840 (medium), 1610 (strong), 1585 (weak), 1505 (strong), 1465 (medium), 1440 (medium), 1300 (medium), 1250 (very strong), 1175 (strong), 1105 (medium), 1070 (weak), 1045 (strong), 870 (strong), and 825 (medium) cm^{-1}; $\delta_{60\ MHz}$ (CCl_4): 2.95 (s, 2H), 3.7 (s, 6H), and 6.96 (q, 8H).

***trans*-1,2-Diphenylcyclopropane (IX*a*)**—The reductive method of Dale and Swartzentruber (9) was used. To a 250-ml three-necked flask, fitted with a dry ice–acetone condenser and a dropping funnel, were added 3.3 g (0.012 mole) of 1,1-dichloro-*trans*-2,3-diphenylcyclopropane (III) and 40 ml of ether. This solution was stirred (magnetic stirrer) and cooled in an ice water bath. Sodium metal (5.5 g, 0.25 g-atom) was added in small pieces as 60 ml of methanol–water (100:3.3 ml) was added dropwise. The sodium reacted after 2 hr, and a white solid was observed. When all of the sodium had reacted, 20 ml of water was added and the aqueous layer was extracted with two 30-ml portions of ether.

The aqueous phase was neutralized slowly and carefully on an ice–salt bath with concentrated hydrochloric acid and extracted with two 20-ml portions of ether. The ether extracts were dried over anhydrous magnesium sulfate and filtered. The solvent was evaporated at reduced pressure, and the light-yellow liquid was distilled and collected in three fractions at 0.01 mm.

Fraction 1 (bp 38–52°) was kerosene (used for storing sodium), fraction 2 (bp 67°) was a mixture, and fraction 3 (bp 90–92°) yielded 1.6 g (69%) of 1,2-diphenylcyclopropane.

An analytical sample was obtained by refractionation, bp 90° (0.01 mm) [lit. (37–40) mp 15.3°, bp 144–145.3°(3.8 mm)]; ν_{max} (neat): 3065 (medium), 3030 (strong), 2938 (medium), 2860 (weak), 1948 (medium), 1875 (weak), 1795 (weak), 1605 (very strong), 1585 (medium), 1495 (very strong), 1450 (strong), 1280 (weak), 1212 (strong), 1183 (medium), 1158 (weak), 1118 (strong), 1072 (strong), 1030 (strong), 1002 (weak), 989 (weak), 940 (medium), 905 (strong), 840 (weak), 775 (medium), 750 (strong), and 695 (very strong) cm^{-1}; $\delta_{60\ MHz}$ ($CDCl_3$): 1.4 (m, 2H), 2.15 (m, 2H), and 7.18 (s, 10H).

***cis*-1,2-Diphenylcyclopropane (IX*b*)**—A solution of 2.0 g (0.008 mole) of IV and 30 ml of ether in a 250-ml three-necked flask, fitted with a dry ice–acetone condenser, was stirred (magnetic stirrer) in an ice water bath. Sodium metal (6.9 g, 0.3 g-atom) was added in small pieces over 1.5 hr, and 60 ml of wet methanol (2 ml of water) was introduced slowly through a dropping funnel with stirring (magnetic stirrer). After all of the sodium metal reacted, 20 ml of water was added and the aqueous layer was extracted with two 30-ml portions of ether.

The aqueous phase was neutralized slowly with concentrated hydrochloric acid on an ice–salt bath and extracted with two 30-ml portions of ether. The ether extracts were dried over anhydrous magnesium sulfate and filtered. Evaporation of ether at 30° under vacuum yielded 1.5 g of a yellow oil, which solidified when left at 0°. Sublimation at 40–50° (0.04–0.05 mm) with the cold finger at −40° yielded 1.0 g (68%) of white needles, mp 38–38.5° [lit. (37–40) mp 38–38.5°]; ν_{max} (neat): 3015 (strong), 1950 (medium), 1880 (weak), 1805 (weak), 1603 (strong), 1580 (weak), 1493 (strong), 1443 (strong), 1380 (weak), 1362 (medium), 1200 (medium), 1160 (medium), 1110 (weak), 1073 (strong), 1030 (strong), 915 (medium), 833 (medium), 775 (medium), 760 (medium), 720 (medium), 690 (medium), and 625 (medium) cm^{-1}; $\delta_{60\ MH_z}$ ($CDCl_3$): 1.42 (m, 2H), 2.5 (t, 2H), and 7.0 (s, 10H).

1,2-Diethyl-*trans*-1,2-(4,4′-dimethoxyphenyl)cyclopropane (XII)—To 150 ml of ether in a 1-liter three-necked flask, fitted with a dry ice–acetone condenser, dropping funnel, and mechanical stirrer, was added 8.34 g (0.02 mole) of VI. To this stirred mixture was added 40 g (1.7 g-atom) of sodium metal in small portions over 3.5 hr, along with 300 ml of wet methanol (10 ml of water), which was introduced slowly through a dropping funnel.

After all of the sodium metal had reacted, 100 ml of water was added slowly and carefully and the aqueous layer was extracted with two 50-ml portions of ether. The aqueous phase was neutralized with concentrated hydrochloric acid slowly on an ice–salt bath and extracted twice with 50 ml of ether. Ether extracts were collected and dried over anhydrous magnesium sulfate and filtered. Evaporation of ether *in vacuo* yielded 8.4 g of a yellow-brown oil, which solidified on standing at 0°. The crude compound was dissolved in hot methanol, treated with activated charcoal, filtered, and allowed to remain at 37° until crystals formed. Light-yellow crystals were obtained in four different crops[8], totaling 5.25 g (77%), mp 75–78°.

An analytical sample was obtained through sublimation at 70° (0.03 mm), mp 75–76°; ν_{max} (CCl_4): 3030 (weak), 2985 (medium), 2955 (strong), 2935 (medium), 2870 (weak), 2835 (weak), 1605 (strong), 1575 (weak), 1503 (strong), 1455 (medium), 1435 (medium), 1368 (weak), 1300 (weak), 1285 (medium), 1235 (very strong), 1165 (strong), 1103 (medium), 1063 (weak), 1033 (strong), 825 (strong), 692 (weak), and 608 (medium) cm^{-1}; $\delta_{60\ MHz}$ ($CDCl_3$): 0.6 (m, 6H), 0.95 (s, 2H), 1.48 (m, 4H), 3.78 (s, 6H), and 7.03 (q, 4H); mass spectrometry M^+: *m/e* 310.

1,2-Diethyl-*trans*-1,2-(4,4′-dihydroxyphenyl)cyclopropane (X)—A reported demethylation procedure (30–32) was followed; 3.1 g (0.01 mole) of XII was dissolved in 60 ml of anhydrous methylene chloride (dried and distilled from anhydrous calcium hydride) contained in a 250-ml, flame-dried, single-necked flask fitted with a dropping funnel with a calcium chloride drying tube. The single-necked flask was placed in a dry ice–acetone bath (−80°); then 4.7 g (0.019 mole) of boron tribromide[3], which was weighed in the hood and quickly diluted with 60 ml of dry methylene chloride and transferred to the dropping funnel, was added dropwise to the dimethyl ether solution over 10–15 min while the mixture was stirred (magnetic stirrer).

After 15 min, the cooling bath was removed and the reddish mixture was stirred at room temperature for 20 hr. The resulting pale-brown mixture was placed in an ice water bath and decomposed slowly with 100 ml of water. The organic material was extracted with two 100-ml portions of ether, and the combined ether layers were extracted with 150 ml of 2 *N* sodium hydroxide solution.

The alkaline solution was neutralized with dilute hydrochloric acid and extracted with ether. The ether was washed with water, dried over anhydrous magnesium sulfate, and filtered. Evaporation of the ether *in vacuo* yielded a pale-brown oil, which was dissolved in hot chloroform, treated with activated charcoal, filtered, and cooled, yielding 1.98 g (70%) of white crystals, mp 138–140°.

Recrystallization from hot benzene provided an analytical sample, mp 139–141°; ν_{max} (KBr): 3300 (broad), 3043 (weak), 2960 (medium), 2872 (weak), 2792 (weak), 2074 (weak), 1890 (medium), 1764 (weak), 1607 (strong), 1592 (strong), 1507 (strong), 1432 (strong), 1347 (strong), 1307 (weak), 1292 (weak), 1222 (strong), 1164 (weak), 1097 (medium), 1067 (medium), 1034 (medium), 1007 (medium), 963 (weak), 952 (weak), 922 (weak), 892 (weak), 860 (weak), 827 (strong), 764 (weak), 734 (weak), 672 (weak), 612 (weak), and 522 (weak) cm^{-1}; $\delta_{60\ MHz}$ (CCl_4–CD_3OD): 0.6 (m, 6H), 0.95 (s, 2H), 1.55 (m, 4H), 2.55 (s, 2H), and 6.98 (q, 8H); mass spectrometry M^+: *m/e* 282.

***trans*-1,2-Bis(*p*-methoxyphenyl)cyclopropane (XI)**—The method reported by Doering and Hoffman (8) was followed; 1.6 g (0.005 mole) of V and 6.0 g (0.26 g-atom) of sodium metal were added to 60 ml of wet methanol in 30 ml of ether. A light-yellow oil (1.2 g), which solidified when absolute ethanol was added, was obtained. The mixture was heated on a steam bath and filtered. The solution was allowed to cool slowly and was stored at 0° overnight. A white solid (0.42 g), mp 66–68°, was collected. The filtrate was concentrated by evaporation and placed into a refrigerator. Another 0.6 g of white crystals, mp 68–70°, brought the total yield to 1.02 g (78%).

Sublimation at 70–75° (0.05 mm) with the cold finger at −5° (ammonium chloride–sodium nitrate–sodium chloride–ice–water mixture) yielded 0.86 g (67%) of a white solid, mp 70.5–71.5° [lit. (41) mp 70.5–71.5°]; $\delta_{60\ MHz}$ ($CDCl_3$): 1.3 (M= 2H), 2.05 (m, 2H), 3.78 (s, 6H), and 6.95 (q, 8H).

[8] Cooling of the concentrated solution at 0° caused separation of oil instead of crystals; therefore, it was necessary to crystallize first at room temperature and then at 10°. The concentration of the mother liquor gave an additional crop of crystals.

Effect of pKb on Lipophilic Binding of Disopyramide Derivatives to Human Plasma

YIE W. CHIEN ˣ, MICHAEL J. AKERS *, and PETER K. YONAN

Abstract □ The extent of plasma binding, the partition coefficient, and the pKb of 13 disopyramide derivatives were determined. The structural variation on the diisopropylaminoethyl group of disopyramide molecules influenced these physical parameters to varying degrees. Results demonstrated that the extent of interaction between drugs and human plasma was a linear function of their lipophilicity and inversely proportional to the magnitude of the pKb value.

Keyphrases □ Disopyramide derivatives—determination of plasma binding, partition coefficient and pKb, relationship between pKb and binding □ Lipophilic binding of 13 disopyramide derivatives to human plasma—relationship to pKb □ Plasma binding, 13 disopyramide derivatives—determination, relationship to pKb □ Partition coefficients, 13 disopyramide derivatives—determination

Previously, it was reported (1) that the extent of plasma binding for 20 disopyramide derivatives was linearly related to their lipophilicity, log (p.c.), as defined by the following relationship:

$$\log (D_b/D_f) = \log (D_b/D_f)_0 + \log (\text{p.c.}) \qquad \text{(Eq. 1)}$$

Effect of pKb on Lipophilic Binding of Disopyramide Derivatives to Human Plasma

YIE W. CHIEN ˣ, MICHAEL J. AKERS *, and PETER K. YONAN

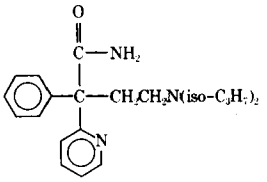
Abstract □ The extent of plasma binding, the partition coefficient, and the pKb of 13 disopyramide derivatives were determined. The structural variation on the diisopropylaminoethyl group of disopyramide molecules influenced these physical parameters to varying degrees. Results demonstrated that the extent of interaction between drugs and human plasma was a linear function of their lipophilicity and inversely proportional to the magnitude of the pKb value.

Keyphrases □ Disopyramide derivatives—determination of plasma binding, partition coefficient and pKb, relationship between pKb and binding □ Lipophilic binding of 13 disopyramide derivatives to human plasma—relationship to pKb □ Plasma binding, 13 disopyramide derivatives—determination, relationship to pKb □ Partition coefficients, 13 disopyramide derivatives—determination

Previously, it was reported (1) that the extent of plasma binding for 20 disopyramide derivatives was linearly related to their lipophilicity, log (p.c.), as defined by the following relationship:

$$\log (D_b/D_f) = \log (D_b/D_f)_0 + \log (\text{p.c.}) \qquad \text{(Eq. 1)}$$

Table I—Linear Relationship between the Extent of Plasma Binding and the Lipophilicity of Disopyramide Derivatives with the Structural Variation of their Amide, Pyridyl, or Phenyl Moieties



Structural Variation on	n^a	Observed Relationships[b]
	10	$\log (D_b/D_f) = -0.303 + 0.473 \log$ (p.c.) $R = 0.986$ $s^2 = 0.0034$
	7	$\log (D_b/D_f) = -0.369 + 0.641 \log$ (p.c.) $R = 0.982$ $s^2 = 0.0059$
	6	$\log (D_b/D_f) = -0.476 + 0.734 \log$ (p.c.) $R = 0.923$ $s^2 = 0.0303$

[a] n = number of derivatives used in the analysis. [b] R = correlation coefficient; s^2 = residual variance.

IV		2.680	−0.553	5.40
V		0.999	0.560	8.50
VI		1.190	0.689	8.86
VII		0.495	−0.373	9.95

[a] SC-13957, SC-13268, SC-24566, SC-13251, SC-13212, SC-13482, and SC-27829, respectively.

where log (D_b/D_f) was theoretically derived and related to the equilibrium constant for drug–plasma interactions; D_b and D_f are the concentrations of drug bound to plasma protein and freely existing in the solution phase, respectively; and log $(D_b/D_f)_0$ is the intercept of log (D_b/D_f) *versus* log (p.c.) plots.

It was observed that the structural variation of the amide, pyridyl, or phenyl moieties resulted in varying degrees of influence on the extent of plasma binding and the lipophilicity of disopyramide derivatives (Table I). It also was found that the omission of the diisopropylaminoethyl group produced no change in the degree of plasma binding while the lipophilicity was enhanced more than 10-fold (fraction of drug bound remained at 27.3% although the partition coefficient in the *n*-octanol–phosphate buffer system was increased from 0.66 to 6.87). This observation was rationalized by the fact that the diisopropylaminoethyl group (with a pKb of 8.36) was protonated at the physiological pH of 7.4 and did not interact with the plasma protein itself.

For a better understanding of the behavior of the diisopropylaminoethyl group during the interaction of the other three moieties of disopyramide molecules with plasma protein, the studies were extended to cover a new series of disopyramide derivatives with structural variation on the diisopropylaminoethyl moiety only while the other three functional groups were held constant. These results are reported in this paper.

EXPERIMENTAL

Binding of disopyramide derivatives to human plasma and partitioning studies in the system of *n*-octanol–pH 7.4 phosphate buffer were carried out in the same manner as described earlier (1).

Potentiometric pH titration[1] was employed for the determination of pK values. This method is highly reproducible (pK ± 0.03 unit) for acids or bases having pK values between 2.5 and 11 (2). Apparent pK's were determined by the Parke and Davis method (3) instead of by the conventional half-neutralization method because the solubility of the compounds was low and the inflection of the titration curves was not very sharp.

An aqueous solution containing 2.5×10^{-4} *M* compound was titrated with standardized 0.1 *N* hydrochloric acid. An identical solution containing no compound was subsequently titrated, and the difference between these two pH *versus* titrant volume titration curves was calculated. The apparent pKb value was then measured as the pH at the point of inflection of the "pH-different titrant volume curve." Determinations of pKb values were run in duplicate for each compound. No pKb was observed for the compound without the diisopropylaminoethyl group.

RESULTS AND DISCUSSION

In solution, disopyramide derivative molecules (D) exist as an equilibrium mixture of neutral and protonated species (Scheme I):

$$D + H_3O^+ \rightleftharpoons HD^+ + H_2O$$

Scheme I

The degree of protonation (σ) of the diisopropylaminoethyl group varies according to its basicity (K_b) in a series of disopyramide derivatives and the pH profile of the drug solution:

$$\sigma = \frac{[H^+]}{K_b + [H^+]} \qquad \text{(Eq. 2)}$$

If drug molecules are bound to plasma protein only as the neutral form, the equilibrium constant (K_n) for the interaction (4) between the neutral species of disopyramide derivatives and plasma protein is related to the overall equilibrium binding constant (K) as follows:

$$K_n = \frac{K}{1 - \sigma} = \frac{K}{K_b/K_b + [H^+]} \qquad \text{(Eq. 3)}$$

or:

$$\log K_n = \log K - \log K_b + \log (K_b + [H^+]) \qquad \text{(Eq. 4)}$$

As analyzed previously (1), the equilibrium constant, K_n, for the interaction between the neutral species of drug and plasma protein was linearly related to its lipophilicity [as represented by log (p.c.)]:

$$\log K_n = \frac{\mu_0^\circ - \mu_p^\circ}{2.303RT} + \log \text{(p.c.)} \qquad \text{(Eq. 5)}$$

[1] Copenhagen Radiometer, London Co., Westlake, Ohio.

Table III—Disopyramide Derivatives Series (II)

Compound[a]	R	log (D_b/D_f) + log $(K_b$ + $[H^+])$	log (p.c.)	pKb
VIII		1.203	0.083	6.86
IX		0.808	0.501	7.81
X		3.894	0.874	4.74
XI		4.234	0.956	4.68
XII		3.079	1.122	6.90
XIII		1.617	0.877	8.11

[a] SC-13127, SC-13173, SC-13209, SC-13733, SC-13489, and SC-13486, respectively.

where $\mu_0°$ and $\mu_p°$ are the standard chemical potentials for a drug species existing in the organic phase and bound to a protein molecule, respectively.

Substituting Eq. 5 for the log K_n term in Eq. 4 gives:

$$\log K + \log (K_b + [H^+]) = \frac{\mu_0° - \mu_p°}{2.303RT} + \log (\text{p.c.}) - \text{pKb} \quad \text{(Eq. 6)}$$

The Scatchard relationship (5) may be expressed alternatively as:

$$K = \frac{D_b}{D_f} \times \frac{1}{\bar{n}p} \quad \text{(Eq. 7)}$$

since $\bar{n} \gg \bar{v}$. Therefore:

$$\log (D_b/D_f) + \log (K_b + [H^+]) = \log (D_b/D_f)_0 + \log (\text{p.c.}) - \text{pKb} \quad \text{(Eq. 8)}$$

where:

$$\log (D_b/D_f)_0 = \frac{\mu_0° - \mu_p°}{2.303RT} + \log \bar{n}p \quad \text{(Eq. 9)}$$

The terms $\bar{n}$ and p were defined earlier (1) as the total number of binding sites on a protein molecule and the total concentration of plasma protein in the bloodstream, respectively.

Equation 8 predicts that the extent of plasma binding is dependent on both the lipophilicity, log (p.c.), and the pKb of disopyramide derivatives. When the pH of a drug–plasma mixture is maintained at the physiological pH of 7.4, the higher the lipophilicity of drug the greater is the extent of the drug–plasma interaction. On the other hand, as the magnitude of pKb value of diisopropylaminoethyl group increases, the degree of plasma binding decreases.

Table IV—Comparison between the Observed and the Calculated Fraction of Disopyramide Derivatives Bound to Plasma Protein in Table II

Compound[a]	Fraction of Drug Bound, %[b]		
	Observed	Calculated	
		Eq. 10	Eq. 12
I	27.30	30.74	32.89
II	14.35	13.11	9.56
III	12.26	8.91	5.48
IV	10.43	8.67	27.04
V	18.81	22.16	29.10
VI	27.4	28.22	20.47
VII	7.25	9.33	5.26

[a] SC-13957, SC-13268, SC-24566, SC-13251, SC-13212, SC-13482, and SC-27829, respectively. [b] Fraction of drug bound (%) = $[D_b/(D_b + D_f)] \times 100$.

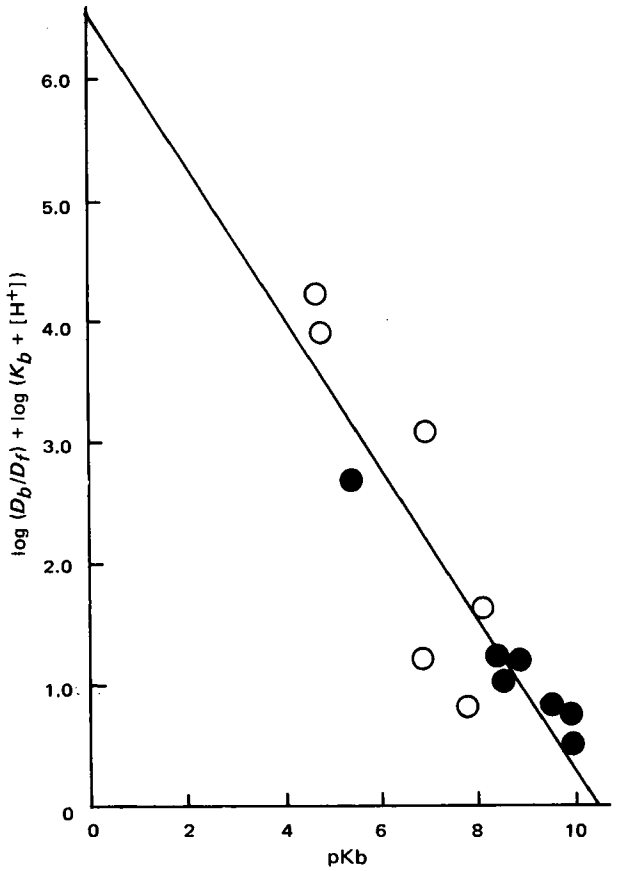

Figure 1—*Linear plot between log* (D_b/D_f) + log $(K_b + [H^+])$ *and pKb as defined by Eq. 12. All terms are defined in the text. The open circles are the data points from Table III, and the solid circles are the data points from Table II.*

The values of log (D_b/D_f) + log $(K_b + [H^+])$, log (p.c.), and pKb tabulated in Tables II and III were submitted separately to multiple regression analysis. Two relationships were obtained:

$$\log (D_b/D_f) + \log (K_b + [H^+]) = 5.035 - 0.448(\pm 0.039)\text{pKb} \quad \text{(Eq. 10)}$$

n	R	s^2
7	0.982	0.016

$$\log (D_b/D_f) + \log (K_b + [H^+]) = 5.835 + 1.857(\pm 0.29) \log (\text{p.c.}) - 0.726(\pm 0.074)\text{pKb} \quad \text{(Eq. 11)}$$

n	R	s^2
6	0.992	0.028

Both the multiple correlation coefficient (R) and the residual variance (s^2) demonstrate that the degree of plasma binding of disopyramide derivatives is highly related to their pKb values and/or their lipophilicity. An F test indicates that both Eq. 10 [$F_{1,5}$ = 134.4; $F_{1,5}$ (when α = 0.01) is 16.26] and Eq. 11 [$F_{2,3}$ = 94.16; $F_{2,3}$ (when α = 0.01) is 30.80] are highly significant statistically.

By using Eqs. 10 and 11, estimated β values (fraction of drug bound) for the disopyramide derivatives were computed and tabulated in the third column of Tables IV and V together with the observed β values (second column).

Equations 10 and 11 demonstrated that structural variation on the diisopropylaminoethyl group resulted in two subgroups whose

Table V—Comparison between the Observed and the Calculated Fraction of Disopyramide Derivatives Bound to Plasma Protein in Table III

Compound[a]	Fraction of Drug Bound, %[b]		
	Observed	Calculated	
		Eq. 11	Eq. 12
VIII	8.23	5.46	50.92
IX	10.48	18.59	46.31
X	30.03	36.41	17.35
XI	45.03	43.91	16.61
XII	87.85	83.12	51.20
XIII	46.35	44.17	39.15

[a] SC-13127, SC-13173, SC-13209, SC-13733, SC-13489, and SC-13486, respectively. [b] Fraction of drug bound (%) = $[D_b/(D_b + D_f)] \times 100$.

plasma binding was dependent, in a different degree, on the magnitude of pKb and lipophilicity as demonstrated by the difference in their slopes (−0.448 and −0.726, respectively).

If the influence of lipophilicity, log (p.c.), is neglected and only the pKb values are related to the extent of plasma binding for these two subgroups of disopyramide derivatives, the importance of pKb can be clearly shown. The linear relationship (Fig. 1) is defined by the following expression:

$$\log (D_b/D_f) + \log (K_b + [H^+]) = 6.528 - 0.621(\pm 0.090)\text{pKb} \quad \text{(Eq. 12)}$$

n	R	s^2

Because of the neglect of the lipophilicity term in Eq. 12, the data points from Table III were noticeably displaced from the slope (Fig. 1). The deviation of the calculated from the observed values was significantly greater for the chemicals in Table III (comparing column 2 with column 4 in Table V) than for the chemicals in Table II (comparing column 2 with column 4 in Table IV). The results demonstrate that the series of disopyramide derivatives in Table II will be better expressed by Eq. 10 and that the extent of plasma binding is linearly correlated with the magnitude of pKb with a slope of −0.448. On the other hand, the extent of plasma binding for the disopyramide derivatives in Table III is a linear function of their lipophilicity and inversely proportional to the magnitudes of pKb. This relationship is best defined by Eq. 11.

In conclusion, the extent of interaction between plasma protein and disopyramide derivatives is significantly influenced by the magnitude of the pKb of the diisopropylaminoethyl group.

Preparation, Isolation, and Identification of 4-Dedimethylamino-11-methoxyanhydrotetracycline

L. J. STOEL *, E. C. NEWMAN ‡, G. L. ASLESON, and C. W. FRANK x

Abstract □ The reaction of diazomethane with 4-dedimethylaminoanhydrotetracycline produced a number of mono-, di-, and trimethylated products. The isolation of one monomethylated product (4-dedimethylamino-11-methoxyanhydrotetracycline) and its subsequent identification utilizing mass spectral and NMR data are described.

Keyphrases □ 4-Dedimethylamino-11-methoxyanhydrotetracycline—isolation and identification after diazomethane methylation of 4-dedimethylaminoanhydrotetracycline □ Methylation of 4-dedimethylaminoanhydrotetracycline with diazomethane—isolation and identification of one reaction product □ Mass spectrometry—identification, 4-dedimethylamino-11-methoxyanhydrotetracycline

During investigations of metal-ion complexation with tetracyclines, it was necessary to prepare, isolate, and identify tetracyclines with blocked or removed functional groups. One method employed was the preparation of methyl ethers of the acidic hydroxy proton sites of anhydrotetracycline by reaction with diazomethane. While preparation of the methyl ethers by this method was relatively simple, the difficulty remained in separating and identifying the reaction products. This paper describes the isolation and structural identification of one product of the methylation reaction.

EXPERIMENTAL

NMR spectra were obtained using high-resolution NMR spectrometers[1]. The chemical shift data were measured relative to tetramethylsilane as an internal standard and reported as parts per million. All NMR spectra were recorded using d_6-dimethyl sulfoxide as the solvent. The mass spectra were obtained on a medium

plasma binding was dependent, in a different degree, on the magnitude of pKb and lipophilicity as demonstrated by the difference in their slopes (−0.448 and −0.726, respectively).

If the influence of lipophilicity, log (p.c.), is neglected and only the pKb values are related to the extent of plasma binding for these two subgroups of disopyramide derivatives, the importance of pKb can be clearly shown. The linear relationship (Fig. 1) is defined by the following expression:

$$\log (D_b/D_f) + \log (K_b + [H^+]) = 6.528 - 0.621(\pm 0.090)\text{pKb} \quad \text{(Eq. 12)}$$

resolution mass spectrometer[2] utilizing the direct inlet at approximately 250°. An ionization energy of 70 ev was used for all spectra reported.

Significant methylation of the C-4 dimethylamine group was reported for the reaction of diazomethane with tetracycline (1). Therefore, this functional group was first removed from the starting material (tetracycline hydrochloride[3]).

Preparation of 4-Dedimethylaminotetracycline—The synthesis of 4-dedimethylaminotetracycline from tetracycline with tetracycline methiodide as an intermediate product, as reported by McCormick *et al.* (2), was used for this preparation. TLC on silica gel H, using acetone–ethyl acetate–water (20:10:3) as the eluting solution revealed a long streaking spot of R_f 0.33. This spot turned pink when exposed to air for about 15–20 min. Nonaqueous titration of the sample in dimethylformamide resulted in an equivalent weight of 411 ± 15 (calc. 401). Mass spectral analysis revealed a parent ion at *m/e* 401.

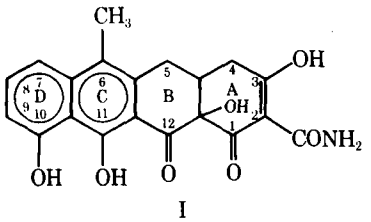
Preparation of 4-Dedimethylaminoanhydrotetracycline—4-Dedimethylaminotetracycline (0.5096 g) was dissolved in 150 ml of a 50% chloroform–isopropanol mixture to which was added 25 ml of concentrated hydrochloric acid. The resulting solution was refluxed for 2 hr and filtered. The volume of the solution was decreased by vacuum, and the remainder was cooled to 0°. The resulting 4-dedimethylaminoanhydrotetracycline (3, 4) was filtered, washed with distilled water, and dried at 40° for 12 hr in a vacuum oven.

The product (0.4314 g), mp 235° dec, had a mass spectral parent ion at *m/e* 383. Nonaqueous titration in dimethylformamide resulted in an equivalent weight of 382 ± 3 (calc. 383).

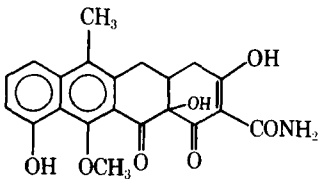
Anal.—Calc. for $C_{20}H_{17}NO_7$: C, 62.66; H, 4.47; N, 3.65. Found: C, 63.06; H, 4.43; N, 3.65.

Preparation and Separation of Methyl Ethers—An ethereal solution of diazomethane was prepared, using *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide as the precursor, by the methods outlined by the manufacturer[4]. A solution of 4-dedimethylaminoanhydrotetracycline dissolved in a minimum amount of chloroform was treated with the ethereal diazomethane solution. After standing at room temperature for 2 hr, the sample was evaporated to dryness under vacuum and stored under nitrogen.

The methylated mixture was redissolved in chloroform and separated on preparative silica gel H TLC plates. Acetone–ethyl acetate–water (20:10:3) was used as the eluting solvent. Bands were observed at R_f values of 0.47, 0.54, 0.64, and 0.81. The band at R_f 0.54 was extracted into chloroform and subsequently purified by



I



II

separation on 10% $CaCl_2$-treated silica gel preparative TLC plates using the previously mentioned eluting solution. The isolated band was extracted from the silica gel by treatment with a heterogeneous mixture of 0.1 *N* HCl and chloroform. The chloroform layer was dried with anhydrous sodium sulfate and evaporated to dryness under vacuum. The sample was dried at 60° in a vacuum oven, mp 210° dec.

The band at R_f 0.47 was identified as 4-dedimethylaminoanhydrotetracycline by mass spectrometry and NMR spectroscopy. Isolation and examination of the other TLC bands indicated that di-, tri-, and, possibly, tetramethylated products are present.

DISCUSSION

The structure of the methylated product of 4-dedimethylaminoanhydrotetracycline (R_f 0.54) was determined from the mass spectral and NMR data. The 70-ev mass spectral fragmentation patterns of some tetracyclines were reported, and several common fragments were assigned in these spectra (5). As in steroid systems (6), the dimethylamino group was observed to have a major effect on the fragmentation pattern of tetracyclines. In cases where the dimethylamino group had been removed, the carbonyl groups exhibited a dominating influence on the fragmentation pathways. In all cases, the initial fragmentation involved the loss of water to form a corresponding anhydro analog. The subsequent fragmentation patterns were reported to be the same as those of the corresponding 5a,6-anhydrotetracycline (5).

A fragmentation pathway involving the loss of NH_3 (*m/e* 17) and H_2O (*m/e* 18) and the subsequent single-step loss of CH_3NCH_2 and CO (combined *m/e* 71) was observed in the mass spectrum of anhydrotetracycline (5). This fragmentation sequence was confirmed by metastable peaks (*m/e* 393, 374, and 262, respectively) and is outlined in Scheme I. A similar fragmentation pattern was observed for 4-dedimethylaminoanhydrotetracycline (I).

A fragment corresponding to the loss of $CONH_3$ (*m/e* 45) from the parent ion was observed at *m/e* 381 in the mass spectrum of anhydrotetracycline and at *m/e* 338 in the mass spectrum of 4-dedimethylaminoanhydrotetracycline. Metastable peaks at *m/e* 341 and 298, respectively, confirmed these fragmentations. These resulting fragments retained the tetracyclic structure of the parent compound.

Somewhat similar fragmentation patterns were observed in the mass spectrum of the methylated product of 4-dedimethylaminoanhydrotetracycline; however, possibly as a result of methyl substitution, ring cleavage was the favored fragmentation pathway for this compound. The mass spectrum of the methylated 4-dedimethylaminoanhydrotetracycline (Fig. 1) contained a parent ion peak at *m/e* 397. The loss of NH_3 (*m/e* 17) from the parent ion resulted in a peak at *m/e* 380 and was confirmed by an observed metastable peak at *m/e* 364. Peaks at *m/e* 362 and 334 indicated the subsequent loss of H_2O and CO, respectively, as was previously observed

for 4-dedimethylaminoanhydrotetracycline. A peak at *m/e* 352 was also observed for the loss of $CONH_3$ from the parent ion. The presence of these peaks indicated that only one methyl ether group was present in the methylated product and was retained on these fragments.

Because the C and D rings are aromatic, most ring cleavages of anhydrotetracyclines were reported to occur in the A or B rings. Peaks observed at *m/e* 313, 270, and 256 in the mass spectrum of anhydrotetracycline were reported to be a result of A ring fragmentation (5). Fragmentation of the A ring of 4-dedimethylaminoanhydrotetracycline was observed at *m/e* 298, 270, 266, 256, and 241. Corresponding peaks were observed at *m/e* 312, 284, 279, 269, and 255 in the mass spectrum of the monomethyl ether of 4-dedimethylaminoanhydrotetracycline (II) and indicated that the methyl ether was not on the A ring of this tetracycline.

Cleavage of the B ring was observed by fragments at *m/e* 227 and 214 in the mass spectra of both anhydrotetracycline and 4-dedimethylaminoanhydrotetracycline. Possible structures (III and IV) for these fragments are related to the intact C and D rings (5).

The 70-ev mass spectrum of the methylated product contained peaks at *m/e* 241 and 228; the *m/e* 228 fragment (V) was the dominant peak. A possible structure for this fragment, analogous to III, was derived from the intact C and D rings, since both can be generated by a similar fragmentation process. The presence of these fragments indicated that the methyl ether function was located on the C or D ring.

The *m/e* 228 fragment subsequently decomposed, losing CH_3 (*m/e* 15) and CO (*m/e* 28). This stepwise loss of C_2H_3O was observed and reported for the mass spectra of a number of aryl methyl ethers (7, 8). A metastable peak was observed at *m/e* 199, confirming the decomposition path.

The addition of methylene to the C-10 or C-11 hydroxy of 4-dedimethylaminoanhydrotetracycline was confirmed by the use of deuterodiazomethane (CD_2N_2). The 70-ev mass spectrum of the isolated product contained a dominant peak at *m/e* 230, and the subsequent decomposition of this fragment to the *m/e* 213 fragment was noted. This stepwise loss of CD_2H and CO was the same as was previously observed for the monomethyl ether of 4-dedimethylaminoanhydrotetracycline and indicated that the CH_3 fragment was from the methyl ether functional group. The loss of this methyl group made further assignment of the smaller fragments very difficult; however, it was concluded that the methyl ether function was located at either the C-10 or C-11 position.

The differentiation between methylation at the C-10 or C-11 position was accomplished using NMR spectroscopy. A number of exchangeable protons were observed downfield from 8 ppm in the NMR spectra of tetracyclines in d_6-dimethyl sulfoxide (9). Based on observations from model compounds, these signals were assigned to the hydrogen-bonded hydroxy protons of the C-10, C-11, and C-3 positions and the amide protons. The NMR spectrum of 4-dedimethylaminoanhydrotetracycline contained the signals of five exchangeable protons downfield from 8 ppm. The signals at 8.9 and 9.0 ppm were assigned to the amide protons of the carboxamido group, while the signals at 9.9, 15.3, and 18.2 ppm were assigned to the hydroxy protons of the C-10, C-11, and C-3 positions, respectively (9).

The NMR spectrum of methylated 4-dedimethylaminoanhydrotetracycline contained signals at 8.9, 9.1, 10.1, and 18.3 ppm. The absence of a signal in the 15-ppm region indicated that the C-11 hydroxy proton had been replaced by a methyl group. An additional singlet at 3.95 ppm, corresponding to three protons, was observed for these methoxy protons.

Bioavailability Assessment under Quasi- and Nonsteady-State Conditions I: Theoretical Considerations

K. C. KWAN ˣ, J. V. BONDI *, and K. C. YEH

Abstract □ A strategy was devised to permit bioavailability estimations at quasi- and nonsteady states. The proposed method retains most attributes of a steady-state comparison without being burdened by its protractiveness. The only necessary requirements are that drug disposition obeys linear kinetics and that succeeding doses are administered during the log-linear phase free from the influence of continuing absorption.

Keyphrases □ Bioavailability—estimations under quasi- and nonsteady states, theoretical considerations and equations □ Drug accumulation under quasi- and nonsteady-state conditions—bioavailability estimations, theory and equations

An accepted method of assessing the relative bioavailability of dosage forms is to compare their mean plasma concentrations with those of a reference over a comparable dosage interval at steady state. The theoretical basis for this kind of comparison is analogous to that of comparing total areas under the plasma concentration curve in single-dose studies (1). In either case, the underlying assumptions are that plasma clearance is not concentration dependent and is constant between treatments.

Implicit in the choice of steady-state measurements is that there will be drug accumulation for the specified dosage regimen. Relative to single-dose studies, the steady-state approach has several obvious advantages. First, fewer data points are required because the time course of change in plasma concentrations is less precipitous and sampling times are bounded by the dosage interval. Second, plasma concentrations are higher. Third, the method is model independent so long as drug disposition obeys linear kinetics. The main disadvantage is that the clinical aspects are much more difficult to control and execute. It may take days or even weeks to achieve steady state. In any protracted study, the potential for lapses in subject compliance increases with time.

Unfortunately, many factors that lend support to steady-state measurements also prolong the clinical phase. Plasma half-life, $t_{1/2}$, is by far the most important parameter in drug accumulation. With increasing $t_{1/2}$, the extent of accumulation increases for a given dosage regimen, the differences between peak and trough plasma concentrations are diminished, and the plasma time course is less sensitive to the effect of variations in absorption rates.

Provided that one is not attempting to demonstrate timed-release properties, a long half-life tends to make steady-state studies more attractive. On the other hand, the study becomes more unwieldy because the time to achieve steady state also increases with increasing $t_{1/2}$. Additionally, prudent planning dictates that the longest $t_{1/2}$ among individuals should be accommodated, which simply means that the best designed studies must also be the most time consuming.

Thus, even though drug accumulation can be anticipated, the steady-state option may not always be a practical alternative to single-dose comparisons. The purpose of this article is to propose an alternative strategy to utilize the obvious advantages of drug accumulation in bioavailability assessment.

THEORETICAL

The overall strategy is to effect sufficient drug accumulation to facilitate an assessment of bioavailability without unduly prolonging the clinical phase of the study.

For a drug obeying one-compartment model kinetics, it has been shown (1–3) that the mean plasma level (the first *noncentral moment* over τ) following the administration of a fixed dose at equal time intervals is estimated by:

$$\bar{C}p^{(ss)} = \frac{FD}{\tau k_e V_d} \qquad \text{(Eq. 1)}$$

and:

$$\bar{C}p^{(i)} = \frac{k_a FD}{\tau V_d (k_e - k_a)}\left[\frac{(1 - e^{-ik_a\tau})}{k_a} - \frac{(1 - e^{-ik_e\tau})}{k_e}\right] \qquad \text{(Eq. 2)}$$

where $\bar{C}p^{(ss)}$ and $\bar{C}p^{(i)}$ are the mean plasma concentration at steady state and at the ith dose, respectively, after repeated administration of the drug at interval τ; k_a and k_e are first-order rate constants for absorption and elimination; V_d is the apparent volume of distribution; and F is the fraction of the dose, D, absorbed.

The extent and rate of drug accumulation may be calculated by:

$$\bar{C}p^{(ss)} = \frac{(k_e - k_a)\bar{C}p^{(i)}}{k_e(1 - e^{-ik_a\tau}) - k_a(1 - e^{-ik_e\tau})} \qquad \text{(Eq. 3)}$$

and:

$$\left[1 - \frac{\bar{C}p^{(i)}}{\bar{C}p^{(ss)}}\right] = \frac{k_e}{k_e - k_a}e^{-ik_a\tau} - \frac{k_a}{k_e - k_a}e^{-ik_e\tau} \qquad \text{(Eq. 4)}$$

When $k_a \gg k_e$, Eqs. 3 and 4 may be further simplified to:

$$\bar{C}p^{(ss)} \cong \frac{\bar{C}p^{(i)}}{1 - e^{-ik_e\tau}} \qquad \text{(Eq. 5)}$$

and:

$$\ln\left[1 - \frac{\bar{C}p^{(i)}}{\bar{C}p^{(ss)}}\right] \cong -k_e(i\tau) \qquad \text{(Eq. 6)}$$

Defining the half-time for accumulation, $(i\tau)_{1/2}$, as the time required to reach 50% of steady state, *i.e.*, when $\bar{C}p^{(i)} = \bar{C}p^{(ss)}/2$, one obtains:

$$(i\tau)_{1/2} \cong \frac{\ln 2}{k_e} = (t_{1/2})_e \qquad \text{(Eq. 7)}$$

Thus, the half-time for accumulation is approximately equal to the half-life for elimination. Equation 7 represents the limiting case described by van Rossum (3).

Analogous expressions for a general N-compartment mammilla-

ry model with first-order absorption are:

$$\bar{C}p^{(i)} = \frac{k_a F D}{\tau V_1}\left[\frac{(1-e^{-ik_a\tau})\prod_{j=2}^{N}(E_j-k_a)}{k_a(\alpha-k_a)(\beta-k_a)\ldots(\psi-k_a)} + \frac{(1-e^{-i\alpha\tau})\prod_{j=2}^{N}(E_j-\alpha)}{\alpha(k_a-\alpha)(\beta-\alpha)\ldots(\psi-\alpha)} + \cdots + \frac{(1-e^{-i\psi\tau})\prod_{j=2}^{N}(E_j-\psi)}{\psi(k_a-\psi)(\alpha-\psi)\ldots(\chi-\psi)}\right] \quad \text{(Eq. 8)}$$

$$\bar{C}p^{(ss)} = \frac{FD\Pi_j E_j}{\tau V_1 \alpha\beta\ldots\psi} \quad \text{(Eq. 9)}$$

where E_j is the sum of exit rate constants from compartment $j = 2, 3, \ldots, N$; $\alpha, \beta, \ldots, \psi$ are the hybrid rate constants, of which there are N in number; and V_1 is the apparent volume of distribution for the central compartment. Their derivation is given in the *Appendix*. It can be seen that Eqs. 1–7 are for the special case where $N = 1$.

One can define ω as the smallest plasma decay constant and V_0 as an operational constant such that ωV_0 is an estimate of body drug clearance. If ω is much smaller (say, one-fifth or less) than any exit rate constant, E_j, and the next larger hybrid constant, including k_a, then:

$$\bar{C}p^{(ss)} \cong \frac{\bar{C}p^{(i)}}{1-e^{-i\omega\tau}} \quad \text{(Eq. 10)}$$

$$\ln\left[1-\frac{\bar{C}p^{(i)}}{\bar{C}p^{(ss)}}\right] \cong -\omega(i\tau) \quad \text{(Eq. 11)}$$

$$(i\tau)_{1/2} \cong \frac{\ln 2}{\omega} = (t_{1/2})_\omega \quad \text{(Eq. 12)}$$

and combining Eqs. 9 and 10:

$$\bar{C}p^{(i)} = \frac{FD\Pi_j E_j}{\tau V_1 \alpha\beta\ldots\omega}(1-e^{-i\omega\tau}) = \frac{FD}{\tau\omega V_0}(1-e^{-i\omega\tau}) \quad \text{(Eq. 13)}$$

providing τ is chosen such that succeeding doses are administered during the log-linear phase (see *Appendix*).

From the foregoing, it is evident that the most important parameter in drug accumulation is the slowest rate constant for plasma decay, *i.e.*, the terminal slope.

Suppose two treatments of the same drug were to be compared by administering sequentially l doses of formulation x followed immediately by m doses of formulation y according to the same dosage regimen. If conditions for Eq. 10 are met, then:

$$\bar{C}p^{(l)} = \frac{F_x D}{\tau\omega V_0}(1-e^{-l\omega\tau}) \quad \text{(Eq. 14)}$$

and:

$$\bar{C}p^{(m+l)} = \frac{D}{\tau\omega V_0}\left[F_x e^{-m\omega\tau}(1-e^{-l\omega\tau}) + F_y(1-e^{-m\omega\tau})\right] \quad \text{(Eq. 15)}$$

where $\bar{C}p^{(l)}$ and $\bar{C}p^{(m+l)}$ are the observed mean plasma levels during the lth and $(m+l)$th dosage intervals, respectively; and F_x and F_y are the fractions of dose absorbed from formulations x and y, respectively. Implicit in Eqs. 14 and 15 are that ω remains constant, but k_a and F may differ between treatments. (See *Appendix* for derivation.)

The relative bioavailability of formulation y with respect to formulation x can be estimated by solving Eqs. 14 and 15:

$$\frac{F_y}{F_x} = \left[\frac{\bar{C}p^{(m+l)}}{\bar{C}p^{(l)}} - e^{-m\omega\tau}\right]\frac{(1-e^{-l\omega\tau})}{(1-e^{-m\omega\tau})} \quad \text{(Eq. 16)}$$

which collapses to the usual expression for relative bioavailability at steady state; *i.e.*, when $l \to \infty$ and $m \to \infty$:

$$\frac{F_y}{F_x} = \frac{[\bar{C}p^{(ss)}]_y}{[\bar{C}p^{(ss)}]_x} \quad \text{(Eq. 17)}$$

These considerations can be easily extended to accommodate three or more treatments. For example, if treatment y were followed immediately by n doses of treatment z, then:

$$\frac{F_z}{F_x} = \left[\frac{\bar{C}p^{(n+m+l)}}{\bar{C}p^{(l)}} - \frac{\bar{C}p^{(m+l)}e^{-n\omega\tau}}{\bar{C}p^{(l)}}\right]\frac{(1-e^{-l\omega\tau})}{(1-e^{-n\omega\tau})} \quad \text{(Eq. 18)}$$

In the interest of clarity, Eqs. 13, 16, and 18 have been derived with the assumption that the following simplifying conditions prevail: *(a)* the same dosage is administered repetitively for a given treatment, *(b)* the same dosage regimen is followed for all treatments, *(c)* the time intervals between successive doses are uniform throughout, *(d)* there are no discontinuities (extended "washout" periods) between treatments, *(e)* the terminal half-life for a given subject remains constant, *(f)* body drug clearance remains constant, and *(g)* succeeding doses are administered during the log-linear phase which is not influenced by continuing absorption.

Subsequent discussion will attempt to show that most, if not all, of these conditions can be modified, verified, or circumvented through appropriate experimental design and/or data analysis.

DISCUSSION

Experimental strategies for bioavailability estimation have been almost exclusively limited to comparisons following single doses or at steady state. In general, multiple-dose studies are considered only when useful accumulations can be realized through some convenient dosage regimen. However, the attainment of steady state may require an unacceptably long time. As already illustrated, most advantages of multiple-dose comparisons can be incorporated into bioavailability studies without the need to achieve steady state after each treatment. Basically, the proposed method evolves from the observation that in a linear system the incremental change in drug accumulation is largest, and therefore most useful, in the initial, nonsteady-state region.

Implicit in all bioavailability comparisons is the assumption that the observed data following a given dose are a measure of the expected performance of the administered dosage form. The task is one of acquiring a sufficient number of random samples to permit conclusions within a prescribed degree of confidence. Variability in treatment performance is generally regarded to be greater between than within subjects; hence, crossover comparisons are preferred for precision and economy. But even in crossover studies, within subject comparisons of plasma concentrations and urinary recoveries *per se* may be influenced by variations in drug disposition between treatments.

It is evident that experimental designs should include provisions to compensate for possible changes in drug distribution and elimination. Several possibilities for verifying internal consistency in single-dose comparisons were suggested (4). In multiple-dose comparisons, the observed changes in distribution and/or elimination may be considered as random samples of their mean values over the entire time course of the respective treatments. Adjustments, if necessary, are construed to be applied to their respective means in the same sense that the resultant estimates of bioavailability are measures of mean performances.

Experimentally, the direct application of Eqs. 16 and 18 calls for estimates of mean plasma concentration over the last dosage interval for each test preparation and an estimate of ω. Conceptually, what is being attempted is simply a comparison among $\bar{C}p^{(ss)}$ values, each projected from an observed mean plasma concentration at quasi- or nonsteady state, $\bar{C}p^{(i)}$. In other words, bioavailability estimation by the proposed method is analogous to comparing $\bar{C}p^{(ss)}$. For example, $[\bar{C}p^{(ss)}]_x$ for the first treatment is project-

ed from $\bar{C}p^{(l)}$ by Eq. 10, $[\bar{C}p^{(ss)}]_y$ for the second treatment is calculated from $\bar{C}p^{(m+l)}$ by first correcting for the residual contribution due to $\bar{C}p^{(l)}$, and so on. Therefore, the validity of the method is dependent on the accuracy to which $\bar{C}p^{(ss)}$ can be estimated from $\bar{C}p^{(i)}$.

All of the dosage regimen constraints embodied in the derivation of Eqs. 16 and 18 are nonsubstantive, provided that there is an accurate accounting of the dosing sequence. That is to say, the dose and the dosage intervals for the various treatments need not be uniform throughout. Once having estimated F/V_0 through $\bar{C}p^{(ss)}$ for some treatment, it can be compared with that projected from $\bar{C}p^{(i)}$ for all other treatments regardless of how they are given. The sampling periods need not be confined to the last dose of each treatment nor to a single estimate of $\bar{C}p^{(i)}$ per treatment. Dosages may be skipped to permit more extensive sampling during the log-linear phase.

Unlike the extent of drug accumulation at steady state, the predicted time course of accumulation is more or less model dependent. The rate of accumulation approaches model independence when: *(a)* ω is much smaller than E_j, *(b)* ω is much smaller than the next larger eigenvalue, *(c)* succeeding doses are administered during the log-linear phase, and *(d)* the terminal slope is not k_a. From the prior knowledge of drug disposition and from the nature of the dosage forms, it should be possible to discern whether any of these cited conditions is likely to be satisfied. The first is most ambiguous in that E_j's are model-dependent parameters which can assume a wide range of values, albeit always greater than ω, depending on how the model is depicted. However, the degree of uncertainty is no worse than that incurred in any other kinetic method of bioavailability assessment where the model and the disposition parameters are assumed to be constant between treatments in a given subject.

The second and third conditions can be easily verified and accommodated in the experimental design. If absorption is, or is suspected to be, prolonged, then the log-linear phase would be manifestly delayed. In the event that the terminal slope should represent k_a rather than the slowest disposition constant, precautions should be taken to allow for its change among treatments. Therefore, the application of simplified Eqs. 13, 16, and 18 demands that absorption is not continuing when the next dose is administered.

The importance of these constraints diminishes rapidly as steady state is approached. Accordingly, any given treatment suspected to be aberrant may be studied at times as close to steady state as is required for the specified level of accuracy.

Various checks may be included in the experimental design. The constancy of the terminal slope can be verified by judicious sampling during the log-linear phase throughout the study. Alternatively, urine samples may be included so that constancy in plasma clearance may be inferred through estimates of renal clearance (5). Observed changes in ω or $\bar{V}_{cl,r}$ can be incorporated into the analysis by appropriate modifications in Eqs. 14–18. The combined use of plasma and urinary data also permits the identification of data points free from the influence of absorption (4). Finally, most of the simplifying assumptions can be circumvented by pharmacokinetic modeling. This approach would entail the inclusion of an intravenous dosage and the application of Eq. 8 *et sequelae*.

In summary, an experimental strategy was devised for bioavailability estimation at quasi- or nonsteady state. The proposed method may be applied to most situations where steady-state comparisons are favored. The necessary requirements are that drug disposition obeys linear kinetics and that successive doses are administered when absorption is no longer operative.

The method seeks to optimize the obvious advantages and disadvantages of steady-state comparisons. The positive aspects of high drug concentration, limited sampling, and model independence (with minimal constraints) are retained with a concomitant reduction in study duration Experimentally, the nominal requirements consist of estimates of a mean plasma concentration over a specified dosage interval for each treatment and an estimate of the terminal half-life. Additional safeguards may be incorporated into the experimental design for verification.

APPENDIX

The plasma concentration in the central compartment was derived by Benet (6) for any linear N-compartment mammillary model with first-order absorption:

$$Cp = \frac{k_a F D}{V_1}\left[\frac{[\Pi_j(E_j - k_a)]e^{-k_a t}}{(\alpha - k_a)(\beta - k_a)\cdots(\chi - k_a)(\psi - k_a)} + \frac{[\Pi_j(E_j - \alpha)]e^{-\alpha t}}{(k_a - \alpha)(\beta - \alpha)\cdots(\psi - \alpha)} + \cdots + \frac{[\Pi_j(E_j - \psi)]e^{-\psi t}}{(k_a - \psi)(\alpha - \psi)\cdots(\chi - \psi)}\right] \quad \text{(Eq. A1)}$$

where:

- k_a = first-order absorption rate constant
- F = fraction of dose D absorbed
- V_1 = volume of distribution of the sampleable central compartment (compartment 1)
- Π_j = continuous product of terms with index j ranging from 2 to N; the term is defined as 1 when $N = 1$
- N = number of compartments
- j = running index of compartments having exit rate constant into compartment 1
- E_j = sum of exit rate constants from compartment j
- $\alpha, \beta, \ldots, \chi, \psi$ = hybrid rate constants; they are the roots of Laplace parameters, obtained by method of partial fractions such that $\alpha > \beta > \ldots > \chi > \psi$

As examples of Eq. A1, consider the one-compartment open model where $N = 1$ and $\alpha = k_e$:

$$Cp = \frac{k_a F D}{V_1}\left[\frac{e^{-k_a t}}{(k_e - k_a)} + \frac{e^{-k_e t}}{(k_a - k_e)}\right] \quad \text{(Eq. A2)}$$

For a three-compartment model where the three roots are α, β, and γ:

$$Cp = \frac{k_a F D}{V_1}\left[\frac{(E_2 - k_a)(E_3 - k_a)}{(\alpha - k_a)(\beta - k_a)(\gamma - k_a)}e^{-k_a t} + \frac{(E_2 - \alpha)(E_3 - \alpha)}{(k_a - \alpha)(\beta - \alpha)(\gamma - \alpha)}e^{-\alpha t} + \frac{(E_2 - \beta)(E_3 - \beta)}{(k_a - \beta)(\alpha - \beta)(\gamma - \beta)}e^{-\beta t} + \frac{(E_2 - \gamma)(E_3 - \gamma)}{(k_a - \gamma)(\alpha - \gamma)(\beta - \gamma)}e^{-\gamma t}\right] \quad \text{(Eq. A3)}$$

If the drug is repetitively given for i doses with dosage interval τ, the plasma levels during the ith interval become:

$$Cp^{(i)} = \frac{k_a F D}{V_1}\left[\frac{(1 - e^{-ik_a\tau})[\Pi_j(E_j - k_a)]}{(\alpha - k_a)(\beta - k_a)\ldots(\psi - k_a)(1 - e^{-k_a\tau})}e^{-k_a t'} + \frac{(1 - e^{-i\alpha\tau})[\Pi_j(E_j - \alpha)]}{(k_a - \alpha)(\beta - \alpha)\ldots(\psi - \alpha)(1 - e^{-\alpha\tau})}e^{-\alpha t'} + \cdots + \frac{(1 - e^{-i\psi\tau})[\Pi_j(E_j - \psi)]}{(k_a - \psi)(\alpha - \psi)\ldots(\chi - \psi)(1 - e^{-\psi\tau})}e^{-\psi t'}\right] \quad \text{(Eq. A4)}$$

where t' = time from the last dose. The average plasma level during that period is defined as:

$$\bar{C}p^{(i)} = \frac{1}{\tau}\int_0^\tau Cp^{(i)}\,dt' = \frac{k_a F D}{\tau V_1}[Q - P] \quad \text{(Eq. A5)}$$

where:

$$Q = \frac{[\Pi_j(E_j - k_a)]}{k_a(\alpha - k_a)\ldots(\psi - k_a)} + \frac{[\Pi_j(E_j - \alpha)]}{\alpha(k_a - \alpha)\ldots(\psi - \alpha)} + \cdots + \frac{[\Pi_j(E_j - \psi)]}{\psi(k_a - \psi)\ldots(\chi - \psi)} \quad \text{(Eq. A6)}$$

and:

$$P = \frac{[\Pi_j(E_j - k_a)]e^{-ik_a\tau}}{k_a(\alpha - k_a)\cdots(\psi - k_a)} + \frac{[\Pi_j(E_j - \alpha)]e^{-i\alpha\tau}}{\alpha(k_a - \alpha)\cdots(\psi - \alpha)} + \cdots + \frac{[\Pi_j(E_j - \psi)]e^{-i\psi\tau}}{\psi(k_a - \psi)\cdots(\chi - \psi)} \quad \text{(Eq. A7)}$$

At steady state where $i\tau \to \infty$ and $P \to 0$:

$$\bar{C}p^{(ss)} = \frac{k_a FD}{\tau V_1} Q \quad \text{(Eq. A8)}$$

By induction, the quantity Q can be proved to be identical to:

$$Q = \frac{\Pi_j(E_j)}{k_a\alpha\beta\cdots\chi\psi} \quad \text{(Eq. A9)}$$

An operational constant, V_0, is defined such that:

$$V_0 = \frac{\alpha\beta\cdots\chi\psi}{\Pi_j(E_j)}\cdot(V_1/\omega) \quad \text{(Eq. A10)}$$

where ω = terminal slope (slowest disposition constant ψ or k_a, whichever is smaller). Substituting Eqs. A9 and A10 into Eq. A8:

$$\bar{C}p^{(ss)} = \frac{FD}{\tau V_0\omega} \quad \text{(Eq. A11)}$$

Equation A10 is the general expression for the constant V_0, which has a dimension of volume. For example, in a two-compartment open model in which elimination takes place solely from the central compartment, *i.e.*, when $E_2 = k_{21}$:

$$V_0 = V_{d,\text{area}} = \frac{\alpha\beta}{k_{21}}\left(\frac{V_1}{\beta}\right) = \frac{\alpha}{k_{21}}V_1 = \frac{k_{10}}{\beta}V_1 \quad \text{(Eq. A12)}$$

Equation A11 shows that the average plasma levels at steady state are inversely proportional to the dosage interval τ and to the terminal slope ω.

If τ is chosen so that successive doses are given in the log-linear region of the plasma curve with the slope ω (*i.e.*, k_a or ψ, whichever is smaller), the right-hand side of Eq. A7 may be reduced to one single exponential term:

$$P \simeq \frac{[\Pi_j(E_j - \omega)]}{\omega(k_a - \omega)\cdots(\chi - \omega)} e^{-i\omega\tau} \quad \text{when } \omega = \psi \quad \text{(Eq. A13}a\text{)}$$

or:

$$P \simeq \frac{[\Pi_j(E_j - \omega)]}{\omega(\alpha - \omega)\cdots(\psi - \omega)} e^{-i\omega\tau} \quad \text{when } \omega = k_a \quad \text{(Eq. A13}b\text{)}$$

If, furthermore, ω is much smaller than the next hybrid rate constant and is also smaller than any composite exit rate constant, Eqs. A13*a* and A13*b* may be further reduced to their counterparts:

$$P \simeq \frac{\Pi_j(E_j)}{\omega k_a\alpha\cdots\chi} e^{-i\omega\tau} \quad \text{(Eq. A14}a\text{)}$$

or:

$$P \simeq \frac{\Pi_j(E_j)}{\omega\alpha\beta\cdots\psi} e^{-i\omega\tau} \quad \text{(Eq. A14}b\text{)}$$

By substituting Eqs. A9, A10, and A14 into Eq. A5:

$$\bar{C}p^{(i)} \simeq \frac{FD}{\tau V_0\omega}(1 - e^{-i\omega\tau}) \quad \text{(Eq. A15)}$$

Comparison of Eqs. A11 and A15 shows that:

$$\frac{\bar{C}p^{(i)}}{\bar{C}p^{(ss)}} = (1 - e^{-i\omega\tau}) \quad \text{(Eq. A16)}$$

which is identical to Eq. 10 in the text.

Equation 15 of the text was derived as follows. When l doses of formulation x is given with dosage interval τ and followed immediately by additional m doses of formulation y, the average plasma level during the $(m + l)$th period is given by:

$$\bar{C}p^{(m+l)} = \bar{C}p^x + \bar{C}p^y \quad \text{(Eq. A17)}$$

where $\bar{C}p^x$ is the contribution from formulation x and $\bar{C}p^y$ is that from formulation y. The expression for $\bar{C}p^x$ is:

$$\bar{C}p^x = \frac{1}{\tau}\int_{m\tau}^{(m+1)\tau} Cp^{(l)}\,dt' = \frac{k_a{}^x F_x D}{\tau V_1}\left[\frac{(1 - e^{-lk_a{}^x\tau})\,[\Pi_j(E_j - k_a{}^x)]}{k_a{}^x(\alpha - k_a{}^x)\cdots(x - k_a{}^x)(\psi - k_a{}^x)} e^{-mk_a{}^x\tau} + \cdots + \frac{(1 - e^{-l\psi\tau})\,[\Pi_j(E_j - \psi)]}{\psi(k_a{}^x - \psi)\cdots(\chi - \psi)} e^{-m\psi\tau}\right] \quad \text{(Eq. A18)}$$

Again, if the conditions to Eqs. A14*a* and A14*b* are satisfied, then:

$$\bar{C}p^x = \frac{k_a{}^x F_x D}{\tau V_1} Q_x(1 - e^{-l\omega\tau})e^{-m\omega\tau} = \frac{F_x D}{\tau V_0\omega}(1 - e^{-l\omega\tau})e^{-m\omega\tau} \quad \text{(Eq. A19)}$$

$$\bar{C}p^y = \frac{k_a{}^y F_y D}{\tau V_1} Q_y(1 - e^{-m\omega\tau}) = \frac{F_y D}{\tau V_0\omega}(1 - e^{-m\omega\tau}) \quad \text{(Eq. A20)}$$

Therefore:

$$\bar{C}p^{(m+l)} = \frac{D}{\tau V_0\omega}[F_x e^{-m\omega\tau}(1 - e^{-l\omega\tau}) + F_y(1 - e^{-m\omega\tau})] \quad \text{(Eq. A21)}$$

Solution–Solubility Dependency of Controlled Release of Drug from Polymer Matrix: Mathematical Analysis

YIE W. CHIEN ˣ, HOWARD J. LAMBERT, and TENG K. LIN

Abstract □ Two types of drug release mechanisms—matrix controlled ($Q - t^{1/2}$ relationship) and partition controlled ($Q - t$ relationship)—were reported previously. The dependency of the transition between these two processes on the solution solubility of drug is now analyzed. Mathematical expressions are derived to treat the systemic effects of the addition of varying volume fractions of the cosolvent system on the concentration gradients across both the drug depletion zone and hydrodynamic diffusion layer as well as on the partitioning behavior at the polymer–solution interface. The results are in excellent agreement with reported experimental observations.

Keyphrases □ Drug release from polymer matrix, controlled—solution–solubility dependency, equations □ Polymer matrix—controlled drug release, solution–solubility dependency, equations

A rapid *in vitro* drug elution system, which permits direct characterization of drug release mechanisms and rates, was recently reported (1). Two types of release mechanisms—matrix controlled and partition controlled—were observed when the release profiles of ethynodiol diacetate from silicone vaginal devices were followed daily in this system (2). In the region of the partition-controlled process, steady-state drug release profiles were defined by a linear $Q - t$ relationship and found to be linearly dependent on the partition coefficient of drug (K) from polymer toward solution.

In the region of the matrix-controlled process, steady-state drug release profiles were defined by a $Q - t^{1/2}$ linearity and found to be independent of the variation in the magnitude of K. The transition between the matrix-controlled and the partition-controlled processes was observed to be dependent on the solution solubility of drug in the elution medium. This article provides a mathematical analysis of the solution–solubility dependency of the controlled release of drug from a drug-dispersed polymer matrix.

MATHEMATICAL DERIVATION AND EXPERIMENTAL OBSERVATION

For such a system, one can draw a concentration profile, which may exist after a finite time following drug elution, on a unit section of a polymeric device (Fig. 1). In this model, the drug is homogeneously dispersed as solid crystals in the polymer matrix. It is visualized that the solid drug on the surface layer of the device is first eluted; when this layer becomes exhausted, the next layer is then depleted. A depletion zone, with a thickness of δ_m, therefore occurs. The interface of the drug dispersion zone–drug depletion zone moves further into the core of the device for another differential thickness, $d(\delta_m)$, when more solid drug is released.

Microscopically, a thin layer of solution, the hydrodynamic diffusion layer, adheres to the immediate surface of the device. The thickness (δ_D) of this diffusion layer may be controlled at a finite value (3) by a constant angular rotation. In the present study, this diffusion layer thickness ($\leq 70 \times 10^{-4}$ cm) is much smaller than the surface area of the device (33.75 cm^2) available for the diffusion of drug molecules. Therefore, the diffusion of drug molecules to and from the polymeric device across the hydrodynamic diffusion layer may be treated simply as one-dimensional diffusion to a plane surface (4). The flux of diffusional, J_D, across the plane surface of a unit area is defined by Fick's first law of diffusion (5):

$$J_D = -D\frac{dC}{d\chi} \qquad \text{(Eq. 1)}$$

where $dC/d\chi$ is the concentration gradient across the diffusion path of $d\chi$, and D is the diffusivity of a drug species. With the assumptions that: (*a*) diffusion is the primary mode of drug release, (*b*) the diffusion coefficient is constant irrespective of the distance traveled and the difference in concentration, and (*c*) a pseudosteady state exists, Fick's arguments may be extended to describe the mechanisms of drug release from a polymeric device.

Under diffusion laws, the rate of drug diffusion from a point at the drug dispersion zone–depletion zone interface to the polymer–solution interface may be expressed as:

$$\frac{dQ_m}{dt} = \frac{D_m}{\delta_m}(C_p - C_m) \qquad \text{(Eq. 2)}$$

where D_m is the effective diffusivity of drug in the polymer matrix, C_p is the drug concentration at the interface of the drug dispersion zone–depletion zone (that is, the polymer solubility of the drug), and C_m is the drug concentration at the polymer–solution interface.

The rate of drug diffusion across the hydrodynamic diffusion layer (with a thickness of δ_D) at the immediate surface of the device may be described by:

$$\frac{dQ_d}{dt} = \frac{D_s}{\delta_D}[C_d - C_b(t)] \qquad \text{(Eq. 3)}$$

where D_s is the diffusivity of the drug in the elution solution, C_d is the drug concentration at the solution–polymer interface, and $C_b(t)$ is the drug concentration in the bulk of the elution medium at a given time.

When a steady state is established, the rate of drug diffusion across the depletion zone, dQ_m/dt, should be equilibrated with the rate of drug diffusion across the hydrodynamic diffusion layer, dQ_d/dt. That is:

$$\frac{D_m}{\delta_m}(C_p - C_m) = \frac{D_s}{\delta_D}[C_d - C_b(t)] \qquad \text{(Eq. 4)}$$

Rearrangement of Eq. 4 gives:

$$\frac{C_p}{C_m} = 1 + \frac{D_s\delta_m}{D_m\delta_D}\left[\frac{C_d}{C_m} - \frac{C_b(t)}{C_m}\right] \qquad \text{(Eq. 5)}$$

According to Eq. 5, if $C_b(t)/C_m$ is equal to C_d/C_m in their magnitudes, the ratio of C_p over C_m is unity. Under such a circumstance, there is no concentration gradient across the depletion zone and no release of drug is detected. In other words, if the magnitude of $C_b(t)/C_m$ is approaching the value of C_d/C_m, the difference between C_p and C_m is becoming smaller and the rate of drug release (dQ_m/dt in Eq. 2) is reduced (since $dQ_d/dt \rightarrow 0$ in Eq. 3). This

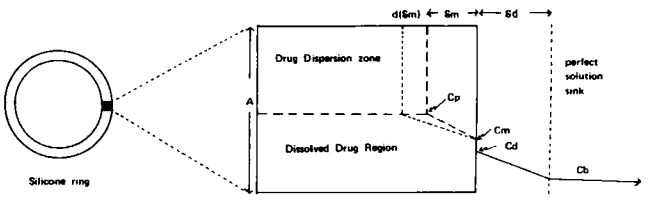

Figure 1—*Theoretical concentration profile existing in a drug-dispersed polymeric device in contact with a perfect solution sink. A is the initial amount of drug impregnated in a unit volume of device. See text for definitions of* C_p, C_m, C_d, $C_b(t)$, δ_m, and δ_D.

Table I—Effect of Polyethylene Glycol 400 on the Solution Solubility (C_s) and Bulk Concentration [$C_b(t)$] of Ethynodiol Diacetate

Volume Fraction of Polyethylene Glycol 400[a], % v/v	C_s, μg/ml	$C_b(t)$[b], μg/ml
0	13.7	—
20	37	6.77
30	64.6	10.66
40	99.7	14.56
50	156	24.18
55	196	36.65
60	437	47.63
62.5	647.5	75.11
65	780	92.0

75	2430	316.7
80	4450	395.2
85	8000	425.8

[a] In distilled water. [b] For maintaining a sink condition, the bulk drug concentration (C_b) in drug elution cells was monitored and the elution solution was renewed daily (Ref. 1). Each value represents the average of the $C_b(t)$ values measured during a 10-day experiment (Ref. 2).

suggests that the magnitude of the $C_b(t)/C_m$ term (Eq. 5) has to be maintained at a level much lower than the value of the C_d/C_m term.

This sink condition may be satisfied either by setting $C_b(t)$ very close to zero or by making C_d much greater than $C_b(t)$. The former approach has been applied in many conventional dissolution and elution studies and is best represented by the use of a large volume (60 liters/day) of distilled water as the elution medium for release studies of medroxyprogesterone acetate (6) (aqueous solubility of 3.25 μg/ml). The other approach was demonstrated by the application of a small volume (150 ml) of cosolvent–water combinations to enhance remarkably the aqueous solubility (13.7 μg/ml) of ethynodiol diacetate by from three- to 584-fold (1, 2), depending on the volume fraction (20–85% v/v) of cosolvent added.

Apparently, the magnitude of $C_b(t)$ in the latter case is a finite value and cannot be approximated to zero as in the former approach. This fact is illustrated in Table I, where $C_b(t)$ has various finite values in various elution media, although they are much smaller than their corresponding C_s (solution solubility) values.

The magnitude of $C_b(t)$ is enhanced by the addition of polyethylene glycol 400 in a manner that seems proportional to the increase in the magnitude of the C_s term. The correlation of $C_b(t)$ with C_s becomes quite apparent when one plots $C_b(t)$ values against their corresponding C_s values (Fig. 2). The use of a log–log scale in Fig. 2 allows the complete coverage of a wide range of both

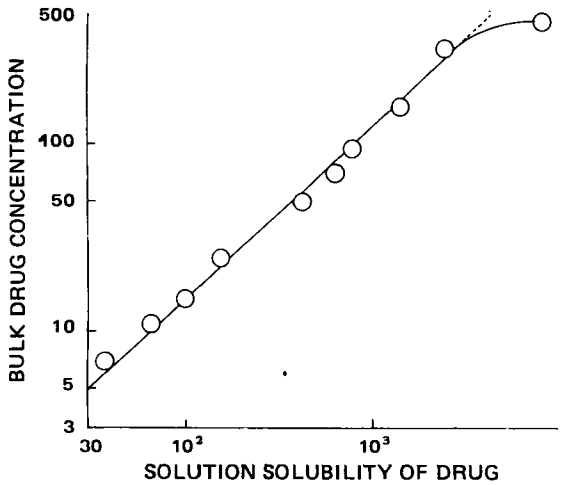

Figure 2—*Logarithmic relationship between the bulk concentration (C_b) of drug in the sink elution medium and the solution solubility of drug (C_s). Slope = 0.933.*

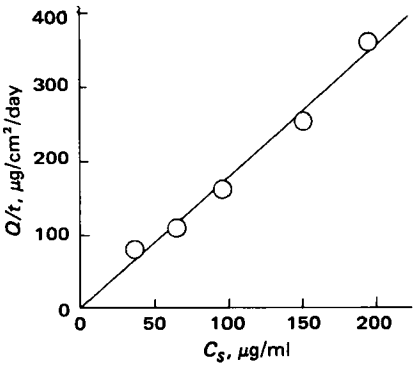

Figure 3—*Linear relationship of the drug release rate (Q/t) with the solution solubility (C_s) of drug following Eq. 24. Slope (kD_s/δ_D) = 1.77 cm/day.*

$C_b(t)$ and C_s values. As expected, a linear relationship with a slope (0.93) close to unity was obtained (Eq. 6a):

$$C_b(t) = \alpha C_s^{(1)} \qquad \text{(Eq. 6a)}$$

Since:

$$C_m = \beta C_p \qquad (\beta \leq 1) \qquad \text{(Eq. 6b)}$$

then:

$$\frac{C_b(t)}{C_m} = \frac{\alpha C_s}{\beta C_p} = k'K \qquad \text{(Eq. 7)}$$

where the partition coefficient, K, for the partitioning of drug molecules from the polymer surface toward the elution solution (6) is expressed as:

$$\frac{C_s}{C_p} = K = \frac{C_d}{C_m} \qquad \text{(Eq. 8)}$$

and:

$$k' = \frac{\alpha}{\beta} \qquad \text{(Eq. 9)}$$

Substituting Eqs. 7 and 8 into Eq. 5 results in:

$$\frac{C_p}{C_m} = 1 + \frac{D_s\delta_m}{D_m\delta_D}[1 - k']K \qquad \text{(Eq. 10a)}$$

or:

$$\frac{C_p}{C_m} = 1 + \frac{D_s\delta_m kK}{D_m\delta_D} \qquad \text{(Eq. 10b)}$$

where:

$$k = 1 - k' \qquad \text{(Eq. 11)}$$

Rearrangement of Eq. 10b gives:

$$C_m = \frac{D_m\delta_D C_p}{D_m\delta_D + D_s\delta_m kK} \qquad \text{(Eq. 12)}$$

If the dissolution of the drug particles into the surrounding polymer matrix in the drug dispersion zone (Fig. 1) is the first step in drug release dynamics (prior to the diffusion of solvated drug molecules across the depletion zone), then the cumulative amounts (Q and Q') of drug released from a unit surface area of device with a thickness of δ_m or ($\delta_m + d\delta_m$) are expressed, respectively, by:

$$Q = \left(A - \frac{C_p + C_m}{2}\right)\delta_m \qquad \text{(Eq. 13a)}$$

$$Q' = \left(A - \frac{C_p + C_m}{2}\right)(\delta_m + d\delta_m) \qquad \text{(Eq. 13b)}$$

The differential cumulative amount (dQ) of drug released due to the formation of a differential zone ($d\delta_m$) of depletion can be calculated from the difference between Q' and Q as follows:

$$dQ = Q' - Q \qquad \text{(Eq. 14a)}$$

$$dQ = \left(A - \frac{C_p + C_m}{2}\right)d\delta_m \qquad \text{(Eq. 14b)}$$

The rate of expansion, dQ/dt, of this differential zone of depletion is then described by:

Table II—Calculation of k

Volume Fraction of Polyethylene Glycol 400, % v/v	D_S/δ_D, cm/day	k[a]
20	56.66	0.031
30	36.82	0.048
40	23.87	0.074
50	15.39	0.114
55	14.30	0.123
60	9.92	0.177
62.5	8.77	0.201
65	8.03	0.219
70	6.44	0.273
75	5.27	0.334
80	4.12	0.427
85	3.38	0.521

[a] Calculated from the relation of $k = 1.77/(D_S/\delta_D)$ (Eq. 24).

$$\frac{dQ}{dt} = \left(A - \frac{C_p + C_m}{2}\right)\frac{d\delta_m}{dt} \qquad \text{(Eq. 14c)}$$

where A is the initial amount of solid drug impregnated homogeneously in a unit volume of device.

The theoretical model shown in Fig. 1 indicates that the rate of expansion (dQ/dt) of the depletion zone will have a finite value only if the surface concentration of drug, C_m, on the polymeric device is maintained at a constantly smaller level than C_p (the polymer solubility of drug) throughout an observation.

Substituting Eq. 12 for the C_m term in Eqs. 2 and 14c and then equating them at a steady state result in:

$$\frac{D_m}{\delta_m}\left[C_p - \frac{D_m\delta_D C_p}{D_m\delta_D + D_s\delta_m kK}\right] = \left[A - \frac{C_p}{2} - \frac{D_m\delta_D C_p}{2(D_m\delta_D + D_s\delta_m kK)}\right]\frac{d\delta_m}{dt} \qquad \text{(Eq. 15a)}$$

Rearrangement of Eq. 15a and integration yield:

$$C_m D_s D_m kK \int_0^t dt = (A - C_p)D_m\delta_D \int_0^{\delta_m} d\delta_m + \left(A - \frac{C_p}{2}\right)D_s kK \int_0^{\delta_m} \delta_m d\delta_m \qquad \text{(Eq. 15b)}$$

and then:

$$\delta_m{}^2 + \frac{2(A - C_p)D_m\delta_D\delta_m}{(A - C_p/2)D_s kK} = \frac{2C_p D_m}{(A - C_p/2)}t \qquad \text{(Eq. 16)}$$

Experimentally, the system was designed so that the initial amount of solid drug (A) dispersed homogeneously in a unit volume of polymer matrix was much larger than the polymer solubility (C_p) of the drug ($A \geq 98.8$ g/10^3 cm^3 and $C_p = 1.4791$ g/10^3 ml). Therefore, $2A \gg (C_p + C_m)$ may be established (since $C_m = \beta C_p$ and $\beta \leq 1$) and Eq. 13a may be approximated:

$$Q \simeq \left(A - \frac{C_p}{2}\right)\delta_m \qquad \text{(Eq. 13c)}$$

or:

$$Q \simeq A\delta_m \qquad \text{(Eq. 13d)}$$

without any significant error involved as long as the condition $2A \gg (C_p + C_m)$ is satisfied.

The value of δ_m is a time-dependent variable and may be estimated by measuring the size of the formed depletion zone by microscopy after sectioning a device (6). The δ_m term in Eqs. 13a, 13c, and 13d also may be calculated from the time-independent parameters, *e.g.*, A, C_p, D_s, D_m, δ_D, and K. These release rate-limiting physicochemical parameters can be measured easily from a diffusion experiment.

Table III—Comparison of k[a] with K[b] for Partition-Controlled Processes

Table IV—Calculated *versus* Observed Rates of Drug Release (Q/t)

Volume Fraction of Polyethylene Glycol 400, % v/v	Q/t, μg/cm²/day	
	Calculated[a]	Observed
20	65.5	82.6
30	114.2	109.8
40	176.1	141.3
50	273.7	245.7
55	344.7	360.0

[a] Calculated from Eq. 24. The C_S data are from Table I, and the D_S/δ_D and k data are from Table II.

In these studies, the magnitude of K was a variable depending on the volume fraction of cosolvent in the elution medium. The following two cases were observed as the value of K was varied to make the magnitude of the $\delta_m{}^2$ term (Eq. 16) either much greater or much smaller than the second term in Eq. 16.

Case 1—For a matrix-controlled process, K is very large; therefore:

$$\delta_m{}^2 \gg \frac{2(A - C_p)D_m\delta_D}{(A - C_p/2)D_s kK}\delta_m \qquad \text{(Eq. 17)}$$

and Eq. 16 is reduced to a $t^{1/2}$-dependent δ_m:

$$\delta_m = \sqrt{4C_p D_m t/(2A - C_p)} \qquad \text{(Eq. 18)}$$

Substituting Eq. 18 for the δ_m term in Eq. 13c results in:

$$Q = \sqrt{D_m(2A - C_p)C_p t} \qquad \text{(Eq. 19)}$$

which is the equation developed earlier by Higuchi (7). Equation 19 is slightly different from Eq. 3 of Ref. 1. In the earlier derivation, the contribution due to the penetration of elution solution in the microscopic channels (formed after the depletion of drug particles) was considered. In the present derivation of Eq. 19, this contribution was considered to be very small in comparison with the contribution from the diffusion across the polymer structure. The difference in the magnitudes of the resultant $Q/t^{1/2}$ values was

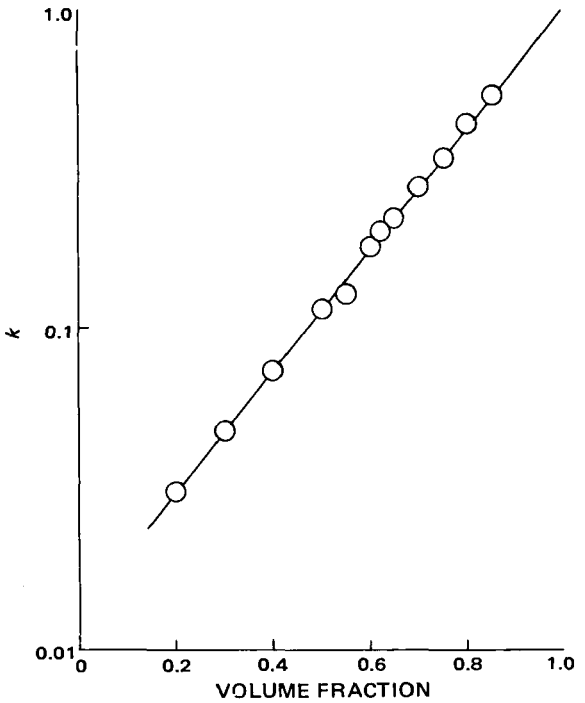

Figure 4—*Semilogarithmic relationship between* k *and the volume fraction of polyethylene glycol 400. Slope* (m) = *1.87.*

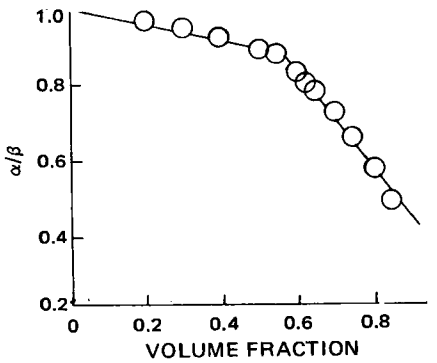

Figure 5—*Biphasic relationship of α/β (relative concentration gradient across diffusion layer over that across depletion zone) with volume fraction of polyethylene glycol 400. The slopes were 0.22 [volume fraction ≤55% (v/v)] and 1.30 [volume fraction ≥60% (v/v)], respectively.*

negligibly small between Eq. 3 ($Q/t^{1/2}$ = 3.03–3.09 mg/cm^2/day$^{1/2}$) and Eq. 19 ($Q/t^{1/2}$ = 3.08 mg/cm^2/day$^{1/2}$).

Case 2—For a partition-controlled process, K is very small; therefore:

$$\delta_m^2 \ll \frac{2(A - C_p)D_m\delta_D}{(A - C_p/2)D_sK}\,\delta_m \qquad \text{(Eq. 20)}$$

and Eq. 16 is reduced to:

$$\delta_m = \frac{kKD_sC_p}{(A - C_p)\delta_D}\,t \qquad \text{(Eq. 21}a\text{)}$$

or:

$$\delta_m \simeq \frac{kKD_sC_p}{A\delta_D}\,t \qquad \text{(Eq. 21}b\text{)}$$

Substituting Eq. 21b for the δ_m term in Eq. 13d gives the following relationship:

$$Q = \frac{kKD_sC_p}{\delta_D}\,t \qquad \text{(Eq. 22)}$$

From Eq. 7, $KC_p = C_s$. Therefore, Eq. 22 is expressed alternatively as:

$$Q = \frac{kD_sC_s}{\delta_D}\,t \qquad \text{(Eq. 23)}$$

The experimental observations on the linear $Q - t$ relationship (Eq. 23) were presented previously (2).

The rate of drug release (Q/t) for a partition-controlled process may be calculated from the slope of the linear Q *versus* t plots and is defined as:

$$\frac{Q}{t} = \frac{kD_s}{\delta_D}C_s \qquad \text{(Eq. 24)}$$

According to Eq. 24, the rate of drug release (Q/t) should be linearly proportional to the magnitude of drug solubility (C_s) in the elution medium used. This linearity is demonstrated in Fig. 3. The slope (kD_s/δ_D) of this linear plot was estimated to be 1.77 cm/day.

Following the addition of polyethylene glycol 400 as a cosolvent, the viscosity of the elution medium was increased. This increase in solution viscosity resulted in an increase in the thickness of the diffusion layer (δ_D) and a decrease in the magnitude of the solution diffusivity (D_s). Therefore, k should be a variable while the overall kD_s/δ_D term is constant (1.77 cm/day) experimentally.

The magnitude of k at various combinations of D_s/δ_D values may be easily calculated (Table II). As expected, the magnitude of k increases as the ratio of D_s over δ_D decreases. Furthermore, a proportionality appears to exist between the values of k and the volume fraction of cosolvent used in the elution medium. This proportionality is plotted semilogarithmically in Fig. 4. Attention is called to the result that k = 1 was obtained at 100% (v/v) of polyethylene glycol 400 (volume fraction = 1). The linear relationship of k with the volume fraction of polyethylene glycol 400 may be expressed as:

$$\log k = m\,(\text{volume fraction of polyethylene glycol 400}) + \text{constant} \qquad \text{(Eq. 25)}$$

with a slope (m = 1.87) very close to 2.

Table V—Calculation of α, β, and C_m

Volume Fraction of Polyethylene Glycol 400, % v/v	α[a]	β[b]	C_m[c], μg/ml	C_s, μg/ml

$\bar{x}$ (±SD)(n = 12)		0.162 (0.028)	240.3 (±41.9)	

[a] Calculated from Eq. 6a; $\alpha = C_b(t)/C_s$. [b] Calculated from Eq. 26; $\beta = \alpha/(1 - k)$. [c] Calculated from Eq. 8; $C_m = \beta C_p$; C_p = 1.4791 × 10^3 μg/ml.

The magnitude of k for the partition-controlled process was essentially equal to that of K, the partition coefficient of drug from the polymer surface toward the elution medium (Table III). The coincidence of k with K ($k/K \simeq 1$) may provide an explanation for previous observations on the linear relationship between the rate of drug release (Q/t) and the partition coefficient for the partition-controlled process. The validity of Eq. 24 is evident when one compares the rates of drug release in various elution solutions with those calculated from the values of C_s, D_s, δ_D, and k (Table IV).

The following relationship may be derived from Eqs. 9 and 11:

$$\beta = \frac{\alpha}{1 - k} \qquad \text{(Eq. 26)}$$

From Eq. 26, the proportionality (β) between the drug concentration (C_m) at the polymer–solution interface and that (C_p) at the interface of the drug dispersion–drug depletion zone (Eq. 8) may be calculated (Table V). A mean value of 0.162 ± 0.028 was obtained. As predicted, the magnitude of β is considerably smaller than unity ($\beta \leq 1$ in Eq. 8). This result indicates that an effective concentration gradient ($C_p - C_m$) was maintained across the depletion zone (Eq. 2) for all volume fractions of polyethylene glycol 400 used.

The drug concentration (C_m) at the polymer–solution interface can be calculated from Eq. 8, using an experimentally predetermined C_p value (1.4791 × 10^3 μg/cm^3) (Table V), and the C_m values found are substantially smaller than C_p. Unlike the behavior demonstrated by both C_s and $C_b(t)$, the magnitude of C_m is quite independent of the variation in the volume fraction of cosolvent added (a mean of 240.3 ± 41.9 μg/ml). The value of C_m is greater than the value of C_s (Table V) for the partition-controlled process [volume fraction of polyethylene glycol ≤55% (v/v)] but smaller than the value of C_s in the region of the matrix-controlled process [volume fraction of polyethylene glycol ≥60% (v/v)].

The effect of cosolvent on the concentration gradient (α) across the diffusion layer relative to that (β) across the depletion zone is significant (Fig. 5). The effect of cosolvent is considerably smaller when its volume fraction is equal to or smaller than 55% (v/v) (slope = 0.22). The magnitude of this effect is enhanced sixfold (from 0.22 to 1.30) when the volume fraction of cosolvent used is increased above 60% (v/v). These observations may provide some insights into the mechanism of the transition between matrix-controlled and partition-controlled processes reported previously (2).

From the enclosed analysis, it was concluded that the variation in the magnitude of solution solubility (C_s) dictates the mechanism and rate of drug release from a drug dispersed in a polymer matrix.

Effects of Selected Drugs on an Auditory or Thalamic Conditioned Stimulus Eliciting Recruitment in the Cat

B. DUBINSKY [x], W. J. KINNARD, Jr. [*], and J. P. BUCKLEY [‡]

Abstract □ Minimally effective oral doses of chlorpromazine, imipramine, and pentobarbital necessary to block a discrete trial (bar-press) conditioned avoidance response were compared in cats chronically implanted with electrodes over the cerebral cortex and in the nucleus centralis medialis of the thalamus. Three conditioned stimulus contingencies consisting of tone and low or high voltage thalamic stimulation were presented. Minimal conditioned response blocking doses of these agents produced only slight qualitative changes in cortically recorded recruitment. Drug treatment affected the conditioned stimulus contingencies differentially, and the rank order in terms of ease of disruption of the conditioned avoidance response was high voltage thalamic conditioned stimulus > low voltage thalamic conditioned stimulus > auditory conditioned stimulus. The differential effect of these drugs might have been due to the additive inhibition of these agents and the thalamic conditioned stimulus on performance. With the exception of chlorpromazine, the behavioral effects of these drugs and their effects on recruitment were dissociated.

Keyphrases □ Chlorpromazine—effects on conditioned avoidance response, conscious cat □ Imipramine—effects on conditioned avoidance response, conscious cat □ Pentobarbital—effects on conditioned avoidance response, conscious cat □ Thalamic recruitment—effects of chlorpromazine, imipramine, and pentobarbital, conditioned avoidance response, conscious cat

Electrical stimulation of midline thalamic nuclei and other subcortical sites evokes potentials which, when recorded cortically, resemble spontaneous spindle bursts. Since these potentials increase in amplitude with time, apparently through the recruitment of additional responsive neurons, the recorded event has come to be known as the recruiting response. Several studies (1–3) defined these properties and examined the sites of origin of the recruiting response. Since these classic studies, many investigators have studied the behavioral effects of electrical stimulation of regions of the brain from which cortical recruitment may be elicited.

Midline thalamic stimulation has been shown to act as a conditioned stimulus for the formation of a conditioned avoidance response in cats (4–6), dogs (7), and squirrel monkeys (8). Changes in the amplitude of recruitment during learning and performance have been variously interpreted as reflecting behavioral facilitatory or inhibitory processes (6). However, Pecci-Saavedra *et al.* (8) attributed these changes to alterations in the level of arousal associated with learning.

The effects of psychotropic drugs which modify learned behavior on the recruiting system have been extensively tested; however, the relationship between the effects of these agents on recruitment and their effects on behavior is unknown since all studies have been done in paralyzed or anesthetized preparations (9–14). The present study was designed to bridge the gap between these studies and, thus, to examine the mutual alterations in behavior induced by stimulation of the recruiting system and the action of psychotropic drugs. The effects of selected drugs on avoidance behavior conditioned by either tone or midline thalamic stimulation were studied to compare directly the behavioral effects of these agents to their effects on recruitment.

EXPERIMENTAL

Adult female cats, 2.5–3.5 kg, were chronically implanted with cortical and subcortical electrodes under aseptic conditions. Stainless steel rivets (3-mm diameter heads) insulated with epoxy varnish (except at their tips) were positioned on the dura through burr holes in the skull, and an uninsulated rivet was cemented in the bone overlying the frontal sinus as a connection to ground. A bipolar concentric electrode, consisting of an outer 23-gauge stainless steel cannula and an inner insulated stainless steel wire [0.01 cm (0.005 in.) diameter], was placed in the region of the nucleus centralis medialis of the thalamus according to reported stereotaxic coordinates (anterior, 9.5 mm; lateral, 0.0 mm; horizontal, 1.0 mm) (15). The electrode was insulated with epoxy varnish, and the tips were bared 0.5 mm and separated by 1.0 mm.

The position of this electrode was considered satisfactory if, during surgery, recruiting potentials could be recorded from the cortical leads upon stimulation of the medial thalamus. The parameters of stimulation[1] are given under *Results*. The electrodes were wired to a connector[2], and the assembly was secured to the skull with dental acrylate.

Experiments were initiated no sooner than 2 weeks following

Table I—Thalamic Conditioned Stimulus (CS) Parameters

Cat	Low Voltage CS, v	High Voltage CS, v	Duration, msec	Frequency, Hz
P-102	4.0	4.5	0.2	10
C-103	4.0	4.5	0.5	8
M-104	5.0	6.4	1.0	8

electrode placement. Cats were trained and tested in a chamber (55.8 × 58.4 × 58.4 cm internal dimensions) which was electrically shielded and grounded. A discrete-trial conditional avoidance–escape schedule with variable intertrial intervals was automatically programmed by conventional timers and relays. One trial consisted of presentation of the conditioned stimulus for 12 sec. If a bar-press response was not made during this time, the conditioned stimulus was terminated and 3 mamp of randomly scrambled foot shock was delivered through a grid floor. After animals had learned to avoid shock by responding during delivery of tone (auditory conditioned stimulus), they were subsequently trained to bar press during presentation of thalamic stimulation which elicited recruitment (thalamic conditioned stimulus).

In drug studies, an experimental session consisted of 10 discrete trials of each of three randomly presented conditioned stimulus contingencies: the auditory conditioned stimulus and two differential voltage levels of the thalamic conditioned stimulus. Selection of these voltages of stimulation is described under *Results*.

The effects of chlorpromazine hydrochloride[3], imipramine hydrochloride[4], and pentobarbital sodium at selected oral doses, administered in gelatin capsules, on these contingencies were studied. The animals were tested 1 hr following drug administration on the day following a control run (lactose); thus, each cat served as its own control for a given experiment. Drugs were given no more frequently than once weekly to avoid dose interaction, and one replicate of each dose was obtained. The cats were observed remotely with the aid of a closed-circuit television system[5], and the effects of these drugs on recruitment and on the spontaneous electrocorticogram (ECoG) were recorded by means of an electroencephalograph[6].

Difference between the conditioned response rate under control and drug conditions was the measure used in an analysis of variance, and differences between means for drug days and preceding control sessions were determined by a paired t-test. Since the subjects were trained to at least a 90% avoidance rate under each contingency, it was expected that drug effects would be unidirectional, and a one-tailed test of statistical significance ($p < 0.05$) was used. Individual animal performance was considered changed if the response rate differed by more than 2 *SD* of the mean response of all previous control days. Mean performance in control sessions under each contingency was compared using the Student t test (two tailed).

RESULTS

The subjects of this experiment learned to avoid shock in 98.5 ± 1.2% of control trials (historical value for 18 sessions) when tone was used. The performance rates in control sessions were 95.6 ± 1.8 and 91.3 ± 2.6% using the low and high voltage thalamic conditioned stimulus, respectively. Compared to tone, the performance rate for either the low ($p < 0.4$) or the high ($p < 0.1$) voltage thalamic conditioned stimulus trials was not significantly less. The parameters of stimulation used in each animal are shown in Table I.

The intensity of the low voltage thalamic conditioned stimulus was selected to be threshold for eliciting recruitment waves that waxed and waned, and the amplitudes of these evoked waves were as high as 500 μv. In preliminary experiments, pairing of the thalamic stimulation with the auditory conditioned stimulus was chosen to be subthreshold for behavioral inhibition. It caused recruiting wave amplitudes as high as 500 μv to be more consistently recorded.

Although no attempt was made to determine the voltage threshold for blockade of performance in each subject, recruitment could be elicited without concurrent conditioned avoidance response disruption by reducing the stimulating voltage to the levels shown in Table I. Thus, stimulation of the thalamus affected performance in a voltage-dependent manner.

The effects of chlorpromazine, imipramine, and pentobarbital on each conditioned stimulus continency are shown in Tables II–IV. Drug effects on duplicate tests at each of three dose levels in three subjects were compared by an analysis of variance. In spite of the variability of the subjects in their sensitivity to the drugs ($F = 6.2$, $df = 2/52$, $p < 0.05$), a highly significant dose–response relationship was obtained ($F = 42.2$, $df = 2/52$, $p < 0.01$). Drug treatment affected the three contingencies differentially ($F = 11.9$, $df = 2/52$, $p < 0.01$), and the rank order in terms of ease of response disruption was high voltage thalamic conditioned stimulus > low voltage thalamic conditioned stimulus > tone.

The lowest dose of chlorpromazine that produced a significant attenuation of performance for the group ($n = 3$) compared to control sessions was 1 mg/kg for either the low ($p < 0.05$) or high ($p < 0.01$) voltage thalamic conditioned stimulus, and it was 2 mg/kg ($p < 0.05$) for the auditory conditioned stimulus (Table II). Ataxia and motor incoordination in these subjects were slight or moderate following doses of 1 and 2 mg/kg, respectively. A dose as low as 1 mg/kg altered the spontaneous ECoG in all animals, but presentation of tone abolished high voltage slow wave activity.

The ECoG representing recruitment evoked by thalamic stimulation in Cat P-102 is shown in Fig. 1. This subject and Cat M-104 terminated the thalamic conditioned stimulus in control trials and in chlorpromazine (0.5 mg/kg) trials following a secondary increase in the negativity of the recruiting response. Chlorpromazine generally increased recruitment amplitude, but the administration of 1 and 2 mg/kg to two animals (P-102 and M-104) prevented the secondary increase in recruitment negativity subsequent to the initial burst in trials in which the avoidance response was disrupted (Fig. 1).

Compared to control sessions, the lowest dose of imipramine studied (2 mg/kg) interfered with the action of the high-voltage thalamic conditioned stimulus ($p < 0.05$); however, performance conditioned to either tone or low voltage thalamic stimulation was not altered significantly in the group ($n = 3$) following 2, 4, or 8 mg/kg (Table III). However, based upon comparison with performance on 18 control days, three out of three subjects in tone trials were affected by the 8-mg/kg dose. Performance was affected in as many as two out of three subjects following 4 mg/kg in low voltage trials. ECoG synchrony was observed following all doses, and presentation of tone usually activated the record. Drug treatment increased the negativity of recruitment elicited by the thalamic conditioned stimuli and increased the tendency for recruitment amplitude to wax and wane during stimulus presentation. In Cat P-102 (Fig. 2), the recruiting response change from control trials was less following 2 mg/kg than following either 4 or 8 mg/kg.

The lowest dose of pentobarbital that produced significant attenuation of performance for the group ($n = 3$) compared to control sessions (Table IV) was 10 mg/kg for tone ($p < 0.01$) and either the low ($p < 0.01$) or high ($p < 0.05$) voltage thalamic conditioned stimulus. Moderate motor incoordination was produced by each dose, and the subjects appeared to doze intermittently following the 10-mg/kg dose. High voltage slow waves and occasional spindle burst activity were recorded in all subjects following 5 mg/kg, and higher doses (7.5 and 10 mg/kg) increased the occurrence of spindle activity that was incompletely blocked by presentation of tone. Recruitment amplitudes were slightly increased; but as shown in Figs. 2 and 3, imipramine and pentobarbital produced essentially similar changes. The general appearance of the recruiting response seemed to be similar following doses of pentobarbital which either did or did not disrupt performance.

The results reported were obtained from subjects in which placement of the electrode within the nucleus centralis medialis of the thalamus was histologically confirmed.

DISCUSSION

Sufficient evidence has been accumulated from several studies (16, 17) to confirm the observation that recruitment occurs in parallel to behavioral inhibition. However, elicitation of the recruiting

response by thalamic stimulation was not exclusively associated with behavioral inhibition and, as shown in the present investigation and as reported by others (4, 5, 7, 8), it was possible to establish avoidance behavior conditioned to thalamic stimulation eliciting recruitment.

Even though the avoidance rate in control trials using the auditory conditioned stimulus was not significantly different from rates obtained using either voltage of the thalamic conditioned stimulus, higher intensities of thalamic stimulation presented concurrent to tone prevented ongoing performance in these subjects in

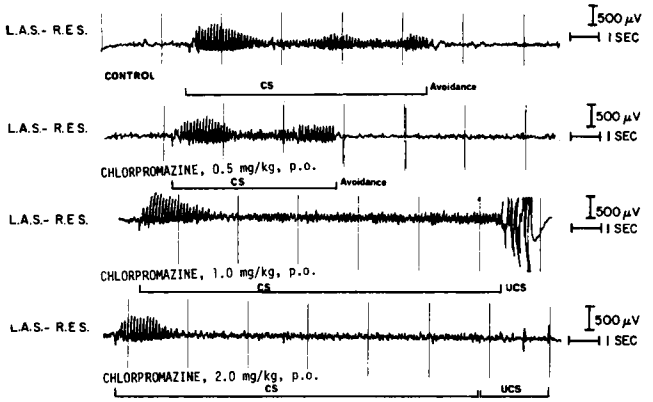

Figure 1—*Effects of chlorpromazine hydrochloride on the ECoG of the recruiting response evoked by the high-voltage thalamic conditioned stimulus (CS) in the cat (P-102). The duration of the conditioned stimulus (CS) (4.5 v, 10 Hz, 0.2-msec stimulation of the nucleus centralis medialis) is shown by the bracketed area beneath each trace here and in Figs. 2 and 3. The unconditioned stimulus (UCS) was an escapable 3-mamp shock applied through a grid floor; the abbreviation L.A.S.-R.E.S. represents a bipolar lead between the left anterior sigmoid gyrus and right ectosylvian gyrus.*

preliminary experiments. Similar cessation of lever pressing in cats by low frequency stimulation of nonspecific thalamic nuclei was previously reported for negatively reinforced behavior (4) and positively reinforced behavior (16). The results of the present investigation suggest that the nonspecific inhibitory effect is voltage dependent; *i.e.*, higher voltages of stimulation produce greater inhibition of behavior.

Conditioned responses are abolished by doses of chlorpromazine that do not seriously affect motor abilities (18); however, much higher doses of imipramine are required to suppress the conditioned avoidance response (19). The barbiturates block conditioned responding only at doses that produce motor incoordination. While similar results were obtained in this study, it was shown that a lower dose of chlorpromazine or imipramine was required to disrupt significantly responses conditioned to thalamic stimulation than to tone. The differential effects of these agents might be explained by the summation of their inhibitory effects on conditioned performance and their facilitation of the diffuse thalamic system (12), which would increase the nonspecific inhibitory effect and decrease response probability to a greater degree than expected.

The fact that pentobarbital did not differentially affect any contingency is in agreement with the results of Rutledge and Doty (20), who compared drug effects on behavior in cats conditioned to either tone or high frequency (50 Hz) cortical stimulation. While the frequencies and sites of brain stimulation in the two studies

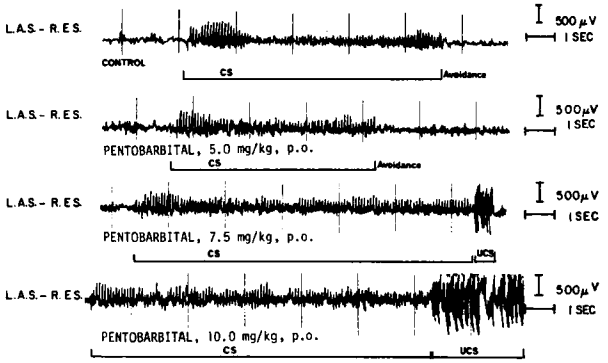

Figure 3—*Effects of pentobarbital sodium on the ECoG of the recruiting response evoked by the high-voltage thalamic conditioned stimulus (CS) in the cat (P-102).*

differed, lower doses of chlorpromazine were required to block responses conditioned to tone than to cortical stimulation. The finding in the present study that chlorpromazine produced reverse differential effects on behavior conditioned to either tone or thalamic stimulation suggests that, compared to cortical stimulation, the motivational effect of thalamic stimulation might be inferior and might provide additional evidence of drug-induced enhancement of a nonspecific inhibitory effect at the thalamic level.

The subjects of this study never bar pressed during the initial recruitment envelope in either control or drug trials, a finding that supports the conclusion of Angyan *et al.* (4) that recruitment is associated with behavioral inhibition. However, in the present experiment, thalamic stimulation was presented for 12 sec rather than for 5 sec as in the former study, allowing an avoidance response to be made following the initial interval of inhibition. The secondary increase of recruiting response negativity observed prior to an avoidance response may be analogous to surface-negative potentials described by Skinner (21) as associated with expectancy or attention or both. Since these increases in recruitment negativity did not appear in trials where chlorpromazine blocked the behavioral response, this type of recruitment change following chlorpromazine may represent the effect of the drug on either expectancy or attention rather than on the recruitment mechanism itself. Chlorpromazine slightly increased recruitment amplitude elicited by the thalamic conditioned stimulus, perhaps through a direct or indirect facilitation of the diffuse thalamic system. There is evidence that chlorpromazine suppresses the cortex and the brain stem reticular formation but stimulates the diffuse thalamic system (12).

The increase in recruitment amplitude produced by imipramine, especially following the 8-mg/kg dose, is in accord with the results of Monnier and Krupp (12), who reported an increased recruiting response in the rabbit cortex by a similar dose. However, Sigg (13) found that imipramine (5–10 mg/kg) did not alter the threshold voltage required to induce recruitment in the cat cortex, and others (14) reported that imipramine decreased both its surface-positive and surface-negative components. Nevertheless, the present results show that imipramine blocks performance conditioned to thalamic stimulation independent of its effects on recruitment.

Domino (9) suggested that the enhancement of recruitment by low doses of pentobarbital was a release phenomenon due to depression of the midbrain reticular formation rather than to direct stimulation of the diffuse projection system; this would account for the small increase in its amplitude observed in the present study. Like imipramine, the effects of pentobarbital on recruitment appear to be independent of its effects on conditioned behavior, and, as noted previously, the barbiturate generally slightly enhanced recruitment following doses that either did or did not prevent responding conditioned to thalamic stimulation. These results suggest that, with the exception of chlorpromazine, the effects of these behavior-modifying drugs upon the characteristics of the cortically recorded recruiting response are not related to their effects on learned behavior.

Nonsink Dissolution Rate Equations

MAHENDRA PATEL and J. T. CARSTENSEN ˣ

Abstract □ In spite of the fact that film theory is based on severe assumptions, it is shown to be a good working model. The Niebergall–Goyan equation, the Short–Sharkey–Rhodes equation, and the Pothisiri–Carstensen equation—all based on simple film theory—are shown to hold through 80–90% of the dissolution process for *p*-hydroxybenzoic acid and sodium chloride, both at values below and above the amount necessary to saturate the dissolution medium. Deviations are attributed to experimental difficulties and to improper definition of monodisperseness rather than to the assumptions made in the theory.

Keyphrases □ Nonsink dissolution of monodisperse powders—various rate equations examined □ Dissolution of monodisperse powders—various rate equations examined □ Powders, monodisperse—various nonsink dissolution rate equations examined

Dissolution of monodisperse powders has been studied and reported by several investigators. The intents of this study are to consolidate a variety of equations, to point out their shortcomings and strengths, and to show that film theory is a good working model.

BACKGROUND

The dissolution rate equations dealt with here are based on the Noyes–Whitney equation (1):

$$-dW/dt = kO(S - C) \qquad \text{(Eq. 1)}$$

where W is the weight remaining, k is the intrinsic dissolution rate constant, O is the surface area, S is the saturation concentration, and C is the concentration at time t.

The assumptions made are: *(a)* a film [the so-called Nernst–Brunner layer (2–4)] surrounds each particle; *(b)* the film need not be hydrodynamically stagnant but behaves so that there is a linear concentration gradient in it; and *(c)* the concentration gradient imparts a concentration, C, at the boundary between the film and the bulk solution. The thickness of this boundary is assumed not to change during dissolution; *i.e.*, it is assumed to be independent of particle size. Niebergall *et al.* (5) studied this point, but it will not be discussed in this report.

Another assumption is that the particles are isotropic and isometric, although Carstensen and Patel (6) showed that this condition need not be a prerequisite. The Ostwald–Freundlich effect (7, 8), where a smaller particle is more soluble than a larger particle, is also neglected.

A dissolution rate equation for monodisperse powders was first suggested by Wilhelm *et al.* (9); they employed graphical integration to solve exact dissolution rate equations. Hixson and Crowell (10) arrived at the cube root law for dissolution of monodisperse powders under sink conditions (*i.e.*, when $C \ll S$):

$$W_o^{1/3} - W^{1/3} = \frac{W_o^{1/3} 2kS}{\rho d} t \qquad \text{(Eq. 2)}$$

where d is the diameter of the particle (assumed spherical), and ρ is the particle density. For Fick's law (11) to apply to film theory, it is required that:

$$k = D/h \qquad \text{(Eq. 3)}$$

where D is the diffusion coefficient of the solute in solution, and h is the thickness of the Nernst–Brunner layer. Since D can be determined experimentally or obtained by the Stokes–Einstein equation (12) or the Wilke equation (13), an estimate of h can be made from dissolution rate studies.

Niebergall and Goyan (14) extended the Hixson–Crowell equation to the situation where the amount studied (W_o) equals exactly

Deviations are attributed to experimental difficulties and to improper definition of monodisperseness rather than to the assumptions made in the theory.

Keyphrases □ Nonsink dissolution of monodisperse powders—various rate equations examined □ Dissolution of monodisperse powders—various rate equations examined □ Powders, monodisperse—various nonsink dissolution rate equations examined

Dissolution of monodisperse powders has been studied and reported by several investigators. The intents of this study are to consolidate a variety of equations, to point out their shortcomings and strengths, and to show that film theory is a good working model.

BACKGROUND

The dissolution rate equations dealt with here are based on the Noyes–Whitney equation (1):

$$-dW/dt = kO(S - C) \qquad \text{(Eq. 1)}$$

where W is the weight remaining, k is the intrinsic dissolution rate constant, O is the surface area, S is the saturation concentration, and C is the concentration at time t.

The assumptions made are: *(a)* a film [the so-called Nernst–Brunner layer (2–4)] surrounds each particle; *(b)* the film need not be hydrodynamically stagnant but behaves so that there is a linear concentration gradient in it; and *(c)* the concentration gradient imparts a concentration, C, at the boundary between the film and the bulk solution. The thickness of this boundary is assumed not to change during dissolution; *i.e.*, it is assumed to be independent of particle size. Niebergall *et al.* (5) studied this point, but it will not be discussed in this report.

Another assumption is that the particles are isotropic and isometric, although Carstensen and Patel (6) showed that this condition need not be a prerequisite. The Ostwald–Freundlich effect (7, 8), where a smaller particle is more soluble than a larger particle, is also neglected.

A dissolution rate equation for monodisperse powders was first suggested by Wilhelm *et al.* (9); they employed graphical integration to solve exact dissolution rate equations. Hixson and Crowell (10) arrived at the cube root law for dissolution of monodisperse powders under sink conditions (*i.e.*, when $C \ll S$):

$$W_o^{1/3} - W^{1/3} = \frac{W_o^{1/3} 2kS}{\rho d} t \qquad \text{(Eq. 2)}$$

where d is the diameter of the particle (assumed spherical), and ρ is the particle density. For Fick's law (11) to apply to film theory, it is required that:

$$k = D/h \qquad \text{(Eq. 3)}$$

where D is the diffusion coefficient of the solute in solution, and h is the thickness of the Nernst–Brunner layer. Since D can be determined experimentally or obtained by the Stokes–Einstein equation (12) or the Wilke equation (13), an estimate of h can be made from dissolution rate studies.

Niebergall and Goyan (14) extended the Hixson–Crowell equation to the situation where the amount studied (W_o) equals exactly

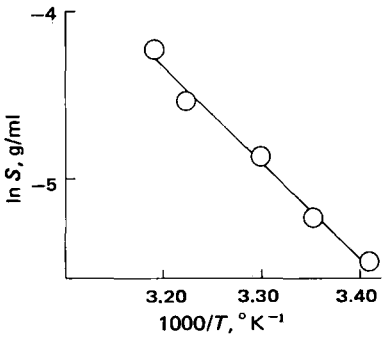

Figure 1—*Temperature dependence of the solubility of* p-*hydroxybenzoic acid.*

the amount needed to saturate the solution (W_s). As shown in the *Appendix*, they found the negative two-thirds law as expressed in Eq. 4:

$$W^{-2/3} - W_o^{-2/3} = \beta t \qquad \text{(Eq. 4)}$$

where the proportionality constant β is given by: $\beta = kN^{1/3}\Gamma/V$, in which N is the number of particles and Γ is a shape factor given by: $\Gamma = [6\sqrt{\pi}/\rho]^{2/3}$. Niebergall and Goyan (14), employing salicylamide and benzoic acid as test substances, showed Eq. 4 to hold but only to about 30% of saturation.

Short *et al.* (15) solved the dissolution rate equation under nonsink conditions, where W_s is different from W_o. The correct form of their equation with the nomenclature used here is:

$$\psi(W) = -[(k\sqrt[3]{N})(\Gamma/V)]t + \psi(W_o) \qquad \text{(Eq. 5)}$$

where:

$$\psi(W) = 0.5F^{-2}\{\ln[(u+F)^2/(F^2 - uF + u^2)]\} + \sqrt{3}F^{-2}\arctan[(2u - F)/(F\sqrt{3})] \qquad \text{(Eq. 6)}$$

and where $F^3 = W_s - W_o$ and $W = u^3$. The derivation of Eq. 5 is shown in the *Appendix*. Short *et al.* (15) tested the equation on the dissolution of hydrocortisone and found it *not* to hold.

Pothisiri and Carstensen (16) developed a similar equation under nonsink conditions; the correct form of their equation with the nomenclature used here is[1]:

$$\psi(r) = \psi(r_o) - \frac{k}{\rho}t \qquad \text{(Eq. 7)}$$

where:

$$\psi(r) = \frac{q}{6\beta}\ln\left[\frac{(r+q)^2}{(r^2 - qr + q^2)}\right] + \frac{q}{\beta\sqrt{3}}\arctan\left[\frac{2r - q}{q\sqrt{3}}\right] \qquad \text{(Eq. 8)}$$

where r is the "radius" of the particle; $\alpha = N\rho 4\pi/(3V)$, where V is the volume of the dissolving medium; $\beta = S - (W_o/V)$; and $q^3 = \beta/\alpha$. All derived equations are based on film theory. Pothisiri and Carstensen (16) showed Eq. 8 to hold up to 65% of saturation. Although simple film theory should fail on many counts (17, 18), it, amazingly, gives excellent correlation with experimental values.

EXPERIMENTAL

p-Hydroxybenzoic acid dissolution was tested in a 1000-ml jacketed beaker[2]. The *p*-hydroxybenzoic acid was recrystallized in a nonisothermal fashion (6) from alcohol USP, air dried, and sieved through a nest of sieves. The fraction retained by a 60-mesh screen and passing a 40-mesh screen was used in most experiments. One particular experiment was conducted with a 16–20-mesh cut; but unless otherwise stated, the experiments refer to the 40–60-mesh cut.

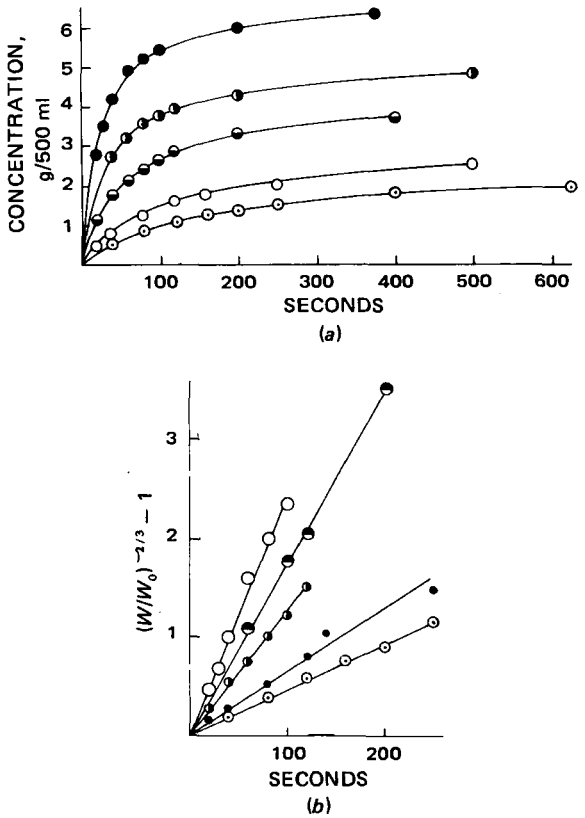

Figure 2—*(a) Concentration* versus *time profile for* p-*hydroxybenzoic acid at different temperatures in 0.1* N *HCl (initial weight* $W_o = W_s$*). Key: ⊙, 20°; ○, 25°; ⊖, 30°; ◑, 35°; and ●, 40°.* (b) *Plots of data from Fig. 2a plotted according to Eq. 4. Key: ⊙, 20°; ●, 25°; ◑, 30°; ⊖, 35°; and ○, 40°. The slopes of the lines are denoted* B.

Several batches were made in this fashion, and the various cuts were pooled to obtain adequate yields for the dissolution rate studies. The dimensions of the 1000-ml jacketed beaker were 8 cm in diameter and 18 cm in height; it was agitated by a Teflon-coated magnetic stirring bar, 8 mm in diameter and 36 mm in length, operating at 120 rpm. The jacket was connected with Tygon tubing *via a pump*[3] *to a thermostated bath, so the jacket temperature* could be maintained to ±0.3°. An amount of 0.1 *N* HCl slightly in excess of 500 ml was placed in a 500-ml volumetric flask, the flask was placed in the water bath, and the temperature was equilibrated.

The amount in excess of 500 ml was removed by pipet, and the 500 ml was transferred to the jacketed beaker. An excess of *p*-hydroxybenzoic acid (*i.e.*, an amount in excess of the solubility) was added to the solution, and the beaker was then covered with aluminum foil. The concentration of *p*-hydroxybenzoic acid in the supernate was determined from time to time; when a steady level had been reached (24 hr), the concentration was assumed to be the saturation concentration. The temperature of the contents was determined periodically and found to vary by less than 0.6° at the extremes, *i.e.*, ±0.3°. The experiment was carried out at 20, 25, 30, 35, and 40°. The assay method used was the spectrophotometric method described by Pothisiri and Carstensen (16). The solubility as a function of temperature is shown in Fig. 1.

The experiment was then repeated except that exactly the amount of *p*-hydroxybenzoic acid necessary to saturate the 500 ml of 0.1 *N* HCl at the test temperature (W_s) was added, and (approximately) 1-ml samples were removed through glass wool with a tared hypodermic syringe which was then weighed. The contents were transferred quantitatively to a volumetric flask, assayed, and

[1] The last fraction in Eq. 11 of the paper by Pothisiri and Carstensen (16) is inverted, and the equation should read as shown in Eq. 8 here. The solubility reported in Ref. 16 is higher (10 mg/ml corresponding to $W_o = 0.82W_s$) than reported here (6.7 mg/ml corresponding to $W_o = 1.27W_s$). Regardless of the solubility figure used, the data of Ref. 16 plot well according to Eq. 7 (as shown in Fig. 7) and Eq. 5 (as shown in Fig. 8).

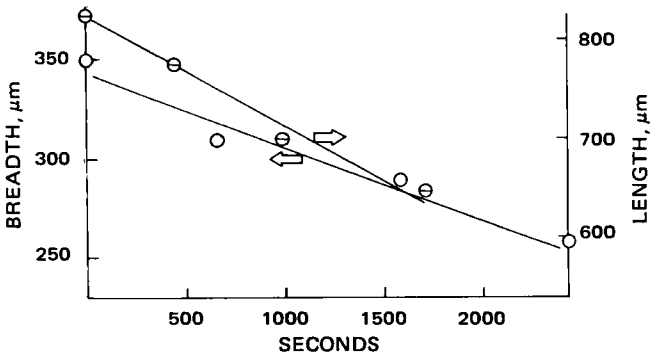

Figure 3—*Dissolution rate experiment conducted with single crystal of* p-*hydroxybenzoic acid in 0.1* N *HCl on microscope slide.*

converted to grams of *p*-hydroxybenzoic acid per 500 ml at the testing temperature by knowledge of the density of *p*-hydroxybenzoic acid solutions (at various concentrations) at the testing temperature. The results of these studies are shown in Fig. 2*a*. No more than five samples were removed during a test; if more points were necessary, the experiment was repeated at the different time points desired.

An experiment was also performed using an amount of *p*-hydroxybenzoic acid corresponding to 1.15 $W_s = W_o$, and an experiment was performed with a 16–20 sieve cut with 1.5 $W_s = W_o$. A dissolution rate experiment on a crystal of *p*-hydroxybenzoic acid was performed on a microscope slide in 3 drops of 0.1 *N* HCl by the method described by Carstensen and Patel (6); the length *(b)* and the breadth *(a)* decrease linearly in time as shown in Fig. 3.

A microscopic determination of the dimensions of 60 particles was performed (Fig. 4). *p*-Hydroxybenzoic acid is actually monoclinic, but the crystals approximate a rectangular parallelepiped with sides *a*, *a* and *b*; Fig. 4 shows that the ratio of *b* to *a* is about 2.4. Since, as seen in Fig. 3, the rate constant for the breadth is $k_a \sim 0.04$ cm/sec and the rate constant for the length is $k_b \sim 0.1$ cm/sec, $k_b/k_a \sim 2.5$, which is close to the ratio of the sides (= 2.4). Since, therefore, the sides decrease in magnitude with rates approximately proportional to the lengths themselves, the dissolution is considered fairly isotropic.

The volumes ($V = a^2b$) of the particles in Fig. 4 were calculated based on the assumption that the particles are parallelepipeds. The cube length equivalents ($\sqrt[3]{V}$) calculated in this fashion are shown in Table I. If the sieve cut were from a single crystallization, it would be expected to have a monotonely decreasing frequency function with increasing particle size (with the assumption that the sieve cut is above the number based mean). Since it is a blend of several batches, this, of course, cannot be expected. In fact, the distribution appears to be a square distribution (*i.e.*, frequency is equal for each size within the cut). The data in Table I fail to show a significant difference from such a distribution ($\chi^2 = 12$, which is smaller than the critical χ^2-value for 11 degrees of freedom and a

probability of 0.05, $\chi^2_{crit} = 19.7$). Brooke (19) recently discussed this type of phenomenon in depth.

DISCUSSION

Although the data by Niebergall and Goyan (14) suggest that the negative two-thirds relation (Eq. 4) holds to 30% of saturation only, data from other literature sources suggest that it may have wider applicability. Figure 5 shows the data from Wilhelm *et al.* (9) for $W_o = W_s$; the test substance was sodium chloride, and the data adhere to Eq. 4 to better than 80%. Deviations above 80% are due to the fact that, in this range, the difference is a small difference between large numbers.

The data from the dissolution of *p*-hydroxybenzoic acid shown in Fig. 2*a* are shown plotted according to Eq. 4 in Fig. 2*b*. Here, again, the data adhere to Eq. 4 to better than 80% of solubility. The deviations from adherance to Eq. 4 are negative and are attributed to the fact that (aside from the poor precision in the higher range) the 40–60-mesh material is not quite monodisperse, so loss of the smallest particles occurs in this range.

As shown in the *Appendix* (Eq. A8), Eq. 4 can be written:

$$(W/W_o)^{-2/3} - 1 = S^{2/3}2kN^{1/3}\Gamma/(3V^{1/3})t = Bt \quad \text{(Eq. 9}a\text{)}$$

or:

$$(W/W_o)^{-2/3} - 1 = [4kS/(\rho d_o)]t \quad \text{(Eq. 9}b\text{)}$$

It follows that the slope, *B*, adheres to:

$$\ln (B/T) = \ln S + \ln (k/T) + \ln[4/(\rho d_o)] \quad \text{(Eq. 10)}$$

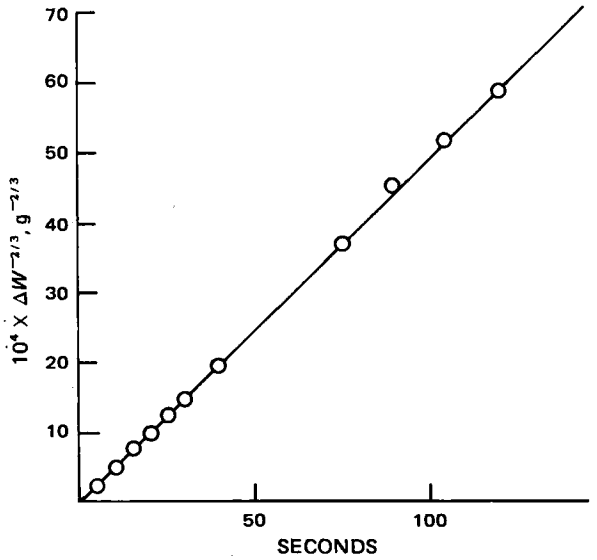

Figure 5—*Data from Ref. 9 plotted according to Eq. 4 when* $W_o = W_s$.

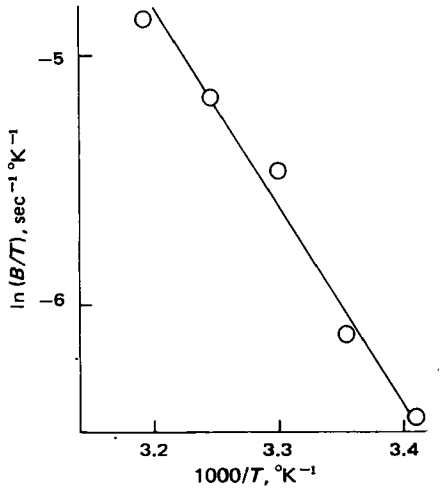

Figure 6—*The slopes,* B, *from Fig. 5 plotted as ln* (B/T) *as a function of reciprocal absolute temperature (1000/T °K^{-1}).*

Carstensen and Patel (6) showed that ln (k/T) is linear with $1/T$ with a slope of between E/R and $2E/R$, where E (<0) is the activation energy for the viscosity of the dissolution medium, and the $2E/R$ term holds with higher agitation intensities such as are reported here. The data in Fig. 1 give ln $S = [-(\Delta H/R)(1/T)] + q$, where ΔH is the heat of solution and q is a constant. From the data in Fig. 1, it is seen that $(\Delta H/R) = 4850$ cal/mole.

Therefore, a plot of ln (B/T) *versus* $1/T$ should be linear and have a slope of $[(2E/R) - \Delta H]$. The linearity is demonstrated in Fig. 6; the slope is −8000 cal/mole. Therefore, $(2E/R) - 4850 = -8000$; *i.e.*, E is between −3150 and −6300 cal/mole, close to E for water (−4700 cal/mole). An equation derived from the film theory (Eq. 4) apparently shows consistency in temperature dependence and the attained slopes are of the expected magnitude.

In spite of several assumptions in the film theory (*viz.*, isotropicity, isometricness, constant film thickness, neglect of convection, and size-independent solubility) and some experimental approximations (*viz.*, geometric surface areas and the assumption of well-defined particle size), the data developed from the theory adhere well to experimental values. This statement is not an attempt to minimize the theoretical importance of the assumptions but simply notes that the effects of the assumptions either cancel out or fall below experimental scrutiny in many cases.

Other equations (15, 16) are also based on simple film theory with the same assumptions. They basically do not differ, and it is apparent from the *Appendix* that data following one should also follow the other. Literature data (9, 16) are shown plotted according to Eq. 7 in Fig. 7 and according to Eq. 5 in Fig. 8, and the data hold up to about 70% of saturation.

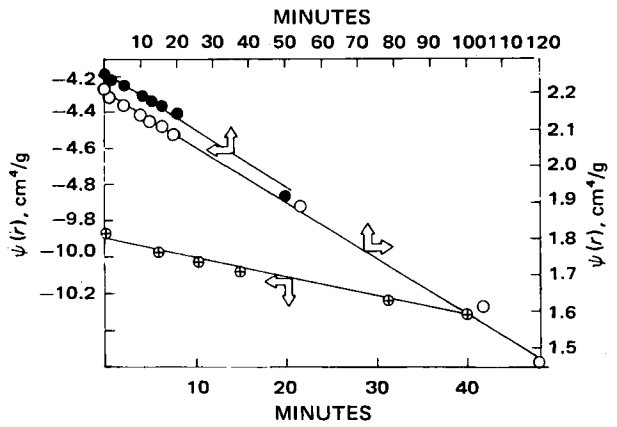

Figure 7—*Data plotted according to Eq. 7. Key:* ⊕, *data from Ref. 9 where initial weight* $W_o = 1.2W_s$; ○, *data from Ref. 16 where initial weight* $W_o = 0.82W_s$; *and* ●, *data from Ref. 16 where initial weight* $W_o = 1.27W_s$.

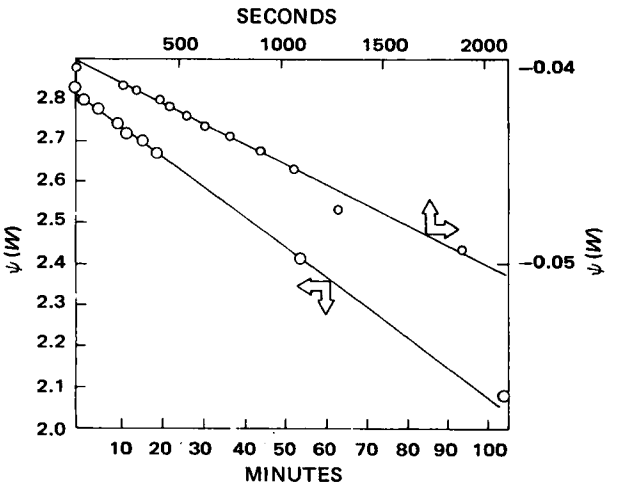

Figure 8—*Data plotted according to Eq. 5. Key:* ○, *sodium chloride data from Ref. 9 where initial weight* $W_o = 1.2W_s$; *and* ○, p-*hydroxybenzoic acid data from Ref. 16 where initial weight* $W_o = 0.82W_s$.

The derivations of Eqs. 5 and 7 require that $W_o < W_s$ or $W_s < W_o$. A dissolution test using p-hydroxybenzoic acid at $W_o = 1.15W_s$ is shown in Fig. 9, and the data, again, adhere to both Eqs. 7 and 5 to about 70% of saturation. In all cases, the deviation is in the direction of smaller k values. Neither the concept that film thickness decreases with the size of the particle nor the concept that solubility increases with a decrease in particle size would explain this result, since the former, in decreasing h, would *increase* k $(=D/h)$ and the latter would increase the concentration gradient and, hence, the dissolution rate. It may, however, be fallacious to consider a sieve fraction comparable to monodisperse powder.

The point here is that, essentially, one is equating the surface area of the "mean" particle size with the surface area of the sieve cut. If particles were isotropic, then the most proper mean to use would be of the volume–surface type; using the cube length equivalent, it is possible to define $\bar{x}_{sv} = \Sigma nx^3/(\Sigma nx^2) = [\int f(x)x^3\,dx]/[\int f(x)x^2\,dx]$, where $f(x)$ is the frequency of the occurrence of the length x. However, the use of the number average mean here gives better results from a surface area point of view.

If one considers the data in Table I as representing a square distribution, then the frequency function, $f(x)$, would be independent of particle length, *i.e.*:

$$f(x) = A \qquad \text{(Eq. 11)}$$

where A is a constant. Normalizing this over the interval of 110–230 μm yields:

$$\int_{110}^{230} f(x)\,dx = 120A = 1 \qquad \text{(Eq. 12}a\text{)}$$

so that:

$$A = 1/120\ (\mu m)^{-1} \qquad \text{(Eq. 12}b\text{)}$$

The surface area (per one particle equivalent) of a sieve fraction

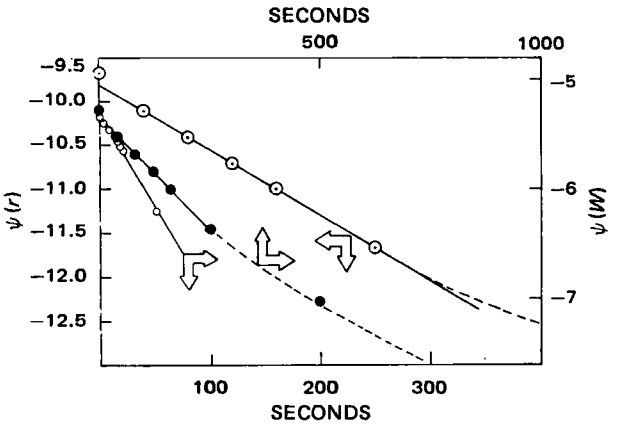

Figure 9—*Data from this study plotted according to Eqs. 5 and 7. Key:* ⊙, *p-hydroxybenzoic acid at 25°, 40–60 mesh, using Eq. 7 with initial weight* $W_o = 1.15W_s$; ●, *p-hydroxybenzoic acid at 25°, 40–60 mesh, using Eq. 5 with initial weight* $W_o = 1.15W_s$; *and* ○, *p-hydroxybenzoic acid at 25°, using Eq. 7 with initial weight* $W_o = 1.27W_s$ *from Ref. 16.*

between x_1 μm and x_2 μm is given by:

$$A = (1/120)\int_{x_1}^{x_2} 6x^2\,dx = (1/60)\,(x_2^3 - x_1^3) \quad \text{(Eq. 13)}$$

The volume (per one particle equivalent) of a sieve fraction between x_1 μm and x_2 μm is given by:

$$A = (1/120)\int_{x_1}^{x_2} x^3\,dx = (1/480)\,(x_2^4 - x_1^4) \quad \text{(Eq. 14)}$$

If one assumes that x_1 decreases at the same rate as x_2, then one can calculate the area of the sieve fraction A as opposed to the area (A^*) it would have had if it had been monodisperse with the arithmetic mean diameter. Data computed in this fashion are shown in Table II. The area estimate is relatively close up to about 65% dissolved, at which point it is 10% high. The A/A^* increases (almost linearly) up to 65% dissolved, after which it rises drastically; this increase would impart linearity to plots *via* Eq. 5 or 7, but the slopes would differ somewhat from those given by the equations.

It is noted that $x_{sv} = 138$ μm; if this value (rather than 170 μm) had been used in Table II, deviations would have been greater. (This would not be so for example with a true sphere.) The assumption that x_1 and x_2 decrease with the same rate is not correct, and actual figures would be less favorable than those shown in Table II.

In a semiquantitative way, the foregoing arguments imply that,

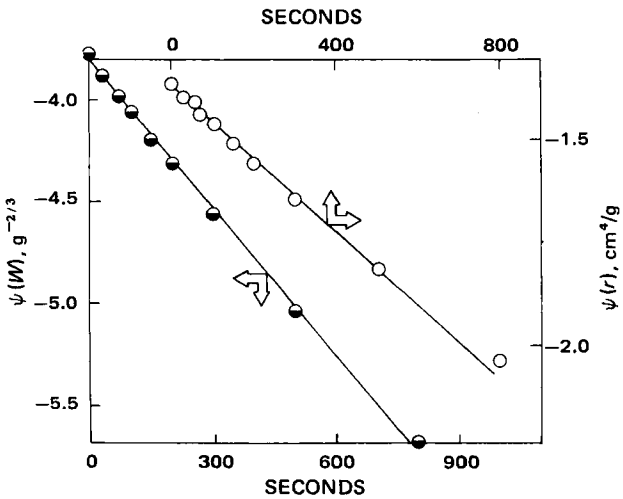

Figure 10—*Data from this study plotted according to Eq. 5 (⊖) and Eq. 7 (○) with p-hydroxybenzoic acid at 25°, 16–20 mesh, and initial weight* $W_o = 1.5W_s$.

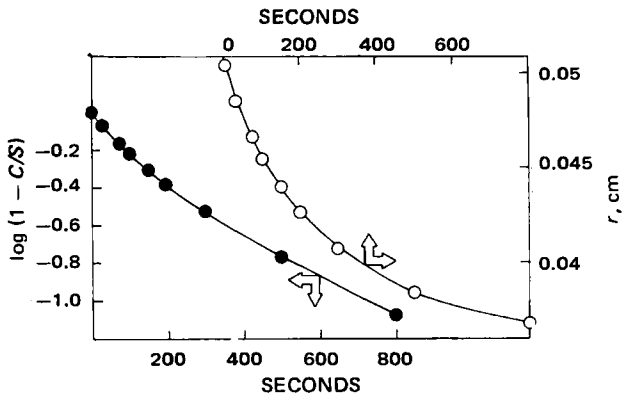

Figure 11—*Data from Fig. 10 plotted (●) according to Eq. 15 (which assumes constant surface area). Curve to the right (○) shows the change in radius (assuming spherical particles) as a function of time.*

in the case of the 40–60 cut, adherance to predicted equations could be expected to only about 65% of complete dissolution of the available solid when $W_o < W_s$ (and to more than 65% of the complete dissolution process when $W_o > W_s$). In Figs. 2*b* and 7–9, linearity prevails to better than 70% of complete dissolution or of the dissolution process; the use of sieve cuts apparently is an explanation for nonadherance beyond this point. The relatively larger A value has the effect of a larger r value in Eq. 7, which gives a higher value of $\psi(r)$ (smaller value of k). This trend is shown in Fig. 9.

Higher W_o's and larger particle sizes should reduce these effects, and the data in Fig. 10 ($W_o = 1.5W_s$, 16–20-mesh fraction) show that this coarser sample in higher amounts adheres to Eqs. 5 and 7 through the whole dissolution process. At very high amounts of material used, the point will be reached where the surface area will stay practically constant during the dissolution process and should follow (11):

$$\ln[1 - (C/S)] = -kOt/V \quad \text{(Eq. 15)}$$

It is seen from Fig. 11 that $W_o = 1.5W_s$ is not a sufficiently large excess of powder to make Eq. 15 apply. Larger excesses are difficult to test, since dissolution becomes rapid with the increased surface areas.

A secondary observation makes the previous considerations pertinent to many actual samples of recrystallized powders. Many crystallizers are built on the principle of nonisothermal crystallization followed by fines destruction (through a raise in temperature at the end of the process). Blending of batches is also a practice, and it would, therefore, be expected that distributions other than log normal would result and that distributions such as the one shown in Table I might be common. As shown in Fig. 12, a cumulative plotting of this type resembles a log-normal distribution, and this may be one reason (other than the reasons stated in the literature) that crystallized materials appear to be log normal.

In conclusion, it should be mentioned once again that a series of

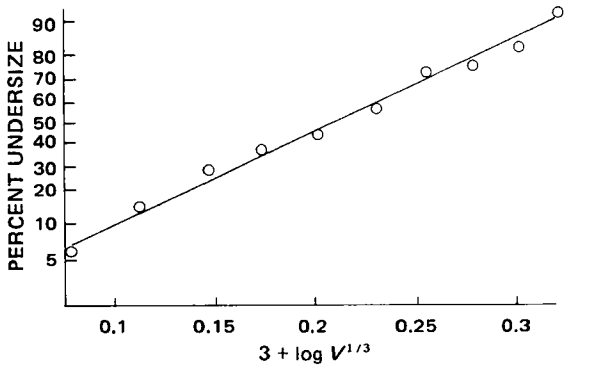

Figure 12—*Data from Fig. 4 shown as a log-normal distribution.*

assumptions is made in the basic film theory of dissolution which cannot be disregarded in dissolution work. However, in studying dissolution behaviors of powder samples, experimental techniques at present do not suffice to detect the effect of the assumptions because of the difficulty in producing monodisperse samples of crystalline samples. In general, film theory has produced equations through a large range of W_o values [Eqs. 5 and 7, Eq. 2 (the cube root law), Eq. 4 (the negative two-thirds law), and Eq. 15], which are workable models for dissolution of powders.

APPENDIX

The Noyes–Whitney equation (1) in the nomenclature used here is:

$$-dW/dt = kO(S - C) \qquad \text{(Eq. A1)}$$

where O is surface area at time t. The concentration, C, may be expressed as $(W_o - W)/V$, and saturation concentration, S, may be expressed as W_s/V, so that Eq. A1 becomes:

$$-V(dW/dt) = kO[W_s - (W_o - W)] \qquad \text{(Eq. A2)}$$

For N particles, the surface area and weights are given by:

$$O = N\pi d^2 \qquad \text{(Eq. A3)}$$

$$W = N\pi d^3\rho/6 \qquad \text{(Eq. A4)}$$

so that:

$$OW^{-2/3} = N^{1/3}[6/(\pi\rho)]^{2/3}\pi = N^{1/3}[6\sqrt{\pi}/\rho]^{2/3} = N^{1/3}\Gamma \qquad \text{(Eq. A5)}$$

Inserting Eq. A5 in Eq. A2 then gives:

$$-V(dW/dt) = kN^{1/3}\Gamma W^{2/3}[W_s - W_o + W] \qquad \text{(Eq. A6)}$$

If $W_s = W_o$, then this becomes:

$$-dW/(W^{5/3}) = (kN^{1/3}\Gamma/V)\,dt \qquad \text{(Eq. A7)}$$

which can be integrated and subjected to initial conditions to give:

$$W^{-2/3} - W_o^{-2/3} = \frac{2kN^{1/3}\Gamma}{3V}t \qquad \text{(Eq. A8)}$$

which is equivalent to the Niebergall equation (Eq. 4).

In general, Eq. A6 can be simplified by introduction of the following substitutions:

$$W_s - W_o = F^3 \qquad \text{(Eq. A9)}$$

$$W = u^3 \qquad \text{(Eq. A10)}$$

in which case it becomes:

$$du/(F^3 + u^3) = (kN^{1/3}\Gamma/3V)dt \qquad \text{(Eq. A11)}$$

which, after integration and use of initial conditions, gives the Short–Sharkey–Rhodes equation (Eq. 5)[4].

High-Pressure Liquid Chromatographic Determination of Sulfamethazine Residue in Bovine Tissue

KARL L. JOHNSON, DELBERT T. JETER ˣ, and ROBERT C. CLAIBORNE

Abstract □ A sensitive high-pressure liquid chromatographic assay procedure is described for residues of sulfamethazine in bovine kidney, liver, muscle, and fat tissue at a sensitivity of 0.04 ppm. Studies were conducted using sulfamethazine-negative bovine tissue to ensure that the peak eluting at the indicated retention volume was sulfamethazine and that the recoveries from spiked tissues were consistent. Data are presented showing the levels of sulfamethazine in the tissue of 12 treated animals found by this technique. The method is more specific than the frequently used colorimetric methods and does not require the tedious separations involved in TLC assays.

Keyphrases □ Sulfamethazine—residues, high-pressure liquid chromatographic determination, bovine tissue □ High-pressure liquid chromatography—residue analysis, sulfamethazine, bovine tissue

Sulfamethazine is frequently used in intravenous injections, oral solutions, tablets, and bolus forms for the treatment of bovine diseases. These veterinary preparations are utilized for mastitis, metritis, calf pneumonia, calf diphtheria, and calf scours (1) caused by pathogens sensitive to sulfamethazine.

Previous analytical methods relied upon diazotization of the aryl amine followed by either a potentiometric titration (2) or a colorimetric assay (3). These methods suffer from a lack of specificity since they react with all aryl amines and, to some extent, with primary and secondary alkyl amines (4) to yield diazotization products and colored addition compounds which interfere with the assay. More recently, TLC methods (2) have been used to separate sulfonamides and their various degradation products but such methods are tedious to perform.

An alternative approach was sought which would allow for the separation from bovine tissue and the quantitation of residues of sulfamethazine remaining in bovine tissue after cessation of treatment. The method outlined in this paper separates sulfamethazine from other tissue components; therefore, it is more specific than existing colorimetric assays. Furthermore, it is sensitive enough to detect levels as low as 0.04 ppm of sulfamethazine present in the tissue. The technique is more specific than most existing assays but does not suffer from decreased sensitivity.

EXPERIMENTAL

Animals—Twelve calves[1] were divided into four groups of three each and administered sulfamethazine sodium, 214.5 mg/kg po for 1 day followed by 107.2 mg/kg/day for 4 days. Group I was slaughtered at 0–6 hr, Group II at 5 days, Group III at 8 days, and Group IV at 10 days posttreatment. Samples of muscle, fat, liver, and kidney were taken for assay purposes.

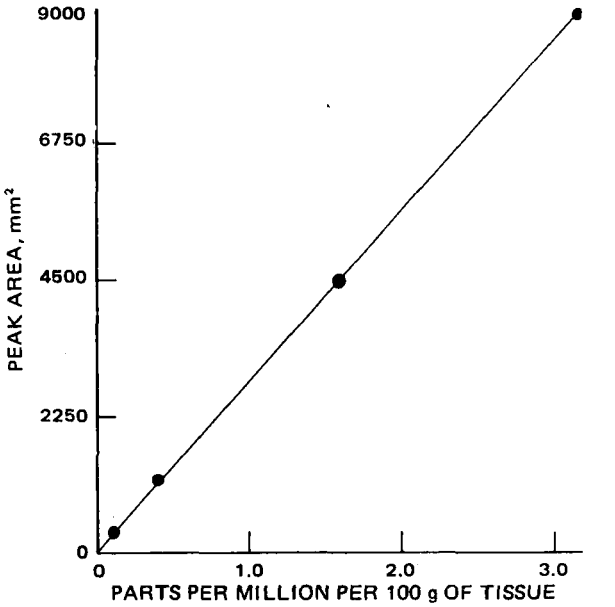

Figure 1—*Calibration curve prepared with sulfamethazine standards (see text).*

Materials—All reagents were ACS or analytical reagent grade, except the *n*-hexane[2] which was technical grade. The *n*-hexane and chloroform were freshly distilled from an all-glass system; the first and last 100 ml from each 2-liter distillation were discarded.

Liquid Chromatography—A 50-μl aliquot of solution was injected by syringe[3] into a high-speed liquid chromatograph[4] equipped with a 254-nm UV detector. The detector signal was fed to a 2-mv strip-chart recorder[5] operating at a chart speed of 0.5 cm/min. A 0.61-m (2-ft) × 2-mm i.d. column, packed with a permanently bonded octadecyl–porous silica[6] material, was purged for at least 2 hr with the mobile phase prior to use. All purging and assay work was done at a constant flow of 0.6 ml/min.

Mobile Phase—The mobile phase, pH 7.70 buffer–2.5% (v/v) isopropyl alcohol, was prepared as follows. Potassium phosphate monobasic crystals, 6.89 g, and 8.79 g of potassium phosphate dibasic (anhydrous) were dissolved in 800 ml of distilled water. The pH was adjusted to 7.70 with 1.0 *M* sodium hydroxide. The solution was transferred to a 1-liter volumetric flask containing 25 ml of isopropyl alcohol and diluted to volume with distilled water.

This solution was poured into a 2-liter round-bottom flask and refluxed for 45 min under a 400-mm Allihn-type water-cooled condenser. The solution was allowed to cool to room temperature with the condenser attached and then was poured gently into the reservoir of the liquid chromatograph. The reservoir was designed to minimize the evaporation of isopropyl alcohol.

Standards—Sulfamethazine USP, 100 mg, was accurately weighed into a 100-ml volumetric flask, dissolved in 0.1 *M* hydrochloric acid, diluted to volume, and mixed. Aliquots of 1.0, 4.0, 16.0, and 32.0 ml were transferred into separate 100-ml volumetric flasks and diluted to volume with distilled water. (These solutions

[1] All animals were located at the Philips Roxane Clinical Research Farm, Cosby, Mo., under identical conditions and were fed antibiotic- and sulfonamide-free rations.

corresponded to 0.01, 0.04, 0.16, and 0.32 mg/ml of sulfamethazine, respectively, and were retained to prepare recovery samples.)

One-milliliter aliquots of each of the four standards were transferred into 50-ml glass-stoppered graduated cylinders, the volumes were adjusted to 30 ml with 1 *M* hydrochloric acid, and the solutions were mixed. (These solutions contained 10, 40, 160, and 320 μg and corresponded to 0.1, 0.4, 1.6, and 3.2 ppm of sulfamethazine

Table I—Sulfamethazine Residue Results

Animal Number	Slaughter Time Post-treatment	Sulfamethazine Residue, ppm			
		Fat	Muscle	Kidney	Liver
132	0–6 hr	325	54.1	88.6	42.5
177	0–6 hr	150	45.3	62.4	28.0
178	0–6 hr	115	42.1	95.6	33.2
138	5 days	0.06	<0.04	<0.04	0.04
168	5 days	0.27	<0.04	0.08	0.09
169	5 days	0.36	0.17	0.37	0.31
174	8 days	0.04	<0.04	<0.04	<0.04
175	8 days	0.06	<0.04	<0.04	<0.04
176	8 days	0.12	<0.04	<0.04	<0.04
170	10 days	0.06	<0.04	<0.04	<0.04
171	10 days	<0.04	<0.04	<0.04	<0.04
172	10 days	0.06	<0.04	<0.04	<0.04

present, respectively, in a 30-ml extract of 100 g of tissue.) Fifty microliters of each of the last four standards was injected into the liquid chromatograph, and the area of the peak eluting at a retention volume (V_r) of 12 ml was determined.

Since the concentration ranges were so great, the detector attenuation was varied between 0.04 and 0.32 absorbance unit full scale (aufs). The equivalent area at 0.04 aufs was then calculated using:

$$\text{corrected area (0.04 aufs)} = \frac{\text{area sulfamethazine peak} \times \text{aufs used}}{0.04} \quad \text{(Eq. 1)}$$

A calibration curve was prepared (Fig. 1) by plotting the corrected area (0.04 aufs) against the concentration (parts per million) present in 100 g of tissue.

Procedure—The tissue was sliced in squares (2 × 2 × 1 mm thick), and 100 g was weighed into a wide mouth glass jar. Then 150 ml of acetone–chloroform (1:1 v/v) was added, and the mixture was shaken vigorously for 2 min and allowed to set for 15–20 min. The samples were again shaken vigorously for 2 min. The solvent was decanted into a funnel containing an 18.5-cm phase-separating

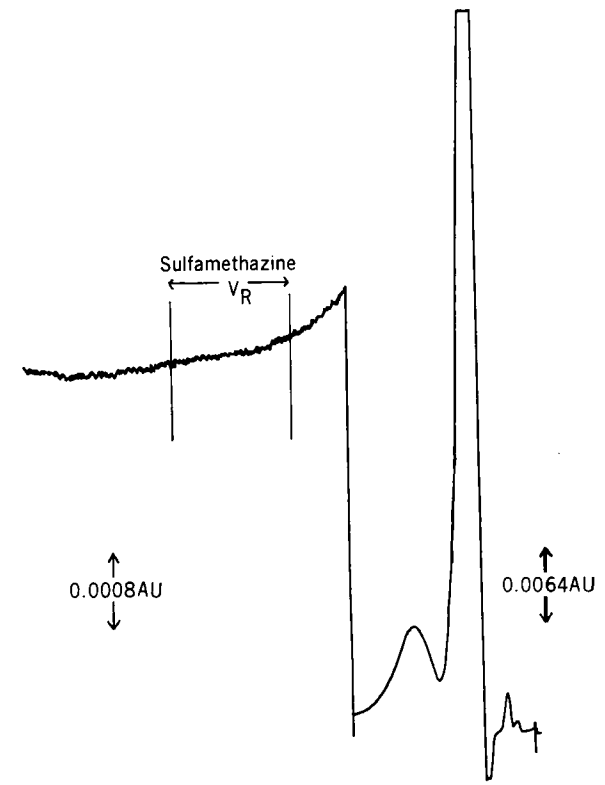

Figure 3—*Chromatogram of control kidney extract.*

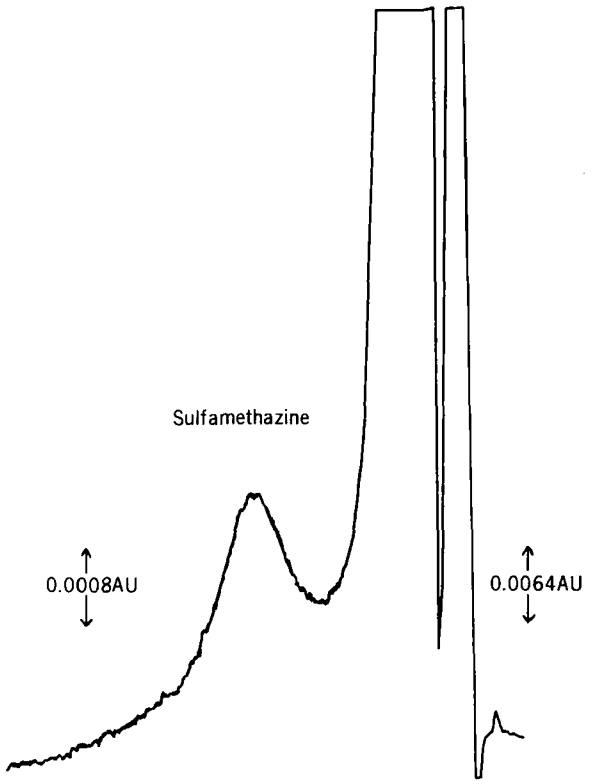

Figure 5—*Chromatogram of bovine kidney containing 0.37 ppm of sulfamethazine.*

paper[7], and the filtrate was collected in a 1-liter round-bottom flask. Two additional 2-min extractions of the tissue were made using 100-ml portions of acetone–chloroform (1:1) and filtering each extract. The filter was rinsed with 100 ml of the acetone–chloroform (1:1). (If water from the muscle tissue seeped through the filter, the filtrate was refiltered through fresh paper.)

The filtrate was evaporated to an oily residue, using a hot water bath at 60° and a rotary thin-film vacuum evaporator[8], and was transferred to a 250-ml separator. The following rinses were used: (*a*) 4 × 25 ml of *n*-hexane, (*b*) 1 × 3 ml of acetone, (*c*) 2 × 10 ml of 3.5 *M* hydrochloric acid (the flask was heated in hot water during this rinse), (*d*) 1 × 3 ml of acetone, and (*e*) 2 × 25 ml of *n*-hexane.

The mixture was shaken gently for 2 min. The emulsion, if present, was allowed to separate. The aqueous layer, including the emulsion, was drained into a 125-ml separator. The organic layer was washed with 3 × 10-ml portions of 1 *M* hydrochloric acid, shaking more vigorously on each successive wash, and the washes were combined in the 125-ml separator. The combined hydrochloric acid extracts were washed gently with 5 ml of chloroform, and the chloroform was discarded. The chloroform wash was repeated twice, shaking more vigorously on each succeeding wash.

The pH of the aqueous phase was adjusted to 8.5–9.0 using 14 *M* ammonium hydroxide. The ammoniacal solution was then washed with 3 × 5-ml portions of chloroform, and the washes were discarded. The aqueous phase was transferred to a 250-ml wide mouth erlenmeyer flask, and the separator was rinsed with a small amount of water. The solution was evaporated on a hot plate until the salts present began to precipitate. Then the mixture was cooled and transferred to a 50-ml glass-stoppered graduated cylinder using 1 *M* hydrochloric acid and diluted to 30 ml with 1 *M* hydrochloric acid. A portion was filtered through a 0.45-μm membrane filter[9] and transferred to a screw-capped test tube. Fifty microliters was injected into the liquid chromatograph under the same conditions as the standard calibration curve.

The corrected area (0.04 aufs) was determined using Eq. 1, and the amount of sulfamethazine present in the tissue was determined from the standard calibration curve. The results obtained from this study are shown in Table I. Representative chromatograms of actual tissue samples are shown in Figs. 2–5.

Recoveries—Sulfamethazine-negative muscle, kidney, fat, and liver tissue were obtained from bovines with a negative antibiotic and sulfonamide treatment history for at least 60 days. Eight control samples (two of each tissue) were then assayed according to the procedure outlined here. Seven were found to be negative; one muscle control was positive but was calculated to be <0.02 ppm.

Six to nine samples of each kidney, fat, muscle, and liver tissue were individually "spiked" with the water dilutions of sulfamethazine prepared in the *Standards* section. Each 1 ml of the 0.01-, 0.04-, 0.16-, and 0.32-mg/ml standard added to 100 g of sample (1–2-mm slices) and mixed well corresponds to 0.1, 0.4, 1.6, and 3.2 ppm of sulfamethazine in the tissue, respectively. These recoveries were assayed according to the procedure, and results are shown in Table II.

DISCUSSION

Several publications (3, 5–7) reported the recoveries of sulfonamides utilizing the colorimetric assays, and all reported values of 75–86%. Only Houston and Umstead (7) reported on sulfamethazine, and these results were a combination of sulfamethazine–sulfathiazole residues in milk.

The major points critical to the sensitivity of this method are the success of the "cleanup" steps and the "noise level" of the liquid chromatograph.

The tissue component eluting just before the sulfamethazine must be reduced to a level so that its tail is not so steep that it ren-

ders quantitation of small sulfamethazine peaks impractical. The chloroform wash of the basic aqueous mixture seems to affect this component most. Overwashing at this point, however, causes a loss of sulfamethazine.

Homogenizing or grinding the tissue prior to extraction tends to improve recovery somewhat but usually generates cleanup difficulties which negate the improved recovery.

Techniques critical to reducing the noise level of the liquid chromatograph include the following:

1. The solvent should be degassed to minimize the effect of small bubbles which are not visible but give detector response. This procedure also helps prevent buildup of air in the pump head, which would result in pulsations.
2. All fittings should be very tight to eliminate even the smallest leaks.
3. Detector electronics and cell windows should be dry, and any air or gas used to purge the reference cell should be scrupulously clean and dry.
4. In some instances, an arrangement to equilibrate the solvent thermally to the temperature of the detector might be helpful.
5. The electrical line to which the chromatograph is connected must be free of interference and large fluctuations. Both the chromatograph and the recorder should be well grounded.
6. The final aqueous solution must be adjusted to pH 8.5–9.0 before evaporation to reduce the volume. If the solution is acidic at this point, the sulfamethazine can be hydrolyzed to sulfanilamide and sulfanilic acid which elute with tissue components.

Comparative Pharmacokinetics of Coumarin Anticoagulants XIV: Relationship between Protein Binding, Distribution, and Elimination Kinetics of Warfarin in Rats

AVRAHAM YACOBI and GERHARD LEVY [x]

Abstract □ The relationships between the protein binding, distribution in the body, and kinetics of elimination of warfarin were studied. Individual rats eliminated warfarin by apparent first-order kinetics, with a biological half-life of 5.9–41 hr and a total plasma clearance of 2.4–22 ml kg^{-1} hr^{-1}. There is a strong positive correlation between the apparent volume of distribution (V_d) and the elimination rate constant (k_{el}). There was no apparent concentration dependence of warfarin binding to serum proteins over a wide concentration range, but there were pronounced intersubject variations in protein binding, with the free fraction of drug (f) in serum ranging from 0.172×10^{-2} to 1.53×10^{-2}. There are strong positive correlations between f and k_{el}, f and V_d, and f and the kidney–serum concentration ratio of warfarin. Consistent with theory, there is an excellent positive linear correlation between f and total plasma clearance of the drug. The intersubject variation in f is not related to variations in serum albumin or total protein concentration. There is a strong correlation between values of f for serum and liver homogenate in individual animals, consistent with the lack of correlation between f in serum and the liver–serum concentration ratio of warfarin. These results show that the pronounced intersubject variation in the elimination of warfarin observed in this investigation was related to interindividual differences in plasma protein binding of the drug. The differences in protein binding cannot be ascribed to differences in plasma protein concentrations and may reflect configurational differences of proteins or the presence of an endogenous displacing agent at different concentrations.

Keyphrases □ Coumarin anticoagulants—relationship between protein binding, distribution, and elimination kinetics of warfarin in rats □ Warfarin—relationship between protein binding, distribution, and elimination kinetics in rats □ Plasma protein binding, warfarin—relationship to distribution and elimination, rats

The anticoagulant warfarin is a highly plasma protein bound drug with pronounced intersubject variability in its elimination kinetics in humans and animals (1–7). In this investigation, the relationships between the protein binding, distribution in the body, and kinetics of elimination of warfarin were studied in individual rats. A theoretical basis for a relationship between plasma protein binding and the total clearance of warfarin by the body was presented in a preliminary report (8).

EXPERIMENTAL

The studies were carried out on adult male Sprague–Dawley rats, weighing 400–450 g. They were selected from a larger number of animals on the basis of the results of a dicumarol screening test (9, 10) in order to obtain a group of animals with a wide difference

in warfarin elimination kinetics. The rats received an intravenous injection of ^{14}C-warfarin, 0.6 mg/kg, and blood samples were obtained at frequent intervals.

The rats were killed at a time after injection when the warfarin concentration in plasma was expected to have decreased to about 0.4 μg/ml. They were killed by removing all blood from the aorta under ether anesthesia. Liver and kidneys were removed rapidly, each was cut into five or six slices, and the slices were compressed slightly between paper tissue to remove any remaining blood. The organs were weighed and homogenized with two (liver) or five (kidneys) volumes of ice-cold 0.9% sodium chloride solution, using a homogenizer[1] with a 50-ml Teflon-coated stainless steel sealed container at a rheostat setting of 70 for about 1 min. The blood samples were kept at room temperature for 15 min, and then the serum was separated by centrifugation at 1000×*g* for 10 min.

Warfarin concentrations in serum and plasma were determined by scintillation spectrometry following extraction and TLC, as previously described (7). Warfarin concentrations in liver and kidney homogenates were determined similarly after extracting a mixture of 1 ml of homogenate and 1 ml of 0.3 *N* hydrochloric acid with 10 ml of ethylene dichloride. Recovery of added ^{14}C-warfarin from these homogenates was 85 ± 5% (mean ± *SD*, n = 12) and was independent of concentration in the 0.05–2.5-μg/ml range.

Serum protein binding determinations were carried out by equilibrium dialysis at 25° and subsequently with serum from 12 additional rats at both 25 and 37°. Undiluted serum obtained from the individual animals at the end of the experiment, with no added drug (*i.e.*, with only the concentrations of warfarin and metabolites from the injection of warfarin), was dialyzed for 20 hr against isotonic 0.15 *M* pH 7.4 phosphate buffer in Plexiglas cells separated

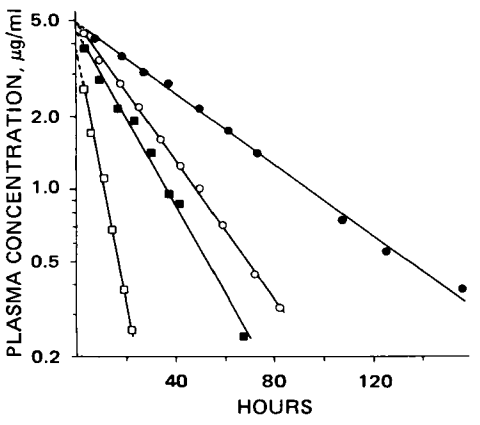

Figure 1—*Concentration of warfarin in the plasma of four rats as a function of time after intravenous injection of ^{14}C-warfarin, 0.6 mg/kg. Key: □, Rat 1; ■, Rat 8; ○, Rat 11; and ●, Rat 13.*

by a cellophane membrane[2]. Liver binding was determined similarly, using liver homogenate diluted with 0.15 *M* pH 7.4 phosphate buffer to yield a final concentration of 1 g of liver/10 ml. The liver homogenates were spiked with ^{14}C-warfarin, 0.3 μg/ml of homogenate.

Total protein concentrations in serum were determined by the method of Gornall *et al.* (11), using rat albumin as the standard. The fraction of albumin and other serum proteins was determined by electrophoresis[3], and concentrations of these proteins were determined from the product of the fraction and total protein concentration. The coefficient of variation of the serum albumin concentration determinations averaged 3.7% in six determinations on each of five samples.

For the correlation studies between certain pharmacokinetic parameters and serum protein binding, additional data from control experiments of other studies[4] were included. The fraction of warfarin *(F)* in the liver or kidneys relative to the amount of warfarin (free and protein bound) in the entire body was calculated from Eq. 1:

$$F = W_t C_s{}^0 C_t (C_s \times \text{dose})^{-1} \qquad \text{(Eq. 1)}$$

where W_t is the weight of the organ, C_t is the drug concentration

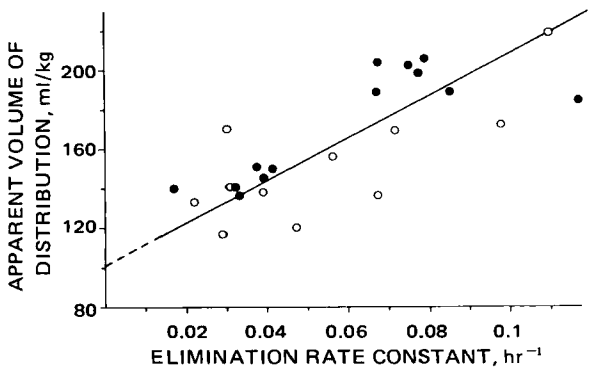

Figure 2—*Relationship between the apparent volume of distribution and the apparent first-order elimination rate constant of warfarin in individual rats that received an intravenous injection of ^{14}C-warfarin, 0.6 mg/kg (r = 0.761, p < 0.001). in the organ, C_s^0 is the zero-time drug concentration in plasma, and C_s is the drug concentration in the serum when the liver and kidneys were removed. Other experimental details and the methods of pharmacokinetic analysis were described previously (7).

RESULTS

The biological half-life, the apparent volume of distribution, and the total plasma clearance of warfarin in 13 rats are listed in Table I. Figure 1 shows the time course of plasma concentrations in the animals with the shortest and longest half-lives of warfarin and in two animals with intermediate half-life values. There is a positive and highly statistically significant correlation between the apparent volume of distribution and the apparent first-order elimination rate constant for warfarin in individual rats (Fig. 2).

The average serum warfarin concentration when the animals were killed was about 0.4 μg/ml (Table II). The concentrations of warfarin in the liver were about 2.5 times higher on the average, while the concentrations in the renal tissues were 56–94% of the serum concentrations (Table II). The livers contained about 44% of the total amount of warfarin in the body on the average (F_{liver} = 0.44); the kidneys contained only 2.7% on the average. There is no significant correlation between F_{liver} and the elimination rate constant of warfarin.

The extent of serum protein binding of warfarin, expressed as the free fraction (f_{serum}), varied widely between animals, with f_{serum} values ranging from 0.00172 to 0.0153 at 25°, equivalent to 98.47–99.83% protein binding. The f_{serum} value in any one animal was essentially constant over a wide concentration range, irrespective of whether the animal was one with a relatively high or low f_{serum} value (Table III). There is an excellent correlation between f_{serum} values at 25 and 37° for the serum from any one animal (Fig. 3); the average ratio of f_{serum} values, 37°/25°, was 1.32.

There are highly statistically significant positive correlations between f_{serum} and the apparent volume of distribution (Fig. 4) and between f_{serum} and the elimination rate constant of warfarin (Fig. 5) in individual rats. The f_{serum} values obtained at 25° were multiplied by 1.32 to obtain equivalent values at 37° since f_{serum} determinations in subsequent studies were done at the higher temperature.

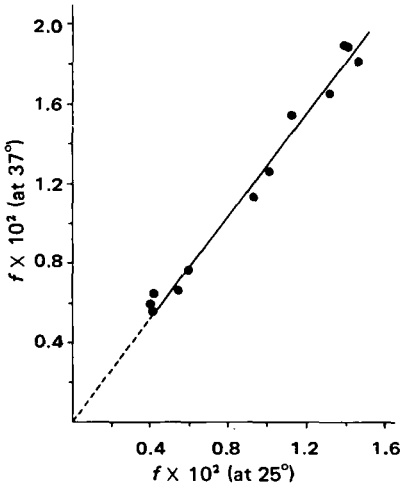

Figure 3—*Effect of temperature on serum protein binding of warfarin. The graph shows the relationship between the free fraction of warfarin at 25 and 37° in the same samples of serum, with a warfarin concentration of 0.3–2.1 μg/ml (r = 0.989, p < 0.001). The average ratio of the free fraction at 37 and 25° is 1.32.*

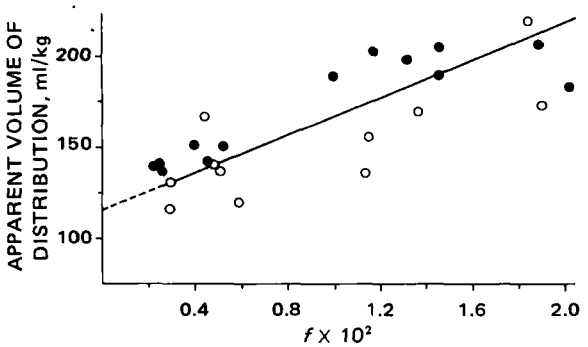

Figure 4—*Relationship between the apparent volume of distribution of warfarin and the fraction of free drug in serum of individual rats (r = 0.787, p < 0.001). Symbols are as given in Fig. 2. The ● values in this figure and in Figs. 5–7 are the experimental values multiplied by 1.32 to obtain f at 37°.*

A theoretical pharmacokinetic equation was formulated recently which predicts a linear correlation between the total plasma or serum clearance of warfarin and f_{serum}, with a zero intercept (8). The experimental data are in excellent agreement with this theory, showing a strong and statistically highly significant positive linear correlation between total clearance and f_{serum}, with the intercept of the regression line close to the origin (Fig. 6).

There is no relationship between individual f_{serum} values and either the albumin or total protein concentration in the serum of a total of 42 rats (Fig. 7). Binding studies carried out with diluted, ^{14}C-warfarin-spiked liver homogenates from seven rats yielded f_{liver} values that correlate strongly and highly statistically significantly (r = 0.946, $p < 0.005$) with f_{serum} values in the same animals (Table IV). To rule out the possibility that this correlation is an artifact due to retained blood in the liver, f_{serum} values in 1:100 diluted serum were determined (Table V). The significance of these data will be considered under *Discussion*.

There is no correlation between the liver–serum concentration ratio of warfarin (Table II) and f_{serum}, but there is a strong and highly statistically significant correlation between the kidney–serum concentration ratio and f_{serum} in individual rats (r = 0.918, $p < 0.005$).

DISCUSSION

The results of this investigation indicate that plasma protein binding is the major determinant of the pronounced interindividual differences in warfarin elimination kinetics in the rats studied.

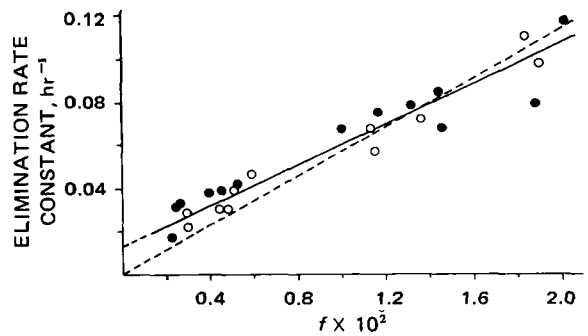

Figure 5—*Relationship between the apparent first-order elimination rate constant of warfarin and the fraction of free drug in the serum of individual rats (r = 0.970, p < 0.001). Symbols are as given in Fig. 2. The continuous line was fitted to the data by the double regression method (13); the stippled line was forced through the origin.*

Table IV—Protein Binding of Warfarin in Serum and Liver Homogenate of Individual Rats

Rat[a]	Free Fraction[b] × 100	
	Serum	Liver[c]
3	1.43	18.0
7	1.11	20.8
8	0.396	9.80
10	0.300	9.04
11	0.198	9.22
12	0.191	7.26
13	0.172	7.46

[a] Determinations of free fraction in liver homogenate of Rats 1, 2, 4, 5, 6, and 9 were not made. [b] At 25°. [c] A 1:10 homogenate of liver containing about 0.1 μg/ml (final concentration) of added ^{14}C-warfarin.

It was suggested earlier (8) that:

$$\text{total plasma clearance} = k''f_{serum} \qquad \text{(Eq. 2)}$$

where k'' is an intrinsic clearance constant equal to the product of k' (an intrinsic elimination rate constant) and V_w (a physiological space consisting of plasma water and other water exclusive of dissolved macromolecules capable of binding warfarin). The results of this investigation are in excellent agreement with this prediction (Fig. 6).

These results imply that the activity of the warfarin-metabolizing enzyme system(s) did not vary significantly between different rats under the experimental conditions. A subsequent study[4], in which the activity of the warfarin-metabolizing enzyme system(s) was altered by pretreatment of the animals with an enzyme inhibitor, did show a change in k'' value (*i.e.*, a decrease in the slope of the total clearance *versus* f_{serum} plot) as a result of such treatment.

The experimental data shown in Figs. 4 and 5 yield the empirical relationships:

$$V_d = a + bf_{serum} \qquad \text{(Eq. 3)}$$

$$k_{el} = a' + b'f_{serum} \qquad \text{(Eq. 4)}$$

The experimental value of a' in Eq. 4 does not differ significantly from zero, as should be the case if the rate of biotransformation is a function of only the free drug concentration. Combination of Eqs. 3 and 4 yields:

$$V_d k_{el} = aa' + (ab' + a'b)f_{serum} + bb'f_{serum}^2 \qquad \text{(Eq. 5}a\text{)}$$

or:

$$\text{total clearance} = k_1 + k_2 f_{serum} + k_3 f_{serum}^2 \qquad \text{(Eq. 5}b\text{)}$$

Equation 5*b* suggests a parabolic rather than a linear relationship between total clearance of warfarin and f_{serum}. The curvature of the parabola is, however, very slight over the range of the f_{serum} values observed in this study (Fig. 8). It is not feasible, therefore, to distinguish on the basis of the experimental data between the linear relationship represented by Eq. 2 (which is based on theoretical considerations) and the parabolic relationship represented by Eq. 5*b* (which was obtained empirically by assuming that Eqs. 3 and 4 describe the experimental data in Figs. 4 and 5). The apparently linear relationship between V_d and k_{el} (Fig. 2) is consistent with the reasonably good fit of the experimental data to Eqs. 3 and 4. When a' is assumed to be near zero, combination of the two equations by eliminating f_{serum} yields:

$$V_d = a + \frac{b}{b'}k_{el} \qquad \text{(Eq. 6)}$$

which describes the experimental data in Fig. 2 quite well.

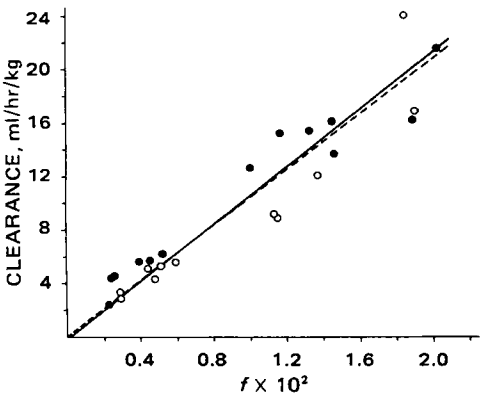

Figure 6—*Relationship between total plasma clearance of warfarin and free fraction of drug in the serum of individual rats (r = 0.947, p < 0.001). Symbols are as given in Fig. 2; regression lines are as given in Fig. 5.*

Table V—Effect of Dilution on Protein Binding of Warfarin in Rat Serum

Rat	Free Fraction[a] × 100	
	Undiluted Serum	Serum Diluted 1:100
1-V	0.560	26.7
4-V	0.660	33.3
9-V	1.65	57.9
12-V	1.89	58.3

[a] Undiluted serum contained 0.3–0.7 μg of ^{14}C-warfarin/ml; diluted serum contained 0.6–0.7 μg/ml. Binding studies were carried out at 37°.

Surprisingly, the striking interindividual differences in the serum protein binding of warfarin are not due to differences in the concentration of serum proteins (Fig. 7). The serum concentrations of albumin and total protein observed in this study are in good agreement with the concentrations reported by other investigators (12). The correlation between the extent of warfarin binding to serum proteins and liver in any one animal is another very significant observation. It is not an artifact due to retention of blood in the excised livers. Even if the excised livers retained as much as 10% of their weight of blood, the diluted liver homogenate (one part of liver in 10 parts of diluted homogenate) would contain only about 0.5% plasma.

The free fraction values obtained with a 1% aqueous solution of serum are much higher than the f_{liver} values obtained with the di-

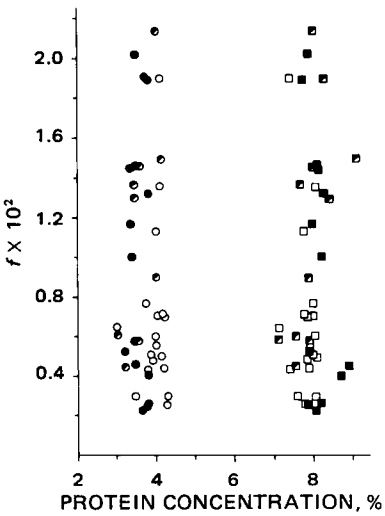

Figure 7—*Relationship between serum protein binding of warfarin and the concentrations of albumin (circles) and total protein (squares) in the serum of individual rats. Solid symbols represent data obtained in this investigation; open and half-open symbols represent data from two other studies carried out in this laboratory (to be published).*

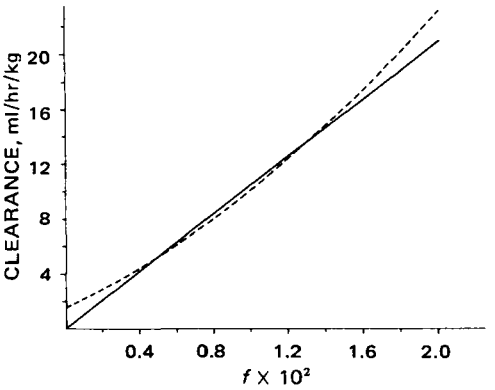

Figure 8—*Comparison of the directly determined relationship between total plasma clearance of warfarin and free fraction in serum (continuous line from Fig. 6) and the relationship as calculated from the regression equations for the data in Figs. 4 and 5 (stippled line).*

luted liver homogenates (Tables IV and V), showing that the liver tissues are responsible for the warfarin binding in liver homogenates. The fact that the liver–serum concentration ratio of warfarin is 2.5 (Table II), *i.e.*, considerably above unity, is consistent with this conclusion. Also consistent is the observation that the liver–serum concentration ratio of warfarin shows no correlation with f_{serum}; a parallel change in f_{serum} and f_{liver} would minimize any changes in the liver–serum concentration ratio as a function of f_{serum}. No direct studies of warfarin binding to kidney tissues were performed, but the fact that the kidney–serum concentration ratios correlate strongly with f_{serum} suggests that the f_{kidney} values do not change in parallel with the f_{serum} values in individual rats.

Since there is no correlation between f_{serum} and serum protein concentrations, one or more other factors must be responsible for the pronounced differences in the serum protein binding of warfarin. All animals were of the same strain and were obtained from the same supplier. They received identical food and housing. Whatever accounts for any one animal's f_{serum} value is unlikely to vary appreciably with time since the kinetics of warfarin elimination in any given animal are highly reproducible with time (9). Among the reasons potentially responsible for interindividual differences in protein binding of warfarin are *(a)* differences in the structure of certain plasma and liver proteins, and *(b)* the presence of an endogenous displacing agent at different concentrations in different animals. These and other mechanisms, as well as possible genetic influences on them, are being explored.

Photolytic Degradation of α-[(Dibutylamino)methyl]-6,8-dichloro-2-(3′,4′-dichlorophenyl)-4-quinoline Methanol: An Experimental Antimalarial

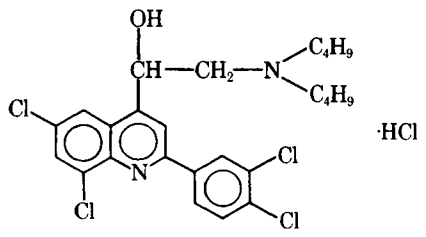
H. OKADA *§, V. STELLA *x, J. HASLAM ‡, and N. YATA *¶

Abstract □ A study of the effects of various storage conditions on the rate and products of degradation of the quinoline methanol antimalarial agent, α-[(dibutylamino)methyl]-6,8-dichloro-2-(3′,4′-dichlorophenyl)-4-quinoline methanol, was undertaken. The degradation was followed by high-pressure liquid chromatography and TLC in oxygenated and deoxygenated methanol, ethanol, chloroform, and chloroform–heptane mixtures under UV and laboratory fluorescent lighting irradiation, as well as in the absence of light. The kinetics of degradation confirmed the major catalyzing factor to be UV irradiation. The compound was stable in the absence of light and reasonably stable under fluorescent lighting both in the presence and absence of oxygen. The degradation resulted in a major product, 6,8-dichloro-2-(3′,4′-dichlorophenyl)-4-quinolinecarboxaldehyde, whose structure was confirmed by elemental analysis and IR, NMR, and mass spectral data.

Keyphrases □ α-[(Dibutylamino)methyl]-6,8-dichloro-2-(3′,4′-dichlorophenyl)-4-quinoline methanol—photolytic degradation □ Photolysis—degradation of α-[(dibutylamino)methyl]-6,8-dichloro-2-(3′,4′-dichlorophenyl)-4-quinoline methanol

The antimalarial agent α-[(dibutylamino)methyl]-6,8-dichloro-2-(3′,4′-dichlorophenyl)-4-quinoline methanol monohydrochloride[1] (I) has been shown to be useful in the treatment of resistant strains of *Plasmodium vivax* and *Plasmodium falciparum*. However, it has been shown to cause photosensitivity in some experimental animals and humans, although this effect is minor when compared to a number of other quinoline methanol antimalarials.

In the process of accumulating data on the physical and chemical properties of I and the free base form (II) in various organic solvents, it was noted that chemical degradation was occurring, particularly in standard solutions of II dissolved in chloroform and blood extractant solutions of II that were allowed to stand in the presence of laboratory lighting. Therefore, a study of the effects of various solvents and storage conditions on the rate and products of degradation of II was undertaken. The products of such degradation were of interest from a mechanistic viewpoint as well as from a toxicity viewpoint. That is, could the products of photolysis of II be the agents causing the phototoxicity reaction in animals and humans.



I

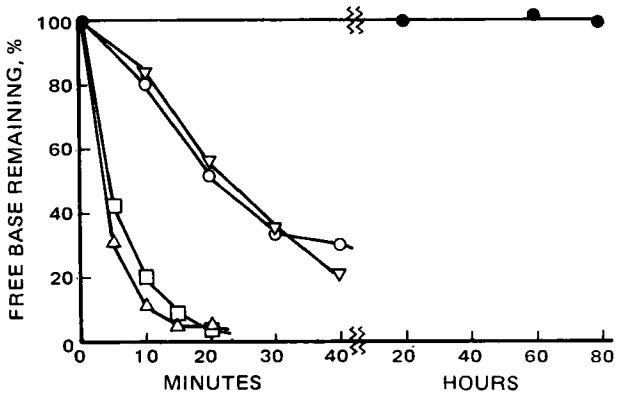


Figure 1—*Plot of percent of II remaining in various organic solvents as a function of time. Open points represent solutions exposed to direct sunlight; closed points represent a solution protected from direct irradiation or exposed only to laboratory fluorescent lighting. Key:* □, *methanol (0.001% II);* △, *20% methanol–ethanol (0.001% II);* ○, *chloroform (0.005% II); and* ▽, *20% chloroform–heptane (0.005% II).*

Most of the work was done on II and not I because preliminary data indicate that II is the predominant form of I at physiological pH[2].

RESULTS AND DISCUSSION

Degradation of II, which was followed quantitatively by high-pressure liquid chromatography (HPLC) and qualitatively by TLC, was found to be strongly catalyzed by UV irradiation, but solutions of II in various solvents were stable when protected from light. Exposure to normal laboratory fluorescent lighting catalyzed the breakdown of II but only after 4–5 days of exposure. Typical plots of the loss of II from UV-irradiated solutions in various solvents, concentrations, and UV energy sources, as a function of time, are shown in Figs. 1 and 2.

Solutions of II in chloroform exposed to UV irradiation, with and without oxygen-free nitrogen bubbled through the solution, showed no quantitative or qualitative differences in their degradation rates or products.

Factors other than the presence of UV irradiation affected the rate of photolytic decomposition of II. These factors included:

1. The concentration of II dissolved in the organic solvent. The higher the concentration of II in the solvent, the smaller was the percent loss of II per unit time. This result is consistent with the degradation rate passing from a rate-determining loss of II to an apparent pseudo-zero-order degradation dependent on the amount of incident UV energy (1).

[1] This compound, abbreviated WR-30,090, is currently under testing by the Walter Reed Research Institute. WR-30,090 itself is the hydrochloride salt. Most work in organic solvent and extraction systems requires the use of the free base because of the poor solubility of the hydrochloride salt in organic solvents.

[2] The pKa of I in aqueous solvents is suspected to be unpredictably low. The loss of I and II from aqueous solution and their unusual physical and chemical properties in aqueous solutions will be discussed later.

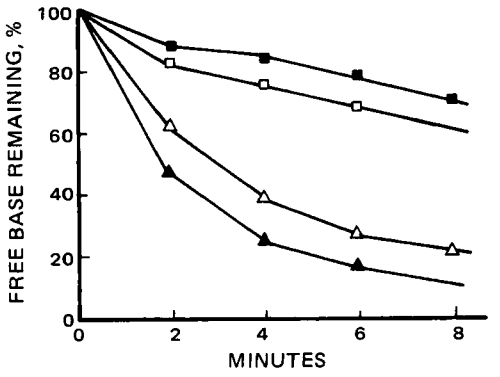

Figure 2—*Plot of percent of II remaining in various organic solvents containing various concentrations of II exposed to UV irradiation in a photochemical reactor at 3000 Å as a function of time. Key: ■, chloroform (0.005% II); □, chloroform (0.001% II); △, methanol (0.001% II); and ▲, methanol (0.0002% II).*

2. At the same concentration, the degradation of II was solvent dependent. UV-irradiated solutions of II degraded faster in methanol and methanol–ethanol than in chloroform and chloroform–heptane solvents.

3. Compound I, *i.e.*, the hydrochloride salt, was stable to short-term exposure to UV irradiation. Long-term exposure (>1 day) to irradiation at 2537 and 3000 Å in a photochemical reactor produced degradation, but the degradation products were numerous and not the same as the degradation products of II.

4. The degradation of II was quenched by the removal of the UV irradiation source; *i.e.*, the reaction was UV irradiation catalyzed and not just UV irradiation initiated. This result is adequately demonstrated in Fig. 3.

5. The UV-catalyzed degradation of I or II in aqueous and aqueous methanol solutions could not be studied because of apparent adsorption of II onto glass and its very poor aqueous solubility.

There did not appear to be any quantitative differences in degradation rates between solutions irradiated at 2537 or 3000 Å. However, corrections for light intensities, *etc.*, were not made.

Isolation of the major degradation product using column chromatography resulted in a yellow product, mp 195.5–197°, which gave methanol or ethanol solvates when recrystallized from methanol or ethanol solutions. The solvent-free compound gave a characteristic IR aldehyde carbonyl band at 1700 cm^{-1} and an aldehydic C—H stretch at 2860 cm^{-1}. Mass spectral data showed a peak at 368 and peaks at 370, 372, 374, and 376, consistent with P − 1, P + 1, P + 3, P + 5, and P + 7 peaks, respectively, of 6,8-dichloro-2-(3′,4′-dichloro)phenyl-4-quinolinecarboxaldehyde (III). A molecular weight of 35 was assumed as the base for chlorine. This structure was confirmed by NMR spectroscopy, and elemental analysis confirmed an empirical formula of $C_{16}H_7Cl_4NO$, the empirical formula for III (see *Experimental* for details).

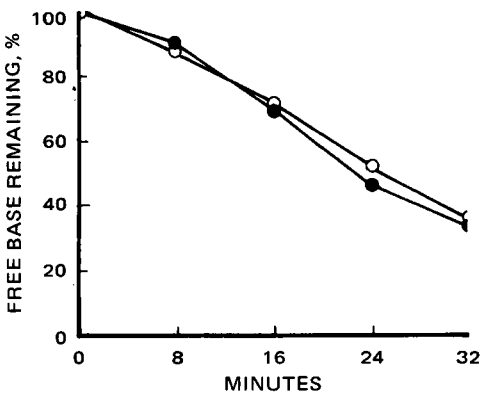

Figure 3—*Plot showing the effect of sunlight on the stability of II, 0.005% in chloroform. Key: ○, samples analyzed immediately upon sampling of the reaction mixture; and ●, samples taken at the same time but analyzed after 24 hr (these samples were protected from light during this period).*

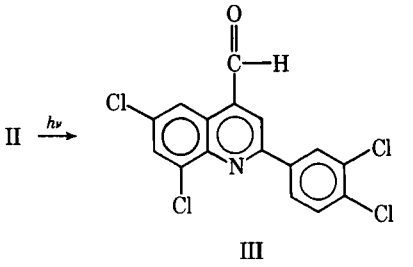


III

Scheme I

A minor degradation product (as yet unidentified), mp 214–215.5°, was also isolated and is currently under investigation. By TLC, the reaction products did not appear to be solvent dependent. Isolation of the major degradation product from chloroform and methanol was accomplished. The characteristically yellow product, III (Scheme I), appeared to be the major degradation product in each case.

Davidson and Orton (2) recently showed that the fragmentation of 2-aminoethanols occurs in the presence of UV irradiation and suitable sensitizer molecules. Their results suggest that the mechanism illustrated in Scheme II may be involved in the fragmentation of 2-aminoethanols, where Y* is a sensitizer molecule such as anthraquinone, perylene, 2,3-diphenylquinoxaline, or acenaphtho[1,2-*b*]quinoxaline.

In the present study, it was initially felt that this sensitizer may have been the photoinduced free radicals in chloroform such as $Cl_3C\cdot$. Because the reactions proceeded just as fast if not faster in methanol and methanol–ethanol, it was felt that II, being a heterocyclic polychlorinated molecule, may be quite capable of acting as a sensitizer, catalyzing its own degradation *via* an autosensitizing photolytic decomposition.

The results of the present study concerning the decomposition of II to III in various organic solvents in the presence of UV irradiation appear consistent with the results of Davidson and Orton (2).

Because of the possible photoinduced fragmentation of other 2-amino alcohol antimalarial agents by UV irradiation to reactive aldehydes, a study of the susceptibility of these agents to photolysis and a correlation to their photosensitization properties might be desirable.

EXPERIMENTAL

Kinetic Studies—Solutions of II at various concentrations in a number of oxygenated and deoxygenated organic solvents were prepared. Methanol, methanol–ethanol, ethanol, chloroform, and chloroform–heptane were the various solvents[3] studied. Concentrations of II in the various solvents from 0.001 to 0.005% were studied. These solutions were exposed to sunlight, exposed to laboratory fluorescent lighting, protected from light by wrapping containers in aluminum foil, or photolyzed in a photochemical reactor[4] at 2537 or 3000 Å.

The degradation of II in the presence and absence of UV irradiation at ambient room temperature was followed by withdrawal of 5-μl samples from the quartz sample tubes at various predetermined times. Analysis of II was accomplished by HPLC[5]. The eluting solvent of choice was determined to be degassed and dried heptane–dioxane–methanol (80:20:5). An external standard of II dissolved in 20% chloroform–heptane protected from light was used. That this solution remained undegraded was confirmed by TLC. After isolation of one minor and one major degradation product, subsequent injections of these products on the HPLC column showed that neither interfered with the assay of II under the conditions described.

TLC using silica gel plates[6] with an eluting solvent of acetic

[3] All solvents were reagent grade quality from various sources.

[4] Rayonet Reactor, Southern New England Ultraviolet Co., Middletown, Conn. Two RPR 2537 Å lamps were used for the 2537-Å study, and two RPR 3000-Å lamps were used for the 3000-Å study. Ten-centimeter long quartz sample tubes, 1 cm in diameter, containing 5 or 15 ml of reaction solution provided the reaction vessel.

[5] Varian model 4000 liquid chromatograph equipped with a 280-nm detector and a Corasil II column (Waters Associates).

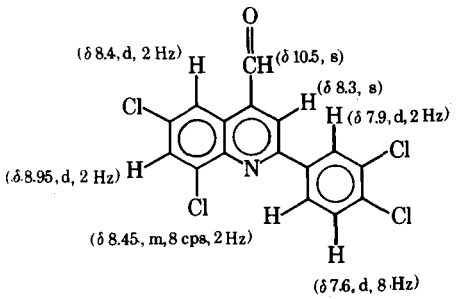
[6] Baker-Flex prepared silica gel plates.

acid–methanol–water (3:40:5) separated II satisfactorily from its apparent degradation products.

Preparation, Isolation, and Identification of Major Degradation Product—Eighty-seven milligrams of II dissolved in 50 ml of chloroform (or methanol) was exposed to direct UV irradiation in a photochemical reactor at 2537 Å for 2.5 hr. The photolyzed sample was evaporated to dryness, reconstituted in a minimum amount of chloroform, and added to a packed column[7]. The eluting solvent was chloroform. Fractionation resulted in the isolation of a small amount of unreacted II and approximately 50 mg of a yellow crystalline material, III, mp 195.5–197° (II, mp 129.5–130°; I, mp 215–218°).

Compound III was recrystallized from methanol or ethanol, either of which formed solvates with III, and dried overnight in a vacuum oven. TLC of III, using the previously described systems, showed a single spot with an R_f value of 0.70 (II, R_f 0.91), confirming it to be the major degradation material.

The IR spectrum[8] (KBr dispersion) of III gave a characteristic >C=O stretch at 1700 cm^{-1} and a C—H aldehyde stretch at 2860 cm^{-1}. NMR[9] of III, dissolved in $CDCl_3$ with tetramethylsilane as an internal standard, gave a spectrum consistent with the postulated aldehyde, III. The following assignments were tentatively made:



In the parentheses the first numbers refer to chemical shifts, in parts per million, from an internal standard of tetramethylsilane; s = singlet, d = doublet, and m = multiplet (also partially buried); and the last numbers are approximate spin-coupling constants. Integration was consistent with this structure when the single aldehydic proton was used as an internal standard.

If the molecular weight for the chlorine atom is assumed to be 35, the molecular weight of III is 369. A mass spectrum[10] of III showed a peak at 368 (P − 1), corresponding to $R—C{\equiv}O^+$, and a smaller P peak. The P + 1, P + 3, P + 5, and P + 7 peaks at 370, 372, 374, and 376 (as well as smaller P, P + 2, P + 4, P + 6, and P + 8 peaks), respectively, of magnitude relative to the P − 1 peak, 1.28:0.66:0.125:~0.01, confirm the presence of the four chlorine atoms in III. These relative peaks sizes are very close to the expected ratio of 1.31:0.64:0.14:0.01 (3). A peak corresponding to 369 − R′, where R′ = mass of —CHO at 340, is also consistent with the postulated structure of III.

Elemental analysis of III gave: C, 51.97; H, 2.08; N, 3.57. Calculated values for III, assuming the postulated structure, were: C, 51.75; H, 1.89; N, 3.77.

CONCLUSION

The degradation of the 2-aminoethanol (II), the free base form of I, in various organic solvents was found to be photoinduced, with the major degradation product being III. Compound II can be successfully extracted from blood or stored as standard solutions in various organic solvents as long as direct sunlight and long-term exposure to fluorescent lighting are excluded.

GLC Determination of Plasma Drug Levels after Oral Administration of Clorazepate Potassium Salts

D. J. HOFFMAN and A. H. C. CHUN ˣ

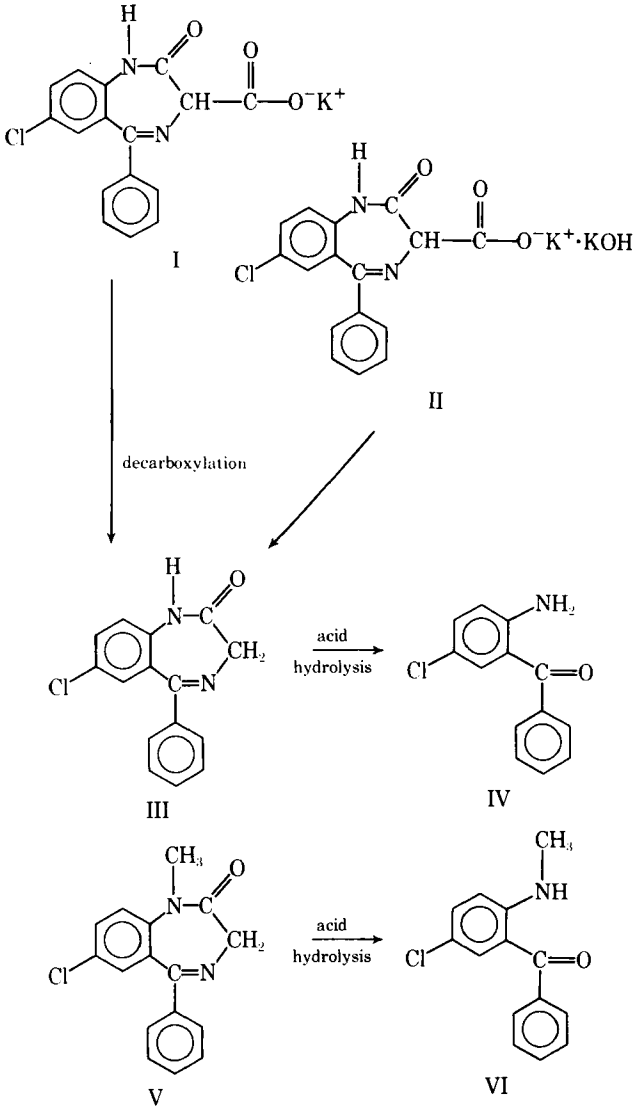
Abstract □ Plasma nordiazepam levels resulting from the oral administration of clorazepate potassium salts were determined by a sensitive GLC assay. Nordiazepam and the internal standard (diazepam) were selectively extracted into ether at pH 9.2, hydrolyzed to their respective benzophenones, and quantified by electron-capture detection. The assay was used in a comparative bioavailability study of single equimolar oral doses of monopotassium and dipotassium salts of clorazepate in dogs. Both clorazepate salts were rapidly absorbed and exhibited mean peak total drug levels after 1 hr. Clorazepate levels accounted for about 50% of the total drug levels present. No statistical difference in the plasma drug levels of clorazepate mono- and dipotassium salts and the metabolite was found in dogs.

Keyphrases □ Clorazepate monopotassium and dipotassium salts—determination of plasma levels after oral administration, dogs, GLC analysis of nordiazepam metabolite □ Nordiazepam—GLC analysis in plasma as clorazepate metabolite, dogs □ GLC—analysis, nordiazepam as clorazepate metabolite after oral administration, determination of clorazepate plasma levels

Clorazepate potassium salts (I and II) are new 1,4-benzodiazepine antianxiety agents (1–4). These salts are highly water soluble and rapidly decarboxylate (Scheme I) to nordiazepam (III) at a low pH. Decarboxylation also occurs at physiological pH but at a much slower rate[1].

This paper describes an assay procedure for nordiazepam (III) in plasma. The procedure is a modification of the GLC method of de Silva *et al.* (5), which converts III to 2-amino-5-chlorobenzophenone (IV) with subsequent quantification by GLC using electron-capture detection (Scheme I). Diazepam (V), which is converted by hydrolysis to 2-methylamino-5-chlorobenzophenone (VI), is used as the internal standard.

Plasma clorazepate levels were calculated from the difference between the total measured nordiazepam levels, by converting the residual parent drug (clorazepate) to nordiazepam, and the nordiazepam levels measured after immediate extraction. The method was applied to the determination of the bioequivalence of a single equimolar oral dose of clorazepate mono- and dipotassium salts in dogs.



Scheme I

EXPERIMENTAL

Drug Administration to Dogs—Twelve female beagle dogs of approximately equal weights were used in this crossover study to determine the bioequivalency of these two compounds after oral administration. Six dogs were randomly assigned 6.5-mg doses of the monopotassium salt or 7.5-mg doses of the dipotassium salt during the first period of the study. The administration of formulations to the dogs was reversed during the second period 1 week later. These doses were equivalent on a molar basis to 5.8 mg of the free acid. The capsule formulations were administered to the dogs in the morning after an overnight fast, and 30 ml of water then was given to each dog.

Blood samples were taken in 5-ml heparinized vacuum tubes before dosing and at 0.5, 1, 1.5, 2, 3, 4, 6, 8, 12, and 24 hr after dosing. Samples (3 ml) were cooled and centrifuged within 3 min after collection. One-half milliliter of the 0.5-, 1-, 1.5-, 2-, 3-, and 4-hr plasma samples was placed into tubes containing buffer and ether, and these samples were immediately extracted after collection to minimize conversion of clorazepate to nordiazepam (Scheme I). The remaining portion of the plasma samples was frozen until they were assayed.

Instrumental Conditions—Analysis was performed with a gas chromatograph[2] equipped with a ^{63}Ni electron-capture detector, containing a 2 mCi ^{63}Ni β-ionization source, and an electronic inte-

grator[3]. Argon–methane[4] (95:5) was used as the carrier gas, and the column head pressure was preset at 40 psig. A 1.56-m (6-ft), 2-mm i.d. borosilicate helical glass column was packed with 3% Poly A-103 on Gas Chrom Q[5] and conditioned for 15 hr at 270° with the carrier gas flowing at 25 ml/min. Column life was 2–3 months when the carrier gas was passed through an oxygen trap[6].

The temperature settings were as follows: oven, 250°; injection port, 265°; and detector, 325°. The electrometer[7] range was set at 10^3, the output attenuation of the integrator was set at 2, and the recorder[8] chart speed was 0.6 cm (0.25 in.)/min. The pulse interval for the electron-capture detector was 150 μsec. Under these conditions, IV (hydrolysis product of III) and VI (5) (hydrolysis product of V; internal standard) had retention times of 5.0 and 3.9 min, respectively. By using the following procedure, the minimum measurable amount of III is 0.01 μg/ml of plasma.

Assay Procedure—*Preparation of Plasma Standards*—Prepare a nordiazepam primary standard of 100 μg/ml in ethanol. Use

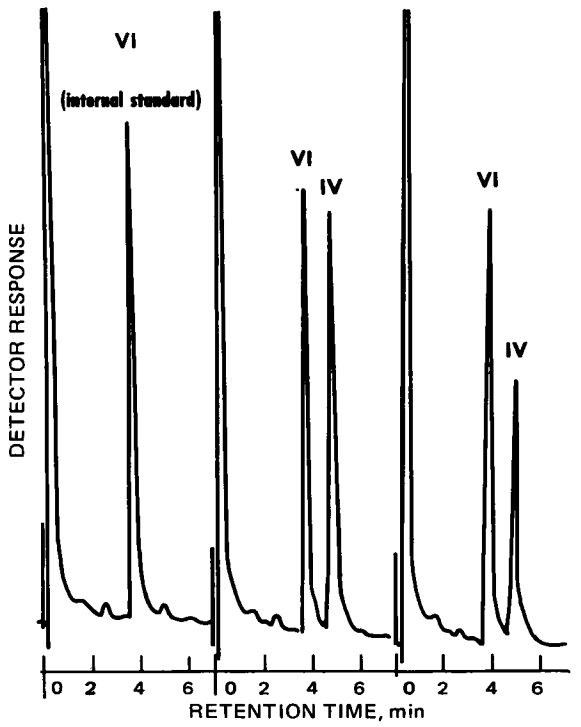

Figure 1—*Gas–liquid chromatograms (electron-capture detector) of plasma extracts: left, normal plasma specimen with internal standard; middle, plasma specimen after a single oral dose of a clorazepate salt; and right, plasma standard containing 0.15 μg/ml of nordiazepam.*

1.0 ml of the ethanolic standard to prepare 100 ml of plasma standard at a concentration of 1.00 μg/ml. Further dilute the plasma to 0.50, 0.25, and 0.125 μg/ml with plasma.

Determination of Nordiazepam—Immediately centrifuge (within 3 min) freshly collected heparinized blood in a refrigerated centrifuge set at 2°. Transfer 0.5 ml of plasma to a 20-ml screw-capped test tube containing 5 ml of cold (5°) 0.1 *M* K_2HPO_4 buffer (pH 9.2) containing 0.10 μg of diazepam/ml (freshly prepared). Add ether[9] (7 ml) immediately, shake the tube on a reciprocal shaker at 250 cpm for 10 min, and then separate by centrifugation for 10 min at 2000 rpm. Transfer 5 ml of ether to a 20-ml screw-capped tube containing 5 ml of 6 *N* HCl. After shaking and centrifuging as already described, discard the ether layer by aspiration. Also aspirate off a small amount of the acid layer to assure complete removal of ether.

Place the samples in a water bath and heat to boiling with occasional shaking of the samples. Cap the tubes tightly and leave them in the boiling water bath for 1 hr to convert completely III to IV and V to VI. After cooling samples in an ice bath, add 5.5 ml of

[a] No significant differences were found at the 0.05 level.

6 *N* NaOH and 6 ml of ether[9]. Shake and centrifuge the samples as previously described.

Transfer 5 ml of the ether phase to a 15-ml conical screw-capped tube and evaporate to dryness at 50° with a stream of air. Dissolve the residue in 1.0 ml of benzene and inject 2 μl into the GLC. This procedure results in GLC tracings essentially free of coextracted impurities (Fig. 1).

Determination of Clorazepate—Plasma clorazepate concentrations[10] were determined by subtracting immediately extracted nordiazepam levels from the total drug levels obtained after hydrolysis and multiplying the difference by 1.16 to correct for the molecular weight difference.

Plasma nordiazepam concentrations were determined after immediate extraction under conditions that minimized *in vitro* conversion of clorazepate to nordiazepam. Another aliquot of the plasma sample was incubated at 40° overnight and extracted as previously described to determine the total drug concentration (nordiazepam and clorazepate). Incubation converts essentially all (>99%) of the clorazepate to nordiazepam[11].

Calculations—The peak area ratios of IV to VI are plotted against known standards of nordiazepam, expressed as micrograms per milliliter of plasma. Values for unknown concentrations of nordiazepam in plasma are read directly from the calibration curve (Fig. 2).

RESULTS AND DISCUSSION

Assay Reproducibility, Sensitivity, and Specificity—The analysis of eight plasma samples at 0.15 μg/ml gave a coefficient of variation of 4.31% (Table I). Comparable reproducibility was found with samples at other concentrations. Under the described assay conditions, the lower limit of the quantitative detection of nordiazepam in plasma is 0.01 μg/ml. This value is based on a sample signal equivalent to about 2% of full-scale response. A linear relationship between peak area ratios and concentration was obtained over the 0.01–0.80-μg/ml range. Quantification from a calibration curve was used (Fig. 2).

The method is not specific for nordiazepam. If significant levels of other 1,4-benzodiazepines, such as oxazepam, are present, they also are hydrolyzed to IV (6). Oxazepam, a metabolite of nordiazepam, is found almost exclusively in urine (7, 8) with small but insignificant amounts in plasma (9).

Serum or plasma samples for human subjects receiving clorazepate salts do not require incubation since little, if any, clorazepate is present[12].

Plasma Nordiazepam Levels in Dogs—Mean (±*SD*) nordiazepam peak levels of 0.29 ± 0.15 and 0.31 ± 0.13 μg/ml occurred 1 hr after oral administration of equimolar doses of the monopotassium and dipotassium salts, respectively. These levels declined to about 0.07 μg/ml at 4 hr (Table II). There were no significant differences by crossover analysis of variance ($p < 0.05$) in the nordiazepam levels at all sampling times and in the 0–4-hr area under the plasma level curve between the two compounds.

Plasma Clorazepate Levels—Plasma clorazepate levels were calculated based on the difference between total nordiazepam levels (parent drug plus metabolite) and nordiazepam levels (Table III). About one-half of the total nordiazepam level was present as clorazepate, although large variations (10–90% clorazepate) existed between dogs. However, no significant differences in clorazepate levels were obtained with both salts (Table IV).

Total Drug[13] Plasma Levels—Total plasma drug levels expressed as nordiazepam were determined after converting plasma clorazepate to nordiazepam and measuring the combined concentrations as nordiazepam. The mean total nordiazepam levels are given in Table IV. Both clorazepate salts were rapidly absorbed, with mean (±*SD*) peak total plasma nordiazepam levels of 0.51 ± 0.24 μg/ml for the monopotassium salt and 0.61 ± 0.24 μg/ml for the dipotassium salt (Fig. 3). Total levels declined to about 0.01 μg/ml at 12 hr and were undetectable after 24 hr.

There were no significant differences ($p < 0.05$) in plasma levels between the two clorazepate salts at all sampling times. Also, no significant differences were found between the areas under the plasma level curve for various time intervals (Table III). The total levels of combined parent drug and metabolite levels are more representative than either species alone in the assessment of bioavailability of these two potassium salts of clorazepate.

[10] Clorazepate concentrations are based on the free ionized form since both potassium salts would exist as such at a physiological pH.

[11] Clorazepate has an *in vitro* half-life of 70 min in dog plasma at 38°. This value was determined by the rate of formation of ether-soluble radioactivity from ^{14}C-clorazepate.

[12] A. H. Chun, Abbott Laboratories, North Chicago, IL 60064, 1974, unpublished data.

[13] "Total drug levels" is the term used for the combined levels of parent drug and metabolite measured as nordiazepam.

Hansch Analysis of Interaction of Haptens with Benzylpenicilloyl Antibodies

A. E. BIRD

Abstract □ Hansch analysis is applied to inhibition data obtained from the interaction of penicilloic and penilloic acid haptens with benzylpenicilloyl specific antibodies. Significant regressions with partition coefficient and molar volume parameters indicate the importance of hydrophobic and steric effects in these interactions.

Keyphrases □ Benzylpenicilloyl antibodies—interaction with penicilloic and penilloic acid haptens, Hansch analysis of inhibition data, hydrophobic and steric effects □ Penicilloic and penilloic acid haptens—interaction with benzylpenicilloyl specific antibodies, Hansch analysis of inhibition data □ Hansch analysis—interaction of haptens with benzylpenicilloyl antibodies □ Structure–activity relationships—interaction of penicilloic and penilloic acid haptens with benzylpenicilloyl specific antibodies

Munro *et al.*[1] studied the cross-reaction with benzylpenicilloyl specific antibodies of the penicilloic (I) and penilloic (II) acids obtained from several penicillins (III). They determined the extent of this interaction by measuring the inhibition by the haptens of agglutination of sensitized erythrocytes caused by the antibodies.

[1] A. C. Munro, M. G. Chainey, and S. R. Woroniecki, to be published.

In this paper the data so obtained are subjected to Hansch quantitative structure–activity analysis to evaluate the role of various physicochemical properties of the haptens in their interaction with the antibodies. Published applications of Hansch analysis to hapten antibody interactions appear to be confined to a single paper in which Kutter and Hansch (1) showed the importance of steric factors in such interactions.

EXPERIMENTAL

The term C in log $1/C$ in Table I is the molar concentration of hapten required to give 50% inhibition of hemagglutination by benzylpenicilloyl specific antibodies.

Hydrophobic effects are modeled by log P, where P is the octanol–water partition coefficient of the parent penicillins in their unionized form. Values of P are not available for the penilloic or penicilloic acids, but the variation of P with changes in the side chain is expected to be the same for these compounds as for the parent penicillins. Log P for penicillin G (benzylpenicillin), cloxacillin, methicillin, phenethicillin, penicillin V (phenoxymethyl penicillin), and propicillin are measured values from Bird and Marshall (2). The log P values for ampicillin and carbenicillin are calculated from those for penicillin G with the appropriate hydrophobic frag-

Abstract □ Hansch analysis is applied to inhibition data obtained from the interaction of penicilloic and penilloic acid haptens with benzylpenicilloyl specific antibodies. Significant regressions with partition coefficient and molar volume parameters indicate the importance of hydrophobic and steric effects in these interactions.

Keyphrases □ Benzylpenicilloyl antibodies—interaction with penicilloic and penilloic acid haptens, Hansch analysis of inhibition data, hydrophobic and steric effects □ Penicilloic and penilloic acid haptens—interaction with benzylpenicilloyl specific antibodies, Hansch analysis of inhibition data □ Hansch analysis—interaction of haptens with benzylpenicilloyl antibodies □ Structure–activity relationships—interaction of penicilloic and penilloic acid haptens with benzylpenicilloyl specific antibodies

Munro *et al.*[1] studied the cross-reaction with benzylpenicilloyl specific antibodies of the penicilloic (I) and penilloic (II) acids obtained from several penicillins (III). They determined the extent of this interaction by measuring the inhibition by the haptens of agglutination of sensitized erythrocytes caused by the antibodies.

[1] A. C. Munro, M. G. Chainey, and S. R. Woroniecki, to be published.

In this paper the data so obtained are subjected to Hansch quantitative structure–activity analysis to evaluate the role of various physicochemical properties of the haptens in their interaction with the antibodies. Published applications of Hansch analysis to hapten antibody interactions appear to be confined to a single paper in which Kutter and Hansch (1) showed the importance of steric factors in such interactions.

EXPERIMENTAL

The term C in log $1/C$ in Table I is the molar concentration of hapten required to give 50% inhibition of hemagglutination by benzylpenicilloyl specific antibodies.

Hydrophobic effects are modeled by log P, where P is the octanol–water partition coefficient of the parent penicillins in their unionized form. Values of P are not available for the penilloic or penicilloic acids, but the variation of P with changes in the side chain is expected to be the same for these compounds as for the parent penicillins. Log P for penicillin G (benzylpenicillin), cloxacillin, methicillin, phenethicillin, penicillin V (phenoxymethyl penicillin), and propicillin are measured values from Bird and Marshall (2). The log P values for ampicillin and carbenicillin are calculated from those for penicillin G with the appropriate hydrophobic frag-

Table I—Inhibition Data and Physicochemical Parameters for Inhibition of Erythrocyte Agglutination by Penilloic and Penicilloic Acids

Ticarcillin		0.94	136.5	5.0	3.11	3.63	−0.52	2.63	2.96	−0.33

[a] See text for sources of these constants. [b] From A. C. Munro, M. G. Chainey, and S. R. Woroniecki, to be published. [c] Calculated from Eq. 2. [d] Calculated from Eq. 4.

mental constants and proximity effect (3). For example:

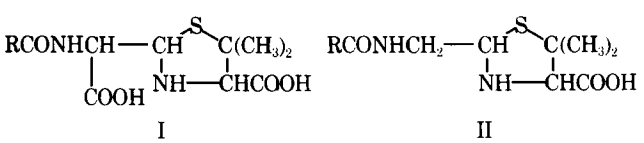
$$\log P(\text{ampicillin}) = \log P(\text{penicillin G}) - f(CH_2) + f(NH_2) + f(CH) + \text{p.e.} \quad \text{(Eq. 1}a\text{)}$$

$$\log P(\text{ampicillin}) = 1.76 - 0.52 + (-1.38) + 0.24 + 0.8 = 0.9 \quad \text{(Eq. 1}b\text{)}$$

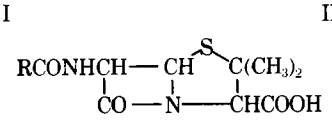
The proximity effect (p.e.) is used because the amino or carboxy group is separated by one carbon from the side-chain amide function. Log P for amoxicillin was calculated as for ampicillin plus a Hansch π term for the hydroxy group [−0.50, from substituted phenylacetic acids (4)]. Log P for floxacillin was calculated from that for cloxacillin plus a π term for the fluoro group (0.14, from substituted nitrobenzenes[2]). Log P for ticarcillin was calculated as for carbenicillin minus 0.32, which is the difference in log P between benzene and thiophene (5).

The molar volume of the side chain was used as a parameter, giving a measure of variations in size of the haptens. These values were calculated from the atomic volumes of Le Bas given by Partington (6). Where a range of values was given (*e.g.*, ring sulfur 21.6–22.5), the average was used. An average nitrogen value of 12.9 was used for the nitrogen of the isoxazole ring. The fluorine value used for floxacillin was from Exner (7) because there is no value in Le Bas' list. Exner's values for chlorine and bromine are very similar to those of Le Bas, so the fluorine value should be consistent.

The pKa values of the side-chain acids (R—COOH) were used as a measure of the variation in electronic effects with a change of side chain. The values for phenylacetic, phenoxyacetic, and phenylmalonic acids are from the literature (8). Phenylmalonic acid has pKa values of 2.6 and 5.0. The relevant value for carbenicillin was taken as that at which one carboxy group is ionized, *i.e.*, 5.0, because the side-chain carboxy of carbenicillin is ionized at the pH of the inhibition experiments. The pKa values for the side chains of amoxicillin, ampicillin, methicillin, phenethicillin, and cloxacillin are approximate values measured in these laboratories. The values for the side-chain acids of floxacillin, propicillin, and ticarcillin



I II



III

were assumed to be the same as those for cloxacillin, phenethicillin, and carbenicillin, respectively.

Regression equations were obtained in the usual way by computer calculation using the method of least squares. Initially the penicilloic and penilloic acids were treated separately, but a final equation was calculated for all data.

RESULTS AND DISCUSSION

Penicilloic Acids—Linear regressions with log P, pKa, and molar volume (MV) had correlation coefficients (r) of 0.458, 0.189, and 0.371, respectively, and the t test showed that they were not statistically significant at the 90% level. Two-parameter equations in log P and pKa and in pKa and MV were also not significant, with correlation coefficients of 0.469 and 0.441, respectively; log P and MV gave:

$$\log(1/C) = \underset{(\pm 0.425)}{0.977 \log P} - \underset{(\pm 0.011)}{0.024\ \mathrm{MV}} + 5.961 \quad \begin{matrix} n & r & s \\ 11 & 0.899 & 0.350 \end{matrix} \quad \text{(Eq. 2)}$$

where n is the number of data points, s is the standard deviation from the regression, and the figures in parentheses are the 95% confidence limits on the regression coefficients. The t test shows that both terms in Eq. 2 are significant at the 99.5% level.

Addition of a pKa term to Eq. 2 gave:

$$\log(1/C) = \underset{(\pm 0.456)}{0.956 \log P} + \underset{(\pm 0.263)}{0.079\ \mathrm{pKa}} - \underset{(\pm 0.012)}{0.024\ \mathrm{MV}} + 5.725 \quad \begin{matrix} n & r & s \\ 11 & 0.906 & 0.362 \end{matrix} \quad \text{(Eq. 3)}$$

This equation has a higher standard deviation than Eq. 2, and the pKa term is not statistically significant.

Penilloic Acids—Linear regressions were not statistically significant, with correlation coefficients of 0.080, 0.001, and 0.658 for log P, pKa, and MV, respectively. Two-parameter equations in log P and pKa and in pKa and MV were also not significant, with correlation coefficients of 0.115 and 0.675, respectively; log P and MV gave:

$$\log(1/C) = \underset{(\pm 0.562)}{0.506 \log P} - \underset{(\pm 0.011)}{0.017\ \mathrm{MV}} + 4.757 \quad \begin{matrix} n & r & s \\ 9 & 0.828 & 0.333 \end{matrix} \quad \text{(Eq. 4)}$$

The t test shows that log P is significant at 90% and MV at 98%. Addition of a pKa term to Eq. 4 gave:

$$\log(1/C) = \underset{(\pm 0.785)}{0.837 \log P} + \underset{(\pm 0.575)}{0.334\ \mathrm{pKa}} - \underset{(\pm 0.011)}{0.018\ \mathrm{MV}} + 3.101 \quad \begin{matrix} n & r & s \\ 9 & 0.884 & 0.304 \end{matrix} \quad \text{(Eq. 5)}$$

Although this equation has a slightly lower s value than Eq. 4, the pKa term is not statistically justified (t found 1.488; t 90%, 5 df 2.015).

Penicilloic and Penilloic Acids—A regression for the combined data was calculated with log P, MV, and a dummy parameter assigned a value of zero for the penicilloic and of 1 for the penilloic acids; this parameter was introduced to allow for the inherent difference in activity of the two sets of acids:

$$\log(1/C) = \underset{(\pm 0.316)}{0.801 \log P} - \underset{(\pm 0.341)}{0.930\ (0/1)} - \underset{(\pm 0.007)}{0.021\ \mathrm{MV}} + 5.780 \quad \begin{matrix} n & r & s \\ 20 & 0.903 & 0.353 \end{matrix} \quad \text{(Eq. 6)}$$

The t test shows that all three terms are significant at the 99.9% level.

Intuitively, one would not expect $(\log P)^2$ to be a significant factor in describing this type of biological activity, because the inhibition apparently depends on a single-step binding of hapten to antibody. Therefore, multiple interactions in a "random walk" to the active site, which can produce (9) parabolic dependence of activity on the partition coefficient, do not occur. However, $(\log P)^2$ terms were tried in some regressions. For penilloic acids, the two-parameter equation in log P and $(\log P)^2$ had both terms significant at the 95% level, but the r and s values of 0.751 and 0.393, respectively, were poor. In other cases, particularly when $(\log P)^2$ was added to the log P and MV regressions, $(\log P)^2$ terms were not significant.

Hansch (10) pointed out that partition coefficient and molar volume are not independent variables for simple substituents. The collinearity of these variables for the 11 compounds studied here was 33% ($r^2 = 0.33$). This value shows that although the variables are not completely independent, they are not very highly correlated and their use in the same equation to model different aspects of the binding process seems to be justifiable (11).

Thus, Eqs. 2, 4, and 6 are the best regressions obtained. Although they are statistically significant, the standard deviations of these regressions are quite high, due in part perhaps to experimental error in the inhibition data. A twofold dilution method was used to obtain these data, so the experimental error may be quite large and the regressions may be as good as can be expected with data of this accuracy. It is also possible that the effect of the large variations in the side chain of the compounds studied cannot be fully explained by the simple models used. For example, Kutter and Hansch (1) showed that separate parameters are required in regression equations for *ortho*-, *meta*-, and *para*-substituents in benzoic and arsonic acid haptens. This indicated a fine degree of dependence of the interaction with antibodies on the steric properties of the haptens. It is not possible to analyze the present data in such detail. However, some useful conclusions can be drawn from the regression analysis.

The nonsignificance of pKa indicates that electronic effects induced by variation of the side chain can play only a minor part in the binding of hapten to antibody.

The positive and negative coefficients for log P and MV, respectively, show that inhibitory activity increases with an increase in log P and a decrease in MV. This finding is consistent with an increase in hydrophobic binding of hapten to antibody as log P increases and with a decrease in binding due to steric or bulk effects as MV increases. Corresponding regression coefficients in Eqs. 2 and 4 are not significantly different (the 95% confidence limits overlap), indicating that the dependence of activity on log P and MV is similar for penilloic and penicilloic acids, although the data are not sufficiently precise to be certain of this dependence. However, the good fit of all data obtained with Eq. 6 encourages the view that the interaction of both sets of haptens with antibody depends in the same way on log P and MV.

The cause of the near 10-fold difference in the inhibitory activity of corresponding penilloic and penicilloic acids is of interest. The log P and MV values for the penicilloic acid whole molecule (not just the side chain) are less and greater, respectively, than the values for the corresponding penilloic acid. Since inhibitory activity is promoted by an increase in log P and a decrease in MV, penilloic acid would be expected to be more active than the corresponding penicilloic acid if these were the only factors involved in the interaction of the haptens and antibody. Thus, it is clear that some overriding factor (presumably binding *via* the C_6 carboxy group) promotes the activity of penicilloic acids relative to that of penilloic acids.

Examination of the differences between observed and calculated values of log $(1/C)$ in Table I shows particularly high differences for carbenicillin and ticarcillin in the penicilloic acid series and for carbenicillin in the penilloic acid series. The estimated log P values for these compounds may be open to question. However, a systematic error in log P or MV cannot explain the high differences because it would affect both compounds in the same way and the sign of the difference is positive for carbenicillin and negative for ticarcillin. The high differences for these compounds and for benzylpenilloic acid may be due to random errors in the data.

The fragmental constant of the carboxy group used to calculate log P for carbenicillin and ticarcillin relates to an unionized carboxy group (3), so that log P relates to the unionized penicillin. At the pH of the inhibition experiments (7.2), the side-chain carboxy group will be ionized, so log P for the molecule with this group ionized might be more appropriate. Hansch (12) gave a difference in π value between neutral and ionized carboxy groups of 4.1, which gives log P values of −2.84 and −3.16 for carbenicillin and ticarcillin, respectively, with the carboxy group ionized.

Use of these values in log P and MV regressions gave nonsignificant log P terms. Omission of carbenicillin and ticarcillin from the regressions had only slight effects on the regression coefficients and the r and s values given in Eqs. 2 and 4. Thus, it is clear that the activity of the carboxy compounds fits with that of the other

penicillin derivatives when log P for the unionized form is used rather than log P of the apparently more appropriate ionized form. Similar behavior was found in relating log P to the extent of binding of carbenicillin and ticarcillin to serum proteins[2]. Possibly this effect is coincidental due to ionic binding by the side-chain carboxy group to an extent approximately sufficient to offset the low hydrophobic binding due to the ionic nature of this group.

Nishida *et al.* (13) reported binding constants (k_{rel}) relative to benzylpenicilloic acid for binding to benzylpenicilloyl specific antibodies of some penicilloic acids not studied in this work. Included were the penicilloic acids of *o*-, *m*-, and *p*-chloro- and *o*-, *m*-, and *p*-nitrobenzylpenicillins and of methyl- and ethylpenicillins. Equation 2 was used to calculate values of log (1/C) (and of k_{rel} using the experimental C value for benzylpenicilloic acid) for these compounds. This equation cannot distinguish the effect of varying the substituent position in the benzene ring, but values were calculated for chloro- and nitrobenzylpenicilloic acids using the appropriate MV values (131.1 and 143.7, respectively) and log P values (2.47 and 1.48, respectively) calculated from those of penicillin G with Hansch π values of 0.71 and −0.28 for chloro and nitro, respectively (14). The k_{rel} values obtained were 1.02 and 0.06 for the chloro and nitro compounds, respectively. These values are reasonably close to the experimental values of 1.36–5.17 for the three chloro compounds and 0.115–0.33 for the three nitro compounds, especially when it is recalled that Nishida *et al.* (13) used a fivefold dilution technique for their determinations so their results may not be very precise.

The log P value for methylpenicillin was calculated in two ways: (*a*) from log P penicillin G minus π phenyl, 1.76 − 1.89 = −0.13; and (*b*) from log P heptylpenicillin (15) minus 6 π methylene, 3.32 − 3.0 = 0.32. The mean value of 0.22 is used, and log P of ethylpenicillin then becomes 0.72 by addition of π methylene. Substitution of these values with MV values of 25.9 and 48.1 in Eq. 2 leads to k_{rel} values of 2.16 and 1.96 for methyl- and ethylpenicilloic acids, respectively.

These values are very different from Nishida *et al.*'s experimental values of 0.009 and 0.016. Thus, penicilloic acids with such small side chains are outside the range of applicability of Eq. 2. Intuitively, it seems probable that Eq. 2 will be applicable only to a limited range of penicilloic acids, presumably with log P and MV values centered about those of benzylpenicilloic acid because the antibodies were raised to a benzylpenicilloyl antigen. Experiments with antibodies raised to other penicilloyl antigens would be interesting in this context.

Cytotoxic Principles of *Parquetina nigrescens* (Afzel.) Bullock (Asclepiadaceae)

W. H. MARKS, H. H. S. FONG ˣ, M. TIN-WA, and N. R. FARNSWORTH

Abstract □ Systematic fractionation of the cytotoxic extracts of the roots of *Parquetina nigrescens* (Afzel.) Bullock (Asclepiadaceae) on silica gel column chromatography led to the isolation of three cardenolides: cymarin, strophanthidin, and a strophanthidin glycoside (XS-89). Also isolated during the investigation were β-sitosterol-β-D-glucoside, a mixture of α- and β-amyrins, a mixture of alkanols, and a mixture of plant sterols.

Keyphrases □ *Parquetina nigrescens* (Afzel.) Bullock (Asclepiadaceae)—isolation and identification of cytotoxic principles □ Cytotoxicity—isolation and identification of cymarin, strophanthidin, and strophanthidin glycoside from *Parquetina nigrescens* □ Cardenolides—isolation and identification from *Parquetina nigrescens*

Parquetina nigrescens (Asclepiadaceae), a woody shrub native to Africa, is sometimes referred to as *Periploca nigrescens* (1). Previous studies (2–5) showed it to contain cardiac glycosides of the strophanthidin type. Strophanthidiol-β-glucoside acetates, strophanthidin, strophanthidiol, 16-hydrostrophanthidin, convallatoxin, 17α-strophanthidin, 16-acetoxystrophanthidin, 16-acetoxystrophanthidin rhamnoside, 16-dehydrostrophanthidin, 16-dehydrostrophanthidol, nigrescigenin, tetra-*O*-acetylstrophanthidin-β-D-glucoside, and several incompletely identified cardenolides have been isolated from this plant.

Other species of the genus have also been investi-

penicillin derivatives when log P for the unionized form is used rather than log P of the apparently more appropriate ionized form. Similar behavior was found in relating log P to the extent of binding of carbenicillin and ticarcillin to serum proteins[2]. Possibly this effect is coincidental due to ionic binding by the side-chain carboxy group to an extent approximately sufficient to offset the low hydrophobic binding due to the ionic nature of this group.

Abstract □ Systematic fractionation of the cytotoxic extracts of the roots of *Parquetina nigrescens* (Afzel.) Bullock (Asclepiadaceae) on silica gel column chromatography led to the isolation of three cardenolides: cymarin, strophanthidin, and a strophanthidin glycoside (XS-89). Also isolated during the investigation were β-sitosterol-β-D-glucoside, a mixture of α- and β-amyrins, a mixture of alkanols, and a mixture of plant sterols.

Keyphrases □ *Parquetina nigrescens* (Afzel.) Bullock (Asclepiadaceae)—isolation and identification of cytotoxic principles □ Cytotoxicity—isolation and identification of cymarin, strophanthidin, and strophanthidin glycoside from *Parquetina nigrescens* □ Cardenolides—isolation and identification from *Parquetina nigrescens*

Parquetina nigrescens (Asclepiadaceae), a woody shrub native to Africa, is sometimes referred to as *Periploca nigrescens* (1). Previous studies (2–5) showed it to contain cardiac glycosides of the strophanthidin type. Strophanthidiol-β-glucoside acetates, strophanthidin, strophanthidiol, 16-hydrostrophanthidin, convallatoxin, 17α-strophanthidin, 16-acetoxystrophanthidin, 16-acetoxystrophanthidin rhamnoside, 16-dehydrostrophanthidin, 16-dehydrostrophanthidol, nigrescigenin, tetra-*O*-acetylstrophanthidin-β-D-glucoside, and several incompletely identified cardenolides have been isolated from this plant.

Other species of the genus have also been investi-

gated for the presence of cardenolides (6–8). Periplogenin and cymarose have been isolated from *P. calophylla* (6) and *P. sepium*. Periplogenin and periplocymarin (7) as well as periplocin (8) were found in *P. graeca*.

P. graeca has folkloric uses as a herbal or arrow poison (9), and *P. sepium* has been an ingredient of a cure-all drug in Chinese herbal medicine (2, 10). Pharmacological studies on various species of the genus have centered on their cardiotonic effects (11–13).

DISCUSSION

A 50% alcoholic extract of the roots of *P. nigrescens* was found to be cytotoxic[1] ($ED_{50} < 8.8 \times 10^{-1}$ μg/ml). However, this extract and fractions from subsequent workups of the plant material were inactive when tested in the P-388 leukemia system in mice.

TLC of the alcoholic extract indicated the presence of several cardenolides (positive reactions to the Kedde spray reagent).

Partition of a 95% alcoholic extract between water and chloroform resulted in the isolation and identification of β-sitosterol-β-D-glucoside and cymarin from the chloroform-soluble fraction (C). The isolation of cymarin represents the first reported occurrence of this cardenolide in *P. nigrescens*.

Chromatographic separation of a 50% alcoholic extract of the marc resulted in the isolation of strophanthidin and a novel cardenolide, which was partially characterized as a strophanthidin glycoside.

The petroleum ether solubles (Fraction A) yielded mixtures of alkanols, phytosterols (campesterol, stigmasterol, and β-sitosterol), and triterpenes (α- and β-amyrins).

Biological evaluation of the isolates demonstrated that the cytotoxic activity of this plant was due, at least in part, to the three cardenolides present.

EXPERIMENTAL[2]

Plant Material—The plant material[3] was collected in Ghana during March 1971. The roots were collected, air dried, and ground to a coarse powder.

Extraction and Initial Fractionation—A 4.5-kg sample of the plant material was defatted with petroleum ether (bp 30–60°), and the extractive was concentrated *in vacuo* to yield 119 g of Fraction A. The defatted marc was air dried and then continuously extracted with 95% ethanol to give Fraction B (199 g).

A 100-g portion of Fraction B was taken to a syrupy consistency and partitioned between chloroform and water to give Fractions C (24 g) and D (70 g), respectively.

The 95% ethanol-exhausted marc was air dried and continuously extracted with 50% ethanol to yield Fraction E (64 g).

Separation of Fraction C—Fraction C was subjected to column chromatography on 600 g of silica gel PF-254[4], using benzene–95% ethanol (3:1) as the eluent. Then 120 15-ml fractions were collected, and fractions were combined on the basis of TLC monitoring.

Isolation and Identification of β-Sitosterol Glucoside—Fractions 33–44 were combined, filtered, and taken to dryness. The residue was dissolved in hot dioxane and, upon cooling, yielded a copious white amorphous precipitate. The substance had a melting point of 260–270°, gave a transparent UV spectrum, and showed IR absorptions at 3425 (s, OH), 2980 (s, CH_3 stretch), 2890 (w), 1470 (w), 1380 (w), 1180 (s), and 1025 (s) cm^{-1}.

The mass spectrum was superimposable with that of β-sitosterol, but the sample did not vaporize until 270° *in vacuo*. The latter point, plus the compound's different TLC, IR, and solubility properties as compared to reference β-sitosterol, suggested that the isolate was a glycoside. A comparison of the IR spectrum with that of reference β-sitosterol-β-D-glucoside[5] showed them to be superimposable. Furthermore, a mixed melting-point determination did not lower the melting-point range of the mixture. Therefore, the isolate was identified as β-sitosterol-β-D-glucoside.

Isolation and Identification of Cymarin—Fractions 47–50 were combined and dried *in vacuo* to a residue (500 mg), which was rechromatographed on a column of 75 g silica gel PF-254 and eluted with benzene–absolute ethanol (3:1). Forty-one 10-ml fractions were collected, and fractions 33–37 were combined on the basis of their TLC patterns. The dried, pooled fraction (200 mg) was dissolved in methanol, and ether was added until a cloudy appearance was observed.

The flask was stoppered and clear crystalline needles (72 mg) were obtained after 4 hr. These needles gave a Kedde positive reaction and had a melting point of 138–141°. Mass spectra of the isolate were run at 15 and 70 ev and showed fragmentation patterns consistent with those of cymarin (14). In addition, the NMR, UV, and IR spectra were superimposable with those of reference cymarin[6], and a mixed melting-point determination showed no depression.

Separation of Fraction E—Fraction E, the 50% alcoholic extract of the 95% ethanol-exhausted marc, was partitioned between chloroform and water. The chloroform layer was shown to be devoid of Kedde-positive material. The aqueous layer was evaporated *in vacuo*, and the residue (250 mg) was chromatographed on a 75-g silica gel PF-254 column, eluting with benzene–methanol (8:1). Forty 10-ml fractions were collected.

Isolation of Strophanthidin—Column fractions 15–20 were combined on the basis of their TLC patterns and taken to dryness. The residue (70 mg) was dissolved in hot methanol, ether was added to slight turbidity, and the flask was stoppered and allowed to stand overnight. The resulting colorless crystals (50 mg) were recrystallized from methanol–ether to afford an analytical sample which gave both positive Kedde and Liebermann–Burchard reactions.

The product had a melting point of 140–142° and exhibited NMR, UV, and IR spectra superimposable with those obtained for reference strophanthidin[7]. The mass spectrum of the isolate was consistent with that of strophanthidin (14). That this isolate was strophanthidin was further supported by an undepressed mixed melting-point determination.

Isolation and Characterization of the Strophanthidin Glycoside (XS-89)—Column fractions 21–25 were combined and evaporated, and the residue (80 mg) was dissolved in methanol. Water was added to the methanolic solution until it became cloudy, and the flask was stoppered and set aside in the refrigerator. The crystalline needles that formed were collected and dried *in vacuo* to give a total weight of 62 mg. The mother liquor was concentrated by slow evaporation at room temperature, and a second crop was harvested (8 mg). This compound was subsequently determined to be a new cardenolide possessing cytotoxic activity.

The isolate had a melting point of 163–168° and exhibited a UV spectrum at λ_{max} 218 nm ($\log \epsilon^{1\%}_{1cm}$ 2.47). IR spectral absorptions were observed at 3500 (s, OH), 2980 (s, CH_3 stretch), 2910 (w), 1750 (s, α,β-unsaturated lactone), 1725 (w, aldehyde), 1500 (m),

[1] The extracts were tested through the auspices of the Drug Research and Development branch of the National Cancer Institute. An extract is considered cytotoxic if it exhibits an $ED_{50} \leq 20$ μg/ml, and an isolate is considered active it it shows an $ED_{50} \leq 4$ μg/ml in the 9KB cell culture *in vitro* (17).

[2] All melting points reported were determined using a Kofler hot-stage melting-point apparatus and are uncorrected. UV spectra were recorded using a Beckman model DB-G spectrophotometer with methanol as the solvent. IR spectra in KBr were recorded using a Beckman model 18-A spectrophotometer with polystyrene calibration at 1601 cm^{-1}. Absorption bands are recorded in wave numbers ($centimeters^{-1}$) and intensities as s (strong), m (medium), and w (weak). NMR spectra were recorded in deuterochloroform on Varian Associates models A-60 and T-60 instruments using tetramethylsilane as the internal standard. Chemical shifts are reported in parts per million (δ, ppm). Mass spectra were determined using a Hitachi Perkin-Elmer model RMU-60 spectrometer; samples were introduced as solids. GLC analysis was carried out using a Perkin-Elmer model 881 gas chromatograph with helium as the carrier gas. The glass column was coiled, 1.8 m, 0.6 cm (6 ft, 0.125 in.) o.d., packed with a 5% OV-101 stationary phase on Gas Chrom Q, 100–120 mesh.

[3] The plant material was collected and identified by Mr. O. B. Dokosi, University of Ghana. Herbarium specimens are on file in the Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612

and 1080 (w) cm^{-1}. The NMR spectrum in deuterochloroform showed major signals as singlets at δ 0.80 (3H, angular methyl), 4.83 (2H, methylene protons of lactone ring), 5.90 (1H, olefinic proton of lactone ring), and 10.00 (1H, aldehyde).

The mass spectrum showed the expected fragmentation pattern for a strophanthidin-type cardenolide (14), with significant fragments being recorded at *m/e* 368 (8.3), 358 (4.1), 340 (45.8), 322 (31.6), 308 (4.1), 215 (4.1), 197 (7.5), 188 (20.8), 160 (15.0), 147 (100.0), 145 (12.0), and 131 (40.0).

A sample of the isolate (2 mg) was hydrolyzed by refluxing overnight in 20 ml of a mixture of 95% ethanol–water–concentrated hydrochloric acid (85:15:10). The solution was taken to dryness *in vacuo* and extracted with a small volume of water. The aqueous solution was filtered and mixed with an ion-exchange resin[8] (OH-form) until it was neutral to pH paper. The neutralized solution was filtered, dried *in vacuo*, and trimethylsilylated[9].

GLC of the silylated glycone portion demonstrated the presence of glucose. Several other peaks were also present, but their identity could not be discerned. However, fructose, digitoxose, galactose, mannose, arabinose, and rhamnose were absent.

TLC of the water-insoluble residue remaining from the hydrolysis demonstrated the presence of a component which was Kedde test positive and identical with reference strophanthidin in two solvent systems [1-butanol–acetic acid–water (4:4:1) and chloroform–methanol (8:1)]. These results, coupled with the observed mass spectral fragmentation pattern of the parent glycoside, indicated the aglycone to be strophanthidin. Attempts are underway to elucidate the structure of this compound.

Separation of Fraction A—Ten grams of the petroleum ether-soluble extract was dissolved in boiling acetone. Upon cooling, a copious, white, plate-like precipitate formed, which was collected and set aside. It exhibited a low broad melting-point range (64–72°). GLC analysis indicated the presence of several compounds which were not identified.

The mother liquor was evaporated, and the residue (6.24 g) was chromatographed on silica gel PF-254 (300 g), using benzene–ethyl acetate–acetone (10:1:1) as the eluent. A total of 38 fractions of 15 ml each was collected.

Isolation of Alkanol Mixture—Column fractions 20–24 were combined on the basis of TLC and evaporated. The residue (2.5 g) was dissolved in benzene, and acetone was added. The resulting white, plate-like precipitate, mp 60–68°, exhibited a transparent UV spectrum and the IR spectrum was typical of an alkanol (15). On comparison with reference alkanols, GLC analysis indicated the presence of 1-docosanol, 1-tetracosanol, and 1-hexacosanol.

Isolation of Triterpene Mixture—Column fractions 28–32 were combined and evaporated. This residue (1.9 g) was dissolved in chloroform, and a mixture of methanol–water (9:1) was added until a cloudy solution persisted. The microcrystalline precipitate that formed was collected and dried. The isolate (1.2 g), mp 125–130°, had a transparent UV spectrum, and it gave a positive Liebermann–Burchard test for triterpenes.

The mass spectrum showed a molecular ion at *m/e* 426 and a base peak, indicative of the amyrin series of triterpenes (16), at *m/e* 218. GLC analysis of this sample with reference standards showed the isolate to be a mixture of 70% α-amyrin and 30% β-amyrin.

Isolation of Phytosterols—Column fractions 36–38 were combined and dried *in vacuo*. On dissolving the residue (0.23 g) in 95% ethanol, small needle-like crystals (50 mg), mp 132–137°, were obtained. The isolate gave a positive Liebermann–Burchard test and exhibited a transparent UV spectrum. The IR spectrum (KBr) was identical to that of reference β-sitosterol[10]. The mass spectrum showed a molecular ion at *m/e* 414 and a base peak at *m/e* 218.

GLC of the sample at 260°, however, indicated the isolate to be composed of three constituents. These were tentatively identified as campesterol (20%), stigmasterol (7%), and β-sitosterol (73%) by comparison with chromatographically pure reference sterols, using cholestane as the internal standard.

Table I—Cytotoxic Results of Isolates from *P. nigrescens*

Isolate	9KB Cell Culture Test[a], μg/ml
β-Sitosterol-β-D-glucoside	$>1 \times 10^{1}$
Cymarin	$<1 \times 10^{-1}$
Strophanthidin	$<1 \times 10^{0}$
Unidentified strophanthidin glycoside (XS-89)	$<2.5 \times 10^{-1}$
Mixture of alkanols	$>1 \times 10^{2}$
Mixture of α- and β-amyrins	Not tested
Phytosterol mixture	$>4 \times 10^{1}$

[a] A compound is deemed active if it exhibits an $ED_{50} \leqq 4$ μg/ml.

Biological Activity—The results of biological evaluation indicated that the three cardenolides isolated, cymarin, strophanthidin, and the strophanthidin glycoside (XS-89), are cytotoxic but inactive in the P-388 lymphocytic leukemia (3PS) system (Table I). All other isolates tested were inactive in both systems.

Fluorometric Determination of Drug–Protein Association Constants: Binding of Pamaquine by Bovine Serum Albumin

DATTA V. NAIK, W. LARRY PAUL, and STEPHEN G. SCHULMAN ˣ

Abstract □ The binding of pamaquine to bovine serum albumin is accompanied by the enhancement of the fluorescence efficiency of the former but without shifting its fluorescence energy. This phenomenon was used to evaluate the stoichiometry and strength of the binding. The results indicate that three singly protonated pamaquine molecules are bound by each bovine serum albumin molecule. The individual binding constants were calculated by using the Bjerrum technique. The average values of the three constants were $K_1 = 6.4 \times 10^7$, $K_2 = 3.1 \times 10^6$, and $K_3 = 1.9 \times 10^5$, indicating that, compared to anionic drugs and fluorescent probes, pamaquine is very strongly bound by the protein.

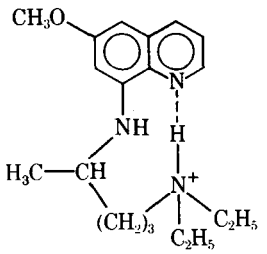
Keyphrases □ Pamaquine—binding by bovine serum albumin, fluorometric determination of drug–protein association constants □ Bovine serum albumin—pamaquine binding, fluorometric determination of drug–protein association constants □ Binding—pamaquine to bovine serum albumin, fluorometric determination of association constants □ Fluorometry—determination, drug–protein association constants, binding of pamaquine by bovine serum albumin

Recently, it was observed in this laboratory that the fluorescence intensity of the antimalarial pamaquine was enhanced in the presence of bovine serum albumin at pH 7.4. Consequently, it was felt that by systematically studying the variation of the quantum yield of fluorescence of pamaquine as a function of relative protein concentration, the parameters of the binding of the drug to the protein could be quickly and reasonably accurately established.

EXPERIMENTAL

Purified pamaquine phosphate[1] and crystalline bovine serum albumin of A grade[2] were used. The concentrations of bovine serum albumin solutions were calculated from the weight of the sample and then checked by determining absorbance at 280 nm. The average molecular weight of 69,000 and the molar absorptivity of 4.55×10^4 at 280 nm were used in the calculations. The bovine serum albumin concentrations determined directly by weighing were in excellent agreement with the concentrations determined photometrically.

All bovine serum albumin and pamaquine solutions were prepared 2 hr prior to fluorometric titration from distilled, deionized water buffered to pH 7.4 with a total phosphate ($[H_2PO_4^-] + [HPO_4^{-2}]$) concentration of 0.1 M. The fluorometric titrations were carried out as follows: 2.0 ml of the protein solution of appropriate concentration in a 1-cm silica cell was titrated by successive additions of 1-μl volumes of a 1×10^{-3} M solution of pamaquine, delivered from an air- and liquidtight microsyringe[3]. The temperature during the titrations was maintained at 25°. The fluorescent intensity measurements were made on an uncorrected fluorescence spectrophotometer[4] with excitation at 367 nm and fluorescence monitored at 518 nm.



I

DISCUSSION

Pamaquine (I) exists in its singly protonated form at pH 7.4, and an intramolecular hydrogen bond is present between the protonated diethylamino group and the ring nitrogen (1).

It has been suggested (1) that in the thermally equilibrated, excited state, the proton would be covalently bonded to the ring nitrogen and electrostatically hydrogen bonded to the diethylamino group. When pamaquine is bound to bovine serum albumin at pH 7.4, the fluorescence band does not shift but the fluorescence intensity is enhanced. The ratio of the quantum yields of the bound pamaquine to that of the pamaquine is 2.5. The fact that the fluorescence band of pamaquine does not shift on binding indicates that the intramolecular hydrogen bond of pamaquine is not broken in the process of binding to the protein, because any change in the electron density around the ring nitrogen would result in shifting of the fluorescence band.

For substrates like pamaquine, which have some fluorescence in the free form and whose fluorescence is enhanced without a change in the emission wavelength when bound to a protein, the fraction of substrate bound, α, can be determined by using Eq. 1 (see *Appendix* for derivation):

$$\alpha = \frac{F_p - F_f}{F_b - F_f} \qquad \text{(Eq. 1)}$$

where F_p and F_f are the fluorescence intensities of a given concentration of substrate in solutions of low protein concentration and in solutions without any protein, respectively; and F_b is the fluorescence intensity of the same concentration of the fully bound substrate. The latter is taken to be the fluorescence intensity of the substrate in the presence of excess protein. Such a treatment will yield values of α, provided the fluorescence intensities of the bound pamaquine and of the free pamaquine are linear functions of the respective concentrations.

The value of F is calculated using:

$$F = \phi I_0 \left[2.3A - \frac{(2.3A)^2}{2!} + \frac{(2.3A)^3}{3!} - \frac{(2.3A)^4}{4!} + \cdots \right] \qquad \text{(Eq. 2)}$$

where ϕ is the quantum yield of the emitting species, I_0 is the intensity of the exciting radiation, and A is the absorbance. The linearity of F with the concentration of the emitting species can only be taken for granted at very low absorbance (<0.02) at the exciting wavelength, in which case the higher power terms in Eq. 2 become negligible by comparison with the first term. For example, when $A > 0.02$, the deviation from linearity is greater than 2%. At absorbances of $0.02 < A < 0.15$, the second term in Eq. 2 results in $115 \times A$% deviation from linearity at any point in the fluorometric titration. At higher absorbances ($A > 0.15$), the third term in Eq. 2 generally also becomes large enough to have to be considered.

Several fluorometric titrations were carried out by increasing

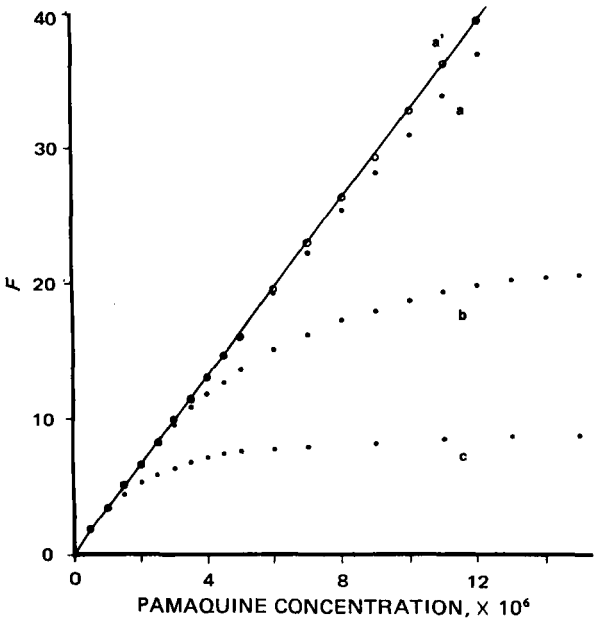

Figure 1—*Plots of relative fluorescence intensities,* F, *as a function of total pamaquine concentration for the bovine serum albumin–pamaquine titrations with a constant amount of the protein* (P_T). *Key: curve a,* $P_T = 2.5 \times 10^{-5}$ *and* 5×10^{-5} M; *curve b,* $P_T = 2.5 \times 10^{-6}$ M; *and curve c,* $P_T = 1 \times 10^{-6}$ M. *The straight line a′ is obtained after correcting the fluorescence intensities in curve a for the absorbance effect (see text).*

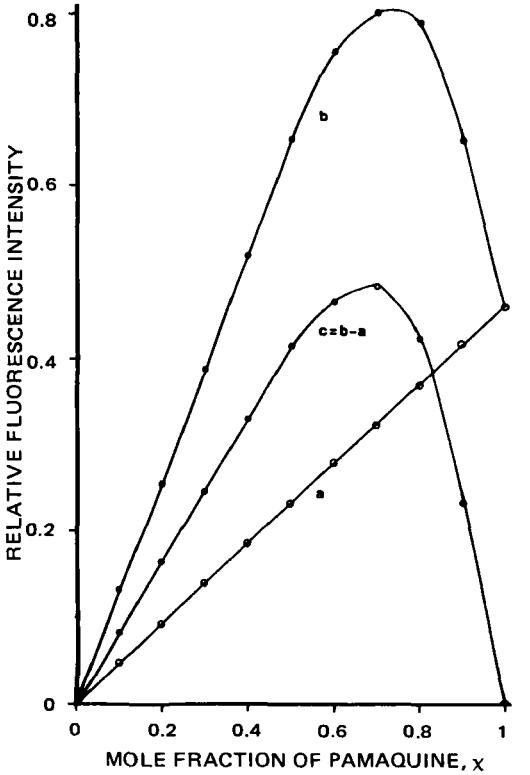

Figure 2—*Job's plot for the bovine serum albumin–pamaquine binding. Line a is the variation of the fluorescence intensity with the concentration of pamaquine in the 0–1* $\times 10^{-5}$ M *range. Curve b is the total observed fluorescence intensity as a function of the mole fraction (χ) of pamaquine. Curve c is the apparent enhancement in the fluorescence intensity as a function of χ. The total concentration of the protein plus pamaquine was kept constant at 1* $\times 10^{-5}$ M.

the initial protein concentration. The titrations with the protein concentrations of 2.5×10^{-5} and 5.0×10^{-5} *M* both gave exactly the same net enhancement in fluorescence intensity for a given amount of pamaquine, indicating that at these concentrations of bovine serum albumin the added pamaquine was essentially in the bound form. At the excitation wavelength, 367 nm, the molar absorptivity for the pamaquine–bovine serum albumin system was determined to be 5.2×10^3 liters $mole^{-1}$ (pamaquine) cm^{-1}. Hence, at pamaquine concentrations greater than 3.85×10^{-6} *M* ($A = 0.02$), the deviation from linearity will be greater than 2%, and appropriate corrections to the observed intensities should be applied to compensate for the second term in Eq. 2.

For the two titrations with the high protein concentrations (2.5×10^{-5} and 5.0×10^{-5} *M*) and for the titration with no protein, the observed fluorescence intensities (F_b and F_f, respectively) at every point during the titration were corrected by applying the correction factor 1.15*A*. Curve a in Fig. 1 was plotted using the observed values of $F_b - F_f$. After applying the correction to the observed fluorescence intensities, line a′ was obtained, verifying that the deviation from linearity of curve a was indeed due to the absorbance effect.

When the titrations are carried out at low protein concentration so that the substrate is only partially bound, the fluorescence intensity, F_p, is the sum of the fluorescence intensities of both the bound and unbound forms of pamaquine; therefore, F_p cannot simply be corrected for the second term in Eq. 2 unless the concentration of bound (or free) pamaquine is known in advance. To circumvent this problem, the concentration of bound pamaquine was estimated from Eq. 1 using the uncorrected F_p values and these approximate values were then used to correct the F_p values for the absorbance effect. Curves b and c in Fig. 1 are the plots of corrected $F_p - F_f$ values *versus* total concentration of pamaquine for bovine serum albumin concentrations of 2.5×10^{-6} and 1.0×10^{-6} *M*, respectively. The binding parameters were calculated by using the corrected values of F_f, F_p, and F_b.

The maximum number of binding sites, *N*, was determined from Job's plot (2, 3) as follows. First, the fluorescence intensity of pamaquine in pH 7.4 buffer was measured for solutions having concentrations from 0 to 1.0×10^{-5} *M* (line a in Fig. 2). The total fluorescence intensities of several pamaquine–bovine serum albumin solutions, made by varying the mole fraction (χ) of pamaquine and keeping the total concentration of pamaquine plus bovine serum albumin at 1.0×10^{-5} *M* (curve b in Fig. 2), were then measured. The apparent enhancement of fluorescence intensity due to the binding at different mole fractions of pamaquine is the difference between curve b and line a in Fig. 2. Curve c is plotted with the apparent enhancement of fluorescence intensity as a function of mole fraction of pamaquine. The point of inflection is at $\chi = 0.74$, which corresponds to a ratio of pamaquine to bovine serum albumin of 2.85. This value indicates that the maximum number of binding sites on the protein molecule for pamaquine is three.

In the evaluation of protein binding equilibria, the commonly used equation is the Scatchard equation (4):

$$\frac{\bar{n}}{[D]} = Nk - \bar{n}k \qquad \text{(Eq. 3)}$$

where $\bar{n}$ represents the ratio of moles of bound substrate per mole of protein, *[D]* is the concentration of unbound substrate, *N* is the maximum number of binding sites on a protein molecule, and *k* is the binding constant. The value of $\bar{n}$ can be calculated from the fraction of pamaquine bound by using the relationship:

$$\bar{n} = \alpha \frac{D_T}{P_T} \qquad \text{(Eq. 4)}$$

where D_T and P_T are the formal concentrations of pamaquine and bovine serum albumin, respectively. The concentration of unbound pamaquine was obtained by multiplying D_T by $(1 - \alpha)$. When the *N* binding sites are noninteracting and have the same binding affinities, a plot of $\bar{n}/[D]$ *versus* $\bar{n}$ (known as the Scatchard plot) gives a straight line with the *x*-axis intercept at $\bar{n} = N$, the *y*-axis intercept at $\bar{n}/[D] = Nk$, and the slope of $-k$. However, if the individual binding sites have different binding affinities, due either to the distinct nature of the sites or to the interaction be-

Table I—Equilibrium Constants for the Binding of Pamaquine to Bovine Serum Albumin at 25°[a]

	$P_T = 2.5 \times 10^{-6}$ M		$P_T = 1.0 \times 10^{-6}$ M		
	Scatchard Treatment	Bjerrum Treatment	Scatchard Treatment	Bjerrum Treatment	Average
$\log k_1$	7.81	7.82	7.80	7.78	7.80
$\log k_2$	6.55	6.37	6.60	6.43	6.49
$\log k_3$	5.36	5.15	5.45	5.21	5.29

[a] P_T is the total concentration of the protein.

tween the bound substrates at different sites, the Scatchard plot gives a downward curve instead of a straight line.

If the binding strength of the individual binding sites are significantly different from each other, the Scatchard plot may still be used to estimate binding parameters by appropriately analyzing the curve in relation to the following modified form of Eq. 3, where k_i is the binding constant for the ith site. Figure 3 shows the Scatchard plot for the bovine serum albumin–pamaquine system at the protein concentration of 2.5×10^{-6} M.

The curve obtained indicates that the three binding sites on bovine serum albumin for pamaquine have different binding strengths. Graphical analysis of this plot according to:

$$\bar{n} = \sum_{i=1}^{i=N} \frac{k_i[D]}{1 + k_i[D]} \qquad \text{(Eq. 5)}$$

yielded binding constants for the three sites. The values are listed in Table I along with the values obtained for another titration at $P_T = 1.0 \times 10^{-6}$.

Multiple equilibria involving a small number of ligands can be best treated by the Bjerrum technique (5). This approach is applicable to any system in thermodynamic equilibrium and makes no presupposition concerning the equivalence of binding sites or the relative magnitude of successive equilibrium constants. In the case of the bovine serum albumin–pamaquine system, the three successive equilibria (Scheme I, P = protein and D = pamaquine) are characterized by equilibrium constants k_1, k_2, and k_3 such that:

$$P + D \overset{k_1}{\rightleftharpoons} PD_1$$
$$PD + D \overset{k_2}{\rightleftharpoons} PD_2$$
$$PD_2 + D \overset{k_3}{\rightleftharpoons} PD_3$$

Scheme I

$$k_1 = \frac{[PD]}{[P][D]} \qquad \text{(Eq. 6)}$$

$$k_2 = \frac{[PD_2]}{[PD][D]} \qquad \text{(Eq. 7)}$$

$$k_3 = \frac{[PD_3]}{[PD_2][D]} \qquad \text{(Eq. 8)}$$

The average number of bound pamaquine molecules per mole of protein can now be expressed as:

$$\bar{n} = \frac{[PD] + 2[PD_2] + 3[PD_3]}{[P] + [PD] + [PD_2] + [PD_3]} \qquad \text{(Eq. 9)}$$

which, when combined with Eqs. 6–8, gives:

$$\bar{n} = \frac{k_1[D] + 2k_1k_2[D]^2 + 3k_1k_2k_3[D]^3}{1 + k_1[D] + k_1k_2[D]^2 + k_1k_2k_3[D]^3} \qquad \text{(Eq. 10)}$$

Equation 10 predicts that if k_1, k_2, and k_3 are widely different from each other so that essentially only one equilibrium is experimentally detectable at any point in the titration, a plot of $-\log [D]$ *versus* $\bar{n}$ (known as the Bjerrum plot) would show (for the present system) three distinct inflection regions corresponding to $-\log [D] = \log K_1$ when $\bar{n} = 0.5$, $-\log [D] = \log K_2$ when $\bar{n} = 1.5$, and $-\log [D] = \log K_3$ when $\bar{n} = 2.5$.

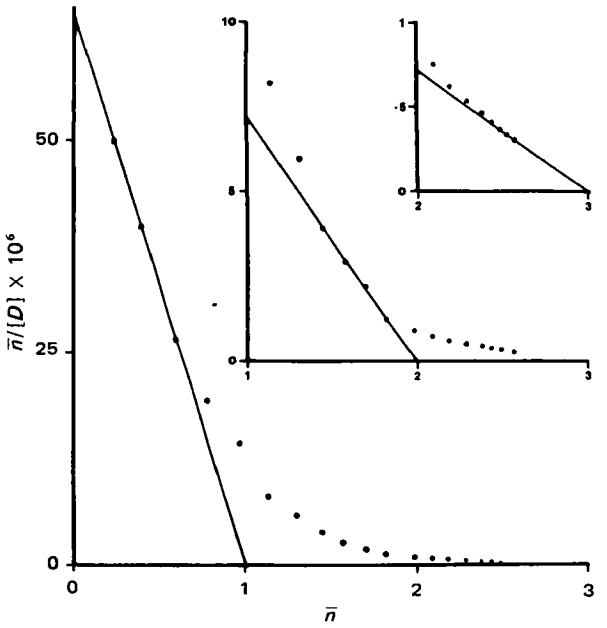

Figure 3—*Scatchard plot of* $\bar{n}$/[D] versus $\bar{n}$ *for the bovine serum albumin–pamaquine titration with the protein concentration of* 2.5×10^{-6} M. *Insets are the plots with an expanded* y*-axis.*

Figure 4 shows the Bjerrum plot of $-\log [D]$ *versus* $\bar{n}$ for the bovine serum albumin–pamaquine titration ($P_T = 2.5 \times 10^{-6}$ M). The absence of sharp inflection regions is indicative of overlapping successive equilibria. However, the plot does show shallow inflection regions at the expected values of $\bar{n}$; therefore, $-\log [D]$ values at $\bar{n} = 0.5$, 1.5, and 2.5 can be taken as a fair estimate of $\log k_1$, $\log k_2$, and $\log k_3$, respectively. The results obtained from this Bjerrum plot are given in Table I along with the results obtained for another titration at $P_T = 1.0 \times 10^{-6}$ M. The binding constants thus obtained are in good agreement with those estimated from the Scatchard treatment.

The overall magnitude of the binding constants obtained for the bovine serum albumin–pamaquine system is quite large compared, for example, to the binding of negatively charged 8-anilino-1-naphthalenesulfonate (6), indicating that pamaquine binds strongly to bovine serum albumin. Because of the positively charged nature of pamaquine, it is probable that the binding site on the protein for pamaquine is negatively charged. The most common anionic sites on bovine serum albumin consist of ionized carboxyl groups of various amino acids. There are about 37 free glutamic

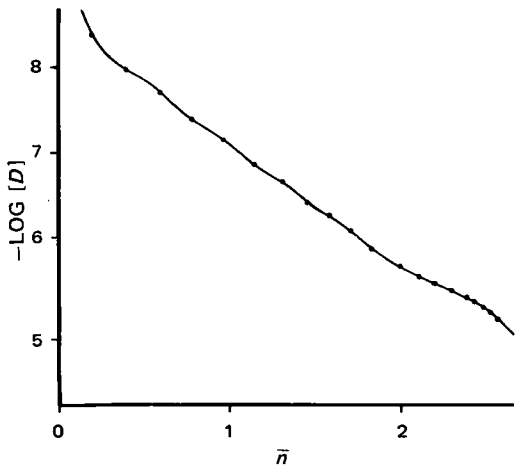

Figure 4—*Bjerrum plot of* $-\log$ [D] *as a function of* $\bar{n}$ *for the bovine serum albumin–pamaquine titration with the protein concentration of* 2.5×10^{-6} M.

acid residues and 56 free aspartyl acid groups (7).

However, in spite of the presence of such a large number of negative centers on bovine serum albumin, only three pamaquine molecules bind to it. Apparently, not all negative centers are available for the binding of pamaquine. Clearly, many are buried in the interior of the protein. Moreover, it is possible that the binding sites of pamaquine are ionized carboxyl groups on the outside of the protein with a suitable juxtaposition of other substituents or side chains so as to make the pamaquine–bovine serum albumin interaction energetically favorable. Even though pamaquine is positively charged, the quinoline ring, the alkyl side chain, and the ethyl groups on the terminal amino nitrogen could make its interaction with water less favorable than with a site on the protein which is negatively charged and has nonpolar side groups.

APPENDIX

The following illustrates the derivation of the equation to calculate the fraction of substrate bound when bound and free substrate both fluoresce, but with different intensities, at the analytical emission wavelength.

If F_p is the observed fluorescence intensity of a solution containing a total protein concentration of P and a total substrate concentration of S, then:

$$F_p = F_U + F_B \qquad \text{(Eq. A1)}$$

where F_U and F_B are the fluorescence intensities due to the unbound and bound fractions of substrate, respectively.

Assuming that the absorbance, A, by the emitting species at the wavelength of excitation is less than 0.02, the fluorescence intensity is related to the concentration of emitting species as:

$$F = 2.303 I_0 \phi \epsilon c l \qquad \text{(Eq. A2)}$$

where I_0 = intensity of incident radiation, ϕ = quantum yield of the emitter, ϵ = molar absorptivity, c = concentration of the emitter, and l = path length.

Since $I_0 l$ is an instrumental constant, Eq. A2 can be rewritten as:

$$F = k\phi\epsilon c \qquad \text{(Eq. A3)}$$

Substituting Eq. A3 into Eq. A1 yields:

$$F_p = k(\phi_U \epsilon_U [U] + \phi_B \epsilon_B [B]) \qquad \text{(Eq. A4)}$$

where subscripts U and B stand for unbound and bound fractions of substrate, respectively. But since $S = [U] + [B]$, Eq. A4 can be rewritten as:

$$F_p = k[\phi_U \epsilon_U (S - [B]) + \phi_B \epsilon_B [B]] \qquad \text{(Eq. A5)}$$

Similarly, when all of the substrate is free, *i.e.*, in the absence of protein, the fluorescence intensity F_f will be given by:

$$F_f = k\phi_U \epsilon_U S \qquad \text{(Eq. A6)}$$

and when all of the substrate is bound to protein, *i.e.*, in presence of excess protein, the fluorescence intensity F_b will be given by:

$$F_b = k\phi_B \epsilon_B S \qquad \text{(Eq. A7)}$$

Taking the ratio of Eqs. A6 and A7 gives:

$$\phi_U \epsilon_U = \frac{F_f}{F_b} \times \phi_B \epsilon_B \qquad \text{(Eq. A8)}$$

Substituting Eq. A8 into Eq. A5 yields:

$$F_p = k\left[\frac{F_f}{F_b}\phi_B \epsilon_B (S - [B]) + \phi_B \epsilon_B [B]\right] \qquad \text{(Eq. A9a)}$$

$$F_p = k\phi_B \epsilon_B \left\{\frac{F_f}{F_b} S - \frac{F_f}{F_b}[B] + [B]\right\} \qquad \text{(Eq. A9b)}$$

Dividing Eq. A9 by Eq. A7 gives:

$$\frac{F_p}{F_b} = \frac{\frac{F_f}{F_b} S - \frac{F_f}{F_b}[B] + [B]}{S} \qquad \text{(Eq. A10)}$$

Dividing throughout by S gives:

$$\frac{F_p}{F_b} = \frac{F_f}{F_b} - \frac{F_f [B]}{F_b S} + \frac{[B]}{S} \qquad \text{(Eq. A11)}$$

But $[B]/S = \alpha$, the fraction of substrate bound, and Eq. A11 becomes:

$$\frac{F_p}{F_b} = \frac{F_f}{F_b} - \frac{F_f}{F_b}\alpha + \alpha \qquad \text{(Eq. A12)}$$

Solving for α yields:

$$\alpha = \frac{F_p - F_f}{F_b - F_f} \qquad \text{(Eq. A13)}$$

Separation and Quantitative Determination of Impurities in Tetracycline

GILBERT J. WILLEKENS

Abstract □ Anhydrotetracycline, epianhydrotetracycline, epitetracycline, and chlortetracycline are generally found as impurities in tetracycline. A new thin-layer partition chromatographic method is described in which the impurities are separated on a kieselguhr layer impregnated with ethylene glycol–water–acetone–ethyl acetate (2:2:15:15). Compared to previous methods, this determination is easier to perform and more versatile and it prevents rapid epimerization. The quantitative determination of the tetracyclines utilizes spectrophotometry or direct TLC fluorometry.

Keyphrases □ Tetracycline—separation and analysis of impurities □ TLC—separation, tetracycline impurities

The quantitative determination of tetracycline antibiotics by titrimetry (1), polarography (2), colorimetry (3), paper chromatography (4), and column chromatography (5–8) has been reported, but TLC has proved most useful. The identification of three tetracyclines using a kieselguhr layer impregnated with glycerin was reported (9), and several tetracyclines were separated from their epimers using a similar system (10). Three tetracyclines were separated using kieselguhr previously washed several times with 6 *N* HCl to remove the binder (11). Anhydrotetracycline (I), epianhydrotetracycline (II), and epitetracycline (III) were separated from tetracycline (IV) and were quantitated by spectrophotometry (12).

Dijkhuis and Brommet (13) determined I and chlortetracycline (V) in IV on a layer impregnated with a citrate–phosphate buffer containing 10% glycerin. Van den Bulcke (14) studied the influence of the binder and polyalcohols in the stationary phase and of the solvent systems both on the separation of tetracyclines and the detection of their impurities. Microcrystalline cellulose was used to separate I and other impurities from IV (15–18).

Gyanchandani *et al.* (19) first impregnated the plates with the solvent system, a process that conditioned them so that they could be stored for several weeks. Finally, van Hoeck *et al.* (20) separated I, II, and III from IV on a solvent-impregnated plate and determined IV by direct fluorometry. The methods described in Refs. 12–14, 19, and 20 seem to be the most reliable, although they are subject to important criticism.

The use of acid-washed kieselguhr is undesirable (14) because the washing process is lengthy and does not result in reproducible separations. Microcrystalline cellulose is also unsatisfactory because the support, as described by Simmons *et al.* (15–17), is difficult to prepare and does not allow a good separation while the use of citrate and/or phosphate buffers may markedly increase the epimerization of the tetracyclines (19, 21, 22). For the same reason, the temperature should be controlled during the development (21). Most investigators used solutions of IV at concentrations ranging from 0.05% (20) to 0.2% (12, 19), but their procedures failed when higher concentrations of 0.5–1% were used to increase the sensitivity of detection of the impurities to an acceptable level. Failure resulted from the tailing of the IV spot.

Table I—TLC of I–V

Compound	Concentration, μg/μl	$R_f \times 100$ I[a]	II[b]	III[c]
I	0.025	98	86	95
V	0.025	21	32	72
II	0.025	16	27	30
IV	5.0	10	20	50
III	0.025	4	10	28

[a] With 10% VI plates. [b] With 3.7% VI plates used immediately after impregnation. [c] With 3.7% VI plates used 24 hr after impregnation.

The purpose of this research was to develop a TLC procedure allowing separation of traces of I–III and V as impurities in a 0.5% (w/v) solution of IV and their quantitation by means of spectrophotometry or direct TLC fluorometry.

EXPERIMENTAL

Reagents—Disodium ethylenediaminetetraacetate (VI), ethylene glycol, acetone, ethyl acetate, and sodium hydroxide were analytical grade.

Kieselguhr—Both MN-kieselguhr G[1] and kieselguhr G[2] were used. The former was preferred since the slurry was easier to handle and provided a coating with a more homogeneous appearance; it also gave a higher resolution.

Preparation of Plates—Two different supports were prepared using: *(a)* a slurry of 20 g of kieselguhr and 47 ml of 10% VI solution adjusted to pH 8.5 with 20% NaOH, and *(b)* a slurry of 20 g of kieselguhr and 47 ml of 3.7% VI solution. Plates (20 × 20 cm), four at a time, were prepared[3] with a layer thickness of 0.25–0.30 mm. The plates were dried at room temperature (25°) and at a relative humidity of 30–50% for 1 hr. Prior to use, they were developed with the solvent system for 1–2 hr and dried at room temperature for 1 hr.

Solvent System—The system was made up of ethylene glycol–water–acetone–ethyl acetate (2:2:15:15 v/v).

Preparation of Solutions—The substances were dissolved in methanol or a mixture of methanol and 0.1 *N* HCl (9:1). For identification of I–III and V, a concentration of 0.025 μg/μl was used. The solution of IV was used at 5 μg/μl. Calibration curves for di-

	265	35.60	0.670	33.50	0.840	94

[a] Each result is the mean of five determinations.

rect TLC fluorometry were prepared using appropriate concentrations.

Apparatus—A TLC chromatotank (20 × 20 × 8 cm) was lined with filter paper, and 120 ml of solvent was added. The tank was allowed to equilibrate for at least 1 hr. A spectrophotometer[4], a TLC spectrophotometer[5], an electrobalance[6], and a recorder[7] were also used.

Application of Solutions—Volumes of 50 or 100 μl were spotted by syringe[8], and volumes of 1 μl were spotted by disposable pipets[9].

Qualitative Chromatography—One-microliter volumes were applied as spots on a line 2.5 cm above the lower edge of the plate. The plate was placed in the tank and developed for 40 min at 25°. After drying the plate, the spots were observed under UV light (366 nm) and fluorescence was increased by exposure to ammonia vapor. The R_f values observed are listed in Table I. Typical TLC separations on 10% VI plates and 3.7% VI plates are shown in Figs. 1 and 2.

Quantitative Analysis—*Spectrophotometric Assay*—A suitable volume (50–100 μl) of a solution of the test mixture was applied as a 15-cm band on a line 2.5 cm above the lower edge of a 10% VI plate and developed until the solvent front had moved 13–14 cm. After the plate was dried, the fluorescing zones were quickly marked under UV light, removed separately, and extracted with 0.1 *N* HCl. Since centrifuging did not produce a clear solution, the kieselguhr was removed using a porcelain filter A_1, which was washed with 0.1 *N* HCl; the filtrates were combined and adjusted to volume. Further dilutions were prepared using 0.1 *N* HCl.

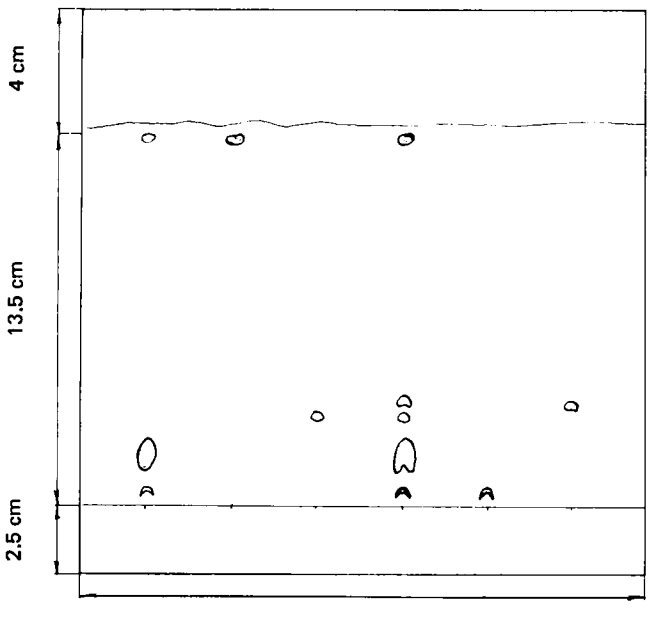

Figure 1—*Example of a typical TLC separation of tetracycline impurities on kieselguhr with 10% VI at pH 8.5. Key (left to right): 5 μg of IV, 0.025 μg of I, 0.025 μg of II, mixture (I–V), 0.025 μg of III, and 0.025 μg of V.*

Compounds I and II were determined using the absorbance at 430 nm, Compounds III and IV were determined at 355 nm, and Compound V was determined at 265 or 367.5 nm against a blank prepared in the same way as the test solutions. The absorbance of the blank at 430 nm was 0.002–0.008 for 20 cm^2 of the kieselguhr layer; at 355 nm, it was 0.050; and at 265 and 367.5 nm, it was 0.240 and 0.038, respectively.

The amount of substance in the mixture was calculated as follows:

$$\% = \frac{(A)(f)100}{(a)(p-l)} \qquad \text{(Eq. 1)}$$

where p is the concentration of sample in grams per liter, l is the loss on drying, f is the dilution factor, a is the absorptivity of the substance being examined, and A is the absorbance measured.

The absorptivities *(a)* were determined for the pure reference substances (Table II). The values a_w were obtained from measurements on the eluates after chromatographing the pure reference substances.

Spectrophotometric determination of the impurities was difficult, because rather large quantities were necessary to produce reliable measurements, *i.e.*, absorbances between 0.150 and 0.750. The final concentration of the extracts from the kieselguhr ranged from 10 to 40 μg/μl. At lower concentrations, the errors increased significantly.

Direct TLC Fluorometry—An irregular distribution of the substances within the spot is unimportant when direct TLC fluorometric evaluation is used. Spots with a regular form are measured with a circular aperture, and the recorded value is proportional to the total fluorescence and, thus, to the concentration of the sample. When using a circular aperture, a slit width of approximately 1.5 mm is used.

With spots of an irregular shape, a rectangular aperture is used. In this case, the area between the curve and the abscissa should be determined on the recorded graph. Disturbing effects such as background, front line fluorescence, and, particularly, dust particles may influence the measurement and are to be avoided. For drawing a calibration curve, the internal standard method is used.

Assay—For the evaluation of II, III, and V, 10% VI plates were used; for the evaluation of I, 3.7% VI plates were used. For each impurity, five solutions with concentrations in geometric progression were prepared; 1 μl of each was spotted at 2.5-cm intervals on the baseline together with 1 μl of the solution of IV. One microliter of the test solution of IV was also applied separately. Two or more impurities were evaluated on a single plate by preparing a combined standard solution of these impurities in a definite proportion and diluting it in a geometric progression.

After separation, the plate was allowed to dry at room temperature for 10 min. The TLC spectrophotometer was adjusted to the spot with the highest concentration, and the transmission scale was adjusted to 100 units. A rectangular aperture was used for all measurements; the other conditions used for each impurity are listed in Table III.

The fluorescence was excited by the 365-nm Hg line and measured by scanning the accurately positioned spots in the x axis or, if necessary, in the y axis direction with a scanning speed of 3 cm/min. The recorded speed was kept at 5 cm/min. The results obtained are reported in Table IV.

Each fluorescent spot was recorded as a peak and was quantitated by measuring the peak area either by triangulation (results by

[a] Amplification of the TLC spectrophotometric response corresponding to different concentrations of the substances in the spot.

this procedure were unreliable and variable) or, preferably, by cutting out and weighing the peak areas. These weights are a measure of the areas and were used as such in the calculation of the regression line (23) as follows. Let y be the weight of an area corresponding to a concentration x of a spot on the chromatogram and $\tilde{y}$ is the true value of y at any given value of x. Then the equation of the true regression line will be:

$$\tilde{y} = a + bx \qquad \text{(Eq. 2)}$$

where b is the slope and a is the intercept on the y axis at $x = 0$. This equation can be rearranged to:

$$\tilde{y} = \bar{y} + b(x - \bar{x}) \qquad \text{(Eq. 3)}$$

since the point $(\bar{x},\bar{y})$ lies on the estimated regression line. The slope b is given by the following equation:

$$b = \frac{\Sigma xy - \dfrac{(\Sigma x)(\Sigma y)}{n}}{\Sigma x^2 - \dfrac{(\Sigma x)^2}{n}} \qquad \text{(Eq. 4)}$$

where n = sample size.

To draw the estimated regression line, first $(\bar{x},\bar{y})$ is plotted. A convenient amount is added to $\bar{x}$ and b times this amount to $\bar{y}$. Thus, a second point can be plotted. These two points determine the regression line. The standard deviation of the individual y values about the regression line is designated $s_{y.x}$ and is computed by the square root of the following expression:

$$s^2_{y.x} = \frac{1}{n-2}\left\{\Sigma y^2 - \frac{(\Sigma y)^2}{n} - b\left[\Sigma xy - \frac{(\Sigma x)(\Sigma y)}{n}\right]\right\} \qquad \text{(Eq. 5)}$$

The regression was calculated in this way for each impurity and is illustrated for II and V in Fig. 3.

It has been verified that the assay procedure gives a valid estimate. Therefore, the recovery of the concentration of the impurity added in geometrical progression to the spot of the unknown mixture was calculated. The mean of each series of these values was plotted against the corresponding amount of impurity added. An example of the correlation between I added and I recovered is shown in Fig. 4.

RESULTS AND DISCUSSION

Separation of Tetracyclines—Rapid and accurate evaluation of the tetracycline impurities requires a very sensitive separation method. Both the 10% VI method and the 3.7% VI method were suitable for qualitative and quantitative purposes. Figures 1 and 2 show that III, IV, II, V, and I separated in that order. Epichlortetracycline was also separated, with an R_f value between that of III and IV.

Both methods allowed a spectrophotometric determination of the separated substances. However, the 10% VI method gave the best separation; the spots were round and regular in shape with a good resolution appropriate for direct TLC fluorometry. This procedure was adopted for most experiments (Table IV). The spot of I moved so close to the solvent front in this procedure that it could not be evaluated by direct fluorometry and the 3.7% VI method had to be used to estimate this impurity. Before use, the plates were impregnated with the solvent system for at least 1 hr. However, the optimum impregnation time, resolution of the spots, and R_f values varied slightly with the ambient atmospheric conditions such as temperature and relative humidity. Activation of the plates prior to impregnation did not improve the results but resulted in tailing of the spots.

Care was taken to dry layers slowly, preferably at 30–50% relative humidity and a temperature of 25°. Unimpregnated plates prepared in this way could be stored for an unlimited time. The solvent used for impregnation could be used two or three times. Test and standard solutions, when kept at 0° in the dark, were stable for at least 1 week.

Sensitivity—Mixtures of IV with impurities ranging from 4 to 16 mg/ml were adequately resolved by these methods. It was possible to resolve a 16-mg/ml solution of IV containing impurities as follows: IV, 99.78%; I and III, 0.1%; II, 0.07%; and V, 0.5% (Table IV).

Since high concentrations of IV increased tailing, it was preferable to apply the samples as 4–8-mg/ml solutions, using a 1-μl micropipet to prevent overloading of the layer and to keep the spot size small enough to allow estimation by direct fluorometry.

Spectrophotometric Analysis—Spectrophotometry, although an accurate procedure, was less sensitive. If, for instance, 100 μl of a 16-mg/ml tetracycline solution was streaked onto the plate over a distance of 15 cm, the impurities had to be present in quantities of at least 3% of total tetracycline to be detected. Indeed, spectrophotometric determination required a minimum concentration in the eluate of 10 μg/ml of the substance concerned. An impurity percentage less than 3% could be estimated by spotting a greater volume or by increasing the concentration of the solution, but both procedures gave a poor separation.

The absorptivities of I–V are listed in Table II. Each result is the mean of five determinations and the relative standard deviation was less than 3.5% in all instances. The a_w values, however, showed a relative standard deviation up to 6%. Compound V

[a] Each result is the mean of five determinations. [b] $p = 0.05$, 4 *df*, $t^* = 2.78$.

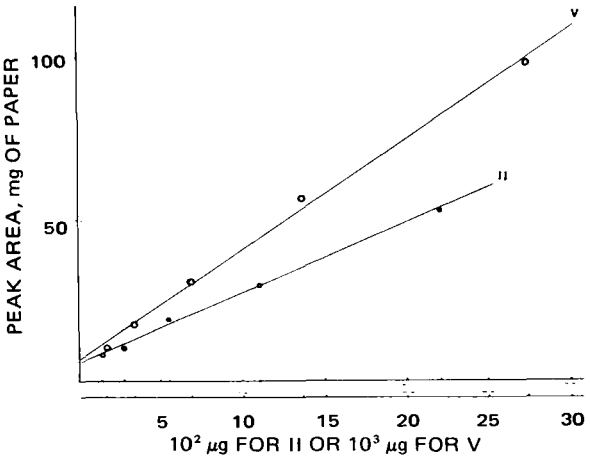

Figure 3—*Example of a calibration graph for II and V separated from a 4-mg/ml tetracycline solution on a 10% VI layer.*

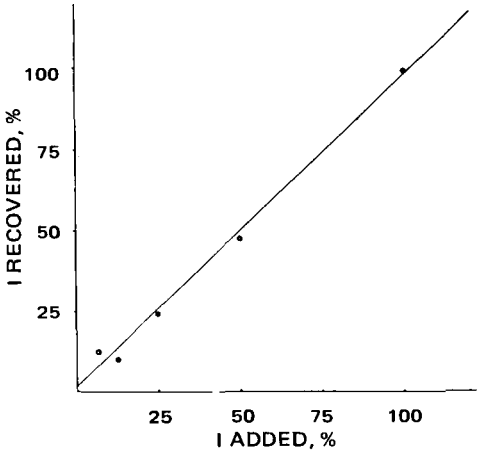

Figure 4—*Example of the correlation between I added and I recovered from an 8.8-mg/ml tetracycline mixture on a 3.7% VI layer by direct TLC fluorometry.*

should be measured at 367.5 nm because the great absorbance of the blank at 265 nm could interfere with an exact evaluation.

Direct TLC Fluorometry—As mentioned previously, a rectangular aperture was used for the measurements since the slit width was much easier to handle and to adjust to the spot concerned; it also allowed a three to fourfold amplification. Since the slit height could not be altered continuously, poor accuracy was obtained where the spots were not completely resolved. Before making quantitative measurements, plates were always inspected under UV light to allow removal of fluorescing dust particles. A chart speed of 5 cm/min was desirable to allow the cutting out of the peak areas. The computation of results by estimation of a regression line and its confidence limits seems somewhat tedious. In cases of routine tetracycline analysis, however, when impurities will occur in quantities of 1% or more and great accuracy is not needed, sufficiently accurate evaluations can be achieved graphically.

The individual regression lines calculated for each impurity separated from 4- and 8-mg/ml tetracycline solutions showed good linearity with a significant correlation coefficient (lowest value 0.9529). Consequently, the mean results of the correlation between the impurity added (%) and the impurity recovered (%) showed good linearity. Compounds I, with a linear equation of $y = 0.27 + 0.99x$ (correlation coefficient 0.9958), and V, with a linear equation of $y = 0.19 + 0.997x$ (correlation coefficient 0.9998), separated from a 4-mg/ml mixture had especially good linearity; $y = 1.68 + 0.962x$ (0.9956) and $y = 0.09 + 0.998x$ (0.998) were obtained, respectively, from an 8.8-mg/ml solution of tetracycline.

The confidence limits (95% confidence interval) of the means are given by $\bar{x} \pm (\sigma/\sqrt{n} \times t^*)$, where $\sigma/\sqrt{n}$ is the standard error and t^* is 2.78 (df 4 and $p = 0.05$)[10]. These values are listed in Table IV and indicate the acceptable accuracy of the direct fluorometric method; each result is the mean of five determinations. For fewer determinations, the critical t^* value becomes much larger and it is better to express the confidence interval as $\bar{x} \pm (1.96 \times \sigma_x)$, where σ_x is the standard deviation. The results, using a 16-mg/ml solution of tetracycline, were not very reliable. Compounds II and III gave regression lines for which the slopes were not significant, although the recoveries were very close to the expected values. For these reasons, the separation of II and III from a 16-mg/ml solution has only a qualitative use. For quantitative purposes, 4–8-mg/ml solutions should be used.

CONCLUSIONS

The TLC method described allows a separation of anhydrotetracycline, epianhydrotetracycline, epitetracycline, and chlortetracycline from a 16-mg/ml solution of tetracycline. Effective measurements of epichlortetracycline at low concentration is impeded by the luminous background left by the spot of tetracycline. A good separation probably can be achieved with other impurities such as doxycycline, rolitetracycline, methacycline, and oxytetracycline.

Direct TLC fluorometry is a very sensitive means of evaluating the impurities in tetracycline, allowing the determination down to a concentration of 0.5% (w/w) in tetracycline. The limit of detection is 50–100 times greater than when spectrophotometry is used.

GLC Analysis of Caffeine and Codeine Phosphate in Pharmaceutical Preparations

MARIO R. STEVENS

Abstract □ A procedure for the determination of caffeine and codeine phosphate in pharmaceutical preparations was developed. It depends upon a one-step extraction followed by GLC analysis of the concentrated extract.

Keyphrases □ Caffeine and codeine phosphate—GLC analysis in pharmaceutical products □ Codeine phosphate and caffeine—GLC analysis in pharmaceutical products □ GLC—analysis, caffeine and codeine phosphate

Caffeine and codeine phosphate are used singly or in combination with other drugs in various pharmaceutical preparations. Quality control requirements (1) have made it mandatory to determine both the caffeine and codeine phosphate content uniformity. James (2) reported a procedure for the determination of the codeine and caffeine contents of individual aspirin, phenacetin, caffeine, and codeine phosphate tablets based upon a fluorometric–UV spectroscopic assay. While accurate, this method and other spectroscopic assays (3, 4) involve time-consuming multiple extractions which are liable to inherent errors.

The reported GC methods are either not amenable to single-tablet assay, do not include codeine, or are rather involved (2, 5).

The developed GLC procedure is simple, and the sample preparation involves only two extractions per tablet. This process represents a 77% reduction in the extraction requirements when compared with the compendial method (1) with no loss in accuracy. Caffeine, codeine phosphate, and phenacetin are extracted from the tablet matrix into a common solvent, and no further separation is needed.

EXPERIMENTAL

Equipment—A gas chromatograph[1] equipped with a flame-ionization detector was used. The detector signal was fed into a 1-mv recorder[2] operated with a chart speed of 1.3 cm (0.5 in.)/min. One-microliter samples were injected with a 10-μl syringe[3].

Materials—High purity helium was the carrier gas. Purified hydrogen and compressed air were used in the detector. The stationary phase was 3%, OV-17 on Chromasorb W[4] (80–100 mesh), acid washed and silanized, packed in a 1-m × 0.64-cm o.d. glass column. All chemicals employed were spectrograde. All sample and standard materials were of NF or USP grade.

Operating Conditions—The column was operated isothermally at 240°. Both the detector and the injector port were held at 250°. The carrier gas flow rate was 28 ml/min at an inlet pressure of 40 psig. The initial electrometer range and attenuation settings were 10^2 and 32, respectively. After the elution of the solvent and the first two components, the range setting was 10 and the attenuation setting was 8 for the duration of the run.

Preparation of Standard Solutions—Two standard solutions were prepared, an internal standard and the working standard.

Internal Standard—Three hundred milligrams of nortriptyline hydrochloride was dissolved in 20 ml of 15% sodium chloride solution in a 125-ml separator. The solution was made basic by the addition of 5 ml of 2 *N* NaOH and extracted with 2 × 15 ml of chloroform. The extracts were filtered through filter paper[5] containing 5 g of anhydrous sodium sulfate, and the extracts were combined in a 50-ml volumetric flask. The filter was washed with 15 ml of chloroform, and the washings were added to the combined extracts. Chloroform was used to bring the contents to volume.

Working Standard—In a 125-ml separator, 234 mg of aspirin, 150 mg of phenacetin, 30 mg of caffeine, and 15–60 mg of codeine phosphate were combined. The exact amount of codeine phosphate varied depending upon its concentration in the tablet preparation to be analyzed. The mixture was treated in the same way as the internal standard preparation, except that the extracts and the

Table III—Analysis of Caffeine and Codeine Phosphate in Prepared Aspirin, Phenacetin, Caffeine, and Codeine Phosphate Tablets

Tablet Number	Codeine Phosphate, mg		Caffeine, mg	
	Claim	Found	Claim	Found
A-1	30	33.4	30	30.0
A-2	30	28.9	30	27.3
A-3	30	32.9	30	30.7
B-1	60	60.4	30	31.9
B-2	60	60.4	30	31.9
B-3	60	60.5	30	30.9
C-1	15	15.0	30	30.5
C-2	15	16.0	30	29.7
C-3	15	14.8	30	31.3

washings were collected in a 50-ml erlenmeyer flask and evaporated to dryness on a steam bath under nitrogen flow. The dried extract was redissolved in 3 ml of the internal standard solution prior to use.

Preparation of Sample Solutions—One tablet, or one tablet weight, of aspirin, phenacetin, caffeine, and codeine phosphate was put into a 125-ml separator. Twenty milliliters of 15% sodium chloride solution was added, and the contents were shaken until the tablet disintegrated. The mixture was then treated exactly as described for the working standard beginning with: "The mixture was treated in . . . ."

Calculations—For the standard chromatogram, the ratio, R-1, of the areas of the nortriptyline/caffeine peaks and the ratio, R-2, of the areas of the nortriptyline/codeine peaks were obtained. For the sample chromatogram, the ratio, R-3, of the caffeine/nortriptyline peak areas and the ratio, R-4, of the codeine/nortriptyline peak areas were obtained. Then:

$$(R\text{-}1) \times (R\text{-}3) \times Cf = \text{mg caffeine in sample} \quad \text{(Eq. 1)}$$

where Cf is the milligrams of caffeine in the working standard, and:

$$(R\text{-}2) \times (R\text{-}4) \times Cc = \text{mg codeine phosphate in sample} \quad \text{(Eq. 2)}$$

where Cc is the milligrams of codeine phosphate in the working standard.

RESULTS AND DISCUSSION

Nortriptyline hydrochloride served as the internal standard in the compendial procedure for the analysis of codeine phosphate (1). In this study, it was equally satisfactory for the quantitative evaluation of both caffeine and codeine phosphate. Figure 1 illustrates a typical chromatogram. Area ratios were used rather than peak height ratios, since the area ratios yielded analytical data without repetitive chromatograms. As the figure shows, isothermal operation of the column at the temperature and carrier gas flow rate employed resulted in excellent resolution of the compounds. Table I presents the associated GLC data.

The accuracy of the method is evident from the data given in Table II. Each of the two simulated preparations contained the four active ingredients in amounts similar to the sample tablet preparations. Each mixture was subjected to the entire analytical procedure. Use of an integrator to measure the peak areas would enhance the accuracy further. The present error is estimated to be about 2%.

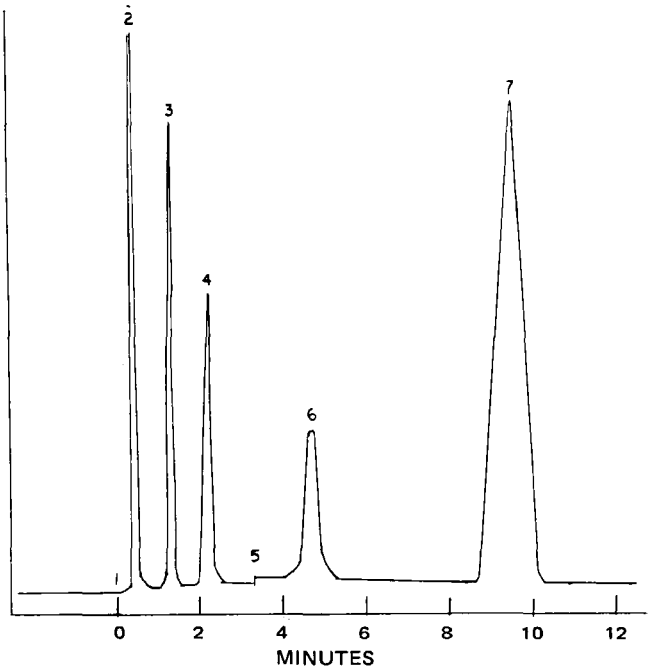

Figure 1—*Gas chromatogram of a sample extract with internal standard. Key: 1, inject; 2, solvent; 3, phenacetin; 4, caffeine; 5, attenuation change; 6, nortriptyline (internal standard); and 7, codeine.*

Application of the procedure to the analysis of tablet preparations is given in Table III. By first extracting the mixture with chloroform, then making the solution basic, and then extracting again with chloroform, all four ingredients are present in the combined extracts. In the present case, the aspirin remains in the aqueous phase as the sodium salt. Temperature programming would allow all active ingredients to be analyzed, but now only phenacetin, caffeine, and codeine phosphate can be analyzed.

Use of Factorial Design to Evaluate Granulations Prepared by Spheronization

HENRY JOHN MALINOWSKI * and WILLIAM E. SMITH ˣ

Abstract □ This study was designed to demonstrate that properties of a granulation with a given composition, prepared by the spheronizing technique, could be altered by slight changes in process variables alone to satisfy the requirements of the formulator. A complete factorial experimental design was found satisfactory for demonstrating the range of properties to be expected and for showing statistically significant main effects and any linear interactions between selected variables. Results using two levels of five variables showed that initial water content and spheronizer speed had significant main effects on all primary granulation properties studied. While only one formulation was studied, the data suggest that the factorial design can have utility in predicting the properties of granulations prepared at conditions within the limits imposed by the equipment or formulation.

Keyphrases □ Spheronization—process variables, effect on granulation properties □ Tablet granulation—spheronization method utilized to control granule properties □ Factorial experimental design—utility for optimizing pharmaceutical process conditions

Extruded particles processed to exhibit a fairly uniform spherical shape with a narrow size distribution were reported (1, 2) to offer advantages in pharmaceutical formulations for tableting. The selection of spheronization process variables had a significant effect on tablet hardness and dissolution when acetaminophen tablets were prepared by this unique granulation procedure (3). Studies of tablet granulations prepared with an instrumented single-screw extruder also demonstrated the importance of solvent selection on the final characteristics of the particles (4).

These studies, plus the popularity of pellet-type pharmaceuticals, particularly for capsule fills, suggest the need for detailed information describing the effects of processing variables on the properties of uniform, free-flowing particles in the sieve ranges employed for pharmaceutical products, no matter what process is used for their preparation. In a previous report, a factorial experimental design was recommended to identify significant variables and to predict the effects of changes in processing conditions on selected tablet properties (3). The work presented here summarizes the effect of selected variables on the properties of extruded spheronized granulations utilizing this procedure.

EXPERIMENTAL

Materials—Microcrystalline cellulose, containing 11% sodium carboxymethylcellulose[1], and acetaminophen NF[2] were used. A sieve analysis of both materials appears in Table I.

Processing—The equipment for preparing granulations was described previously (3) and consisted of an extruder[3] and a spheronizer[4] unit. Processing conditions (3) were carried out on a batch composed of 1 kg of materials plus the required quantity of purified water.

Testing Procedures—The temperature of the extruder chamber was monitored by a thermocouple[5] attached to the screen surfaces. Percent loss on drying of the extrudate was determined during extrusion and ranged between 17.6 and 25%. Analysis showed that the extrudate moisture content was determined only by the amount of water added prior to extrusion.

Percent loss on drying was recorded for each dried product, employing a 5.5-w lamp setting at 3.8 cm for 15 min on an IR balance[6]. Bulk density, expressed as grams per milliliter, was determined by measuring the volume occupied by 50.0 g of granulation in a 100.0-ml graduated cylinder.

A sieve analysis of each product was performed using 200-g samples passed through U.S. Standard sieves, from 8- to 60-mesh sizes, with the aid of a sieve shaker[7] at the number 6 setting for 5 min.

Flow rate was determined for each granulation using a conical stainless steel funnel, 23.5 cm high with a top 22.9 cm in diameter and a lower orifice 1.27 cm in diameter. The time required for 500 g of granulation to flow through the orifice was measured. Tests were run in triplicate; the mean value, expressed as grams per second, was used in calculations. Granule friability was evaluated by a procedure described previously (3).

Experimental Design—Details of the experimental design and mathematical treatment of the data as used to evaluate tablet properties were reported previously (3). The results reported here were obtained from the same series of experiments using data generated by various tests on the granulations. The methods described by Yates and Anderson (5) were used to identify main effects (ME) and to indicate first- and second-order interactions between the five variables chosen: water content (A), 250 or 325 ml; extruder speed (B), 39 or 59 rpm; screen size (C), 0.8 or 1.5 mm; spheronizer speed (D), 700 or 1010 rpm; and spheronizer residence time (E), 1.0 or 3.0 min. The ranges were selected to give a wide variation of granule properties within the limitations of the equipment and the requirements of the various tests.

RESULTS AND DISCUSSION

Test values for the various parameters are given in Tables II and III, and the ranges observed for each are included in Table IV. The data on percent fines and maximum amount on one screen are in Table V. An example of the analysis of variance results for flow rate is given in Table VI. Discussion of results will include significant main effects and first-order interactions (those between two variables). A summary of all significant main effects is given in Table VII.

Three parameters—extruder screen temperature, escape, and extrudate water content—were measured during the extrusion step of the spheronization process and could only be affected by water content, extruder speed, and screen size.

Table I—Particle-Size Distribution of Starting Materials[a]

U.S. Standard Sieve No.	Microcrystalline Cellulose	Acetaminophen
20	—	1.1
40	—	9.5
60	—	13.6
80	0.3	34.4
100	0.8	3.0
120	2.6	10.0
<120	96.3	28.4

[a] Weight percent.

Maximum Extruder Screen Temperature—Analysis of variance indicated that water content and extruder speed were significant main effects. No significant interactions were found. An increased water level decreased the maximum extruder screen temperature whereas an increased extruder speed increased the maximum extruder screen temperature. With heat-labile materials, it would be desirable to maintain the temperature at the extruder screens at a minimum. This could be accomplished at high water content and also at low extruder speed.

Escape—Material that passed down the overflow chute during extrusion was collected, weighed, and corrected for moisture content to arrive at a value for the weight of dry material that was not acceptable for spheronization. Water content was the only significant main effect, and the interaction of water content–screen size was the only significant interaction. An increased water content decreased the weight of escape. The significant first-order interaction is shown in Table VIII.

An increased water content resulted in a greater decrease in escape at the low screen size. An increased screen size resulted in a decrease in escape at the low water content whereas escape increased at the high water content. To arrive at maximum product yield, escape should be kept at a minimum. This condition would result from a high water content and a low screen size.

Extrudate Water Content—Analysis of variance of water content of the wet, extruded material indicated only the obvious main effect; namely, an increased water content resulted in an increased water content of the extrudate. The results are presented only to indicate that neither speed nor screen size affected the extrudate water content. Theoretical values would be 20.0% at the low water content and 24.5% at the high water content.

[a] Mean of three values.

Intermediate Level Experiment (No. 33)—An experiment was run at mean levels of the five variables studied in the factorial experiment (Table IV). The variable levels were: water content, 290 ml; extruder speed, 50 rpm; screen size, 1.0 mm; spheronizer speed, 85 rpm; and spheronizer time, 2.0 min. In all cases, the value of the parameter for Experiment 33 fell within the range of the original experiments. This finding indicated that it was possible to use the results of this study to modify the characteristics of a given formulation to be spheronized. Details of the complete factorial analyses of the primary granulation properties are included here.

Flow Rate—The significant main effects indicate that an increased water content, spheronizer speed, or spheronizer time resulted in granulations with an increased flow rate.

The first-order interaction, spheronizer speed–spheronizer time, is shown in Table IX. As spheronizer speed increased, a greater in-

32	0.0	0.0	0.1	28.3	57.0	12.8	1.8

crease in flow rate was noted at the high spheronizer time. An increased spheronizer time resulted in a greater increase in flow rate at the high level of spheronizer speed. The maximum flow rate would be obtained at high levels of water content, spheronizer speed, and spheronizer time. If it were necessary to use larger extruder screens, improved flow rates would result with an increased spheronizer time at either level of water content.

Bulk Density—The significant main effects indicated that an increased water content, spheronizer speed, or spheronizer time resulted in granulations with an increased bulk density. As spheronizer speed was increased, a greater increase in the value for bulk density was observed at the low water content, although values for bulk density were higher overall at the high water content (Table X). An increased water content resulted in similar effects, that is, a greater increase at the low spheronizer speed but with higher values for bulk density overall at the high spheronizer speed.

If it were desirable to have high values for bulk density, a high water content, spheronizer speed, and residence time in the spheronizer would be required. Experiments run at the high level of either water content or spheronizer speed resulted in nearly identical bulk density values. When both of these variables were at the high level, even greater values for bulk density were obtained.

Mean Particle Size—Calculated mean particle sizes were obtained from plots of cumulative percent undersize on the probability scale *versus* particle size on the arithmetic scale. Sieve analysis data appear in Table V. The significant main effects indicated that an increased water content or screen size resulted in granulations with an increased mean particle size whereas an increased spheronizer speed resulted in a decreased mean particle size.

As screen size increased, a greater increase in mean particle size was observed at the low spheronizer speed. As spheronizer speed increased, no change in mean particle size was observed at the low screen size whereas mean particle size decreased at the high screen size (Table XI). The mean particle size resulting from a given extruder screen size is considerably smaller than the screen size itself. The average of mean particle sizes for 16 experiments using screens with 0.8-mm openings was 0.578 mm; when using screens with 1.5-mm openings, the average of mean particle sizes was 0.744 mm. A low water content, small screen size, and high spheronizer speed would result in smaller particles in the final granulation. If it were necessary to use larger screens, a smaller mean particle size would be obtained at a high spheronizer speed. With small screens, no change in mean particle size was obtained by increasing spheronizer speed.

Table VI—Analysis of Variance: Flow Rate

Source of Variation	Sum of Squares	Degrees of Freedom	Variance	$F_{1,6}$
Water content (A)	4.805	1	4.805	11.10[a]

Higher order	2.598	6	0.433	

[a] Significant at $p < 0.05$. [b] Significant at $p < 0.001$.

Percent Fines—For this study, fines were particles passing a 60-mesh sieve. The amounts present are listed in Table V. The significant main effects indicated that an increased screen size or spheronizer speed resulted in granulations with increased fines whereas an increased water content or spheronizer time resulted in decreased fines.

Significant first-order interactions are shown in Table XII. The water content–screen size interaction may be explained by observing that little increase in percent fines occurred at the high water content as screen size was increased. At the low water content, an increased screen size resulted in a large increase in percent fines.

The water content–spheronizer speed interaction may be explained in the same manner. At the high water content, an increased spheronizer speed resulted in little change in percent fines. At the low spheronizer speed, an increased water content resulted in a smaller decrease in fines than at the high spheronizer speed, both percent fines values being equivalent at the high water content.

The water content–spheronizer time interaction may be described by noting that, at the low water content, the percent of fines was decreased by increasing spheronizer time; at the high

Table VII—Summary of Significant Main Effects[a]

	Water Content	Extruder Speed	Screen Size	Spheronizer Speed	Spheronizer Time

Table VIII—Values for Escape (Grams)[a]

Screen Size, mm	Water Content, ml	
	250	325
0.8	208	91
1.5	151	130

[a] Mean of eight experiments.

Table IX—Mean Flow Rate (Grams per Second) of Eight Experiments

Spheronizer Time, min	Spheronizer Speed, rpm	
	700	1010
1.0	17.5	18.5
3.0	18.6	20.8

water content, a much smaller decrease in percent fines occurred since few fines were present. A greater decrease in percent fines occurred at the low spheronizer time as water content was increased, although fewer fines were present throughout at the high spheronizer time. The screen size–spheronizer speed interaction was explained by noting that no change in percent fines was observed as spheronizer speed was increased at the low screen size but a large increase in percent fines occurred at the high screen size. As screen size increased, a much greater increase in percent fines was noted at the high spheronizer speed.

The screen size–spheronizer time interaction was explained by noting that, as spheronizer time was increased, a greater decrease in percent fines was apparent at the high screen size, although fewer fines were present throughout at the low screen size. As screen size increased, a greater increase in percent fines occurred at the low spheronizer time. The spheronizer speed–spheronizer time interaction was explained by noting that, as spheronizer time increased, a greater decrease in percent fines occurred at the high spheronizer speed, the values at both levels of spheronizer speed being nearly equal at the high spheronizer time. As spheronizer speed increased, a greater increase in percent fines occurred at the low spheronizer time.

Lower levels of fines may be obtained at high water content and spheronizer time but low screen size and spheronizer speed. If it were necessary to use screens with relatively large openings, low percent fines could be obtained at high water content. Even lower percent fines would be obtained under these conditions at low spheronizer speed or high spheronizer time. When using screens with small openings, changing spheronizer speed or spheronizer time had little effect on percent fines.

Maximum Percent on One Sieve Fraction—From sieve analysis data, the maximum percent of granules on a single sieve fraction was obtained. When using 0.8-mm screens in the extruder, this maximum occurred in the 20–30-mesh fraction for the eight experiments run at the high water content and in the 30–40-mesh fraction for the eight experiments run at the low water content.

When using 1.5-mm screens in the extruder, the maximum occurred 12 times in the 20–30-mesh fraction and four times in the 16–20-mesh fraction, the latter all occurring at the high water content.

Granule Friability—A value of 10.0 is maximum and would indicate 100% friability of a 10.0-g sample. The significant main effect indicated that an increased water content, spheronizer speed, or spheronizer time resulted in granulations with a decreased granule friability. The significant first-order interaction is shown in Table XIII. An increased spheronizer speed increased granule friability much more at the low water content. A decreased water content resulted in a greater increase in granule friability at the low spheronizer speed.

If, as indicated in this study, slight changes in process variables can significantly affect granulation properties, the spheronizing system might prove to be a useful research tool in addition to its production-oriented applications. Certainly, if granule properties can be controlled, correlation of other observed data should be facilitated.

While only one system was studied, experiments with other substances give reason to expect that most formulations could be modified to provide soft granulations for tablet compression or harder, more dense particles suitable for coating once the effects of process variables have been characterized.

Properties of the granules may change on aging, and Reier and Shangraw (6) reported effects of aging related to storage of tablets prepared with microcrystalline cellulose as the inert ingredient. The friability test used here plus a granule strength test such as was proposed by Ganderton and Hunter (7) could be of value in specific formulations where aging effects might be expected.

The advantages provided by pellet-type pharmaceuticals have led to a renewed interest in several techniques for agglomerating powders, including the subjecting of wet powders to a vibrating surface or a cascading motion inside a tilted rotating drum (8). This agglomerating process has been called balling, glomulation, or pelletizing. The term spheronizing has been used (9), and it seems to be suited to the process performed by this system, particularly since the particulate product usually has a spherical shape, narrow size distribution, and increased density (10).

SUMMARY

The use of a complete factorial analysis to define the significant main effects and interactions between the variables of water content, extruder speed, screen size, spheronizer speed, and spheronizer residence time on various properties of pelletized granulations of acetaminophen produced by the spheronizing process was studied. Water content and spheronizer speed had a significant effect on all primary granulation properties studied and were involved in most of the first-order interactions noted.

The utility of factorial analysis as a tool for modifying product properties *via* changes in process conditions was given further support by a final experiment using intermediate values for the variables. All data from tests on the final batch fell within the ranges exhibited by the original series.

Dissolution Studies with a Multichannel Continuous-Flow Apparatus

C. CAKIRYILDIZ, P. J. MEHTA, W. RAHMEN, and D. SCHOENLEBER ˣ

Abstract □ A multichannel continuous-flow apparatus for dissolution rate measurements is described. Typical data are presented to demonstrate its utility for studies with bulk drug powders as well as with tablets and capsules without any change of setup. Procedures are given for the preparation of powder samples for dissolution studies and for a simple method of changing pH for "retard" tablets. The precision in dissolution rates obtained with this apparatus and method is 1–10% mean *RSD*. The advantages of the method are flexibility, reproducibility, and ability to obtain data in integral or differential form.

Keyphrases □ Dissolution rate measurements—design and evaluation of multichannel continuous-flow apparatus, application to powders, tablets, and capsules □ Tablet dissolution rates—design and evaluation of multichannel continuous-flow apparatus, also applied to powders and capsules □ Capsule dissolution rates—design and evaluation of multichannel continuous-flow apparatus, also applied to powders and tablets □ Drug powder dissolution rates—design and evaluation of multichannel continuous-flow apparatus, also applied to tablets and capsules

During the past several years, several dissolution rate testing methods have been developed. The beaker method (1, 2), the rotating-basket method (3–5), the rotating-flask method (6), the pressure change method (7), continuous-flow methods with or without cumulating reservoirs (8–22), and others (23–25) are important.

The continuous-flow (7, 8) and pressure change (7) methods have been stated to possess several advantages over the other methods. These advantages include flexibility, reproducibility, the possibility of obtaining data in differential or integral form, the ability to discriminate between similar formulations of the same drug, and the maintenance of sink conditions in the system.

Although a modified beaker method is both simple and adaptable for dissolution rate testing with solid dosage forms, this method gave poorly reproducible dissolution measurements with micronized and difficult-to-wet substances in bulk form. Therefore, a continuous-flow apparatus suitable for both drug substances (powders) and solid dosage forms was developed. The cell is designed to obtain a free flow of the dissolution medium even with large tablets, and

Dissolution Studies with a Multichannel Continuous-Flow Apparatus

C. CAKIRYILDIZ, P. J. MEHTA, W. RAHMEN, and D. SCHOENLEBER ˣ

Abstract □ A multichannel continuous-flow apparatus for dissolution rate measurements is described. Typical data are presented to demonstrate its utility for studies with bulk drug powders as well as with tablets and capsules without any change of setup. Procedures are given for the preparation of powder samples for dissolution studies and for a simple method of changing pH for "retard" tablets. The precision in dissolution rates obtained with this apparatus and method is 1–10% mean *RSD*. The advantages of the method are flexibility, reproducibility, and ability to obtain data in integral or differential form.

Keyphrases □ Dissolution rate measurements—design and evaluation of multichannel continuous-flow apparatus, application to powders, tablets, and capsules □ Tablet dissolution rates—design and evaluation of multichannel continuous-flow apparatus, also applied to powders and capsules □ Capsule dissolution rates—design and evaluation of multichannel continuous-flow apparatus, also applied to powders and tablets □ Drug powder dissolution rates—design and evaluation of multichannel continuous-flow apparatus, also applied to tablets and capsules

During the past several years, several dissolution rate testing methods have been developed. The beaker method (1, 2), the rotating-basket method (3–5), the rotating-flask method (6), the pressure change method (7), continuous-flow methods with or without cumulating reservoirs (8–22), and others (23–25) are important.

The continuous-flow (7, 8) and pressure change (7) methods have been stated to possess several advantages over the other methods. These advantages include flexibility, reproducibility, the possibility of obtaining data in differential or integral form, the ability to discriminate between similar formulations of the same drug, and the maintenance of sink conditions in the system.

Although a modified beaker method is both simple and adaptable for dissolution rate testing with solid dosage forms, this method gave poorly reproducible dissolution measurements with micronized and difficult-to-wet substances in bulk form. Therefore, a continuous-flow apparatus suitable for both drug substances (powders) and solid dosage forms was developed. The cell is designed to obtain a free flow of the dissolution medium even with large tablets, and

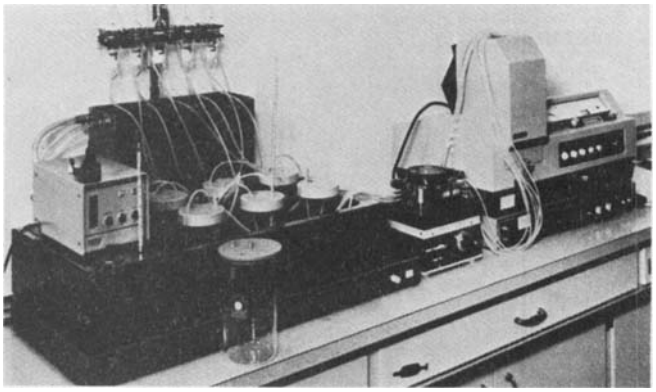

Figure 1—*Multichannel continuous-flow apparatus.*

it is leakproof under the pressure generated when using membrane filters of a very small pore size.

The apparatus is multiple channel, so up to five samples can be studied at one time, and it is capable of being automated. Several automated dissolution devices are described in the literature where spectrophotometry (26–35), potentiometry (4, 36), conductometry (37, 38), and other methods (39, 40) are employed for the measurement of drug in solution. Since most drug substances possess a chromophore in the UV region, spectrophotometry is widely used.

Examples of the determination of the dissolution rate of compressed powders (41, 42) and pellets (43) are known. Some trials have been reported concerning bulk drug powders, but a satisfactory and reproducible method has not been described (7, 8, 10–16, 24), especially for difficult-to-wet powders.

This report deals with a six-channel apparatus for the determination of the dissolution rate of drug powders as well as of tablets and capsules. The special treatment of powder samples is described in detail.

EXPERIMENTAL

Apparatus—The dissolution system (Fig. 1) consists of a six-channel peristaltic pump[1], a thermostatted water bath[2] with a magnetic stirring plate for six beakers, an additional smaller water bath[2], a spectrophotometer[3] equipped with an automated cell changer[4] and a recorder[4], and five identical independent dissolution units with a sixth one for circulation of a reference solution.

The dissolution cell (sample compartment: height 60 mm, i.d. 25 mm) is shown in an exploded view in Fig. 2. A filter[5] is placed between the upper and the lower flanges to restrict the dissolution process to the cell by preventing any undissolved particles from being carried over to the reservoir containing the dissolution medium. A stainless steel sieve is placed above the filter to provide mechanical strength against pressure which may develop from the use of membrane filters. Strong clamps are used to make the system leakproof.

From the reservoir, the dissolution medium goes (*via* the pump) to the flow-through quartz cell, to the bottom of the dissolution cell, and, from its top, returns to the reservoir. All connections are made by silicone tubing (3 mm i.d., 5 mm o.d.).

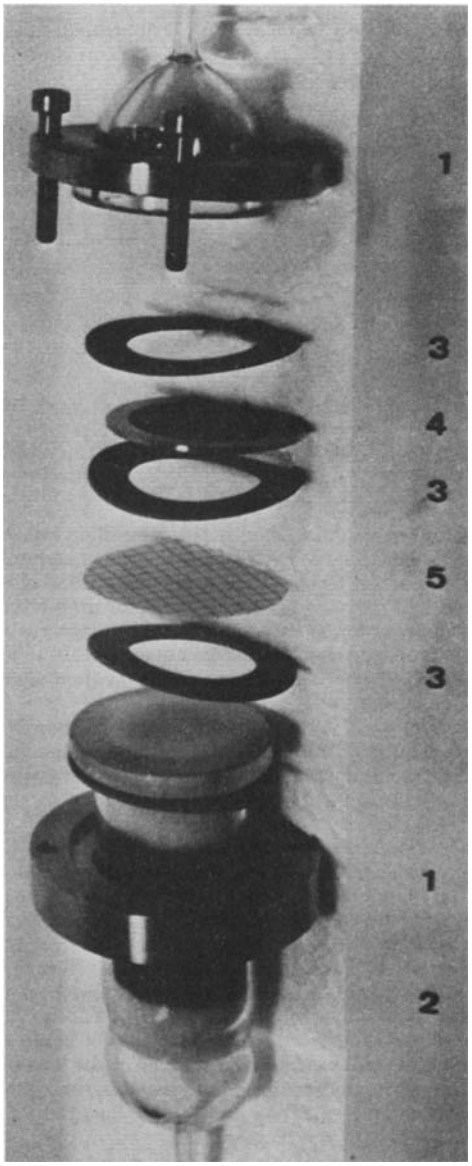

Figure 2—*Dissolution cell filled with drug powder–glass beads mix (exploded view). Key: 1, stainless steel clamp; 2, upper and lower parts of dissolution cell (sample compartment in lower part: height 60 mm, i.d. 25 mm); 3, rubber gaskets; 4, stainless steel sieve (18 mesh U.S.); and 5, filter.*

Preparation of Drug Powder Samples—About 35 g of glass beads (0.2 mm diameter) are divided into two portions. The first portion is placed in a special mixing flask (Fig. 3), and a calculated amount of drug powder is weighed onto these beads. Then the second portion is poured on top of the powder. The flask is rotated at the lowest speed on a rotary evaporator[6] without vacuum for 5 min. The mixture is then quantitatively transferred over a 1-cm bed of glass beads in the lower part of the dissolution cell. The remaining space is filled with more glass beads to the ground joint. A membrane filter (0.47 μm) and a stainless steel sieve are placed between rubber gaskets, the upper portion of the dissolution cell is placed in position, and the flanges are securely clamped (Fig. 2).

General Procedure—*Capsule Dissolution Studies*—One capsule, weighted by a ring of stainless steel wire slipped carefully over it, is placed on a bed of glass beads (0.2 mm, 20 g) in the dissolution cell. A membrane filter (0.47 μm) is used. The cell is closed as described previously.

Tablet Dissolution Studies—One tablet is placed on top of a

5	33	68	93
7	49	83	99
10	58	91	102
15	67	94	
20	79	95	
25	86	96	
30	92	97	
Mean *RSD*	7.4% (8 runs)	4.7% (10 runs)	1.6% (10 runs)
$t_{63.2\%}$	12.5 min	4.7 min	2.6 min

bed of glass beads (0.2 mm, 20 g) in the dissolution cell. A cellulose fleece filter is used. The cell is closed as described earlier.

Measurement of Drug Dissolution—One liter of simulated gastric fluid USP (without pepsin) is used for drug powders. Less liquid is employed for capsules and tablets so that the maximum concentration of drug in solution does not exceed 10–15% of its saturation solubility. The temperature of the medium is maintained at 37°.

A flow rate of 8.0 ± 0.2 ml/min is used for drug powder, and the same rate or 16.0 ± 0.5 ml/min is used for capsule dissolution studies. These rates minimize a buildup of pressure at the membrane filter and provide enough points of measurement to characterize the dissolution curve.

For tablet dissolution studies, a flow rate of 33.0 ± 1.0 ml/min (about 2 liters/hr) and a cellulose fleece filter are used. The cellulose fibers are randomly arranged, and the pores are small enough to prevent particles formed by tablet disintegration from passing through the filter.

Changing pH of Dissolution Medium for "Retard" Tablets and Capsules—Simulated gastric fluid USP (without pepsin) is used for the first 2 hr. To change the pH, 22.50 g of trisodium phosphate ($Na_3PO_4 \cdot 12H_2O$) is added per liter of fluid.

The circulating pumps should be stopped at the time of addition and restarted when all trisodium phosphate has gone into solution. After circulation of the medium for 3–5 min, the pH is 7.5 ± 0.1.

RESULTS AND DISCUSSION

Apparatus—The apparatus as described has been used successfully during the past 3 years for various dissolution studies. Before that time, several trials using a Millipore cell[7] had been made. Experience showed that the inside of the cell was easily scratched by the glass beads. A more serious drawback was the low recovery observed in the powder studies, due to the retention of the undissolved drug in scratches on the inner wall of the cell and the adhesion of powder particles to the polycarbonate material. Tingstad *et al.* (11, 44) recently employed the same cell for tablets (but without using glass beads).

Drug Powder Dissolution Studies—Measurement of dissolution of drug powders in media of high surface tension (such as water or simulated gastric fluid) is frequently difficult because of irregular wetting of the powder by the medium. Even weak agglomerates, which are present in every fine powder or are formed when the substance is poured, dissolve very slowly (at a rate comparable to the dissolution of similarly sized large single crystals), thus yielding unrealistic dissolution times. In some cases there was no complete solution even after 24 hr.

This effect is especially observed with particles carrying small electrostatic charges, *e.g.*, very fine and micronized powders. When such powders are mixed with small glass beads (average weight about 10 μg) as described under *Experimental*, the effective surface for dissolution is considerably increased. The majority of clusters and single substance agglomerates is destroyed by the mixing process, and the buildup of new ones is substantially reduced. Sim-

ilar phenomena take place during dry powder mixing for a solid formulation.

At this point, checking by microscope showed no instance of any breakdown of primary particles during the mixing step. Therefore, the increase of the dissolution-affecting surface area of a powder is exclusively due to the disintegration of agglomerates and not to a size diminution of primary particles. So the mixing procedure helps to create better defined starting conditions (and more similarity to a formulation mix), thus providing a more reproducible drug powder dissolution process than without pretreatment.

Table I presents results obtained from the same relatively insoluble drug substance (Drug Substance A) in micronized and unmicronized form after mixing with 0.2-mm glass beads. As expected, the micronized powder dissolved more rapidly than the nonmicronized powder; without pretreatment, more than 24 hr was required for the dissolution of both forms due to cluster formation. This trial and other experience led to the conclusion that the more homogeneous the glass bead mix is, the smaller the relative standard deviation of the measurement will be. Drug Substance A has a strong agglomeration tendency, so a mean relative standard deviation of only 4.7% compared to the nonmicronized value of 7.4% was achieved. Fairly soluble and easily wettable drug powders usually yield more reproducible values, with relative standard deviations of about 2% as shown for Drug Substance B in Table I.

Capsule and Tablet Dissolution Studies—In contrast to the procedure used for powder dissolution studies, capsules and tablets have to be placed on top of the glass beads to ensure an unimpeded decay or swelling of the pharmaceutical form. Capsules are weighted by a coil of stainless steel wire so that they will not float in the dissolution medium.

Tablets usually float in the liquid at the beginning of the dissolution rate measurement for about 10 sec. They then become wetted and sink onto the glass beads where they remain. Since this movement of the tablets only occurs in the first few seconds, the dissolution process is not influenced.

The dissolution profile of a drug substance as well as that of formulations is very strongly affected by changes in the liquid flow rate. With aspirin as an example, the dissolution behavior as a function of flow rate is shown in Table II for samples of differing particle size. Due to this interdependence, a highly constant flow rate of the dissolution medium is necessary; this point was considered in establishing the rather tight specifications.

The 8.0-ml/min flow rate was chosen as a standard for powders since—in contrast to higher rates—it permitted the ready recognition of differences in the first, steep range of the dissolution profile. The data in Table II also confirm the well-known findings of the reduction of dissolution rate with increasing particle size (45).

The 33.0-ml/min (2 liters/hr) rate for tablets was chosen because this flow showed an optimum dissolution rate correlation with the USP rotating-basket method, corresponding to the findings described by Tingstad *et al.* (12). Figure 4 gives an example of a typical correlation plot for two kinds of compression-coated tablets tested with both methods.

The reproducibilities of the flow-through method and the USP method were compared measuring the same batch of tablets. The results are listed in Table III for four different tablet series. Obviously, the method described here is capable of providing more reproducible data than the official rotating-basket method, a fact that allows better discrimination between different species.

Even slight variations in manufacturing or in the composition of a formulation can be detected by measuring the dissolution rate. Figure 5 depicts the dissolution profiles of two tablet series having exactly the same composition but manufactured on different tablet machines. The results are plotted by the Rosin–Rammler–Sperling (RRS) method (46, 47). The $t_{63.2\%}$ corresponds to the time for dissolution of 63.2% of the drug. As can be seen from the plot, the variation of dissolution rate from one tablet to the other is significant.

Another example of the discriminating capability of this flow-through method is illustrated in Fig. 6. Here two tablets, differing only in the quality of a single excipient (cellulose acetate phthal-

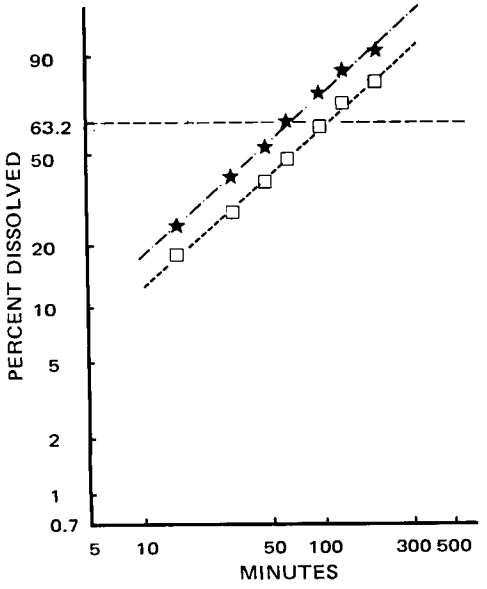

Figure 6—*Dissolution profile of equally composed and identically manufactured retard tablets, differing only in quality of a single excipient (cellulose acetate phthalate) (RRS diagram). Key: ★, Tablet A, cellulose acetate phthalate quality I, $t_{63.2\%}$ = 63 min; and □, Tablet B, cellulose acetate phthalate quality II, $t_{63.2\%}$ = 101 min.*

Table III—Experimental Comparison of Reproducibilities of Rotating-Basket and Flow-Through Methods Established with Four Completely Different Tablets

Tablet Series	Mean *RSD*, out of Eight Values, %: USP Rotating-Basket Method, 60 rpm	Flow-Through Method, 33.0 ml/min
1	2.9	2.7
2	6.5	5.1
3	4.5	2.4
4	12.2	6.8

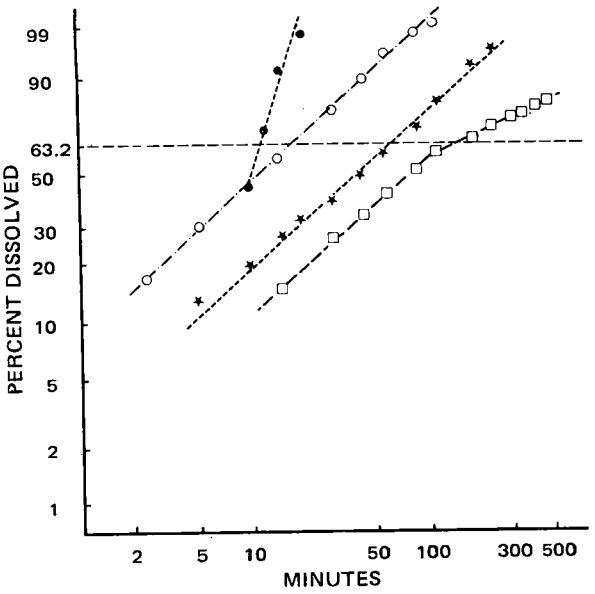

Figure 7—*Dissolution rate data. Key:* ●, *tetracycline capsule;* ○, *Tablet 1, antiobesity drug;* ★, *Tablet 2, neuroleptic drug; and* □, *Tablet 3, retard formulation.*

ate) but manufactured in the same way in every respect, were measured. The plot exhibits a significantly different dissolution behavior.

In Fig. 7, applications are presented of the flow-through method to a hard gelatin capsule, a tablet, a sugar-coated tablet, and a retard tablet.

Dissolution from hard gelatin capsules of tetracycline hydrochloride was carried out using a 16.0-ml/min flow rate. The capsules needed more than 5 min to open, but drug dissolution was rapid thereafter.

The dissolution data of an antiobesity drug (Tablet 1) showed good tablet-to-tablet uniformity (s_{mean} from six values was less than 1%). The slope of the straight line in the RRS plot is about 0.95, indicating an apparent first-order dissolution process. The $t_{63.2\%}$ is 17 min.

The profile for a neuroleptic drug from a sugar-coated tablet (Tablet 2) yielded a slope of 0.9 and a $t_{63.2\%}$ of 70 min in the RRS plot (Fig. 7). The tablet-to-tablet uniformity was not as good as in the previous case (s_{mean} from eight values was about 6%).

Release of phenylpropanolamine from an experimental retard formulation (Tablet 3) is also shown in Fig. 7. The pH of the dissolution medium was changed to 7.5 after 2 hr, as described under *Experimental.* At this point, a decrease in slope indicates a slowdown of the dissolution process at higher pH.

The procedure for the change of pH described here involves a simple addition of solid trisodium phosphate. An increase of about 2% in the volume of the dissolution medium takes place. The resulting pH of 7.5 is equal to that of simulated intestinal fluid USP; the ionic strength is, however, 0.248, almost twice as much as that of the USP solution. This procedure is suitable in all cases where drug dissolution is not affected by ionic strength in the 0.12–0.25 range, and it is applicable to the USP–NF dissolution tests as well as to continuous-flow methods with cumulating reservoirs. For the latter procedure, the well-known half-change method can be used.

Unfortunately, many modern drugs are used in low doses and, therefore, yield only low absorbance values. For the determination of the dissolution rate of such drugs from their retard dosage forms, the described procedure for change of pH is very useful because there is no impediment to the analytical assay by the dilution. Tromethamine has been used to change pH when working with phosphate-incompatible drugs.

CONCLUSION

The described apparatus is versatile enough to determine the dissolution patterns of drug powders and of tablet and capsule formulations without any change of the experimental setup. The novel preparation of drug powder samples for dissolution studies is given in detail as well as a facile procedure to change pH during dissolution of retard preparations. In 3 years' experience with the apparatus, it has been simple to use and has yielded reproducible dissolution data. In addition to being capable of showing formulation differences, the apparatus is sensitive enough to reveal process changes.

The criteria for a dissolution apparatus proposed by Wagner (48) are satisfied. Although the apparatus has been used with a cumulating reservoir to yield integral dissolution data, it is quite suitable for obtaining data in the differential form. Finally, the multichannel capability allows the determination of up to five dissolution rates concomitantly.

Enhancing Fluidity of Concentrated Antacid Suspensions

ALLEN HEYD [x] and DADI J. DHABHAR

Abstract □ Highly concentrated antacid suspensions can be fluidized by adding a colloidal polyelectrolyte to alter the charge on antacid particles from positive to negative. A deflocculated state is assumed to exist in such preparations, as supported by electrophoretic and viscometric analyses. When viscosity is directly correlated with the ζ-potential, viscometry becomes particularly useful in confirming that the suspension has been maximally fluidized.

Keyphrases □ Antacid suspensions, concentrated—fluidized by addition of colloidal polyelectrolyte, viscosity correlated with ζ-potential, electrophoretic and viscometric measurements □ Fluidized antacid suspensions—preparation using colloidal polyelectrolyte, viscosity correlated with ζ-potential, electrophoretic and viscometric measurements

Primary goals in formulating stable suspensions of coarse particles are to prevent caking and, thus, to maintain a stable shelflife. Obtaining these objectives becomes particularly difficult when preparations are highly concentrated because the classical techniques of flocculation no longer apply.

Flocculation appears to be the preferred method for preparing coarse suspensions which can be redispersed easily by shaking (1–3). In the phenomenon of flocculation, the force of attraction between particles predominates, causing the particles to form loose aggregates. Should repulsion forces prevail, however, the particles separate or deflocculate, settling slowly. A suspending and/or gelling agent is required to stabilize such a preparation to prevent caking.

In a study of the surface characteristics of particles and the intensity of particle interaction related to the caking of insoluble particles in aqueous dispersion, flocculation was controlled by adding an electrolyte; the resulting product did not cake (4). Martin (5), in reviewing the physicochemical principles applicable to caking and flocculation, emphasized that maximal flocculation occurred within a range of low positive to low negative ζ-potential. Deflocculation and caking occurred at either extreme, *e.g.*, high positive or high negative (Fig. 1). Haines and Martin (6), in studying the electrokinetic behavior of insoluble drug particles, correlated the magnitude of the ζ-potential, as calculated from electrophoresis data, with the tendency to cake.

Flocculation technology evolved from research performed on suspensions containing no more than 10% solids. Thus, current flocculation technology did not seem applicable to the preparation of coarse suspensions containing, for example, 40% solids. Antacid preparations containing 40% solids do not contain enough free water to achieve a low enough viscosity and easy flow. Furthermore, concentrated suspensions cannot be flocculated to a maximal extent since the potential maximum sedimentation volume on dilution would greatly exceed the original total volume (7).

An alternative to flocculation is fluidization. An elegant system was described for a superior barium sulfate suspension used as a diagnostic contrast medium (8). The use of radiographic techniques to evaluate the *in vivo* performance of the system was also described (8). In addition, Brown (9) referred to increased fluidity in the preparation of highly concentrated, gelating, antacid systems.

In an investigation of this system (8, 9), the fluidization technique was evaluated. Highly concentrated antacid suspensions of high fluidity (*e.g.*, marked flowability and low viscosity) can be successfully pre-

pared by this technique using a low molecular weight, colloidal polyelectrolyte as a "fluidizing" agent.

Theoretically, in this system (8, 10) the negatively charged colloidal polyelectrolyte would selectively adsorb onto the surfaces of insoluble particles, such as antacid particles, and deflocculate them once the ζ-potential exceeds the critical value. The purposes of this study were: (*a*) to determine whether such concentrated suspensions can, in fact, be fluidized; (*b*) to determine whether electrophoresis can be utilized to follow the degree of fluidization; and (*c*) to correlate ζ-potential results with viscosity data.

EXPERIMENTAL

Materials—The physical characteristics of the substances used in preparing two antacid suspensions are listed in Table I. Carrageenan sodium[1] of low molecular weight (8000–10,000) served as the negatively charged colloidal polyelectrolyte in each instance.

Aluminum Hydroxide Suspension (25%)—For viscosity measurements, a 25% dispersion of aluminum hydroxide was prepared. The concentration of carrageenan sodium was increased stepwise from 0.2 to 3.2% in seven replicate samples intended for viscosity determinations. Because its small particle size produces a good suspension and allows unhindered movement in the electrophoresis cell, a 0.025% dispersion of aluminum hydroxide served as a

[1] Marine Colloids Inc., Springfield, N.J.

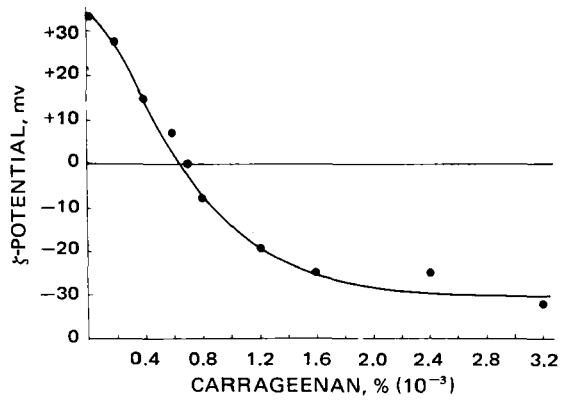

Figure 2—*ζ-Potential of aluminum hydroxide as a function of carrageenan concentration.*

model for the initial measurements of the ζ-potential. It was assumed that this dilution from a 25% dispersion would not alter the equilibrium between the electrolyte and solids and thereby affect the results from a practical standpoint. Concentrations of carrageenan sodium added to the 0.025% suspension were increased stepwise from 0.0002 to 0.0032% in seven replicate samples to determine the effect of a negatively charged colloidal polyelectrolyte upon the ζ-potential of aluminum hydroxide.

Antacid Mixture (38%)—A prototype antacid mixture (38% suspension) was prepared consisting of magnesium hydroxide, dried aluminum hydroxide gel, and calcium carbonate (1:2:6). The content of carrageenan sodium was increased stepwise from 0.2 to 3.2% in eight replicate samples intended for viscosity determinations. The relatively large size of the magnesium hydroxide and calcium hydroxide particles did not permit accurate electrophoretic measurements so the ζ-potential could not be calculated.

Measuring ζ-Potential—Samples of the aluminum hydroxide preparation containing graded amounts of polyelectrolyte were placed in an electrophoresis cell[2] having a molybdenum anode and a platinum cathode. The setting was 150 v. Particles were tracked on a stereoscope[3] using an 8× objective. The ζ-potential was calculated from electrophoretic mobility (EM) data using a standard conversion formula (9):

$$\text{absolute EM} = \frac{(\mu\text{m/sec})}{(\text{v/cm})} = \frac{(\mu\text{m})(\text{cm})}{(\text{v})(\text{sec})} \qquad \text{(Eq. 1)}$$

The mobility of charged particles (expressed in micrometers) was determined from their tracking length as seen in a full-scale 8× ocular micrometer. The time required to traverse 1 full-scale μm division was measured in seconds, v represented the voltage applied, and the distance between electrophoresis cell ports was measured in centimeters.

Measuring Viscosity—Viscosity was determined with a viscometer[4] mounted on a helipath stand. T-bar spindles were used in obtaining measurements of the 25% aluminum hydroxide suspension, while standard round spindles were employed in testing the 38% antacid mixture. The effect upon viscosity resulting from controlling the surface potential of suspended particles with carrageenan could not be determined in the presence of a suspending or gelling agent because the latter "dampened out" the fluidizing action of a polyelectrolyte. However, carrageenan sodium in the low molecular weight range used did not contribute to viscosity.

RESULTS AND DISCUSSION

In the aluminum hydroxide suspension, a change in the ζ-potential was associated with increasing concentrations of carrageenan sodium (Fig. 2). This negatively charged, hydrophilic, colloidal polyelectrolyte reduced the positive charge, causing a rapid fall in the ζ-potential. A negative ζ-potential was reached at 0.7×10^{-3}% carrageenan concentration.

Maximum fluidization was achieved at approximately 1.6 ×

[2] Riddick Type II UVA, Riddick Zeta Meter Inc., New York, N.Y.

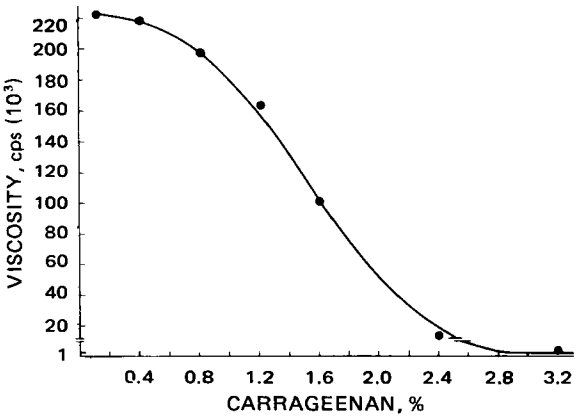

Figure 3—*Viscosity of aluminum hydroxide in water as a function of carrageenan concentration.*

10^{-3}% colloid, as evidenced by a plateau in the ζ-potential and as confirmed with viscosity data. Higher concentrations produced no further change. The ζ-potential curve indicates that the aluminum hydroxide particles acquired a negative charge, corresponding to a negative ζ-potential, which was great enough to surpass the critical value and thus become deflocculated (5). If deflocculation occurs, then it is the mechanism by which fluidization is achieved.

Viscosity of the 25% aluminum hydroxide suspension decreased as the carrageenan concentration increased (Fig. 3). A plateau in viscosity occurred at about 2.4% colloid. Initially, the viscosity of the 25% suspension was approximately 220,000 cps; this preparation had a light paste-like consistency and did not pour. After 3.2% carrageenan was added, the viscosity decreased to approximately 1000 cps; the suspension poured easily from a narrow-necked bottle. An inverse correlation is apparent between colloid concentration and viscosity (Fig. 3) as well as ζ-potential (Fig. 2).

Similarly, the viscosity of the 38% antacid mixture decreased with increasing amounts of carrageenan (Fig. 4). Initially, the viscosity of the mixture was about 1900 cps; it had a thick, lotion-like consistency. Viscosity began to approach the plateau at a concentration of 1.2% carrageenan; and at a concentration of 2.0% carrageenan, the viscosity reached a plateau. This preparation was a thin, smooth liquid which poured easily from a narrow-necked bottle. This change correlated closely with the change in the ζ-potential (Fig. 2).

When comparing viscosity data (Figs. 3 and 4) with ζ-potential values (Fig. 2), it appears that in both antacid systems the decrease in viscosity following the addition of a colloidal polyelectrolyte is correlated with a change from a positive to a negative ζ-potential. Viscometry, therefore, becomes a simple and practical replacement for ζ-potential determinations in this and similar systems. Viscometry can be particularly important when establishing a condition of maximal or optimal fluidization during the large-scale manufacture of antacid suspensions.

These data demonstrate that fluidity of a concentrated antacid mixture can be achieved by using a colloidal polyelectrolyte (fluidizer) such as low molecular weight carrageenan sodium. The mechanism appears to be that the fluidizing agent—electronegatively

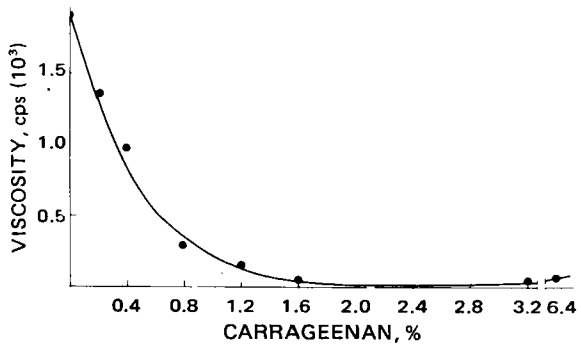

Figure 4—*Viscosity of an antacid mixture in water as a function of carrageenan concentration.*

charged—selectively adsorbs onto the positively charged antacid particles, deflocculating them (Fig. 1). Such adsorption imparts an electronegative charge (as measured by the ζ-potential) onto the antacid particles, decreasing the demand for water. In effect, particles become *dehydrated* relative to their earlier electropositive hydrated state (11).

The Derjaguin–Landau–Verwey–Overbeek theory, which describes the role of electrolytes in flocculation, is another possible explanation for the fluidization phenomenon. This theory has been reviewed frequently (1–4) and can be used to describe the concept of less water being associated with the antacid particles. As a result, a greater number of particles may be suspended in a given volume of water, thus enhancing the fluidity of the preparation. This fluidized suspension of low viscosity can then be made physically stable by incorporating suitable suspending and/or gelling agents.

Synthesis of *d*-Pilocarpine-*N*-$^{14}CH_3$

JOSEPH I. DeGRAW *x, JOHN S. ENGSTROM *, and EDWARD WILLIS ‡

Abstract □ The total synthesis of *d*-pilocarpine specifically labeled as *N*-$^{14}CH_3$ is reported. *dl*-Homopilopic acid was prepared as a key intermediate and resolved into the *d*-enantiomer *via* the α-methylbenzylamine salt. The penultimate intermediate, 2-mercaptopilocarpine, was desulfurized by oxidation with dilute hydrogen peroxide, minimizing isomerization to isopilocarpine. Procedures for the analysis of pilocarpine–isopilocarpine mixtures by *high-pressure* liquid chromatography are also described.

Keyphrases □ Pilocarpine-*N*-$^{14}CH_3$—synthesis *via dl*-homopilopic acid □ High-pressure liquid chromatography—analysis, pilocarpine–isopilocarpine mixtures

Comparative studies of pilocarpine bioavailability and pharmacokinetics, when administered by membrane-controlled drug delivery systems or eyedrops, have required the preparation of natural pilocarpine specifically labeled with ^{14}C. Accordingly, a total synthesis of pilocarpine-*N*-$^{14}CH_3$ was undertaken. At the terminal stage of the work, it was necessary to establish the purity of the pilocarpine, especially with regard to contamination by isopilocarpine. Chromatographic techniques such as GLC and TLC were not useful for detecting 1–5% of the isomeric impurity, but high-pressure liquid chromatography (HPLC) was quite effective.

DISCUSSION

Methods for the total synthesis of pilocarpine starting from furfural were reported previously (1, 2). The method used in this study is shown in Scheme I. The key intermediate, homopilopic acid (I), was prepared by a previously reported procedure (1). Optical resolution of the racemic acid so obtained was achieved *via* salt formation with (+)-α-methylbenzylamine to afford the required *d*-homopilopic acid. The *d*-acid was converted to the acid chloride, which was used to acylate di-*tert*-butylacetamidomalonate.

Acid hydrolysis of the ester (II) caused cleavage of the *tert*-butyl groups and subsequent decarboxylation to afford the *d*-homopilopyl aminomethyl ketone (III) as the hydrochloride salt. Condensation of III with methyl isothiocyanate yielded 2-mercaptopilocarpine (IV). The ring closure reaction was intensively investigated in cold runs, and a consistent yield of 38% was obtained regardless of changes in solvents, temperature, or ratio of reactants.

Removal of the 2-mercapto group by desulfurization with nickel produced unacceptable amounts of isopilocarpine, probably because of isomerization catalyzed by residual alkali in the nickel. In fact, even stirring pilocarpine hydrochloride with silver oxide in ethanol at room temperature to prepare the free base caused substantial isomerization. However, treatment of IV with aqueous hydrogen peroxide, followed by neutralization with sodium bicarbonate to pH 8 and subsequent extraction into methylene chloride, gave high yields of pilocarpine (V) containing about 5% isopilocarpine.

Methyl isothiocyanate-$^{14}CH_3$ was prepared from ^{14}C-methylamine hydrochloride by the procedure of Moore and Crossley (3). Condensation with III gave *d*-2-mercaptopilocarpine-*N*-$^{14}CH_3$ (IV), which was desulfurized with peroxide to afford *d*-pilocarpine-*N*-$^{14}CH_3$ (V). Thick-plate chromatography, followed by dilution with four parts of natural pilocarpine and recrystallization of the nitrate salt, yielded material containing 2% isopilocarpine as the only significant contaminant.

EXPERIMENTAL

Aliquots of ^{14}C-pilocarpine were subjected to HPLC[1] calibrated to separate pilocarpine, isopilocarpine, and pilocarpic acid (Fig. 1). The system used a cation-exchange resin[2] in a 10 × 0.6-cm i.d. column. The mobile phase was 0.2 *M* tromethamine buffer containing 5% isopropanol, pH 9.2. The flow was 0.4 ml/min at a pressure of 200–300 psi.

The locations of pilocarpine and isopilocarpine were verified by UV detection of unlabeled standards run simultaneously with the radioactive sample. Two-minute fractions were collected from the high-pressure column directly into counting vials. The fractions were counted in scintillator fluid[3], and a previously constructed quench curve was used for converting counts per minute to disintegrations per minute.

***d*-Homopilopic Acid (I)**—*dl*-Homopilopic acid was prepared by the procedure of DeGraw (1). A solution of 16.0 g (0.093 mole) of the *dl*-acid in 140 ml of warm absolute ethanol was treated with 11.3 g (0.093 mole) of *d*-α-methylbenzylamine followed by 490 ml of ether. After 2 hr, the crystals were collected and dried to leave 8.9 g, mp 106–119°. Four recrystallizations from ethyl acetate (30 ml/g) afforded 3.7 g of white crystals, mp 113–121°.

The salt was partitioned between 3 *N* hydrochloric acid and ether. The ether was dried over magnesium sulfate and evaporated to leave the theoretical weight of *d*-homopilopic acid as a clear

syrup, $[\alpha]_D^{23}$ + 82.2° (1% in ether). The melting point of the salt was not a reliable index of optical purity.

^{14}C-Methyl Isothiocyanate—This labeled reagent was prepared essentially by the procedure of Moore and Crossley (3). ^{14}C-Methylamine hydrochloride (387 mg, 5.73 mmoles) was dissolved in 0.68 ml of water, cooled to 0–5°, and treated with 0.38 ml (6.3 mmoles) of carbon disulfide followed by 515 mg (12.9 mmoles) of sodium hydroxide in 1.1 ml of water. After 30 min, the ice bath was removed and the mixture was stirred at ambient temperature for 60 hr. Ethyl chloroformate (0.61 ml, 6.40 mmoles) was added dropwise and stirring was continued for 1 hr.

The mixture was extracted with six 1-ml portions of methylene chloride, and the combined extracts were dried over magnesium sulfate. The solution was concentrated to one-half volume on a rotary evaporator and then transferred to a microdistillation assembly with an ice-cooled receiver. The remaining solvent was removed (bp 30–35°), and the product fraction was collected from 70 to 100° to afford 200 mg (48%) of yellow semisolid distillate. Yields of 65–70% were obtained in larger scale cold runs.

***d*-2-Mercaptopilocarpine-*N*-$^{14}CH_3$ (IV)**—*d*-Homopilopyl aminomethyl ketone hydrochloride (III) was prepared in 51% yield from I by the reported procedure (1), proceeding through the acyl di-*tert*-butylacetamidomalonate (II). To a stirred mixture of 200 mg (2.7 mmoles) of ^{14}C-methyl isothiocyanate, 277 mg (2.0 mmoles) of potassium carbonate, and 6.6 ml of 70% tetrahydrofuran was added 670 mg (2.7 mmoles) of *d*-amino ketone hydrochloride (III); stirring was continued for 14 hr. The upper layer was removed by pipet, and the lower aqueous phase was twice extracted with 1-ml portions of ether.

The combined organic extracts were evaporated *in vacuo*, and the residue was successively triturated with 2-ml portions of water and warm isopropanol. The residual solid was washed with ether and dried to leave 210 mg (32%) of pale-yellow crystals. TLC [silica gel, chloroform–acetone (1:1)] showed a single spot, R_f 0.75, identical with authentic IV as detected by UV and iodine vapor; radioautography also showed a minor spot at the origin.

***d*-Pilocarpine-*N*-$^{14}CH_3$ (V)**—A mixture of 210 mg (0.87 mmole) of IV and 1.35 ml (4.0 mmoles) of 8% hydrogen peroxide was stirred for 2 hr at ambient temperature, and then 3.2 ml of saturated sodium bicarbonate was added (pH 7–8). The solution was extracted with three 5-ml portions of methylene chloride, and the extracts were dried over magnesium sulfate and evaporated *in vacuo* to leave 190 mg of a clear gum.

The crude material was subjected to preparative chromatography [silica gel, chloroform–methanol (9:1)]. The chromatogram showed an elongated single spot at R_f 0.30–0.45. The material from R_f 0.30–0.35 was scratched out and extracted with methanol to afford 11 mg of gum; HPLC indicated 97% of pilocarpine, 2% of isopilocarpine, and approximately 1% of an unidentified substance near the origin; $[\alpha]_D^{23}$ + 106° (1.1% in methylene chloride) [lit. (4) $[\alpha]^{18}$ + 106°]. The material at R_f 0.35–0.45 was similarly handled to afford 109 mg; HPLC showed 85% of pilocarpine, 9% of isopilocarpine, and 6% at the origin.

A 30-mg portion of this latter fraction (specific activity 38 mCi/mmole) was diluted with 119 mg of natural pilocarpine and treated with an equivalent of 0.5 *N* nitric acid. The water was removed *in vacuo*, and the residual nitrate salt was twice recrystallized from ethanol to afford 150 mg (77%) of white crystals. The salt was dissolved in 5 ml of water and treated with 2 ml of saturated sodium bicarbonate. This solution was extracted with three 2-ml portions of methylene chloride which, after drying and evaporation, yielded 118 mg; HPLC showed 97% of pilocarpine, approximately 2% of isopilocarpine, and less than 1% at the origin.

Paramethadione and Metabolite Serum Levels in Humans after a Single Oral Paramethadione Dose

D. J. HOFFMAN and A. H. C. CHUN ˣ

Abstract □ A GLC method was developed to determine quantitatively paramethadione and its major metabolite, 5-ethyl-5-methyl-2,4-oxazolidinedione, in serum. The method was reproducible and sensitive to 0.2 μg/ml. After administering a single 300-mg oral dose to human subjects, the average paramethadione serum levels of 6.0 μg/ml occurred at 1 hr and decreased to 0.3 μg/ml after 48 hr. Metabolite serum levels gradually increased to 8.4 μg/ml at 32 hr and were still at this level at 48 hr, which was the last sampling point.

Keyphrases □ Paramethadione and metabolite—serum levels, single oral dose, humans, GLC analysis □ 5-Ethyl-5-methyl-2,4-oxazolidinedione—paramethadione metabolite, GLC determination of serum levels, single oral dose, humans □ GLC—analysis, paramethadione and metabolite serum levels, humans

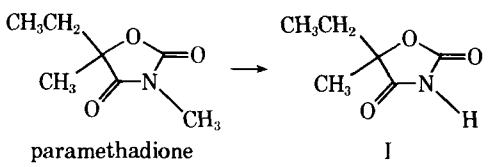
Several GLC methods (1, 2) are available for the quantitative determination of anticonvulsants in biological fluids. However, these methods lack the sensitivity needed to determine serum levels after a single oral dose. Butler (3) studied the metabolism of paramethadione in humans given multiple doses of paramethadione. A UV spectrometric method (4) was used to determine metabolite, 5-ethyl-5-methyl-2,4-oxazolidinedione (I), serum levels. Paramethadione levels were not determined by this method.

The metabolism of paramethadione to I is shown in Scheme I. A method is presented that can quantitatively determine paramethadione and its metabolite in serum after administration of a single oral 300-mg dose of paramethadione to humans.

EXPERIMENTAL

Subjects—Three normal, healthy, adult male subjects were fasted 8 hr prior to dosing (only water was allowed). Paramethadione capsules[1] were administered with 120 ml (4 oz) of water. A standard breakfast was provided to the subjects after the 2-hr blood sample was withdrawn. Twenty milliliters of blood was taken before dosing and at 0.5, 1, 2, 4, 8, 24, 32, and 48 hr after dosing. The serum was separated and frozen until assayed.

GLC—Chromatographic separations were performed with a gas chromatograph[2] equipped with an electronic integrator[3], automatic sampler, and dual flame-ionization detectors. Two 1.85-m × 2-mm (i.d.) glass columns were treated overnight with a 5% dimethylchlorosilane solution in toluene and then packed with 3% OV-17 coated on 100–120-mesh Gas Chrom Q[4]. All glass wool was also treated with the 5% dimethylchlorosilane solution. Before the columns were connected to the detectors, they were further silated by injecting 5 μl of *N,O*-bis(trimethylsilyl)acetamide three times at 10-min intervals and were conditioned overnight at 260°.



paramethadione I

Scheme I

The flow of helium carrier gas was 45 ml/min. The hydrogen flow rate was 30 ml/min, and the air flow rate was 250 ml/min. The temperature of the injection port was 172° and that of the detector was 190°. The oven temperature was programmed as follows: 2 min at 90°, then to 130° at 8°/min, and hold at 130° for 2 min. The electrometer range was 10 with an attenuation of ×4.

Isolation and Assay Procedures (1)—To 4 ml of serum in a 15-ml conical centrifuge tube was added 3 ml of 1 *N* H_2SO_4 and 3

[a] Sample lost.

ml of 10% sodium tungstate dropwise, and the solution was mixed. After standing for 15 min, the samples were centrifuged at 3000 rpm for 15 min. The supernate (6 ml) was transferred to a 20-ml screw-capped tube containing 0.2 ml of 1 *N* H_2SO_4. Three grams each of anhydrous sodium sulfate and crystalline magnesium sulfate (0.7 μg/ml) was added with mixing. Chloroform (7 ml) containing the internal standards trimethadione (0.3 μg/ml) and 5-dimethyl-2,4-oxazolidinedione (0.7 μg/ml) was added, and the sample was shaken for 10 min and centrifuged at 2500 rpm for 10 min.

The aqueous layer was discarded by aspiration, and 5 ml of the chloroform layer was evaporated to about 0.1 ml at 30° with a gentle stream of air. Chloroform (0.1 ml) was added with mixing and then transferred to a microvial[5] and capped. The sample (10 μl) was automatically injected into the gas chromatograph, and the temperature program was initiated.

Standard serum solutions of both paramethadione and I were prepared in duplicate at concentrations of 0, 0.5, 1.0, 2.0, 4.0, and 8.0 μg/ml. Standard curves were constructed by plotting concentration *versus* paramethadione–trimethadione and I–5-dimethyl-2,4-oxazolidinedione peak area ratios.

RESULTS AND DISCUSSION

This GLC method has sufficient sensitivity to determine quantitatively paramethadione and its metabolite in serum after a single oral dose of paramethadione. The sensitivity of the method is 0.2 μg/ml. This value is based on a sample signal equivalent to about 2% of full-scale deflection. The precision of the assay is shown in Table I. Variance, as expected, was greater for the low concentrations. Coefficients of variation for paramethadione ranged from 5.5% at 8 μg/ml to 10.2% at 0.5 μg/ml. For I, they ranged from 3.7 to 8.4% at the same concentrations. Standard curves of serum paramethadione or metabolite concentrations *versus* peak area ratios were linear to at least 8 μg/ml. As shown in Fig. 1, GLC tracings were free of interfering peaks.

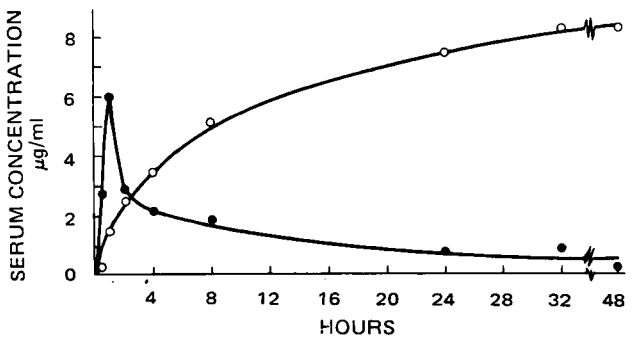

Figure 2—*Mean serum paramethadione and metabolite levels after oral administration of 300 mg of paramethadione in humans. Key: ●, paramethadione; and ○, Metabolite I.*

Individual paramethadione and metabolite serum levels are shown in Table II. The mean serum levels are plotted in Fig. 2. Paramethadione is rapidly absorbed with peak serum levels of 5.4–7.6 μg/ml occurring between 0.5 and 1 hr after a single 300-mg oral dose of paramethadione. A biphasic decline of serum paramethadione was observed, with serum levels decreasing to 0.3 μg/ml at 48 hr.

There appeared to be a slight rise in levels at 32 hr. The average serum half-life of the β-phase determined graphically was estimated to be 16 hr for the three subjects. This value is comparable to a serum half-life of 17 hr for trimethadione[6].

Metabolite serum levels were detectable within 1 hr after drug administration and gradually increased to 8.4 μg/ml in 32 hr; they remained at this level up to the last sampling time (48 hr) (Fig. 2). These results suggest that paramethadione is rapidly metabolized to I and that this metabolite has a long serum half-life, as evidenced by the apparent plateau of serum levels after 48 hr. This view is in accord with the data of Butler (3), from which a serum half-life of 14 days was estimated.

5-Dimethyl-2,4-oxazolidinedione, the metabolite of trimethadione, has a half-life of about 13 days in humans (4) and appears to play a considerable role in the anticonvulsant effect of trimethadione (5). The long serum half-life of 5-dimethyl-2,4-oxazolidinedione is attributed to its extremely slow, pH-dependent, renal excretion (6). The structural similarity of 5-dimethyl-2,4-oxazolidinedione and I and the apparently long serum half-life suggest that the latter metabolite also has a slow renal excretion rate.

IR Studies on Carrageenan of *Ahnfeltia concinna*, a Marine Red Alga

GERTRUDES A. SANTOS and MAXWELL S. DOTY ˣ

Abstract □ The principal polysaccharide of *Ahnfeltia concinna* gave IR absorptions at 1240, 930, 845–850, and 805 cm^{-1}, all typical of a carrageenan. The polysaccharide was separated into soluble and insoluble fractions with potassium chloride.

Keyphrases □ Carrageenan—isolation from *Ahnfeltia concinna*, IR identification □ *Ahnfeltia concinna*—isolation of carrageenan, IR identification □ IR spectrophotometry—identification, carrageenan isolated from *Ahnfeltia concinna* □ Alga—IR identification of carrageenan isolated from *Ahnfeltia concinna*

Carrageenan is a red seaweed polysaccharide extensively used as a food additive, especially in dairy products, and as a suspending agent in the cosmetic and pharmaceutical industries. Carrageenan is prepared from different species of *Chondrus, Gigartina, Eucheuma, Hypnea,* and *Iridaea.* These genera and the genus *Ahnfeltia* belong to the order Gigartinales. Although *Ahnfeltia plicata* has long been been known as the major source of agar in Russia, *Ahnfeltia durvilliae* of Peru was reported to contain carrageenan (1).

There are three main groups of carrageenans: the κ-, λ-, and ι-carrageenan groups. The three types differ only in their 3,6-anhydrogalactose content and in their content and position of ester sulfate groups in the molecule. Scheme I shows the idealized structure of κ-, ι-, and λ-carrageenans proposed previously (2). The μ- and ν-carrageenans are the precursors of κ- and ι-carrageenans, respectively.

From the report of Lawson *et al.* (3), *A. durvilliae* contains a "deviant" ι-carrageenan. Methylation studies showed that the polysaccharide consists of β-D-galactopyranose 4-sulfate (45%), β-D-galactopyranose (5%), 3,6-anhydro-α-D-galactopyranose (24%), 3,6-anhydro-α-D-galactopyranose 2-sulfate (12%), 4-linked α-D-galactopyranose 2,6-disulfate (7%), and 4-linked α-D-galactopyranose (7%) (4).

A. concinna is a marine red alga widely distributed in the Hawaiian Islands. It forms a yellow-brown to dark red-brown band in the intertidal region on basalt rocks. In a preliminary report on the polysaccharide of this alga, the name ahnfeltan was given to the principal carbohydrate (5). The purpose of this investigation was to show whether the polysaccharide of *A. concinna* is definitely a carrageenan or at least not an agar.

EXPERIMENTAL

The sample used was collected from north of Makapuu Point on the island of Oahu, Hawaii. The seaweed was quite clean and devoid of epiphytes. The fresh live seaweed gave as much as 27% clean dry weed.

Extraction of Polysaccharide—Clean dry weed (20 g) was heated in water (700 ml) adjusted to pH 9 by addition of 2% sodium hydroxide solution in a boiling water bath for 1 hr. The seaweed was then blended to a paste and heated for a further 3 hr. A filter aid[1] (50 g) was added, and the mixture was stirred continuously for 30 min and then filtered with pressure. The filtrate, about 700 ml–1 liter, was about 1% carrageenan.

A sodium chloride solution (10%, 50 ml) was added, and the mixture was poured into twice its volume of 85% isopropanol with rapid stirring. The precipitate was strained through nylon cloth, washed twice with 600 ml of the 85% isopropanol, and dried at 60°. The dried polysaccharide was ground to a powder, yielding 11.92 g (59.6%); SO_3Na, 31.86%; 3,6-anhydrogalactose ($C_6H_{10}O_4$).

The modified carrageenan was prepared by treating the dry seaweed (20 g) in water (700 ml) with lime (4 g) instead of a 2% sodium hydroxide solution and heating and filtering as already described. The filtrate was adjusted to pH 8.5–9.0 with dilute hydrochloric acid. Addition of 10% sodium chloride was not necessary before precipitation of the polysaccharide with 85% isopropanol. The yield was 11.86 g (59.3%); SO_3Na, 26.29%; 3,6-anhydrogalactose.

Fractionation of Carrageenan—The fractionation method used was that of Stancioff and Stanley (1). The powdered carrageenan (8.00 g) was dispersed by continuous stirring for 1 hr at room temperature in 2.5% potassium chloride solution, and the mixture was allowed to sit overnight. A filter aid (40 g) was stirred into the mixture for 1 hr, the mixture was filtered with suction, the filter cake was washed with potassium chloride solution (2.5%, 100 ml), and the filtrate and washing were combined and evaporated to 600 ml and precipitated with 2.5 volumes of 85% isopropanol. The precipitate was washed twice with 300-ml portions of the solvent, dried at 60° for 5 hr, and ground into a powder, yielding 1.13 g (15.76%); SO_3Na, 31.12%; 3,6-anhydrogalactose, 11.00%.

The filter cake was then suspended in hot water (800 ml), the mixture was stirred for 1 hr at 85–100° and filtered with pressure, and the cake was washed with hot water (100 ml). The filtrate and washing were combined and heated to 70°, and sodium chloride solution (10%, 50 ml) was added with stirring. The hot mixture was poured into twice its volume of 85% isopropanol with vigorous stirring. The coagulum was squeezed, washed twice with 500-ml por-

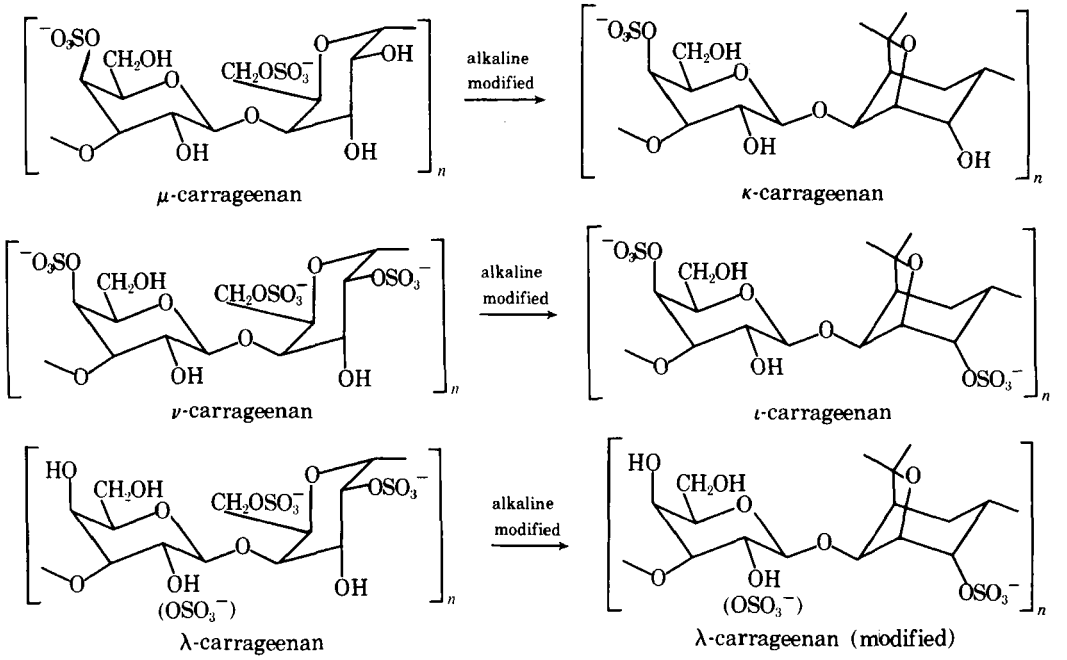

Scheme I

tions of isopropanol, and dried in a 60° oven for 5 hr, yielding 6.04 g (84.24%); SO_3Na, 33.13%; 3,6-anhydrogalactose, 27.03%.

Sodium Borohydride Treatment of Potassium Chloride-Soluble Fraction—The Rees method (6) was used in which the polysaccharide (1.6 g) was dissolved in water (600 ml), sodium borohydride was added (0.2 g), and the solution was allowed to sit overnight at room temperature. More sodium borohydride (7.2 g) and sodium hydroxide (24 g) were added to the solution with cooling. After the rapid evolution of gas had subsided, the solution was heated on a water bath at 80° for 2 hr. The solution was neutralized with acetic acid and then poured, with stirring, into 2.5 times its volume of 85% isopropanol. The coagulum was squeezed, washed twice with isopropanol, and dried at 60° for 5 hr, yielding 1.46 g (91.25%); SO_3Na, 24.37%; 3,6-anhydrogalactose, 23.63%.

IR Determination—The polysaccharide (30 mg) was dissolved in distilled water (15 ml), and 3 ml of the solution was poured onto mercury (4 ml) contained in a 15-ml porcelain crucible. The solution was dried to a thin film in a heated vacuum desiccator (70°). The mercury was poured off, the film was mounted between two 15 × 5-cm pieces of cardboard provided with 2.5 × 1.3-cm windows, and the spectra were determined[2].

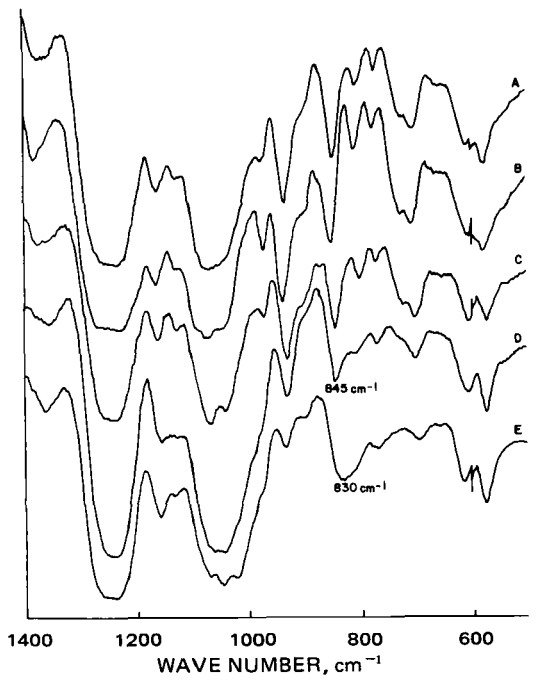

Figure 2—*IR spectra of: A,* A. concinna *carrageenan; B, the modified* A. concinna *carrageenan; C, the potassium chloride-insoluble fraction; D, the potassium chloride-soluble fraction; and E, λ-carrageenan.*

[2] Beckman IR 467 spectrophotometer.

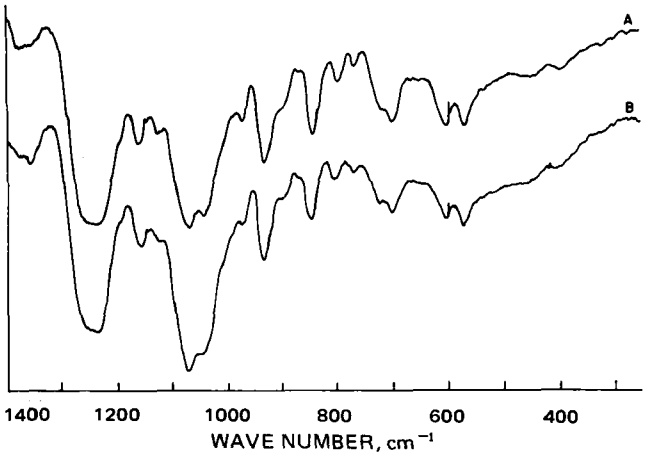

Figure 4—*IR spectra of: A, potassium chloride-insoluble fraction of* A. concinna *carrageenan; and B, modified potassium chloride-soluble fraction.*

RESULTS AND DISCUSSION

The IR spectra of the polysaccharide from *A. concinna* showed absorption bands characteristic of a carrageenan with: 1240 cm^{-1}, S—O stretching vibration; 930 cm^{-1}, typical of the presence of 3,6-anhydrogalactose; and 845–850 cm^{-1}, due to the secondary axial 4-sulfate absorption. But it is neither a κ- nor an ι-carrageenan as shown in Fig. 1. As shown in Fig. 2, the broadening at the base of the 850- and 805-cm^{-1} absorptions was possibly due to the presence of the primary equatorial 6-sulfate absorption at 820 cm^{-1}, which disappeared upon alkaline modification with the elimination of the primary 6-sulfate and the formation of the 3,6-anhydrogalactose (1, 2, 7–16).

Fractionation of the polysaccharide with 2.5% aqueous potassium chloride yielded the potassium chloride-insoluble and potassium chloride-soluble fractions. The IR spectrum (Fig. 2) of the potassium chloride-insoluble fraction is very similar to that of modified carrageenan. The potassium chloride-soluble fraction could not be λ-carrageenan, because the broad absorption at 850–800 cm^{-1} has a maximum at 850 cm^{-1} while that of the λ-carrageenan is at 830 cm^{-1}. The broad absorption band at 850–800 cm^{-1} of the potassium chloride-soluble fraction was resolved into two sharp peaks (Fig. 3) at 850 and 805 cm^{-1} upon modification with sodium borohydride, and the IR spectrum of the product (Fig. 4) was very similar to that of the potassium chloride-insoluble fraction. However, the potassium chloride-soluble fraction of the *A. concinna* carrageenan cannot possibly be the precursor of the potassium chloride-insoluble fraction because of the low sulfate and 3,6-anhydrogalactose content of the modified carrageenan.

There is a possibility that the structure of the carrageenan of *A. concinna* could be identical or closely related to that of *A. durvilliae*, which Lawson *et al.* (3) investigated and classified as a deviant ι-carrageenan.

According to the physical properties and IR studies, the polysaccharide of *A. concinna* is definitely a carrageenan; however, further studies are still needed to determine the different monosaccharide units in the molecule and to clarify the chemical structure.

Analysis of *N*-Glycosyl Bond Length in Crystal Structures of Nucleosides and Nucleotides

ALBERT LO *, ELI SHEFTER *x, and TODD G. COCHRAN ‡

Abstract □ A relationship was found between the *N*-glycosyl bond length in β-nucleosides and nucleotides and the spatial relationship of this bond with respect to the lone-pair orbitals on the furanose ring oxygen. This relationship may be relevant to the geometry involved in the hydrolysis of the glycosidic bond.

Keyphrases □ Nucleosides and nucleotides—analysis of *N*-glycosyl bond length in crystal structures □ Glycosyl bonds—analysis of bond length in crystal structures of nucleosides and nucleotides □ Hydrolysis—glycosyl bonds, analysis of bond length in crystal structures of nucleosides and nucleotides

The *N*-glycosyl bonds of nucleic acids are readily hydrolyzed by either enzymes (specific nucleosidases) or acid-catalyzed reactions. Although the mechanism of enzymatic cleavage of these glycosidic bonds has been poorly characterized, numerous kinetic studies on the acid-catalyzed hydrolysis of these bonds in nucleosides have produced some definitive ideas on the hydrolytic mechanism (1–3).

Two schemes have been proposed for the acid-catalyzed route. One involves the opening of the protonated furanose ring at the C_1'—O_1' bond, with subsequent water attack and the formation of the base and sugar products. In the other scheme, the glycosidic bond of the base-protonated species (mono- or dication) is directly cleaved. Evidence for the latter scheme appears to be strongest for most nucleosides (3). Although mechanisms have been developed, there is a dearth of any detailed structural information concerning the geometry of the minimum energy pathway followed by the reaction, *i.e.*, reaction coordinates.

Recently, crystal structure data were used to analyze the geometry of some nucleophilic addition reactions (4, 5). The general approach was to examine the atomic coordinates of a large number of molecules possessing similar chemical subunits for structural variations that might correspond to existing knowledge about these subunits in a reaction scheme. The geometrical parameters observed for any molecule in a crystal are a complicated function of inter- and intramolecular forces. Therefore, one would expect to find differing geometries for a particular subunit in a series of molecular structures.

The hypothesis behind the use of these data is that the interplay of forces that displaces the subunit of interest from its geometrical minimum energy configuration in the crystal can provide a clue as to the path that may occur in the chemical breakdown of the entity. This hypothesis assumes that the initial stages of the chemical breakdown and the geometrical distortions in the crystal structures both follow similar minimum energy routes.

It was deemed worthwhile to utilize this approach to analyze the *N*-glycosyl linkage of nucleotides and nucleosides. For this purpose, published crystal structures whose accuracy was sufficient for such a correlation were selected. The structures examined are listed in Table I together with some pertinent parameters describing the glycosidic bond.

DISCUSSION

A scrutiny of the parameters in the table shows that there is a significant variation in the C_1'—N bond length among the tabulated structures. Since the range of C—N bond lengths is reflective of distortions that could occur at the initial stages of the hydrolytic sequence, one might glean some clues from them as to the beginning of the hydrolytic reaction.

The change in the glycosidic bond length is not accompanied by any significant alteration in bonding parameters about C_1', *i.e.*, bond lengths and angles. However, some subtle trends in these parameters are worth noting even though they are not *highly* significant. As the glycosidic bond lengthens, the N—C_1'—C_2' angle decreases slightly and the furanose ring angle (O_1'—C_1'—C_2') tends to enlarge.

The torsion angle about the C_1'—O_1' bond [τ(N—C_1'—O_1'—C_4')] provides an indication of the spatial relationship of the lone pair of orbitals on O_1' with regard to the glycosidic bond (Fig. 1). Geometric constraints imposed by the furanose ring limit the values obtained for the C_1'—O_1' torsion angle to those between synclinal (60°) and antiperiplanar (180°). The manner by which

[b] σ_d and σ_a are the average standard deviations reported for bond lengths and angles, respectively, of parameters not involving hydrogen. Those for hydrogen are much greater.

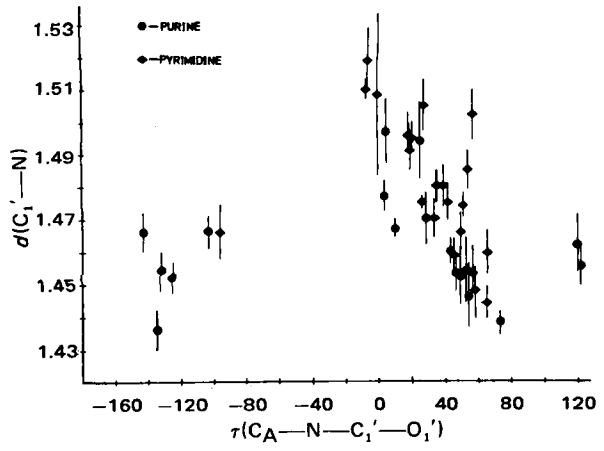

Figure 3—*Correlation of $\tau(C_A—N—C_1'—O_1')$ and glycosidic bond length.*

the furanose ring puckers influences the value of this torsion angle.

A relationship between τ(N—C_1'—O_1'—C_4') and the glycosidic bond length appears to exist (Fig. 2). The *N*-glycosyl linkage is shortest when this constellation of atoms is antiperiplanar and longest when synclinal. The orientation of a lone-pair orbital on the oxygen becomes antiperiplanar as this angle tends toward a synclinal value. Thus, the *N*-glycosyl bond length appears to be longest when it is antiperiplanar to a lone-pair orbital on the oxygen.

The following regression equation (r = 0.80) was derived for the relationship shown in Fig. 2:

$$d(C_1'—N) = 1.625 - 0.00112\tau(N—C_1'—O_1'—C_4') \quad \text{(Eq. 1)}$$

This equation predicts the shortest value possible for the glycosidic bond (occurring at τ = 180°) to be 1.43 Å. This length is much shorter than an N(sp^2)—C(sp^2) single bond (1.485 Å) (6) or the N—C bonds of alkylated nucleic acid bases (7).

In a structural analysis of tetrahedral dioxo compounds and orthoesters, a similar type of relationship was found (5). The C—O′ bond in these compounds was a function of the O′—C—O″—H torsion angle. The C—O′ bond length was longest when a lone-pair orbital on O″ was antiperiplanar to it. This observation is supported by studies carried out on the decomposition of conformationally rigid hemi-orthoesters (8) and hemi-amide acetals (9), where the bond most readily cleaved appeared to be the one with two lone-pair orbitals antiperiplanar to it.

Jeffrey *et al.* (10), using nonempirical molecular orbital calculations, found a similar relationship between bond length and conformation for methylenediol. The difference in bond length for the synclinal and antiperiplanar arrangements is also reflected in the stretching force constants (11). The calculated values are 5.8 and 6.0 mdynes/Å for the longer and shorter bonds, respectively. Therefore, the reaction that cleaves the longer bond (antiperiplanar conformation with respect to a lone-pair orbital) would be energetically favored, at least in the initial phase.

Other investigators (12, 13) indicated that the observed differences in glycosidic bonds could be attributed to nonbonded interactions between the base and the sugar. The conformation of the base relative to the sugar can be described by the torsion angle, $\tau(C_A—N—C_1'—O_1')$. This angle was correlated by these investigators to the glycosidic bond length. With the tabulated data, the correlation appears to break down (Fig. 3). However, this correlation is valid if no differentiation is made between the sides of the purine or pyrimidine rings, *i.e.*, between the *syn*- and *anti*-conformations (14). If 180° is added to the $C_A—N—C_1'—O_1'$ torsion angle of the six nucleosides with a *syn*-conformation that show a marked deviation from the linear trend in Fig. 3, a linear correlation is observed (r = 0.65).

Since the torsion angles about the $C_1'—O_1'$ and $C_1'—N$ bonds can both be related to the glycosidic bond length, the conformations about these bonds appear to be dependent upon one another. Regression analysis of the tabulated values for these two torsion angles is suggestive of this, showing a linear correlation (r = 0.67) for the 43 nucleosides and nucleotides in Table I. This result is not unexpected in light of work (15) showing that the freedom of rotation about the glycosidic bond in nucleosides and nucleotides is closely related to the puckering in the furanose ring.

In terms of reaction coordinates, the tabulated data show that a conformation in which the $N—C_1'—O_1'—C_4'$ torsion angle tends toward a synclinal value would be favorable for a direct cleavage mechanism of hydrolysis, since this conformation is associated with an increasing glycosidic bond length and an antiperiplanar orientation between the glycosidic bond and a lone-pair orbital on the oxygen. While this cannot be construed as direct evidence that such a geometry occurs during hydrolysis, it is easily envisioned that a catalytic species (nucleosidase) could induce such a conformational change in a nucleoside or nucleotide, thus facilitating the hydrolysis.

Plasma Protein Binding of Drugs as a Function of Age in Adult Human Subjects

A. DOUGLAS BENDER *x, ALEX POST *, JOSEPH P. MEIER *, JOHN E. HIGSON *, and GEORGE REICHARD, Jr. ‡

Abstract □ The intent of this study was to determine what influence, if any, increasing age has on the binding of drugs by plasma proteins. Plasma from healthy subjects ranging in age from 21 to 94 years was used. The binding of phenytoin (diphenylhydantoin) (acid), penicillin G potassium (benzylpenicillin potassium), and phenobarbituric acid was determined by equilibrium dialysis of ^{14}C-labeled compounds. No differences were found in total protein concentration; however, albumin was reduced in subjects over 50 years of age. Plasma binding of each drug studied was not related to age; this finding suggests that age *per se* is not a factor in the binding of drugs by plasma proteins.

Keyphrases □ Plasma protein binding—drugs, effect of age, adult human subjects ■ Binding—drugs to plasma protein, effect of age, adult human subjects □ Age—effect on binding of drugs to plasma proteins, human subjects

Several years ago, Ehrnebo *et al.* (1) reported that human fetal and neonatal plasma has a lower binding capacity for drugs than plasma from young healthy adult subjects. The investigators attributed the lower binding capacity to lower total protein and albumin concentrations in fetal and newborn plasma. They also implied that qualitative differences in protein binding may have contributed to the decrease in binding capacity.

From a practical viewpoint, the decreased drug binding capacity in the newborn means that more free drug is available at a given total drug concentration in the plasma. Therefore, there exists the potential for an increase in drug activity and the incidence of undesirable effects.

Elderly patients exhibit an increased sensitivity to drugs (2–4), which in some cases has been shown to be related to higher and more prolonged blood drug levels brought about by a slower rate of drug metabolism and elimination in older patients (5–7). The objectives of the present study were to assess the influence of increasing age on the binding of drugs by plasma proteins and, thus, to determine whether or not altered drug binding could potentially contribute to the enhanced effect of drugs in geriatric patients.

Table I—Concentrations and Specific Activities of Drugs Used in Determining Drug Binding Capacity of Human Plasma

Drug	Concentration, μg/ml	Specific Activity, μCi/mg
Phenytoin (acid)		
Day 1	16.87	0.82
Day 2[a]	12.93	2.92
Phenobarbituric acid		
Day 1[b]	20.21	4.14
Penicillin G potassium		
Day 1[b]	13.78	2.43

[a] A fresh solution was prepared for the analysis of a second batch of human plasma. [b] The same solution was used with succeeding batches of human plasma on different days. The solution was stored at −10° when not in use.

Table II—Total Protein, Globulin, and Albumin Concentrations, A/G Ratio, and Other Laboratory Parameters of Plasma from Normal Subjects

	Subjects Less than 50 Years of Age (n = 14, Mean = 29 Years)	Subjects Greater than 50 Years of Age (n = 10, Mean = 63.5 Years)
Total protein, g/100 ml	7.1 ± 0.10[a]	7.0 ± 0.10
Globulin, g/100 ml	3.1 ± 0.08	3.5 ± 0.16[b]
Albumin, g/100 ml	4.0 ± 0.06	3.4 ± 0.09[c]
A/G ratio	1.3 ± 0.04	1.0 ± 0.06[c]
Blood urea nitrogen, mg/100 ml	14.5 ± 0.44	16.5 ± 1.16
Serum glutamic pyruvic transaminase, I.U.[d]	13.5 ± 1.03	11.7 ± 1.25
Serum glutamic oxaloacetic transaminase, I.U.	16.5 ± 1.21	15.0 ± 1.68
Alkaline phosphatase, I.U.	54.0 ± 2.84	58.0 ± 4.30

[a] Mean and standard error. [b] Significant difference at $p < 0.05$. [c] Significant difference at $p < 0.01$. [d] I.U. = international units.

EXPERIMENTAL

Plasma Samples—Blood was obtained by venipuncture from 25 healthy subjects ranging in age from 21–94 years. The subjects had not received any drug for at least 1 week prior to the time blood was withdrawn. All blood samples were heparinized and centrifuged, and the red cell-free plasma was stored at −10°. Prior to analysis, the plasma was thawed at 4° and then allowed to reach room temperature. Ehrnebo *et al.* (1) showed that freezing and thawing plasma samples do not affect the drug binding capacity of plasma.

Clinical Chemistry—Total protein[1], serum glutamic oxaloacetic transaminase[1], serum glutamic pyruvic transaminase[1], alkaline phosphatase[1], globulin[2], and blood urea nitrogen[2] levels were determined using commercially available procedures. Plasma albumin concentration was calculated as the difference between the total protein and globulin concentrations.

Radioactive Compounds—5,5-Diphenylhydantoin-4-^{14}C as the acid[3] (specific activity, 5.21 mCi/mmole), phenobarbituric acid-2-^{14}C[3] (specific activity, 3.34 mCi/mmole), and potassium 6-phenyl-1-^{14}C-acetamidopenicillinate[4] (specific activity, 24.7 mCi/mmole) were obtained commercially. All radiochemical purities were reported by the suppliers to be greater than 98%.

Because of the high specific activities of these compounds, it was necessary to dilute them with their respective nonradioactive carriers. Both the labeled and nonlabeled compounds were diluted in pH 7.38 buffer (1) to a suitable concentration that was amenable

Table III—Drug Binding, Total Protein Concentration, and Albumin Concentration of Plasma from Normal Subjects[a]

Drug	Subjects Less than 50 Years of Age				Subjects Greater than 50 Years of Age			
	Patients	Total Protein, g/100 ml	Albumin, g/100 ml	Percent Drug Bound	Patients	Total Protein, g/100 ml	Albumin, g/100 ml	Percent Drug Bound
Phenytoin (acid)	6	7.0 ± 0.08[b]	4.0 ± 0.07	82.4 ± 0.84	3	7.3 ± 0.18	3.4 ± 0.18	83.6 ± 0.35
Phenobarbituric acid	5	7.3 ± 0.23	4.1 ± 0.09	41.8 ± 1.33	3	6.8 ± 0.12	3.4 ± 0.22	41.9 ± 2.07
Penicillin G potassium	5	7.0 ± 0.16	3.9 ± 0.13	42.4 ± 3.00	4	6.9 ± 0.15	3.5 ± 0.15	45.1 ± 3.62

[a] With one exception (plasma from 21-year-old subject), plasma samples were subjected to a single drug binding experiment. Not included are data from a 94-year-old subject with a serum albumin of 1.3 g/100 ml, elevated serum glutamic oxaloacetic transaminase, and alkaline phosphatase levels. These data are referred to in the text. [b] Mean and standard error.

to the drug binding experiment. The concentrations and specific activities are listed in Table I.

Equilibrium Dialysis—Equilibrium dialysis was carried out in two-compartment Lucite cells[5]. The compartments on each side of the dialysis membrane measured 17.46 mm in diameter and 3.98 mm in depth. The volume of each compartment was approximately 0.87 ml. The viscose membrane[6] had a thickness of 0.203 mm with an average pore size of 4.8 mμ. This type of membrane retains components in aqueous solutions with molecular weights of 12,000 and higher. Prior to its use, the membrane was soaked overnight in deionized water and the excess water was removed before placing it into the apparatus.

A plasma sample, 0.87 ml, was placed into one compartment of the cell and the labeled drug dissolved in the buffer was placed into the other. The cell was sealed with tape and attached to an apparatus described in USP XVIII (8). This device raised and lowered the dialysis cell 30 times/min in a 37 ± 1° water bath for 6 hr. This time period[7] was the same as was used previously (1).

Assay of Drugs—Liquid scintillation counting of the radioactivity was used to determine the amount of labeled drug in the plasma and buffer solutions. Exactly 0.300 ml of each solution was removed, and 0.6 ml of a 25% aqueous tetramethylammonium hydroxide solution was added to solubilize the protein in the plasma aliquot. The solutions were allowed to digest overnight at room temperature; then 15 ml of a liquid scintillator solution[8] was added, shaken, and counted[9] for 10 min. The absolute disintegration rate was obtained by determining the quench effect by conventional internal standardization technique with hexadecane-^{14}C.

Calculation of Binding Capacity—Equation 1 (1) was used to determine the percentage of bound drug:

$$\% \text{ bound} = \frac{[C_{plasma} - C_{buffer}] \times 100}{C_{plasma}} \qquad \text{(Eq. 1)}$$

where C_{plasma} = concentration of drug in the plasma compartment after dialysis, and C_{buffer} = concentration of drug in the buffer compartment after dialysis.

RESULTS AND DISCUSSION

With the exception of elevated serum glutamic oxaloacetic transaminase and alkaline phosphatase levels in a 94-year-old subject, results of the clinical laboratory studies reveal no abnormal or significant findings (Table II) and thus confirm that the subjects were healthy and free of complicating disease. Data for this subject are not included in the statistical analysis but are discussed in reference to the relationship of drug binding capacity to plasma albumin levels.

In Table II, mean values are given for total protein, globulin (G), and albumin (A) concentrations along with the A/G ratio for subjects of different ages. These data show that plasma total protein is not altered by increasing age, while plasma albumin is significantly reduced in patients over 50 years of age with a corresponding increase in plasma globulin. The calculated A/G ratio is decreased from 1.3 for patients under 50 years of age to 1.0 for patients 50 years and over. These results are consistent with data reported by Libow (9). In this latter study, a total protein concentration of 7.2 g/100 ml was reported for healthy subjects 18–36 years of age and a value of 6.9 g/100 ml was given for healthy subjects 65–92 years of age. This difference was not statistically significant. Serum albumin, however, was significantly reduced in the older subjects. In the young group, the albumin concentration was 3.8 g/100 ml; in older subjects, the value was 3.3 g/100 ml.

The plasma binding values reported here are lower than those reported previously (1); however, the significance or explanation of this difference is difficult to judge since the specifications for the membrane used in the earlier investigation were not given. It has been pointed out that it is difficult to interpret the results of binding studies in which a single drug concentration was used, as was the case in this study. However, Shah *et al.* (10) showed that the percentage of phenytoin (diphenylhydantoin) bound to plasma protein is constant for a wide range of concentrations (1–40 μg/ml). Nevertheless, these issues, although of interest certainly to future studies in this area, do not affect the interpretation of the current results since the interest here was to establish the influence of age on the *relative*, not necessarily the *absolute*, drug binding capacity of plasma.

In Table III, the binding of each drug is compared for subjects under 50 years of age and those over 50 years of age. This comparison was made because after age 50 there was a significant reduction in serum albumin levels. Despite a reduction in plasma albumin concentration, no changes were noted in plasma binding capacity. These data suggest that age *per se* does not influence the binding of drugs to plasma proteins. More specifically, they indicate that increasing age is not associated with: (*a*) a defect in drug binding proteins or (*b*) the production of an endogenous substance which competes with a drug for binding sites on the protein molecule. With a reduction in serum albumin and no change in drug binding, the amount of drug bound for a given amount of albumin is increased with age.

While the data from the normal subjects in this study show no change in plasma binding capacity, this finding does not rule out the potential for a reduction in binding capacity in elderly patients, as with any other patients whose plasma albumin and/or total protein may be lower than that encountered in this study. For example, Ehrnebo *et al.* (1) reported a reduction in drug binding capacity in the newborn associated with a significant reduction in both plasma albumin and total protein. Andreasen (11) found a reduced binding capacity associated with lower concentrations of albumin in surgical patients with acute renal failure.

Indeed, in the present study, in a single subject of 94 years of age (not included in Table III) with a plasma albumin level of 1.3 g/100 ml, the percentage of phenobarbital bound to plasma protein was reduced to 12.1%, a figure far below the mean value for all patients regardless of age. In two other 90-year-old subjects with plasma albumin levels above 3.0 g/100 ml, plasma protein binding of phenytoin and phenobarbital was the same as that found for younger subjects.

The results of a recent study (12) are relevant to this issue. The incidence of unwanted central nervous system depression with diazepam was significantly greater in patients with a plasma albumin level of less than 3.0 g/100 ml than in patients with a value of greater than 4.0 g/100 ml. Interestingly, age was not a factor.

[5] Fabricated at the Smith Kline & French Laboratories.
[6] Catalog No. EDR3787-D22, A. H. Thomas Co., Philadelphia, Pa.
[7] In other studies in these laboratories with other drugs, no statistical difference in binding determined after 6 and 12 hr of dialysis was observed.
[8] Omnifluor–Cabosil–naphthalene–absolute ethanol–dioxane (9.6 g:50 g:100 g:100 ml:1000 ml).

Activity of Local Anesthetic Agents in Goldfish

STUART FELDMAN ˣ, MARY DeFRANCISCO, and PETER J. CASCELLA

Abstract □ The activity of procaine hydrochloride, lidocaine hydrochloride, tetracaine hydrochloride, and dibucaine hydrochloride in producing overturn in goldfish was measured in pH 8.0 buffer. Calculation of the apparent minimum effective concentration of local anesthetic necessary to result in overturn of the goldfish showed that the activity of these agents increased in the following order: procaine hydrochloride < lidocaine hydrochloride < tetracaine hydrochloride < dibucaine hydrochloride. The effect of these agents on goldfish can be correlated with previous work on the minimum concentration necessary to block conduction in isolated nerve and muscle fibers. The activity of the local anesthetic agents could be explained, in part, by the relationship between the chloroform–pH 8 buffer partition coefficient and the minimum effective concentration in goldfish. Experimental results indicate that the unionized drug molecule is responsible for the observed effects.

Keyphrases □ Anesthetics, local—activity of procaine hydrochloride, lidocaine hydrochloride, tetracaine hydrochloride, and dibucaine hydrochloride in producing goldfish overturn, structure–activity relationships □ Structure–activity relationships—local anesthetics, goldfish overturn □ Goldfish—model for determining structure–activity relationships of local anesthetics

Recent reports (1–3) indicated that goldfish may serve as a biological test model in the assessment of structure–activity relationships of drugs. The goldfish was an adequate test system for discerning structure–toxicity relationships of substituted phenothiazine derivatives (1), and the goldfish was used as a model to study the effects of alkyl chain length on the alkyl *p*-aminobenzoate-induced narcosis in the fish (2). The use of this simple and inexpensive biological test system to study the correlation between pharmacological and toxicological activity with physical–chemical properties has many advantages (1). The present report concerns preliminary findings as to the relationships that may exist between structure and activity of local anesthetic agents in goldfish.

hydrochloride[1] in pH 8.0 phosphate buffer (0.01 *M*) was determined. The solutions were freshly prepared before each experiment. At least five goldfish were used at each local anesthetic drug concentration. The goldfish tank and test solutions were maintained at 22 ± 2°.

Partition coefficients of each local anesthetic agent were determined between chloroform and pH 8.0 phosphate buffer (0.01 *M*). Fifteen milliliters of organic phase and 15 ml of aqueous phase containing the local anesthetics were placed in glass bottles and shaken[3] until equilibrium was established by repetitive sampling. Assay for drug in the aqueous phase after appropriate dilution was done spectrophotometrically[4] at 288 nm for procaine, 262 nm for lidocaine, 310 nm for tetracaine, and 328 nm for dibucaine. All determinations were made at room temperature (22–24°).

RESULTS AND DISCUSSION

Inspection of Table 1 and Fig. 1 reveals that good agreement exists with the four local anesthetic agents tested between the reciprocal of overturn time (1/OT) and drug concentration (4). The data were analyzed by linear regression, and the intercept on the *x*-axis was calculated for each local anesthetic. This value was taken as the apparent minimum effective concentration (MEC) necessary to produce overturn in the goldfish. While it has been shown (5) that the relationship between 1/OT and concentration is not linear at concentrations of drug near the MEC but is hyperbolic, it was felt that this extrapolation would not lead to a significant error in the determination of the MEC. The apparent MEC values for the local anesthetic agents investigated in the present study are listed in Table II.

According to the values listed in Table II, the potency of the local anesthetics in producing overturn in goldfish increases in the following order: procaine < lidocaine < tetracaine < dibucaine. This order of activity is similar to previous results reported for these anesthetics on isolated nerve preparations (6) and in clinical evaluations in human subjects (7).

Agin *et al.* (6), in a report on the action of anesthetic agents on excitable membranes, tabulated the minimum blocking concentration (MBC) of the anesthetic agents necessary to produce conduction blockage on isolated nerve or muscle fibers. These values for

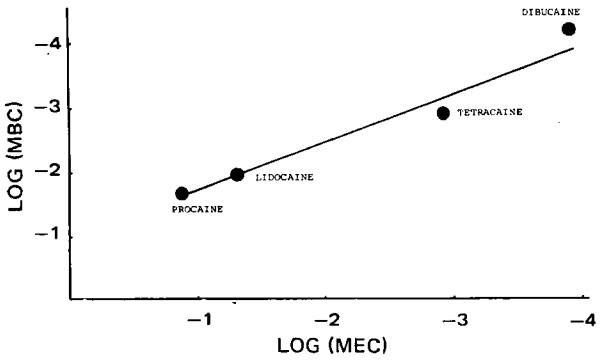

Figure 2—*Plot of the logarithm of the minimum blocking concentration (MBC) of local anesthetics on isolated nerve and muscle fibers* versus *the logarithm of the minimum effective concentration (MEC) of these agents in goldfish. (Data for MBC were obtained from Ref. 6.)*

Table II—Minimum Effective Concentrations (MEC) in Goldfish, Minimum Blocking Concentrations (MBC) in Isolated Fibers, and Partition Coefficients of Local Anesthetics

Local Anesthetic	MEC, m*M*	Log MBC, m*M*[a]	Partition Coefficient[b]
Procaine hydrochloride	0.136	−1.67	19
Lidocaine hydrochloride	0.049	−1.96	41
Tetracaine hydrochloride	0.0012	−2.9	800
Dibucaine hydrochloride	0.00013	−4.2	2200

[a] Data obtained from Ref. 6. [b] Between chloroform and pH 8 buffer.

procaine, lidocaine, tetracaine, and dibucaine are listed in Table II. A comparison of the results of the present study with those of Agin *et al.* (6) are presented in Fig. 2; the agreement between the two sets of data is good, and the results of present experiments utilizing the goldfish would give a good prediction as to the effect of the local anesthetics on isolated nerve and muscle fibers.

The correlation of biological activity with physical–chemical properties of the drug has been well documented (8). To determine the role of lipid solubility on the effect of the local anesthetic agent on overturn time in goldfish, partition coefficients between chloroform and pH 8 buffer were measured (Table II). The order of increasing lipid solubility of the agents between chloroform and pH 8 buffer is as follows: procaine < lidocaine < tetracaine < dibucaine. The relationship between partition coefficient and the apparent MEC is illustrated in Fig. 3. The fit is rather good and demonstrates that the activity of the local anesthetics in producing overturn in goldfish is due, in part, to the lipophilicity of the drug molecule.

Experimental results also appear to indicate that the nonionized drug molecule is responsible for the observed effect of the anesthetics on overturn time. In an experiment with lidocaine where the pH of the buffer solution was varied, the mean overturn time in goldfish for a 0.4 m*M* solution was 2.6 min at pH 8 and 16.8 min at pH 7; there was no response at pH 6. Lidocaine, with a pKa of approximately 7.9 (9), is 55.7% unionized at pH 8, 11.2% unionized at pH 7, and 1.2% unionized at pH 6. Thus, with decreasing pH and the subsequent decrease in in the concentration of unionized drug and the ability of the drug to penetrate biological membranes, there is a reduction in the pharmacological activity of lidocaine in the goldfish. A similar effect of pH on the overturn of goldfish in the presence of the other anesthetics investigated was noted.

The results of the present study illustrated the potential usefulness of goldfish as a model for the prediction of drug activity. Investigations are currently underway concerning the structure–activity relationships involved in producing overturn and death in goldfish for a series of lidocaine derivatives.

Characterization of Poison Oak Urushiol

MICHAEL D. CORBETT [*] and STEPHEN BILLETS [‡x]

Abstract □ Procedures are described that were used in the isolation and characterization of urushiol components reported to be the allergenic constituents of poison oak, *Toxicodendron diversilobum*. Characterization of these components by spectral techniques indicated they are unsaturated congeners of 3-heptadecylcatechol, possessing one, two, or three double bonds in an unbranched C_{17} side chain. These components are shown to differ from those isolated from poison ivy, *Toxicodendron radicans*, by a $—CH_2CH_2—$ unit in the unbranched alkyl side chain.

Keyphrases □ Poison oak—isolation and characterization of urushiol components □ *Toxicodendron diversilobum*—isolation and characterization of urushiol components □ Urushiol components of poison oak (*Toxicodendron diversilobum*)—isolation and characterization

Plants of the genus *Toxicodendron* (Anacardiaceae) have long been known for their ability to produce contact dermatitis in susceptible individuals. The best known species of this genus in the United States are *Toxicodendron radicans* (poison ivy), *Toxicodendron diversilobum* (western poison oak), and *Toxicodendron vernix* (poison sumac). The systematics of this genus have been well characterized (1).

The composition of the allergenic urushiol components (2–4) of poison oak (*T. diversilobum*) was studied. A prior study of the urushiol content of poison

Characterization of Poison Oak Urushiol

MICHAEL D. CORBETT [*] and STEPHEN BILLETS [‡x]

Abstract □ Procedures are described that were used in the isolation and characterization of urushiol components reported to be the allergenic constituents of poison oak, *Toxicodendron diversilobum*. Characterization of these components by spectral techniques indicated they are unsaturated congeners of 3-heptadecylcatechol, possessing one, two, or three double bonds in an unbranched C_{17} side chain. These components are shown to differ from those isolated from poison ivy, *Toxicodendron radicans*, by a $—CH_2CH_2—$ unit in the unbranched alkyl side chain.

Keyphrases □ Poison oak—isolation and characterization of urushiol components □ *Toxicodendron diversilobum*—isolation and characterization of urushiol components □ Urushiol components of poison oak (*Toxicodendron diversilobum*)—isolation and characterization

Plants of the genus *Toxicodendron* (Anacardiaceae) have long been known for their ability to produce contact dermatitis in susceptible individuals. The best known species of this genus in the United States are *Toxicodendron radicans* (poison ivy), *Toxicodendron diversilobum* (western poison oak), and *Toxicodendron vernix* (poison sumac). The systematics of this genus have been well characterized (1).

The composition of the allergenic urushiol components (2–4) of poison oak (*T. diversilobum*) was studied. A prior study of the urushiol content of poison

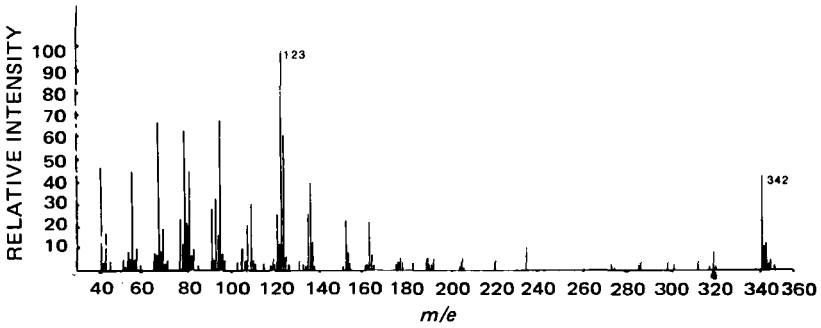

Figure 1—*Mass spectrum of isolated urushiol fraction. Molecular ions at 342, 344, 346, and 348 are for a series of unsaturated C_{17} catechol congeners.*

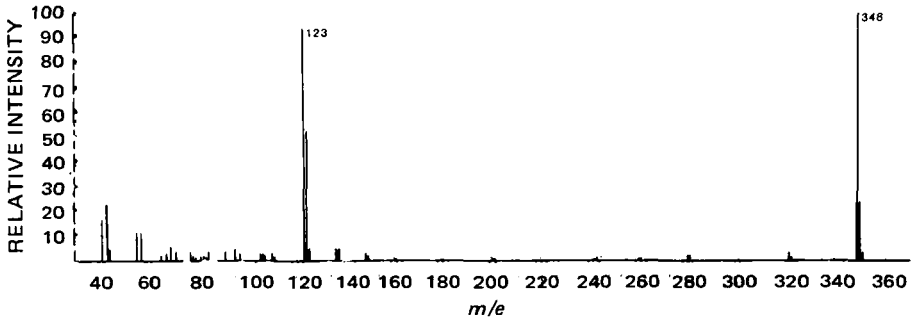

Figure 2—*Mass spectrum of hydrogenated urushiol extract. Molecular ion of heptadecylcatechol is at* m/e *348.*

ivy (*T. radicans*) indicated that it consists of four components (5, 6) having the carbon skeleton of 3-pentadecylcatechol (I), with the components differing from each other only in the degree of unsaturation in the C_{15} side chain. An early investigation (4) of the active component of poison oak indicated the presence of a catechol nucleus; however, a complete structural identification was not made.

This report demonstrates that the urushiol of poison oak is composed principally of a similar series of catechol components with a C_{17} side chain (II). The structural characterization of poison oak urushiol was made by mass spectrometry and UV and NMR analyses.

DISCUSSION

Pure urushiol was isolated as 0.18% of the fresh weight of *T. diversilobum*, employing two chromatographic steps. Additional urushiol fractions, totaling 0.10% of the fresh weight, were contaminated by nonphenolic materials and were not used for characterization of poison oak urushiol. The pure urushiol was a pale-amber-colored oil which solidified below 0°. The double bond number showed that most of the urushiol is the triunsaturated component.

The UV absorption spectrum of the hydrogenated urushiol was virtually identical with that of the urushiol etract with regard to the position and magnitude of their absorption maxima and minima. This observation parallels that reported for the poison ivy analysis (6) and thus precludes the existence of any conjugation in either the diolefinic or triolefinic component. In addition, the maximum absorption peak at 275 nm compares favorably with that of free catechol (λ_{max} 274 nm), which also indicates that there is no interaction between the centers of unsaturation in the side chain and the aromatic ring.

A direct probe mass spectral analysis of the isolated urushiol fraction shows a series of intense ions characteristic of an olefinic homologous series, ranging in mass from *m/e* 342 to 348 (Fig. 1). Although the relative intensities of these ions vary slightly with probe and source temperature, the ion at *m/e* 342 is always the most abundant; this ion is due to the molecular species of the triolefin. The most intense fragment ion occurs at *m/e* 123 and is probably a dihydroxytropylium ion, as might be expected from alkyl–aromatic compounds of this type.

To confirm that the spectrum represents a homologous series of molecular ions having a varying number of double bonds, a sample of the extract was reduced by hydrogenation and again analyzed by mass spectrometry. The results in Fig. 2 show a single intense peak in the molecular ion region at *m/e* 348. A compound of this molecular weight would be the product of a reduction reaction involving mono-, di-, and triolefinic precursors. The most intense fragment ion again occurs at *m/e* 123, which is consistent with the structure previously postulated since the aromatic nucleus is not reduced by the mild hydrogenation process.

Confirmation of the molecular formula of these species was made by high-resolution mass spectrometry (Table I). A weak intensity ion at *m/e* 320 was detected in the hydrogenated sample;

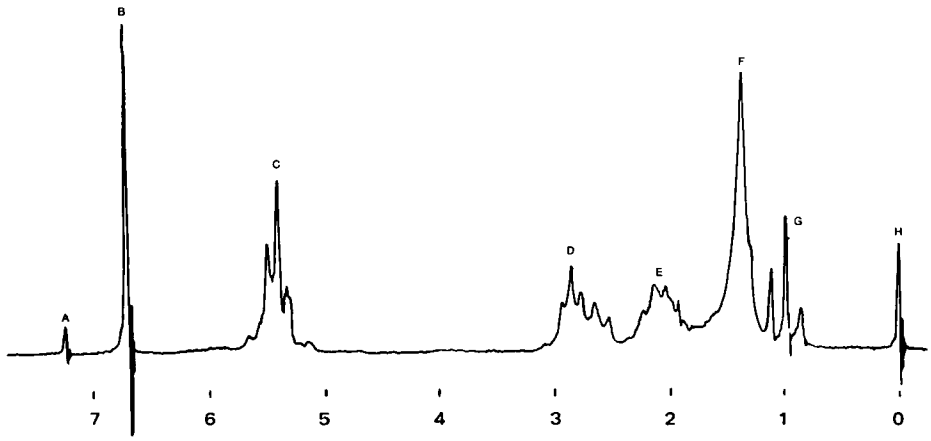

Figure 3—*NMR spectrum of isolated urushiol fraction. Key: A, chloroform; B, phenyl; C, vinyl; D, benzyl; E, allyl; F, methylene; G, methyl; and H, internal standard.*

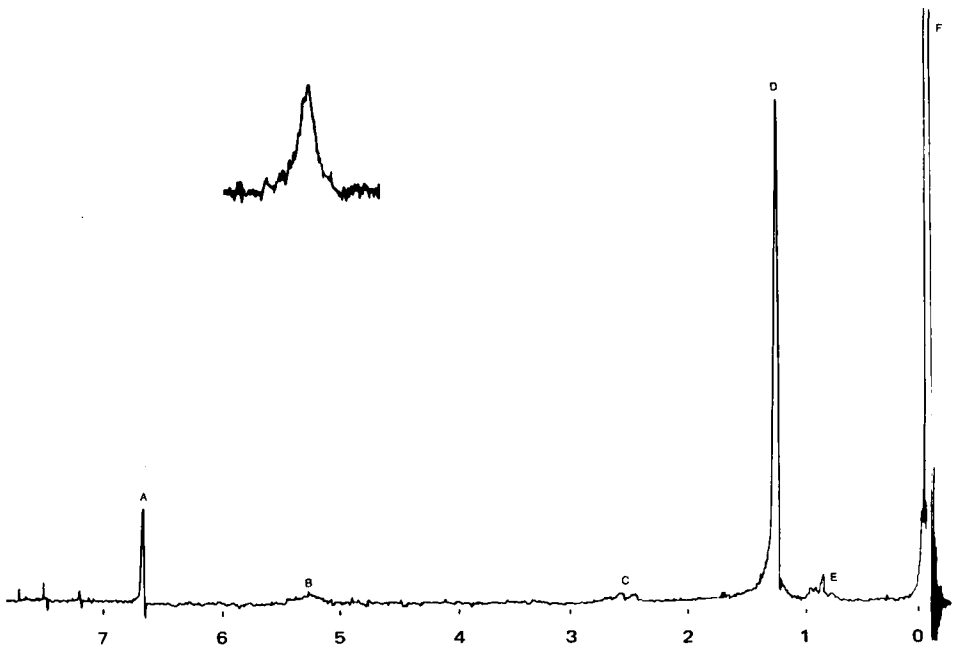

Figure 4—*NMR spectrum of hydrogenated urushiol extract. Key: A, phenyl; B, phenol (also expanded scale); C, benzyl; D, methylene; E, methyl; and F, internal standard.*

high-resolution mass spectrometry showed it to be the molecular ion of pentadecylcatechol, which is the saturated urushiol component reported in poison ivy. Subsequent analysis of the poison oak sample by mass spectrometry indicated that some of the C_{15} isomer is present in the poison oak urushiol, although the dominant component is clearly a series of C_{17} unsaturated congeners of catechol.

The complexity of the mixture and the uncertainty as to the relative rates of volatilization of each component precluded any effort to quantitate accurately the various homologs by direct insertion probe mass spectrometry. However, an approximate visual analysis indicated the triolefin to be the most abundant species and the saturated heptadecylcatechol to be the least. Use of direct probe mass spectrometry allowed for the incorporation of the molecular distillation technique which, in turn, provided sufficient control of sample volatility for analysis.

Efforts to resolve the sample components by GC so that a GC–mass spectrometric analysis could be made have been unsuccessful. The underivatized catechols or their trimethylsilyl derivatives have not been completely resolved under the GC conditions used. Efforts are underway to determine techniques to separate these olefinic catechols so that a quantitative result can be obtained. Furthermore, the double bond positions cannot be unambiguously assigned until the pure components can be analyzed. Structural information of this type was obtained from the mass spectra of various polyunsaturated fatty acids (7) and epoxy-derivatized olefins (8).

The NMR spectra of the urushiol components support the structure of a 3-*n*-alkylcatechol (Fig. 3). The benzylic, phenolic, aromatic, allylic, vinylic, methylene, and terminal methyl protons are all clearly identified. A spectrum of the reduced product (Fig. 4) retains only the aromatic, phenolic, benzylic, methylene, and methyl protons. The integrated NMR spectrum of the hydrogenated sample is easier to analyze than is the extract because of the unresolved nature and unsaturation of the urushiol prior to reduction. The integration of the methylene–methyl region (0.5–1.5) accounts for 33 protons. Two benzylic protons are observed at 2.6, and the aromatic and phenolic groups account for the remaining protons expected for this structure.

The conclusion to be drawn from the presented data is that the urushiol sample is a long chain C_{17} unbranched hydrocarbon, present as part of a catechol molecular structure. Thus, while poison ivy urushiol consists of the linear C_{15} side-chain components (9), poison oak urushiol is primarily composed of catechols with

Table II—Identification of Urushiol Fractions by TLC

Fraction	Weight, g	Purity (TLC)	R_f Solvent I	R_f Solvent II	Urushiol Test ($FeCl_3$)
A	0.3	Two major spots	0.50	0.60	— —
			0.35	0.30	+ +
B	0.9	Single spot	0.35	0.30	+ +
C	0.2	One major spot plus origin material	0.35	0.30	+ +

linear C_{17} side chains. These components, isolated from poison oak (*T. diversilobum*), are shown to differ from those reportedly found in poison ivy (*T. radicans*) by a $-CH_2CH_2-$ unit in the unbranched alkyl side chain.

EXPERIMENTAL[1]

Isolation and Purification of Urushiol—Fresh leaves, berries, and green stems of *T. diversilobum*[2] were collected in northern California, packed in dry ice, and shipped air freight. The material was processed immediately upon receipt. All extractions, evaporations, and chromatography were performed under a nitrogen atmosphere to retard air oxidation of the urushiol.

Fresh plant material (500 g) was covered with 4 liters of ethanol and allowed to stand for 4 days at 5°. Then the ethanol was decanted and evaporated *in vacuo* (40°) to give a black syrupy residue. This residue was partitioned between 500 ml of benzene and 200 ml of 5% NaCl solution and evaporated *in vacuo* to give 5.2 g of a dark-green oil. All of the oil was chromatographed on 100 g of silicic acid[3] packed in a 1.5-cm i.d. column. Elution with pure benzene and combination of all fractions producing a positive phenol test with 2% ethanolic ferric chloride gave 2.3 g of a dark-brown oil after evaporation *in vacuo*. Final purification of the urushiol was achieved by use of dry column chromatography (10).

The silicic acid[3] (100 g) was deactivated by treatment with 5 ml of water and was then treated with 10 ml of 10% ether–hexane. The treated silicic acid was packed in a 1.5-cm i.d. glass column in portions with the aid of a mechanical vibrator and 4.5 kg (10 lb) gauge of nitrogen pressure. The crude urushiol was dissolved in 2 ml of 10% ether–hexane and applied to the column. Development of the column with 10% ether–hexane was assisted by the application of 2.6 kg (5 lb) of nitrogen pressure.

Recovery of materials was made by complete elution from the column, as is occasionally done with dry columns (11). Thirty 15-ml fractions were collected and analyzed by TLC on silica gel plates[4] with the following solvents: I, ethyl acetate–hexane (3:10); and II, methylene chloride. Visualization of separate plates was made with 1% ferric chloride in 0.1 *N* HCl in methanol and with 10% sodium dichromate in 30% H_2SO_4. Combination of similar fractions gave three urushiol fractions of varying purity (Table II).

Fraction B, a pale-amber-colored oil, was considered to be pure urushiol; n_D^{25} 1.5201 ± 0.0002; double bond number based on a molecular weight of 348 ($C_{23}H_{40}O_2$): 2.8. UV λ_{max} (methanol): 275 nm; IR (neat): 3450 (medium, broad), 3025 (sh 3080, medium), 2980 (medium), 2950 (strong), 2875 (medium), 1630 (weak), 1605 (weak), 1490 (strong), 730, 775, and 830 (medium) cm^{-1}.

Mass spectral data are shown in Fig. 1 and NMR data are given in Fig. 3.

Hydrogenation of Urushiol—A 100-mg sample of the urushiol was hydrogenated[5] in 20 ml of methanol, with 10 mg of 10% palladium-on-charcoal as the catalyst. After filtration and evaporation of the solvent, the residue was recrystallized (methanol) to give 70 mg of a white amorphous solid, mp 63–65°; UV λ_{max} (methanol): 277 nm.

Mass spectral data are shown in Fig. 2 and NMR data are given in Fig. 4.

Distinction of Synthetic Cannabidiol, Cannabichromene, and Cannabivarin by GLC Using On-Column Methylation

KEITH BAILEY ˣ and DENISE GAGNÉ

Abstract □ The on-column flash methylation of synthetic cannabidiol, cannabichromene, and cannabivarin by trimethylanilinium hydroxide offers a rapid, simple GLC method for their distinction. The phenolic groups of other cannabinoids are methylated by the procedure described.

Keyphrases □ Cannabidiol, cannabichromene, and cannabivarin synthetic mixtures—GLC separation and analysis, on-column methylation □ Cannabichromene, cannabidiol, and cannabivarin synthetic mixtures—GLC separation and analysis, on-column methylation □ Cannabivarin, cannabidiol, and cannabichromene synthetic mixtures—GLC separation and analysis, on-column methylation □ Cannabinoid synthetic mixtures (cannabidiol, cannabichromene, and cannabivarin)—GLC separation and analysis □ GLC—separation and analysis, cannabidiol, cannabichromene, and cannabivarin synthetic mixtures, on-column methylation

Work in these laboratories has confirmed reports (1–3) that it is difficult to distinguish mixtures of synthetic cannabidiol (I), cannabichromene (II), and cannabivarin[1] (III) (4) by GLC analysis. Turner and Hadley (3) recently showed that trimethylsilylation of cannabidiol and cannabichromene gave the corresponding ethers, which were clearly separated by GLC on an OV-17 column, but cannabivarin was not examined in their study.

These three cannabinoids have phenolic groups which were expected to be amenable to on-column flash methylation using trimethylanilinium hydroxide (5, 6). The present study showed that the flash methylation technique offers a rapid and simple GLC method for the unequivocal distinction of the three pure compounds and for their separation in synthetic mixtures.

EXPERIMENTAL

GLC analyses were performed on two gas chromatographs[2], both equipped with flame-ionization detectors and fitted with 0.6-cm (0.25-in.) by 1.8-m (6-ft) glass columns packed with 5% OV-7[3] on 80–100-mesh Chromosorb W. Both the injection port and flame-ionization detector temperatures were 275°, and the nitrogen flow rate was 30 ml/min. Retention times were measured at several oven temperatures (Table I), and relative retention times were compared to the internal standard, 4-androstene-3,17-dione[4].

For methylation, 10 μl of a 0.5% cannabinoid solution in methanol (~0.16 μmole) was treated with 6–10 μl of 0.2 *M* trimethylanilinium hydroxide in methanol[5] (1.2–2 μmoles), and ~0.2 μl of the mixture was injected into the gas chromatograph. Emergent materials from the gas chromatograph was collected by extinguishing the detector flame and placing an open-ended glass capillary tube of the melting-point type over the jet at the predetermined time of peak emergence. The materials were examined by mass spectrometry[6] at an ionizing voltage of 70 ev and a probe temperature of 200°.

RESULTS AND DISCUSSION

Complete methylation of I, II, and III was shown to take place under the described conditions by the appearance of a single GLC peak and by examination of the emergent material by mass spectrometry. Thus, the mass spectrum of cannabidiol dimethyl ether had abundant ions at *m/e* (relative percent) 342 (14), 275 (36), 274 (100), 259 (11), 244 (21), 243 (91), 235 (19), 234 (17), 221 (67), 174 (13), 173 (57), and 158 (16). Cannabichromene methyl ether had abundant ions at *m/e* (relative percent) 328 (6), 313 (5), 246 (21), 245 (100), 231 (6), and 188 (8). Cannabivarin methyl ether had abundant ions at *m/e* (relative percent) 296 (6), 295 (21), 281 (35), 280 (100), 266 (9), 252 (9), 245 (9), 238 (21), and 209 (11).

Insufficient quantities of the trimethylanilinium hydroxide reagent resulted in the formation of the monomethyl ether of I, which had approximately the same retention time as the methyl ether of II. The mass spectrum of cannabidiol monomethyl ether had ions at *m/e* (relative percent) 328 (5), 327 (16), 313 (8), 286 (6),

4-Androstene-3,17-dione			38.0	15.5	1.00	1.00

[a] Varian Aerograph model A-700. [b] Hydro-Flow Systems Series 3000.

261 (10), 260 (41), 246 (27), 245 (100), 243 (9), 229 (8), 220 (9), and 207 (30).

Methylation of Δ^8-tetrahydrocannabinol (IV), Δ^9-tetrahydrocannabinol (V), cannabigerol (VI), and cannabinol (VII) also took place under these conditions; relative retention time and retention time data measured at two column temperatures on both instruments[2] are presented in Table I.

Synthetic cannabidiol, cannabichromene, and cannabivarin are easily distinguished by the simple methylation procedure described here. A chromatogram of a methylated mixture of the three is shown in Fig. 1. The applicability of the method to the determination of the cannabinoid content of *Cannabis* preparations, important when pharmacological studies are undertaken (7), remains to be investigated.

Rapid Methods for Bioavailability Determination Utilizing Urinary Excretion Data

PAUL J. NIEBERGALL ˣ, EDWIN T. SUGITA, and ROGER L. SCHNAARE

Abstract □ Two equations were developed which enable urinary excretion data to be utilized for estimating drug bioavailability within 12 hr starting between one and two half-lives of the drug, depending upon the relative rates of absorption, distribution, and elimination. Both equations were examined using simulated data for both the one- and two-compartment open models. One equation was tested using literature data with excellent results.

Keyphrases □ Urinary excretion data—equations for rapid estimation of bioavailability □ Bioavailability—equations for rapid estimation using urinary excretion data

The most widely used methods for estimating bioavailability for drugs following linear compartmental pharmacokinetics are based upon the measurement of unchanged drug in blood or urine after the administration of a single dose of drug. While the former readily yields estimates of peak blood level and time to reach peak blood level, as well as the extent of bioavailability, it does contain a number of rather serious pitfalls (1). Among these are:

1. The total area under the curve must be estimated, involving a model-dependent correction for the period between the cessation of sampling and time infinity.
2. The correction term requires a knowledge of the rate constant for the elimination phase.
3. Depending upon the model, parameters such as renal clearance, various rate constants, and volumes of distribution must be assumed to be constant either inter- or intrasubject.
4. The assay procedure must be sensitive enough to determine drug levels approximately one-tenth to one-twentieth that of the peak level.

Measurement of intact drug in the urine has certain advantages. The method is model independent as long as the drug does not exhibit nonlinear pharmacokinetics; samples are easier and less costly to obtain; urinary excretion data are more meaningful in instances where drugs are used to treat urinary tract infections or where there is no correlation between blood levels and pharmacological activity; and the only major assumption is that the average fraction of drug reaching the circulation that is excreted in the urine for a given panel is the same for two or more treatments.

The most serious disadvantage of using urinary excretion data for estimating the extent of bioavailability is that urine samples should be collected for at least seven to 10 half-lives of the drug (1). This requirement can be quite a problem with drugs having relatively long half-lives. This report presents two methods for analyzing urinary excretion data which demonstrate that, provided care is taken during the sampling procedure, the extent of bioavailability can be estimated with urine samples taken over 12 hr starting at one or two half-lives of a drug.

THEORY

When the absorption phase for drugs conforming to the one-compartment open model and both the absorptive and distributive phases for the two-compartment open model have been completed, the equations (2) describing the cumulative amount of drug excreted in the urine as a function of time for the one-compartment open model become:

$$U = U_\infty - \frac{U_\infty k_a}{k_a - k_e} e^{-k_e t} = U_\infty - P_1 e^{-k_e t} \qquad \text{(Eq. 1)}$$

and for the two-compartment open model:

$$U = U_\infty - \frac{U_\infty(k_{tc} - \beta)}{\beta(k_a - \beta)(\alpha - \beta)} e^{-\beta t} \doteq U_\infty - P_2 e^{-\beta t} \qquad \text{(Eq. 2)}$$

in which U is the cumulative amount of drug excreted unchanged in the urine up to time t, U_∞ is the total amount of drug excreted unchanged in the urine, k_a is the absorption rate constant, k_e is the overall elimination rate constant, k_{tc} is the rate constant for the transfer of drug from the tissue to the central compartment, and both α and β are the usual collections of constants representing the distributive and elimination phases, respectively.

In the interest of brevity, since both Eqs. 1 and 2 have the same general form, all further developments will be given using Eq. 1 as the example. If urine samples are collected at uniform time intervals, Δ, the cumulative amount, U', of drug excreted up to time $t + \Delta$ is:

$$U' = U_\infty - P_1 e^{-k_e(t+\Delta)} \qquad \text{(Eq. 3)}$$

Equations 1 and 3 can be rearranged to:

$$U - U_\infty = -P_1 e^{-k_e t} \qquad \text{(Eq. 4)}$$

and:

$$U' - U_\infty = -P_1 e^{-k_e t} e^{-k_e \Delta} \qquad \text{(Eq. 5)}$$

Dividing Eq. 4 by Eq. 5 and rearranging give (3):

$$U' = U(e^{-k_e \Delta}) + U_\infty(1 - e^{-k_e \Delta}) \qquad \text{(Eq. 6)}$$

Thus, a plot of U' *versus* U should give a straight line with a slope equal to $e^{-k_e\Delta}$ and an intercept equal to $U_\infty(1 - e^{-k_e\Delta})$. The intercept divided by 1 minus the slope yields U_∞, and the natural logarithm of the slope divided by the collection time interval (Δ) yields $-k_e$. The final equation for the two-compartment open model is the same as Eq. 6, with the exception that β replaces k_e.

RESULTS

To determine whether the equations describing the cumulative amount of drug excreted in the urine as a function of time would simplify to the forms given by Eqs. 1 and 2 within a reasonable period of time, data were simulated for both pharmacokinetic models. For the one-compartment open model, the fraction of the dose (400 mg) absorbed was assumed to be 0.80, the fraction excreted in the urine unchanged was 0.65, and the volume of distribution was 10 liters.

Data were generated for drugs having half-lives ($T_{1/2}$) of 12, 18, 24, and 48 hr. In each instance, the absorption rate constant was varied, being equal to 2, 5, 10, and 20 times the elimination rate constant, respectively. Constants for the two-compartment open

Table I—Percent of Actual Bioavailability from Data Evaluated over a 12-hr Period Starting at n Half-Lives Using Eq. 6

	R^a			
n	20	10	5	2
1	100.0	100.1	102.7	141.0
2	100.0	100.0	100.1	104.4
3	100.0	100.0	100.0	100.8

[a] R is the ratio of the absorption rate constant to the elimination rate constant.

model were taken from the literature for nortriptyline (4), having a $T_{1/2}$ of approximately 34 hr, assuming that 80% of a given dose would be absorbed and 65% of the dose would be excreted in the urine unchanged.

The data for all simulations were evaluated over 12 or 16 hr starting at one, two, and three half-lives. Thus, when $T_{1/2}$ was equal to 12 hr, the cumulative amount of drug excreted up to 14 hr was plotted *versus* the cumulative amount excreted up to 12 hr, the amount excreted up to 16 hr was plotted *versus* the amount excreted up to 14 hr, and the amount excreted up to 18 hr was plotted *versus* the amount excreted up to 16 hr. This procedure was continued for a 12-hr interval if the collection interval (Δ) was equal to 2 hr; it was continued for a 16-hr interval if the collection interval was equal to 4 hr. The procedure was repeated starting at 24 hr and again at 36 hr.

Except for round-off error in the calculations (percent relative bioavailability was calculated to three significant figures), all data for the one-compartment open model yielded the same results regardless of the $T_{1/2}$ or the collection interval. Therefore, the results obtained for the drug with $T_{1/2}$ equal to 12 hr and a collection interval of 2 hr are representative of the results obtained in the entire study (Table I). It can be seen from Table I that acceptable estimates of bioavailability should be obtainable from urine collections starting at approximately one half-life if the absorption rate constant is equal to at least five times the elimination rate constant. Acceptable values can be obtained after two half-lives if the absorption rate constant is at least equal to twice the elimination rate constant. The data for the two-compartment open model ($T_{1/2}$ = 34 hr) were evaluated over the period of 68–80 hr with a constant time interval of 2 hr. The bioavailability was estimated to within 99.9% of the correct value.

Unfortunately, studies involving the urinary excretion of drugs are not necessarily designed for adequate testing of Eq. 6. In one study (5), urine specimens were collected at constant time intervals starting at approximately two half-lives. The drug, phosphonomycin, has a $T_{1/2}$ of approximately 2.3 hr. The data were evaluated (5) for the pharmacokinetic parameters of a two-compartment open model, and predicted as well as observed cumulative urinary excretion values of the drug were given at various times up to, and including, 36 hr (about 16 half-lives). The data for the 4–8- and the 8–12-hr collection periods were analyzed according to Eq. 6 (Table II). The agreement between U_∞ predicted from Eq. 6 and the actual value is remarkable, considering the fact that only two collection periods could be utilized.

Table II—Evaluation of Literature[a] Data for Phosphonomycin Using Eq. 6

		U_∞, mg	
Subject Number	Eq. 7	Literature Predicted	Literature Actual
9	479.5 (0.99)[b]	479.5 (0.99)	484.3
10	376.1 (1.70)	375.4 (1.51)	369.8
11	460.4 (0.09)	461.4 (0.30)	460.0
12	597.4 (0.20)	598.0 (0.10)	598.6
13	438.4 (0.90)	438.0 (0.99)	442.4
14	407.6 (1.32)	408.2 (1.47)	402.3

[a] Reference 5. [b] The relative error for each prediction is given in parenthesis ($T_{1/2}$ = 2.3 hr).

Since times corresponding to one or two half-lives might not be convenient, a reasonable method would be to give the drug in the morning and start timed urine collections at 24, 48, 72, *etc.*, hr, whichever is equal to at least one half-life. The drug could also be given in the evening and timed urine collections started at 12, 36, 60, *etc.*, hr.

In some instances, it might not be convenient to collect urine specimens at constant time intervals. In such situations, urinary excretion rates can be utilized to predict U_∞. Differentiating Eq. 1 with respect to time gives:

$$dU/dt = \dot{U} = P_1 k_e e^{-k_e t} \qquad \text{(Eq. 7)}$$

Substituting the value for $P_1 e^{-k_e t}$ from Eq. 1 into Eq. 7 and rearranging give:

$$U = U_\infty - (\dot{U}/k_e) \qquad \text{(Eq. 8)}$$

A plot of U *versus* $\dot{U}$ should be linear with the intercept equal to U_∞. Equation 2 can be developed in a similar manner to yield an equation resembling Eq. 8, with the exception that β would replace k_e. All data were analyzed according to Eq. 8 with results identical to those already shown, within round-off error.

SUMMARY

Although technical problems do exist, urine specimens can be collected at short time intervals during the initial phase of a bioavailability study and the data can be analyzed (6) to yield an estimate of the absorption rate constant. Specimens can then be collected at times convenient to each test subject. At 24, 48, *etc.*, hr, whichever is closest to one or two half-lives (depending upon the estimated ratio of the absorption rate constant to the elimination rate constant), all initial samples should be pooled. Samples should then be collected at exactly 2-hr intervals for 12 hr. The data for the 12-hr period should then be analyzed utilizing Eq. 6. If the collection intervals cannot be kept constant during the 12 hr, the data should be analyzed according to Eq. 8.

The data in Tables I and II indicate that the methods presented are valid. Whether useful estimates of bioavailability are obtained in practice will depend upon the care with which the data are collected. The methods presented probably are more sensitive to incomplete bladder emptying than the method in which specimens are collected over seven to 10 half-lives of a drug. However, forcing fluids should dilute the urine enough that the magnitude of this problem can be reduced. Patient variability in bladder emptying can be further reduced through the use of a crossover study. Finally, shortening the collection period from seven to 10 half-lives to approximately one or two half-lives should help with subject compliance with the study protocol.

In Vitro and *In Vivo* Availability of Commercial Prednisone Tablets

TIMOTHY J. SULLIVAN, ERMELINDA SAKMAR, KENNETH S. ALBERT, DONALD C. BLAIR, and JOHN G. WAGNER ˣ

Abstract □ A three-way crossover bioavailability study was performed using nine adult male volunteers with three different commercial prednisone tablets. Plasma samples were assayed for prednisolone, the active metabolite of prednisone, by a radioimmunoassay method. Statistical analysis showed significant differences in the rate of appearance of prednisolone in plasma but not in the amount converted to prednisolone. The results suggest that differences in *in vivo* rates of appearance of prednisolone in plasma correlate with *in vitro* rates of dissolution.

Keyphrases □ Prednisone—*in vitro* and *in vivo* bioavailability of commercial tablets □ Bioavailability—commercial prednisone tablets

Previous studies (1, 2) demonstrated that the clinical effectiveness of prednisone tablets can be correlated with *in vitro* dissolution rates. Two generic prednisone tablets that were inactive clinically dissolved much slower than a clinically active brand of prednisone tablet. Based at least in part on this discovery, USP XVIII included a dissolution test for prednisone tablets (3).

It is well documented that orally administered prednisone is rapidly metabolized to prednisolone, which is believed to be the bioactive form (4–6). With the development of a radioimmunoassay for prednisolone (6), it is now possible to measure the plasma levels of prednisolone following oral administration of single, low doses of prednisone.

This paper reports the results of a three-way crossover bioavailability study with commercially available prednisone tablets.

EXPERIMENTAL

The *in vitro* dissolution studies and content uniformity tests were performed in the laboratories of the Food and Drug Administration (FDA) according to USP XVIII specifications.

A three-way crossover bioavailability study was performed using nine healthy adult male volunteers between the ages of 24 and 31 years and weighing between 67.6 and 93.4 kg. The criteria for subject selection were previously reported (7). In each phase of the crossover study, each subject ingested 10 mg of prednisone as two 5-mg tablets of Tablet A, B, or C[1]. The treatment schedule is shown in Table I. Treatments were separated by 1 week.

The evening before each treatment period, 1.0 mg of dexamethasone was administered orally to each subject to suppress endogenous secretion of cortisol. The suppression was maintained by administration of 0.5 mg of dexamethasone 8 hr after the administration of prednisone.

Whole blood samples were taken from a forearm vein at 0, 0.25, 0.5, 1, 2, 3, 4, 6, 8, 12, and 24 hr postdosing with prednisone. Each sample was centrifuged as soon as possible after collection; the plasma was placed in a stoppered vial, quick-frozen, and kept frozen until just prior to assay.

[1] Tablet A was Meticorten, 5 mg (Schering Corp.), Lot No. 2ABB804; Tablet B was prednisone, 5 mg (Marshall Pharmacal Corp., South Hackensack, N.J.), Lot No. 7165; and Tablet C was prednisone, 5 mg (Heather Drug Co., Cherry Hill, N.J.), Lot No. 090156.

Table I—Treatment Schedule

Subjects	Group	Phase I (Week 1)	Phase II (Week 2)	Phase III (Week 3)
1, 2, 3	I	A	B	C
4, 5, 6	II	B	C	A
7, 8, 9	III	C	A	B

Table II—Results of USP Tests on Tablets Used in Human Study

	96.2	96.7	Average	11.4
			SD	2.07
	Average	99.6		
	SD	2.78		

[a] The higher than label values are most probably caused by nonsteroidal components which absorb at the wavelength used in the tablet dissolution test. [b] Standard deviation. [c] Not in compliance with USP specifications.

All plasma samples were assayed for prednisolone using a modification of the procedure of Colburn and Buller (6), described previously (7).

All calibration curves were fitted essentially perfectly to a biexponential equation using the program NONLIN and a computer[2]. The amount of drug in the experimental plasma samples was then determined with an iterative program using an electronic calculator[3].

RESULTS AND DISCUSSION

In Vitro—Results of the USP content uniformity and tablet dissolution tests are summarized in Table II. Tablet A passed both the content uniformity and the tablet dissolution tests as well as the assay test (101.0% of label). Tablets B and C failed the tablet dissolution test since they gave values of 12.3 and 11.4% dissolved, respectively; the USP requires at least 60% of the labeled amount of prednisone to be dissolved in 20 min.

[a,b,c] See footnotes to Table III. [d] From observed peak plasma levels of individual subjects.

Tablet B failed the initial phase of the content uniformity test since one of the 10 tablets tested was out of compliance, but the results of the second phase of this test were not available. Tablet C passed the content uniformity test. These results were of interest because all three lots of tablets were purchased on the open market by the FDA.

In Vivo—One lot of generic tablets (Tablet B or C) had a history of clinical failure, and the following is a statement written by the FDA concerning this lot (designated 078-692F by the FDA):

> *The FDA documented therapeutic failures with the prednisone tablets in two patients afflicted with congenital adrenal hyperplasia in December, 1971. Immediate follow-up by FDA's Newark District Office ascertained that the subject lot of tablets failed the USP dissolution test. Further investigation by the FDA revealed that the product was no longer in the channels of distribution and thus was not available for recall or seizure. A "Consent Decree of Permanent Injunction" was signed by the firm on May 1, 1972 in the U.S. District Court of New Jersey which stipulated that the firm will not manufacture and introduce products into interstate commerce which fail to meet appropriate standards.*

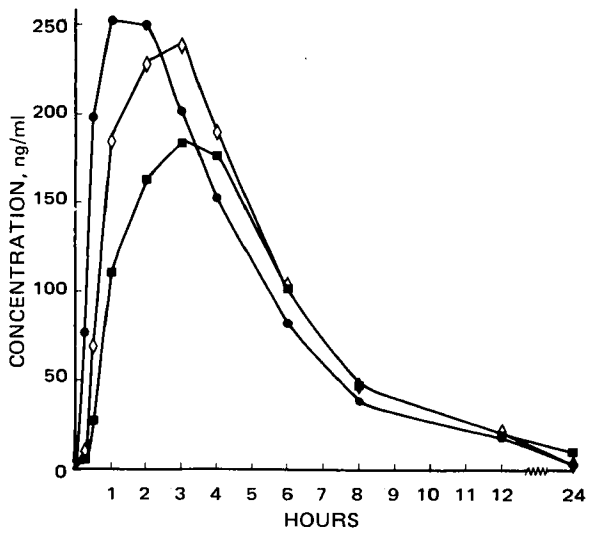

Figure 1—*Average plasma concentrations of prednisolone following oral administration of prednisone as Tablet A (●), Tablet B (■), or Tablet C (◊).*

In the human bioavailability study, it was important to consider the cross-reactivity of prednisolone and cortisol with the antiserum (7). To obtain a specific assay for prednisolone, it was necessary to suppress endogenous secretion of cortisol. This suppression was accomplished by the administration of dexamethasone (8). Any effect of dexamethasone on the conversion of prednisone to prednisolone is unknown, but it would be expected to be minimal and unimportant under the study conditions because of the time interval between doses and the relative magnitudes of the doses.

Dexamethasone, even in high concentrations, does not interfere with the binding of prednisolone to the antibody. Prednisone has also been shown not to interact significantly with the antibody (6).

Tables III and IV summarize the results of the bioavailability study and the statistical analysis of the data. It is apparent from Table III that there are significant differences in the rates of appearance of prednisolone in plasma. Analyses of variance of plas-

ma concentrations indicated highly significant differences among average plasma concentrations from 0.25 to 4 hr, inclusive. Tukey's Multiple Comparison Test (9) was used to identify significant differences between treatment pairs. The test indicated significant differences during the absorptive phase when Tablet A was compared to either Tablet B or C. The particular patterns of significant differences between treatments can be rationalized by considering the average plasma level curves for each (Fig. 1).

Differences in peak plasma concentrations and time of the peak were also seen (Table IV). The average peaks and rates of appearance were in the order: A > B or C. Since Tablet A was the innovator's product and considered the "standard" preparation, comparisons of only Tablet A *versus* B and Tablet A *versus* C were made. No statistical comparison of Tablet B *versus* C should be inferred (Tables III and IV).

After the 4-hr sampling time, the differences among average plasma prednisolone concentrations were not significant ($p > 0.10$). At the 24-hr sampling time, 11 out of the total 27 samples produced measurable levels of steroid, which in some cases were as high or higher than those of the 12-hr sample. Ten of these incidents occurred within the same four subjects. It seems reasonable to conclude that these levels may be due to the recovery of normal adrenal function rather than to the presence of prednisolone in the sample.

There were no significant differences among treatment average areas, either 0–12 hr or 0–24 hr (Table IV). This finding suggested that the efficiencies of absorption of prednisone, as indicated by the presence of prednisolone, did not differ significantly among treatments. The logarithm of area from 0 to 12 hr and the ratio of area divided by the dose in milligrams per kilogram times the half-life were investigated as additional measures of efficiencies of absorption, but the differences among these average parameters were not significant. The rationale for analyzing the logarithm of area was proposed by Westlake (10).

The differences among mean half-lives of prednisolone were not significant. The half-life ranged from 1.51 to 3.65 hr. The overall average half-life was 2.47 hr. None of the 24-hr points was used to calculate the half-life; the 4–12-hr points generally gave a straight line on semilogarithmic paper. The half-lives estimated are similar to those reported when prednisolone itself was administered orally (7).

CONCLUSIONS

The data presented indicate that prednisone Tablets A, B, and C differ only in the rate of appearance of prednisolone in the plasma and not in the amount of prednisone that reaches the circulation. The results document that differences in *in vivo* rates of appearance of prednisolone in humans correlate with *in vitro* rates of dissolution of prednisone and with a reported clinical failure in the use of prednisone.

Intestinal pH as a Factor in Selection of Animal Models for Bioavailability Testing

WILLIAM G. CROUTHAMEL[x], CRAIG R. ABOLIN*, JOAN HSIEH, and JAMES K. LIM

Abstract □ Previous *in situ* studies showed that intestinal drug absorption is strongly influenced by intestinal pH. Three animal species considered for bioavailability testing were studied *in situ* to determine intestinal pH. Results from the rat and dog correlated well with results in humans, while results from the rabbit did not. The rabbit appears to be a poor candidate for attempted animal–human bioavailability correlations.

Keyphrases □ Intestinal pH, rats, dogs, and rabbits—*in situ* determination, factor in selection of animal model for bioavailability testing □ Bioavailability correlations, animal–human—intestinal pH of rats, dogs, and rabbits as a factor in model selection □ Animal models for bioavailability testing—intestinal pH as factor for model selection, *in situ* determination in rats, dogs, and rabbits

New drug entities are routinely tested in animal models. Following initial and toxicological tests, candidate dosage forms are frequently tested in animals to determine the best dosage forms for further clinical testing. Although it is recognized that there are many differences between animals and humans and between animal species, little information is available concerning differences in absorption between these groups. With the recent increase in emphasis on bioavailability testing, the search for better animal models for these tests has intensified.

The Food and Drug Administration (1) recently suggested that animal models be developed that correlate bioavailability in animals with similar results in humans. However, before this plan can be accomplished on a widespread basis, more information must be available on the similarities and dissimilarities of these animal models. Dogs have occasionally been used in these studies, but other animals have also been suggested (2).

Previous studies (3) in animals showed that the absorption of drugs from the intestine is highly dependent on intestinal pH. This study was undertaken to determine intestinal pH in several animal species suggested for bioavailability studies.

EXPERIMENTAL

The *in situ* method of Doluisio *et al.* (4) was used in these experiments. Briefly, in each animal model the intestine was exposed by midline incision. The intestinal section to be studied was prepared by making a small slit in the intestinal wall at each end of the segment, inserting a small polyethylene cannula in each slit, and ligating these cannulas into place to form a cannulated intestinal segment. Care was taken to keep trauma to the intestine to a minimum and to maintain an intact blood supply.

A plastic syringe barrel was then attached to the exposed end of each cannula, and the intestinal solution was placed in the intestinal loop. The intestinal solutions used were isotonic saline in the rat, isotonic phosphate buffer (0.055 *M*) in the rabbit, and isotonic phosphate buffer (0.095 *M*) in the dog. All solutions were checked for isotonicity and adjusted to pH 6.0 prior to instillation. At time intervals of 10–20 min, the solution was gently forced into one syringe barrel by air pressure from the other, and the pH was determined by a micro-pH electrode. The solution was then returned to the intestine.

This procedure ensured that the contents of the intestine were thoroughly mixed during the experiment. Although the solutions used differed in buffer capacity, the intestine has a large intrinsic ability to buffer its contents. The equilibrium pH values reported in Table I were recorded at 50, 60, and 100 min in the dog, rat, and rabbit, respectively.

In the rat studies, the duodenal section consisted of approximately 10 cm of duodenum measured from the pylorus to 4 cm distal to the ligament of Trietz. The bile duct was either left intact (normal bile) or ligated (no bile). The rat upper jejunal section consisted of 45 cm of jejunum beginning 4 cm distal to the ligament of Trietz, and the lower jejunal section consisted of an equal length of jejunum measured proximally beginning 5 cm proximal to the cecum.

In the rabbit studies, the duodenal section consisted of 25 cm of duodenum measured distally beginning 1 cm below the bile duct, and the jejunal section consisted of an equal length measured distally beginning 45 cm below the pylorus. In the dog experiments, the jejunal section consisted of 26 cm of jejunum measured distally beginning 26 cm below the ligament of Trietz.

Although the upper jejunal sections used are not exactly comparable in the three species due to experimental limitations, intestinal pH in the dog upper jejunum was found constant in four different sections studied.

RESULTS AND DISCUSSION

The pH values reported in Table I indicate that there is little difference in pH between the duodenum and upper jejunum and between the presence and absence of bile flow in the rat. In the rabbit, duodenal and jejunal pH values are also quite similar but are considerably higher than those found in either the rat or dog. Human intestinal pH values in normal subjects are reported to be (5): duodenum, 4.7–6.5, upper jejunum, 6.2–6.7, and lower jejunum, 6.2–7.3. Thus, pH values reported in humans correspond well with those found in the rat and dog but not with those found in the rabbit. Based on pH considerations alone, the rabbit does not appear to be a good animal model for attempting human–animal correlations.

The pH values reported here are equilibrium values in the bulk intraluminal fluid and may not necessarily be representative of the pH found in the "unstirred layer," the thin aqueous film located directly next to the absorbing membrane (6). However, previous studies (3) in the *in situ* model showed a good correlation between the rate of drug absorption and intraluminal pH over a wide pH range. Therefore, it is not unreasonable to speculate that drug ab-

Table I—Intestinal pH Values *In Situ*

Intestinal Section	pH Values, Mean ± *SD*		
	Rat	Rabbit	Dog
Duodenum (no bile flow)	6.6 ± 0.2 (6)[a]	7.8 ± 0.1 (15)	—
Duodenum (normal bile flow)	6.5 ± 0.3 (6)	—	—
Upper jejunum	6.4 ± 0.1 (4)[b]	7.5 ± 0.1 (19)	6.2 ± 0.1 (10)
Lower jejunum	7.2 ± 0.1 (5)	—	—

sorption may be influenced by the differences in pH described here.

Under any circumstances, the intraluminal pH will have an important effect on the disintegration and dissolution characteristics of dosage forms administered to intact animals. This is particularly true of special dosage forms such as suspensions, coated tablets, and timed-release products where pH is an inherent part of the product design. Just as differences in biliary recycling between species can influence the pharmacokinetics of drugs administered in intact animals, intraspecies differences in intestinal pH can also be expected to influence the site and extent of absorption as well as the intestinal contribution to the volume of distribution (7).

When selecting an animal model for pharmacokinetic or bioavailability studies, intestinal pH should be considered as a potential determinant of the outcome. Of course, some drugs are potentially too toxic (*e.g.*, methotrexate) to be tested for bioavailability in normal human subjects, so for these drugs the development of suitable animal models is especially important.

Effect of an Antacid on Absorption of Digoxin in Dogs

Keyphrases □ Digoxin—effect of antacids on absorption, dogs □ Absorption—digoxin, effect of antacid, dogs □ Antacids—effect on absorption of digoxin, dogs

To the Editor:

Recently, Khalil demonstrated that the *in vitro* dissolution of digoxin tablets[1] was suppressed by a commercial antacid containing aluminum hydroxide (0.31 g/5 ml) and magnesium trisilicate (0.60 g/5 ml). The present study examined the effect of this commercial antacid[2] on the absorption of digoxin in dogs after oral administration.

Following overnight fasting, each of four mongrel dogs was given either two digoxin tablets[3] (1.0 mg) or 20 ml of the commercial antacid plus two tablets at weekly intervals in accordance with a crossover design. The antacid was given by stomach intubation, and 50 ml of water was given to each dog following administration of the dosage formulation.

Blood (4 ml) was withdrawn from the radial vein at 0, 0.5, 1, 1.5, 2, 2.5, 3, 4, 7, and 24 hr following drug administration (Table I). The plasma samples were analyzed using a commercial digoxin assay kit[4]. A standard curve was obtained for each animal using its blank plasma.

Analysis of variance on each data point indicated that there was no significant difference ($p \leq 0.01$) between concentrations at any time point following the

Blood Levels from a Sustained-Release Dosage Form

Keyphrases □ Dosage forms—sustained release, blood levels, fast and slow release drug components, equations □ Timed-release dosage forms—blood levels, fast and slow release components, equations □ Blood levels—sustained-release dosage form, fast and slow release components, equations

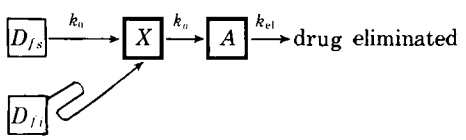
To the Editor:

The ideal oral dosage form for obtaining a desired plateau level of drug rapidly in the body is one that releases part of the dose instantaneously and the balance by a slow zero-order process. Pharmacokinetic approaches to calculate the desired proportion of fast and zero-order release components have been described (1, 2).

One method (1) gives the desired steady-state drug level at the peak time, t_p, for the fast release component and also later during the sustained-release period. Between these times, however, drug levels tend to be higher, producing a hump in the overall blood drug level *versus* time profile.

Another method (2) provides a constant plateau level of drug C_{ss}, which is reached slightly later than time t_p. The constancy of the drug levels and the somewhat simpler calculations probably make it the method of choice in most situations.

The objective of this communication is to describe a method of calculating fast and slow release drug components. While similar to the method of Robinson and Eriksen (2), it facilitates more rapid calculation of the drug fractions and permits considerable simplification of the rather lengthy equations used



Scheme I

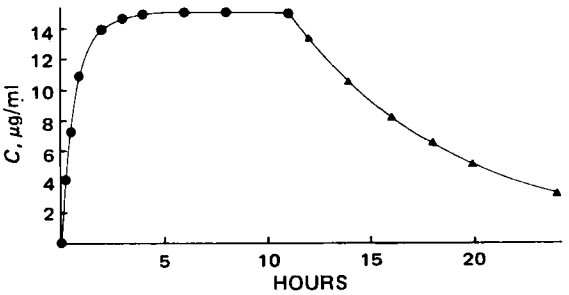


Figure 1—*Simulated blood level curve using data from Table I and Eqs. 6 (●) and 7 (▲).*

hitherto to describe this model. The overall process is described in Scheme I.

In the model, D_{fs} and D_{fi} are the sustained-release and fast release components of the total dose D, respectively; X is the amount of drug in solution and available for absorption in the gut; A is the amount of drug distributed in a single homogeneous volume, V, in the body to give a concentration, C; k_0 is the zero-order rate constant for release of D_{fs}; and k_a and k_{el} are first-order rate constants for drug absorption into the body and elimination by all routes, respectively. The crooked arrow represents instantaneous release of D_{fi} into X.

The assumptions in this model are as stated previously (1): all drug in the body is homogeneously distributed in one apparent volume, V, and the rate of drug absorption is invariant throughout the GI tract. The sustained-release component, D_{fs}, releases drug from time zero to time T, so $D_{fs} = k_0 T$ and both D_{fi} and D_{fs} contribute to the blood level beginning at time zero.

Integrated expressions to describe the amounts of drug D_{fs}, X, and A at any time during drug release are given by Eqs. 1–3:

$$D_{fs}(t) = D_{fs} - k_0 t \qquad \text{(Eq. 1)}$$

$$X = \frac{k_0}{k_a}[1 - e^{-k_a t}] + D_{fi}e^{-k_a t} \qquad \text{(Eq. 2)}$$

$$A = \frac{k_0}{k_{el}}(1 - e^{-k_{el}t}) + \left(\frac{k_a D_{fi} - k_0}{k_{el} - k_a}\right)(e^{-k_a t} - e^{-k_{el}t}) \qquad \text{(Eq. 3)}$$

To calculate D_{fi}, Rowland and Beckett (1) set A equal to A_{ss} at the single time t_p. This method, as previously stated, results in a hump in the drug blood level profile for an intermediate time following t_p. An alternative approach is based on k_0 being equal to $(k_{el})(A)$ at the steady state. Then substituting for k_0 in Eq. 3 and rearranging give Eq. 4, where $A = A_{ss}$:

$$D_{fi} = \left(\frac{1}{k_a} + \frac{(k_{el} - k_a)e^{-k_{el}t}}{k_{el}k_a(e^{-k_a t} - e^{-k_{el}t})}\right)(k_{el})(A_{ss}) \qquad \text{(Eq. 4)}$$

To avoid a hump in the blood level profile, A must be maintained at A_{ss}, which requires that Eq. 4 be time independent. Since $k_a > k_{el}$ in the usual case, time independency occurs only when $e^{-k_a t}$ becomes insignificant relative to $e^{-k_{el}t}$. Then Eq. 4 simplifies to:

$$D_{fi} = A_{ss} = \frac{k_0}{k_{el}} \qquad \text{(Eq. 5)}$$

crossover administrations. The results of this study ran contrary to a possible implication (*i.e.*, impairment of digoxin bioavailability by the antacid) of Khalil's *in vitro* findings in which the dissolution of digoxin tablets was virtually completely suppressed by the antacid (1).

Further experiments in humans are necessary to substantiate these findings in dogs.

Keyphrases □ Dosage forms—sustained release, blood levels, fast and slow release drug components, equations □ Timed-release dosage forms—blood levels, fast and slow release components, equations □ Blood levels—sustained-release dosage form, fast and slow release components, equations

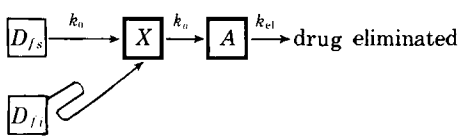
To the Editor:

The ideal oral dosage form for obtaining a desired plateau level of drug rapidly in the body is one that releases part of the dose instantaneously and the balance by a slow zero-order process. Pharmacokinetic approaches to calculate the desired proportion of fast and zero-order release components have been described (1, 2).

One method (1) gives the desired steady-state drug level at the peak time, t_p, for the fast release component and also later during the sustained-release period. Between these times, however, drug levels tend to be higher, producing a hump in the overall blood drug level *versus* time profile.

Another method (2) provides a constant plateau level of drug C_{ss}, which is reached slightly later than time t_p. The constancy of the drug levels and the somewhat simpler calculations probably make it the method of choice in most situations.

The objective of this communication is to describe a method of calculating fast and slow release drug components. While similar to the method of Robinson and Eriksen (2), it facilitates more rapid calculation of the drug fractions and permits considerable simplification of the rather lengthy equations used



Scheme I

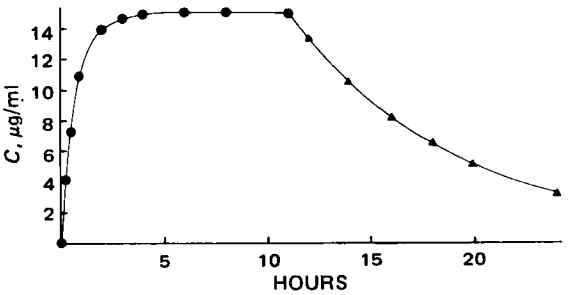


Figure 1—*Simulated blood level curve using data from Table I and Eqs. 6 (●) and 7 (▲).*

hitherto to describe this model. The overall process is described in Scheme I.

In the model, D_{fs} and D_{fi} are the sustained-release and fast release components of the total dose D, respectively; X is the amount of drug in solution and available for absorption in the gut; A is the amount of drug distributed in a single homogeneous volume, V, in the body to give a concentration, C; k_0 is the zero-order rate constant for release of D_{fs}; and k_a and k_{el} are first-order rate constants for drug absorption into the body and elimination by all routes, respectively. The crooked arrow represents instantaneous release of D_{fi} into X.

The assumptions in this model are as stated previously (1): all drug in the body is homogeneously distributed in one apparent volume, V, and the rate of drug absorption is invariant throughout the GI tract. The sustained-release component, D_{fs}, releases drug from time zero to time T, so $D_{fs} = k_0 T$ and both D_{fi} and D_{fs} contribute to the blood level beginning at time zero.

Integrated expressions to describe the amounts of drug D_{fs}, X, and A at any time during drug release are given by Eqs. 1–3:

$$D_{fs}(t) = D_{fs} - k_0 t \qquad \text{(Eq. 1)}$$

$$X = \frac{k_0}{k_a}[1 - e^{-k_a t}] + D_{fi}e^{-k_a t} \qquad \text{(Eq. 2)}$$

$$A = \frac{k_0}{k_{el}}(1 - e^{-k_{el}t}) + \left(\frac{k_a D_{fi} - k_0}{k_{el} - k_a}\right)(e^{-k_a t} - e^{-k_{el}t}) \qquad \text{(Eq. 3)}$$

To calculate D_{fi}, Rowland and Beckett (1) set A equal to A_{ss} at the single time t_p. This method, as previously stated, results in a hump in the drug blood level profile for an intermediate time following t_p. An alternative approach is based on k_0 being equal to $(k_{el})(A)$ at the steady state. Then substituting for k_0 in Eq. 3 and rearranging give Eq. 4, where $A = A_{ss}$:

$$D_{fi} = \left(\frac{1}{k_a} + \frac{(k_{el} - k_a)e^{-k_{el}t}}{k_{el}k_a(e^{-k_a t} - e^{-k_{el}t})}\right)(k_{el})(A_{ss}) \qquad \text{(Eq. 4)}$$

To avoid a hump in the blood level profile, A must be maintained at A_{ss}, which requires that Eq. 4 be time independent. Since $k_a > k_{el}$ in the usual case, time independency occurs only when $e^{-k_a t}$ becomes insignificant relative to $e^{-k_{el}t}$. Then Eq. 4 simplifies to:

$$D_{fi} = A_{ss} = \frac{k_0}{k_{el}} \qquad \text{(Eq. 5)}$$

Table I—Calculation of Sustained-Release Parameters for Theophylline

Parameter	Value	Method of Calculation
A_{ss}	480 mg	$A_{ss} = C_{ss}V$
D_{fi}	480 mg	Eq. 5
k_0	57.6 mg/hr	$k_0 = (k_{el})(A_{ss})$
D_{fs}	633.6 mg	$D_{fs} = k_0 T^b$
D^a	1113.6 mg	$D_{fs} + D_{fi}$
D_{fi}/D_{fs}	0.76	

[a] D may be contained in two or more dosage units, provided k_0 is 57.6 mg/hr and D_{fi}/D_{fs} is constant. [b] T = 11 hr.

Substitution from Eq. 5 into Eq. 3 gives Eq. 6*a* or 6*b*:

$$A = D_{fi}[1 - e^{-k_a t}] \qquad \text{(Eq. 6a)}$$

or:

$$C = \frac{A_{ss}}{V}[1 - e^{-k_a t}] \qquad \text{(Eq. 6b)}$$

which provides a simple expression to describe blood levels from this type of formulation for all values of $t \leq T$. After this time, the first-order decline in blood levels is given by:

$$C = C_{ss}e^{-k_{el}(t-T)} \qquad \text{(Eq. 7)}$$

where $t \geq T$.

The value of D_{fi} is independent of k_a and t_p. However, the lag time between t_p and the time taken for A to approach A_{ss} increases as k_a decreases. Since the blood levels of a drug administered as a zero-order release dosage form with no fast release component are given by:

$$C = \frac{k_0}{k_{el}}[1 - e^{-k_{el}t}] + \frac{k_0}{k_a - k_{el}}[e^{-k_a t} - e^{-k_{el}t}] \qquad \text{(Eq. 8)}$$

the reduction in the time taken to reach plateau blood levels with the introduction of a fast release component is clearly a function only of the relative values of k_a and k_{el}.

The method may be demonstrated using theophylline as an example. A recent study in normal human subjects yielded average values for k_a, k_{el}, and V of 1.3 hr^{-1}, 0.12 hr^{-1}, and 32 liters, respectively (3). With the assumption that a desirable therapeutic blood level C_{ss} is 15 μg/ml (4), values for a suitable sustained-release formulation are given in Table I.

The blood level resulting from these calculations is given in Fig. 1. The t_p value resulting from the fast release component is 2.0 hr (5), and the time taken for blood levels to reach 95% of their asymptotic value is only slightly greater at 2.3 hr (Eq. 6*b*).

This approach is not meant to imply that the ideal sustained-release blood profile can be obtained in all patients. Each individual patient will have different rates of absorption and elimination, as exemplified in Ref. 3. However, this method provides a simple approach which is of general application for dosage calculation with this type of sustained-release formulation.

Effect of Propantheline on Nitrofurantoin Absorption

Keyphrases □ Propantheline—effect on nitrofurantoin absorption □ Nitrofurantoin—absorption, effect of propantheline □ Absorption—nitrofurantoin, effect of propantheline

To the Editor:

Since an adverse reaction to nitrofurantoin therapy is gastric upset, the manufacturers recommend that the drug be given with food or milk to minimize this effect (1). However, concurrent administration of food with nitrofurantoin apparently not only reduces the possibility of GI reaction but also significantly increases the bioavailability of the drug, especially in relation to the macrocrystalline form (2). The increase in absorption has been attributed to food causing an increase in the gastric emptying time, which would also increase the residence time of the drug in the gastric fluids, thereby allowing for a greater amount of nitrofurantoin to be dissolved prior to its passage into the duodenum where absorption is optimal.

Since other studies showed that increases in the serum level of digoxin (3) and the urinary excretion of riboflavin (4) occur when these drugs are administered with propantheline due to its effect of reducing gastric motility, it was felt that concurrent administration of nitrofurantoin with propantheline would be a good means of confirming whether increased gastric emptying time modifies nitrofurantoin absorption, as postulated by Bates *et al.* (2).

Six healthy subjects (three males and three females) were administered a single 100-mg oral dose of nitrofurantoin macrocrystals[1] with 100 ml of water. A crossover design was employed; three subjects received 30 mg of propantheline[2] 45 min prior to nitrofurantoin administration while the other three subjects received only nitrofurantoin. One week later the experimental conditions were re-

Table I—Calculation of Sustained-Release Parameters for Theophylline

Parameter	Value	Method of Calculation
A_{ss}	480 mg	$A_{ss} = C_{ss}V$
D_{fi}	480 mg	Eq. 5
k_0	57.6 mg/hr	$k_0 = (k_{el})(A_{ss})$
D_{fs}	633.6 mg	$D_{fs} = k_0 T^b$
D^a	1113.6 mg	$D_{fs} + D_{fi}$
D_{fi}/D_{fs}	0.76	

[a] D may be contained in two or more dosage units, provided k_0 is 57.6 mg/hr and D_{fi}/D_{fs} is constant. [b] T = 11 hr.

Substitution from Eq. 5 into Eq. 3 gives Eq. 6*a* or 6*b*:

$$A = D_{fi}[1 - e^{-k_a t}] \qquad \text{(Eq. 6a)}$$

or:

$$C = \frac{A_{ss}}{V}[1 - e^{-k_a t}] \qquad \text{(Eq. 6b)}$$

which provides a simple expression to describe blood levels from this type of formulation for all values of $t \leq T$. After this time, the first-order decline in blood levels is given by:

$$C = C_{ss}e^{-k_{el}(t-T)} \qquad \text{(Eq. 7)}$$

where $t \geq T$.

The value of D_{fi} is independent of k_a and t_p. However, the lag time between t_p and the time taken for A to approach A_{ss} increases as k_a decreases. Since the blood levels of a drug administered as a zero-order release dosage form with no fast release component are given by:

$$C = \frac{k_0}{k_{el}}[1 - e^{-k_{el}t}] + \frac{k_0}{k_a - k_{el}}[e^{-k_a t} - e^{-k_{el}t}] \qquad \text{(Eq. 8)}$$

the reduction in the time taken to reach plateau blood levels with the introduction of a fast release component is clearly a function only of the relative values of k_a and k_{el}.

The method may be demonstrated using theophylline as an example. A recent study in normal human subjects yielded average values for k_a, k_{el}, and V of 1.3 hr^{-1}, 0.12 hr^{-1}, and 32 liters, respectively (3). With the assumption that a desirable therapeutic blood level C_{ss} is 15 μg/ml (4), values for a suitable sustained-release formulation are given in Table I.

The blood level resulting from these calculations is given in Fig. 1. The t_p value resulting from the fast release component is 2.0 hr (5), and the time taken for blood levels to reach 95% of their asymptotic value is only slightly greater at 2.3 hr (Eq. 6*b*).

This approach is not meant to imply that the ideal sustained-release blood profile can be obtained in all patients. Each individual patient will have different rates of absorption and elimination, as exemplified in Ref. 3. However, this method provides a simple approach which is of general application for dosage calculation with this type of sustained-release formulation.

Table I—Cumulative Excretion (Milligrams) of Nitrofurantoin for Six Subjects under Propantheline and Control Conditions

Subject	Control (Nitrofurantoin Only)	Nitrofurantoin and Propantheline
1	17.2	30.2
2	29.0	34.7
3	12.3	19.5
4	15.2	31.8
5	13.0	33.6
6	16.0	22.3
Mean ± *SE*	17.1 ± 2.49	28.7 ± 2.57

versed. All subjects fasted overnight and for 4 hr after drug administration. Total urine specimens were collected for 24 hr. Nitrofurantoin in the urine was determined by a spectrophotometric method (5) specific for unchanged drug.

The results (Table I) indicate a statistically significant increase in nitrofurantoin excretion when propantheline was coadministered as compared with the control condition ($p < 0.01$ as determined by paired t-test). No statistical significance was observed for differences in urinary volume or urinary pH between the two conditions. Thus, the results are consistent with the hypothesis that a delay in gastric emptying possibly will increase the bioavailability of nitrofurantoin and indicate that this effect might explain why food produces similar effects.

Simple Method for Monitoring Flow Rate during Gravity Perfusion

Keyphrases □ Flow rates—apparatus for continuous monitoring during perfusion studies □ Perfusion studies—apparatus for continuous monitoring of flow rate □ Equipment—apparatus for monitoring flow rate during gravity perfusion

To the Editor:

The apparatus described here fills the need for an inexpensive, easily constructed device for continuously monitoring flow rates during perfusion studies. Although extremely simple in design, it can be employed to advantage with modern electronic recording equipment.

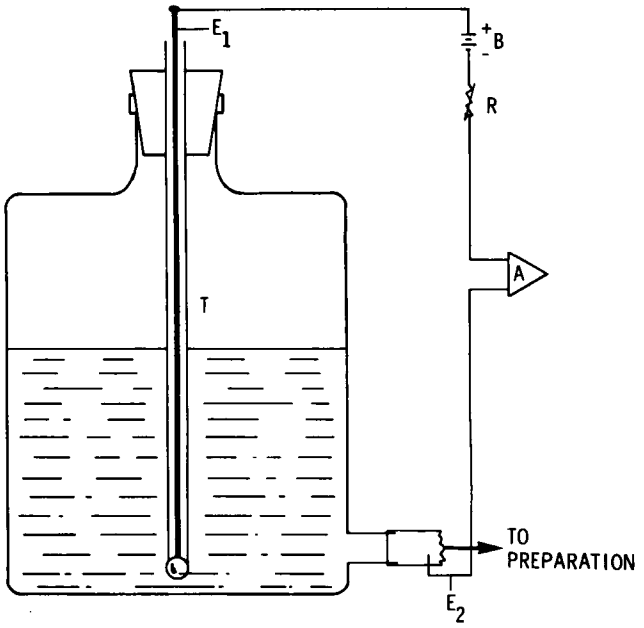

Figure 1—*Components of device for continuously monitoring flow rates during perfusion studies.*

The device makes use of the familiar air bubbles which emerge from the pressure regulating tube (T) of the well-known Marriotte bottle. The last 1 or 2 cm of this tube is coated on both the inner and outer surfaces, most simply by dipping the tubing in melted paraffin. One electrode (E_1)—essentially a length of stainless steel wire insulated except at the tip—is passed down the glass tubing (Fig. 1). A second electrode (E_2), which can be much shorter, is placed in the perfusion solution, usually through a piece of rubber tubing leading from the outlet of the reservoir.

Leads from these two electrodes are connected to the input of the recorder amplifier (A) with an ordinary 1.5-v flashlight battery (B) and variable resistor (R) placed in the circuit as indicated. As the perfusion proceeds, the column of air in the glass tubing (T) descends and "breaks off" in the form of air bubbles. These bubbles serve to break the circuit, and this breakage is registered on the recorder. Changes in flow caused by interventions that alter the perfusion rate are rapidly indicated on the chart. This system avoids the time-consuming process of collecting and measuring the effluent to determine whether a change in flow has actually occurred. The amount of change can thus be measured, either by collecting the effluent or counting the marks on the chart recorder over a specific length of time.

By its nature, a tracing provides a stronger visual impact than does a number, and this advantage is particularly noticeable when other parameters are being recorded simultaneously on the same strip chart. The system has been very valuable also for demonstrations to large classes, using closed circuit T.V. with the camera focused on the chart. The apparatus described here has been employed extensively

Simple Method for Monitoring Flow Rate during Gravity Perfusion

Keyphrases □ Flow rates—apparatus for continuous monitoring during perfusion studies □ Perfusion studies—apparatus for continuous monitoring of flow rate □ Equipment—apparatus for monitoring flow rate during gravity perfusion

To the Editor:

The apparatus described here fills the need for an inexpensive, easily constructed device for continuously monitoring flow rates during perfusion studies. Although extremely simple in design, it can be employed to advantage with modern electronic recording equipment.

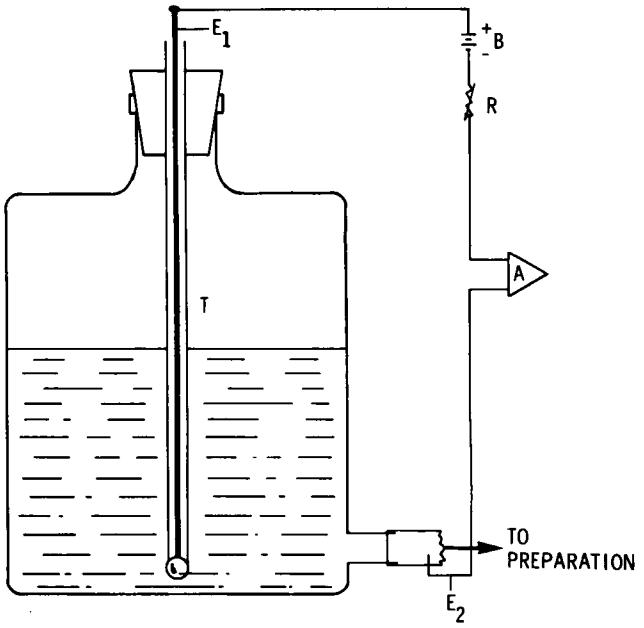

Figure 1—*Components of device for continuously monitoring flow rates during perfusion studies.*

The device makes use of the familiar air bubbles which emerge from the pressure regulating tube (T) of the well-known Marriotte bottle. The last 1 or 2 cm of this tube is coated on both the inner and outer surfaces, most simply by dipping the tubing in melted paraffin. One electrode (E_1)—essentially a length of stainless steel wire insulated except at the tip—is passed down the glass tubing (Fig. 1). A second electrode (E_2), which can be much shorter, is placed in the perfusion solution, usually through a piece of rubber tubing leading from the outlet of the reservoir.

Leads from these two electrodes are connected to the input of the recorder amplifier (A) with an ordinary 1.5-v flashlight battery (B) and variable resistor (R) placed in the circuit as indicated. As the perfusion proceeds, the column of air in the glass tubing (T) descends and "breaks off" in the form of air bubbles. These bubbles serve to break the circuit, and this breakage is registered on the recorder. Changes in flow caused by interventions that alter the perfusion rate are rapidly indicated on the chart. This system avoids the time-consuming process of collecting and measuring the effluent to determine whether a change in flow has actually occurred. The amount of change can thus be measured, either by collecting the effluent or counting the marks on the chart recorder over a specific length of time.

By its nature, a tracing provides a stronger visual impact than does a number, and this advantage is particularly noticeable when other parameters are being recorded simultaneously on the same strip chart. The system has been very valuable also for demonstrations to large classes, using closed circuit T.V. with the camera focused on the chart. The apparatus described here has been employed extensively

to study the effects of drugs or procedures on isolated perfused hearts, lungs, and blood vessels. The very small current employed (approximately 0.2 mamp) has no observable effects on either the preparation or the actions of the drugs studied.

In short, this apparatus provides a method for rapidly detecting changes in flow by using the Marriotte bottle to provide graphic information as well as to serve simply as a reservoir for the perfusion solution. Ease of construction and low cost make it particularly useful for teaching purposes, since each group of students can be supplied with one of these devices.

Controlled Release from Matrix Systems

Keyphrases □ Matrix systems—controlled release of ethynodiol diacetate from silicone rubber devices, comments □ Silicone rubber matrix—release of ethynodiol diacetate, comments on controlled release □ Release, controlled—ethynodiol diacetate from silicone rubber devices, comments

To the Editor:

Two publications by Chien and coworkers (1, 2) described the release of ethynodiol diacetate from silicone rubber devices. These authors treated two cases for the matrix release process: matrix-controlled and partition-controlled drug release mechanisms. The equations describing the diffusional process were previously presented by Higuchi (3) and Roseman and Higuchi (4). With the assumptions that (*a*) the matrix acts as the diffusion medium, (*b*) a pseudo-steady-state condition exists during the release process, and (*c*) the drug particles are uniformly distributed throughout the matrix and are quite small relative to the average distance of diffusion, Higuchi (3) derived the following relationship for the release of drug from a planar homogeneous matrix:

$$Q = [D_s C_s (2A - C_s)t]^{1/2} \quad \text{(Eq. 1)}$$

where Q = amount of drug released per unit area, D_s = diffusion coefficient of drug in the homogeneous matrix phase, C_s = solubility of drug in the matrix phase, t = time, and A = total amount of drug present per unit volume of matrix.

When $A \gg C_s$, Eq. 1 reduces to:

$$Q = (2AD_s C_s t)^{1/2} \quad \text{(Eq. 2)}$$

Chien *et al.* (1), however, incorrectly quoted the Higuchi equation as:

$$Q = [D_s C_s (2A - C_a)t]^{1/2} \quad \text{(Eq. 3)}$$

where C_a is the solubility of drug in the elution medium[1]. Although the $(2A - C_a)$ term does not appear to have any physical significance (except, of course, when $C_a = C_s$), Eq. 3 does yield Eq. 2 when $2A$ is much greater than C_a.

The equations derived by Roseman and Higuchi (4) are an extension of the concepts discussed by Higuchi (3) for the specific case where diffusion from the surface of the device is considered in series with the diffusional step through the matrix. In this instance, the release of drug from a planar matrix is given by the following expressions, when $A \gg C_s$:

$$Q = Al \quad \text{(Eq. 4)}$$

$$l^2 + \frac{2D_e h_a l}{D_a K} = \frac{2D_e C_s t}{A} \quad \text{(Eq. 5)}$$

where[1] l = diffusional distance in the matrix (depleted zone); K = partition coefficient (C_a/C_s); h_a = diffusional distance in the boundary diffusion layer; $D_e = D_s\epsilon/\tau$ where ϵ and τ are the volume fraction and tortuosity of the matrix,respectively; and D_a = diffusion coefficient of drug in the elution medium. The other terms were defined previously.

Except for consideration of the boundary diffusion layer, the basic assumptions in the derivation of these equations are the same as those used to derive Eq. 2. Equations 4 and 5 describe a general case for matrix release, which was termed the matrix-boundary diffusion layer model (4). This nomenclature corresponds to the partition-controlled and matrix-controlled cases subsequently used by Chien and Lambert (2) for the two limiting cases. When $l \gg 2D_e h_a/D_a K$, Eqs. 4 and 5 yield Eq. 2 (matrix-controlled case)[2]. Conversely, when $l \ll 2D_e h_a/D_a K$, Eqs. 4 and 5 yield:

$$Q = \frac{D_a C_a t}{h_a} \quad \text{(Eq. 6)}$$

which is boundary layer controlled release (partition-controlled release).

In the publication by Chien and Lambert (2), the Higuchi equation is again misquoted as the authors derived a series of equations following the theoretical treatment resulting in Eqs. 4 and 5. For the limiting condition that yields Eq. 6, Chien and Lambert (2) presented the following expressions[1]:

$$Q = \frac{KD_a C_s t}{h_a} \quad \text{(Eq. 7)}$$

$$Q = \frac{KD_a C_a t}{h_a} \quad \text{(Eq. 8)}$$

Equation 7 is correct since it reduces to Eq. 6 (note that $K = C_a/C_s$). However, Eq. 8 is only valid for the trivial case when $C_s = C_a$. But the data on ethynodiol diacetate indicate that C_s does not equal C_a; therefore, analysis of the data does not support the contention that Eq. 8 is valid.

I hope this communication clarifies the discrepancies between the original equations reported in Refs.

[1] Symbols used for the various parameters differ among authors. In this communication, each term is defined to avoid confusion. For example, in Ref. 1, D_m, C_p, and C_s are equivalent to D_s, C_s, and C_a, respectively, while in Ref. 2, D_s, δ_D, and δ_m are equal to D_a, h_a, and l, respectively.

[2] Equation 2 was derived for a homogeneous matrix; therefore, ϵ and τ were unity.

to study the effects of drugs or procedures on isolated perfused hearts, lungs, and blood vessels. The very small current employed (approximately 0.2 mamp) has no observable effects on either the preparation or the actions of the drugs studied.

In short, this apparatus provides a method for rapidly detecting changes in flow by using the Marriotte bottle to provide graphic information as well as to serve simply as a reservoir for the perfusion solution. Ease of construction and low cost make it particularly useful for teaching purposes, since each group of students can be supplied with one of these devices.

Controlled Release from Matrix Systems

Keyphrases □ Matrix systems—controlled release of ethynodiol diacetate from silicone rubber devices, comments □ Silicone rubber matrix—release of ethynodiol diacetate, comments on controlled release □ Release, controlled—ethynodiol diacetate from silicone rubber devices, comments

To the Editor:

Two publications by Chien and coworkers (1, 2) described the release of ethynodiol diacetate from silicone rubber devices. These authors treated two cases for the matrix release process: matrix-controlled and partition-controlled drug release mechanisms. The equations describing the diffusional process were previously presented by Higuchi (3) and Roseman and Higuchi (4). With the assumptions that (*a*) the matrix acts as the diffusion medium, (*b*) a pseudo-steady-state condition exists during the release process, and (*c*) the drug particles are uniformly distributed throughout the matrix and are quite small relative to the average distance of diffusion, Higuchi (3) derived the following relationship for the release of drug from a planar homogeneous matrix:

$$Q = [D_s C_s (2A - C_s)t]^{1/2} \quad \text{(Eq. 1)}$$

where Q = amount of drug released per unit area, D_s = diffusion coefficient of drug in the homogeneous matrix phase, C_s = solubility of drug in the matrix phase, t = time, and A = total amount of drug present per unit volume of matrix.

When $A \gg C_s$, Eq. 1 reduces to:

$$Q = (2AD_s C_s t)^{1/2} \quad \text{(Eq. 2)}$$

Chien *et al.* (1), however, incorrectly quoted the Higuchi equation as:

$$Q = [D_s C_s (2A - C_a)t]^{1/2} \quad \text{(Eq. 3)}$$

where C_a is the solubility of drug in the elution medium[1]. Although the $(2A - C_a)$ term does not appear to have any physical significance (except, of course, when $C_a = C_s$), Eq. 3 does yield Eq. 2 when $2A$ is much greater than C_a.

The equations derived by Roseman and Higuchi (4) are an extension of the concepts discussed by Higuchi (3) for the specific case where diffusion from the surface of the device is considered in series with the diffusional step through the matrix. In this instance, the release of drug from a planar matrix is given by the following expressions, when $A \gg C_s$:

$$Q = Al \quad \text{(Eq. 4)}$$

$$l^2 + \frac{2D_e h_a l}{D_a K} = \frac{2D_e C_s t}{A} \quad \text{(Eq. 5)}$$

where[1] l = diffusional distance in the matrix (depleted zone); K = partition coefficient (C_a/C_s); h_a = diffusional distance in the boundary diffusion layer; $D_e = D_s\epsilon/\tau$ where ϵ and τ are the volume fraction and tortuosity of the matrix,respectively; and D_a = diffusion coefficient of drug in the elution medium. The other terms were defined previously.

Except for consideration of the boundary diffusion layer, the basic assumptions in the derivation of these equations are the same as those used to derive Eq. 2. Equations 4 and 5 describe a general case for matrix release, which was termed the matrix-boundary diffusion layer model (4). This nomenclature corresponds to the partition-controlled and matrix-controlled cases subsequently used by Chien and Lambert (2) for the two limiting cases. When $l \gg 2D_e h_a/D_a K$, Eqs. 4 and 5 yield Eq. 2 (matrix-controlled case)[2]. Conversely, when $l \ll 2D_e h_a/D_a K$, Eqs. 4 and 5 yield:

$$Q = \frac{D_a C_a t}{h_a} \quad \text{(Eq. 6)}$$

which is boundary layer controlled release (partition-controlled release).

In the publication by Chien and Lambert (2), the Higuchi equation is again misquoted as the authors derived a series of equations following the theoretical treatment resulting in Eqs. 4 and 5. For the limiting condition that yields Eq. 6, Chien and Lambert (2) presented the following expressions[1]:

$$Q = \frac{KD_a C_s t}{h_a} \quad \text{(Eq. 7)}$$

$$Q = \frac{KD_a C_a t}{h_a} \quad \text{(Eq. 8)}$$

Equation 7 is correct since it reduces to Eq. 6 (note that $K = C_a/C_s$). However, Eq. 8 is only valid for the trivial case when $C_s = C_a$. But the data on ethynodiol diacetate indicate that C_s does not equal C_a; therefore, analysis of the data does not support the contention that Eq. 8 is valid.

I hope this communication clarifies the discrepancies between the original equations reported in Refs.

[1] Symbols used for the various parameters differ among authors. In this communication, each term is defined to avoid confusion. For example, in Ref. 1, D_m, C_p, and C_s are equivalent to D_s, C_s, and C_a, respectively, while in Ref. 2, D_s, δ_D, and δ_m are equal to D_a, h_a, and l, respectively.

[2] Equation 2 was derived for a homogeneous matrix; therefore, ϵ and τ were unity.

Metabolic Fate of Flurazepam II: A New Potent Metabolite Obtained by *In Vitro* Liver Drug-Metabolizing Enzyme System

Keyphrases □ Flurazepam—isolation of new metabolite using *in vitro* liver drug-metabolizing enzyme system □ Metabolism—flurazepam, isolation of potent metabolite, *in vitro* liver drug-metabolizing enzyme system

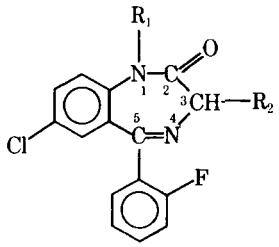
To the Editor:

Although a few investigations on the metabolism of flurazepam (I), 7-chloro-1-[2-(diethylamino)ethyl]-5- (*o*-fluorophenyl) -1,3-dihydro-2*H*- 1,4-benzodiazepin-2-one, in humans (1,2) and experimental animals (1, 3, 4) have been reported, its detailed *in vitro* metabolism is still unknown. This communication describes a new potent metabolite found using an *in vitro* liver drug-metabolizing enzyme system[1].

Reaction mixtures contained the following: 0.5 ml of male DDY mouse or Wister rat liver 9000×*g* supernate or the microsomal fraction (150 mg as fresh liver), NADPH generating system (1 μmole of NADP, 30 μmoles of glucose-6-phosphate, 25 μmoles of nicotinamide, 37.5 μmoles of magnesium chloride, 1.4 units of glucose-6-phosphate dehydrogenase), 5 μmoles of substrate, and 225 μmoles of tromethamine–hydrochloric acid buffer in 2.75 ml of total volume. After incubation at 37° for 90 min, the reaction mixtures were adjusted to pH 9.0 and were extracted once with 10 ml of ethyl acetate. Organic phases were concentrated *in vacuo*, and aliquots of the concentrated organic phases were applied to TLC plates [Kieselgel GF_{254}, benzene–methanol–acetic acid (90:10:10)].

Besides some of the known major metabolites, *e.g.*, II–IV, a minor unknown spot was detected under UV light when I was used as the substrate. Since this metabolite (V) was the predominant metabolite of IV, which is one of the known metabolites of I, 90 mg of authentic IV was then metabolized using mice liver enzyme for the preparation of V.

The metabolite was purified by preparative TLC (Kieselgel GF_{254}) followed by alumina (Woelm, neutral) column chromatography to yield 11.7 mg of oily material. Purified V gave a single spot with several TLC solvent systems, and its chromatographic behavior differed from that of the known metabolites. The IR spectrum of the metabolite showed the increased strength of the OH stretching band at 3400 cm^{-1} and the appearance of a CO stretching band at 1130 cm^{-1}, suggesting that the introduction of the secondary OH to the parent compound (IV) had occurred.



I: $R_1 = CH_2CH_2N(C_2H_5)_2$, $R_2 = H$
II: $R_1 = CH_2CH_2NHC_2H_5$, $R_2 = H$
III: $R_1 = CH_2CH_2NH_2$, $R_2 = H$
IV: $R_1 = CH_2CH_2OH$, $R_2 = H$
V: $R_1 = CH_2CH_2OH$, $R_2 = OH$

The mass spectrum (25 ev) of V showed a weak, but apparent, molecular ion at *m/e* 348 (11%) followed by other prominent fragments at *m/e* 320 (21), 319 (100), 301 (33), 287 (14), 275 (28), and 260 (13). This increment of molecular weight by 16 mass units from that of IV also indicated that one oxygen atom had been introduced to the substrate (IV), but the lack of an M − 16 ion suggested that it might not be any oxide form. The molecular ion of acetylated V (*m/e* 432) and the successive split of two ketenes, giving fragments at *m/e* 390 and 348, were additional supports for the idea.

The proton NMR spectrum of V run in $CDCl_3$,

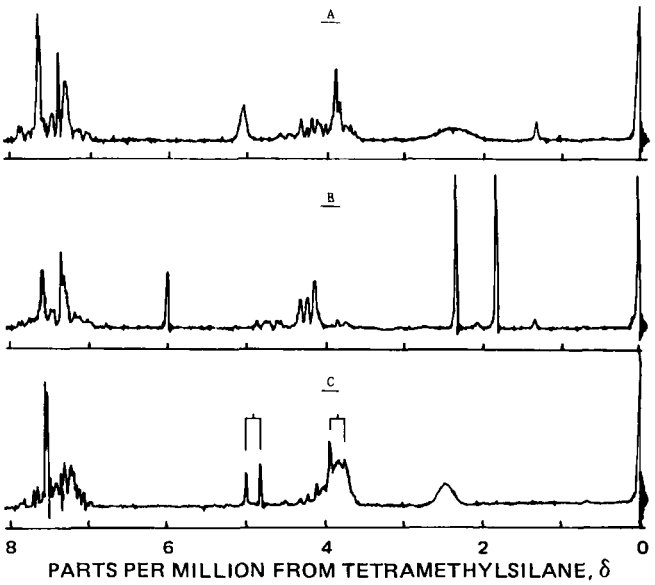


Figure 1—*Proton NMR spectra of V, V-acetate, and authentic parent compound IV in $CDCl_3$: Key: A, V; B, V-acetate; and C, authentic IV (two methylene protons of C_3 at 3.84 and 4.90 ppm are specified).*

The proton NMR spectrum of V run in $CDCl_3$,

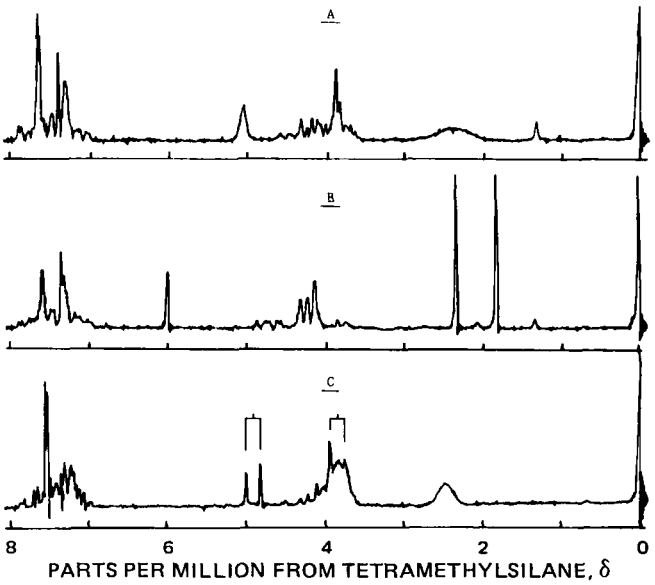

Figure 1—*Proton NMR spectra of V, V-acetate, and authentic parent compound IV in $CDCl_3$: Key: A, V; B, V-acetate; and C, authentic IV (two methylene protons of C_3 at 3.84 and 4.90 ppm are specified).*

[1] For part I, see M. Hasegawa and I. Matsubara, *Chem. Pharm. Bull.*, in press.

with tetramethylsilane as the internal standard, is shown in Fig. 1 along with the spectra of V-acetate and IV. The signals of the methylene protons at the C_3 position of IV at δ 3.84 (doublet, 1H) and 4.90 (doublet, 1H) ppm turned into a singlet signal (1H), shifting toward lower field to 5.05 ppm, by the metabolic transformation to V. The integration of the broad signal of V at 2.30 ppm, which could be replaced by deuterium adding CD_3OD, counted as two protons. These facts indicated that the structural change, *i.e.*, hydroxylation, had occurred at C_3 of IV. Further evidence was that the spectrum of V-acetate showed two acetyl signals at δ 1.83 and 2.26 ppm; the former was assigned to the N_1-2-acetoxyethyl group and the latter to the C_3-acetoxy group. The signal of the C_3 proton of V shifted toward lower field to 6.00 ppm by acetylation. Thus the structure of the metabolite was determined to be as shown in V.

This compound was then synthesized in a separate experiment, and its psychotropic activity was studied. Its CNS-depressant activity in DDY strain male mice was at the 50-mg/kg dose level (oral), which was approximately the same potency as unchanged I. It is of interest that V was found to be one of the metabolites in humans, and details of this work will be reported.

Pithed Rat Blood Pressure in the Assay of Norepinephrine

Keyphrases □ Norepinephrine—analysis in plasma and cerebrospinal fluid of rats by pithed blood pressure method □ Sympathomimetics—norepinephrine, assay, pithed rat blood pressure

To the Editor:

Measurement of rat blood pressure is a standard method in biological estimations of acetylcholine (1–5), angiotensin (6), norepinephrine (6, 7), epinephrine (6, 7), and vasopressin (8). Preparations reported for norepinephrine assay show a sensitivity of 1–2 × 10^{-7} g/ml. The pithed rat blood pressure in 250 preparations, with some modifications used in our study for the estimation of norepinephrine in plasma (9) and cerebrospinal fluid (10), was sensitive from 1 × 10^{-9} to 5 × 10^{-10} g/ml. The changes followed in these preparations are described here since a highly sensitized preparation could be mounted with the additional operations.

Albino Wistar rats of either sex, 200–350 g, were used. The rats, after being fasted overnight, were injected intraperitoneally with 0.4 ml (0.4% in 0.85% saline) of atropine sulfate[1] 20 min before anesthetization. Anesthesia was induced by spraying ethyl chloride into the glass funnel initially and was maintained with anesthetic ether until the rat became unconscious.

The anesthetized rat was opened for tracheotomy, and a polyethylene cannula with a side opening was immediately introduced into the trachea and tied in position. The rat was then turned on its back to one side and pithed as described previously (6). Once the brain and spinal cord were destroyed, as seen by spasticity of contralateral muscles, the rat was immediately ventilated mechanically by connecting the tracheal cannula to a mini-respiratory pump. The regulator was adjusted to ensure sufficient ventilation so that inflation and deflation of the chest and heart rate were 30–40 strokes/min.

Both carotid arteries were ligated at the central end. Then a laparotomy was done, and the viscera were removed from the esophagus to the rectum, including the spleen; the liver was left *in situ* as per the method of Venkatakrishna-Bhatt and Haranath (3), and the bleeding points were carefully ligated. The left carotid artery and the right femoral vein were cannulated and connected to a manometer[2] and saline stand, respectively. Heparin[3], 0.5 mg, was injected into the femoral vein to prevent clotting. Then 1–3 ml of saline was injected to compensate for the loss of blood volume during evisceration.

Initially, the response with a low concentration of norepinephrine[4] (10^{-11} g/ml) was recorded on a kymograph. Sensitivity increased on repeated injections of standard norepinephrine into the femoral vein at regular intervals. Thus, when the blood pressure reached a steady level, usually after 10–15 trials, the test solution was injected. The volume of fluid injected was always kept constant, usually being 0.1 ml followed by 0.1 ml of saline. Care was taken to prevent leakage or passing of air bubbles from the syringe or leaking points.

This preparation was frequently found to be sensitive to a concentration of 10^{-9}–10^{-10} g/ml of norepinephrine when prepared in saline with 5 × 10^{-6} g/ml of ascorbic acid. Ascorbic acid in saline as a control, when injected in a way similar to the test and standard norepinephrine solutions, did not elicit a peak response as did the test solutions. Although skill and precision are essential for handling the preparation,

Estimation of Hepatic First-Pass Effect of Acetaminophen in Humans after Oral Administration

Keyphrases □ Acetaminophen—estimation of hepatic first-pass effect, oral administration, humans □ Metabolism—acetaminophen, estimation of hepatic first-pass effect, oral administration, humans □ First-pass effect, hepatic—acetaminophen, estimation, oral administration, humans

To the Editor:

Acetaminophen is one of the most frequently used analgesics and antipyretics today. It is primarily metabolized in humans after oral administration. In one study, only about 3–4% of the dose was recovered in urine as intact compound after dosing (1). Recently, Cohen *et al.* (2) reported that its availability to the systemic circulation after intraperitoneal administration to rats was only 34% of that after intravenous administration, indicating an extensive hepatic first-pass metabolic effect. This finding prompted them to speculate (2) that a marked variation in peak acetaminophen plasma concentrations in humans with different stomach emptying rates (3) might be caused to a varying degree by the hepatic first-pass effect.

The purpose of this communication is to estimate theoretically the extent of the hepatic first-pass effect of acetaminophen in humans, using an equation derived recently (4, 5). The following assumptions were made in the derivation: (*a*) the metabolism takes place only in the liver; (*b*) the excretion of intact drug occurs only from the kidney and/or lung; (*c*) the liver, kidneys, and lungs are part of the central compartment; (*d*) the elimination and distribution processes between the central and other peripheral compartments are all first-order processes; and (*e*) the administered drug is all absorbed after oral or intraperitoneal administration.

The fraction of the dose metabolized during the first passage to liver, f_m, can be estimated by the following equation:

$$f_m = \frac{(F_m)(\text{dose})}{\text{dose} + (HFR)(AUC)} \qquad \text{(Eq. 1)}$$

where F_m = fraction of the administered dose metabolized at infinite time, HFR = hepatic blood flow rate, and AUC = total area under blood concentration *versus* time curve in infinite time.

A search and evaluation of past studies related to acetaminophen oral absorption in humans revealed that some work reported by McGilveray *et al.* (1) was suitable for this pharmacokinetic prediction analysis. That article reported the acetaminophen blood level data up to 6 hr after oral administration of 1 g of the drug dissolved in 200 ml of water to 10 normal subjects 1.5 hr after a light breakfast. Based on the urinary excretion data and the solution dosage form administered, one could reasonably assume that all of the dose was completely absorbed (1, 6, 7).

An AUC of 5626 (min) (μg/ml) was obtained by the summation of the area from 0 to 6 hr calculated by the trapezoidal rule and of the area from 6 hr to infinity calculated by the extrapolation method (5, 7). An average biological half-life of 3.26 hr (1) was used in the calculation for the extrapolated area. This half-life is similar to (7), but different than (8), the values from studies reported by other workers, indicating the possibility of intersubject variation. The F_m was assumed to be 0.96. By substituting a value of 1500 ml/min for HFR (4, 5) and other appropriate data into Eq. 1, one obtains an f_m value of 0.102. This value is obviously much lower than those observed (f_m = 0.66) and predicted (f_m = 0.60) for rats (2).

These results indicate that there is a marked interspecies variation in the extent of the first-pass effect. Although absorption of several drugs from intraperitoneal administration has been shown to occur predominantly *via* the portal circulation in dogs and rats (9), this has not been proven for acetaminophen.

The f_m value estimated by Eq. 1 generally represents a maximum value. If the hepatic metabolic process deviates from pseudo first order as the absorption rate of drug increases (based on Michaelis–Menten enzyme kinetics), the observed f_m value would be lower than that predicted by Eq. 1. In other words, the maximum fraction of the orally administered acetaminophen dose metabolized in the liver during the first pass is only about 0.10, and the effect of the

the method is convenient and sensitive for the estimation of norepinephrine. The preparation lasts for 1–3 hr if the assay is commenced soon after mounting.

Estimation of Hepatic First-Pass Effect of Acetaminophen in Humans after Oral Administration

Keyphrases □ Acetaminophen—estimation of hepatic first-pass effect, oral administration, humans □ Metabolism—acetaminophen, estimation of hepatic first-pass effect, oral administration, humans □ First-pass effect, hepatic—acetaminophen, estimation, oral administration, humans

To the Editor:

Acetaminophen is one of the most frequently used analgesics and antipyretics today. It is primarily metabolized in humans after oral administration. In one study, only about 3–4% of the dose was recovered in urine as intact compound after dosing (1). Recently, Cohen *et al.* (2) reported that its availability to the systemic circulation after intraperitoneal administration to rats was only 34% of that after intravenous administration, indicating an extensive hepatic first-pass metabolic effect. This finding prompted them to speculate (2) that a marked variation in peak acetaminophen plasma concentrations in humans with different stomach emptying rates (3) might be caused to a varying degree by the hepatic first-pass effect.

The purpose of this communication is to estimate theoretically the extent of the hepatic first-pass effect of acetaminophen in humans, using an equation derived recently (4, 5). The following assumptions were made in the derivation: (*a*) the metabolism takes place only in the liver; (*b*) the excretion of intact drug occurs only from the kidney and/or lung; (*c*) the liver, kidneys, and lungs are part of the central compartment; (*d*) the elimination and distribution processes between the central and other peripheral compartments are all first-order processes; and (*e*) the administered drug is all absorbed after oral or intraperitoneal administration.

The fraction of the dose metabolized during the first passage to liver, f_m, can be estimated by the following equation:

$$f_m = \frac{(F_m)(\text{dose})}{\text{dose} + (HFR)(AUC)} \qquad \text{(Eq. 1)}$$

where F_m = fraction of the administered dose metabolized at infinite time, HFR = hepatic blood flow rate, and AUC = total area under blood concentration *versus* time curve in infinite time.

A search and evaluation of past studies related to acetaminophen oral absorption in humans revealed that some work reported by McGilveray *et al.* (1) was suitable for this pharmacokinetic prediction analysis. That article reported the acetaminophen blood level data up to 6 hr after oral administration of 1 g of the drug dissolved in 200 ml of water to 10 normal subjects 1.5 hr after a light breakfast. Based on the urinary excretion data and the solution dosage form administered, one could reasonably assume that all of the dose was completely absorbed (1, 6, 7).

An AUC of 5626 (min) (μg/ml) was obtained by the summation of the area from 0 to 6 hr calculated by the trapezoidal rule and of the area from 6 hr to infinity calculated by the extrapolation method (5, 7). An average biological half-life of 3.26 hr (1) was used in the calculation for the extrapolated area. This half-life is similar to (7), but different than (8), the values from studies reported by other workers, indicating the possibility of intersubject variation. The F_m was assumed to be 0.96. By substituting a value of 1500 ml/min for HFR (4, 5) and other appropriate data into Eq. 1, one obtains an f_m value of 0.102. This value is obviously much lower than those observed (f_m = 0.66) and predicted (f_m = 0.60) for rats (2).

These results indicate that there is a marked interspecies variation in the extent of the first-pass effect. Although absorption of several drugs from intraperitoneal administration has been shown to occur predominantly *via* the portal circulation in dogs and rats (9), this has not been proven for acetaminophen.

The f_m value estimated by Eq. 1 generally represents a maximum value. If the hepatic metabolic process deviates from pseudo first order as the absorption rate of drug increases (based on Michaelis–Menten enzyme kinetics), the observed f_m value would be lower than that predicted by Eq. 1. In other words, the maximum fraction of the orally administered acetaminophen dose metabolized in the liver during the first pass is only about 0.10, and the effect of the

absorption rate on the extent of the first-pass effect should be clinically insignificant.

This contention is also supported by a study that showed that although food could significantly reduce the absorption rate and peak blood levels of acetaminophen in humans, it had no significant effect on total bioavailability, as indicated by similar areas under blood concentration curves of acetaminophen (10). From this finding, it is also reasonable to suggest that differences in the contribution of the first-pass effect for rectally and orally administered acetaminophen would not be of clinical significance.

BOOKS

REVIEWS

Drug Metabolism Reviews, Vol. 2. Edited by F. J. DICARLO. Dekker, New York, NY 10016, 1974. 308 pp. 16 × 24 cm. Price $25.50.

Drug Metabolism Reviews is presently published as an annual volume in two issues. The publisher also reissues it as a single hardbound volume. Hopefully, this removes the need for errata.

Because it originates from a periodical, this book has no master theme except that, paradoxically, while its existence cannot necessarily prove the existence of drug metabolism as a discipline its contents will help operationally define the nature and extent of the discipline; it is a series of monographs of specific interest. The value of such a collection of reviews can really be estimated only by an individual who needs the facts and/or theories presented in a review or who needs an entry into the literature of a research area. There is, then, a very definite place for such a book as *Drug Metabolism Reviews;* it does a good job of meeting a well-defined need. It should not be expected to be of uniformly general interest.

Some monographs are of more general interest in that they cover general drug metabolic interrelationships or mechanisms illustrated by specific examples. There are four such reviews. Comparative Aspects of Mixed Function Oxidation by Lung and Liver of Rabbits (Gram), Intermediates in Drug Metabolism Reactions (Hucker), The Influence of Stereochemical Factors on Drug Disposition (Jenner and Testa), and The Nature and Distribution of Enzymes Catalyzing the Conjugation of Glutathione with Foreign Compounds (Chasseaud).

Other monographs deal with a specific compound or compounds of a given structural or therapeutic class. There are four such in this book; The Role of Ascorbic Acid in Drug Metabolism (Zannoni and Lynch), The Metabolism of Biological Alkylating Agents (Jones), Metabolism and Biochemical Pharmacology of Guanethidine and Related Compounds (Lukas), and Recent Views on the Mechanisms of Nitrate Ester Metabolism (Litchfield). There is one review on methodology, another important area; Automated Assay of Drugs in Body Fluids (Rhodes and Hone). Each of these reviews contains at least some degree of critical evaluation of the subject matter. The editor is to be congratulated for avoiding the presentation of a series of annotated bibliographies.

Clinical Pharmacokinetics: A Symposium. Edited by GERHARD LEVY. American Pharmaceutical Association, Academy of Pharmaceutical Sciences, 2215 Constitution Ave., N.W., Washington, DC 20037, 1974. 180 pp. 15 × 23 cm. Price $5.00.

Clinical pharmacokinetics represents the embodiment of sophisticated advances in Clinical Pharmacology and Pharmacokinetics with the promise of rational drug therapy. It allows for quantitative precision in defining and evaluating a predictable and reproducible clinical response. The book "Clinical Pharmacokinetics: A Symposium" provides a compilation of manuscripts by acknowledged investigators in the field of pharmacokinetics. Although it contains a potpourri of contributions rather than being a tightly organized and coordinated series of presentations, it represents a useful overview and starting point in the organization and implementation of a clinical pharmacokinetics program.

The chapters dealing with the organization of a clinical pharmacokinetics laboratory are somewhat personalized. However, contrasting these two chapters emphasizes the point that the organization and design of such a laboratory depends, to a large extent, on the interactions established with the other disciplines of the clinical team. Defining this orientation must precede the development of the laboratory. This can vary from an analytically oriented laboratory which monitors drug levels as a service function, to the research laboratory where pharmacokinetic and pharmacodynamic interrelationships are defined.

One essential aspect of a clinical pharmacokinetics program which is not sufficiently emphasized in the book is the develop-

absorption rate on the extent of the first-pass effect should be clinically insignificant.

This contention is also supported by a study that showed that although food could significantly reduce the absorption rate and peak blood levels of acetaminophen in humans, it had no significant effect on total bioavailability, as indicated by similar areas under blood concentration curves of acetaminophen (10). From this finding, it is also reasonable to suggest that differences in the contribution of the first-pass effect for rectally and orally administered acetaminophen would not be of clinical significance.

Defining this orientation must precede the development of the laboratory. This can vary from an analytically oriented laboratory which monitors drug levels as a service function, to the research laboratory where pharmacokinetic and pharmacodynamic interrelationships are defined.

One essential aspect of a clinical pharmacokinetics program which is not sufficiently emphasized in the book is the develop-

ment of analytical procedures. One chapter deals with the radioimmunoassay for digoxin. The successful growth and vitality of a clinical pharmacokinetics program depend on the investigators' ability to measure drug levels in biological specimens. Therefore, innovators of diversified analytical methodology must be an integral part of such a group.

Several of the chapters deal with the pharmacokinetic control of the clinical therapy of different drugs or drug classes. These chapters provide the greatest insight into the contributions that clinical pharmacokinetics can provide for rational drug therapy. Although dealing with specific drugs, the chapters contain much in the way of providing the basis for other investigators to monitor drug levels and/or design studies for other drugs which should be monitored as outlined in the final chapter.

Two chapters deal with the use of a clinical pharmacokinetics laboratory for bioavailability assessment and discuss the design and evaluation of bioavailability studies. Another chapter discusses the role of the clinical pharmacist as an interface with the physician. However, the book lacks input from the clinical pharmacologist involved in such studies.

Overall, the book represents a useful contribution which provides a valuable insight into the potential of clinical pharmacokinetics in rational drug therapy.

Principles of Medicinal Chemistry. Edited by WILLIAM O. FOYE. Lea & Febiger, Philadelphia, Pa., 1974. 857 pp. 19 × 27 cm. Price $29.50.

This text, as the editor notes in the preface, is aimed primarily at undergraduate students, and it has been written by 38 teachers and researchers in medicinal chemistry. The book demonstrates that extensive literature has been taken into consideration in developing an account of the various classes of drugs and types of drug action. The reviewer agrees with the editor that the major objective of introducing the appropriate fundamental chemical principles to beginning students is to provide the basis for the understanding of drug action. Moreover, the reviewer feels that the understanding of chemical principles of drug action is essential to the study of therapeutics, biopharmaceutics, and clinical pharmacy; hence this book should be useful not only to students in medicinal chemistry, but also to students in pharmacology, clinical pharmacy, and pharmaceutics.

Foye excellently edited a total of 37 chapters as a review of the vast area of medicinal chemistry. The first six chapters cover general topics which are usually found in contemporary medicinal chemistry and pharmacology textbooks: historical milestones in the development of drug therapy; physicochemical properties and bioactivity; modern approaches to rational drug design; the relationship between stereochemistry and pharmacological properties; drug metabolism; and drug–receptor interactions. These preliminary chapters provide an effective introduction to the rest of the book and to the fields of medicinal chemistry and pharmacology.

The treatment of the major classes of medicinal agents begins with those affecting the central nervous system—an effective approach to the study of the chemistry of drug action relating to neuropharmacology. Subsequently, agents acting on the peripheral nervous system are surveyed. Cardiovascular drugs, anticoagulants, coagulants, plasma expanders, and diuretics are included in three chapters by the same author, thus providing continuity that makes for easy reading. Anti-allergenic agents are well covered with emphasis on the relevant biochemical principles and discussion of the major structural classes.

The medicinal chemistry of steroid endocrinology is introduced with sections on cholesterol metabolism and antilipidemic agents. For more effective utilization by undergraduates, it seems that the chapter (24) on amino acids, peptides, and proteins should precede or immediately follow the consideration of steroid hormones to relate the hypothalamic and pituitary peptides to their effects on steroid hormone production; then, the chapter on insulin and other agents affecting carbohydrate metabolism would follow logically with the thyroid agents.

The field of chemotherapy is covered (nine chapters) as an overview emphasizing modern concepts of metabolite antagonism, antibiotics, and the various classes of chemotherapeutics. As the author notes, the chapter titled, "Antibiotics," discusses only those antibiotics used in the treatment of infections caused by Gram-positive and by Gram-negative bacteria, whereas respective chapters deal with antimycobacterial, antifungal, antineoplastic, and antiprotozoan antibiotics.

Most principal chemotherapeutic agents are structurally characterized and their biochemical actions are related to therapeutic significance.

Finally, miscellaneous medicinals affecting the respiratory system (*e.g.*, nasal decongestants, antitussives, *etc.*,) and diagnostic agents are presented in two chapters.

Perhaps other educators agree with the reviewer that for undergraduate teaching a combination of texts (*e.g.*, Foye's; Burger's *Medicinal Chemistry;* and Wilson, Gisvold, and Doerge's *Textbook of Organic Medicinal and Pharmaceutical Chemistry*) together with appropriate journal articles serve the best purpose in presenting a well-balanced complementation of lecture material in medicinal chemistry, thus providing students with a good introduction to the literature *via* selected bibliographies. In this capacity, Foye's text will be a contribution to the pharmaceutical sciences and pharmaceutical education in general. This book can also serve as a useful review for pharmaceutical scientists who feel a need for updating in elementary medicinal chemistry. Furthermore, pharmacy and medical practitioners will find this text important for refamiliarization with the chemical basis of modern drug therapy.

Principles of Medicinal Chemistry. Edited by WILLIAM O. FOYE. Lea & Febiger, Philadelphia, Pa., 1974. 857 pp. 19 × 27 cm. Price $29.50.

This text, as the editor notes in the preface, is aimed primarily at undergraduate students, and it has been written by 38 teachers and researchers in medicinal chemistry. The book demonstrates that extensive literature has been taken into consideration in developing an account of the various classes of drugs and types of drug action. The reviewer agrees with the editor that the major objective of introducing the appropriate fundamental chemical principles to beginning students is to provide the basis for the understanding of drug action. Moreover, the reviewer feels that the understanding of chemical principles of drug action is essential to the study of therapeutics, biopharmaceutics, and clinical pharmacy; hence this book should be useful not only to students in medicinal chemistry, but also to students in pharmacology, clinical pharmacy, and pharmaceutics.

Foye excellently edited a total of 37 chapters as a review of the vast area of medicinal chemistry. The first six chapters cover general topics which are usually found in contemporary medicinal chemistry and pharmacology textbooks: historical milestones in the development of drug therapy; physicochemical properties and bioactivity; modern approaches to rational drug design; the relationship between stereochemistry and pharmacological properties; drug metabolism; and drug–receptor interactions. These preliminary chapters provide an effective introduction to the rest of the book and to the fields of medicinal chemistry and pharmacology.

The treatment of the major classes of medicinal agents begins with those affecting the central nervous system—an effective approach to the study of the chemistry of drug action relating to neuropharmacology. Subsequently, agents acting on the peripheral nervous system are surveyed. Cardiovascular drugs, anticoagulants, coagulants, plasma expanders, and diuretics are included in three chapters by the same author, thus providing continuity that makes for easy reading. Anti-allergenic agents are well covered with emphasis on the relevant biochemical principles and discussion of the major structural classes.

The medicinal chemistry of steroid endocrinology is introduced with sections on cholesterol metabolism and antilipidemic agents. For more effective utilization by undergraduates, it seems that the chapter (24) on amino acids, peptides, and proteins should precede or immediately follow the consideration of steroid hormones to relate the hypothalamic and pituitary peptides to their effects on steroid hormone production; then, the chapter on insulin and other agents affecting carbohydrate metabolism would follow logically with the thyroid agents.

The field of chemotherapy is covered (nine chapters) as an overview emphasizing modern concepts of metabolite antagonism, antibiotics, and the various classes of chemotherapeutics. As the author notes, the chapter titled, "Antibiotics," discusses only those antibiotics used in the treatment of infections caused by Gram-positive and by Gram-negative bacteria, whereas respective chapters deal with antimycobacterial, antifungal, antineoplastic, and antiprotozoan antibiotics.

Most principal chemotherapeutic agents are structurally characterized and their biochemical actions are related to therapeutic significance.

Finally, miscellaneous medicinals affecting the respiratory system (*e.g.*, nasal decongestants, antitussives, *etc.*,) and diagnostic agents are presented in two chapters.

Perhaps other educators agree with the reviewer that for undergraduate teaching a combination of texts (*e.g.*, Foye's; Burger's *Medicinal Chemistry;* and Wilson, Gisvold, and Doerge's *Textbook of Organic Medicinal and Pharmaceutical Chemistry*) together with appropriate journal articles serve the best purpose in presenting a well-balanced complementation of lecture material in medicinal chemistry, thus providing students with a good introduction to the literature *via* selected bibliographies. In this capacity, Foye's text will be a contribution to the pharmaceutical sciences and pharmaceutical education in general. This book can also serve as a useful review for pharmaceutical scientists who feel a need for updating in elementary medicinal chemistry. Furthermore, pharmacy and medical practitioners will find this text important for refamiliarization with the chemical basis of modern drug therapy.

NATIONAL RESEARCH POLICY

A frequently heard criticism relates to the absence of any clearly defined national science policy on the part of the United States government. Inasmuch as research is a key element of science—and in the minds of many is synonymous with it—it is evident that what is equally lacking is a clear federal policy concerning research *per se*.

Naturally, what is of greatest interest to us and to the majority of our readers is that biomedical research constitutes one facet of this great policy wasteland.

We were heartened, therefore, when U.S. President Ford—at the urging of Congress—appointed a group of knowledgeable scientists to review, study, and report on the subject of biomedical and behavioral research. The group, designated "The President's Biomedical Research Panel," is to come up with specific recommendations based upon its year-long analysis.

As part of the fact-finding and opinion-soliciting phase of operation, the panel identified a number of organizations in the health-care field and invited comments from them. Included among these organizations was the American Pharmaceutical Association. APhA accepted the invitation to offer its views and, in turn, solicited input from its two academies—the Academy of Pharmaceutical Sciences and the Academy of Pharmacy Practice.

Ultimately, a rather comprehensive paper was prepared and submitted by APhA based upon the collective input provided from its academies, its officers, and its staff. Reflected in this paper is a broad spectrum of views and thinking which hopefully will have a positive impact on the report prepared by the President's panel. And, subsequently, we trust that the panel's report will, in fact, result in the establishment of the long-needed federal biomedical research policy. If, as we hope and anticipate, the panel prepares a report at least compatible with—if not patterned after—the views expressed by APhA, then it is our further wish that the President will respond favorably, with the result that the panel's report forms the basis of the national research policy that is established.

In light of the fact that many of our readers have a basic interest in this subject, we are publishing in full, on pages iii–vi in this issue of the *Journal of Pharmaceutical Sciences*, the comments approved by the APhA Board of Trustees and submitted by the Association. We respectfully suggest that these comments be read in their entirety by everyone having an interest in the subject of Biomedical Research.

REVIEW ARTICLE

Microbial Models of Mammalian Metabolism

ROBERT V. SMITH *x **and JOHN P. ROSAZZA** ‡

Keyphrases □ Drug metabolism—mammals, microorganisms, mechanisms, C-hydroxylation, *N*-dealkylation, *O*-dealkylation, *N*-oxidation, S-oxidation, alcohol dehydrogenation, keto reduction, nitro reduction, azo reduction, review □ Mammalian biotransformations—parallel microbial transformations, review □ Microbial transformations—parallel mammalian metabolism, review

An understanding of the metabolism of drugs and other foreign chemicals in mammals has been pursued actively during the past 15 years. Metabolism can include the phenomena of absorption, distribution, and excretion (1). However, in this paper, it will be used synonymously with the more strictly defined term biotransformation. Study of mammalian biotransformations has been stimulated by the fact that useful information on the mechanism of action and/or toxicity of certain compounds can often be obtained.

While there is considerable impetus to perform metabolism studies, several practical problems are encountered including: (*a*) development of analytical methods suitable for the determination of drugs and their metabolites in biological media; (*b*) qualitative and quantitative metabolic differences in various species of animals, especially when attempting to compare lower animals to humans; and (*c*) procurement of sufficient quantities of metabolites for structure elucidation and biological testing. Considerable effort has been expended in solving the first two problems. The refinement of radiochemical techniques (2) and the development of GC (3) and mass spectral (4, 5) methodology have aided significantly in the first case, while recent emphasis on comparative metabolism should ultimately provide solutions to the second difficulty (6, 7).

Until recently, however, there have been relatively few solutions to the problem of preparative synthesis of metabolites. Although direct structural information is often obtainable (through mass spectrometry) on the mere microgram quantities of metabolites usually available from biological specimens, there is no substitute for having larger (gram) quantities for complete structure elucidation and biological evaluation. While organic synthetic methods provide an obvious solution for metabolites of relatively simple drugs, preparation of metabolites of more complex molecules may require vast expenditures in time and effort. Although mammalian tissue preparations (*e.g.*, liver microsomes) occasionally may be utilized in synthesizing preparative quantities of metabolites, there are difficulties related to the stability of such systems (8).

Recently, Smith and Rosazza (9) suggested that it might be possible to define microbial transformation systems that could mimic many biotransformations observed in mammals. As a descriptive name, these systems are called "microbial models of mammalian metabolism." It is important to realize that a microbial transformation system is viewed as a selected group of microorganisms that could be used together to conduct parallel mammalian and microbial xenobiotic metabolism studies. It is unlikely, although not impossible, that a single microorganism can mimic all of the biotransformations conducted by mammalian systems (*e.g.*, liver microsomal preparations). Where metabolites common to both the microbial transfor-

mation system and mammalian systems are observed, the microbial system would be used to obtain sizable quantities (grams) of metabolites *via* routine fermentation scale-up techniques. By this process, difficult-to-synthesize metabolites would be readily obtained for structure elucidation and biological testing. Further advantages of the microbial transformation system, especially with polyfunctional molecules, center about the selectivity and mild conditions with which biotransformations occur.

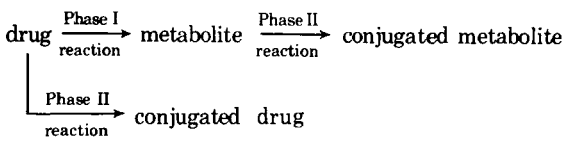
The literature abounds with reports on the metabolism of many types of compounds by microorganisms. These include steroids (10–13), alkaloids (11, 14), antibiotics (15, 16), amino acids (17, 18), and insecticides (19, 20). The general approach taken is one of revealing biogenetic pathways by which compounds are metabolized by one or more microorganisms. The fields of microbial conversions with steroids and antibiotics represent some of the most serious attempts at harnessing the synthetic potential of microorganisms.

Although the literature reveals many types of reactions by microorganisms, many of these are low yielding; few systematic studies on the use of microorganisms for the preparation of metabolites (except steroids and antibiotics) have been made (10–13, 15, 16). The fundamental bases for the selection and use of these microbial systems and their potentialities are the subjects of this paper.

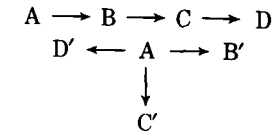
PRINCIPLES OF MAMMALIAN BIOTRANSFORMATIONS

Most drugs or other foreign chemicals entering the mammalian organism are chemically altered. In many instances, changes are effected in a biphasic process. Phase I consists of oxidation, reduction, and hydrolysis reactions, while Phase II involves conjugative reactions (sometimes known as synthetic reactions) between the drug (or metabolite) and common body constituents. These processes are diagrammatically represented in Scheme I. Through biotransformations, drugs are generally converted into more polar compounds which can be readily excreted (primarily *via* the kidney) from the organism. Thus, biotransformation reactions may act as mechanisms for terminating the pharmacological activity of drug substances. Indeed, it has been suggested that in lieu of metabolic transformations, certain drug entities might have biological lifetimes far exceeding those of most animal organisms (21).

In general, biotransformations lead to chemical entities possessing less biological activity and/or toxicity; however, there are exceptions. Particularly with Phase I reactions, cases are now well documented wherein metabolites possessing enhanced activities are produced.



Scheme I—Biotransformations of drugs



Scheme II—Parallel versus *sequential biotransformations of drugs*

Study of the metabolic fate of foreign compounds is complicated by the fact that parallel or sequential biotransformations may occur (Scheme II). Consequently, for some complex molecules (*e.g.*, phenothiazine tranquilizers), tens of metabolites can be formed in mammals (22).

OXIDATIVE TRANSFORMATIONS

Of the three Phase I reactions, oxidative biotransformations are quantitatively of greatest importance. A tremendous explosion has occurred over the past decade regarding the understanding of the mechanisms of oxidation of all types of compounds. In 1962, Hayaishi (23) paid great attention to the gross aspects of oxygen metabolism. Since that time, an understanding of the basic mechanisms of oxygen activation and of the physiological function of the oxygenases has increased (24). New classes of oxygen-activating enzymes appeared during this period, including cytochrome P-450 enzyme systems, flavoprotein oxygenases, and α-ketoglutarate-requiring oxygenases. A greater understanding of superoxide anion, superoxide dismutase, and superoxide-using enzymes also has been gained.

Most oxidative Phase I reactions are catalyzed by cytochrome P-450-linked monooxygenases (Table I), located primarily in the liver of mammals but also occurring in the kidneys, lungs, small intestine, spleen, and steroidogenic organs such as the adrenal cortex, testes, ovary, and placenta (8). Considerable effort has gone into unraveling the electron-transport chain associated with these rather nonspecific enzyme systems (8, 25, 26). Briefly, the oxidized form of cytochrome P-450 (Fe III) complexes with substrate, apparently at a site near the iron atom of the heme protein. The resulting complex undergoes rapid reduction *via* cytochrome P-450 reductase (Fe III reduced to Fe II). This reduction is followed by formation of a ternary reduced cytochrome–substrate–molecular oxygen complex.

After reduction of the oxygen by the cytochrome iron atom (Fe II → Fe III) and further reduction by another electron from an unknown source, the resulting complex internally disproportionates with the transfer of one oxygen to bound substrate and acceptance of two protons by the second oxygen atom. Finally, the complex dissociates into water, oxidized substrate, and oxidized cytochrome P-450. This mechanism (Scheme III) is important because of its apparent similarity to monooxygenases occurring in microorganisms (*vide infra*).

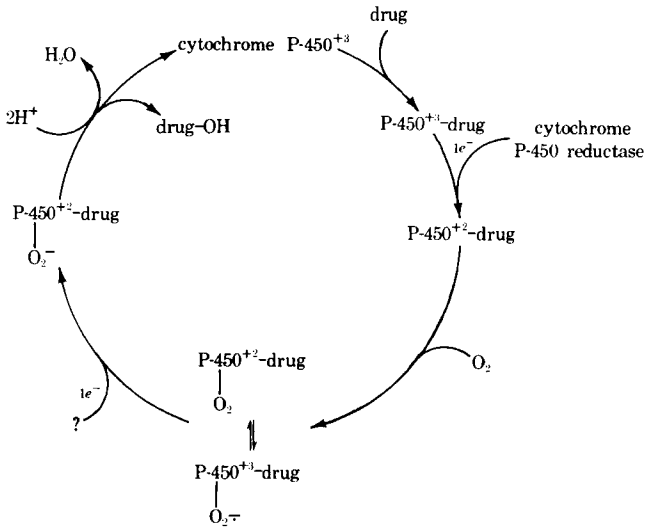
Cytochrome P-450 monooxygenases are believed to mediate aliphatic and aromatic hydroxylations and *N*-, *O*-, and S-dealkylations in mammals. In general, they can be visualized as mediating the attack of sub-

Table I—Mammalian Oxidative Biotransformations

Reaction Type	Substrate	Intermediate	Product
Hydroxylation	Aliphatic and alicyclic compounds	—	Alcohols
	Aromatic compounds	Arene oxides	Phenols
N-Dealkylation	Secondary and tertiary amines	$HOCHRNR_2'$	Aldehyde plus primary or secondary amine
O-Dealkylation	Alkyl–alkyl and alkyl–aryl ethers	HOCHROR'	Aldehyde plus alcohol or phenol
S-Dealkylation	Alkyl–alkyl and alkyl–aryl sulfides	HOCHRSR'	Aldehyde plus thiol or thiophenol
S-Oxidation	Sulfides	—	Sulfoxide
	Sulfoxide	—	Sulfone
N-Oxidation	Primary and secondary amines and amides	—	Hydroxylamine and *N*-hydroxyamides
	Tertiary amines	—	*N*-Oxides
Deamination	Primary and secondary amines	RCHNHR' OH	Ammonia and primary amine plus aldehyde
Dehydrogenation	Primary alcohol	—	Aldehyde
	Secondary alcohol	—	Ketone
	Aldehyde	—	Carboxylic acid
	trans-Dihydrodiol	—	Catechol

strate by an electron-deficient oxygen atom; in most instances, this results in the formation of unstable intermediates that rearrange to the metabolites indicated in Table I. In the case of aliphatic hydroxylations, this process can be thought of as an insertion reaction; in aromatic hydroxylations, arene oxides primarily occur as intermediates (27, 28). In most cases, the hydroxyalkyl intermediates formed during *N*-, *O*-, and S-dealkylations are so unstable that they spontaneously decompose to their corresponding dealkylated metabolites.

S-Oxidation, *N*-hydroxylation (primary and secondary amines), *N*-oxide formation (tertiary amines), and deaminations (primary amines) are mammalian biotransformations (Table I) that occur in a manner similar to that already described. However, these reactions probably involve enzymes other than cytochrome P-450 monooxygenases. All of the oxidative reactions, except oxidative deamination, that occur in mammalian tissues can be duplicated *in vitro* with so-called microsomal fractions (1). The latter arise as microglobular bodies, formed (as artifacts) during disruption of the endoplasmic reticulum of cells.



Scheme III—Oxidation of drugs via cytochrome P-450-linked monooxygenase

Alcohols are oxidized to aldehydes and ketones by a number of oxidoreductases or alcohol dehydrogenases. In this regard, the enzyme of principal importance is (the soluble) liver alcohol dehydrogenase. The coenzyme for this transformation is NAD; the stoichiometry of the reversible reaction involved is shown in Scheme IV.

$$NAD + \text{alcohol} \rightleftharpoons NADH + \text{ketone or aldehyde} + H^+$$

Scheme IV

Because of proton formation, the carbonyl product is favored at higher pH's (optimum = 10). *In vivo*, the conversion of alcohols to aldehydes is favored due to subsequent facile conversion to readily excreted carboxylic acids. Aldehydes are converted to carboxylic acids by a series of soluble enzymes, including aldehyde dehydrogenases, aldehyde oxidase, and xanthine oxidase.

Oxidative deamination of naturally occurring amines is catalyzed by mitochondrial amine oxidases (principally monoamine oxidase). Monoamine oxidase also attacks various exogenous amines.

Enzymes associated with oxidative transformation of xenobiotics appear to exhibit a low degree of substrate specificity; that is, practically all classes of compounds serve as substrates. Within classes of compounds, however, certain directional influences seem to play a major role in determining what position becomes oxidized. For instance, with a given aromatic hydrocarbon, a preponderance of one phenolic metabolite over another is often observed. Such observations pose a dilemma in that it is difficult to discern whether specificities regarding sites of oxidation are qualitative (involving different enzymes) or quantitative (involving different amounts of enzymes) manifestations of enzyme activity. Although considerable research is required to answer such questions, certain generalizations may be noted for given types of oxidative biotransformations.

As a convenient means of representing parallels between microbial and mammalian biotransformations, various reactions that appear to be important

in the metabolism of drug substances will be discussed.

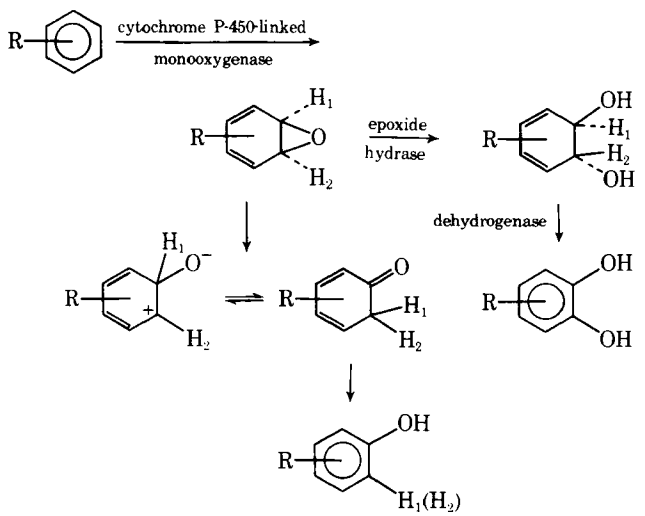
Aromatic Hydroxylations—Aromatic compounds are often converted to phenols in mammalian systems. Patterns of hydroxylations frequently follow the rules of electrophilic substitution reactions. Activated (electron-rich) aromatic rings are readily hydroxylated, whereas deactivated (electron-deficient) aromatic rings are hydroxylated slowly or not at all. Furthermore, hydroxylation occurs at positions predicted by concepts of electrophilic substitution; activated rings [*e.g.*, aniline and anisole (27–30)] are hydroxylated in *ortho*- and *para*-positions, while certain deactivated rings [*e.g.*, benzoic acid and benzamide (30)] are hydroxylated in the *meta*-position. The proportions of *ortho*- to *para*-hydroxylated products generally favor the latter; as expected, in di- and trisubstituted systems, hydroxylation is directed to positions predicted by a summation of substituent effects (29, 31).

Aromatic hydroxylation can be viewed as proceeding by a number of different mechanisms. However, most data are consistent with an oxenoid mechanism involving the intermediacy of an arene oxide and the formation of phenolic metabolites *via* nonenzymatic rearrangement (32). This process is usually accompanied by the so-called NIH shift (27, 28, 33–35) or retention of a substituent at the site of hydroxylation by rearrangement to an adjacent carbon (Scheme V).

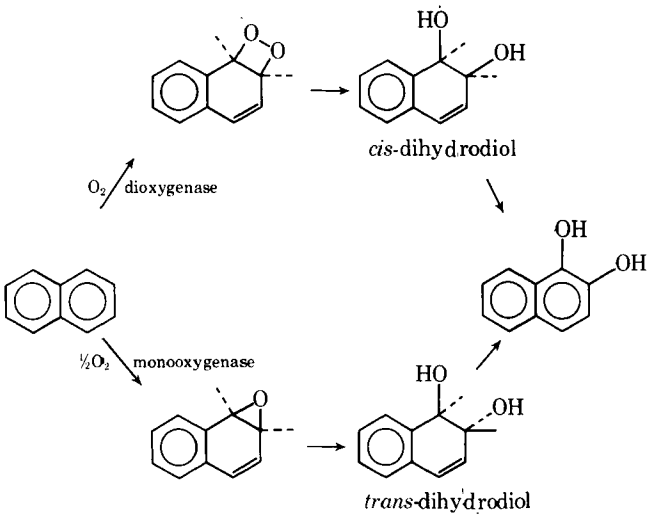
The same enzymes that form arene oxides from aromatic compounds seem to be capable of forming epoxides from isolated and conjugated olefins (32).

Catechols and their conjugates are important metabolites of certain organic compounds [*e.g.*, chlorobenzene (36)]. These metabolites appear to be formed through the action of soluble hepatic dehydrogenases on dihydrodiols rather than by hydroxylation of monophenols (37).

In many biological systems, cytochrome P-450 monooxygenases appear to be linked to epoxyhydrases. Thus, where more stable arene oxides are formed [*e.g.*, naphthalene-1,2-oxide (33, 38)], these may be converted to *trans*-dihydrodiols. When "stable"



Scheme V—Mammalian oxidative biotransformations of aromatic compounds



Scheme VI—Effect of dioxygenase versus *monooxygenase enzymes on naphthalene*

arene oxides are formed, they may participate in alkylation reactions with cellular components. Such processes may be important with respect to the toxicity and/or carcinogenicity of certain aromatic compounds (27, 28).

Lack of a primary isotope effect in enzymatic phenol formation (*e.g.*, deuterated aromatic substrates), demonstration of the NIH shift, and *trans*-dihydrodiol formation are becoming recognized as *prima facie* evidence for the presence of oxenoid monooxygenase activity (27, 28, 39). Such evidence has been useful in differentiating monooxygenases from dioxygenases in microorganisms.

In bacteria, aromatic compounds were traditionally thought to be degraded solely by dioxygenase pathways (40–43) (Scheme VI). A substrate such as naphthalene is converted through the hypothetical cyclic peroxide intermediate to a dihydrodiol and, ultimately, to the catechol derivative. These catechols are further degraded to carbon dioxide and water in bacteria. Jerina *et al.* (44) demonstrated that the reaction was dioxygenase mediated by isolating the *cis*-dihydrodiol of naphthalene, which was characterized by NMR spectral analysis. Prior to this time, a *trans*-dihydrodiol intermediate had been suggested as being predominantly involved in the degradation of naphthalene and other aromatic compounds in microorganisms (44–49). In contrast to this mechanism in microbiological systems, mammalian systems form *trans*-dihydrodiol intermediates *via* a monooxygenase oxidation step; the resulting arene oxide is opened by enzymatic hydration (33, 50, 51).

More recent data indicate that microorganisms may oxidize aromatic compounds like naphthalene through the formation of arene oxide intermediates similar to those obtained in the mammalian system. Cytochrome P-450 enzyme systems have been characterized in *Pseudomonas* species (52), *Claviceps purpurea* (53), and yeasts (54). Additionally, reactions that apparently operate through arene oxides formed in cytochrome P-450 monooxygenase systems from liver occur in fungi (55, 56).

In 1971, Auret *et al.* (55) reported the first occur-

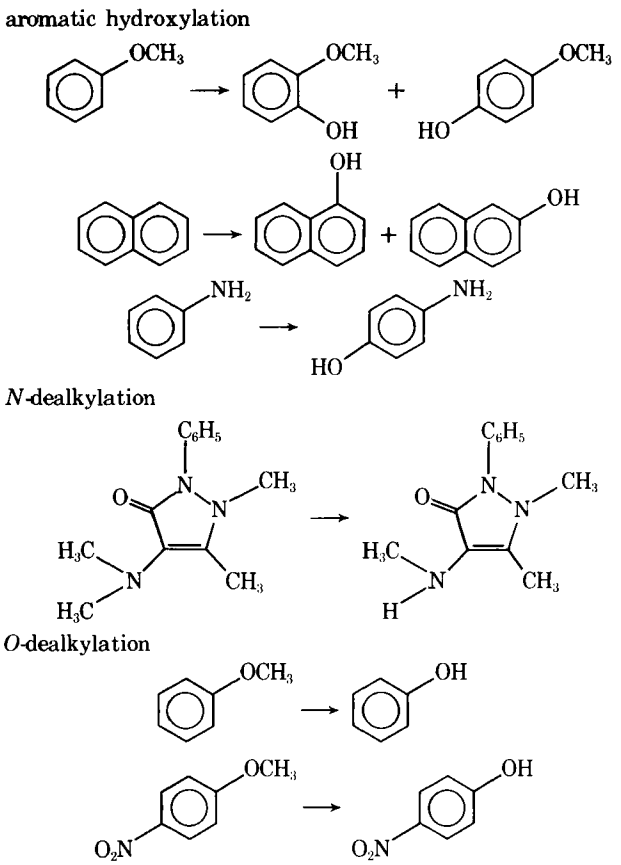
rences of the NIH shift in the hydroxylation of aromatic compounds by fungi. Both 4-D- and 2-D-anisoles were added as substrates to cultures of *Aspergillus niger, Sporotrichum sulfurescens, Cunninghamella elegans, Rhizopus arrhizus, Helicostylum piriforme, Mucor parasiticus, Rhizopus stolonifer, Curvularia falcata,* and *Cunninghamella bainieri,* which displayed the NIH shift during aromatic hydroxylations (55, 56). For *p*-anisole, 69–72% migration and retention of deuterium were observed in the 4-hydroxylated product; 35–57% migration and retention were observed with 2-hydroxylation. The magnitude of the NIH shift observed was consistent with that observed in hydroxylations of anisole by hepatic microsomes (57, 58).

Hydroxylations of these anisole derivatives and other substrates were rationalized on the basis of the involvement of arene oxide intermediates which ultimately gave the phenolic products. Several interesting observations were made on the data obtained in these early experiments:

1. Aryl oxidase enzymes of fungi appear to be similar to monooxygenases of hepatic microsomes, since both show the NIH shift and both have broad substrate specificities.
2. *ortho*-Hydroxylation appears to be predominant in fungi, while *para*-hydroxylation occurs to a greater extent in hepatic systems.
3. Polar substrates seem to oxidize more readily than nonpolar materials in fungi, while the reverse appears to be true in hepatic systems.
4. Arene oxide isomerases similar to those found in plant systems apparently are absent in fungal species.

The importance of this work has been underlined through studies by Ferris *et al.* (56) on the monooxygenase enzyme system in *C. bainieri.* When resting cells were used, monooxygenase activity nearly paralleling that seen in hepatic monooxygenase systems was observed. Naphthalene was converted into a *trans*-dihydrodiol, demonstrating the presence of the enzyme epoxide hydrase. Furthermore, a mixture of α- and β-naphthols was obtained in the ratio of 9:1; this result was very close to that obtained with *in vivo* and *in vitro* mammalian systems (33). Both 2- and 4-hydroxylations of anisole as well as *O*-dealkylation, were observed with this microorganism; however, the ratio of these products was different than that reported in mammalian systems (29). Other transformations reported included *N*-demethylation of aminopyrine, *O*-dealkylation of *p*-nitroanisole, and 4-hydroxylation of aniline (Scheme VII). Ferris *et al.* (56) observed that no other fungal or bacterial system had ever exhibited such a close metabolic parallelism to the drug-metabolizing system of liver microsomes.

In this work, 4-hydroxylation greatly exceeded 2-hydroxylation of anisole. Thus, the conclusion reached by Auret *et al.* (55) that *ortho*-hydroxylation predominates in fungal systems may be faulty, or differences in results obtained by the two groups of workers (55, 56) may be related to the experimental conditions employed by each.



Scheme VII—Transformations affected by C. bainieri (*Ref. 56*)

All previous results that pointed to the similarities in microbial and mammalian enzyme systems represented a foundation for establishing microbial models of mammalian metabolism. Our attention was initially focused on aromatic hydroxylation to test the feasibility of this proposal for three reasons: (*a*) it represents a commonly occurring mammalian biotransformation; (*b*) aryl hydroxylase activity similar to that displayed by mammalian cytochrome P-450 had been demonstrated in several microbial species (53, 55, 56); and (*c*) phenol formation, vis-à-vis arene oxide intermediates, had been implicated in mechanisms of toxicity of certain aromatic compounds (27, 28, 60).

A literature survey indicated that a number of microorganisms possessed aromatic hydroxylating activity (18, 55, 56); 11 microorganisms [*A. niger* (ATCC[1] 9142), *Penicillium chrysogenum* (ATCC[1] 10002), *Cunninghamella blakesleeana* (ATCC[1] 8688a), *Aspergillus ochraceous* (ATCC[1] 1008), *Gliocladium deliquescens* (1086), *Streptomyces* species (1158w), *R. stolonifer* (NRRL[2] 1477), *Curvularia lunata* (NRRL[2] 2178), *Streptomyces rimosus* (ATCC[1] 23955), *C. bainieri* (ATCC[1] 9244), and *H. piriforme* (QM[3] 6945)] were selected as microbial models of mammalian aromatic hydroxylation (9). A selection

Table II—Metabolites Formed by Microorganisms

Substrate	Metabolite	Organism(s) Causing Transformation
Acetanilide	2-Hydroxyacetanilide	*A. ochraceous*
	Aniline	*A. niger, Pen. chrysogenum, A. ochraceous, G. deliquescens,* and *S. rimosus*
Acronycine	9-Hydroxy-, 11-hydroxy-, and 9,11-dihydroxy-acronycines	*A. niger, C. blakesleeana, S. rimosus,* and *C. bainieri*
Aniline	Acetanilide	*C. blakesleeana* and *C. bainieri*
	2-Hydroxyacetanilide	*C. blakesleeana, A. ochraceous,* and *C. bainieri*
	4-Hydroxyaniline	*C. bainieri*
Anisole	2-Hydroxyanisole	*C. blakesleeana, A. ochraceous, G. deliquescens, Streptomyces* sp., *R. stolonifer, C. bainieri,* and *H. piriforme*
	4-Hydroxyanisole	*Pen. chrysogenum, C. blakesleeana, A. ochraceous,* and *C. bainieri*
	Phenol	*A. niger, C. blakesleeana, A. ochraceous, Streptomyces* sp., *R. stolonifer, C. bainieri,* and *H. piriforme*
	Hydroquinone	*A. ochraceous*
Benzene	Phenol	*Pen. chrysogenum, C. blakesleeana, G. deliquescens, Streptomyces* sp., and *C. bainieri*
Benzoic acid	2-Hydroxybenzoic acid	*A. niger* and *C. bainieri*
	4-Hydroxybenzoic acid	*Cur. lunata* and *C. bainieri*
	3,4-Dihydroxybenzoic acid	*A. ochraceous*
Biphenyl	2-Hydroxybiphenyl	*A. niger, S. rimosus,* and *H. piriforme*
	4-Hydroxybiphenyl	*A. niger, C. blakesleeana, Streptomyces* sp., *Cur. lunata, C. bainieri,* and *H. piriforme*
	4,4′-Dihydroxybiphenyl	*C. blakesleeana* and *C. bainieri*
Chlorobenzene	2-Hydroxychlorobenzene	*A. ochraceous, G. deliquescens, Streptomyces* sp., *R. stolonifer,* and *C. bainieri*
	4-Hydroxychlorobenzene	*A. ochraceous* and *C. bainieri*
Coumarin	7-Hydroxycoumarin	*G. deliquescens, Streptomyces* sp., *C. bainieri,* and *H. piriforme*
Naphthalene	1-Hydroxynaphthalene	*A. niger, C. blakesleeana, A. ochraceous, Streptomyces* sp. *stolonifer, C. bainieri,* and *H. piriforme*
	2-Hydroxynaphthalene	*A. niger, C. bainieri,* and *H. piriforme*
trans-Stilbene	*trans*-4-Hydroxystilbene	*A. niger, C. blakesleeana, A. ochraceous, Streptomyces* sp., *R. stolonifer,* and *C. bainieri*
	trans-4,4′-Dihydroxy-stilbene	*Streptomyces* sp. and *C. bainieri*
Toluene	2-Hydroxytoluene	*Pen. chrysogenum, A. ochraceous, Streptomyces* sp., *R. stolonifer, C. bainieri,* and *H. piriforme*
	4-Hydroxytoluene	*Pen. chrysogenum, R. stolonifer,* and *C. bainieri*

of aromatic compounds was chosen to be incubated with growing cultures of each microorganism. These included acetanilide, acronycine, aniline, anisole, benzene, benzoic acid, biphenyl, chlorobenzene, coumarin, naphthalene, nitrobenzene, *trans*-stilbene, and toluene. Mammalian systems have been shown to hydroxylate each of these compounds, and this permitted a comparison of mammalian and microbial aromatic hydroxylase activities. Furthermore, these compounds represent the aromatic portions of numerous chemical entities of environmental importance and of drugs.

All of these compounds were incubated with growing cultures of the 11 microorganisms. The results of TLC analyses (61, 62) of the fermentations are summarized in Table II.

The microbial system demonstrated substantial capacity to hydroxylate simple substituted benzenoid compounds. 2- and 4-Hydroxylations were observed in all cases, except with acetanilide where the 2-hydroxyacetanilide product was obtained exclusively. In earlier reported work, Theriault and Longfield (63) showed a *Streptomyces* species to be capable of hydroxylating acetanilide exclusively in the 4-position, while one *Basidiomycete* hydroxylated acetanilide in the 2-position. Hydroxylation at either the 2- or 4-position almost exclusively was observed for microorganisms with anisole, benzoic acid, aniline, and chlorobenzene (9). The microbial metabolites obtained are compared to the mammalian metabolites reported from *in vitro* and *in vivo* metabolism studies in Table III. In general, a good correlation was obtained between the microbial and mammalian metabolizing systems. Nitrobenzene was the only simple substituted benzenoid compound that failed to yield hydroxylated products with the microbial system. The 2-, 3-, and 4-hydroxynitrobenzenes are obtained with mammalian systems.

Additional biotransformations occurred with these substrates. Five microorganisms demonstrated ami-

Table III—Comparison of Metabolites Formed by Microorganisms and Mammalian Systems

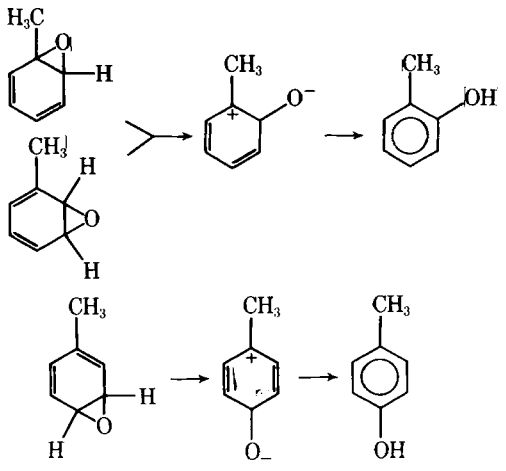
Substrate	Microbial Metabolite[a]	Mammalian Metabolite	
		In Vitro (Reference)	*In Vivo* (Reference)
Acetanilide	2-Hydroxyacetanilide and aniline	2-Hydroxyacetanilide, 4-hydroxyacetanilide, and aniline (57, 64)	4-Hydroxyacetanilide and aniline (65)
Acronycine	9-Hydroxy-, 11-hydroxy-, and 9,11-dihydroxyacronycines	Not reported	9-Hydroxy-, 11-hydroxy-, and 9,11-dihydroxyacronycines (66)
Aniline	Acetanilide, 2-hydroxyacetanilide, and 4-hydroxyaniline	4-Hydroxyaniline (57)	Acetanilide and 2-hydroxy-, 3-hydroxy-, and 4-hydroxyanilines (67)
Anisole	2- and 4-Hydroxyanisoles and phenol	2- and 4-hydroxyanisoles and phenol (64)	2- and 4-Hydroxyanisoles (68)
Benzene	Phenol	Phenol (57)	Phenol (69)
Benzoic acid	2- and 4-Hydroxybenzoic acids and 3,4-dihydroxybenzoic acid	3-Hydroxybenzoic acid (57)	2-, 3-, and 4-Hydroxybenzoic acids (71)
Biphenyl	2- and 4-Hydroxybiphenyls and 4,4′-dihydroxybiphenyl	2- and 4-Hydroxybiphenyls (57, 70)	4-Hydroxy-, 3,4-dihydroxy-, and 4,4′-dihydroxybiphenyls (72)
Chlorobenzene	2- and 4-Hydroxychlorobenzenes	2-, 3-, and 4-Hydroxychlorobenzenes (57)	2-, 3-, and 4-Hydroxychlorobenzenes (73)
Coumarin	7-Hydroxycoumarin	7-Hydroxycoumarin (74)	3- and 7-Hydroxycoumarins [4-, 5-, 6-, and 8-hydroxycoumarins[b] (75, 76)]
Naphthalene	1- and 2-Hydroxynaphthalenes	1- and 2-Hydroxynaphthalenes (33, 59)	1- and 2-Hydroxynaphthalenes (77)
Nitrobenzene	—	4-Hydroxynitrobenzene (57)	2-, 3-, and 4-Hydroxynitrobenzenes and 2-, 3-, and 4-hydroxyanilines (78, 79)
trans-Stilbene	*trans*-4-Hydroxy- and *trans*-4,4′-dihydroxystilbenes	*trans*-4-Hydroxystilbene and *trans*-4,4′-dihydroxystilbene (80)	*trans*-4-Hydroxy-, *trans*-3,4-dihydroxy-[c], and *trans*-4,4′-dihydroxystilbenes (80)
Toluene	2- and 4-Hydroxytoluenes	2- and 4-Hydroxytoluenes and benzyl alcohol (57)	Benzoic acid and conjugates (67)

[a] See Ref. 9. [b] Formed in trace quantities. [c] Presumed metabolite based on characterization of mono-*O*-methyl ethers.

dase activity in removing the acetyl group from acetanilide, a minor mammalian biotransformation. Acetylase activity was observed in four microorganisms with aniline; this pathway is common in mammals. *A. ochraceous* gave good yields of 2-hydroxyacetanilide when incubated with acetanilide as the substrate. In this microorganism, acetylation apparently must precede hydroxylation. This requirement for an amide functional group in the hydroxylation of various substrates was reported by Johnson *et al.* (81) and Fonken *et al.* (82), who have observed that in an extensive series of carbocyclic amines and nitrogen heterocycles an acyl substituent is required on the nitrogen atom for hydroxylation to occur.

With anisole, seven microorganisms caused *O*-demethylation. This reaction was common and occurred with cultures that caused 2-hydroxylation as well. Our results were consistent with those observed by Auret *et al.* (55). *O*-Demethylase activity was reported before, particularly with certain *Pseudomonads* (83, 84) and with *A. niger* (85). With our culture of *A. niger* (9), *O*-demethylase activity was dominant; phenol was the only metabolite of anisole detected. With *A. ochraceous*, greater than 50% conversion of benzoic acid to 3,4-dihydroxybenzoic acid was obtained (9). Microorganisms convert benzoic acid into various hydroxylated products (85–87); in fungi, 3,4-dihydroxybenzoic acid is commonly produced with 3- or 4-hydroxybenzoate serving as intermediates (86, 87).

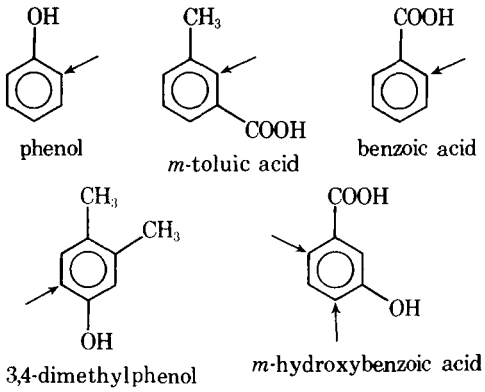
Another interesting, albeit somewhat hidden, result was obtained with the microbial system of Smith and Rosazza (9). Although the number of microorganisms in the study was insufficient to establish a complete trend, ring-activating groups generally resulted in a greater number of microorganisms giving hydroxylated products and provided higher yields. As expected, the products obtained were hydroxylated *ortho* and *para* to ring substituents, a result that may be predicted by considering a composite of the various cationic intermediate forms of possible epoxide ring openings as shown in Scheme VIII (27). The relative reactivities of simple benzenoid compounds (R—C_6H_5) toward microbial hydroxylases follow the order R = OCH_3 > NH_2, CH_3 > H, Cl, $NHCOCH_3$ > NO_2 (9). The highest yields and inci-



Scheme VIII—Conceptualized cationic intermediates associated with ring openings of arene oxides

dences of microbial hydroxylation occurred with anisole, while no hydroxylation was obtained with nitrobenzene as the substrate. Benzoic acid was eliminated from the sequence because it is a more natural substrate for microorganisms.

Omori and Yamada (88) related the position of hydroxylation of several simple aromatic compounds to their electronic structures. The π-electron distributions of various aromatic compounds selected from the literature were calculated using the assumption that microbiological hydroxylation occurs *via* a radial type of mechanism. With phenol, *m*-toluic acid, benzoic acid, 3,4-dimethylphenol, and *m*-hydroxybenzoic acid, good correlation was obtained between the position of hydroxylation [shown by arrows (88)] and the



points of highest calculated frontier electron densities. This work represented a purely theoretical approach to the problem of predicting sites of hydroxylation since no experimental verification of the results was reported. Furthermore, the simple compounds studied render themselves quite readily to simple first-order predictions regarding sites of oxygenation. A more vigorous application of this approach would involve complicated substrates which, after predicting sites of hydroxylation, could be incubated with selected microorganisms.

Excellent correlation between the metabolites obtained in the microbial system of Smith and Rosazza (9) and mammalian *in vitro* and *in vivo* systems was observed with more complicated aromatic compounds such as acronycine, biphenyl, coumarin, naphthalene, and *trans*-stilbene (Table III). A somewhat stronger parallel existed between the *in vitro* mammalian studies and the microbial model system with biphenyl, chlorobenzene, coumarin, and *trans*-stilbene. Table III shows some of the discrepancies in results obtained in *in vitro* and *in vivo* metabolic studies. These findings indicate that intercomparison between *in vivo* and *in vitro* metabolic systems is not always valid and, in fact, may be no more valid than comparisons of metabolic profiles of microorganisms and liver systems.

The production of 9-hydroxyacronycine as a microbial metabolite by *Cunninghamella echinulata* serves as an excellent example of the potential for obtaining gram quantities of difficult-to-synthesize compounds *via* microbial aromatic hydroxylation (61). Acronycine is an antitumor compound, and its metabolism has been studied in humans, rats, pigs, dogs, and mice (66). The major metabolite produced in mammalian systems is 9-hydroxyacronycine, although minor amounts of other metabolites are also observed. In the microbial system (9), acronycine was hydroxylated by four microorganisms in the 9-position. Other metabolites also were detected in small-scale fermentation screening studies (9, 61). In a scaled-up fermentation, 4 g of acronycine was added as the substrate to 7.5 liters of a fully grown culture of *C. echinulata;* a 31% yield of 9-hydroxyacronycine was isolated and fully characterized (61).

Other examples of the use of microbial transformations for the production of hydroxylated metabolites are 5-anilino-1,2,3,4-thiatriazoles (89), fenclozic acid (90), 5-hydroxytryptophol (17), α-methylfluorene-2-acetic acid (91), and levodopa (18).

Mammalian *N*-, *O*-, and S-Dealkylations—Hydroxylation of sp^3 carbon atoms alpha to a nitrogen, oxygen, or sulfur atom generally leads to dealkylation due to the instability and subsequent rearrangement of the C—OH intermediates. The *N*-, *O*-, and S-dealkylations are important biotransformations, because they can significantly alter the lipid solubility and biological potency of drugs.

N-Dealkylation of numerous amines, amides, and imides has been described. Tertiary amines containing dimethylamino functions are often rapidly *N*-demethylated to their corresponding secondary amines, while the latter are much more slowly transformed into primary amines (92). This finding is in accord with the report that *N*-demethylation rates are directly proportional to lipid solubility and inversely proportional to pKa values (93).

The rate of *N*-dealkylation generally seems to decrease as the size and/or complexity of the *N*-alkyl groups increase (94–97). However, Abdel-Monem and Portoghese (98) found that the degree of *N*-dealkylation increased in a series of *N*-substituted normeperidines, going from methyl to ethyl to *n*-propyl, and then progressively decreased with homologs from *n*-butyl to *n*-nonyl. Because of the lack of an α-hydrogen, *N*-*tert*-butyl groups should be resistant to *N*-dealkylation. However, Kamm and coworkers (99, 100) showed that, by a sequence of oxidation reactions (beginning with hydroxylation of the C-methyl group), this alkyl function can be removed *in vivo* and *in vitro*. *N*-De-*tert*-butylation also emphasizes the fact that C-oxidation probably becomes more important as the size of the *N*-alkyl function increases.

A significant degree of stereospecificity has been shown in the *N*-dealkylation of several enantiomeric pairs of drugs. In light of the fact that biological activity often resides in one enantiomer, this observation deserves further attention (101).

Axelrod (102) first reported that *O*-alkyl functions were cleaved in a similar fashion to *N*-alkyl groups. In addition, *para*-substituted ethers are more readily cleaved than their corresponding *ortho*- or *meta*-isomers (102). In 22 *p*-nitrophenyl ethers, the rate of *O*-dealkylation decreased as the size and/or complexity of the *O*-alkyl function increased (103). Creaven *et al.* (104) found a similar relationship for a homologous series of alkoxy biphenyls, although they noted

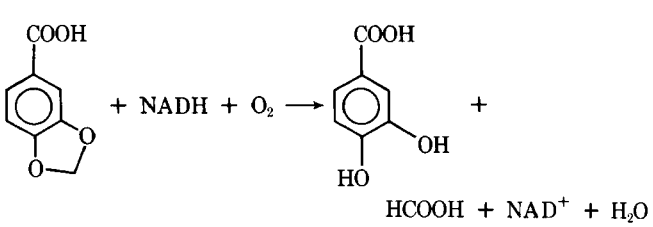
an increase in *O*-dealkylation from methyl to ethyl. Tsukamoto *et al.* (105) reported that *n*-butyl-*p*-nitrophenyl ethers were slowly *O*-dealkylated while ω-1 hydroxylation of the *n*-butyl function predominated in rabbits. The dimethylaminoethyl ether function, often incorporated into drug substances, appears to be quite resistant to *O*-dealkylation *in vitro* and *in vivo* in rats (103).

S-Dealkylation has not been extensively studied, primarily because alkyl–aryl and alkyl–alkyl thioethers are not widely used in drugs. Sulfides embodied in heteroaromatic systems are fairly prevalent among drug entities but are more prone to S-oxidation. The few reported studies indicate that S-demethylation proceeds by a similar mechanism to *N*- and *O*-dealkylation in intact animals and with hepatic microsomal systems (92).

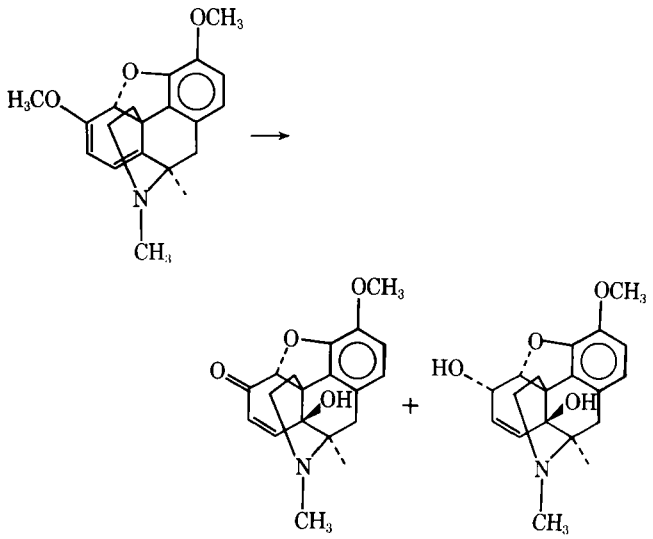
Microbial *O*-Dealkylations—The biodegradation of *O*-alkyl aromatic ethers in bacteria is a monooxygenase-mediated process requiring pyridine nucleotides and oxygen (84). In general, an active form of oxygen attacks the α-carbon of alkyl ethers; the former alkyl group, which exists as an unstable hemiacetal, is easily removed.

Bernhardt *et al.* (84) prepared a cell-free extract and a purified enzyme system from *Pseudomonas putida* capable of *O*-demethylating 4-methoxybenzoate. The purified enzyme system consisted of an iron-flavoprotein and an iron-sulfur protein and was obtained from *P. putida* cells grown on 4-methoxybenzoic acid as the sole carbon source. NADH and oxygen represented cofactor requirements for this enzyme. The purified system acted on many different substrates, but the greatest affinity was observed for 4-methoxybenzoate itself. *para*-Substituted benzoic acid derivatives were the best substrates, while *m*- and *o*-benzoic acids were only slowly demethylated. In this microbial enzyme system, the carboxyl group was an absolute requirement for *O*-demethylation.

Methylenedioxy compounds, which are represented in many natural products, are also converted to their respective phenolic products by *Pseudomonas* species (83). Demethylenation has been reported to occur in NADPH-dependent monooxygenases of rat liver (106). The essential features of the reaction are shown in Scheme IX. Each reaction product was characterized. The catabolism of piperonylic acid by *Pseudomonas fluorescens* appears to be an example of cooxidation in that the methylenedioxy compound did not serve as the sole carbon and energy source and was only degraded when 4-methoxybenzoate (anisic acid) was present. *O*-Dealkylation of various simple methoxylated compounds such as 3-hydroxy-



Scheme IX—Microbial O*-demethylenation of 3,4-methylenedioxybenzoic acid by* Pseudomonas *species (Ref. 83)*



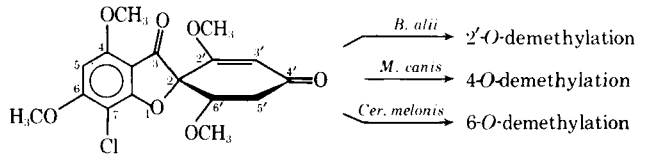
Scheme X—Microbial transformations of thebaine (Refs. 110 and 111)

4-methoxybenzoate (107), anisole (9, 56, 108), and methyl anisate (109) also has been reported in fungi.

Several more complicated examples of *O*-dealkylation have been reported. The alkaloid thebaine undergoes a series of reactions in which the methoxy group is lost (Scheme X). The mechanism by which this reaction occurs is obscure and may involve concerted elimination of the methyl group as a result of hydroxylation (110, 111). The alkaloid aconitine obtained from *Aconitum napellus* (Wolfbane) is also *O*-demethylated by *Streptomyces paucisporogenes* to a compound that is less toxic than the parent alkaloid (112). Boothroyd *et al.* (113) studied the demethylation of griseofulvin by fungi. Several microorganisms were screened for *O*-dealkylase activity; four of these, *Microsporum canis, Alternaria solani, Botrytis alii,* and *Cercosporum melonis,* could metabolize griseofulvin to phenolic products. Each of the three methoxy groups on the griseofulvin molecule could be selectively removed by a different microorganism (Scheme XI). Such selective *O*-demethylase activity has great synthetic utility.

An unusual example of the reverse reaction, *O*-alkylation, was reported (114). With *Lentinus lepideus* surface cultures, *p*-hydroxycinnamic acid was converted into 4-methoxycinnamate in the presence of methionine. This result was confirmed by using ^{14}C-labeled methionine. The methoxy group formed was cleaved by the same fungus when prolonged incubations were conducted.

We have conducted several experiments on microbial *O*-dealkylations, predominantly with methoxylated aporphine and benzylisoquinoline derivatives

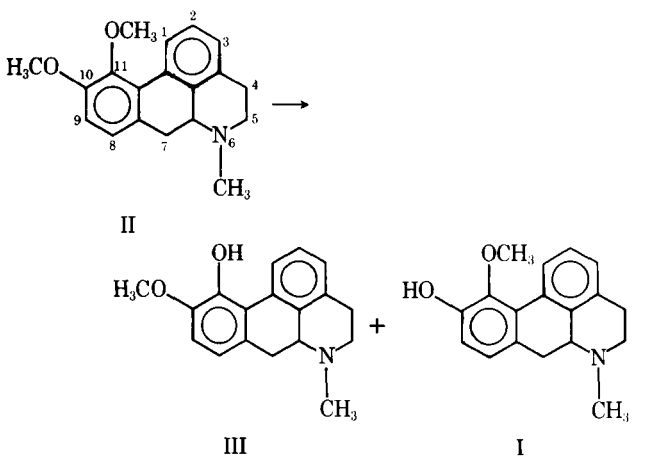


Scheme XI—Microbial O*-demethylation of griseofulvin (Ref. 113)*

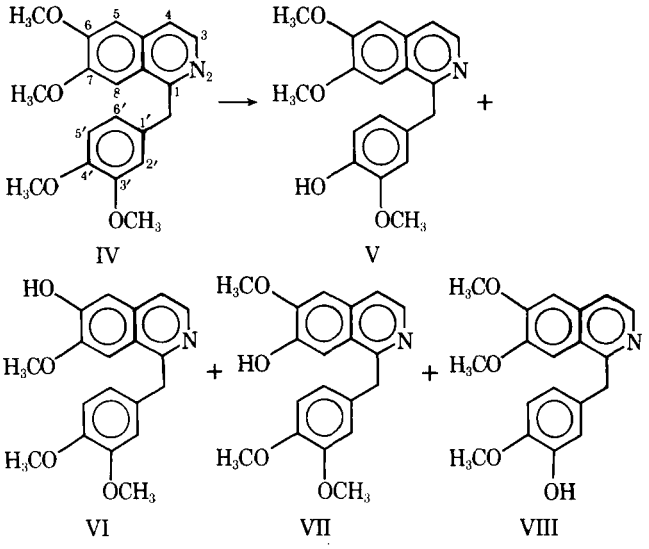
(115). Cannon *et al.* (116) studied the synthesis of the isomeric monomethyl metabolites of apomorphine and metabolism of apomorphine in a catechol-*O*-methyltransferase liver preparation. Considerable difficulty was encountered in the synthesis of one of the possible monomethyl ether isomeric metabolites, isoapocodeine (I). In preliminary experiments, we demonstrated that a *Streptomyces* species converts 10,11-dimethoxyaporphine (II) into an equal mixture of apocodeine (III) and I in about 50% estimated yield (Scheme XII). This process occurs within 24 hr after the substrate is added to growing cultures of the microorganisms.

Two cultures of the microorganisms, *C. blakesleeana* and *C. echinulata,* yielded I as the predominant metabolite, with only traces of III being formed. These results are interesting in view of the results obtained by Cannon *et al.* (116), where the ratio of apocodeine–isoapocodeine obtained in the mammalian liver system was about 75:1. It was rationalized that the formation of isoapocodeine was prohibited due to the sterically hindered hydroxy group at position 11 (Scheme XII). One might expect the reverse reaction (*i.e.,* *O*-dealkylation at position 10) also to be influenced so that isoapocodeine would predominate. Our findings with *C. blakesleeana* and *C. echinulata* (115), which produced mostly isoapocodeine, support the result of Boothroyd *et al.* (113) that selective *O*-dealkylation may be achieved with different microorganisms.

We have also been studying the microbial metabolism of the drug papaverine (IV) (115). Papaverine has been used in treating cerebral and peripheral ischemia associated with arterial spasm (117). The metabolic disposition of papaverine in humans and other mammals has been studied (118). Negligible amounts of the drug are excreted unchanged in urine, indicating that it must be nearly completely metabolized. Only one compound, 4′-*O*-desmethylpapaverine (V), was chemically characterized in the mammalian studies (118). We are developing microbial systems capable of providing gram quantities of all possible *O*-dealkylated isomers, which will be used for structure elucidation and biological testing.



Scheme XII—Microbial O-demethylation of 10,11-dimethoxyaporphine



Scheme XIII—Microbial O-demethylation of papaverine

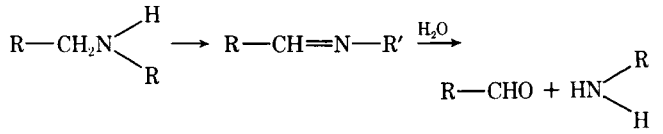
C. echinulata is capable of producing four phenolic metabolites of papaverine (115); two of these have been chromatographically identified as 6-hydroxy-7-methoxy-(3′,4′-dimethoxybenzyl)isoquinoline (VI) and 7-hydroxy-6-methoxy-(3′,4′-dimethoxybenzyl)-isoquinoline (VII) (Scheme XIII). The 3′-hydroxy-4′-methoxybenzyl-6,7-dimethoxyisoquinoline product (VIII) [or its 4′-hydroxy-3′-methoxy isomer (V)] is believed to be the sole product with *C. blakesleeana* (115). Again, this finding demonstrates the selectivity in *O*-dealkylation that may be achieved with microorganisms. Screening of microorganisms is being continued to detect other cultures that might selectively *O*-dealkylate similar systems.

Microbial *N*-Dealkylations—According to Large (119), three major types of pathways are involved in the *N*-dealkylation of amines by microorganisms (Scheme XIV). The oxidases may involve the intermediacy of hydrogen peroxide, while the oxygen of the aldehyde produced comes from water in both the oxidases and dehydrogenases. The third type of reaction is mediated by monooxygenases where molecular oxygen is the source of the oxygen in the aldehyde product.

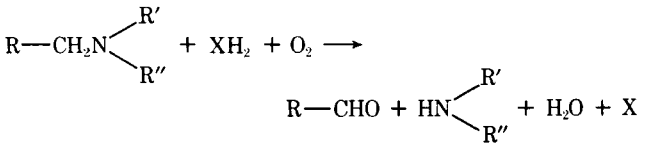
Secondary and tertiary amines are degraded by more than one pathway by bacterial monooxygenases. In *Pseudomonas aminovorans,* trimethylamine is converted into trimethylamine *N*-oxide by an NADPH-dependent tertiary amine monooxygenase enzyme (Scheme XV). The trimethylamine *N*-oxide is then nonoxidatively demethylated by trimethylamine *N*-oxide demethylase to formaldehyde and dimethylamine.

This latter enzyme has been isolated in two bacteria, *P. aminovorans* and a *Bacillus* species (120). This type of *N*-demethylation of an *N*-oxide is apparently not restricted to microbial systems but has been described in the metabolism of tertiary amines by liver microsomal systems (121). Similarities and differences between microsomal and bacterial amine monooxygenases have been compiled (119). The similarities include secondary amines converted to pri-

oxidases and dehydrogenases



monooxygenases

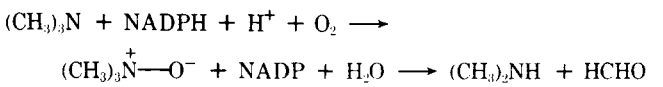


Scheme XIV—Types of microbial N*-dealkylations*

mary amines plus the appropriate aldehyde; tertiary amines converted to amine oxides; tertiary amine oxidation not inhibited by carbon monoxide, cyanide, or proadifen hydrochloride[4]; amine oxide enzymatically converted to secondary amine plus aldehyde; and NADH and NADPH serving as active electron donors.

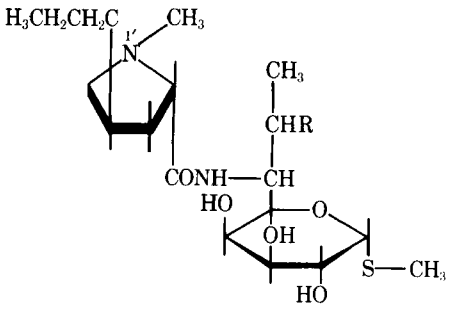
However, in the microsomal system, identical enzymes *N*-dealkylate secondary and tertiary amines, a very wide range of compounds are oxidized, and amine oxide demethylase is inhibited by carbon monoxide, proadifen hydrochloride, and pyridine but not cyanide. In contrast, in the bacterial system, different enzymes affect *N*-dealkylation of secondary and tertiary amines; active substrates must possess one of these structures: CH_3NHR, CH_3CH_2NHR, $(CH_3)_2NR$, or $(CH_3CH_2)_2NR$, where R = C_1 to C_4; and amine oxide demethylase of *P. aminovorans* is inhibited by cyanide but not carbon monoxide, proadiphen hydrochloride, or pyridine. Most importantly, substrate specificity of bacterial *N*-dealkylases appears to be narrower than those of mammalian systems. However, this has not yet been fully explored.

Microbial *N*-dealkylations have been observed in more complicated structures than those already described, although few studies have been conducted concerning the mechanism(s) of these reactions. Clindamycin (IX) and lincomycin (X) are related antibiotics metabolized by various *Streptomyces* species (122, 123). Argoudelis *et al.* (122) produced the 1′-demethylclindamycin compound when clindamycin was added to fermentations of *Streptomyces punipalus*. However, when the compound was metabolized by *Streptomyces armentosus*, primarily the clindamycin sulfoxide was obtained. Other species of microorganisms could convert clindamycin to either the sulfoxide or the 1′-demethylated product or a mixture of both (122). These transformations are significant because the latter two compounds are mammalian metabolites of clindamycin (124), while the *N*-demethylated product is about twice as active as the



Scheme XV—Dealkylation of trimethylamine by P. aminovorans

[4] SK&F 525-A.



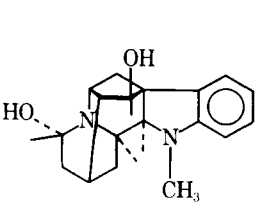
IX: R = Cl
X: R = OH

parent antibiotic. Lincomycin, a structurally related antibiotic, also undergoes *N*-demethylation and sulfoxidation (123). The product in the latter case, however, is approximately one-twentieth as active as the parent antibiotic.

Various compounds that are either drugs or structurally related to classes of drugs are *N*-dealkylated by microorganisms. Bellet and Van Thuong (125) reported the *N*-dealkylation of the dihydroindole alkaloid ajmaline (XI) in 40% yields with a culture of *Streptomyces platensis*. *N*-Demethylation of agroclavine (XII) (126) and certain 6,14-*endo*-ethenotetrahydrothebaine alkaloids (such as XIII) (127) by *C. echinulata* has been reported. Mitscher *et al.* (127) commented on the parallel between the latter *N*-dealkylation and a similar biotransformation observed in mammalian systems.

Tropine (XIV), the basic nucleus of a number of anticholinergic drugs, is *N*-demethylated by *Arthrobacter atropini;* the tranquilizer diazepam (XV) is similarly transformed by *Pellicularia filamentosa* and in 12% yields by *Sp. sulfurescens* (12). This latter transformation again represents a parallel to mammalian metabolism.

Methamphetamine is *N*-demethylated by the intestinal microflora of guinea pigs. Observing differences in recoveries of metabolites of methamphetamine (XVI) fed to animals, Caldwell and Hawksworth (128) concluded that microflora of the intestine could play a role in degrading the drug. The



XI

XVI

cecal contents of Dunkin–Hartley guinea pigs were removed and incubated with (±)-2-methylamino-1-phenyl-1-^{14}C-propane hydrochloride. Twenty-nine percent of the dose was recovered unchanged while the *N*-dealkylated product, amphetamine, was recovered in 47% yield. An unknown product was also observed. Several genera of human gut bacteria were isolated and examined for their potential to metabolize methamphetamine. In particular, *Lactobacilli, Enterococci,* and *Clostridia* showed the ability to metabolize methamphetamine.

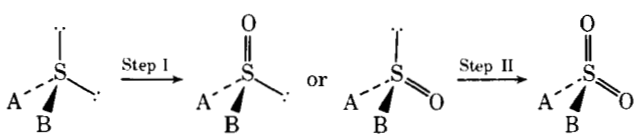
Little is known concerning microbial S-dealkylations. The reported conversion of the thioether group of lincomycin (X) to a hydroxy function by *Streptomyces lincolnensis* (123) might involve S-dealkylation.

S-Oxidations—Sulfides are metabolized to sulfoxides and sulfones in mammals (67) (Table I). No systematic studies have been performed on these biotransformations. The fact that certain sulfide-containing drugs could be converted to optically active sulfoxides (129) appears to have been overlooked. From work with model compounds, there is some reason to believe that low stereoselectivity will be observed with mammalian sulfoxidations (*vide infra*).

Microbiological sulfur oxidations recently have been studied. In general, the oxidation of thioethers (sulfides) proceeds stepwise through the sulfoxide (Step I) to the sulfone derivatives (Step II), as shown in Scheme XVI. In microorganisms, it is possible to stop the reaction at the sulfoxide level, obtaining only small amounts of the sulfone derivative. Two primary advantages exist in using microbiological systems in the oxidation of sulfur-containing compounds:

1. Selective oxidations are possible when other labile groups are found on the substrate molecules.
2. Stereospecificity is obtained to a variable extent, sometimes resulting in sulfoxide products with high degrees of optical purity (12).

One early example of microbial production of optically active sulfoxides was in the isolation of very low yields of (−)-biotin sulfoxide formed as a metabolite of biotin by *A. niger* (130). More recently, Auret *et al.* (131–133) conducted extensive studies related to the microbiological formation of optically pure sulfoxides. *A. niger* cultures and acetone powders obtained from this microorganism produce optically active sulfoxides when unsymmetrical thioethers are added as substrates to fermentations (131). Stereoselectivities ranging from 4 to 100% were observed, depending on the thioethers used as substrates. In the case of *tert*-butyl-*p*-tolyl sulfide, the *R*-(+)-sulfoxide was obtained with a higher optical rotation than ever before recorded.



Scheme XVI—Microbiological oxidation of sulfides

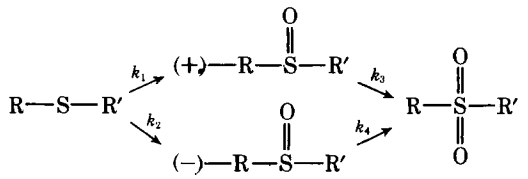
As indicated in Scheme XVI, the absolute configuration of products reflects a demand of various groups for either position A or B. A *p*-tolyl group, for example, prefers position A, while a *tert*-butyl prefers position B. When both substituents were present on the same substrate molecule, optical purities of 94% were obtained (24% yield). Interestingly, with *tert*-butyl-*p*-tolyl sulfide, acetone powders of *A. niger* cells yielded 98–100% optically pure sulfoxide in about 25% yield. With *p*-tolyl sulfides, stereoselectivity in forming sulfoxides depended on the degree of substitution of the α-carbon atom where it was found that alkyl = *tert*-butyl (99%), isopropyl (70%), and *n*-butyl (32%) (average optical purities in percent).

Auret *et al.* (132) extended this work by describing a process whereby optically pure sulfoxides could be obtained from racemic sulfoxide mixtures. When growing cultures of *A. niger* were used, both sulfoxide and sulfone products are obtained, whereas acetone powders seem to be capable of stopping the reaction at the sulfoxide stage. With growing cultures, it was suggested that optical activities observed with sulfoxides could arise partly by further selective oxidation of one or the other sulfoxide intermediate. This proposal is illustrated in Scheme XVII.

To check this hypothesis, racemic mixtures of various sulfoxides were added to growing cultures of *A. niger.* In some instances, the recovered sulfoxides were optically active (132). In addition to substituent effects and selective oxidation of sulfoxides, the influence of species and strain of microorganisms on stereoselectivity of sulfur oxidations was studied (133). Strains originating from the same parent culture yielded sulfoxide products of different configuration and in different yields. This result suggests the importance in reproducing in detail the experimental conditions reported in the literature with this and possibly other biotransformations.

Although a similarity in the pattern of products formed by the hydroxylation of aromatic compounds and other type of reactions by microorganisms and mammalian systems has been noted, stereoselectivity in the oxidation of thioethers to sulfoxide apparently is lower in animals (rat liver microsomes) than in fungal processes. Auret *et al.* (133) incubated *p*-tolyl benzyl sulfide with a rat liver microsomal preparation and obtained a sulfoxide only slightly enriched (1.3% optical purity) in the *R*-enantiomer.

Other examples of the microbial sulfoxidation of drug substances can be cited. Both lincomycin (X) and clindamycin (IX) may be converted into their respective sulfoxide derivatives. *S. lincolnensis* yields lincomycin sulfoxide and 1-demethylthio-1-hydroxylincomycin (123), while *S. armentosus* produces primarily clindamycin sulfoxide (122). *Calonectria de-*



Scheme XVII—Enantiomeric enrichment of sulfoxide racemates; optical purity enhanced when $k_3 > k_4$ *or* $k_4 > k_3$ *(Ref. 132)*

cora converts the steroidal thioether (XVII) into its optically active sulfoxide (134).

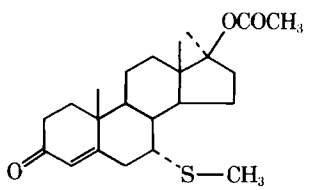
N-Oxidations—Since the *N*-oxidation products of numerous therapeutic agents possess enhanced toxicities, there is considerable interest in this biotransformation (135, 136). The instability and/or low incidence of *N*-oxidized metabolites, however, have hampered such investigation.

In the mammalian system, *N*-oxidation of primary and secondary amines leads to hydroxylamines, while the oxidation of tertiary amines results in *N*-oxides (Table I). These two types of metabolites possess considerably different physicochemical properties. Because certain arylamines are believed to cause methemoglobinemia or tumor formations *via* hydroxylamine metabolites, there has been particular interest in the *N*-oxidation of this class of compounds.

The extent of *N*-oxidation is affected by the nature of the substituent groups on the nitrogen atom. *N*-Methyl- and *N*-ethylaniline are *N*-hydroxylated much faster than aniline. As the alkyl chain length increases, however, the degree of *N*-hydroxylation decreases and the amount of *para*-hydroxylation increases (137). *N*-Hydroxylation is also enhanced in *para*-substituted anilines (136). *ortho*-Substitution seems to inhibit *N*-hydroxylation of *N*-arylamines (135).

N-Hydroxylated metabolites have been reported for *N*-acylated aromatic amines (135), a variety of alicyclic and aliphatic amines (138–141), and the simple carbamate urethan (136). Furthermore, Beckett (140) reported significant stereochemical influences on *N*-hydroxylation *versus* *N*-dealkylation in *N*-benzylamphetamines.

N-Oxides are generally formed as minor metabolites of tertiary amines. Yet, there continues to be considerable interest in these biotransformation products because of their suspected roles in biological activity and/or toxicity of certain drugs (142). *N*-Oxides have been implicated as intermediates in the *N*-dealkylation of tertiary amines, although evidence has been provided to contradict this implication (121, 135, 142). Correlations between structures of tertiary amines and their potential for *N*-oxide formation apparently have not been studied in mammalian systems.



XVII

In microorganisms, several examples may be cited in which primary amines are metabolized to their respective nitro analogs. The reaction conducted by *Streptomyces thioluteus* was studied with a series of aromatic amines such as *p*-aminobenzoic acid (143–145). Rates of conversion were slower with *p*-aminophenylacetic acid and *p*-amino-L-phenylalanine, indicating a rather narrow substrate specificity for this reaction. Mechanistically, it was proposed that the primary amino group was converted into a hydroxylamine by the action of an oxygenase and molecular oxygen; this intermediate is subsequently oxidized to the corresponding nitro derivative. Other examples of the amino to nitro oxidation include various aminoimidazoles (146, 147) and the conversion of a chloramphenicol amine precursor to the antibiotic (148).

The production of *N*-oxides by microorganisms has not been widely described, because chemical conversions of tertiary amines to their *N*-oxides may be accomplished with relative ease. Microorganisms were used to make the *N*-oxides of hydroxycodeinone analogs (111) and strychnine and brucine (149). The formation of trimethylamine *N*-oxide by *P. aminovorans* was described earlier (119). Enzymes involved in this microbial oxidation were not fully characterized with regard to substrate selectivity.

Hydroxylation of Aliphatic Compounds—In mammals, acyclic aliphatic compounds are typically hydroxylated at ω and ω-1 positions. Microorganisms also attack terminal and subterminal carbons in series of alkanes (150, 151). When an aliphatic chain is attached to an aromatic ring, the resulting benzylic position becomes prone to hydroxylation by mammalian (152) and microbial (153) systems. Substrates typically hydroxylated by mammals at aliphatic carbons include *n*-propylbenzene (XVIII) (152), the psychotomimetic 1-(2,5-dimethoxy-4-methylphenyl)-2-aminopropane (XIX) (154), and tolbutamide (XX) (155, 156) (site of hydroxylation indicated by arrows).

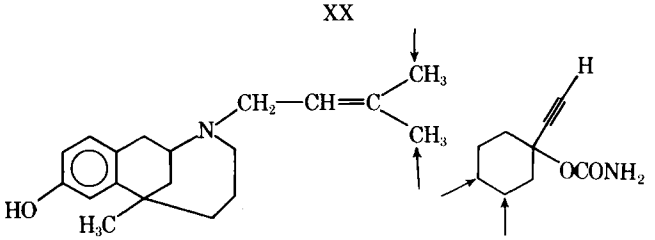
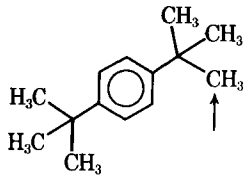
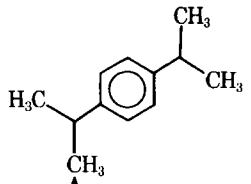
XX



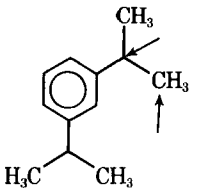
XXIV XXV



XXI



XXII



XXIII

The microbial oxidation of several branched aliphatic substrates (XXI–XXIII) has been systematically studied (153) (site of hydroxylation indicated by arrows). Products obtained with XXII were optically active. By shifting the isopropyl function to a 1,3-orientation on the benzene ring, mixtures of products, some exhibiting optical activity, were obtained (153). In mammalian systems (32), isotopic labeling experiments suggest that alkyl side-chain oxygenations occur by direct insertion of oxygen atoms.

Compounds with allylic carbon atoms, such as pentazocine (XXIV), are hydroxylated in mammalian systems (157). Microbial oxidations of allylic and benzylic positions have been adequately described (12). Ring positions of alicyclic compounds are often oxidized; ethinamate (XXV) (158), for example, is hydroxylated at positions 3 and 4 of the ring. This hydroxylation pattern possesses similarities to the hydroxylation of alicyclic amides by the mold *Sp. sulfurescens* (82).

Oxidative Deamination—Compounds containing the basic structural unit R—CH_2NH_2 are the best substrates for monoamine oxidase. Substitution at the methylene carbon reduces reactivity, while increasing the chain length of an alkyl R group or the complexity of R can reduce reactivity of a substrate with this enzyme (159, 160). On the other hand, monoamine oxidase can accommodate compounds with a variety of aryl—R groups (159). If R is a phenyl group, substitution in the *ortho*-position can substantially decrease deamination (161). In contrast, substitution with electron-withdrawing groups improves substrate susceptibility to enzymatic transformation (161, 162).

Secondary amines can be deaminated by monoamine oxidase, although the reaction rates are substantially slower than with primary amines. Microbial deamination of amine substrates has been demonstrated with tryptamine (163, 164). This type of reaction is much less common in microorganisms than the usual deamination of amino acids, which may occur *via* pyridoxal-mediated transaminases or typical oxidative deamination enzymes.

Oxidation of Alcohols and Aldehydes—Foreign primary alcohols, except methanol, are readily oxidized to aldehydes and finally to carboxylic acids in mammals. Liver alcohol dehydrogenase, the enzyme principally responsible for the initial oxidation reaction, has been extensively studied (165–168). The rate of oxidation increases in the order ethanol < *n*-propanol < *n*-butanol but then decreases. However, higher molecular weight alcohols (*e.g.*, benzyl and furfuryl) are still good substrates for liver alcohol dehydrogenase (166).

With the apparent exception of cyclohexanol (166, 167), secondary alcohols are oxidized substantially slower than primary alcohols. Liver alcohol dehydrogenase appears to have no effect on the following secondary alcohols: 2-propanol, cyclopentanol, methyl phenyl carbinol, 1-indanol, and 1-tetralol (169). McMahon (169) surveyed other mammalian alcohol oxidoreductases that may play a role in the oxidation of xenobiotic alcohols. Most of these, however, seem to have considerably narrower substrate specificities than liver alcohol dehydrogenase and are probably of lesser significance.

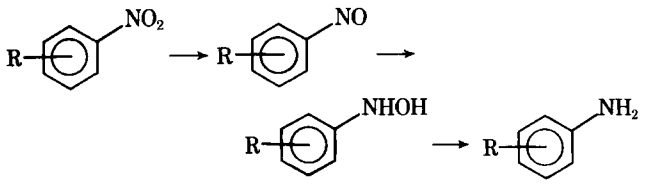
Mammalian aldehyde dehydrogenases oxidize a wide range of aldehydes. While formaldehyde is oxidized at only half the rate of acetaldehyde by liver aldehyde dehydrogenase, higher homologs, including propionaldehyde, butyraldehyde, and isovaleraldehyde, are only slightly poorer substrates than acetaldehyde (170). Substituted benzaldehydes serve as substrates for mammalian aldehyde dehydrogenase (170, 171). Benzaldehyde is the best substrate, while substitution with electron-withdrawing or electron-donating groups decreases activity. A good correlation was observed between log k and Hammett sigma values for this biphasic phenomenon (171).

Several aldehydes have been shown to be substrates for hepatic aldehyde oxidase (172, 173). This enzyme has been described as a hydroxylase (160) rather than a dehydrogenase. Aldehyde oxidase also attacks the α-carbon of a wide variety of *N*-heteroaromatic compounds (*e.g.*, quinoline), causing conversions to their corresponding α-lactam derivatives (173). Xanthine oxidase appears to have similar specificities to those of aldehyde oxidase (169).

Microorganisms commonly oxidize alcohols and aldehydes into their next higher oxidation states (10, 12, 13, 126, 174). These reactions often occur sequentially when a methyl group is first hydroxylated and then converted through the aldehyde to a carboxylic acid derivative. Polyol, terpene, and steroidal alcohol oxidations have been described (13). Various aldehydes are oxidized to carboxylic acids by an aldehyde dehydrogenase from *P. fluorescens* (175).

REDUCTIVE TRANSFORMATIONS

Nitro and Azo Reductions—A number of aromatic nitro compounds are converted to their nitroso, hydroxylamino, or amino derivatives in mammals (Scheme XVIII). This reaction is of considerable importance because of the potential toxicities of these metabolites. It is now generally believed that four to five enzyme systems affect nitro reductions: microsomal enzymes including cytochrome P-450 (176), NADPH-cytochrome c (177), and cytochrome b_5



Scheme XVIII—Bioreduction pathway for aromatic nitro compounds

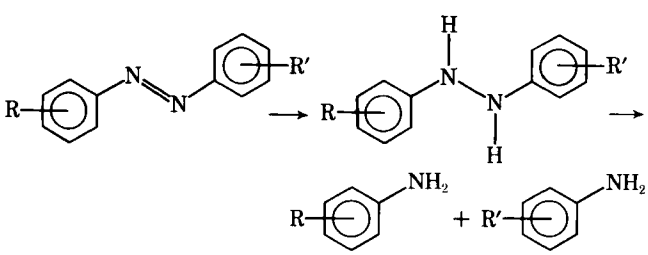
(178) reductases; an unidentified soluble "*p*-nitrobenzoate" reductase (179); and xanthine oxidase (180). All of these enzymes occur in the liver, although unspecified nitroreductase activity has also been detected in kidney, lung, heart, and brain tissue preparations (181).

The extent to which these enzymes reduce nitro compounds *in vivo* can be seriously questioned, because of their dependence on anaerobic conditions and the likely oxidation of proposed intermediates under the oxygen tension in the liver. For these reasons and because of the anaerobic conditions in the gut, bacterial involvement has been implicated in the reduction of aromatic nitro compounds (182). Zachariah and Juchau (183) reported approximately four times greater nitroreductase activity in rat cecal contents than in rat liver preparations.

Numerous aryl nitro compounds are reduced by mammalian and/or bacterial systems (182, 184). However, no systematic study of possible structural correlations has been reported.

The findings with azoreductases in mammals parallel those of nitroreductases. While hepatic azoreductases have been described (184), it seems highly probable that most azo reductions are mediated *in vivo* by gut microorganisms (182, 184, 185). Azo reductions are believed to proceed through hydrazo intermediates (184, 186) and result in the formation of corresponding aromatic amines (Scheme XIX). Because of the production of potentially toxic aromatic amines and the presence of azo linkages in numerous dyestuffs, there is considerable interest in azoreductases. Little seems to be known about possible influences of structural features on the facility with which azo compounds are reduced.

Reductions of Aldehydes and Ketones—Several enzyme systems are responsible for aldehyde and ketone reductions in mammals. Principal among these is liver alcohol dehydrogenase, which reversibly catalyzes reactions with equilibria favoring alcohol formation at physiological pH's (*vide supra*). Simple aliphatic aldehydes are reduced to primary alcohols by liver alcohol dehydrogenase; the activity increases from acetaldehyde through propionaldehyde and is



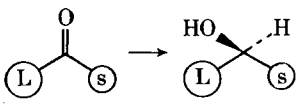
Scheme XIX—Bioreduction pathway for azo compounds

maximum for butyraldehyde (166). As indicated earlier, however, this reaction is of minor importance *in vivo* because of the facile conversion of aldehydes to readily excretable carboxylic acids.

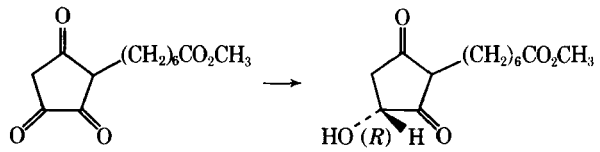
In contrast to the case with aldehydes, reduction of ketones to alcohols by liver alcohol dehydrogenase is an important *in vivo* biotransformation (169). The reduction of cyclic ketones by liver alcohol dehydrogenase has been extensively studied (187, 188). Considering the highly favorable substrate character of cyclohexanone [relative rate of reaction (RRR) = 100], the reduction rates of substituted derivatives are substantially dependent upon stereochemical features. For example, both enantiomers of 2-methylcyclohexanone are poor substrates (RRR = 1–2), while (−)-3-methylcyclohexanone has excellent activity (RRR_{calc} = 102) compared to its (+)-enantiomer (RRR = 0.6). 4-Methylcyclohexanone is a good substrate (RRR = 41), but activity drops dramatically in its more bulky homologs, 4-isopropylcyclohexanone (RRR = 21) and 4-*tert*-butylcyclohexanone (RRR = 2.5). Interesting differences were similarly noted in the reduction of *cis*- and *trans*-2-decalones. Reductions of cyclic ketones are stereoselective, depending on both the position and the absolute configuration of substituents (188). While many six-membered ketones are good substrates for liver alcohol dehydrogenase, cyclopentanone is without activity (169), and adamantanone is essentially inactive (189).

The reduction of ketones by alcohol dehydrogenase from microorganisms leads to the formation of (*S*)-carbinols when the carbonyl is dissymmetrically substituted by a bulky group and a small group (187, 188, 190) (Scheme XX). Presumably, the attack of the carbonyl by the NADH coenzyme in the microorganism is favored on one side only, as has been demonstrated (191) with numerous bi- and tricyclic ketone substrates using a reductase from *Cur. falcata*. On the other hand, alcohols of *R* absolute configuration have been produced by the reduction of compounds such as the triketone (XXVI) in completely stereospecific fashion (192) by *Dipodascus uninucleatus* (Scheme XXI) (193). It has been suggested that the extent of stereospecificity of the reaction product not only depends on interactions of the enzyme–substrate but also on the chirality of the alcohol dehydrogenase of a particular organism (193). Thus, it may be expected that microbial alcohol dehydrogenases capable of producing (*S*)- or (*R*)-alcohol products will be discovered.

In vitro experiments with liver alcohol dehydrogenase are not wholly satisfactory in predicting reductions of aldehydes and ketones in intact animals, because *in vivo* interconversions involving patterns of reduction → oxidation → reduction may occur and additional reductases also may be important in aldehyde and ketone metabolism. The first suggestion is



Scheme XX—Formation of (S)*-carbinol by alcohol dehydrogenase*



Scheme XXI—Formation of (R)-*carbinol by* D. uninucleatus (*Ref. 192*)

demonstrated by the work of Elliott *et al.* (190, 194–196), who showed that cyclohexanones and decalones are converted to their more thermodynamically stable equatorial alcohols in rabbits. This finding is in contrast to the substantial number of axial alcohols produced *in vitro* with liver alcohol dehydrogenase preparations (187, 188).

A number of other aldehyde–ketone reductases have been isolated from mammalian tissues. Similar NADPH-dependent aromatic aldehyde–ketone reductases (A–K reductase) have been isolated from rabbit liver and kidney preparations (169, 197). These enzymes are true reductases in that they do not catalyze the dehydrogenation of carbinols. A relationship similar to that derived for the reduction of benzaldehydes by liver alcohol dehydrogenase (198) was observed for substituted acetophenones and benzaldehydes (197, 199). In addition, a pentanone and adamananone were reduced by kidney A–K reductase (197).

It has been suggested that liver A–K reductase may be the same as the pig liver reductase isolated by Prelog (187). Fraser *et al.* (200) reported the isolation of an α,β-unsaturated ketone reductase from human liver. This enzyme mediates the reduction of either the double bond or carbonyl groups of an α,β-unsaturated ketone and is similar to A–K reductase (197, 199) in that it does not catalyze the reverse reaction (oxidation).

HYDROLYSES

Ester Hydrolyses—Esterases capable of hydrolyzing foreign esters have been found primarily in mammalian plasma, erythrocytes, liver, and kidneys (201). These enzymes include cholinesterase (pseudocholinesterase), carbonic anhydrase, arylesterases, and acetylesterases, which can collectively hydrolyze a vast array of esters. Because of the multiplicity of esterases and significant variation (both qualitative and quantitative) among animal species (67, 201), an understanding of the exact role that ester hydrolyses play in drug metabolism and drug action has been elusive. Some common ester-containing drugs susceptible to ester hydrolysis *in vivo* have been reviewed (201).

Scheline (182) noted that ester hydrolysis may be mediated by intestinal microorganisms. However, in humans this would only be of importance for poorly absorbed drugs (*e.g.*, acetyldigitoxin) capable of reaching the lower intestine. Numerous esterases have been characterized and used in the microbial transformation of steroids (202), and the application of esterases as a synthetic tool in the field of prostaglandin synthesis has been recorded (203). In the latter case, a racemic mixture of esters was stereoselectively hydrolyzed to yield a mixture of the free (*R*)-alcohol and the (*S*)-ester, which could be easily separated.

Amide Hydrolyses—Some amides may serve as substrates, albeit poor ones, of plasma or tissue esterases (67). The prolonged activity of procainamide *versus* procaine can be rationalized in this way. Krisch (204, 205) isolated a microsomal esterase from hog liver which cleaves several amides including acetanilide and lidocaine. In addition, a number of mammalian arylacylamide amidohydrolases have been described as occurring in liver and kidney tissue. These enzymes have been shown to deacylate some acetamido compounds and appear to be especially important in the mechanism of action of sulfonamides (206).

Parke (67) reported that primary amides (*e.g.*, benzamides), hydroxamic acids, hydrazides, and carbamates undergo hydrolysis in mammals, although it is unclear whether all of these are hydrolyzed as the result of enzymatic catalysis. Amide hydrolysis also may be catalyzed by intestinal microorganisms (207). Interestingly, the biotransformation of the sulfamate derivative, cyclamate, to the toxic metabolite, cyclohexylamine, in humans appears to be exclusively mediated by an intestinal microorganism (probably *Enterococci* sp.) (208). Smith and Rosazza (9) observed the hydrolysis of acetanilide in their microbial systems, and amide hydrolyses have been recorded in other microbial systems as well. Particularly well studied is the hydrolysis of amides in several antibiotics by many microorganisms (16).

CONJUGATIONS

The major types of Phase II reactions are indicated in Table IV. Most of these biotransformations lead to conjugates of drugs and their metabolites that are more water soluble (and thus more readily excreted). These conjugates often possess less biological activity than the parent drugs. Thus, attempts are rarely made to characterize fully Phase II metabolites. In lieu of typical structure elucidation approaches, structures of conjugates are often inferred from selective hydrolysis reactions (*e.g.*, glucuronidase–sulfatase and chemical cleavages) and characterization of metabolites is done on the "drug-derived" portion of the conjugate.

Two Phase II reactions are exceptional with respect to these generalizations. *N*-Acetylation of amines and methylation of phenols result in more lipid-soluble metabolites that merit evaluation of biological activity. Foreign aliphatic and aromatic primary amines and hydrazides are substrates for a number of *N*-acetyltransferases which occur widely in mammalian species (206, 209–211). These enzymes are usually dependent on acetylcoenzyme A and are distributed in various tissues (67). The influence of substrate structure *versus* formation of *N*-acetyl metabolites is not well understood.

Monomethylation of catechols by the *S*-adenosylmethionine-dependent enzyme, catechol-*O*-methyltransferase, is an important biotransformation of cat-

echolamine neurotransmitters and their respective metabolites (212, 213). Catechol-*O*-methyltransferase principally occurs in the liver but is found in kidney, spleen, small intestine, lung, and brain tissue (213, 214). In most instances, the oxygen atoms of a catechol are nonequivalent in terms of electronic and/or steric characteristics. Preferential methylation of one group *versus* another was at one time thought to be a function of relative nucleophilicities (215). However, recent studies indicated that the steric and electronic properties of substituents, as well as the relative lipophilicity of substrate, are equally or more important factors affecting relative isomer formation (*e.g., meta–para* ratios) (216–219). Recently, evidence for mammalian enzymes that methylate monophenols and monomethyl catechols has been presented (220–222). The importance of these biotransformations *in vivo,* however, is still unclear.

An enzyme that occurs in the soluble portion of rabbit lung homogenates has been found to *N*-methylate a variety of foreign primary and secondary aliphatic amines (223, 224). An apparently similar enzyme also has been discovered in rat brain (225). The importance of these enzymes with *in vivo* drug biotransformations has not been established.

Interesting microbial parallels to a number of Phase II reactions have been observed, including the phosphorylation of clindamycin (226) by *Streptomyces coelicolor* and the formation of ribonucleotides of this antibiotic (227). *N*-Acetylation occurs commonly with amines such as tryptamine (and with tryptophan) (17), aniline (9), and other compounds (13, 126). Lysine (228), serine (229, 230), and glycine (231) conjugates of 2,3-dihydroxybenzoic acid are produced by microorganisms. A microbial parallel to mammalian *O*-methylation was previously described in this review in the O-*Dealkylation* section (114).

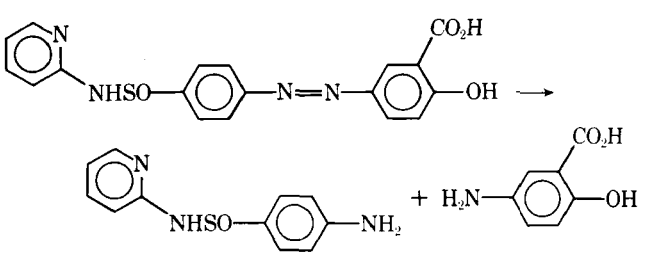
Transformations by Intestinal Microorganisms—Significant interest has been demonstrated recently in the metabolism of drugs by intestinal microorganisms (167, 232, 233). Orally administered drugs, particularly those with low solubility or delayed absorption, pass to the lower portion of the intestinal tract and may be susceptible to biotransformation by the intestinal flora. Additionally, compounds excreted *via* the intestinal route may be susceptible to such biochemical changes. A variety of microorganisms may be found in the intestinal tract.

In a very important study (because of its thoroughness), 113 distinct types of organisms were identified in fecal samples of Japanese–Hawaiians (234). Most fecal organisms are bacteria; however, the nature of the flora may be quite different, depending on such factors as diet, age, health, and use of drugs such as antibiotics, which may destroy the normal GI tract flora. Many types of microbial conversions have been attributed to the intestinal flora, some of which have been described already including *N*-demethylation of methamphetamine (128), reduction of nitro and azo compounds (182), and hydrolysis of esters (182) and amides (208).

Type-reactions carried out by intestinal microorganisms (233) are: hydrolysis of glucuronides, glycosides, ethereal sulfates, amides, glycine conjugates, *N*-acetyl compounds, esters, and sulfamates; C- and *N*-dehydroxylation; decarboxylation; *O*- and *N*-demethylation; dehalogenation; heterocyclic ring fission; reduction of double bonds, nitro groups, azo groups, aldehydes, ketones, alcohols, *N*-oxides, and arsonic acids; aromatization; deamination; nitrosamine formation; acetylation; and esterification.

The mode of action of a drug may be influenced by intestinal flora metabolism (233). For example, it was suggested that when sulfasalazine (salicylazosulfapyridine) (XXVII) (Scheme XXII) (used in ulcerative colitis and other inflammatory diseases of the bowel) is metabolized to its respective components (XXVIII and XXIX), the metabolites were really responsible for the action of the drug. Drug action was ultimately related to the presence of 5-aminosalicylate (salt of XXVIII) in the intestines. When 5-aminosalicylic acid is given orally or parenterally, little of the compound appears in the colon. Thus, sulfasalazine serves as a prodrug and becomes activated only after a microbial conversion step in the intestine.

Other toxicological implications regarding the bio-



Scheme XXII—Microbial transformation of sulfasalazine

transformations of compounds in the GI tract involve the hydrolysis of glucuronides and other conjugates. Many drugs and foreign organic compounds or their metabolites are excreted as glucuronide conjugates and are poorly reabsorbed from the intestines. Bacterial β-glucuronidase activity is high in the intestine; aglycones produced as a result of hydrolytic activity may be reabsorbed and passed again through the liver. For example, glucuronide hydrolysis and reabsorption have been reported with diethylstilbestrol (235) and indomethacin (236).

Microbiological Methodology—Few researchers engaged in mammalian metabolism studies are familiar with microbial transformation experiments, and vice versa. This brief section will provide a simple introduction to some methodology involved in microbial transformation studies. Of course, a review of this scope cannot provide sufficient experimental detail or background to enable the reader to conduct such experiments immediately. Rather, years of experience are required before it becomes possible to deal instinctively with any biological system. Perhaps the ideal situation is one involving the simultaneous efforts of an interdisciplinary team which may include microbiologists (pharmacognosists), analytical medicinal chemists, and pharmacologists.

Microorganisms are convenient sources of the enzymes that mediate reactions like those outlined in the text. Although microbes are capable of conducting single, selective reactions on even the most complex molecule, a host of reactions also can occur simultaneously. It is possible, however, to adjust conditions of microbial experiments to favor formation of a single product or a single type of reaction to increase the yield of a desired metabolite. Typical fermentation conditions that are frequently varied include organic and inorganic medium components, pH, degree of aeration of cultures (usually attained by shaking at different rates), temperature of incubation, and substrate concentration.

Variations in pH, medium composition, and temperature are known to influence the outcome of fermentation experiments. The importance of dissolved oxygen levels for the production of enzymes (237) and on the microbial transformations of steroids (238) has been noted. The time and mode of addition of substrates to fermentations can also influence microbial metabolic profiles (238–244). Several general references detail many aspects of the fermentation process (12, 13, 242, 245). Others dealing with specific types of microbial transformations were cited earlier in this review.

The selection of microorganisms capable of performing a desired chemical transformation may be accomplished in a number of ways. Cultures may be isolated from the soil or from sewage treatment facilities, or they may be obtained in pure form from culture collections. A compilation of sources of microorganisms was published (246), and smaller lists of useful culture collections have been described (10, 12, 13). Microbiologists are often willing to share cultures from the culture collections they maintain. Because cultures from some culture collections are expensive, most workers in the field of microbial transformations maintain collections in their own laboratories (perhaps 100–400 cultures).

Once cultures are on hand, they may be screened for their potential to perform, for example, hydroxylation of aromatic substrates. It is possible to be more discriminating in the choice of microorganisms to conduct a specific type of reaction by taking advantage of the rapidly growing literature in microbial transformations. For success in obtaining active cultures that perform a desired transformation, it is often necessary to combine the "literature" approach and the "random screening" approach.

Several types of microorganisms are used in microbial transformation experiments. These are the bacteria (including the Actinomycetes), yeasts, and filamentous fungi. Growth habits, medium requirements, and culture conditions are generally quite different for each type of microorganism. Some microorganisms are pathogenic and must be handled with extreme care. Most, however, are relatively easy to work with and may be cultivated with little difficulty. Detailed descriptions and taxonomic classifications of various microorganisms have been published (247, 248). Whatever the source of the microorganism, it must be properly identified (*e.g.*, culture collection acquisition number and authentication by suitable authority) and precautions should be taken to prevent contamination with other microorganisms.

To accommodate the diverse growth requirements of different microorganisms, various media have been employed. A large listing of media cross-indexed with various microorganisms is available (249). Media and glassware employed in microbial transformation experiments are usually sterilized in an autoclave (121° for 15 min). After sterilization, solid (agar-containing) medium is caused to solidify into slants in sealed culture tubes. These slants are usually inoculated with various cultures and are incubated for approximately 1 week to obtain fresh and vigorous cultures. The resulting cultures may be maintained in a viable state for long periods (6 months or longer) in a refrigerator at 3–4°. Culture vigor is maintained by periodically transferring stored cultures to fresh slants. Other methods used in the maintenance of culture collections include low temperature storage (from −70 to −198° liquid nitrogen) and lyophilization.

Microbial transformation experiments *per se* are conducted in liquid medium contained in vessels ranging in size from small test tubes to fermentors with several hundred or even thousand gallon capacities. The usual laboratory-scale incubations are carried out in cotton-plugged erlenmeyer flasks containing about one-fifth of their volumes of medium. Table V shows a selection of media used in these kinds of experiments. Note the differences in medium pH used for the cultivation of bacteria and fungi. In general, bacteria grow in media with initial pH values of 7.0 while fungi and yeasts grow well under slightly acidic (pH 4–6) conditions. As a result of the consumption of nutrients and primary metabolic activity, the pH of the medium of most fermentations changes as the cultures grow.

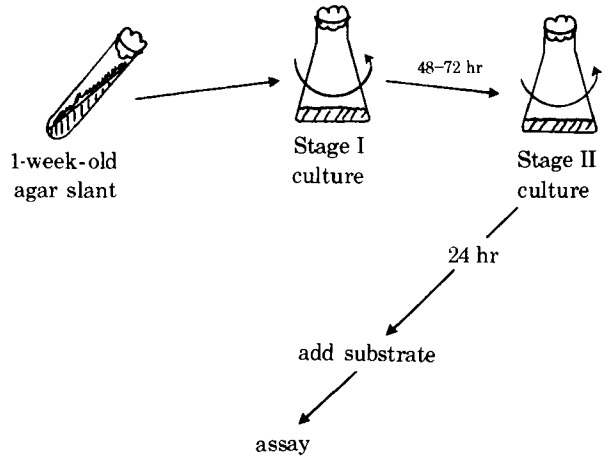
Table V—Various Media Employed in Microbial Transformation Experiments

Research Group	Media Used
Jones *et al.* (250)	Dextrose ($1H_2O$), 30 g; ammonium tartrate, 7.5 g; KH_2PO_4, 2 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; trace elements, 0.1 g; yeast extract, 1.0 g; and distilled water, 1 liter
	For fungi and streptomycetes, use at pH 5.5; for bacteria, use at pH 7.0
Smith and Rosazza (9) and Betts *et al.* (61)	Dextrose, 20 g; yeast extract, 5 g; soybean meal, 5 g; NaCl, 5 g; K_2HPO_4, 5 g; and distilled water, 1 liter
	Adjust to pH 7.0 with 5 *N* HCl; use for yeasts, fungi, and actinomycetes
Kluepfel and Vezina (251)	Dextrose, 50 g; edamine, 20 g; corn steep liquid, 3 g; and distilled water, 1 liter
	For fungi, use at pH 5.8
	Dextrose, 1.5 g; yeast extract, 1.5 g; peptone, 5.0 g; K_2HPO_4, 3.5 g; and distilled water, 1 liter
	For bacteria, use at pH 7.0
Goodman *et al.* (252)	Dextrose, 20 g; peptone, 5 g; tryptone, 5 g; $CaCO_3$, 2.5 g; and distilled water, 1 liter
	Use for various bacteria

Fermentations are conducted in many ways in the laboratory. Small-scale screening-type fermentations are conducted in 50–125-ml erlenmeyer flasks containing 10–25 ml of medium and are usually incubated with shaking to ensure a rich supply of oxygen for the medium. Larger scale incubations are conducted in large carboys or in stirred fermentors agitated by impellers and aerated by sparging air through the medium. Typical laboratory-scale incubations using stirred fermentors range from 1.5 to 10 liters in volume.

A fermentation scheme is outlined in Scheme XXIII. The description of the fermentation provided is applicable to small- and large-scale experiments and has been generally applied successfully in our laboratory.

Cultures are maintained on Sabouraud–maltose agar slants and are stored in a refrigerator at 4° prior to use.



Scheme XXIII—Typical conditions for conducting microbial transformations (Ref. 9)

Cultures are grown in a soybean meal–glucose medium (Table V).

The surface growth from slants of microorganisms is suspended in 5-ml volumes of sterile soybean meal–glucose medium. This suspension is used to inoculate 25 ml of the soybean meal–glucose medium held in cotton-plugged 125-ml erlenmeyer flasks (Stage I). The Stage I flasks are incubated at 27° on a rotary shaker operating at 250 rpm for 48–72 hr, at which time most cultures are late in the log phase or in the stationary phase of growth. Approximately 3-ml volumes of the actively growing Stage I cultures are transferred to 25 ml of fresh medium held in cotton-plugged 125-ml erlenmeyer flasks (Stage II). After 24 hr of incubation on a rotary shaker, 12.5 mg of substrate dissolved in 0.1 ml of dimethylformamide is added to Stage II flasks. The substrate-containing flasks are incubated for an additional 24–72 hr before being terminated.

The time of addition of substrate to a fermentation, as well as its concentration in the medium, may be critical in microbial transformation experiments. Substrates may be added in concentrated solutions of dimethylformamide, dimethyl sulfoxide, ethanol, acetone, or other solvents to facilitate dispersion in aqueous media. Compounds may be added in water-soluble form, as hydrochloride salts of alkaloids or amino acids, or as sodium or potassium salts of carboxylic acids. In the usual screening experiment, a nominal level of substrate of 0.1–0.5 mg/ml of Stage II fermentation has been successfully employed in our laboratory. Limited success in microbial transformation experiments has been obtained when substrates were added too soon to Stage II cultures. Growth is inhibited, and there is evidence that an optimum time for substrate addition exists with microorganisms.

In screening experiments, analyses are usually performed at two times during the fermentation, 24 and 72 hr after substrate addition. Some microorganisms may completely degrade a substrate early in a fermentation, whereas others may possess inducible enzymes which will only produce metabolites after being in contact with substrates for a period of time. This arbitrary selection of two time periods has worked well in our hands.

Liquid–liquid extraction methods are most widely used in the analysis and isolation of microbial metabolites. Occasionally, for difficult to extract solutes, culture samples have been frozen and lyophilized to facilitate the isolation process. Freeze-dried samples may then be extracted with polar solvents such as alcohols or acetone. In general, it is recommended that the whole culture be examined for metabolites rather than culture filtrates alone because some substrates (and their metabolites) may bind to cellular material. We have observed this to be true both with steroids and with alkaloids such as acronycine. In fact, acronycine and its metabolite, 9-hydroxyacronycine, are easily removed from fermentations by centrifugation of the solids from fermentations of *C. echinulata*

(61). Only traces of acronycine and its metabolite are left in supernates, and the centrifuged solids may be simply extracted with hot ethanol to isolate the relatively insoluble 9-hydroxyacronycine.

CONCLUSIONS

The metabolic fate of drugs and other xenobiotics in mammalian organisms represents an area of intense contemporary interest. Typically, biological systems used to study biotransformations are capable of yielding only minute quantities of metabolites. Recent developments in comparative biochemistry have made it possible to link diverse metabolic systems through similarities in the pathways by which they alter foreign organic compounds. Thus, the potential exists for utilizing microbial metabolic systems to study and possibly predict the metabolic fate of a drug or other foreign compounds in mammals. Furthermore, it should be possible to use such systems to produce preparative quantities of drug metabolites for structure elucidation studies and biological testing.

Solvolytic Reactions of Cyclic Anhydrides in Anhydrous Acetic Acid

M. J. HADDADIN *, T. HIGUCHI ˣ, and V. STELLA

Abstract □ The reversible reactions of several cyclic anhydrides with acetic acid to form acetic anhydride and the corresponding dicarboxylic acid, catalyzed by perchloric acid at 25°, were studied. The equilibrium constants, calculated from spectral data, were 4.85×10^{-4}, 1.08×10^{-1}, and 4.6×10^{-1} *M* for succinic, *trans*-1,2-cyclohexanedicarboxylic, and glutaric anhydrides, respectively. Maleic, phthalic, and *cis*-1,2-cyclohexanedicarboxylic anhydrides did not undergo any detectable reaction with acetic acid under these conditions, suggesting still higher stability. The reverse rate constants were found to be relatively independent of the structure of the attacking diacid, while the forward rate constants were found to parallel the equilibrium constants. The rate-determining step for the forward reaction appears to be the breakdown of the tetrahedral intermediate formed by the attack of an acetic acid molecule on the protonated cyclic anhydride.

Keyphrases □ Anhydrides, cyclic—solvolytic reactions in anhydrous acetic acid, rate constants, mechanisms □ Solvolysis of cyclic anhydrides in anhydrous acetic acid—rate constants, mechanisms □ Perchloric acid—catalyst for solvolytic reactions of cyclic anhydrides in anhydrous acetic acid □ Acylation—reversible reactions of cyclic anhydrides in anhydrous acetic acid, rate constants, mechanisms

The chemistry of cyclic and linear anhydrides is of major interest to those concerned with transacylation reactions in both *in vitro* and *in vivo* systems. There is very little doubt that these active chemical species play significant roles in many acyl transfer reactions and in cleavage and formation of polycarboxylic acid derivatives. The present report is concerned with some data obtained on the solvolytic behavior of a series of cyclic anhydrides of varying stability in anhydrous acetic acid. The results indicate relatively strong structural dependency on the ring opening and very little sensitivity to the reverse process.

Anhydrides of dicarboxylic acids have been used in the preparation of hemiesters of water-insoluble

Solvolytic Reactions of Cyclic Anhydrides in Anhydrous Acetic Acid

M. J. HADDADIN *, T. HIGUCHI ˣ, and V. STELLA

Abstract □ The reversible reactions of several cyclic anhydrides with acetic acid to form acetic anhydride and the corresponding dicarboxylic acid, catalyzed by perchloric acid at 25°, were studied. The equilibrium constants, calculated from spectral data, were 4.85×10^{-4}, 1.08×10^{-1}, and 4.6×10^{-1} *M* for succinic, *trans*-1,2-cyclohexanedicarboxylic, and glutaric anhydrides, respectively. Maleic, phthalic, and *cis*-1,2-cyclohexanedicarboxylic anhydrides did not undergo any detectable reaction with acetic acid under these conditions, suggesting still higher stability. The reverse rate constants were found to be relatively independent of the structure of the attacking diacid, while the forward rate constants were found to parallel the equilibrium constants. The rate-determining step for the forward reaction appears to be the breakdown of the tetrahedral intermediate formed by the attack of an acetic acid molecule on the protonated cyclic anhydride.

Keyphrases □ Anhydrides, cyclic—solvolytic reactions in anhydrous acetic acid, rate constants, mechanisms □ Solvolysis of cyclic anhydrides in anhydrous acetic acid—rate constants, mechanisms □ Perchloric acid—catalyst for solvolytic reactions of cyclic anhydrides in anhydrous acetic acid □ Acylation—reversible reactions of cyclic anhydrides in anhydrous acetic acid, rate constants, mechanisms

The chemistry of cyclic and linear anhydrides is of major interest to those concerned with transacylation reactions in both *in vitro* and *in vivo* systems. There is very little doubt that these active chemical species play significant roles in many acyl transfer reactions and in cleavage and formation of polycarboxylic acid derivatives. The present report is concerned with some data obtained on the solvolytic behavior of a series of cyclic anhydrides of varying stability in anhydrous acetic acid. The results indicate relatively strong structural dependency on the ring opening and very little sensitivity to the reverse process.

Anhydrides of dicarboxylic acids have been used in the preparation of hemiesters of water-insoluble

Table I—Wavelengths and Species Monitored for All Reactions Studied

Reaction	Wavelength, nm	Species Monitored[a]
Succinic anhydride + acetic acid	252	Acetic anhydride (A)
Succinic acid + acetic anhydride	252	Acetic anhydride (D)
Glutaric anhydride + acetic acid	268	Acetic anhydride (A)
Glutaric acid + acetic anhydride	255	Acetic anhydride (D)

drugs such as hydrocortisone[1] (1), methylprednisolone[1] (1), and chloramphenicol (2). The popularity of these hemiesters as prodrugs stems from the enhanced aqueous solubility of their salt forms compared to the parent drugs. The ease with which they release the parent drug *in vivo* also has been noted.

The closure of these hemiesters and corresponding acids to their respective anhydrides is often taken as a simple model of intramolecular catalysis. The demonstration of participation of anhydrides in the hydrolysis and formation of amides (3, 4) and in the hydrolysis of hemiesters of dicarboxylic acids (5) strongly supports analogous mechanistic pathways for other related reactions. Transacylations in solid dosage forms, such as the reaction of amines and phenolic compounds with high energy acylators like acetylsalicylic acid, can be simulated by the reactivity of anhydrides (6, 7).

The solvolysis of cyclic anhydrides in aqueous solutions has been studied (8), and the equilibrium constants for the cyclic anhydride–diacid systems in water were largely determined by the formation of the cyclic anhydride.

The possible roles of anhydrides as high energy compounds in biological systems recently received some attention. For example, succinic (9) and acetic (10) anhydrides have been postulated in the biosynthesis of acetyl and succinyl coenzymes. Anhydrides also have been postulated as intermediates in model enzymatic reactions (11).

Attempts in these laboratories to react various drug molecules with succinic anhydride to form hemisuccinate esters using anhydrous acetic acid as a solvent resulted in the formation of acetate esters rather than the hemisuccinate. The results prompted a study of the reactions of several cyclic anhydrides in anhydrous acetic acid in an attempt to understand the quantitative aspects of acetic anhydride formation in anhydrous acetic acid in the presence of cyclic anhydrides and perchloric acid. The objectives were to relate this formation of acetic anhydride to the structure of the cyclic anhydride and to understand the mechanism of this transacylation reaction.

EXPERIMENTAL

Materials—All chemicals used were generally of reagent or analytical reagent grade and were purified before use.

Anhydrous acetic acid was prepared from analytical reagent grade acetic acid[2] by titration with freshly distilled acetic anhydride in the presence of catalytic quantities of perchloric acid. The reaction was monitored either thermometrically or spectrophotometrically. The thermometric technique involved the incremental addition of acetic anhydride until no further heat evolution could be detected. The spectrophotometric technique involved the addition of a slight excess of acetic anhydride. The excess amount of unreacted anhydride was determined at 252 nm and subsequently neutralized with an equivalent amount of water.

Acetic anhydride[2] was distilled over magnesium turnings; the middle fraction distilling at 137.5° was collected [lit. (12) bp 139°].

Acetous perchloric acid was prepared from 70% reagent grade perchloric acid[3] by reaction in an ice bath with a calculated amount of distilled acetic anhydride added slowly to the perchloric acid. The last 2 ml of acetic anhydride was used to titrate the remaining water thermometrically. The acetous perchloric acid was standardized against NBS potassium acid phthalate, using gentian violet as an indicator (2% in nitrobenzene).

Succinic anhydride[3], mp 118° [lit. (12) mp 119.6°], glutaric anhydride[4], mp 55° [lit. (13) mp 56°], phthalic anhydride[5], mp 130° [lit. (12) mp 130.8°], and maleic anhydride[6], mp 52° [lit. (13) mp 52.8°], were purified by refluxing with excess acetic anhydride to remove any diacids. They then were precipitated and washed with petroleum ether and dried in a vacuum oven. *cis*-1,2-Cyclohexanedicarboxylic anhydride[4] was dissolved in benzene, filtered, precipitated with petroleum ether, and dried in a vacuum oven, mp 33–34° [lit. (13) mp 32°]. *trans*-1,2-Cyclohexanedicarboxylic anhydride[4] was used without further purification, mp 145–146° [lit. (13) mp 145–146°].

Succinic acid[4] was recrystallized from benzene, mp 185° [lit. (12) mp 185–187°], while maleic acid, mp 130° [lit. (12) mp 130–131°], and glutaric acid, mp 97° [lit. (12) mp 97.5–98°], were recrystallized from chloroform. Both *cis*-1,2-cyclohexanedicarboxylic acid[4], mp 190° [lit. (13) mp 192°], and *trans*-1,2-cyclohexanedicarboxylic acid[3], mp 221° [lit. (13) mp 221°], were purified by dissolving in hot sodium hydroxide solution, decolorizing with charcoal, and precipitating by the dropwise addition of hydrochloric acid while still hot.

Kinetic and Equilibrium Measurements—The reactions between the various cyclic anhydrides and acetic acid were monitored spectrophotometrically[7] at 25°. Table I gives the wave-

[a] $k'_{-I} = k_{-I}$[glutaric acid].

lengths used and the species monitored. An accurately known quantity of the cyclic anhydride was quickly dissolved in a known volume of solution of perchloric acid (about 1×10^{-3} *M*) in anhydrous acetic acid in a 1-cm cylindrical cell.

The rate constant for the forward reaction, k'_I, as shown in Scheme I:

$$A \underset{k'_{-I}}{\overset{k'_I}{\rightleftharpoons}} B + C$$

Scheme I

where *A* is the cyclic anhydride, *B* is acetic anhydride, and *C* is the dicarboxylic acid, is obtained by plotting the integrated equation (14). For Scheme I, this equation is:

$$\ln \frac{a_0(x_e - x)}{a_0 x_e + x(a_0 - x_e)} = -\frac{2a_0 - x_e}{x_e} k'_I t \qquad \text{(Eq. 1)}$$

where a_0 is the initial concentration of the cyclic anhydride, x_e is the concentration of acetic anhydride at equilibrium, and x is the concentration of acetic anhydride at any time t. The rate constant k'_I is equal to k_I [$HClO_4$]. The acetic anhydride concentration x, at any time t, was calculated from known absorptivity constants (Table II) and measured absorbance readings using Eq. 2:

$$x = \frac{\Delta A}{\Delta \epsilon} \qquad \text{(Eq. 2)}$$

where ΔA is the change in absorbance from $t = 0$ to any time t, and $\Delta\epsilon$ is the difference in absorptivities of acetic and cyclic anhydrides at the wavelength used. Because the reaction between the cyclic anhydride and the solvent, acetic acid, proceeded slowly in the absence of the catalyst, perchloric acid, evaluation of the UV absorptivities of the various cyclic anhydrides could readily be accomplished.

Table III shows the conditions for the evaluation of the reverse rate constant k_{-I}. The unidirectional nature of the reactions was assured by the use of excess reactants, and the rate constant k_{obs} was obtained from normal semilogarithmic plotting procedures.

The equilibrium constant *K*, defined by Eq. 3, was evaluated spectrophotometrically. This was possible because the cyclic anhydride and the formed acetic anhydride were the only absorbing species at the selected wavelength:

$$K = \frac{[(CH_3CO)_2O]_{eq}[\text{diacid}]_{eq}}{[\text{cyclic anhydride}]_{eq}} \qquad \text{(Eq. 3)}$$

$$K = \frac{(\Delta A/\Delta\epsilon)^2}{a_0 - (\Delta A/\Delta\epsilon)} \qquad \text{(Eq. 4)}$$

$$K = \frac{(\Delta A/\Delta\epsilon)(\Delta A/\Delta\epsilon + [\text{diacid}])}{[\text{cyclic anhydride}]_0 - \Delta A/\Delta\epsilon} \qquad \text{(Eq. 5)}$$

where [diacid] is the amount of dicarboxylic acid added to the system, $\Delta A/\Delta\epsilon$ (as defined earlier) is equal to the amount of acetic anhydride formed, and $[\text{cyclic anhydride}]_0$ is the initial concentration of the cyclic anhydride. The subscript eq refers to equilibrium concentration. Equation 4 could be used when no added diacid was needed to observe the equilibrium formation, whereas Eq. 5 was used for systems where free dicarboxylic acid was added along with the cyclic anhydride. The value of *K* was also calculated from the ratio k_I/k_{-I}.

RESULTS

The course of the reaction between cyclic anhydrides with acetic acid in anhydrous acetic acid as a solvent, catalyzed by perchloric acid, to produce acetic anhydride and the corresponding dicarboxylic acid can be readily followed spectrophotometrically and can be described by Scheme II:

$$CH_3COOH \text{ (excess)} + \text{cyclic anhydride} + H^+ \underset{k_{-I}}{\overset{k_I}{\rightleftharpoons}} (CH_3CO)_2O + \text{dicarboxylic acid} + H^+$$

Scheme II

The spectral observations were possible because of differences in absorptivities between acetic anhydride and the cyclic anhydrides at given wavelengths (Tables I and II). The observed change in UV absorbance at 268 nm for a solution containing 0.25 *M* glutaric anhydride in acetic acid in the presence of 1×10^{-3} *M* $HClO_4$ and a similar plot for 0.07 *M* *trans*-1,2-cyclohexanedicarboxylic anhydride in the presence of 3.73×10^{-3} *M* $HClO_4$ at 259 nm as a function of time is shown in Fig. 1.

The reversibility of Scheme II was established spectrophotometrically. Also, when starting with the cyclic anhydride, the dicarboxylic acid could occasionally be isolated. Similarly, when starting with the dicarboxylic acid and an excess of acetic anhydride, the cyclic anhydride could be isolated. The change in UV absorbance of the reaction between succinic anhydride and acetic acid was shown to be a function of added succinic acid. Table IV shows the decrease in absorbance as the added concentration of succinic acid was increased for a constant initial concentration of succinic anhydride. The reverse reaction is applied commercially to prepare succinic anhydride (12). Succinic anhydride was isolated from a reaction mixture of succinic acid and acetic anhydride (in the presence of perchloric acid) in acetic acid and identified by its melting point of 118°.

The same trend in UV absorbance was observed for *trans*-1,2-cyclohexanedicarboxylic anhydride when acetic anhydride was added to the system. When more than 0.35 *M* of the anhydride was dissolved in acetic acid, *trans*-1,2-cyclohexanedicarboxylic acid precipitated out. It was identified by its melting point of 221°.

Table IV—Change in UV Absorbance as a Function of Added Succinic Acid for the Reaction Shown in Scheme II[a]

Added Succinic Acid	Change in UV Absorbance[b]
0	0.45
0.0075	0.33
0.03	0.15
0.075	0.08

[a] Succinic anhydride initial concentration was 0.40 *M* in all cases, and [$HClO_4$] was of the order of 1×10^{-3} *M*. [b] Added succinic acid forced the equilibrium to the left in Scheme II, suppressing the formation of acetic anhydride, the major absorbing species, at 252 nm.

Table V shows the equilibrium constants calculated from spectral data for succinic, *trans*-1,2-cyclohexanedicarboxylic, and glutaric anhydrides based on Eqs. 4 and 5. These were the only anhydrides of those studied that showed an observable reaction under the conditions employed. Spectra of phthalic, *cis*-1,2-cyclohexanedicarboxylic, and maleic anhydrides in acetous perchloric acid did not show any noticeable change. The concentrations of the cyclic anhydrides used in these measurements ranged from 0.1 to 0.5 M, except for phthalic anhydride which was about 1×10^{-4} M. The equilibrium constants reflect the relative stability of cyclic anhydrides which were 1000:5:1 for succinic, *trans*-1,2-cyclohexanedicarboxylic, and glutaric anhydrides, respectively.

The other anhydrides, maleic, *cis*-1,2-cyclohexanedicarboxylic, and phthalic, were much more stable, *i.e.*, $K < 1 \times 10^{-4}$ M.

The effect of moisture on the precision of the equilibrium constant determinations should be noted. Acetic acid is very hygroscopic; it has been estimated (15) that the water content of almost "dry" acetic acid, when exposed to the atmosphere for 0.5 hr, increased by 5×10^{-2} M. Although utmost care was taken to avoid moisture, errors of up to 10% were introduced into the equilibrium constant determinations by moisture. The relatively concentrated solutions of the anhydrides (not less than 0.1 M) used helped reduce the error due to moisture.

The forward rate constant k_I at 25° for the system defined by Scheme II was evaluated from plots of Eq. 1. Figure 2 is a representative plot for the loss of glutaric anhydride from solution. Although all cyclic anhydrides were studied, only k_I values for succinic, glutaric, and *trans*-1,2-cyclohexanedicarboxylic anhydrides could be determined. The concentration range of cyclic anhydrides used in the rate evaluations was 0.1–0.5 M; as mentioned earlier, these relatively high concentrations were employed to help reduce the effect of extraneous moisture. The excellent fit of all data to Scheme I and Eq. 1 suggests that the reaction can be described by Scheme II.

Values of k_I for the three cyclic anhydrides studied are shown in Table VI.

Table VII shows the third-order rate constant k_{-I}, *i.e.*, the rate constant of the reaction of the dicarboxylic acids with acetic anhydride catalyzed by perchloric acid. These rate constants were obtained under pseudo-first-order conditions, *i.e.*, where perchloric acid was maintained constant and an excess of one of the other reactants was used. For example, acetic anhydride was used in excess with acids having good chromophores such as phthalic and maleic acids. The disappearance of the acids followed pseudo-first-order kinetics. The third-order rate constant k_{-I} was then obtained from plots of k_{obs} *versus* the excess reagent. In the case of succinic and *cis*-1,2-cyclohexanedicarboxylic acids, the acids were used in excess and the disappearance of acetic anhydride was followed.

Two typical examples of these plotting techniques are shown in

Table VI—Forward Rate Constants, k_I (Scheme II), at 25° in Acetic Acid

[a] When using the initial slopes, a value of 81 M^{-1} min^{-1} was obtained for this case.

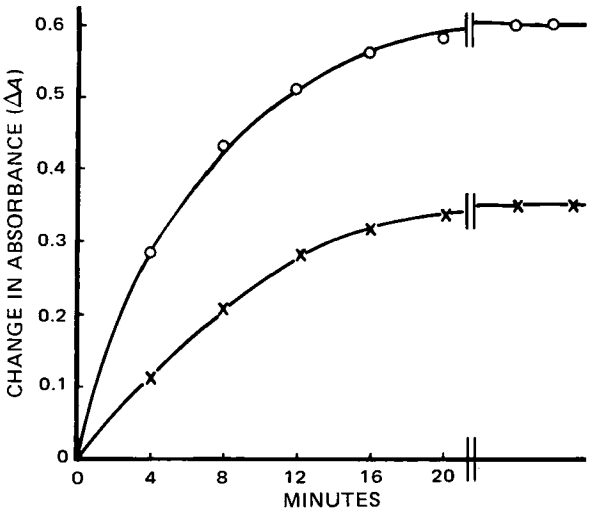

Figure 1—*Increase in absorbance due to production of acetic anhydride as a function of time for the reaction of the cyclic anhydride with acetic acid catalyzed by perchloric acid in acetic acid. The plots show the change in absorbance* versus *time for: 0.25* M *glutaric anhydride (O) in the presence of 1.0 × 10^{-3}* M *$HClO_4$ at 268 nm and 25°, and for 0.07* M trans-*1,2-cyclohexanedicarboxylic anhydride (×) in the presence of 3.73 × 10^{-3}* M *$HClO_4$ at 259 nm and 25°.*

Figs. 3 and 4. The rate constant k_{-1} for glutaric acid cyclization was obtained from the slope of the semilogarithmic plot of absorbance *versus* time where glutaric acid was in excess. The slope of such a line has the value of $k_1 + k_{-1}$ [glutaric acid]. Because k_1 was already estimated, k_{-1} could be calculated. The constant k_{-1} for *trans*-1,2-cyclohexanedicarboxylic acid was obtained from K/k_1 because of the insolubility problems with the dicarboxylic acid and its difficulty of purification.

Table VIII shows that the value of K as obtained from the k_1/k_{-1} ratio is in good agreement with the value of K determined independently by direct spectroscopic measurements.

DISCUSSION

A detailed scheme describing the interaction of the cyclic anhydrides with acetic acid is shown in Scheme III. The part of the reaction scheme played by perchloric acid has not been included, Compound I is used to illustrate a general cyclic anhydride, and Compound V is used to illustrate its equivalent diacid.

Figure 5 shows the good log–log correlation between K and k_1 and the smaller inverse dependency of K on k_{-1}. As can be seen from Table VII, the rate of reaction of the diacids with acetic anhydride is relatively independent of structure, although subtle differences do appear to exist. When referring to Scheme III and, in particular, the reverse reaction pathways, reactions represented by the constants k_{-2} and k_{-1} would be expected to be rather fast relative to the steps represented by the rate constants k_{-3} and k_{-4}. The constant k_{-2} is expected to be quite large because it represents an intramolecular attack by a carboxyl group at an anhydride linkage. Intramolecular reactions are known to be many thousand times faster than their intermolecular equivalents (16).

The subtle differences in k_{-1} possibly suggest that the rate-determining step in the reaction of diacids with acetic anhydride is represented by the attack of the diacids on acetic anhydride. In the presence of perchloric acid, acetic anhydride is probably protonated. Maleic acid and phthalic acid [pKa 2.00 (17) and 2.95 (17), respectively], the two strongest acids in aqueous solution, have the fastest rates when reacting with acetic anhydride whereas the weakest acid, glutaric acid [pKa 4.34 (17)], has the slowest reaction rate. This finding does not imply that the same order of acidity exists in acetic acid; however, it may suggest that the nucleophilicity of the reactant dicarboxylic acids is important. This finding further supports the possibility that the rate-determining step in the

[a] Determined from the UV absorbance of the reaction system at equilibrium and absorptivities of the species involved. [b] Determined from the rate constants $K = (k_1/k_{-1})$. It is recognized that the calculation of the k_1 values utilized equilibrium concentrations and were influenced to a degree by equilibrium data.

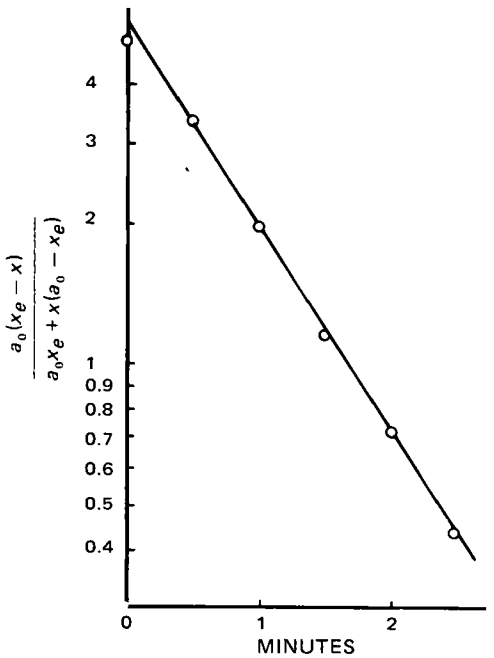

Figure 2—*Perchloric acid-catalyzed reaction of glutaric anhydride with acetic acid. The figure shows a semilog plot of* $a_0(x_e - x)/[a_0x_e + x(a_0 - x_e)]$ *against time of the reaction of glutaric anhydride with acetic acid catalyzed by perchloric acid at 25° as described by:*

$$log\ \frac{a_0(x_e - x)}{a_0x_e + x(a_0 - x)} = -\frac{2a_0 - x_e[HClO_4]k_1t}{x_e 2.303}$$

and:

$$k_1 = \frac{-slope \times 2.303}{[(2a_0 - x_e)/x_e]}[HClO_4]$$

where a_0 *is the initial glutaric anhydride concentration. The concentrations of acetic anhydride at any time and at equilibrium are represented by* x *and* x_e, *respectively;* $a_0 = 0.40$ M; $[HClO_4] = 7.5 \times 10^{-3}$ M; $x_e = 0.242$ M; *and* k_1 *is the pseudo-second-order rate constant.*

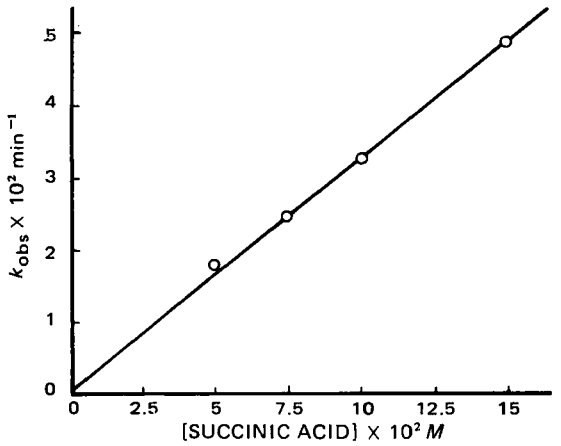

Figure 3—*Perchloric acid-catalyzed reaction of succinic acid with acetic anhydride. The figure shows a plot of* k_{obs} *as a function of succinic acid for the perchloric acid-catalyzed reaction of acetic anhydride with succinic acid in acetic acid at 25°;* k_I = *slope/*$[HClO_4]$, *and* $[HClO_4] = 5.6 \times 10^{-3}$ M.

determination of k_{-1} is the formation of the tetrahedral intermediate IV.

As seen in Table VI, the values of k_1 appear to be a strong function of the molecular structure of the anhydrides. Since the steric and electrophilic factors of acetic anhydride and the mixed anhydride, III, would be considered to be similar, it seems reasonable to assume that the attack of acetic acid on the mixed anhydride and the subsequent breakdown of the intermediate IV would not be strongly influenced by the molecular structure of the diacid part of the mixed anhydride.

Similarly, because the hydrolytic behavior of all anhydrides, including acetic anhydride, is so similar (18) and the rate-determining step in the hydrolysis of the anhydrides is considered to be the formation of the tetrahedral intermediate, it follows that k_1 is probably not sufficiently perturbed by structure to result in the differences in reactivity seen with the various cyclic anhydrides. Therefore, the probable slow step in the reaction of the cyclic anhydrides with acetic acid is the breakdown of the tetrahedral intermediate II.

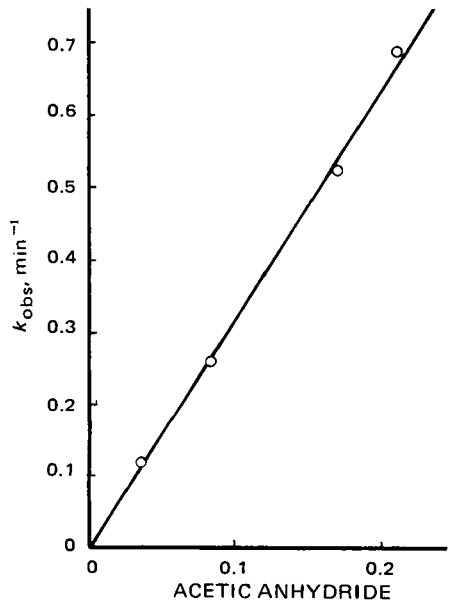

Figure 4—*Perchloric acid-catalyzed reaction of phthalic acid with acetic anhydride as a function of acetic anhydride concentration,* $[(CH_3CO)_2O]$. *The figure shows a plot of* k_{obs} *against acetic anhydride for the perchloric acid-catalyzed reaction of phthalic acid and acetic anhydride in acetic acid at 25°;* k_{-1} = *slope/*$[HClO_4]$, *and* $[HClO_4] = 1.0 \times 10^{-3}$ M.

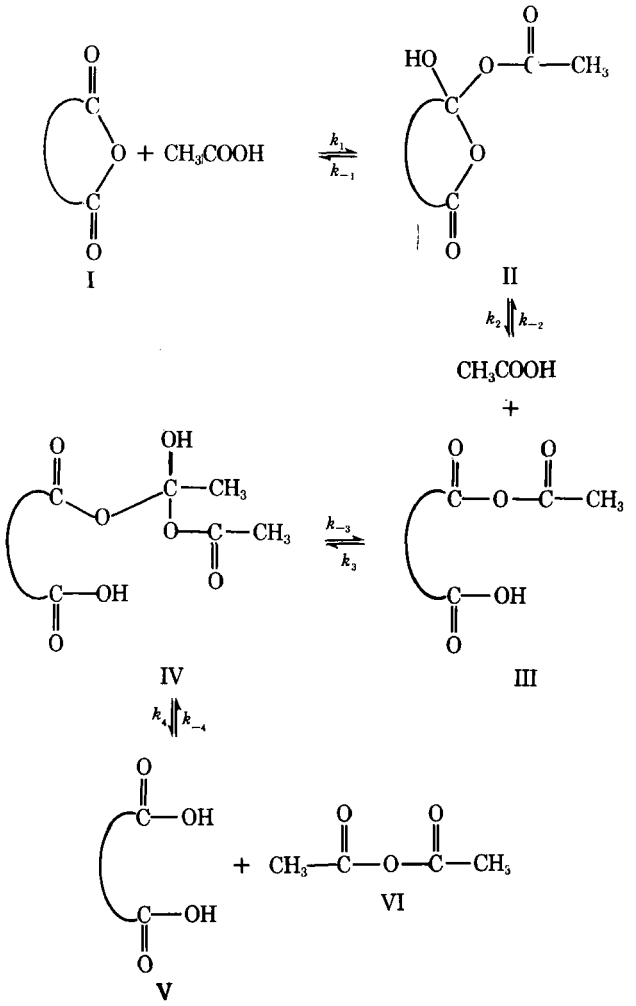
The slowness of this step is rationalized on the basis that the transition state for the step requires the expulsion of the neighboring carboxyl group. The reverse of this step, represented by the constant k_{-2}, involves an intramolecular reaction. Increased rates of intramolecular reactions have been observed due to backbone alkyl substitution. Other means by which intramolecular reaction rates have been increased are by "locking" the reaction center "in line" with the nucleophile by constraining rotation within a ring system by: (*a*) decreasing ring size, *e.g.*, glutaric to succinic; (*b*) placement of a double bond in the ring system to prevent free rotation, *e.g.*, succinic to maleic and succinic to phthalic; or (c) placing the reaction centers near each other using favorable rigid analogs, *e.g.*, *cis*-1,2-cyclohexanedicarboxylic acid compared to *trans*-1,2-cyclohexanedicarboxylic acid. A complete argument on the subtleties of these various points can be found in Refs. 4, 5, 7, 8, and 19–28.

On the basis of the Hammond principle (29), the reverse of such an intramolecular reaction, or the ease with which the neighboring carboxyl group leaves, should be inverse to the ease with which the intramolecular reaction takes place. The order of reactivity of the cyclic anhydrides in the present study follows this pattern. The dependency of K on the constant k_1 and, subsequently, k_2 of Scheme III shows that the thermodynamic stability of the cyclic anhydrides is closely related to their molecular structure and can be rationalized on the basis of the known relative reactivity of intramolecular reactions compared to intermolecular reactions.

By the theory of microscopic reversibility, it follows that k_{-4} cannot be the rate-determining step for the reverse reaction and k_2 be the rate-determining step for the forward reaction. It was stated earlier that k_{-2} should be large relative to other rate constants for the reverse reaction because it involves an intramolecular reaction. Even though k_{-1} is not greatly perturbed by the structure of the cyclic anhydrides (Table VII), the order of reactivity of the dicarboxylic acids with acetic anhydride is consistent with those species most likely to undergo an intramolecular reaction, *i.e.*, maleic > phthalic > succinic > glutaric. It appears, therefore, that the transition state for the reaction of II in equilibrium with III probably represents the species of greatest free energy for the equilibrium formation of acetic anhydride from cyclic anhydrides dissolved in acetic acid.

In summary, the transacylation reaction presented in this study, *i.e.*, the equilibrium formation of acetic anhydride in anhydrous acetic acid in the presence of a high energy acylator such as a cyclic anhydride, could be rationalized on the basis of the known chemical reactivity of the anhydrides. These results provide additional insight into the chemistry of the energy-rich tetrahedral interme-



Scheme III

diates and cyclic anhydrides, which have been postulated in numerous pharmaceutically important reactions. The intermediacy of anhydrides in the hydrolysis of certain hemiesters has been established (5), and the acylating capacity of high energy pharmaceutical esters and amides such as aspirin and penicillin has been noted.

The present study provides a further quantitative picture of the effect of molecular structure on the partitioning of the tetrahedral intermediate between the open high energy configuration and the cyclic anhydride.

Acylation of Phenol by Cyclic and Acyclic Anhydrides in Anhydrous Acetic Acid

M. J. HADDADIN *, T. HIGUCHI ˣ, and V. STELLA

Abstract □ Acylation of phenol with succinic, glutaric, *trans*-1,2-cyclohexanedicarboxylic, maleic, phthalic, and *cis*-1,2-cyclohexanedicarboxylic anhydrides in anhydrous acetic acid generally resulted in phenyl acetate as the major product. The formation of phenyl acetate as the major reaction product could be rationalized as being due to the reactivity of the cyclic anhydrides with acetic acid to form acetic anhydride as well as the greater reactivity of phenol with formed acetic anhydride than with the cyclic anhydride.

Keyphrases □ Phenol—acylation by cyclic and acyclic anhydrides in anhydrous acetic acid, rate constants, mechanisms □ Acylation—phenol by cyclic and acyclic anhydrides in anhydrous acetic acid, rate constants, mechanisms □ Perchloric acid—catalyst for acylation of phenol in anhydrous acetic acid, rate constants, mechanisms □ Anhydrides, cyclic and acyclic—acylation of phenol in anhydrous acetic acid, rate constants, mechanisms

Haddadin *et al.* (1) recently quantitated the equilibrium formation of acetic anhydride from the reaction of cyclic anhydrides with anhydrous acetic acid catalyzed by perchloric acid. Mechanistically, the rate-determining step for the forward reaction was postulated to be the breakdown of the tetrahedral intermediate formed by the attack of acetic acid on the protonated cyclic anhydride. The hydrolysis of cyclic and acyclic anhydrides has been extensively studied (2), and the results suggest that the rate-determining step usually is the formation of the tetrahedral intermediate adduct. The present study concerns the reactivity of a model nucleophile, phenol, with cyclic and acyclic anhydrides in anhydrous acetic acid. The main objective was to gain an understanding of the mechanisms involved in transacylation reactions taking place in nonaqueous media. This study provides a quantitative picture of the effects of molecular structure and the partitioning of tetrahedral intermediate formation and breakdown on leaving group tendencies, especially when cyclic and acyclic anhydrides are the substrates and phenol is the nucleophile. The reactivity of energy-rich tetrahedral intermediates as well as cyclic and acyclic anhydrides will be discussed as models for high energy acylators, as postulated in numerous pharmaceutically important reactions. The pharmaceutical implications of transacylation reactions have been well documented (3–8).

EXPERIMENTAL

Materials—All materials were as described previously (1). Phenyl acetate was vacuum distilled at 211° and 0.7 mm Hg. The refractive index was 1.5008 [lit. (9) 1.5017] at 25°. Phenyl hemisuccinate was synthesized and purified according to the method of Baddar and Assal (10); phenol[1] was purified by sublimation, mp 42° [lit. (9) mp 43°].

p-Methylphenol[2] was sublimed and dried under vacuum, mp 36° [lit. (9) mp 34°]. *p*-Methoxyphenol[3], mp 56–57° [lit. (9) mp 57°], *p*-iodophenol[3], mp 93–94° [lit. (9) mp 93–94°], and *p*-fluorophenol, mp 46–47° [lit. (9) mp 48°], were recrystallized from benzene–petroleum ether.

Apparatus[4]—For the thermometric measurements, a simple dewar calorimeter was assembled from a wheatstone bridge circuit, a 1-mv recorder, a 2-K thermister probe, a dewar flask of convenient size, a thermometer[5], two variable resistance boxes of 111.1 K, and a mercury cell of 1.35 v (11, 12). The recorder was calibrated to read a difference of 0.4° at ambient temperature per full-scale deflection.

All spectroscopic measurements were carried out in the thermostated cell compartment of a UV spectrophotometer[6].

Procedures—The reactions between acetic anhydride and phenol in anhydrous acetic acid, catalyzed by perchloric acid, were followed both spectrophotometrically and thermometrically.

For the spectrophotometric method, a few microliters of approximately 1×10^{-3} *M* phenol in anhydrous acetic acid was injected directly into a thermostated 1-cm cylindrical cell containing 0.1–0.5 *M* acetic anhydride and 1×10^{-3} *M* perchloric acid in anhydrous acetic acid. The disappearance of phenol was conveniently followed at 278 nm.

For the thermometric method, a few milliliters of 1×10^{-2} *M* phenol, dissolved in anhydrous acetic acid, was injected into an anhydrous acetic acid solution containing 0.1–0.5 *M* acetic anhydride and 1×10^{-4} *M* perchloric acid. All experiments were run at approximately 25°. The reaction was monitored by following the small change in the temperature of the solution. In all cases, this change was <0.09°.

The rate constants were obtained under pseudo-first-order conditions in which acetic anhydride was always in excess. The con-

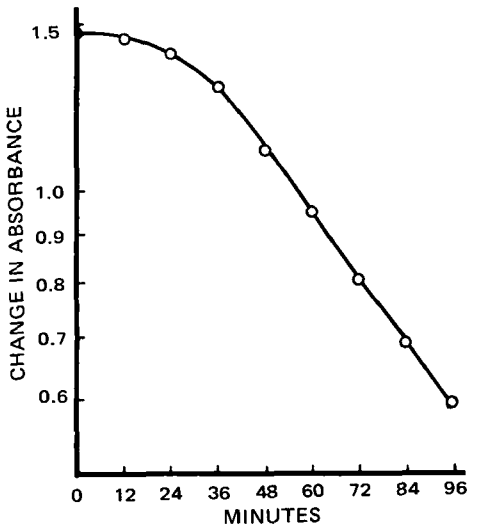

Figure 1—*Semilog plot of change in absorbance against time, demonstrating the lag time for the perchloric acid-catalyzed reaction of phenol with a fresh solution of succinic anhydride in acetic acid at 25°. The initial concentration of succinic anhydride was 0.30* M, *and* $[HClO_4] = 1.244 \times 10^{-2}$ M.

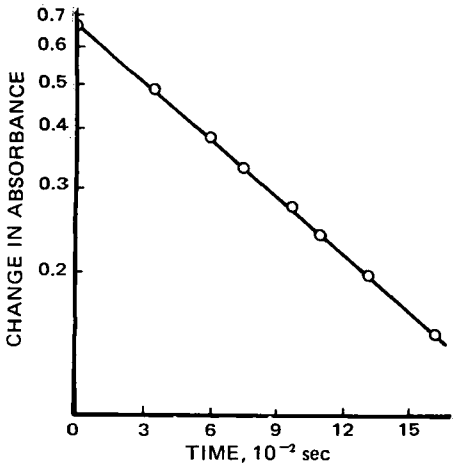

Figure 2—*Semilog plot of change in absorbance against time, demonstrating first-order behavior in phenol when it was reacted with an equilibrated succinic anhydride solution, 0.51* M *in acetic acid, in the presence of* 1.244×10^{-3} M $HClO_4$ *at 25°.*

centrations of acetic anhydride and the catalyst, perchloric acid, were varied independently. The slopes of the observed rate constant, k_{obs}, *versus* acetic anhydride concentrations and perchloric acid concentrations, [$HClO_4$], were used to calculate the third-order rate constant for the reaction of phenol with acetic anhydride.

The reaction of *para*-substituted phenols was followed under the same conditions previously described, except that a convenient wavelength for following the disappearance of the phenol was used.

Reactions between phenol and succinic, glutaric, phthalic, maleic, *cis*-1,2-cyclohexanedicarboxylic, and *trans*-1,2-cyclohexanedicarboxylic anhydrides were studied by adding dilute solutions of phenol in anhydrous acetic acid to preequilibrated solutions of the cyclic anhydride in the anhydrous acetic acid in the presence of perchloric acid. The disappearance of phenol was followed at 278 nm and 25°. The concentrations of the cyclic anhydrides ranged from 0.1 to 0.5 *M*, and the final concentrations of phenol and perchloric acid were 1×10^{-4} and 1×10^{-3} *M*, respectively.

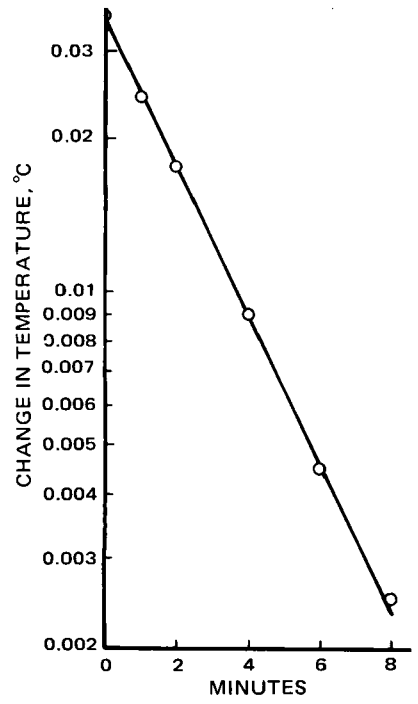

Figure 3—*Semilog plot of change in temperature against time, demonstrating first-order behavior with respect to phenol for the perchloric acid-catalyzed reaction of phenol with acetic anhydride in acetic acid at 25°;* $[(CH_3CO)_2O] = 0.21$ M, *and* $[HClO_4] = 5.0 \times 10^{-3}$ M. *The reaction was monitored thermometrically.*

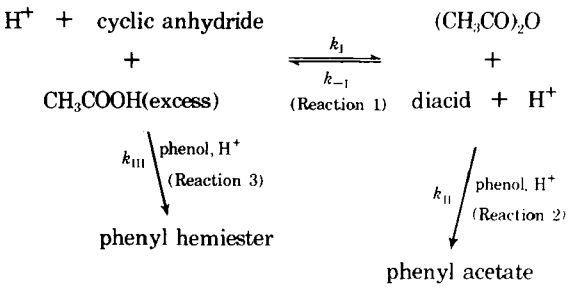

Scheme I

To study the effects of added succinic acid on the reaction of phenol in the succinic anhydride–acetic acid system, succinic anhydride was maintained at 0.4 *M* while the succinic acid concentration was varied from 0.015 to 0.1 *M*. Similar studies with the corresponding acids of the other cyclic anhydrides were not attempted.

Determination of Reaction Products—The quantitative determination of the phenol ester products found in the phenol–cyclic anhydride–acetic acid reaction mixture was accomplished using the following procedure. Phenyl acetate was estimated by neutralizing a pipetted aliquot with ice-cold sodium carbonate solution to pH 9 and extracting with ether or carbon tetrachloride. The extracts were made up to a convenient volume. The UV absorbance of the solution at 266 and 278 nm was used to calculate the amount of phenyl acetate formed. The absence of phenol in the reaction mixture was verified by absorbance measurements at 278 nm. The shape of the absorbance *versus* wavelength scan corresponded to that of phenyl acetate. The concentration of phenyl acetate extracted was estimated by comparison with the absorbance of a standardized sample. The concentration of the phenol hemiester was calculated from the difference between the initial phenol concentration and the phenyl acetate concentration found.

To check if phenyl hemisuccinate underwent a reversible reaction in the perchloric acid–acetic acid solution, a standardized phenyl hemisuccinate solution was compared. Repetitive UV scanning and TLC showed that phenyl hemisuccinate was stable, *i.e.*, did not undergo a transacylation reaction.

TLC was employed to identify the phenol esters and to verify the spectrophotometric results. A few microliters of the reaction mixtures was spotted along with authentic samples of the various reactants and possible products on dry silica gel TLC plates (preheated at 120° for 30 min). The mobile phase was 3% butyl ether in pentane; the spots were developed in iodine vapor.

RESULTS AND DISCUSSION

When phenol was added to a freshly prepared solution of succinic anhydride in acetic acid with perchloric acid present as a catalyst, the disappearance of the phenol showed a lag time of about 30 min followed by an apparent first-order disappearance (Fig. 1). If the reaction mixture of succinic anhydride and acetic acid was allowed to equilibrate before the addition of phenol, no lag time was observed and the disappearance of phenol followed first-order kinetics (Fig. 2). Similar results were obtained with glutaric anhydride and *trans*-1,2-cyclohexanedicarboxylic anhydride.

The presence of a lag time in the freshly prepared solution was postulated to be due to the formation of a more reactive intermediate, *i.e.*, acetic anhydride, which would then react with phenol as shown in Scheme I.

To test Scheme I, the reactivity of phenol with acetic anhydride in anhydrous acetic acid and in the presence of perchloric acid was studied. The products resulting from the reaction of phenol with the cyclic anhydride in acetic acid were determined as described under *Experimental*.

In the reaction of phenol with succinic anhydride in anhydrous acetic acid, for example, TLC revealed only one spot corresponding to phenyl acetate. When exogenous succinic acid was included in the system before adding phenol, both the rate of formation and the amount of phenyl acetate formed decreased. Furthermore, a

Table I—Rate Constants of the Acetic Anhydride–Phenol Reactions at 25° in Acetic Acid with Perchloric Acid Present as a Catalyst

Phenol	k_{II}, M^{-2} min^{-1}
p-Methoxyphenol	884
p-Methylphenol	482

p-Iodophenol	96

[a] From spectrophotometric method. [b] From thermometric method.

second spot corresponding to phenyl hemisuccinate was observed. This finding is consistent with Scheme I because exogenous succinic acid would be expected to force Reaction 1 to the left, thereby reducing the equilibrium concentration of acetic anhydride. Similar results were obtained for glutaric and *trans*-1,2-cyclohexanedicarboxylic anhydrides.

The third-order rate constant, k_{II}, for the reaction of phenol with acetic anhydride catalyzed by perchloric acid was determined independently, *i.e.*, in the absence of the cyclic anhydrides. Pseudo-first-order plots for the disappearance of phenol were obtained when perchloric acid was maintained constant and acetic anhydride was used in excess of the phenol. The disappearance of phenol monitored thermometrically and spectrophotometrically is shown in Figs. 3 and 4, respectively. The first-order dependency in acetic anhydride is shown in Fig. 5, and the first-order dependency on perchloric acid is shown in Fig. 6. The importance of perchloric acid can be seen in the near zero intercept.

The relative reactivity of various *para*-substituted phenols is shown in Table I. Included in this table are the values obtained for phenol. The objective of this study was to gain insight into the mechanism of acetylation of phenol under the reaction conditions. A Hammett plot of log k_{II} for the various phenols *versus* σ *para* is shown in Fig. 7. These data support a mechanism involving nucleophilic attack of the phenol on the protonated acetic anhydride as the rate-determining step.

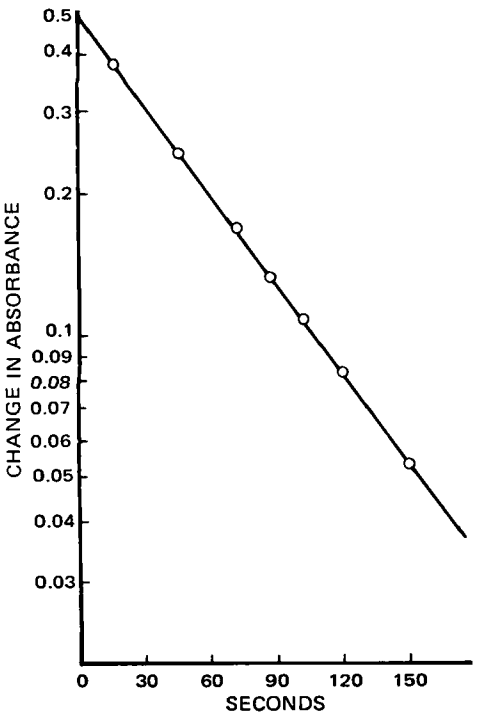

Figure 4—*Semilog plot of change in absorbance against time, demonstrating first-order behavior with respect to phenol for the perchloric acid-catalyzed reaction of acetic anhydride with phenol in acetic acid at 25°; $[(CH_3CO)_2O] = 0.501$ M, and $[HClO_4] = 5.0 \times 10^{-3}$ M.*

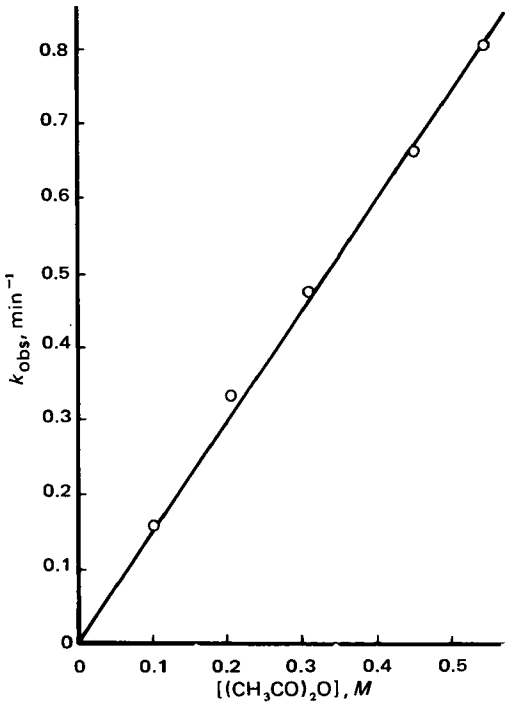

Figure 5—*Plot of k_{obs} against $[(CH_3CO)_2O]$, showing first-order dependency with respect to acetic anhydride in its perchloric acid-catalyzed reaction with phenol; $[HClO_4] = 5.0 \times 10^{-3}$ M. The reactions were monitored thermometrically.*

If a steady-state assumption is made for acetic anhydride in Scheme I, the following equation can be derived:

$$k_{obs} = k'_{III}\,[\text{cyclic anhydride}]_{eq} + k'_{II}\,[(CH_3CO)_2O] \quad \text{(Eq. 1)}$$

It follows that:

$$\frac{k_{obs}}{[\text{cyclic anhydride}]_{eq}} = k'_{III} + \frac{Kk'_{II}}{[\text{diacid}]_{eq}} \quad \text{(Eq. 2)}$$

where k_{obs} is the observed pseudo-first-order rate constant for the disappearance of phenol, k'_{II} is equal to k_{II} $]HClO_4]$, k'_{III} is equal to k_{III} $[HClO_4)$, $[\text{cyclic anhydride}]_{eq}$ is the concentration of the cyclic anhydride in the equilibrated solution, $[\text{diacid}]_{eq}$ is the concentration of the diacid at equilibrium, and $K = k_I/k_{-I}$.

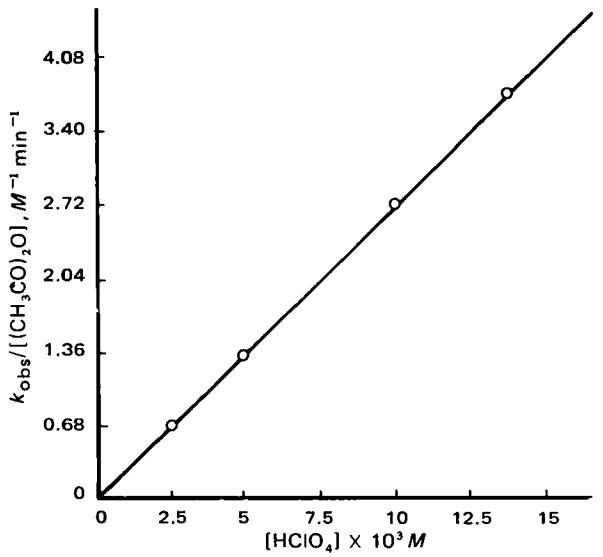

Figure 6—*Plot of $k_{obs}/[(CH_3CO)_2O]$ against the perchloric acid concentration, demonstrating first-order behavior with respect to perchloric acid, the catalyst, in the reaction of acetic anhydride with phenol; $[(CH_3CO)_2O] = 0.53$ M.*

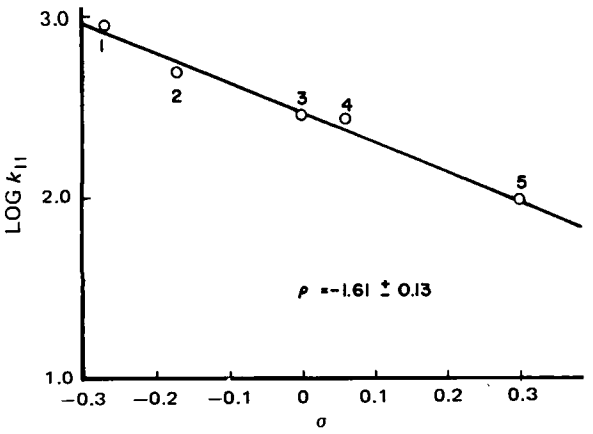

Figure 7—*Semilog plot of* k_{II} *(a third-order rate constant) as a function of the Hammett* σ para *(23). Key: Compound 1,* p-*methoxyphenol; Compound 2,* p-*methylphenol; Compound 3, phenol; Compound 4,* p-*fluorophenol; and Compound 5,* p-*iodophenol.*

The equilibrium concentration of the cyclic anhydride and the corresponding diacid under the experimental conditions described were previously determined (1). If the reaction shown in Scheme I and a steady state for acetic anhydride are assumed, then Eq. 2 predicts that a plot of k_{obs}/[cyclic anhydride]$_{eq}$ *versus* 1/[diacid]$_{eq}$ should be linear with slopes equal to Kk'_{II} and an intercept of k_{III}. Such plots were found to be linear, and a representative one is shown in Fig. 8. The third-order constant k_{III} was calculated to be 1.5, 37, and 48 M^{-2} min^{-1} for succinic, glutaric, and *trans*-1,2-cyclohexanedicarboxylic anhydrides, respectively.

The validity of these intercepts was checked for succinic and *trans*-1,2-cyclohexanedicarboxylic anhydrides by comparing the expected ratios of the phenyl hemiester of the appropriate dicarboxylic acid to phenyl acetate from kinetic data to those found by the quantitative recovery of the products. With 0.2 *M* succinic anhydride in the presence of 0.1 *M* succinic acid and 1×10^{-3} *M* perchloric acid, the ratio of phenyl hemisuccinate to phenyl acetate was expected to be 1:1 but experimentally the recovery was 0.8:1. With 0.2 *M trans*-1,2-cyclohexanedicarboxylic anhydride in the presence of 1×10^{-3} *M* perchloric acid, the kinetically expected ratio of phenyl hemiester of *trans*-1,2-cyclohexanedicarboxylic acid to phenyl acetate was 1:8 whereas the experimental recovery was 1:8.6.

Both from the kinetic and TLC studies, no reaction between phenol and maleic, *cis*-1,2-cyclohexanedicarboxylic, and phthalic anhydrides to form the hemiesters could be detected.

The relative reactivity toward phenol of the various cyclic anhydrides, when compared to the reaction of phenol with acetic anhydride, is not consistent with the relative hydrolytic behavior of these anhydrides (2). Eberson and Landström (2) showed that acetic, succinic, and glutaric anhydrides at 20° and pH 5.20 have almost identical hydrolysis rates, and they stated that there does not seem to be any mechanistic difference between the hydrolysis of open chain and cyclic anhydrides. Recent studies (13) with the slowly hydrolyzing tetramethylsuccinic anhydride suggest that the hydrolysis of this anhydride involves the breakdown of the tetrahedral intermediate whereas the spontaneous hydrolysis of other cyclic and acyclic anhydrides involves rate-determining formation of the tetrahedral intermediate adduct.

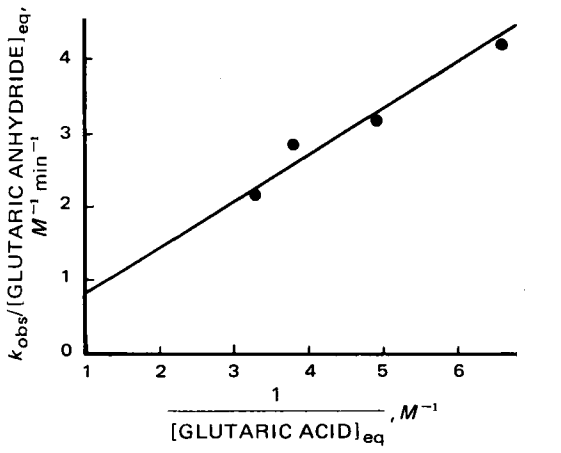

Figure 8—*Plot of* k_{obs}/*[glutaric anhydride]*$_{eq}$ versus *1/[glutaric acid]*$_{eq}$ *for the perchloric acid-catalyzed reaction of phenol with the glutaric anhydride–acetic acid system, varying the initial glutaric anhydride concentration. Slope =* $k_{III}[HClO_4]$*, where* $[HClO_4] = 5.6 \times 10^{-3}$ M.

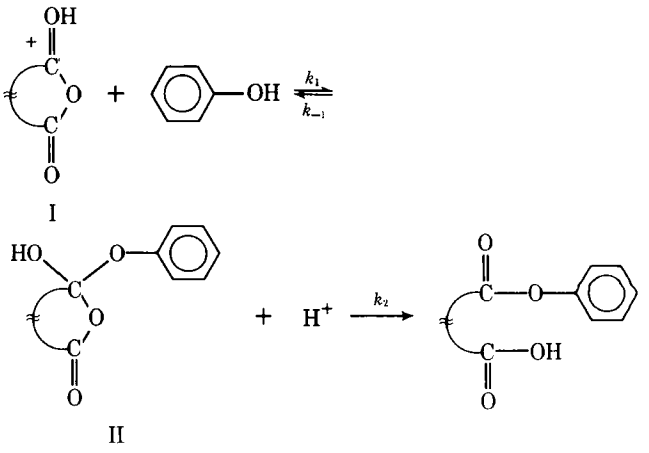

Scheme II

The relative reactivity of the *para*-substituted phenols toward acetic anhydride in anhydrous acetic acid in the presence of perchloric acid suggests that nucleophilicity of the phenol is important. This is consistent with the rate-determining step being the attack of the phenol on the protonated, positively charged, acetic anhydride. The relative reactivity of phenol toward succinic anhydride compared to acetic anhydride suggests that a change in the rate-determining step has occurred. Such a mechanism is shown in Scheme II, where I represents a cyclic or acyclic anhydride.

The ability of hemiesters and amides of cyclic acids to undergo a facile intramolecular reaction to form the corresponding anhydride has been well recognized (14–22). The relative reactivity of cyclic anhydrides to undergo solvolytic reactions with acetic acid was rationalized on the basis of the difficulty of expulsion of a carboxyl group from the tetrahedral intermediate formed by the attack of acetic acid on the protonated anhydride (reaction represented by k_1 in Scheme I of Ref. 1). By the same argument, it appears that the rate-determining step in the reaction of phenol with succinic anhydride under the present conditions may be k_2, *i.e.*, the breakdown of the tetrahedral intermediate II, a conclusion based on the large difference between k_{II} and k_{III}.

The large negative entropy of activation changes and the large solvent isotope effects seen in the spontaneous hydrolytic reactions of various cyclic and acyclic anhydrides suggest that the transition state energy was lowered by hydrogen bonding with solvent molecules (2). The reduced ability to solvate a polar transition state by specific interaction in a lower dielectric medium like acetic acid will contribute to differences in the transition state for nucleophilic reactions in water *versus* those in acetic acid.

The relative reactivity of phenol with the cyclic anhydrides studied in the present case (including those anhydrides for which no measurable reactivity could be determined, *i.e.*, $k_{III} \ll 1\ M^{-2}$ min^{-1}) is inverse to the ability of the hemiester and amides of the corresponding dicarboxylic acid to undergo intramolecular reactions (14–22). This finding suggests that the difficulty in expelling the neighboring carboxyl group, *i.e.*, k_2 of Scheme II, is probably the rate-determining step.

SUMMARY

The formation of phenyl hemiesters of dicarboxylic acids from the reaction of phenol with a dicarboxylic anhydride in anhydrous acetic acid catalyzed by perchloric acid is a function of two interre-

lated factors: (*a*) the reactivity of phenol toward the cyclic anhydride *versus* the reactivity of phenol toward the *in situ* formed acetic anhydride, and (*b*) the equilibrium concentration of acetic anhydride resulting from the solvolytic reaction of acetic acid with the cyclic anhydride. The more reactive the cyclic anhydride, the more readily it reacts with both phenol and acetic acid.

The present study provides a further quantitative picture of the effect of molecular structure on the partitioning between rate-determining formation and breakdown of the energy-rich tetrahedral intermediate for reaction at an acyl function. The poor leaving group tendency of the constrained neighboring carboxyl group in the reaction of phenol with cyclic anhydrides, due to the inclination of the neighboring carboxyl to undergo the reverse intramolecular reaction, resulted in tetrahedral intermediate breakdown being the rate-determining step. It is postulated that the good leaving group tendency of the unconstrained acetic acid in the reaction of phenol with the acyclic anhydride, acetic anhydride, results in tetrahedral intermediate formation being the rate-determining step. These differences in mechanism between the reactivity of cyclic and acyclic anhydrides in acetic acid compared to their hydrolytic reactivity must be due to the reduced ability of acetic acid, when compared to water, to solvate polar transition states.

Dissolution Patterns of Polydisperse Powders: Oxalic Acid Dihydrate

J. T. CARSTENSEN ˣ and MAHENDRA PATEL

Abstract □ The dissolution of oxalic acid dihydrate crystals of log-normal particle-size distribution in 0.1 *N* HCl was studied. A biphasic cube root dependence was found; the slopes of the initial cube root plots were consistent with theory based on dissolution of isometric, isotropic particles where assumptions were made of: (*a*) sink conditions, (*b*) particle-size-independent solubility, and (*c*) particle-size-independent film thickness of adsorbed liquid layers.

Keyphrases □ Dissolution of polydisperse powders (oxalic acid dihydrate)—dissolution patterns, equations □ Oxalic acid dihydrate (polydisperse powder)—dissolution patterns, equations □ Powders, polydisperse—dissolution, oxalic acid dihydrate, equations

The rates of dissolution and the mechanisms involved in the dissolution process have been the subjects of many publications in the last decade. However, most dissolution work done on powders has been restricted to monodisperse powders (1–4).

BACKGROUND

Hixson and Crowell (5), basing their derivation on the Noyes–Whitney equation (6), arrived at the so-called cube root dissolution rate law:

$$\sqrt[3]{W_0} - \sqrt[3]{W} = Kt \qquad \text{(Eq. 1)}$$

where W_0 is the initial weight of the powder, W is the weight of undissolved powder at time t, and K is an apparent dissolution rate constant having units of $(\text{weight})^{1/3}$ per unit time. The assumptions made in the derivation of Eq. 1 are: (*a*) all particles dissolve isotropically, (*b*) the particles are isometric, (*c*) the thickness of the diffusion barrier around each particle (the "film thickness,"

lated factors: (*a*) the reactivity of phenol toward the cyclic anhydride *versus* the reactivity of phenol toward the *in situ* formed acetic anhydride, and (*b*) the equilibrium concentration of acetic anhydride resulting from the solvolytic reaction of acetic acid with the cyclic anhydride. The more reactive the cyclic anhydride, the more readily it reacts with both phenol and acetic acid.

The present study provides a further quantitative picture of the effect of molecular structure on the partitioning between rate-determining formation and breakdown of the energy-rich tetrahedral intermediate for reaction at an acyl function. The poor leaving group tendency of the constrained neighboring carboxyl group in the reaction of phenol with cyclic anhydrides, due to the inclination of the neighboring carboxyl to undergo the reverse intramolecular reaction, resulted in tetrahedral intermediate breakdown being the rate-determining step. It is postulated that the good leaving group tendency of the unconstrained acetic acid in the reaction of phenol with the acyclic anhydride, acetic anhydride, results in tetrahedral intermediate formation being the rate-determining step. These differences in mechanism between the reactivity of cyclic and acyclic anhydrides in acetic acid compared to their hydrolytic reactivity must be due to the reduced ability of acetic acid, when compared to water, to solvate polar transition states.

The rates of dissolution and the mechanisms involved in the dissolution process have been the subjects of many publications in the last decade. However, most dissolution work done on powders has been restricted to monodisperse powders (1–4).

BACKGROUND

Hixson and Crowell (5), basing their derivation on the Noyes–Whitney equation (6), arrived at the so-called cube root dissolution rate law:

$$\sqrt[3]{W_0} - \sqrt[3]{W} = Kt \qquad \text{(Eq. 1)}$$

where W_0 is the initial weight of the powder, W is the weight of undissolved powder at time t, and K is an apparent dissolution rate constant having units of $(\text{weight})^{1/3}$ per unit time. The assumptions made in the derivation of Eq. 1 are: (*a*) all particles dissolve isotropically, (*b*) the particles are isometric, (*c*) the thickness of the diffusion barrier around each particle (the "film thickness,"

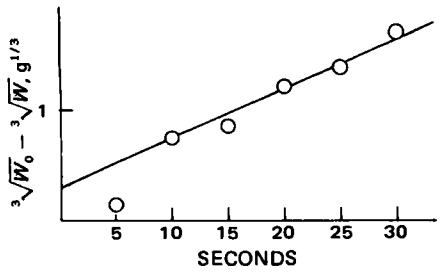

Figure 1—*Dissolution pattern of a "fine" powder of isothermally recrystallized oxalic acid dihydrate.*

h) is constant, (d) there are no particle-size solubility effects, and (e) sink conditions exist.

Most systems in pharmaceutical dosage forms are polydisperse systems; many investigators (7–12) have shown that particles prepared by procedures such as milling and precipitation produce skewed distribution functions which closely resemble log-normal particle-size distributions.

The dissolution of polydisperse powders of log-normal distribution was first studied by Higuchi and Hiestand (13) and Higuchi *et al.* (14). In their treatment, they approximated the log-normal frequency function:

$$f(\log x) = \frac{1}{\sqrt{2\pi}(\sigma)} \exp[(\log x - \log M)^2/2\sigma^2] \qquad \text{(Eq. 2)}$$

when expressed as a cumulative oversize distribution by the cumulative function:

$$g(x) = K/x^4 \qquad \text{(Eq. 3)}$$

where x is the particle diameter, M is the geometric mean diameter, and σ is the standard deviation of the distribution. The nomenclature employed in Eq. 2 is adhered to in this study. Good agreement with experimental values was found previously using the approximation in Eq. 3 (13, 14).

Carstensen and Musa (15) generated log-normal distributions by computer and followed the dissolution under assumptions (a)–(e); they found that the dissolution patterns could be approximated by a cube root law up to a critical time, t_c, when the smallest particle of diameter a_0 would be completely dissolved. Beyond this point, the cube root plot changes slope. The equation that held prior to the critical time was:

$$\sqrt[3]{W_0} - \sqrt[3]{W} = \frac{1.84kC_s \sqrt[3]{W_0}}{\sigma^{0.02}M\rho} t \qquad \text{(Eq. 4)}$$

where C_s is the saturation concentration, and k is the dissolution rate constant in centimeters per second. The distributions generated by Carstensen and Musa were all truncated (at + and -3σ). Equation 4 was found to hold in the limited range of σ values tested; aside from the limitation of the σ range tested, the equation[1] suffers from having the slope, α, tend toward infinity when σ tends toward zero.

Brooke (16, 17) arrived at an exact expression of the dissolution rate profile of a nontruncated, log-normal, particle-size distributed powder with the previously mentioned assumptions (a)–(e). The treatment was expanded to truncated distributions by envoking the Hatch–Choate (11) equation; this equation is applicable when $\sigma < 0.14$ (18, 19). Brooke (17) also showed that a cube root relationship could be explained by the theoretically rigorous treatment and suggested the following equation:

$$\sqrt[3]{W_0} - \sqrt[3]{W} = \exp[-2.54\sigma_D^2] \frac{2kC_s \sqrt[3]{W_0}}{\rho M} t \qquad \text{(Eq. 5)}$$

where $\sigma_D = 2.3\sigma$. Brooke's equation has the same dependence on density, mean diameter, rate constant, initial weight, and solubility as that of Carstensen and Musa (15), but the dependence on standard deviation in Eq. 5 is different; it does not suffer from the limitations with which Eq. 4 is afflicted.

[1] The equation reported by Carstensen and Musa (15) contains an error in the exponent to σ and in the numerical factor; the equation given here is correct in relation to the data reported in Ref. 15.

One main purpose of this study was to test whether real powders that do not contain spherical particles and do not (necessarily) adhere to assumptions (a)–(e) follow a cube root law and, if so, whether Eqs. 4 and 5 are applicable to the dissolution profiles. Benet (20) pointed out that in spite of the theoretical work published to date, no experimental work other than that of Higuchi *et al.* (14) has been published.

The information obtained from dissolution of powders can be valuable regarding the bioavailability of oral dosage forms in solid or suspension form. Carstensen (4), using data from Prescott *et al.* (21), showed the relationship between the mean diameter of an orally administered powder and the fraction of drug absorbed.

EXPERIMENTAL

The test substance used was oxalic acid dihydrate[2]. It was recrystallized by dissolving 100 g of oxalic acid in 200 ml of distilled water at 70° and cooling the solution at a rate of about 1°/10 min. This temperature was measured by a thermometer placed in the center of the beaker containing the solution. The temperature distribution by this procedure is very uneven (differing by as much as 15° between extreme points), giving rise to distributions that are somewhat off the log-normal distribution.

The suspension was allowed to stand for 24 hr at room temperature, and the crystals were then filtered off and air dried. The method produces crystals coarser than 70 mesh and as coarse as 4 mesh. The dried crystals were segregated into mesh fractions with USP sieves. To avoid vitrification[3], the fractions were stored in desiccators over saturated sodium chloride solution with excess sodium chloride (33% relative humidity). Oxalic acid dihydrate crystals of various mesh sizes were then blended in ratios that were log normal on a number basis.

The individual particle weights were obtained by weighing counted numbers of particles in each mesh fraction. A microscopic particle-size distribution was carried out on a random sample of particles from a −20/+30-mesh fraction. The density of oxalic acid was determined pycnometrically, using saturated oxalic acid solution as the liquid vehicle.

The general dissolution method was as follows. A 4-liter beaker was filled with 4 liters of 0.1 N HCl and placed on a magnetic stirrer setup[4] equipped with a Teflon-coated stirring bar, 36 mm long and 8 mm in diameter; the solution was stirred at 400 rpm. This agitation condition allows the crystals to be suspended, whereas lower speeds do not accomplish good dispersion of the solid after it is added. The liquid in the beaker was equilibrated in a water bath at 25.8°[5] in a room at 25 ± 0.2°. Immediately prior to the start of the dissolution experiment, the beaker was transferred to the magnetic stirrer; 80 g of oxalic acid dihydrate powder was then added and the timing was started.

Approximately 6-ml samples were removed by hypodermic syringe at various time points. After removal, the sample was emptied into a test tube, exactly 5 ml was removed, and the oxalic acid content was determined by titration with 0.05 N sodium hydroxide. In dissolution studies carried out at temperatures other than room temperature, the 0.1 N HCl was measured out to 4 liters at room temperature and its temperature was then adjusted to the test temperature. Approximately 6-ml samples were taken as before, but 5 ml was not removed until the sample reached room temperature.

The solubility of oxalic acid dihydrate in 0.1 N HCl was determined at various temperatures, and the determinations were made using a thermostated shaker bath[6].

The dissolution of a single crystal of oxalic acid was determined by placing it on a hemocytometer slide, adding 3 drops of 0.1 N HCl, and observing the length, L, and breadth of the crystal microscopically as a function of time.

RESULTS AND DISCUSSION

It was mentioned previously (1) that substances, when crystallized from solution, tend to have particle sizes with a truncated log-normal distribution. Oxalic acid, when recrystallized isothermally from water, indeed shows a log-normal particle-size distribution. By varying the temperature at which the crystals are allowed to grow, it is possible to alter the mean particle size and standard deviation. However, the magnitudes of the standard deviations are all close so that if it were desired to study the effect of the standard deviation of a powder sample on its dissolution pattern, then isothermally recrystallized powders do not offer an approach that will allow a sufficiently wide variation in the variable to permit data analysis. Such powders, however, dissolve in a cube root fashion as predicted previously (15–17). The dissolution of a sample of isothermally recrystallized oxalic acid with a log-normal distribution, with a mean of 250 μm and a standard deviation of σ = 0.13, is shown in Fig. 1.

It was predicted by computer simulation (15) that when σ is not excessively large, a cube root plot of amounts undissolved *versus* time should give a biphasic linear plot. The point where the two lines intersect occurs at the critical time, t_c, corresponding to the point in time where the smallest particle of the original powder sample has just dissolved completely. It is noted in Fig. 1 that the cube root plot is quite linear but does not appear to be biphasic; on the other hand, it does not intercept at the origin but rather at a positive y value. This result is due to the particles being too small (and the sample, in a relative sense, having too large a standard deviation) to allow detection of the initial phase.

Since attempts to grow particles of substantially larger mean diameters by isothermal recrystallization were not successful, larger crystals were grown nonisothermally. Log-normal populations were then obtained by sieving these coarser crystals and reblending the obtained fractions in ratios that were log normal on a number basis.

The data of numbers of particles from various mesh fractions used to produce these distributions are shown in Table I. The oxalic acid dihydrate crystals are not altogether regular in shape but appear microscopically to be parallelepipeds of length L and breadth B (Fig. 2).

A microscopic count from a −20/+30-mesh fraction is shown in Fig. 3. On the average, the length L is 2.7 times the breadth B. The volume, Q, is $LB^2 = 2.7B^3$, and the dimension is $\sqrt[3]{Q} = (2.7B^3)^{1/3} = 1.39B$ (Table II). The dimensions correspond well with the mesh

Table II—Number Distribution of Crystal Volumes in a −20/+30 Fraction of Nonisothermally Crystallized Oxalic Acid Dihydrate Crystals

Volume, (ml) × 10^{-3}	Dimension, $(Q/2.7)^{1/3}$, cm	Cumulative Percent	SD

1.5	0.082	75	+0.68
1.9	0.089	85	+1.04
2.3	0.095	95	+1.65

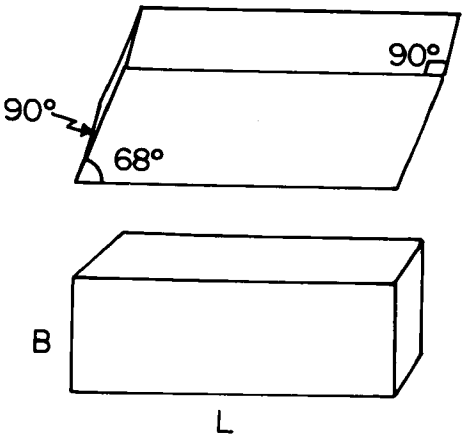

Figure 2—*Actual (top) and idealized (bottom) crystals of oxalic acid dihydrate.*

average (0.070 *versus* 0.0715 cm) and the mesh limits (0.048–0.095 cm). Furthermore, the average volume in Table II (0.73 × 10^{-3} ml) multiplied by the density of oxalic acid dihydrate (1.6 g/ml) gives a result fairly close to the correct weight per particle (1.2 *versus* 1.0 mg).

It is seen from Fig. 3 that the particles within the mesh fraction of a nonisothermally crystallized powder are fairly *normally* distributed[7]. Since the log-normally distributed powders are made by mixing mesh fractions in log-normal ratios, the powders can only be claimed to be approximately log normal, since the distribution within the fractions themselves is normal[7]. Brooke (25) discussed the ramifications of the use of mean mesh size diameters on the results of cube root dissolution.

One assumption made in deriving both Eqs. 4 and 5 is that the particles dissolving are isometric; *i.e.*, the surface area, O, can be related to the volume, Q, by:

$$O = \gamma(Q)^{2/3} \qquad \text{(Eq. 6)}$$

If, as seen in Fig. 2, the volume $Q = LB^2$ and the surface $O = 2B^2 + 4BL$, then Q and O cannot be placed in a relationship as dictated by Eq. 6 without involving B and L. For an isometric shape, *e.g.*, a sphere, the relationship in Eq. 6 is obtained without involvement of dimensions [the factor γ being $(36\pi)^{1/3}$ for a sphere].

It was found microscopically that $L = 2.7B$ on the average. If this is the case throughout the dissolution, then $Q = 2.7B^3$ and $O = 2B^2 + 10.8B^2 = 12.8B^2$. This would lead to $O/[Q^{2/3}] = 10.3$, independent of B or L, so that the particles can be considered isometric only if the ratio stays constant at 2.7 during the dissolution.

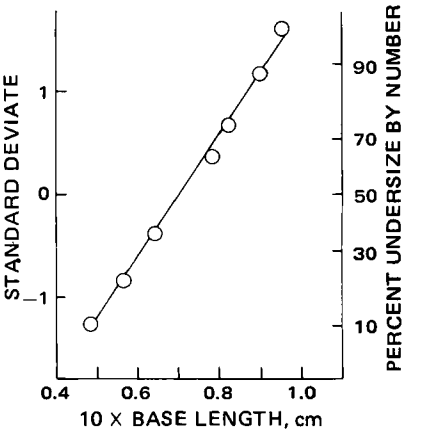

Figure 3—*Distribution of* B *values of oxalic acid dihydrate crystal of a −20/+30-mesh fraction.*

[7] This result is due to the fact that the −20/+30 cut is close to the "mean" of the nonisothermally recrystallized sample. Other cuts may be of a triangular distribution.

Table III—Results from Three Different Runs under Identical Experimental Conditions (Mean = 1050 μm, σ = 0.21)

Seconds	$-\Delta\sqrt[3]{W}$, g$^{1/3}$, Run 1	$-\Delta\sqrt[3]{W}$, g$^{1/3}$, Run 2	$-\Delta\sqrt[3]{W}$, g$^{1/3}$, Run 3	$-\Delta\sqrt[3]{W}$, g$^{1/3}$, Average	Letter Designation in Fig. 5
15	0.43	0.40	0.49	0.44	A

40	1.31	1.24	1.21	1.25	C
50	1.59	1.50	1.53	1.54	D
60	1.83	1.72	1.72	1.76	E
70	2.11	2.00	1.95	2.03	F
80	2.30	2.15	2.13	2.20	G
90	2.48	2.33	2.30	2.37	I
105	2.70	2.54	2.55	2.60	H
120	2.91	2.85	2.79	2.85	J

It was stated previously (15, 16) that the particles should dissolve isotropically (*i.e.*, the dissolution rate constants should be independent of the face of the crystal). This assumption is, however, not rigid, as will be shown. As noted in Fig. 2, there are four surfaces with an area of size LB^2. A decrease in B is due to dissolution from the sides of area LB, so the dissolution rate constant for these faces is denoted k_B. Similarly, there are two sides with areas of size B^2 and a dissolution rate constant of k_L, so that dissolution from the crystal occurs with the rate:

$$-dm/dt = [4k_BLB + 2k_LB^2]C_s \qquad \text{(Eq. 7)}$$

If the length-to-breadth ratio is now denoted as $f = L/B$, then Eq. 7 may be written:

$$-dm/dt = B^2[4k_Bf + 2k_L]C_s \qquad \text{(Eq. 8)}$$

Since $Q = LB^2 = fB^3$, it follows that $-(dm/dt) = -\rho(dQ/dt) = -3\rho fB^2(dB/dt)$, so the equation becomes:

$$-dB/dt = [4k_Bf + k_L]/(3\rho f) \qquad \text{(Eq. 9)}$$

For Eqs. 4 and 5 to be structurally correct, dB/dt must be constant, which it is if f is time independent, *i.e.*, if the particle is isometric throughout the dissolution. It is granted that this isometry is related to it being isotropic, but it is fairly easy to check the constancy of f by conducting a dissolution rate experiment on a single crystal under the microscope. The results of such experiments are shown in Fig. 4; the dimensions decrease linearly with time, implying that $[4k_Bf + 2k_L]/(3\rho f)$ is time independent. The original f value is 0.12/0.045 = 2.7; after 100 sec (when 67% of the crystal is dissolved), the ratio is 0.09/0.03 = 3, *i.e.*, not much different.

The first dissolution rate experiment was carried out at one particular standard deviation and one particular mean. It was carried out three times to check reproducibility and to allow statistical evaluation of the critical time (Table III and Fig. 5). Visual examination of Fig. 5 supports the predicted biphasic nature of the cube root plots and of the existence of critical times. To show this result in a more quantitative manner, the three sets of experiments in

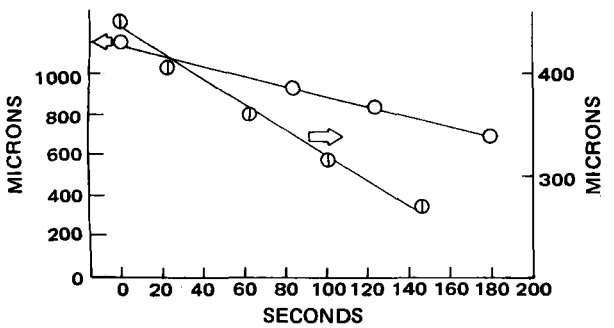

Figure 4—*Dissolution of single crystal of oxalic acid dihydrate at 25° in 0.2 ml of 0.1* N *HCl as determined microscopically. Left axis is length,* L, *of crystal; right axis is breadth,* B, *of crystal.*

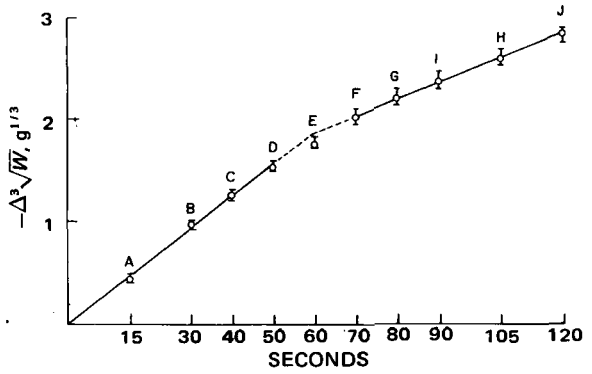

Figure 5—*Results from three different runs under identical experimental conditions; mean = 1050 μm and* SD = *0.21.*

Table III were subjected to statistical analysis. A linear regression analysis with nonzero intercept was carried out on the first four points (A, B, C, and D), and it was shown that the intercept was not significantly different from zero. The points were then fitted by least-squares fitting, and the following equation ensued:

$$-\Delta\sqrt[3]{W} = (0.0308 \pm 0.0014)t \qquad \text{(Eq. 10)}$$

The data points F, G, H, I, and J were then fitted by least-squares fitting, and the observed equation was:

$$-\Delta\sqrt[3]{W} = 0.0163t + 0.894 \qquad \text{(Eq. 11)}$$

By equating Eq. 11 with Eq. 10, one obtains: (*a*) the lower limit for t_c = 56 sec, (*b*) the average value for t_c = 62 sec, and (*c*) the upper limit for t_c = 68 sec.

To show that the curve *is* biphasic, an alternative fit to the set of data was considered. This fit was a monophasic smooth curve, namely a power function of the type $y = ax^n$. The data were fitted to this equation by the method of least squares (Table IV), and the least-squares fit was found to be:

$$\tilde{y} = -\Delta\sqrt[3]{W} = 0.0455t^{0.882} \qquad \text{(Eq. 12)}$$

If this curve is a proper type with which to fit the data, then the deviations from the actual points (y values) to those of Eq. 12 should alternate in sign in fairly random fashion as shown by Durbin and Watson (26). It can be seen from Table IV that this is not the case; six negative deviations occur followed by three positive. A similar argument holds for other smooth curves tested ($[1/y] = a[1/x] + b$ and $y = a[1 - \exp(bx)]$).

In general, in the following, t_c values were obtained in this fashion; the cutoff points between the "first" and "last" points were always determined visually at first and then justified by inclusion of an extra point and demonstration of an increase in the residual sum of squares divided by $n - 2$ (s_{yx}^2). The t_c values obtained in this fashion are ±10%.

Equation 5 may be written:

$$1 - \sqrt[3]{(W/W_0)} = \exp(c\sigma_D^2)\frac{2kC_s}{\rho M}t \qquad \text{(Eq. 13)}$$

This equation will be called a "reduced" form in the following discussion. Equation 4, of course, can be written in reduced form as

Table IV—Points in Fig. 5 Plotted as a Power Function: $\tilde{y} = -\Delta\sqrt[3]{W} = 0.0455t^{0.882}$

120	3.103	2.85	+0.253

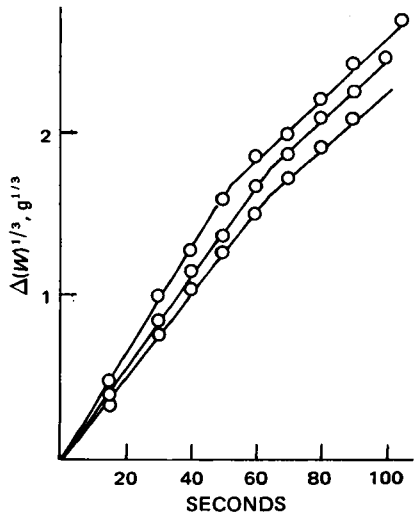

Figure 6—*Dissolution pattern of oxalic acid dihydrate of geometric mean 1500 μm and* SD *0.108 (top), 0.129 (middle), and 0.155 (bottom).*

well. According to this form, lines drawn according to the reduced equations should have slopes independent of the initial weight. To test this assumption, dissolution experiments were carried out with different amounts of oxalic acid dihydrate. The results are listed in Table V; the calculated rate constants are quite independent of the initial amount of solid.

Dissolution rate tests were performed at 25° on powders of identical mean diameter but with different standard deviations (Fig. 6). The slopes of the lines, after division by $\sqrt[3]{W_0}$ (=4.3), should, according to Eq. 13, follow the equation:

$$\ln [\text{slope}/\sqrt[3]{W_0}] = c\sigma_D^2 + \ln (2kC_s/[\rho M]) \quad \text{(Eq. 14)}$$

The plot of the data in Fig. 6 according to Eq. 14 are shown in Fig. 7; the linearity is obvious, and the least-squares fit line of Fig. 7 is:

$$\ln [\text{slope}/\sqrt[3]{W_0}] = -3.07\sigma_D^2 - 4.744 \quad \text{(Eq. 15)}$$

According to Brooke (16, 17), $c = -2.54$, so that both the linearity of Fig. 7 and the numerical value (2.54 being close to 3.07) support his equation. Knowledge of the values of C_s, ρ, and M allows calculation of k from the intercept of Fig. 7; *i.e.:*

$$\ln [2kC_s/(M\rho)] = -4.744 \quad \text{(Eq. 16)}$$

Inserting the values $\rho = 1.60$ g/ml, $C_s = 0.157$ g/ml, and $M = 0.15$ cm gives:

$$k = 6.7 \times 10^{-3} \text{ cm/sec} \quad \text{(Eq. 17)}$$

Equation 14 may be written:

$$\ln [\text{slope}/\sqrt[3]{W_0}] = \ln (1/M) + c\sigma_D^2 + \ln (2kC_s/\rho) \quad \text{(Eq. 18)}$$

To test this equation, dissolution rate studies were conducted at 25° with samples of oxalic acid dihydrate having the same standard deviation and different means (Fig. 8). This plot is a straight

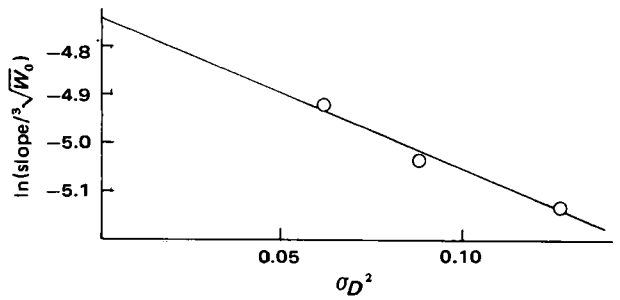

Figure 7—*Plot of weight-independent cube root slope* versus *variance of particle population.*

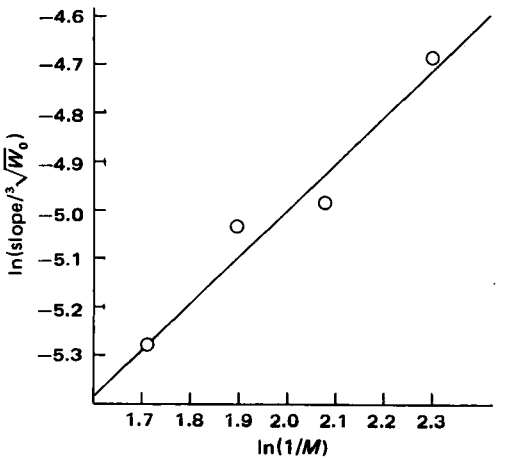

Figure 8—*Plot of weight-independent cube root slope* versus *reciprocal of geometric mean diameter.*

line as predicted by Eq. 18; it has a slope of 0.94 and should have a slope of unity.

Using the value of c from Fig. 7 ($c = -3.07$) and the value of the intercept from Fig. 8 (−6.8752), one can now calculate k, since:

$$c\sigma_D^2 + \ln (2kC_s/\rho) = -6.8752 \quad \text{(Eq. 19)}$$

Inserting the values for c, C_s, ρ, and $\sigma_D = 0.3569$, one obtains:

$$k = 7.8 \times 10^{-3} \text{ cm/sec} \quad \text{(Eq. 20)}$$

Table V shows that the average weight-independent slopes of powders with a mean diameter of 1500 μm and a variance of $\sigma_D^2 = 0.0618$ have a value of 7.16×10^{-3} sec^{-1}. Use of Eq. 14 and $c = -3.07$ gives a value of k of:

$$k = 6.7 \times 10^{-3} \text{ cm/sec} \quad \text{(Eq. 21)}$$

Although they are not identical, the three k values in Eqs. 17, 20, and 21 are of the same order of magnitude. This result supports the views stated in this report.

According to Eq. 5, the slope, α, of a cube root plot is given by:

$$\alpha = \{\exp[c\sigma_D^2]\}\sqrt[3]{W_0}\,2kC_s/(\rho M) \quad \text{(Eq. 22)}$$

Inserting $c = -3.07$, $\sigma_D^2 = 0.0618$, $M = 0.15$ cm, $\rho = 1.60$ g/ml, and $\sqrt[3]{W_0} = 4.3$ g$^{1/3}$, one gets the simpler expression:

$$\alpha = 29.64kC_s \quad \text{(Eq. 23)}$$

The effect of temperature on dissolution is shown in Fig. 9 (and Fig. 4 for 25°). To examine the temperature dependence of α, it is

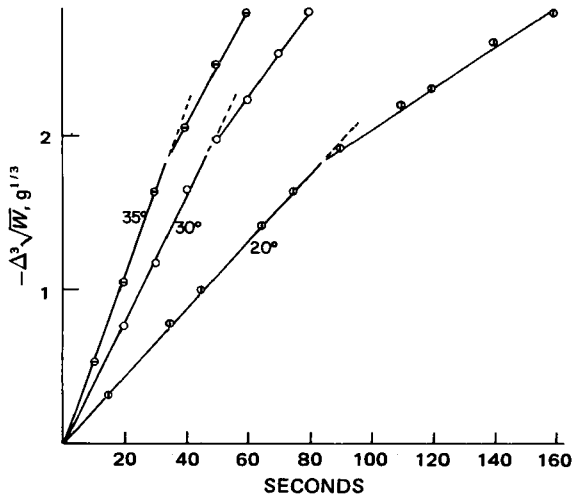

Figure 9—*Cube root plots as a function of temperature; mean = 1500 μm and* SD *= 0.108. The 25° data are shown in Fig. 4.*

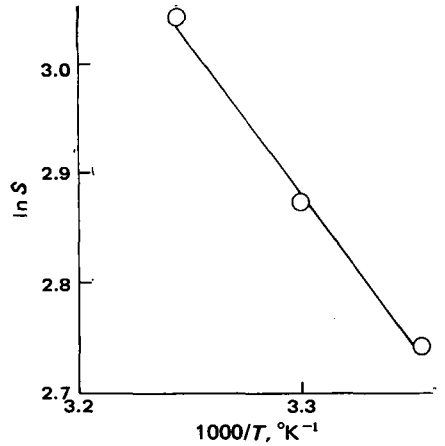

Figure 10—*Solubility–temperature plot of oxalic acid dihydrate.*

necessary to know the temperature dependence of C_s and k; C_s was determined experimentally at various temperatures (Fig. 10). The least-squares fit of the line is:

$$\ln C_s = -\frac{2751}{T} + 7.355 \qquad \text{(Eq. 24)}$$

where C_s is expressed as grams per milliliter. If the viscosity of the dissolving medium (here assumed to be equal to the viscosity of water) is denoted η and r is the radius of the dissolved molecule, then the Stokes–Einstein equation requires that:

$$k = \frac{1.38 \times 10^{-16} T}{hr6\pi\eta} \qquad \text{(Eq. 25)}$$

From Eqs. 23 and 25, the following expression is obtained:

$$\alpha = [(29.64)(1.38 \times 10^{-16})/6\pi]\, C_s T/(hr\eta) = 2.17 \times 10^{-16} C_s T/(hr\eta) \qquad \text{(Eq. 26)}$$

It is noted that (hr) is an unknown quantity. If it is assumed to be temperature independent over the temperature range studied, then:

$$\ln(\alpha/T) = -\ln(\eta) + \ln C_s + \ln[2.17 \times 10^{-16}/(hr)] = -\ln(\eta) + \ln C_s - \ln(hr) - 36.07 \qquad \text{(Eq. 27)}$$

The temperature dependence of the viscosity of water is:

$$\eta = 1.01 \times 10^{-5} \exp(2002/T) \qquad \text{(Eq. 28)}$$

or:

$$\ln(\eta) = 2002\,(1/T) - 11.434 \qquad \text{(Eq. 29)}$$

Inserting Eqs. 24 and 29 into Eq. 27 gives:

$$\ln(\alpha/T) = -\frac{4737}{T} - 17.29 - \ln(hr) \qquad \text{(Eq. 30)}$$

The data from Fig. 9 are plotted according to Eq. 30 in Fig. 11 and the linearity is obvious. The least-squares fit is:

$$\ln(\alpha/T) = -\frac{4760}{T} + 6.756 \qquad \text{(Eq. 31)}$$

That the slopes are identical is evident, although the proximity of the two values in Eqs. 30 and 31 is accidental. Experimental error is such that agreement to within 10% is considered adequate.

Table V—Dissolution with Various Amounts of Initial Powder, W_0, of a Powder with Mean Diameter of 1500 μm and *SD* 0.108 in 0.1 *N* HCl at 25°

W_0, g	$W_0^{1/3}$, $g^{1/3}$	Slope, $g^{1/3}$/sec	Slope/$(W_0^{1/3})$, sec^{-1}
80	4.3	0.0313	$7.28\ 10^{-3}$
70	4.12	0.0281	$6.84\ 10^{-3}$
60	3.91	0.0286	$7.31\ 10^{-3}$
50	3.68	0.0263	$7.15\ 10^{-3}$

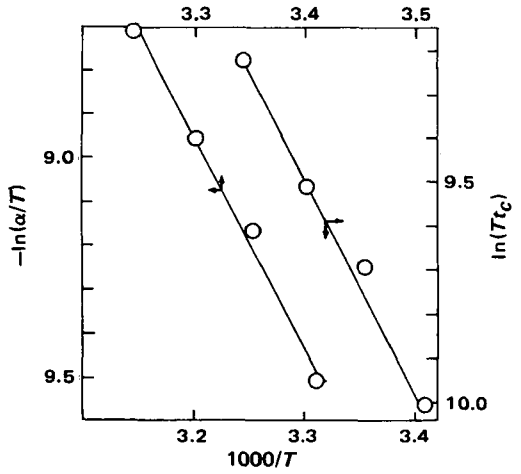

Figure 11—*Arrhenius plots of slope divided by absolute temperature (left) and critical time multiplied by absolute temperature (right).*

The intercept from Eq. 31 equals that from Eq. 30, so:

$$6.76 = 17.29 - \ln(hr) \qquad \text{(Eq. 32)}$$

i.e., $\ln(hr) = -24.05$, so that:

$$hr = \exp(-24.05) = 4 \times 10^{-11} \qquad \text{(Eq. 33)}$$

Since r is of the order of 10^{-8}–10^{-7} cm, h would be of the order of 40–4 μm, which is of the expected order of magnitude (3).

Carstensen and Musa (15) showed that the critical time is given in terms of the smallest diameter, a_0, by:

$$t_c = a_0\rho/(2kC_s) \qquad \text{(Eq. 34)}$$

so that Arrhenius plots of t_cT should have the same numerical slope with opposite sign as Arrhenius plots of α/T. This is the case, as demonstrated in Fig. 11. The definition of a_0 for an actual crystal is vague, and the fact that allows comparison is that all of the powders in Fig. 11 have the same particle distribution and, hence, the same a_0 by whatever definition.

SUMMARY

1. The experimental data presented here demonstrate that initially a powder with log-normal distributed dimensions will dissolve under sink conditions *via* a cube root law as predicted previously (15–17). The plots eventually are biphasic.

2. The dependence of the slopes of the cube root plots on the mean diameter and on weight is as described previously (15).

3. The dependence of the slopes of the cube root plots on the standard deviation of the powder distribution is as described previously (17).

4. The temperature dependence of the slopes of the cube root and of the critical times was derived theoretically and substantiated by experiment.

Controlled Drug Release from Polymeric Delivery Devices III: *In Vitro–In Vivo* Correlation for Intravaginal Release of Ethynodiol Diacetate from Silicone Devices in Rabbits

YIE W. CHIEN [*x], STANLEY E. MARES [‡], JOHN BERG [‡], SUSAN HUBER [‡], HOWARD J. LAMBERT [*], and KENNETH F. KING [§]

Abstract □ Forty female rabbits were implanted with silicone vaginal devices containing ethynodiol diacetate for up to 8 weeks. As predicted from *in vitro* studies, a $Q - t^{1/2}$ (matrix-controlled) release profile was observed *in vivo*. The *in vivo* drug release profile was compared with *in vitro* data measured at three hydrodynamic conditions, and the diffusional resistance across the vaginal wall was estimated. Drug released from silicone devices yielded a prolonged plasma level when compared with data following intravaginal or intravenous administration of a solution dose. The rate constant for elimination was unchanged. The plasma concentration of the drug was related to the intravaginal drug release profile both theoretically and experimentally and was above the concentration required to inhibit fertilization.

Keyphrases □ Drug delivery systems—controlled release, polymeric devices, ethynodiol diacetate in silicone matrix, *in vitro–in vivo* correlation of intravaginal release, rabbits □ Ethynodiol diacetate—intravaginal release from silicone matrix, *in vitro–in vivo* correlation, rabbits □ Silicone matrix—ethynodiol diacetate delivery system, *in vitro–in vivo* correlation for intravaginal release, rabbits □ Vaginal devices—controlled release of ethynodiol diacetate from silicone matrix, *in vitro–in vivo* correlation, rabbits

An *in vitro* drug release system, which allows a direct and rapid characterization of a drug release profile and mechanism, was recently reported from this laboratory (1). Two types of drug release mechanisms, matrix controlled and partition controlled, were observed when the drug release profiles of ethynodiol diacetate from silicone devices were followed daily in this system (2).

To develop a device with a desirable, long-acting, drug release profile, it is necessary to examine intravaginal drug release mechanisms in animals to establish an *in vitro–in vivo* correlation. This paper reports results of drug release studies with silicone devices containing ethynodiol diacetate placed in the vaginal tracts of 40 rabbits for up to 8 weeks.

EXPERIMENTAL

***In Vitro* Release Studies**—The apparatus for *in vitro* drug release studies and the assay of drug samples were essentially the same as those reported previously (1). The ring-shaped silicone device, containing 112.6 mg/cm^3 of ethynodiol diacetate[1], was mounted in the arms of a Plexiglas holder and then rotated at 81 or 30 rpm or held stationary (to simulate more closely the status of implants in the vaginal lumen) in 150 ml of a 75% polyethylene glycol 400 solution as the elution medium at 37°. The solution was mixed well prior to sampling, and the drug concentration in the medium was assayed daily (1, 2). The reproducibility of the *in vitro* $Q/t^{1/2}$ profiles measured at various dates within 1 year was excellent (Table I).

***In Vivo* Release Studies**—The same silicone devices as those used in the *in vitro* drug release studies were cut into sections of 1 cm in length. One segment was inserted into the anterior vagina of each of 40 young adult New Zealand white female rabbits *via* a midventral laparoelytrotomy. It was anchored with a single polyethylene suture knotted on one side of the implant (through the implant perpendicular to the long axis) and then drawn through the vaginal wall and knotted to a 1-cm section of medical-grade tubing[2].

Table I—Reproducibility of *In Vitro* Release Profiles ($Q/t^{1/2}$) of Ethynodiol Diacetate from Silicone Vaginal Devices[a]

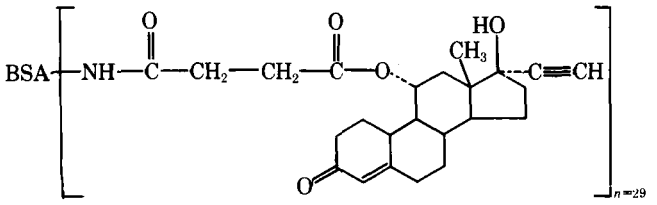
Experiments	Age of Devices, days	$Q/t^{1/2}$, mg/cm²/day$^{1/2}$
121	Initial	3.40
122	312	3.135
123	312	2.985
124	312	2.966
127	331	3.34
Mean (±*SD*) = 3.1652 (±0.185)		

[a] Intravaginal devices were rotated at constant 81 rpm in 150 ml of 75% polyethylene glycol 400 at 37°.

At various intervals, three to six rabbits were sacrificed. The implants were removed, cut into thin slices, and extracted by constant shaking for 2 days in 25 ml of spectral grade methanol. Drug content in the methanolic solution was assayed spectrophotometrically as described earlier (1, 2), and residual drug content was calculated. The results on the residual drug content and the amount of drug released per unit area are shown in Table II.

Radioimmunoassay—Tokuda *et al.* (3) reported that the stepwise hydrolysis of the acetate moieties of ethynodiol diacetate gives its 3β,17β-diol metabolite. This metabolite is rapidly transformed to the 3-keto derivative, norethindrone (Table III), the major metabolite of ethynodiol diacetate.

Preparation of 11α-Hydroxynorethindrone–Bovine Serum Albumin Conjugate—The hemisuccinate of 11α-hydroxynorethindrone was prepared first and then conjugated to bovine serum albumin (BSA). Analysis of the conjugate by UV spectroscopy and nitrogen analysis indicated that each conjugate molecule was composed of 29 steroid molecules to one bovine serum albumin molecule with the following chemical structure:



Preparation of Antiserums—New Zealand rabbits were immunized with norethindrone–bovine serum albumin conjugate by the technique described by Vaitukaitus *et al.* (4). The resultant antiserums were characterized, divided into several small aliquots, and stored at −80°.

Immunoassay Procedure—The assay was carried out in glass tubes (12 × 75 mm), and 0.1% gelatin–phosphate buffer (0.05 *M* phosphate and 0.15 *M* NaCl at pH 7.5) was utilized as the diluent for all dilution preparations of antiserums, standards, and samples. To each tube, 10,000 dpm of 1,2-^{3}H-norethindrone (20 Ci/mmole), 200 μl of diluted antiserum (capable of binding 40% of the labeled antigen added), and 20 μl of sample serum (to calibrate the standard curve, 20 μl of control rabbit serum and 10–1000 pg of crystalline norethindrone were used instead) were added and mixed (vortex).

Duplicate sets of the binding mixture were prepared and incubated at 4° for 12 hr. Antibody-bound antigen was then separated from the unbound antigen by the addition of 0.5 ml/tube of dextran-coated charcoal (prepared from 50 mg of dextran[3] and 500 mg of charcoal in 50 ml of phosphate buffer). The mixtures were immediately mixed and then centrifuged at 2000×*g* and 4° for 10 min. The resultant supernate was mixed with 15 ml of scintillator[4] in glass vials of low background. The radioactivity of each sample was then determined[5].

Conversion of counts per minute to disintegrations per minute was accomplished by the external standard channel ratio method. Disintegrations per minute data were evaluated and converted to the corresponding drug concentration by a computer program utilizing a logit–log transformation of standards.

Table II—Intravaginal Release of Ethynodiol Diacetate from Silicone Devices Implanted in Rabbits

Days[a]	Number of Rabbits	Amount of Drug Remaining in Devices, mg (±*SD*)	Cumulative Amount of Drug[b] Released per Square Centimeter, mg/cm² (±*SD*)
Initial	—	30.428 (0.83)	0.0
7	3	25.948 (2.40)	2.239 (0.97)
14	3	17.660 (0.78)	5.210 (0.32)
25	5	13.964 (3.80)	6.720 (1.60)
42	6	4.997 (6.70)	10.380 (2.70)
49	4	0.083 (0.09)	12.386 (0.04)
52	4	1.238 (0.38)	11.914 (0.15)

[a] Five rabbits were implanted with devices (containing no ethynodiol diacetate) and sacrificed at various dates as the references. [b] Total surface area of the device used is 2.45 cm² each.

A measure of the accuracy of the immunoassay technique is illustrated in Fig. 1. Crystalline norethindrone was added to control rabbit serum and assayed as an unknown. A linear relationship was observed between added and recovered norethindrone, with a tendency for overestimation at high concentrations.

The specificity of the anti-11-hydroxynorethindrone antiserum was demonstrated by examining its cross-reactivity with ethynodiol diacetate and its seven major metabolites. As shown in Table III, this antiserum specifically reacted only with norethindrone.

The cross-reactivity of 11-hydroxynorethindrone antiserum to progesterone, 20α-hydroxyprogesterone, estradiol, corticosterone, hydrocortisone, and testosterone was also examined. These common steroids showed no cross-reactivity except for testosterone, which has a cross-reactivity of only 0.15%.

RESULTS AND DISCUSSION

***In Vivo* Drug Release Studies**—The intravaginal drug release data (Table II) indicate that the longer the period of implantation, the lower the drug content in the device and the greater the quantity of drug released. If the release of ethynodiol diacetate from the silicone vaginal devices implanted in the vaginal tract of rabbits is assumed to be predominately matrix controlled (1) and not partition controlled (2), then the cumulative amount of drug released (Q) in a rabbit's vagina should be defined by:

$$Q = \sqrt{D_m(2A - C_s)C_p t} \qquad \text{(Eq. 1)}$$

where Q is the cumulative amount of drug released from a unit surface area of device (grams per square centimeter); A is the initial amount of solid drug impregnated in a unit volume of device

(grams per cubic centimeter); D_m is the effective diffusivity of the drug species in the matrix; C_s and C_p are the solubilities of the drug in the elution medium and in the silicone polymer phase, respectively; and t is time.

According to Eq. 1, the cumulative amount (Q) of ethynodiol diacetate released from a unit surface area of device should be linearly proportional to the square root of the implantation time ($t^{1/2}$) as shown in Fig. 2. By using Eq. 2:

$$Q/t^{1/2} = \sqrt{D_m(2A - C_s)C_p} \qquad \text{(Eq. 2)}$$

the intravaginal $Q/t^{1/2}$ profile was estimated from the slope of the Q *versus* $t^{1/2}$ plot to be 2.10 mg/cm^2/day$^{1/2}$.

The drug molecules released from the silicone vaginal device are presumably dissolved in the vaginal fluid surrounding the implanted device. They are then transported across the vaginal membrane

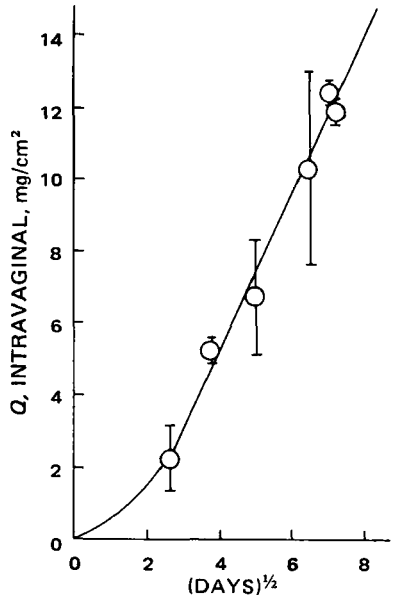

Figure 2—*Linear relationship between the cumulative amount of drug released* (Q) *in the rabbit's vagina and the square root of time* ($t^{1/2}$) *following Eq. 1. The data in Table II (fourth column) were plotted. The* $Q/t^{1/2}$ *value for this intravaginal device was calculated from the slope, following Eq. 2, as 2.10 mg/cm*^{2}*/day*$^{1/2}$.

into a biological sink maintained by hemoperfusion. In such a case, the rate of drug permeation (dQ'/dt) across the vaginal membrane (with an aqueous diffusion layer on each side of the membrane) should be directly proportional to the drug concentration (C_v) in the vaginal fluid (as the driving force for drug permeation) and inversely proportional to the total diffusional resistance (ΣR) encountered by the drug molecules along the way across the vaginal wall:

$$\frac{dQ'}{dt} = \frac{C_v}{\Sigma R} \qquad \text{(Eq. 3)}$$

The total diffusional resistance (5) is the sum of the diffusional resistances as follows:

$$\Sigma R = R_l + R_v + R_c \qquad \text{(Eq. 4}a\text{)}$$

where R_l and R_c are the diffusional resistances across the aqueous diffusion layer on the luminal side and on the circulation side of the vaginal membrane, respectively; and R_v is the diffusional resistance across the vaginal membrane itself. Equation 4*a* is equivalent to:

$$\Sigma R = \frac{\delta_l}{D_l K_{l/l}} + \frac{\delta_v}{D_v K_{v/l}} + \frac{\delta_c}{D_c K_{c/v}} \qquad \text{(Eq. 4}b\text{)}$$

where δ, D, and K represent the thickness, diffusivity, and partition coefficient across two contacting phases, respectively; and the subscripts v, l, and c stand for vaginal membrane and the aqueous diffusion layers on the luminal and the circulatory hemoperfusion sides of the vaginal barrier, respectively.

The instantaneous rate of drug release at time t may be derived by differentiating Eq. 1 with respect to time:

$$\frac{dQ}{dt} = \frac{1}{2}\sqrt{D_m(2A - C_s)C_p/t} \qquad \text{(Eq. 5)}$$

At steady state, the rate of drug release (dQ/dt) should be equal to the rate of drug permeation (dQ'/dt). Equating Eq. 3 with Eq. 5 yields Eq. 6:

$$\Sigma R[D_m(2A - C_s)C_p]^{1/2} = 2C_v(t)^{1/2} \qquad \text{(Eq. 6)}$$

Equation 6 indicates that the drug concentration (C_v) in the vaginal fluid decreases with the square root of time ($t^{1/2}$) as the drug molecules diffuse actively to a sink; that is, under a matrix-controlled process, the magnitude of $2C_v(t)^{1/2}$ is a constant since both ΣR and $[D_m(2A - C_s)C_p]^{1/2}$ are constants under a controlled con-

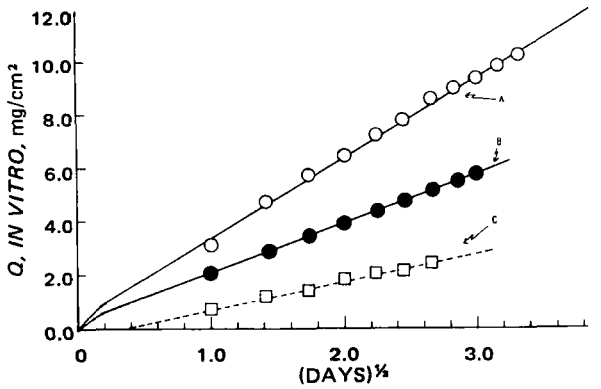

Figure 3—*Linear relationship between the cumulative amount of drug release (Q) and the square root of time ($t^{1/2}$) obtained from the* in vitro *drug release studies conducted at the rotation speed of 81 (A), 30 (B), and stationary state (0) (C) rpm. Each data point represents an average of three determinations. The slope ($Q/t^{1/2}$) was estimated as 3.1652 (A), 1.862 (B), and 1.065 (C) mg/cm²/day$^{1/2}$, respectively.*

dition. Equation 6 also states that the value of C_v is directly proportional to the magnitude of the total diffusional resistance (ΣR) when the same silicone vaginal device is implanted in a different animal with a different value of ΣR. Therefore, the greater the magnitude of ΣR, the higher the value of C_v since the intravaginal permeation of the drug is inhibited. The validity of Eq. 6 will be further analyzed later.

***In Vitro* Drug Release Studies**—A series of parallel *in vitro* drug release studies using similar devices was conducted at low rotation speed (81 or 30 rpm) and at a stationary state to simulate more closely the status of implants in the vaginal lumen. The *in vitro* release of ethynodiol diacetate followed a linear $Q - t^{1/2}$ relationship in all three cases (Fig. 3). The magnitude of the $Q/t^{1/2}$ values calculated for the rotating devices (Table IV, fourth column) are 2.97 (81 rpm) or 1.75 (30 rpm) times higher than that for a stationary one. Since D_m, A, C_s, and C_p were the same in all three *in vitro* studies, the 1.75–2.97-fold difference in the magnitudes of the $Q/t^{1/2}$ value between the rotating and the stationary devices indicates the existence of a rate-limiting parameter, *i.e.*, a hydrodynamic diffusion layer on the immediate surface of the devices.

When a device is immersed stationary in a solution, a diffusion layer is established on the immediate surface of the device. The effective thickness of this diffusion layer (6) varies with the square root of time as follows:

$$(\delta_l)s = \sqrt{D_l \pi t} \qquad \text{(Eq. 7)}$$

If this device is rotated at a constant speed, convection results. The convective transport of the drug to and from the device surface is much faster than when natural diffusion is operating on a stationary device, because the concentration gradient of drug extends over a thinner diffusion layer (7). The effective thickness of the diffusion layer on the rotating device becomes time independent and may now be defined by the Levich equation:

$$(\delta_l)r = 1.62 D_l^{1/3} v^{1/6} w^{-1/2} \qquad \text{(Eq. 8)}$$

where v and w represent the kinematic viscosity of the elution medium and the angular rotation speed of the silicone device, respectively; and the subscripts s and r stand for stationary and rotation states, respectively. This equation was developed originally for the relationship of the thickness of the convective diffusion layer at a rotating disk and also was successfully applied to the case of a polymeric membrane-covered rotating disk (8). Using Eq. 8, the magnitude of $(\delta_l)r$ on a rotation device can be calculated if D_l, v, and w are known or predetermined. The $(\delta_l)r$ values were calculated and are given in Table IV.

In the *in vitro* elution studies, the elution medium was maintained at sink conditions throughout the experiment. In this case, only the thickness of the hydrodynamic diffusion layer (δ_l) exists between the surface of the device and the bulk of the elution medium. Both the R_v and R_c terms in Eq. 4 may be dropped, and Eq. 4 may be reduced to:

$$\Sigma R = R_l = \frac{\delta_l}{D_l} \qquad \text{(Eq. 9)}$$

where $k_{l/l} = 1$ and Eq. 6 becomes:

$$\delta_l[D_m(2A - C_s)C_p]^{1/2} = 2D_l C_v(t)^{1/2} \qquad \text{(Eq. 10)}$$

Equation 10 indicates that at a given value of $2D_lC_v(t)^{1/2}$, the magnitude of $[D_m(2A - C_s)C_p]^{1/2}$ should be inversely proportional to the effective thickness, δ_l, of the diffusion path on the immediate surface of the silicone device. In other words, the larger the value of δ_l on a device, the less is the amount of drug released at a given time (the lower the magnitude of $Q/t^{1/2}$). This relationship is shown by the data of Table IV. For instance, the magnitude of $Q/t^{1/2}$ for the device rotating at 81 rpm (3.165 mg/cm²/day$^{1/2}$) is 1.7 times higher than that for the device rotating at 30 rpm (1.862 mg/cm²/day$^{1/2}$).

This difference in the magnitudes of $Q/t^{1/2}$ may be explained by comparing the value of δ_l for the device rotating at 81 rpm (154.7 μm) to that for the device rotating at 30 rpm (254.0 μm). The δ_l value for the higher rotating device (81 rpm) is 1.64-fold lower than that for the lower rotating one (30 rpm). When all other experimental conditions are the same, the thickness of the diffusion layer (δ_l) becomes the rate-determining parameter in the process of drug release (Eq. 10). The increase in the thickness of the diffusion layer, due to the reduction in the angular rotation speed of the device, tends to decrease proportionally the magnitude of $Q/t^{1/2}$.

***In Vitro–In Vivo* Correlation**—Analysis of the intravaginal drug release data (Fig. 2) yields an *in vivo* $Q/t^{1/2}$ value of 2.10 mg/cm²/day$^{1/2}$. This value is between those observed for the two *in vitro* rotation experiments (Table IV). Since the smooth muscle of the vaginal lumen shows a periodic constriction and dilatation, it may be assumed that the implanted silicone device was moved

Table IV—Comparison of *In Vivo* and *In Vitro* Data on $Q/t^{1/2}$

Conditions	n, rps	δ_l[a], cm × 10⁴	$Q/t^{1/2}$ Observed, mg/cm²/day$^{1/2}$
In Vitro			
81 rpm	1.328	154.7	3.165
30 rpm	0.500	254.0	1.862
Stationary	0.0	—	1.065
In Vivo, intravaginal			2.10

[a] Calculated from $\delta_l = 1.62 D^{1/3} v^{1/6} W^{-1/2} = 4.5027 \times 10^{-4} \times W^{-1/2}$, where $W = 2n\pi$.

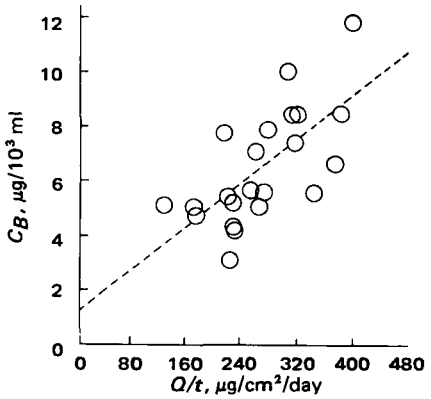

Figure 4—*Correlation between the plasma concentration (C_B) of norethindrone, the major metabolite of ethynodiol diacetate, in each rabbit and the flux (Q/t) of ethynodiol diacetate released from a silicone vaginal device at a given time. The slope = 1.96 (±0.49) × 10⁻⁵ day/cm, and the intercept = 1.199 × 10⁻³ μg/ml; F = 16.583 [F1, 20 (α = 0.01) = 8.10].*

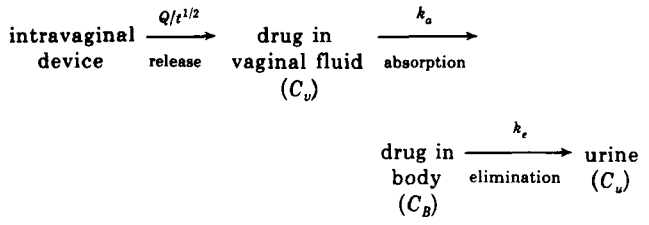

Scheme I

slightly in a periodic fashion. Therefore, a diffusion layer (δ_l) (on the lumen side of the vaginal wall) with an effective thickness smaller than 254 μm (slow rotation state) and larger than 154.7 μm (high rotation state) may be expected. Literature data do not allow the calculation of the total diffusional resistance term (ΣR) of Eq. 4. The absence of a known ΣR makes the prediction of *in vivo* release from *in vitro* data impossible. However, the data may be utilized to establish a proportionality between *in vivo* and *in vitro* $Q/t^{1/2}$ profiles. This proportionality should be equivalent to the ratio of *in vitro* diffusional resistance (R_l) over *in vivo* total diffusional resistance (ΣR) as follows:

$$\frac{R_l}{\Sigma R} = \frac{(Q/t^{1/2})\ in\ vivo}{(Q/t^{1/2})\ in\ vitro,\ 30\ rpm} = \frac{2.10}{1.862} = 1.13 \quad \text{(Eq. 11)}$$

Such a proportionality may be useful for predicting the magnitude of $(Q/t^{1/2})$ *in vivo* from the *in vitro* drug release profiles measured under controlled conditions (when R_l is constant).

Pharmacokinetics of Intravaginal Absorption—If the absorption, distribution, and elimination of ethynodiol diacetate after its release from an intravaginal device follow Scheme I, then the instantaneous rate of change in the body concentrations of drug may be expressed as:

$$\frac{d(C_B)}{dt} = k_a C_v - k_e C_B \quad \text{(Eq. 12)}$$

where k_a and k_e are the respective rate constants for absorption and elimination, and C_v, C_B, and C_u are the drug concentrations in the vagina, body (including blood, tissues and related compartments), and urine, respectively. Equation 12 may be transformed to Eq. 13 by substituting Eq. 2 into Eq. 6 and then for the C_v term in Eq. 12:

$$\frac{d(C_B)}{dt} = \left(\frac{k_a \Sigma R}{2}\right)\left(\frac{Q}{t}\right) - k_e C_B \quad \text{(Eq. 13)}$$

At steady state, the change in the body concentration of the drug will be very small, that is, $dC_B/dt \simeq 0$, and the body concentration of norethindrone (C_B), the major metabolite of ethynodiol diacetate (9), may be related to the amount of ethynodiol diacetate (Q) released at time (t) as follows:

$$C_B = \left(\frac{k_a \Sigma R}{2k_e}\right)\left(\frac{Q}{t}\right) \quad \text{(Eq. 14)}$$

Equation 14 states that the plasma concentration of norethindrone in each rabbit should be directly proportional to the flux of ethynodiol diacetate released from the vaginal devices (Q/t) at a given time. The result is illustrated in Fig. 4. When the correlation of C_B with Q/t was submitted to an F test, the analysis resulted in an F value of 16.583, indicating that the correlation was statistically significant at the 99% confidence level ($F1, 20\ [\alpha = 0.01] = 8.10$).

To inhibit fertilization effectively, a rabbit required a subcuta-

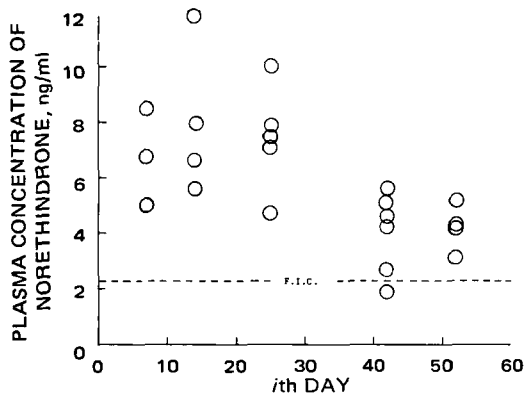

Figure 5—*Plasma concentration of norethindrone from each rabbit measured by radioimmunoassay at the time of sacrifice and removal of the intravaginal device. The fertilization inhibitory concentration (FIC) of 2.27 ng/ml, resulting from the daily subcutaneous injection of 30–50 μg of ethynodiol diacetate per rabbit for 6 days prior to mating and 1 day after reduced fertilization, is also shown. Most data resulting from the intravaginal absorption of ethynodiol diacetate in silicone devices are higher than the FIC required.*

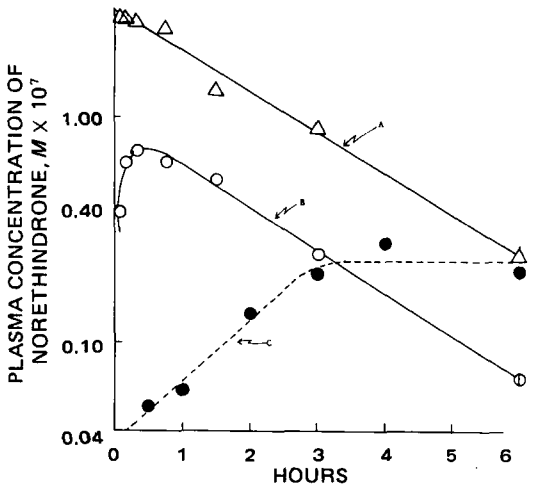

Figure 6—*Time course of plasma norethindrone concentration after the administration of a single solution dose (1 mg/0.2 ml) of norethindrone via intravenous injection (A) and ethynodiol diacetate via intravaginal absorption (B), and intravaginal absorption of ethynodiol diacetate from a silicone vaginal device (C) (A = 0.1126 g/cm³). The rate constants for absorption (k_a) are: 10.6 (B) and 0.244 (C) hr⁻¹. The rate constants for elimination (k_e) are 0.40 (A) and 0.42 (B) hr⁻¹.*

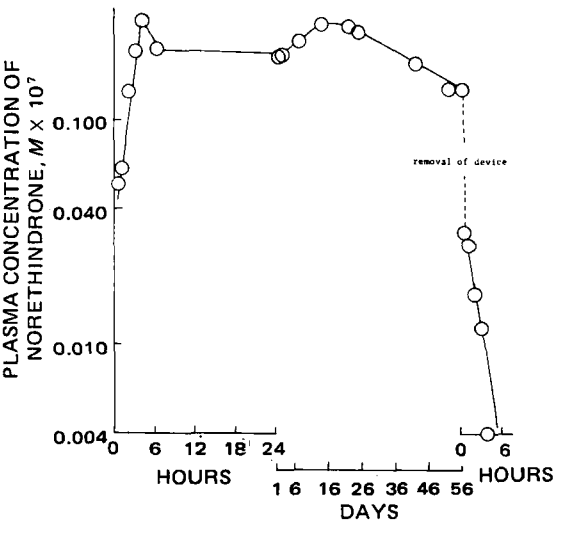

Figure 7—*Overall plasma norethindrone concentration profile after the intravaginal implantation of silicone devices containing ethynodiol diacetate in rabbits for up to 56 days. The k_a and k_e values are 0.244 and 0.511 hr⁻¹, respectively. The k_e value after the removal of the devices (elimination of the residual drug content in the body) is 0.436 hr⁻¹.*

Table V—Comparison of Calculated and Observed Plasma Concentrations of Norethindrone

Days	Plasma Concentration of Norethindrone, ng/ml: Calculated[a]	Observed[b]: Range	Observed[b]: Mean (±SD)	Observed/Calculated
22	8.77	6.15–9.41	7.78 (1.63)	0.89
56	5.49	2.32–7.42	4.12 (1.80)	0.75

[a] Calculated from $C_B = (k_a \Sigma R)/2k_e \times (1.13) \times (Q/t)$ *in vitro* = 22.11 (Q/t) *in vitro* (ng/ml). [b] Data of four to six rabbits for each scheduled interval.

neous dose of 30–50 μg/day of ethynodiol diacetate for 6 days prior to and 1 day after mating. These doses normally resulted in a maximum plasma concentration of 2–3 ng/ml of norethindrone in a 4-kg rabbit. The latter concentration is referred to as the fertilization inhibitory concentration (FIC). As shown in Fig. 5, the release of ethynodiol diacetate from implanted silicone devices resulted in a plasma concentration of norethindrone well above the required FIC. This concentration was maintained for up to 8 weeks.

The plasma norethindrone profile after the intravaginal absorption of ethynodiol diacetate from a solution dose of 1 mg/0.2 ml is compared to the profile after an intravenous injection of an equivalent dose of norethindrone in Fig. 6. As illustrated, the intravaginal dose of ethynodiol diacetate (curve B) was rapidly absorbed ($k_a = 10.6\ hr^{-1}$) and showed a peak plasma level of norethindrone within 20 min after administration. The observed elimination rate constant ($k_e = 0.42\ hr^{-1}$) agreed with the value of $0.40\ hr^{-1}$ found for the intravenous dose of norethindrone (curve A) in the same animal. From the ratio of the area under the curve (AUC) for intravaginal absorption over that for the intravenous dose, the availability of norethindrone from an intravaginal dose of ethynodiol diacetate was calculated to be 34.76%.

The plasma level of norethindrone following intravaginal absorption from a vaginal device containing ethynodiol diacetate is also shown in Fig. 6 (curve C). The rate of appearance of drug in plasma was sustained (C in Fig. 6), and the plasma level of norethindrone was significantly prolonged (Fig. 7). After removal of the device, the residual drug content in the body (Fig. 7) was eliminated with a rate constant ($0.436\ hr^{-1}$) comparable to those seen after the intravenous and intravaginal administrations.

Figure 7 illustrates the overall plasma norethindrone concentration profile after the implantation and removal of the silicone vaginal devices. A prolonged drug level was maintained for up to 56 days. After the removal of the device, the residual plasma drug content was eliminated as fast as after a solution dosage.

The rate constants for absorption ($k_a = 10.6\ hr^{-1}$) and for elimination ($k_e = 0.42\ hr^{-1}$), determined earlier from the intravaginal absorption study of a solution dose of ethynodiol diacetate, may be applied into the slope ($k_a \Sigma R/2k_e$) of the C_B *versus* Q/t profile to estimate the total diffusional resistance (ΣR) across the vaginal membrane of the rabbit:

$$\Sigma R = \frac{\delta_l}{D_l k_{l/l}} + \frac{\delta_c}{D_c k_{v/l}} + \frac{\delta_c}{D_c k_{c/v}} \quad \text{(Eq. 15a)}$$

$$= \frac{2ke \times 1.96 \times 10^{-5}}{k_a} \quad \text{(Eq. 15b)}$$

$$= 1.55 \times 10^{-6}\ \text{day/cm} \quad \text{(Eq. 15c)}$$

The resultant ΣR value will be useful as a working factor for predicting plasma norethindrone levels (C_B) from the *in vivo* release profile (Q/t) of ethynodiol diacetate (using Eq. 14). The *in vivo* $Q/t^{1/2}$ value may be estimated from *in vitro* drug release data after a correction factor of 1.13 is made (Eq. 11). This information should facilitate the future development of a suitable long-acting delivery system, directly from short-term *in vitro* drug release experiments, for the vaginal administration of ethynodiol diacetate. For instance, based on a 1-week *in vitro* experiment, it was predicted that a plasma concentration of norethindrone at 8.77 and 5.49 ng/ml will be found after 22- and 56 days of implantation, respectively (Table V). Intravaginal implantation of such devices in 10 rabbits for 22 and 56 days resulted in a plasma concentration of 7.78 (±1.63) and 4.12 (±1.80) ng/ml, respectively (Table V).

In conclusion, in developing a long-acting delivery system for a given drug, a study should be performed to evaluate the *in vitro–in vivo* correlation of both the mechanisms and the rates of drug release. This study should also measure the pharmacokinetic parameters for the absorption, distribution, and elimination of the drug *via* a given route of administration. The information so gained can then be applied to additional studies to develop a device that delivers the drug at a programmed rate, thereby maintaining constant plasma drug levels for an optimum duration of treatment.

Kinetics and Mechanisms of Monolayer Interactions III: Models to Explain Time-Dependent Effects of Injected Cetrimonium Bromide

EDWARD R. GARRETT and FEDERICO A. VILALLONGA ˣ

Abstract □ Two kinetic models are derived to explain the time-dependent effects of cetrimonium ions injected beneath an air–aqueous solution interface without any previously adsorbed or spread monolayer at different ionic strengths. The data show excellent fit and consistency with a multicompartmental kinetic model which postulates a barrier or intermediate compartment between the ionic surfactant in the subphase and the sites on the surface. Such a barrier inhibits free diffusion of the surfactant from the bulk of the solution to these sites. The experimental data are not inconsistent with a model that postulates a time-dependent binding process and the absence of a diffusion-limiting subinterface since, within the limits of the error, the derived rate constants conform to the model prediction that they should be proportional to the surfactant-ion concentration.

Keyphrases □ Monolayer interactions—kinetics and mechanisms for time-dependent effects of cetrimonium bromide injected beneath air–aqueous solution interface without previously adsorbed or spread monolayer at different ionic strengths □ Cetrimonium bromide—kinetics and mechanisms for time-dependent effects after injection beneath air–aqueous solution interface without previously adsorbed or spread monolayer at different ionic strengths

Recent studies on the kinetics and mechanisms of the interaction of phospholipid monolayers at the air–water interface with long hydrocarbon ionic surfactants injected in the subphase demonstrated a time-dependent process for achievement of a final value of surface pressure (1, 2).

The present study describes changes of the surface tension with time after the injection of surfactant ions beneath an air–water interface without any previously adsorbed or spread monolayer and the effect of ionic strength on the adsorption kinetics and final equilibrium surface pressure.

EXPERIMENTAL

Materials—Cetrimonium bromide[1] was the same sample used in previous studies (1, 2). No detectable minimum in the plots of surface tension against the logarithm of the molar concentration was observed. Analytical reagent sodium chloride and potassium chloride were roasted at 650–700° for 6 hr prior to preparation of the aqueous solutions to remove surface-active organic impurities. Deionized, triple-distilled water was used throughout the study. Its pH, after air equilibration, was consistently between 5.6 and 6.0, and its surface tension (γ_0) was within 99.8–100.2% of the value calculated from the Harkin equation (3). The air–water interfacial potential (V_0) was −500 mv (±20 mv).

Instruments and Methods—A 9-cm diameter Teflon dish, provided with two identical micropipets[2] and a Teflon-coated magnetic stirring bar (1.25 × 0.8 cm), was used as a trough in a closed system described previously (1). The final liquid volume in the trough was always 45 ml, corresponding to a liquid depth of 1.58 cm.

Surface tension was measured with a Wilhelmy platinum plate (2.5 × 1.25 × 0.01 cm) attached to an electrobalance[3]. Surface potential was measured with an americium 241 air electrode attached to an electrometer[4]. The outputs of both instruments were fed into a dual-pen recorder[5].

With the platinum plate, the electrodes, and the micropipets in position, water (or the saline solution) was added slowly (42–43 ml) so that it just made contact with the lower edge of the platinum plate (4). After 1 min the surface tension and the interfacial potential were measured and recorded. The liquid volume was adjusted to 45 ml, and the surface tension (γ_0) and interfacial potential (V_0) were measured again. These control values were used for the calculation of the surface pressure ($\Delta\pi$) and surface potential (ΔV) of the final surfactant solution: $\Delta\pi = \gamma_0 - \gamma_s$ and $\Delta V = V_s - V_0$. The subscript s indicates the values that correspond to the surface tension and interfacial potential, respectively, of the final surfactant solution.

A given volume, equal to the volume of the concentrated surfactant solution to be injected, was withdrawn from the dish using the appropriate micropipet. With the other micropipet filled previously with the concentrated surfactant solution, the injection was then started simultaneously with the magnetic stirrer. Within the limits of the experimental error, no significant differences were observed in the $\Delta\pi$ values by stirring 1, 3, 5, or 10 min for a given final concentration. Consequently, after 1 min of stirring, the recording of the surface tension (γ_s) and interfacial potential (V_s) was started. The time necessary for the injection of the desired amount of concentrated surfactant solution was between 10 and 35 sec. The criteria for equilibrium were the constancy of the surface tension (±0.2 dyne cm^{-1}) and the constancy of the interfacial potential (±20 mv) during 30 min. The experiments were performed at 21 ± 1°.

The concentration of the concentrated surfactant solution to be injected was kept below the critical micelle concentration (CMC), and the volumes injected were such as to obtain a final concentration in the 45 ml in the Teflon dish of 8, 4, or 2 μM; at these concentrations, cetrimonium bromide is completely dissociated (5).

At least three different experiments were performed for each final surfactant concentration. The reproducibility was within ±0.5 dyne cm^{-1} for the variation of the surface pressure and ±25 mv for the variation of the surface potential.

RESULTS

The effects of the injection of cetrimonium bromide on the surface pressure ($\Delta\pi$) are compared in Fig. 1 in the absence and in the presence of different concentrations of sodium chloride. In the absence of sodium chloride, the effective changes in the surface pressures were essentially instantaneous processes under the experimental conditions. In the presence of sodium chloride, the equilibrium surface pressure ($\Delta\pi_{eq}$) varied and was a function of the sodium chloride concentration. The rate of achievement of the equilibrium surface pressure was primarily a function of the surfactant-ion concentration in these latter cases.

In all cases, the plot of the reciprocal of the equilibrium surface pressure ($1/\Delta\pi_{eq}$) against the reciprocal ($1/n$) of the final surfactant concentration (n), expressed in molecules per milliliter, gave reasonably straight lines (Fig. 2) within the concentration limits studied.

The substitution of potassium chloride for sodium chloride gave

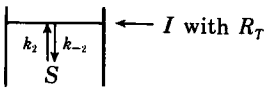
similar results. The various $\Delta\pi_{eq}$ values of the several potassium chloride and sodium chloride concentrations are given in Table I.

DISCUSSION

Although it was proposed early (6) that the time dependence of surface tension of surfactant solutions was diffusion dependent, the kinetics of the adsorption processes in many cases could not be explained in terms of simple diffusion alone (7–13) and the concept of a surface potential energy barrier had to be introduced (14–23). These time-dependent processes of adsorption can be quantified by applying the principles of compartmental analysis to a system that is composed of several kinetically distinct compartments.

Model I—Model I postulates a rate-determining process of binding of surfactant ions (S) to a finite number of sites at the interface (I) (Scheme I).



Scheme I

The process can be described by Scheme II:

$$S + R \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (SR)$$

Scheme II

where an amount, S, of surfactant is homogeneously dispersed in a volume, V_s, of solution. The total number of receptor sites at the interface, R_T, is the sum of the amount bound, (SR), and free, R:

$$R_T = R + (SR) \qquad \text{(Eq. 1)}$$

The rate of change of bound sites with time can be formulated as:

$$d(SR)/dt = k_2S(R) - k_{-2}(SR) = k_2S[R_T - (SR)] - k_{-2}(SR) \qquad \text{(Eq. 2)}$$

which can be put into integral form as:

$$\int_0^{(SR)} \frac{d(SR)}{k_2SR_T - (k_2S + k_{-2})(SR)} = \int_{t_0}^{t} dt \qquad \text{(Eq. 3)}$$

If it is postulated that the total number of sites is so small that even when completely saturated, *i.e.*, when $(SR) = (SR_T)$, there is no significant depletion of the surfactant amount in bulk solution so that $S = S_{eq}$, a constant, Eq. 3 can be integrated to:

$$\ln\left[\frac{k_2S_{eq}R_T - [k_2S_{eq} + k_{-2}](SR)}{k_2S_{eq}R_T}\right] = -(k_2S_{eq} + k_{-2})(t - t_0) \qquad \text{(Eq. 4)}$$

and:

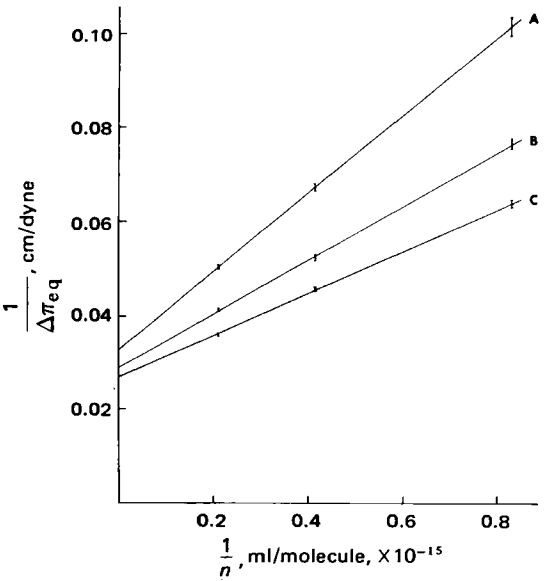


Figure 2—*Typical plots of $1/\Delta\pi_{eq}$ against 1/n for the adsorption of cetrimonium bromide at the air–aqueous solution interfaces, where n is the final surfactant concentration in molecules per milliliter and $\Delta\pi_{eq}$ is the equilibrium surface pressure. Key: A, 0.15 M NaCl; B, 0.30 M NaCl; and C, 0.45 M NaCl.*

$$(SR) = \frac{k_2S_{eq}R_T}{k_2S_{eq} + k_{-2}}[1 - e^{-(k_2S_{eq} + k_{-2})(t - t_0)}] \qquad \text{(Eq. 5)}$$

When final equilibrium is achieved:

$$\lim_{t \to \infty}(SR) = \frac{k_2S_{eq}R_T}{k_2S_{eq} + k_{-2}} = (SR)_{eq} \qquad \text{(Eq. 6)}$$

and:

$$(SR) = (SR)_{eq}[1 - e^{-(k_2S_{eq} + k_{-2})(t - t_0)}] \qquad \text{(Eq. 7)}$$

If the surface pressure ($\Delta\pi$) is proportional to the number of bound sites at the interface, as was postulated previously (24):

$$\Delta\pi = \alpha(SR) \qquad \text{(Eq. 8)}$$

and:

$$(\Delta\pi)_{eq} = \alpha(SR)_{eq} \qquad \text{(Eq. 9)}$$

Equation 7 can be expressed in terms of experimental values as:

$$\Delta\pi = \Delta\pi_{eq}[1 - e^{-(k_2S_{eq} + k_{-2})(t - t_0)}] \qquad \text{(Eq. 10)}$$

or in logarithmic form as:

$$\log(\Delta\pi_{eq} - \Delta\pi) = -\frac{k_2S_{eq} + k_{-2}}{2.303}(t - t_0) + \log \Delta\pi_{eq} \qquad \text{(Eq. 11)}$$

so that a plot of the logarithm of the difference between the final value of the surface pressure ($\Delta\pi_{eq}$) and any value of the surface pressure at a time t should be a straight line of negative slope, m, and intercept $\log \Delta\pi_{eq}$ (Fig. 3*a*) where:

$$-2.303m = k_2S_{eq} + k_{-2} \qquad \text{(Eq. 12)}$$

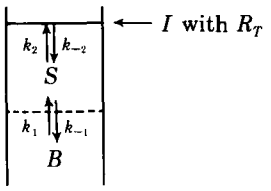
It follows that m should be a linear function of the amount of surfactant added to a constant volume, V_s, of solution. When the obtained $-m$ values are plotted against surfactant concentration $[S]$:

$$-m = \frac{k_2}{2.303}[S]V_S + \frac{k_{-2}}{2.303} \qquad \text{(Eq. 13)}$$

a straight line should result of slope $V_sk_2/2.303$ and intercept $k_{-2}/2.303$

The plots of $-m$ against the bulk surfactant concentration (Fig. 4) are not inconsistent with Eq. 13 within the limits of concentration studied based on the principles underlying Model I.

Model II—Model II postulates a rate-determining process of diffusion from the bulk solution (B) into the subsurface (S) with



Scheme III

an instantaneous equilibrium with receptor sites (Scheme III). There is strong evidence to postulate the structural ordering of water adjacent to any interface, solid–water, liquid–water, or air–water (24). Particularly in the case of solid–water interfaces (25), anomalous values of thermal expansion, electro- and thermal conductivity, and degeneration of the degree of molecule rotation demand a high degree of ordering for molecules at the interface to produce a new interfacial quasisolid structure.

This model presumes that a compartment exists between the interface (*I*) and the surfactant that is dissolved in the bulk solution. This compartmental model postulates the following compartments.

The Interface (I)—The boundary between the aqueous and the gaseous phases that contains the "active sites" postulated by Langmuir (26).

The Subinterface (S)—A thin region with a thickness of $10–10^3$ water molecule diameters immediately beneath the interface, postulated previously by Ward and Tordai (9). It is further assumed that water molecules are oriented in a given array in this region (25, 27), so that the surfactant must diffuse from a normal homogeneously dispersed solution through this array before it can reach the sites on the interface.

The Bulk Aqueous Phase (B)—The region below the subinterface. Water and solute molecules are distributed at random in this region.

The process can be described by Scheme IV:

$$[B] \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [S] + R \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (SR)$$

Scheme IV

in which $[B]$ and $[S]$ represent the surfactant-ion concentration in the bulk phase and subinterface, respectively; R is the number of active sites per unit of surface area of the interface (I); and (SR) is the number of surfactant ions attached per unit area.

If it is postulated that the interaction of molecules of the surfactant in the subinterface (S) with sites in the interface (I) is instantaneous so that the interaction between S and R in Scheme III is in equilibrium:

$$K_2 = \frac{k_2}{k_{-2}} = \frac{(SR)}{[R][S]} \qquad \text{(Eq. 14)}$$

The fraction, θ, of the total number of sites, R_T, occupied by surfactant molecules is:

$$\theta = \frac{(SR)}{R_T} = \frac{K_2[S]}{1 + K_2[S]} \qquad \text{(Eq. 15)}$$

so that if the surface pressure ($\Delta\pi$) is proportional to the number of bound sites at the interface:

$$\Delta\pi = \alpha(SR) = \alpha\theta R_T = \frac{\alpha R_T K_2[S]}{1 + K_2[S]} = \frac{\Delta\pi_\infty K_2[S]}{1 + K_2[S]} \qquad \text{(Eq. 16)}$$

in which:

$$\Delta\pi_\infty = \alpha R_T \qquad \text{(Eq. 17)}$$

is the maximum value of $\Delta\pi$ that can be achieved with any concentration $[S]$.

If the total number of interface sites, R_T, is relatively small so that $[S]$ is not significantly depleted by binding of the surfactant ions to those sites, the rate of change of surfactant concentration with time from Scheme III is:

$$\frac{d[S]}{dt} = k_1[B] - k_{-1}[S] \qquad \text{(Eq. 18)}$$

As the volume of the subinterface, S, is small with respect to the bulk solution, B, the rise in concentration in the subinterface will not significantly deplete the concentration in the bulk solution; then, for all apparent purposes, $k_1[B]$ is a constant and Eq. 18 may be integrated to give:

$$[S] = \frac{k_1[B]}{k_{-1}}[1 - e^{-k_{-1}(t - t_0)}] \qquad \text{(Eq. 19)}$$

The substitution of this value for $[S]$ in Eq. 16 results in:

$$\Delta\pi = \frac{\frac{\Delta\pi_\infty K_2 k_1[B]}{k_{-1}}[1 - e^{-k_{-1}(t-t_0)}]}{1 + \frac{K_2 k_1[B]}{k_{-1}}[1 - e^{-k_{-1}(t-t_0)}]} = \frac{\Delta\pi_\infty[1 - e^{-k_{-1}(t-t_0)}]}{k_{-1}/K_2 k_1[B] + [1 - e^{-k_{-1}(t-t_0)}]} \qquad \text{(Eq. 20)}$$

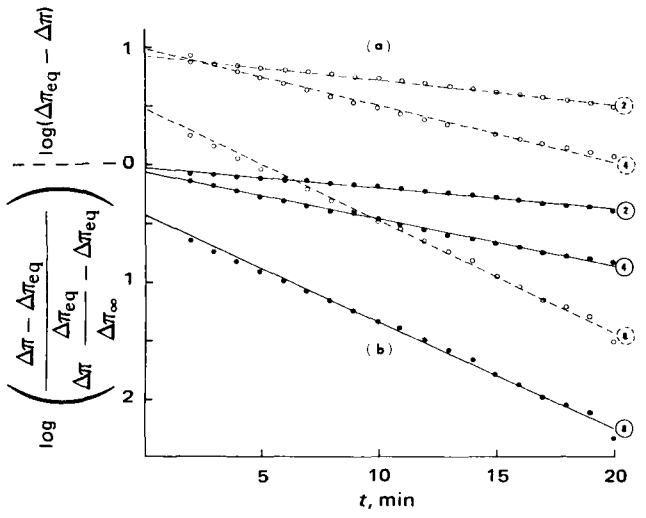


Figure 3—*Plots of log ($\Delta\pi_{eq} - \Delta\pi$) (Model I) and log $\{(\Delta\pi - \Delta\pi_{eq})/[(\Delta\pi)(\Delta\pi_{eq}/\Delta\pi_\infty) - \Delta\pi_{eq}]\}$ (Model II) against time for the adsorption of cetrimonium ions at the air–0.15 M NaCl interface. Lines are labeled as to micromolar final concentration of the injected cetrimonium ions.*

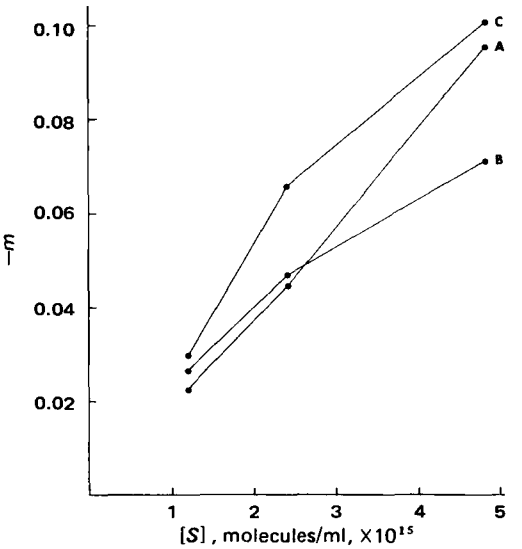

Figure 4—*Plots of −m against the final concentration of cetrimonium ions [S] in molecules per milliliter. Key: A, 0.15 M NaCl; B, 0.30 M NaCl; and C, 0.45 M NaCl.*

Table I—Evaluated Parameters for Adsorption of Various Solution Concentrations of Cetrimonium Ion at the Air–Water Interface for Various Concentrations of Sodium Chloride and Potassium Chloride

		Cetrimonium Ion, Final Concentration					
		2 μM		4 μM		8 μM	
Concentration, M	$\Delta\pi_\infty$, dynes/cm	$\Delta\pi_{eq}$, dynes/cm	k_{-1}, min^{-1}	$\Delta\pi_{eq}$, dynes/cm	k_{-1}, min^{-1}	$\Delta\pi_{eq}$, dynes/cm	k_{-1}, min^{-1}
Sodium chloride							
0.15	30.4	9.9	0.050	14.9	0.086	19.9	0.201
0.30	34.5	13.2	0.050	19.2	0.086	24.2	0.145
0.45	37.1	15.8	0.069	21.8	0.124	27.7	0.218
Potassium chloride							
0.15	30.1	9.8	0.069	14.8	0.108	19.9	0.185
0.30	34.0	13.1	0.066	18.9	0.124	24.1	0.157
0.45	36.6	15.6	0.079	21.7	0.129	27.5	0.248

so that:

$$\lim_{t\to\infty} \Delta\pi = \frac{\Delta\pi_\infty}{1 + k_{-1}/k_1[B]K_2} = \Delta\pi_{eq} \qquad \text{(Eq. 21)}$$

and:

$$\Delta\pi_\infty = \Delta\pi_{eq}\left(1 + \frac{k_{-1}}{k_1[B]K_2}\right) \qquad \text{(Eq. 22)}$$

$$\frac{1}{\Delta\pi_{eq}} = \frac{1}{\Delta\pi_\infty} + \frac{k_{-1}}{k_1K_2\Delta\pi_\infty}\left(\frac{1}{[B]}\right) \qquad \text{(Eq. 23)}$$

so that a plot of the reciprocal of the equilibrium surface pressure ($1/\Delta\pi_{eq}$) against the reciprocal of a particular concentration ($1/[B]$) should be a straight line of positive slope equal to k_{-1}/k_1K_2 ($\Delta\pi_\infty$) and intercept $1/\Delta\pi_\infty$.

When $[1 + (k_{-1}/k_1K_2[B])]$ of Eq. 22 is substituted in Eq. 20:

$$\Delta\pi = \frac{\Delta\pi_\infty(1 - e^{-k_{-1}(t-t_0)})}{\Delta\pi_\infty/\Delta\pi_{eq} - e^{-k_{-1}(t-t_0)}} \qquad \text{(Eq. 24)}$$

and:

$$\frac{\Delta\pi - \Delta\pi_{eq}}{(\Delta\pi)\dfrac{\Delta\pi_{eq}}{\Delta\pi_\infty} - \Delta\pi_{eq}} = e^{-k_{-1}(t-t_0)} \qquad \text{(Eq. 25)}$$

or:

$$\log\left[\frac{\Delta\pi - \Delta\pi_{eq}}{(\Delta\pi)\dfrac{\Delta\pi_{eq}}{\Delta\pi_\infty} - \Delta\pi_{eq}}\right] = \frac{k_{-1}}{2.303}(t - t_0) \qquad \text{(Eq. 26)}$$

so that the logarithmic function for a change in surface pressure from $\Delta\pi$ to its final equilibrium value, $\Delta\pi_{eq}$, when plotted against time should be linear (Fig. 3b) of slope $-k_{-1}/2.303$, where k_{-1} is the first-order rate constant for the return of surfactant from the subinterface to the bulk solution.

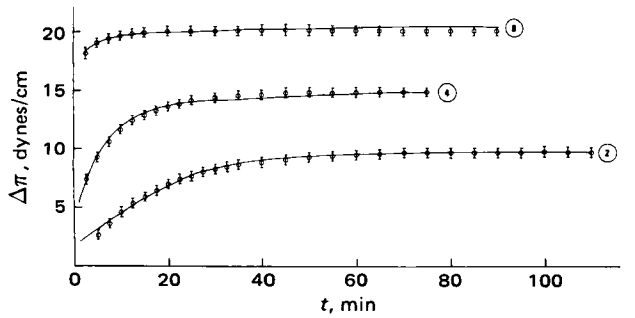

Figure 5—*Plots of surface pressure ($\Delta\pi$) against time (t) for the adsorption of cetrimonium ions at the air–0.15 M NaCl interface; Φ = surface pressures calculated with Eq. 25 (Model II). Curves are labeled as to micromolar final concentrations of the injected surfactant ion.*

The fact that the data conform to Eq. 26 is demonstrated by the linearity of the plots given in Fig. 3b. It was not expected that the data at initial times would conform to Eq. 26, since the agitation of the experimental procedure close to time zero would definitely perturb and accelerate the kinetic processes in the initial moments. When the values of k_{-1} (Table I) obtained from the slopes of the plots are substituted into Eq. 24, the resultant $\Delta\pi$ values fit the $\Delta\pi$–t experimental curves (Fig. 5) excellently within the limits of the experimental error for all saline concentrations studied. Thus, the kinetics of the adsorption of cetrimonium ions at the air–aqueous solution interfaces can be described by the postulation of an intermediate compartment between the interface and the bulk phase.

The product of certain important constants can be estimated from the ratio of the intercept and slope of Eq. 23:

$$\frac{\text{intercept}}{\text{slope}} = \frac{\dfrac{1}{\Delta\pi_\infty}}{\dfrac{k_{-1}}{k_1K_2\Delta\pi_\infty}} = \frac{k_1K_2}{k_{-1}} = K_1K_2 \qquad \text{(Eq. 27)}$$

where $K_1 = k_1/k_{-1}$ and $K_2 = k_2/k_{-2}$ (Scheme IV) are the equilibrium constants of the distributive and surface interaction processes, respectively.

It was shown previously (1, 2) that the energy of activation (ψ) for the process of the interaction of injected cetrimonium ions with a monomolecular layer spread at the air–water interface may be estimated on the assumption that each molecule forming the monolayer constitutes one active site. Thus, the value of (Ns/A) (Eq. 7 of Ref. 1) that represents the number of active sites per square centimeter was given by the known number of molecules necessary to form the monolayer at a given surface pressure.

In the case of an air–water interface without any previously adsorbed or spread monolayer, the term (Ns/A) may be estimated on the basis of the available space per adsorbed surfactant molecule. Molecular models show that the cross-sectional area of the cetrimonium ion is 26.3×10^{-16} cm^2/ion, so that the reciprocal 3.80×10^{14} ions/cm^2 is the maximum number of cetrimonium ions that may exist per square centimeter at the interface at the condition defined by $\Delta\pi = \Delta\pi_\infty$. It is reasonably assumed that this number is

Table II—Estimated Equilibrium Constants for Receptor Site Binding at Interface (K_2) and Partition across a Diffusional Barrier (K_1) and Their Associated Free Energies

physically equivalent to the number of active sites.

Equation 8 of Ref. 1 can be rewritten in the form:

$$\frac{1}{\Delta\pi_{eq}} = \frac{1}{\Delta\pi_{\infty}} + \frac{(Ns/A)(2\pi m/kT)^{1/2}\nu e^{-\psi/kT}}{\Delta\pi_{\infty}}\left(\frac{1}{n}\right) \quad \text{(Eq. 28)}$$

in which $\Delta\pi_{eq}$ is the equilibrium surface pressure obtained for a final concentration of injected surfactant ion, n (molecules per milliliter); $\Delta\pi_{\infty}$ is the maximum value of $\Delta\pi$ that can be achieved with any final concentration of surfactant ion; (Ns/A) is the number of active sites per square centimeter; π is 3.14 . . . ; m is the absolute mass of the cetrimonium ion; k and T are the Boltzmann constant and the absolute temperature, respectively; ν is the classical frequency of a harmonic oscillator at room temperature (10^{12}/sec); and ψ is the energy of activation of the process of the interaction of cetrimonium ions with active sites at the interface.

The values of ψ obtained for different concentrations of sodium and potassium chlorides on the assumption of $(Ns/A) = 3.80 \times 10^{14}$ active sites/cm^2 are listed in Table II.

The free energy of adsorption per methylene group of a hydrocarbon chain that adsorbs at a clean air–water interface was estimated to be between −0.600 and −0.625 kcal/mole (23, 26, 28, 29). Thus, the value estimated for the hexadecyl hydrocarbon chain of the cetrimonium ion is between −9.6 and −10.0 kcal/mole and compares reasonably with the absolute values of ψ listed in Table II.

The van't Hoff equation:

$$\psi = \Delta G = -RT \ln K \quad \text{(Eq. 29)}$$

permits estimation of the numerical values of K_2 (Table II). It can be observed that these values are a function of the ionic strength of the saline solution in the bulk phase.

Thus, the numerical value of the equilibrium constant K_1 can be estimated from the K_1K_2 value (Eq. 27) and the estimated value of K_2 (Eq. 29). The corresponding free energy values can be calculated from Eq. 29 (Table II). These values do not appear to depend on the ionic strength of the bulk solution.

Effect of Ionic Strength—The experimental values of $\Delta\pi_{\infty}$, $\Delta\pi_{eq}$, and, less consistently, k_{-1} increase with increasing ionic strength (Table I). These facts are reflected in increases of the estimated K_1 and K_2 values with ionic strength (Table II). Log K_1 and log K_2 are plotted against $\sqrt{\mu}/(1+\sqrt{\mu})$ (30), where μ is the ionic strength (Fig. 6).

Such plots of log K_2 were linear with correlation coefficients of 0.99999 and 0.99833 for sodium and potassium chlorides, respectively, whereas the plots of log K_1 showed only small, nonlinear dependence on the ionic strength of the bulk solution. It is reasonable that in this last case the effect of the ionic strength of the bulk solution is counterbalanced by a proportional increase in the ionic strength of the subinterface.

In summary, the following facts are consistent with Model II:

1. The plots of $1/\Delta\pi_{eq}$ against $1/[n]$ are linear as predicted by Eq. 23.
2. The values of k_{-1} estimated from the plot of the logarithmic function of $(\Delta\pi - \Delta\pi_{eq})/[(\Delta\pi)(\Delta\pi_{eq}/\Delta\pi_{\infty}) - \Delta\pi_{eq}]$ against time (Eq. 26) when substituted in Eq. 24 give $\Delta\pi$ values that fit the $\Delta\pi$–t experimental curves excellently between the limits of the experimental error in all saline concentrations studied.
3. The free energy of adsorption estimated from the equilibrium constant K_2 and the van't Hoff equation coincide with those expected from the adsorption of a hexadecyl hydrocarbon chain at the air–water interface.
4. The effect of the ionic strength of the bulk solution on the $\Delta\pi_{\infty}$ and $\Delta\pi_{eq}$ values is consistent with the existence of a subinterface compartment.

The application of this model to the results already obtained with the injection of cetrimonium ions beneath phospholipid monolayers spread at the air–aqueous solution interfaces will be discussed in later papers.

Characterization of Hydrogen Bonding between Selected Barbiturates and Polyethylene Glycol 4000 by IR Spectral Analysis

B. L. CHANG, N. O. NUESSLE, and W. G. HANEY, Jr. [x]

Abstract □ Several barbiturates and primidone were equilibrated with polyethylene glycol 4000 in pyridine. IR spectral properties of these samples indicate that seven disubstituted barbiturates complex with polyethylene glycol 4000 while five disubstituted barbiturates and two trisubstituted barbiturates as well as primidone do not. Forces responsible for complexation of barbiturates with polyethylene glycol 4000, as inferred from spectral data, consist of hydrogen bonds formed between N^1 and N^3 hydrogens of the barbiturate ring and two oxygen atoms of the —O—CH_2CH_2—O— moiety. Also, there appear to be three configurations of intermolecular hydrogen bonding sites between disubstituted barbiturates. Several factors affect the barbiturate–polyethylene glycol 4000 interaction, including the nature of the solvent, C_5 substituents, the number of hydrogen bonds formed between reactants, and the 2-carbonyl group of the barbiturate ring. Complexes of polyethylene glycol 4000 with phenobarbital, butabarbital, and cyclobarbital are stable in water at 26° or below, but complexes of polyethylene glycol 4000 with butethal, cyclopentenyl allylbarbituric acid, pentobarbital, and probarbital are not.

Keyphrases □ Barbiturates—IR characterization of hydrogen bonding with polyethylene glycol 4000 □ Primidone—interaction with polyethylene glycol 4000 □ Hydrogen bonding of barbiturates and primidone with polyethylene glycol—characterized by IR spectrophotometry □ Complexes, barbiturates and polyethylene glycol 4000—IR characterization □ IR spectrophotometry—characterization, hydrogen bonding between barbiturates and polyethylene glycol 4000

Barbiturates may interact with various organic molecules by hydrogen bonding to form soluble or insoluble complexes such as phenobarbital–theophylline (1), phenobarbital–polyvinylpyrrolidone (2), phenobarbital–caffeine (3), barbital–aminopyrine (4), and phenobarbital–poly-*N*-vinyl-5-methyl-2-oxazolidinone (5). Application of such complexation to pharmaceutics has been discussed in the literature (1–7).

In 1968, Kyogoku *et al.* (8) found that barbiturates also form specific and strong hydrogen bonds to adenine derivatives. Since adenine derivatives exist in a number of biochemicals, *e.g.*, coenzymes and adenosine triphosphate, this interaction formed the basis of a hypothesis explaining the molecular mechanism underlying the pharmacological mode of action of barbiturates. Kyogoku and Yu (9–11) extended the research from ethyladenine to nicotinamide adenine dinucleotide (NAD) and flavine adenine dinucleotide (FAD) and postulated that barbiturates inhibit biological oxidation by interaction with the adenine moiety of NAD and FAD. Thus, an understanding of hydrogen bonding properties is important in barbiturate dosage form development and may allow explanation of the mechanism by which barbiturates inhibit biological oxidation. It is of interest, therefore, to study hydrogen bonding properties of the barbiturate ring in detail.

It was shown (8) that phenobarbital–9-ethyladenine has an association constant of 1200 M^{-1}, whereas barbital–9-ethyladenine and pentobarbital–9-ethyladenine have association constants of 1000 M^{-1}. The larger association constant of phenobarbital–9-ethyladenine was attributed to the lower pKa of phenobarbital (7.3) as compared to that of barbital (7.8) and pentobarbital (8.0). However, since pentobarbital–9-ethyladenine has the same association constant

Characterization of Hydrogen Bonding between Selected Barbiturates and Polyethylene Glycol 4000 by IR Spectral Analysis

B. L. CHANG, N. O. NUESSLE, and W. G. HANEY, Jr. [x]

Abstract □ Several barbiturates and primidone were equilibrated with polyethylene glycol 4000 in pyridine. IR spectral properties of these samples indicate that seven disubstituted barbiturates complex with polyethylene glycol 4000 while five disubstituted barbiturates and two trisubstituted barbiturates as well as primidone do not. Forces responsible for complexation of barbiturates with polyethylene glycol 4000, as inferred from spectral data, consist of hydrogen bonds formed between N^1 and N^3 hydrogens of the barbiturate ring and two oxygen atoms of the —O—CH_2CH_2—O— moiety. Also, there appear to be three configurations of intermolecular hydrogen bonding sites between disubstituted barbiturates. Several factors affect the barbiturate–polyethylene glycol 4000 interaction, including the nature of the solvent, C_5 substituents, the number of hydrogen bonds formed between reactants, and the 2-carbonyl group of the barbiturate ring. Complexes of polyethylene glycol 4000 with phenobarbital, butabarbital, and cyclobarbital are stable in water at 26° or below, but complexes of polyethylene glycol 4000 with butethal, cyclopentenyl allylbarbituric acid, pentobarbital, and probarbital are not.

Barbiturates may interact with various organic molecules by hydrogen bonding to form soluble or insoluble complexes such as phenobarbital–theophylline (1), phenobarbital–polyvinylpyrrolidone (2), phenobarbital–caffeine (3), barbital–aminopyrine (4), and phenobarbital–poly-*N*-vinyl-5-methyl-2-oxazolidinone (5). Application of such complexation to pharmaceutics has been discussed in the literature (1–7).

In 1968, Kyogoku *et al.* (8) found that barbiturates also form specific and strong hydrogen bonds to adenine derivatives. Since adenine derivatives exist in a number of biochemicals, *e.g.*, coenzymes and adenosine triphosphate, this interaction formed the basis of a hypothesis explaining the molecular mechanism underlying the pharmacological mode of action of barbiturates. Kyogoku and Yu (9–11) extended the research from ethyladenine to nicotinamide adenine dinucleotide (NAD) and flavine adenine dinucleotide (FAD) and postulated that barbiturates inhibit biological oxidation by interaction with the adenine moiety of NAD and FAD. Thus, an understanding of hydrogen bonding properties is important in barbiturate dosage form development and may allow explanation of the mechanism by which barbiturates inhibit biological oxidation. It is of interest, therefore, to study hydrogen bonding properties of the barbiturate ring in detail.

It was shown (8) that phenobarbital–9-ethyladenine has an association constant of 1200 M^{-1}, whereas barbital–9-ethyladenine and pentobarbital–9-ethyladenine have association constants of 1000 M^{-1}. The larger association constant of phenobarbital–9-ethyladenine was attributed to the lower pKa of phenobarbital (7.3) as compared to that of barbital (7.8) and pentobarbital (8.0). However, since pentobarbital–9-ethyladenine has the same association constant

as barbital–9-ethyladenine, other factors (*e.g.*, the steric effect of the C_5 substituent) must contribute to the strength of hydrogen bonds formed between barbiturates and 9-ethyladenine.

A particularly interesting observation (7) related to hydrogen bonding properties of barbiturates is that phenobarbital interacts with polyethylene glycol 4000 to form a water-insoluble complex with a 1:2 stoichiometric ratio while barbital and pentobarbital do not form this complex. To account for this observation, it was suggested that the interaction mechanism is influenced primarily by the dipole–dipole interaction of reactants and secondarily by the "squeezing-out" effect of water. However, barbital and, especially, the lipophilic pentobarbital are not as favorably affected by the squeezing-out effect as is phenobarbital. Negative results obtained with barbital and pentobarbital were attributed in part to a stereochemical effect and in part to the absence of the aromatic ring, which participates more readily in complexation. It is of interest, therefore, to identify the stereochemical factors and the mechanism by which the phenyl substituent favorably affects the interaction.

This investigation was undertaken to examine the interaction between barbiturates and polyethylene glycol 4000 and to elucidate factors contributing to this interaction using IR spectral analysis. In barbiturates, the hydrogen bond donor is the =N—H group and the hydrogen bond acceptor is the >C=O group. In polyethylene glycol 4000, the oxygen atom of the ether linkage is the acceptor and the contribution of terminal hydroxy groups, present in low proportion, may be neglected. These functional groups have characteristic absorption bands in the IR region.

Stretching and bending force constants for NH, C=O, and ether linkages are changed after hydrogen bond formation, resulting in a shift of the characteristic absorption bands (12). Based on this principle, characteristic C=O, NH, and ether linkage bands in the IR spectra of the barbiturate, polyethylene glycol 4000, and barbiturate–polyethylene glycol 4000 equilibrated sample were examined for shifts. These variations were, in turn, used to characterize the interaction between barbiturates and polyethylene glycol 4000.

EXPERIMENTAL[1]

Reagents—The reagents included phenobarbital, barbital, butabarbital sodium, amobarbital, probarbital sodium, pentobarbital sodium, cyclobarbital, talbutal[2], hexobarbital sodium[2], butethal, vinbarbital, cyclopentenyl allylbarbituric acid[3], allobarbital, primidone, mephobarbital, polyethylene glycol 4000, and pyridine[4].

Preparation of Free Barbiturates from Salts—Butabarbital, hexobarbital, and pentobarbital were obtained as sodium salts. To prepare the free barbituric acid derivative, an aqueous solution of the salt was acidified with 10% hydrochloric acid, and the mixture was cooled and filtered. The white crystalline precipitate was washed with water until the washings were free from chloride ion, and the solid was dried at 105°. The butabarbital so obtained had a melting range of 165–169°, the hexobarbital had a melting range of 145–147°, and the pentobarbital had a melting range of 127–133°.

Probarbital and cyclobarbital were obtained as calcium salts. The calcium salt was suspended in 10% hydrochloric acid, and the

[1] IR spectra were obtained on a Perkin-Elmer 457 grating spectrophotometer.

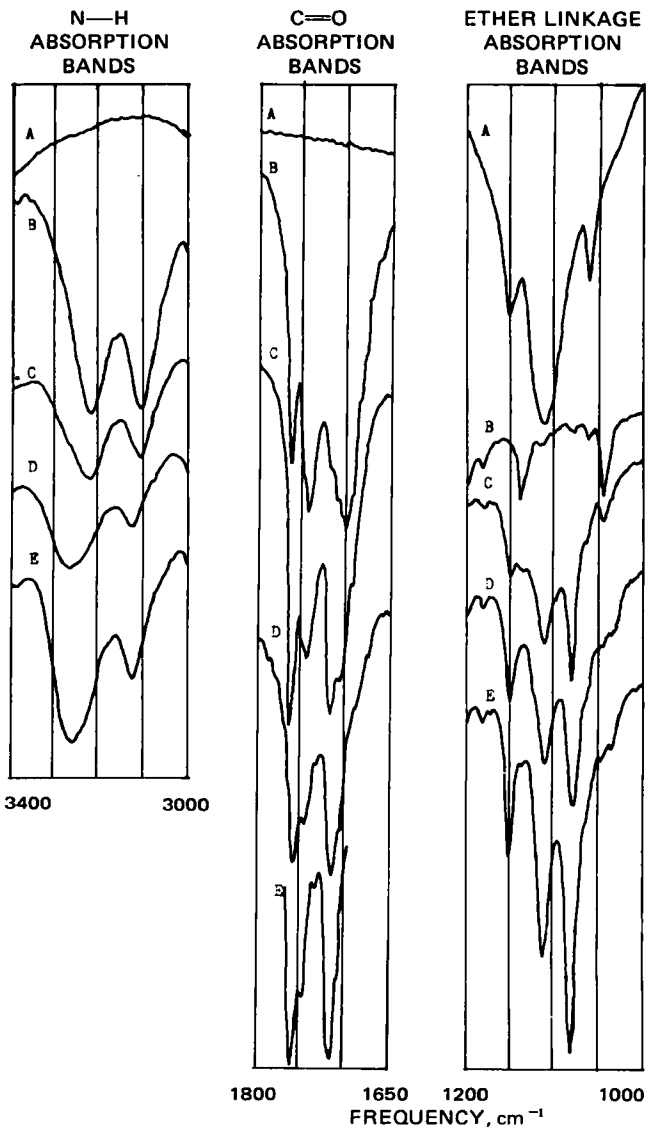

Figure 6—*IR spectra of cyclobarbital–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, cyclobarbital; C, physical mixture of cyclobarbital and polyethylene glycol 4000; D, equilibrated cyclobarbital–polyethylene glycol 4000; and E, aqueous-washed equilibrated cyclobarbital–polyethylene glycol 4000 shown in D.*

mixture was stirred for 10 min. The mixture was extracted three times with ether, and the combined ether extracts were washed with water and evaporated to dryness in a current of air. The residue was dried at 105°. Probarbital so obtained had a melting range of 200–202°, and cyclobarbital had a melting range of 170–174°.

Solvent Selection for Complexation Studies—Initially, a procedure was required for the preparation of barbiturate–polyethylene glycol 4000 complexes. The phenobarbital–polyethylene glycol 4000 complexation in water appears to be a special case, since other barbiturates do not undergo this interaction. Complexes might, however, be prepared from other solvents.

Since the primary mechanism of complexation appears to involve hydrogen bond formation, the ideal solvent should possess only weak hydrogen bond acceptor and donor properties but still dissolve the barbiturate and polyethylene glycol 4000. In addition, IR spectral characteristics of the phenobarbital–polyethylene glycol 4000 complex prepared from this solvent must be the same as those of the complex prepared from water (Fig. 1, curve D). Finally, the solvent should be easily evaporated at room temperature under reduced pressure.

Pyridine was found to be useful for the preparation of barbiturate–polyethylene glycol 4000 complexes. It dissolves both phenobarbital and polyethylene glycol 4000, and after evaporation the complex has an IR spectrum (Fig. 2, curve D) identical to that of the complex obtained from water.

Preparation of Barbiturate–Polyethylene Glycol 4000 Equilibrated Samples from Pyridine—One millimole of the barbiturate and 2 mEq of polyethylene glycol 4000 were dissolved in 3.0 ml of pyridine. The solvent was evaporated in a current of air, and the residue was placed in a reduced-pressure desiccator for 24 hr. The residue was ground and passed through a No. 80 sieve.

Crystallization of Reactants from Pyridine—Polymorphism of barbiturates is well known and has been extensively investigated (13–16). An important contributor to the formation of polymorphs is the solvent of crystallization. Cleverley and Williams (13) and Mesley (16) prepared a series of polymorphs for each barbiturate using different solvents and found that each form exhibited different IR absorption bands. The presence of different polymorphic forms would increase the difficulty of properly interpreting IR spectral changes. Therefore, all constituents of the study

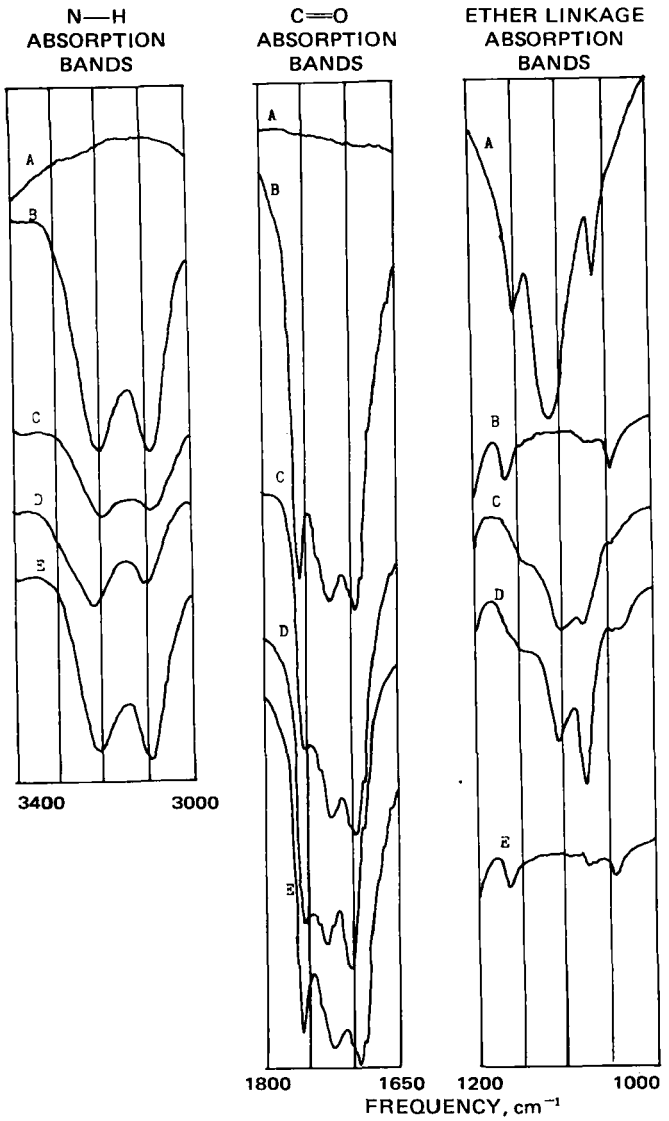

Figure 7—*IR spectra of butethal–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, butethal; C, physical mixture of butethal and polyethylene glycol 4000; D, equilibrated butethal–polyethylene glycol 4000; and E, aqueous-washed equilibrated butethal–polyethylene glycol 4000 shown in D.*

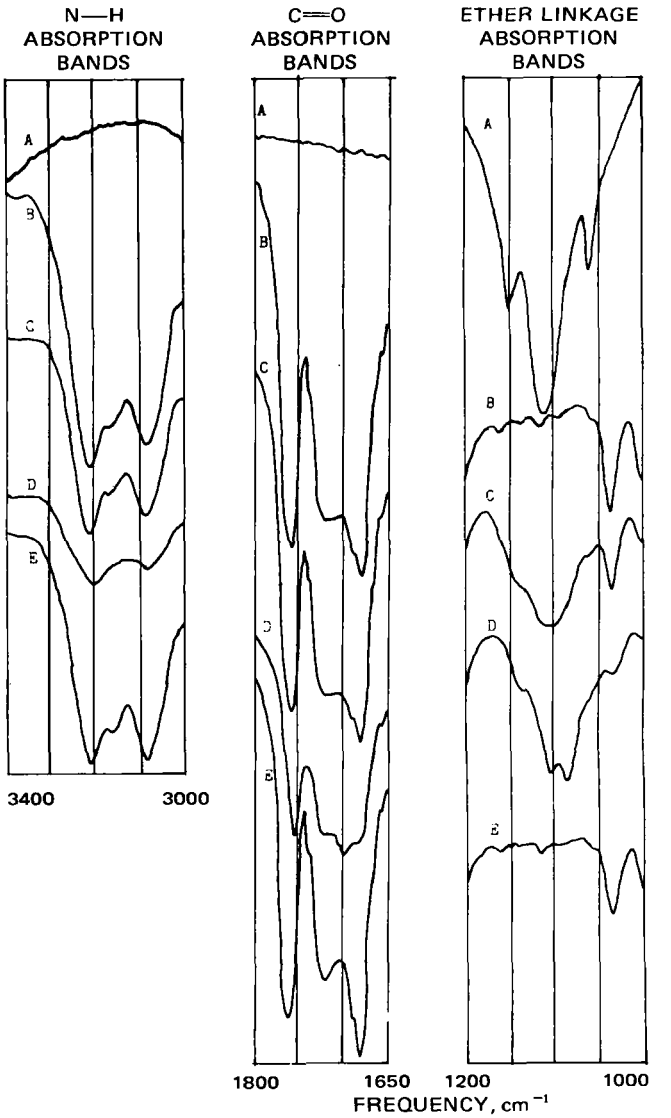

Figure 8—*IR spectra of cyclopentenyl allylbarbituric acid–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, cyclopentenyl allylbarbituric acid; C, physical mixture of cyclopentenyl allylbarbituric acid and polyethylene glycol 4000; D, equilibrated cyclopentenyl allylbarbituric acid–polyethylene glycol 4000; and E, aqueous-washed equilibrated cyclopentenyl allylbarbituric acid–polyethylene glycol 4000 shown in D.*

were recrystallized from a single solvent (pyridine) prior to IR spectral analysis.

Determination of Aqueous Stability of Complexes—A 0.5-g quantity of the complex was suspended in 10.0 ml of water in a screw-capped vial. The vial was fastened in a horizontal position on an agitator, and the shaking speed was adjusted to agitate the vial contents actively. After shaking for 2 hr at 26°, the mixture was filtered and the solids were washed with 20.0 ml of water. The solid was dried at room temperature in a vacuum desiccator for 3 days, and the IR spectrum was taken. Differences between the spectra of the complex before and after treatment with water indicate the stability of the complex.

Preparation of Potassium Bromide Dispersion—The sample and potassium bromide were obtained in proportions by weight of 1:200. The mixture was triturated in a small mortar and pressed in a die under 24,000 psi.

RESULTS AND DISCUSSION

Discussion will focus on the regions from 3400 to 3000 [NH stretching bands (16–19)], from 1800 to 1650 [C=O stretching bands (16, 20)], and from 1200 to 1000 [aliphatic ether bands (21)] cm^{-1}. The 3000–2700-cm^{-1} region will not be discussed since it appears to be of no analytical significance (17). No bands occur between 2700 and 1800 cm^{-1} in any of the tested samples. In the areas from 1650 to 1200 and from 1000 to 250 cm^{-1}, each barbiturate has a characteristic series of bands. Accurate assignment of these bands is difficult with currently available information (16), particularly after they are coupled with absorption bands of polyethylene glycol 4000 in these regions.

In Figs. 1 and 2, N—H stretching absorption bands of the physical mixture of phenobarbital and polyethylene glycol 4000 (curve C) are the same as those of phenobarbital alone (curve B). There are three absorption bands: 3310, 3200, and 3090 cm^{-1}. According to Levi and Hubley (17) and Mesley (16), 3310 cm^{-1} is assigned as a free N—H stretching absorption band while the remaining bands are intermolecular hydrogen-bonded N—H stretching absorption bands. The intermolecular hydrogen bond is between the N—H and C=O of different barbiturate molecules (16).

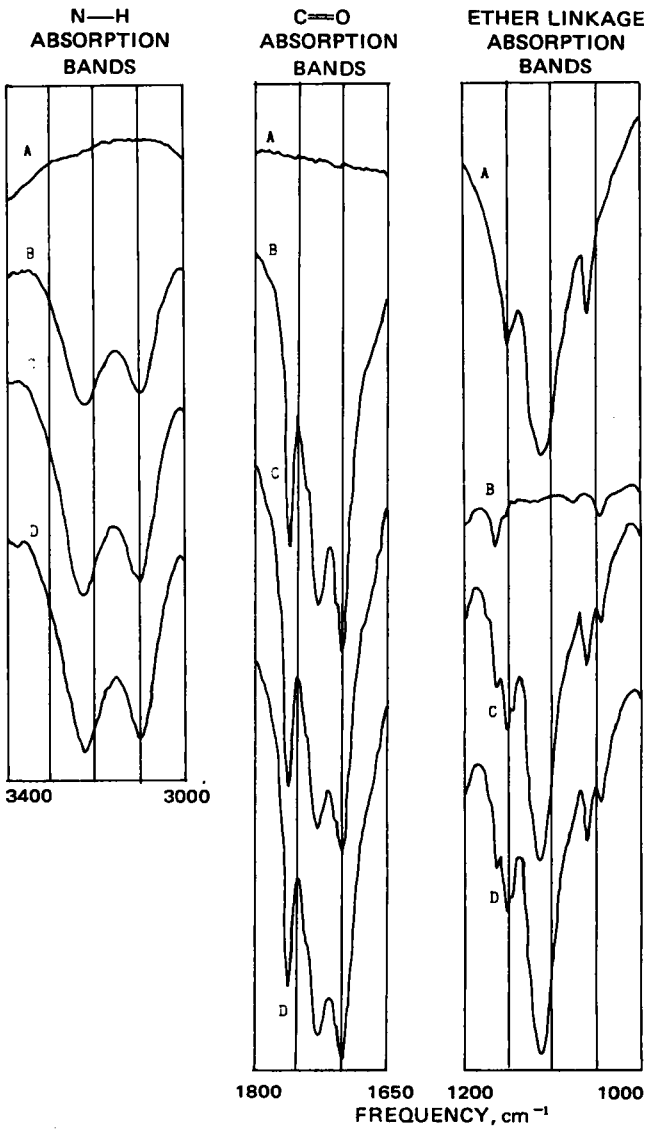

Figure 10—*IR spectra of amobarbital–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, amobarbital; C, physical mixture of amobarbital and polyethylene glycol 4000; and D, equilibrated amobarbital–polyethylene glycol 4000.*

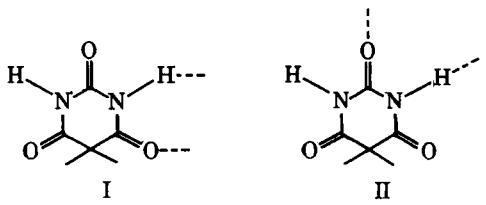
The N—H stretching absorption regions of the phenobarbital–polyethylene glycol 4000 complex from water (Fig. 1, curve D) and equilibrated phenobarbital–polyethylene glycol 4000 from pyridine (Fig. 2, curve D) differ from that of phenobarbital alone (Figs. 1 and 2, curves B). In the spectrum of the complex, the band at 3220 cm^{-1} is stronger and broader than the one at 3110 cm^{-1}. Loss of the free N—H stretching absorption band (present in the spectrum of phenobarbital) in the spectra of the complex from water and the equilibrated samples from pyridine can be attributed to hydrogen bond formation. The 3220- and 3110-cm^{-1} N—H bands of the complex and equilibrated sample have higher frequencies compared to the 3200- and 3090-cm^{-1} N—H bands of phenobarbital. This shifting can be attributed to hydrogen bonds formed between phenobarbital and polyethylene glycol 4000, which displace hydrogen bonds formed between phenobarbital molecules. Since the acceptor molecules are different, the N—H stretching vibration frequency is changed in the complex and equilibrated sample.

In Figs. 3–13, the N—H stretching absorption region of each barbiturate shows the same pattern: two absorption bands, one in the range from 3270 to 3200 cm^{-1} and the other in the range from 3100 to 3090 cm^{-1}. These two bands are assigned as intermolecular hydrogen-bonded N—H stretching bands (16). In Figs. 3–8, the higher frequency band of the equilibrated system is more intense than the lower frequency band, and both bands occur at a higher frequency than those of the barbiturate alone.

The N—H absorption bands of equilibrated samples and the corresponding barbiturates are summarized in Table I. The observed spectral differences indicate that pentobarbital, butabarbital, cyclobarbital, butethal, and cyclopentenyl allylbarbituric acid interact with polyethylene glycol 4000. Mesley (16) already noted the possible existence of intermolecular hydrogen bonds in barbiturate crystals, and Craven and coworkers (22–24) proved it by X-ray diffraction analysis.

Since the phenobarbital spectrum has both free and hydrogen-



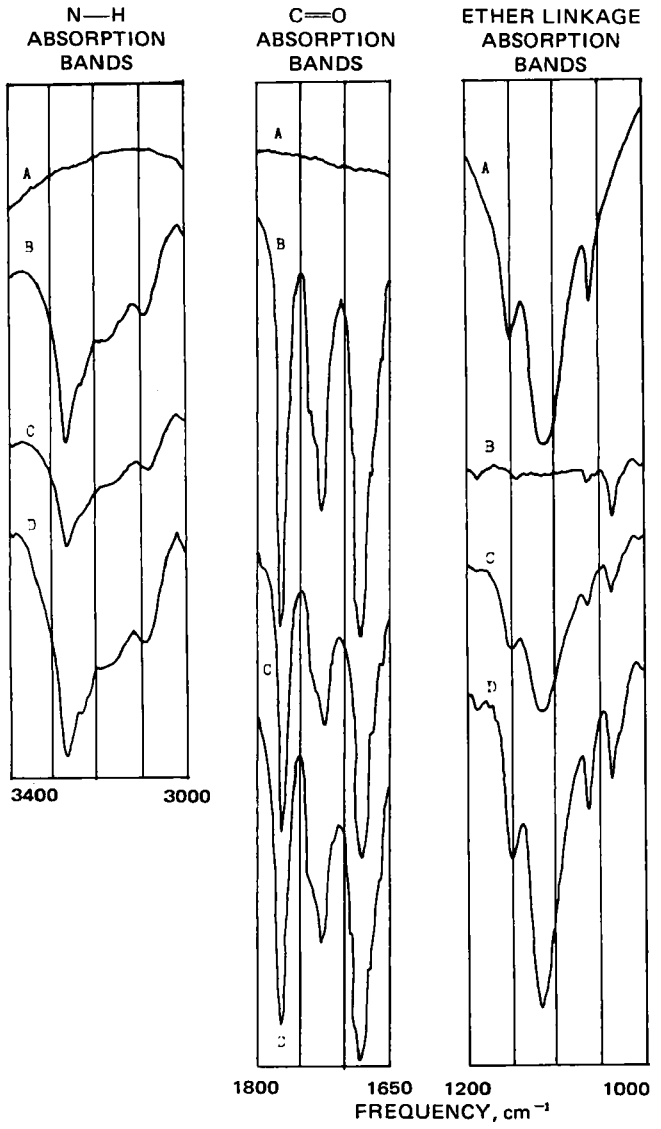


Figure 11—*IR spectra of vinbarbital–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, vinbarbital; C, physical mixture of vinbarbital and polyethylene glycol 4000; and D, equilibrated vinbarbital–polyethylene glycol 4000.*

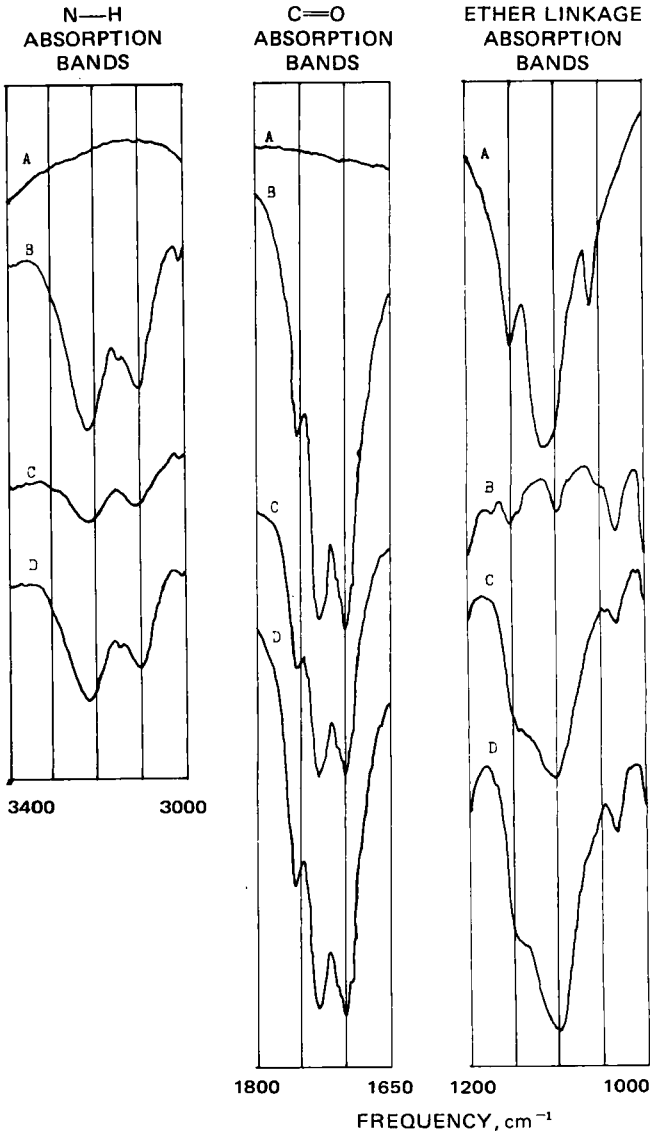

Figure 12—*IR spectra of talbutal–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, talbutal; C, physical mixture of talbutal and polyethylene glycol 4000; and D, equilibrated talbutal–polyethylene glycol 4000.*

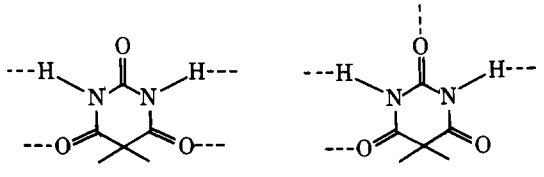
bonded N—H stretching absorption bands, the conformation of hydrogen bonding sites in the phenobarbital crystal would be as in I or II. The lack of free N—H stretching absorption bands in the spectra of the remaining barbiturates implies a conformation of hydrogen bonding sites as in III or IV. Upon complexation, phenobarbital also assumes a hydrogen bonding arrangement as in III or IV, as indicated by the loss of free N—H stretching.

The N—H stretching absorption bands of the barbital–polyethylene glycol 4000 equilibrated sample (Fig. 9) occur at a lower frequency than those of barbital. If hydrogen bond formation between barbiturates and polyethylene glycol 4000 shifts N—H stretching to a higher frequency than intermolecular hydrogen bond formation (as previously discussed), then shifting (Fig. 9) to a lower frequency must not be due to hydrogen bond formation between barbital and polyethylene glycol 4000. Instead, the change may be attributed to an alteration in the configuration of hydrogen bonding sites upon crystallization of barbital from pyridine in the presence of polyethylene glycol 4000.

Hydrogen bonding increases the stability of resonance forms contributing to the resonance stabilization of barbital by decreas-



III IV

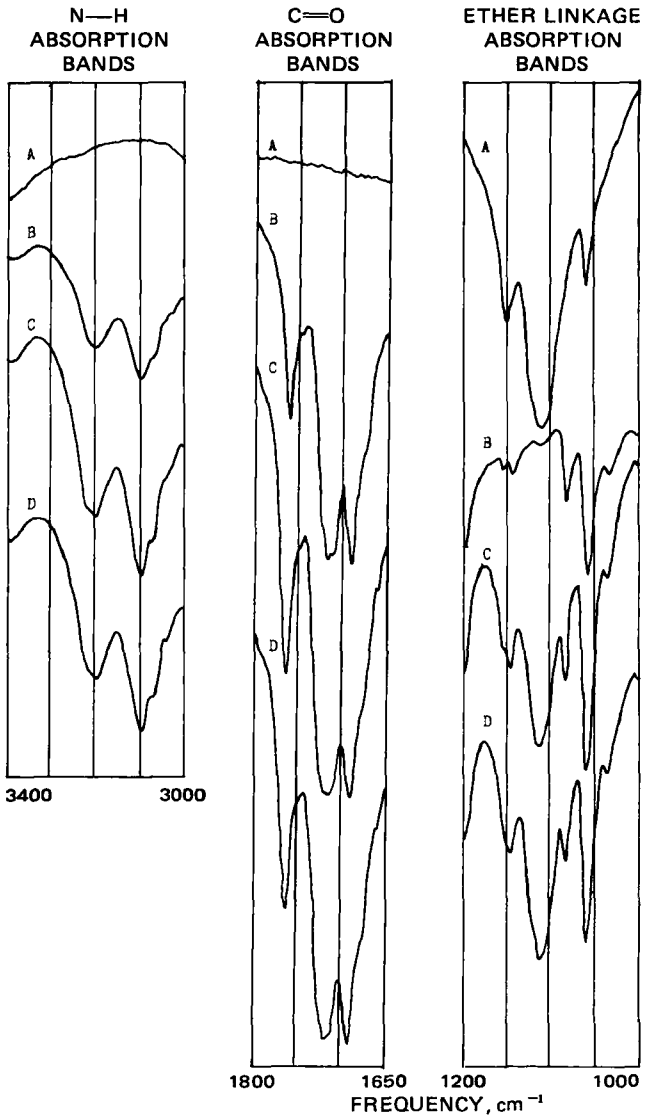

Figure 14—*IR spectra of mephobarbital–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, mephobarbital; C, physical mixture of mephobarbital and polyethylene glycol 4000; and D, equilibrated mephobarbital–polyethylene glycol 4000.*

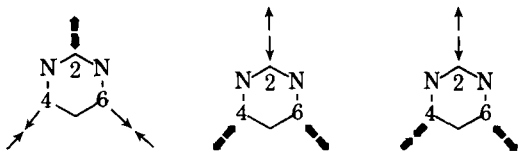
ing the negative charge on the oxygen and the positive charge on the nitrogen. Thus, those canonical forms stabilized by hydrogen bonding in III (Forms 3 and 4) would contribute most to the stabilization energy of barbital molecules hydrogen bonding as in III, while forms stabilized by hydrogen bonding in IV (Forms 1, 2, 5, and 6) contribute most to molecules having bonding sites arranged as in IV. As a result, the N—H stretching of barbital molecules hydrogen bonding as in IV is at a higher frequency due to the more positive character of the nitrogens in these molecules. Based on this rationale and the fact that the N—H absorption of the equilibrated sample is at a lower frequency than barbital, barbital crystallized from pyridine has hydrogen bonding sites as in III, and barbital crystallized from pyridine with polyethylene glycol 4000 hydrogen bonds as in IV.

The N—H stretching absorption bands of amobarbital, vinbarbital, talbutal, allobarbital, mephobarbital, hexobarbital, and primidone (Figs. 10–16) show no evidence of pattern change when equilibrated with polyethylene glycol 4000, indicating that no interaction occurs.

In the carbonyl stretching absorption area of Figs. 1 and 2, the IR spectrum of phenobarbital (curve B) shows three absorption bands: 1780–1770, 1720–1710, and 1680–1670 cm^{-1}. According to Price *et al.* (20), the three carbonyl bonds act as coupled oscillators, giving rise to the following vibration modes:



Vibration 1 (associated mainly with 2-carbonyl vibration) was assigned as the low frequency band because the 2-carbonyl has two neighboring nitrogens to participate in tautomerism and thus the most single bond (C—O^-) character.

Vibration 2 (associated mainly with 4- and 6-carbonyl symmetric vibration) has a higher frequency since the associated carbonyls have only one nitrogen that participates in tautomeric resonance.

Vibration 3 (associated with 4- and 6-carbonyl asymmetric stretching) has a higher frequency than Vibration 2 because the combined force of carbonyl unsymmetric stretching is perpendicular to the 2-carbonyl stretching, and the stretching force of the 2-carbonyl has little influence on it. In contrast, 2-carbonyl stretch-

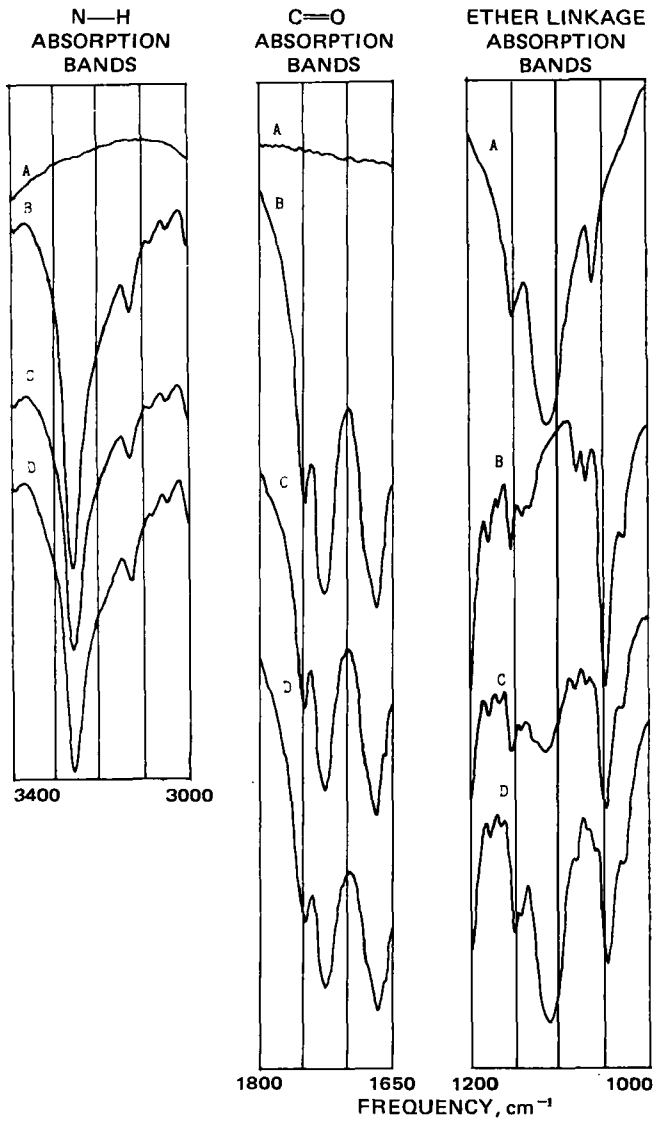


Figure 15—*IR spectra of hexobarbital–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, hexobarbital; C, physical mixture of hexobarbital and polyethylene glycol 4000; and D, equilibrated hexobarbital–polyethylene glycol 4000.*

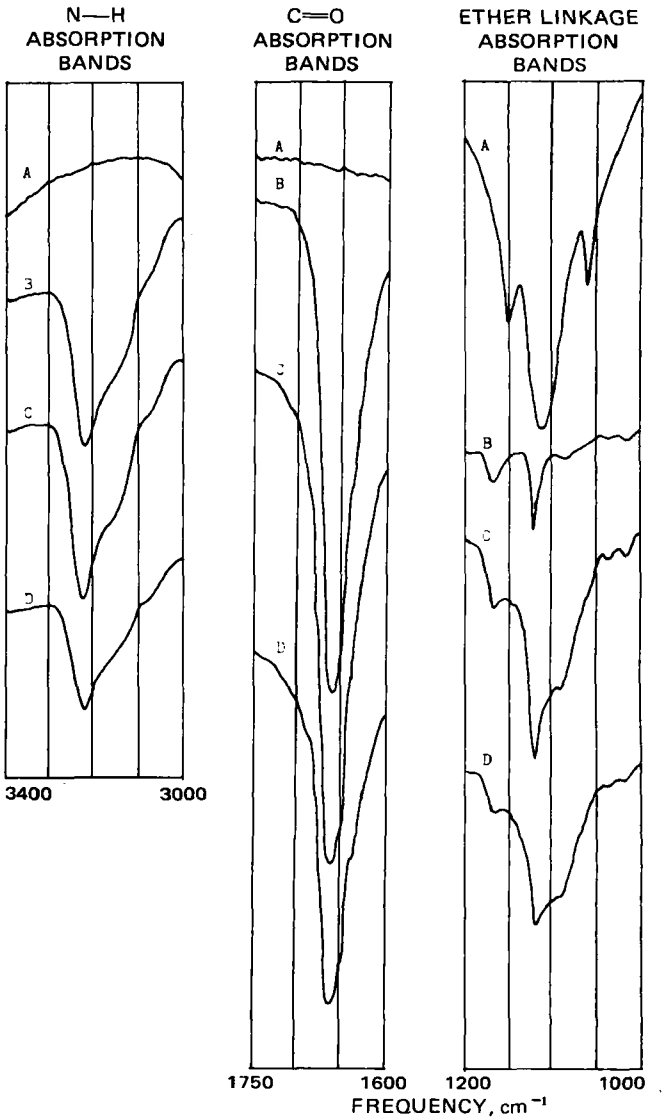

Figure 16—*IR spectra of primidone–polyethylene glycol 4000 from pyridine. Key: A, polyethylene glycol 4000; B, primidone; C, physical mixture of primidone and polyethylene glycol 4000; and D, equilibrated primidone–polyethylene glycol 4000.*

ing in Vibration 2 opposes the combined force of 4- and 6-carbonyl stretching. However, Goenechea (25) assigned the high frequency band to the 2-carbonyl vibration (Vibration 1) because the high frequency band disappears in the 2-thio analog.

Mesley (16) contrasted the frequency of carbonyl absorption bands of barbiturates as determined in ether and in the solid state and showed average changes of 25, 22, and 8 cm^{-1} for the low, middle, and high frequency bands, respectively. Since the 2-carbonyl is free both in the solid state and in ether, the frequency change should be small. The 4- and 6-carbonyl groups, hydrogen bonded in the solid state but free in ether solution, should show much greater frequency changes, leading to an assignment in agreement with that of Goenechea (25).

Although assignment of the high frequency band to the 2-carbonyl is strongly supported by Goenechea's data and in conflict with the assignment of Price *et al.* (20), the coupling oscillator theory stated by the latter is still a powerful method for analyzing force factors of barbiturate vibrations resulting in carbonyl stretching absorption bands. If the assignment of the high frequency band to 2-carbonyl stretching (Vibration 1, or 2-, 4-, and 6-carbonyl unsymmetric in-phase stretching) is accepted, then the middle frequency band must be assigned to 4- and 6-carbonyl out-of-phase stretching (Vibration 3) and the low frequency band must be assigned to 4- and 6-carbonyl symmetric in-phase stretching (Vibration 2), since the latter has the lowest frequency according to this interpretation (20).

The absorption frequencies of carbonyl bands of the barbiturates and their complexes are summarized in Table II. These data indicate that the 2-carbonyl stretching band is shifted to a lower frequency while the 4- and 6-carbonyl out-of-phase stretching and symmetric in-phase stretching are shifted to a higher frequency upon complexation. The 2-carbonyl band of phenobarbital undergoes a large shift upon complexation, indicating a large change in the electronic environment of the 2-carbonyl upon complexation. The direction of the shift indicates that the 2-carbonyl is free in the phenobarbital crystal (I) but hydrogen bonded in the complex (IV).

The shift of 4- and 6-carbonyl out-of-phase stretching and symmetric in-phase stretching to a higher frequency is explicable if the 4- or 6-carbonyl is hydrogen bonded in the barbiturate crystal (III) but free in the complex (IV). Electron density on the free carbonyl is greater than on the hydrogen-bonded carbonyl, giving more double bond character to the carbon–oxygen bond. Thus, both 4- and 6-carbonyl in-phase and out-of-phase stretching are shifted to higher frequencies.

Figures 3–8 have the same pattern of carbonyl absorption bands

when absorption of the equilibrated sample (curve D) is compared to that of the free barbiturate (curve B).

This discussion indicates that the phenobarbital crystal may be represented as I while pentobarbital, probarbital, butethal, and cyclopentenyl allylbarbituric acid have crystal forms such as III. Upon complexation, each barbiturate should be represented as IV.

A comparison of the carbonyl absorption areas in Figs. 10–16 of the barbiturate alone (curve B), the physical mixture (curve C), and the equilibrated sample (curve D) indicates that amobarbital, vinbarbital, allobarbital, talbutal, mephobarbital, and hexobarbital do not interact with polyethylene glycol. Changes observed in the absorption patterns of the barbital system (Fig. 9) may again be rationalized on the basis of a change in hydrogen bond configuration upon crystallization with polyethylene glycol 4000, and complexation need not be implicated.

The ether linkage of polyethylene glycol has a characteristic absorption band at 1110 cm^{-1} (Figs. 1 and 2). Upon complexation, however, a new band is formed at a lower frequency (Figs. 1–8, curves D). The decreased frequency is attributable to the formation of a hydrogen bond upon complexation, in which the oxygen of the ether linkage serves as a hydrogen acceptor.

The aqueous stability of the seven barbiturates found to interact with polyethylene glycol was determined (Figs. 2–8, curves E). The differences between the spectra before (curve D) and after (curve E) water washing are summarized in Table III.

Barbiturates that complex with polyethylene glycol can be classified into three groups on the basis of the water stability of the complexes:

1. Water-stable complexes in which the hydrogen bond between the constituents of the complex is stronger than that between water and the constituents of the complex. Phenobarbital, butabarbital, and cyclobarbital give such complexes.
2. Water-unstable complexes with the barbiturate returning to the original crystal state. Probarbital, butethal, and cyclopentenyl allylbarbituric acid give such complexes, as evidenced by the similarity between curves E and A.
3. Water-unstable complexes with the barbiturate having a different crystal state. Pentobarbital gives such a complex, and the similarity between curves D and E indicates that the hydrogen bonding configuration in the complex is carried over into that of the barbiturate (IV).

SUMMARY

Several factors affecting the barbiturate–polyethylene glycol 4000 interaction have been identified. Since only phenobarbital interacts with polyethylene glycol in water while phenobarbital, butabarbital, butethal, cyclobarbital, cyclopentenyl allylbarbituric acid, pentobarbital, and probarbital interact in pyridine, the nature of the solvent must play an important role. Seven disubstituted barbiturates interact while five disubstituted barbiturates do not, so the nature of the C_5 substituents is critical. Trisubstituted barbiturates do not interact, so two hydrogen bonds are required for complexation. Finally, the fact that primidone does not interact indicates that the 2-carbonyl has an important role in complexation.

Evidence from this study suggests that phenobarbital crystallized from pyridine has hydrogen bonding sites arranged as in I, whereas other barbiturates that complex have bonding sites as in III. All barbiturates, upon complexation, are represented by IV.

Of the seven barbiturate complexes studied, probarbital, butethal, cyclopentenyl allylbarbituric acid, and pentobarbital complexes were unstable in water at 26°. Pentobarbital retains the IV arrangement, but the other three barbiturates revert to III after water washing.

Binding of Metronidazole and Its Derivatives to Plasma Proteins: An Assessment of Drug Binding Phenomenon

DILIP R. SANVORDEKER [x], YIE W. CHIEN, TENG K. LIN, and HOWARD J. LAMBERT

Abstract □ Metronidazole and four derivatives were studied *in vitro* to investigate the differences in the extent of their binding to plasma proteins. Modification at the terminal portion of the alkyl side chain resulted in wide differences in the extent of binding. Molecular orbital calculations were performed by the CNDO and MINDO/2 methods to estimate the frontier electron density on the hetero atom at the 3′-position of the alkyl side chain. A linear correlation between the protein binding parameter ($\log_e P$) and the frontier electron density (q_r) was observed for the binding of this group of trichomonicidal drugs. NMR spectroscopy was used to demonstrate that the alkyl side chain participated in the binding of these compounds to plasma proteins.

Keyphrases □ Metronidazole and four derivatives—plasma protein binding, correlation with frontier electron density □ Plasma protein binding—metronidazole and four derivatives, correlation with frontier electron density □ Electron density, frontier—metronidazole and four derivatives, correlation with plasma protein binding parameters

Several reports provided information on the theoretical, biological, and clinical aspects of drug–protein binding phenomena (1–6). The majority of these investigations was concerned with the drug–serum albumin interaction, since it is the predominant phenomenon occurring in humans. Quantitative correlation has been found between physicochemical parameters such as lipophilicity, pKa, and electronic charge density and the strength of drug binding to serum albumin (7–10).

It is well recognized that the therapeutic activity of a drug is primarily dependent upon the availability of its free (unbound) permeable species at the effective receptor sites located either in the vascular or extravascular compartments of the body (1, 11–14). Recent investigations demonstrated that any structural modification in a functional group can influence significantly both the activity and the extent of protein binding of disopyramide phosphate and its derivatives (14–16).

Metronidazole[1] has been shown to be an effective antiprotozoal agent with a broad spectrum of activity against anaerobes (17–21). In this study, it was observed that the extent of plasma protein binding of

metronidazole and its derivatives is significantly dependent upon the nature of their alkyl side chains. Molecular conformation analysis, coupled with frontier electron density (q_r) calculations by the CNDO[2] and MINDO/2[3] methods, was performed to support and rationalize these observations. NMR spectroscopy was also used to confirm the participation of the alkyl side chain in the binding process. This article reports the results and interpretations of these investigations.

EXPERIMENTAL

Materials—The following were used: metronidazole[4] (I), 1β-thiosulfate sodium methyl-2-methyl-5-nitroimidazole[5] (II), 1β-aminoacetylethyl-2-methyl-5-nitroimidazole[6] (III), 1β-carboxymethyl-5-nitroimidazole[7] (IV), and metronidazole acetate (V). All compounds were tested for structure identity and purity prior to use.

Plasma Protein Binding Study—The procedure reported previously (16) was utilized.

CNDO and MINDO/2 Study—These studies were conducted on the basis of established procedures (22–24). All calculations were performed with a high-speed memory computer[8].

NMR Study—Lyophilized normal human serum[9], 40% NaOD in D_2O[10], and 38% DCl in D_2O[11] were used to prepare appropriate stock solutions in 99.7% pure D_2O[11]. An appropriate amount of the drug was accurately weighed and transferred to a 10-ml volumetric flask, followed by the addition of 3–6 ml of D_2O to dissolve the drug. The pD of the solution was adjusted to a near neutral region (6–8) with the addition of a few drops of dilute NaOD or DCl solution.

Aliquots of a freshly prepared stock solution of human serum (containing 4.6% serum albumin) in D_2O were then added to the solution and the pD was readjusted to 7. The final volume of the solution was made up with D_2O to obtain a 0.0467 *M* solution of the drug without albumin and with human serum containing 1.15 and 2.5% albumin. All NMR spectra were obtained on a high-resolution (60 MHz) NMR spectrometer[12]. A 1% tetramethylsilane[11] solution in $CDCl_3$ was used as an external standard to calibrate the instrument for all measurements.

RESULTS AND DISCUSSION

Table I illustrates the structural formulas and the effect of alkyl side-chain modification on the lipophilic character of metronidazole and its derivatives. In these five nitroimidazole derivatives, the functional group on the *N*-1 position of the imidazole nucleus was varied chemically to assess its effects on the extent of their

binding to plasma proteins (Table II). The concentration range studied for each drug was based on realistic values equivalent to or above the minimum inhibitory concentration (MIC) required against *Trichomonas vaginalis*.

The extent of plasma protein binding (Table II) and the lipophilic character (Table I) of this group of compounds do not show any linear correlation. This finding is demonstrated by the fact that metronidazole acetate (V), despite its high lipophilicity, shows poor protein binding (Tables I and II), whereas II, with poor lipophilic character, exhibits extensive binding to plasma proteins. Thus, a substitution of the hydroxy group with a thiosulfonyl group on II resulted in an approximately 16-fold increase in the binding of II over metronidazole. On the other hand, substitution with an acetamido group in III resulted in a slight increase in the extent of binding of that compound, despite a 10-fold increase in its lipophilicity over that of II.

CNDO and MINDO/2 calculations were performed to investigate conformational similarity and to assess whether the frontier electron density (q_r) on the hetero-atom at the terminal portion of the alkyl side chain contributed to these observed differences in the extent of protein binding. It is reasonable to assume that the contributions of the nitroimidazole moiety common to all these compounds is approximately the same with reference to the plasma protein binding phenomenon. This assumption implies that the observed differences in the protein binding of these compounds are due only to the variation of the functional group on the *N*-1 position of the imidazole ring. Under this condition, electron densities on the terminal molecular groups, namely H_2N—CH_2CH_2OH, H_2N—$CH_2CH_2SSO_3H$, H_2N—$CH_2CH_2NHCOCH_3$, H_2N—CH_2COOH, and H_2N—$CH_2CH_2OCOCH_3$, were computed on the basis that these parts of the molecule form localized molecular orbitals. Consequently, certain physicochemical properties of these functional groups can be considered nearly independent of their associated nitroimidazole nucleus.

The computations were performed in the following manner. At first, molecular conformation was roughly optimized by the CNDO (Complete Neglect of Differential Overlap) method (22). Second, the molecular energy was extensively minimized by the MINDO/2 (Modified Intermediate Neglect of Differential Overlap) method (23). These two methods belong to the classical semiempirical

SCF-MO (Self-Consistent Field Molecular Orbital) method. Although both methods are not quantitatively as accurate as *ab initio* SCF-MO calculations (24), they reflect a quantitative estimation of physicochemical properties, such as frontier electron density of relatively large molecules.

Whereas the MINDO/2 method provides satisfactory results in terms of molecular conformation, the CNDO method provides computation of the frontier electron density (q_r) because its differ-

ential overlaps are completely neglected. The frontier electron density (q_r) can thus be assembled from the parts of the HOMO (Highest Occupied Molecular Orbital) wave function, which can be expressed as follows:

$$q_r = \sum_i 2C_i^2(\eta) \qquad \text{(Eq. 1)}$$

[a] Total energy = −1.24652 a.u. (MINDO/2). Frontier electron density at the 3′ position = 0.06552 (CNDO).

where C_i (η)'s are HOMO eigenvectors of the CNDO at the ηth position, and Σ_i's constitute the sum of s, p_x, p_y, and p_z atomic orbitals of the atom at the ηth position on the functional group of each compound.

Tables III–VII illustrate the optimized coordinates system and minimized energy computed on the basis of these methods. The possibility of intramolecular interaction, such as hydrogen bonding, was also examined by the CNDO method. Except for IV, which showed a gain of 1.272 kcal/mole (possibly through hydrogen bonding), none of these compounds exhibited any intramolecular interaction.

It is recognized that the binding of drugs to plasma proteins, such as serum albumin, proceeds with the interaction at the primary binding site(s) on the protein, followed by a saturation phase involving any secondary and ternary binding sites available. If it is assumed that the drug–serum albumin interaction occurs only at the primary binding sites at a low drug concentration range, then the plasma protein binding index [$\log_e P_{(mean)}$] (defined as the natural logarithm of the mean percent fraction of the total drug in the bound state) becomes important in determining the availability of the free drug to diffuse into the extravascular compartment. This $\log_e P$ value for each compound at and below 6.4×10^{-5} M concentration was observed to be virtually constant (Table II).

In performing molecular orbital calculations, it was observed that the frontier electron density (q_r) at the 3′-position was the highest for all compounds in this series. Table VIII lists the experi-

Table VIII—Relationship between the Protein Binding Parameter ($\log_e P$) and the Frontier Electron Density (q_r) at the 3′-Position on the Alkyl Side Chain of Metronidazole and Its Derivatives

Compound	Fraction of Drug Bound, %, Mean ± SD	Frontier Electron Density, q_r	Protein Binding Parameter, $\log_e P$	
			Experimental	Calculated
I	3.68 ± 0.58	0.1255	1.30	1.18
II	68.25 ± 0.21	1.2487	4.22	4.18
III	11.07 ± 0.26	0.6374	2.40	2.52
IV	4.08 ± 2.06	0.1554	1.41	1.26
V	2.31 ± 0.21	0.0655	0.84	1.02

mental and calculated $\log_e P_{(mean)}$ values and the frontier electron density at the 3′(*)-position of the N_1-alkyl side chain of metronidazole and its derivatives. The calculated values were determined from Eq. 2. A linear correlation between the $\log_e P_{(mean)}$ and the frontier electron density at the 3′-position (calculated by the CNDO and MINDO/2 methods) was observed for this group of compounds. Such a relationship, as illustrated in Fig. 1, is defined by:

$$\log_e P_{(mean)} = 0.848 + 2.668q_r \qquad \text{(Eq. 2)}$$

$$n = 5 \qquad r = 0.994 \qquad s = 0.131$$

where n is the number of compounds, r is the correlation coefficient, and s is the standard deviation.

A correlation coefficient of 0.994 for the regression line reflects excellent fit for the protein binding data with the computed frontier electron density at the 3′-position of the N_1-alkyl side chain. These results suggest that the plasma protein binding of metronidazole and its derivatives is nonspecific in nature and is dependent upon the frontier electron density at the 3′-position. That is, the drug–protein (mostly serum albumin) interaction occurs through a combination of van der Waals and electrostatic forces.

Evidence that the alkyl side chain and the imidazole moiety do participate in the drug binding process was obtained using NMR spectroscopy. This technique has been used to identify the functional groups on a drug molecule that participate in the drug–protein binding process (25–27). Figures 2–4 illustrate the NMR spectra obtained on solutions of metronidazole and its derivatives with and without human serum albumin at two different concentrations. Due to solubility limitations, these studies could not be performed with III and V (metronidazole acetate).

Whereas the methylene (—CH_2—) and methyl (—CH_3) protons of the metronidazole showed very little change in the presence of serum albumin (Fig. 2), the same protons on II (Fig. 3) showed extensive relaxation proportional to the serum albumin concentration. The magnitude of the relaxation effect observed for II as compared to that observed for metronidazole (I) is consistent with the quantitative results on the extent of binding of these two compounds (Table II). The specific relaxation of the methyl protons at the C-2 position and the methylene protons of the alkyl side chain is indicative of the participation of these functional moieties in the overall binding process.

Similar proton relaxation effect for the alkyl and methyl protons of IV in the presence of plasma proteins is illustrated in Fig. 4. The magnitude of methylene proton relaxation observed for this compound is relatively small compared to that observed for II. Such an observation is consistent with the protein binding data (Table II) and strongly suggests a stabilization effect due to the alkyl side chain and the imidazole moiety.

In conclusion, this study demonstrated that modifications of a functional group on the basic metronidazole molecule caused significant differences in its protein binding characteristics. The degree of binding of this group of nitroimidazoles was shown to be primarily dependent upon the frontier electron density on the terminal portion of the alkyl side chain. The greater the frontier electron density, the greater was the degree of drug binding to plasma proteins. On the basis of these observations, it appears that the frontier electron density parameter with reference to a defined position on a drug molecule can provide useful information concerning the drug–protein interaction of a group of drugs with structural similarities.

Utilization of Model Compounds to Evaluate Effects of Slight Chemical Modifications on Their Distribution Pharmacokinetic Parameters in Rats and Mechanisms Inferred for Their Transmembrane Transport

YASHWANT M. AMIN * and JANARDAN B. NAGWEKAR ˣ

Abstract □ The pharmacokinetics of each of the model compounds benzoylformic acid (I), *p*-methylbenzoylformic acid (II), *p*-ethylbenzoylformic acid (III), D-(−)-mandelic acid (IV), D-(−)-*p*-methylmandelic acid (V), D-(−)-*p*-ethylmandelic acid (VI), and D-(−)-*p*-isopropylmandelic acid (VII) were studied in rats to determine the influence of slight chemical modifications of the compounds on their distribution pharmacokinetic parameters in rats. The effects of the specific chemical modifications considered were those of the >CHOH group of IV against the >C=O group of I, the *para*-alkylation of I and IV, and the branched alkyl group (isopropyl) against the straight chain alkyl groups of the homologs of IV. While the disappearance of I from the blood was describable by the three-compartment open model, that of IV was describable by the two-compartment open model. The apparent volume of distribution of the central compartment (V_1) for IV was smaller than that for I, but the volume of the peripheral compartment (V_2) for IV was greater than that ($V_2 + V_3$) for I. The disappearance of V, VI, and VII from the blood was also describable by the two-compartment open model, but the apparent V_1 and V_2 for these compounds were lower than those for the parent compound, IV. However, the disappearance of II and III from the blood was describable by a one-compartment open model. Evaluation of the appropriate distribution pharmacokinetic parameters suggested that the peripheral compartment for the anions of these compounds consisted of moderately perfused tissues and that the transmembrane transport of these organic anions between the central and peripheral compartments occurs by diffusion mainly through the aqueous membrane pores, which are lined with polar portions of the membrane proteins and/or phospholipids. The possible increased hydrophobic bonding between the alkyl groups of these compounds and the hydrophobic groups of the proteins and/or phospholipids of the membrane pores is implicated to decrease the distribution of the *para*-alkylated homologs into the peripheral compartments and, consequently, diminish the volumes of their peripheral compartments. The heteroporosity of the membranes of the tissues of the central compartment is proposed as the reason for the diminished volume of the central compartment for V and VI as compared to that of IV or VII.

Keyphrases □ Pharmacokinetics—distribution parameters, use of model compounds to evaluate effects of chemical modifications, mechanisms of transmembrane transport, rats □ Distribution—model compounds, effects of chemical modifications, pharmacokinetic parameters, transport mechanisms, rats □ Transport—model compounds, effects of chemical modifications, distribution pharmacokinetic parameters, rats

It is well recognized that the extent of pharmacological response of a drug depends not only on the drug–receptor interaction but also on the concentration of the drug at the site of action containing the receptor(s). Therefore, it is common practice to synthesize and use the analogs or homologs of drugs to modify their biological activities. Although theories have been suggested concerning the drug structure–activity relationship on the basis of biological effects, such theories are not complete without considering the influence on the pharmacological actions of the rates of distribution of drugs between plasma and tissues where the site(s) of action may reside. However, the rates of distribution of drugs at the site(s) of action are governed by several processes, namely, binding of drugs to plasma proteins, metabolism of drugs, renal and nonrenal excretion, and renal tubular secretion of drugs, all of which occur simultaneously.

In recent years, studies have been performed to compare the effects of substituent groups of analogs or homologs of drugs on their pharmacokinetic parameters to determine the effect of specific substituent groups on the specific pharmacokinetic parameters of the compounds. However, such efforts do not appear to be too successful, mainly because the determination of the pharmacokinetic parameters is complicated due to the differences of the homologs or analogs in their extent of binding to plasma (1–6), pKa values, rates of metabolism (7), and partition coefficients between aqueous and lipid phases within the body (4, 7).

According to current concepts, biological membranes are composed mainly of proteins and phospholipids; the proportions of these building blocks are not identical for the membranes of all organs. Several mechanisms for the transmembrane transport of solutes (mainly inorganic electrolytes and organic nonelectrolytes) have been proposed, including diffusion of permeant molecules by dissolving in the membrane; diffusion of permeant molecules through the aqueous pores, which are lined with polar portions of the proteins and/or phospholipids as carrier(s); and active transport, which may involve enzymes and adenosine triphosphatase (8). Therefore, depending upon the organ of permeation and mechanism of transport of solutes through the membrane of such organ, the differences in the rates of diffusion of the compounds can be expected.

In view of these various mechanisms for transmembrane transport of solutes and their interaction with components of the membrane through various forces (8) (electrostatic interactions, hydrogen bonding, and hydrophobic bonding), it is apparent that the effects of substituent groups of homologs or analogs of drugs on the distribution pharmacokinetic parameters cannot be determined unless the effects of the various processes (protein binding, metabolism, and renal tubular reabsorption) to which the drug is subjected simultaneously in the body are minimal. Consequently, studies with several drugs and their

homologs and/or analogs were unable to determine exclusively the effects of substituents on the distribution pharmacokinetic parameters (1–7).

In recent years, D-(−)-mandelic acid and several of its *para*-alkylated homologs have been shown to possess ideal properties by virtue of which they are neither metabolized nor reabsorbed from the renal tubules of rats and are negligibly bound to plasma proteins (9–12). Since these compounds have low pKa values, they remain completely ionized in the body fluids and serve as model organic anions.

Therefore, the purposes of this project were to study the pharmacokinetics of benzoylformic acid (I) and its *para*-alkylated homologs *p*-methylbenzoylformic acid (II) and *p*-ethylbenzoylformic acid (III) as well as D-(−)-mandelic acid (IV) and its *para*-alkylated homologs D-(−)-*p*-methylmandelic acid (V), D-(−)-*p*-ethylmandelic acid (VI), and D-(−)-*p*-isopropylmandelic acid (VII) from blood level data in rats and to determine the effects of slight chemical variations on their distribution pharmacokinetic parameters. The effects of the specific chemical modifications considered were those of the >CHOH group of IV against the >C=O group of I, the *para*-alkylation of I and IV, and the branched alkyl group (isopropyl) of VII against the straight chain alkyl groups of V, VI, and D-(−)-*p*-*n*-propylmandelic acid (13).

An additional purpose of this project was to utilize the difference observed in the pharmacokinetic parameters of the compounds to reveal the possible mechanisms for their transmembrane transport between central and peripheral compartments of the body at a molecular level by considering the possible electrostatic, hydrogen bonding, and hydrophobic interactions between the permeant molecules and certain components of the membranes.

EXPERIMENTAL

Materials—The following were used: D-(−)-mandelic acid[1], mp 132–133°, $[\alpha]_D^{25}$ −154°; D-(−)-*p*-methylmandelic acid[2], mp 130–131°, $[\alpha]_D^{25}$ −159°; D-(−)-*p*-ethylmandelic acid[2], mp 119–120°, $[\alpha]_D^{25}$ −120°; D-(−)-*p*-isopropylmandelic acid[3], mp 159–160°, $[\alpha]_D^{25}$ −129°; benzoylformic acid[1], mp 62–64°; *p*-methylbenzoylformic acid, mp 97–99°, synthesized by the method of Kindler *et al.* (14); *p*-ethylbenzoylformic acid, mp 65–67°, also synthesized by the method of Kindler *et al.* (14); and DL-tropic acid[1], mp 118–119°.

Apparatus—Compounds I, IV, and their respective *para*-alkylated homologs present in rat blood were analyzed by GLC[4] using a hydrogen-flame detector.

Methodology—Approximately 250 Sprague–Dawley male rats, weighing between 170 and 230 g (a majority weighed ~200 g), were used. Blood levels of the compounds were determined in eight to 10 rats on a given day. Food was withheld from the rats 12–14 hr prior to their use in the study as well as during the study.

Five milliliters of normal saline was injected intraperitoneally into each rat 20 min prior to intravenous administration of the compound(s) in order to be consistent with the procedure followed previously (9–13) in urinary excretion studies so that the pharmacokinetic parameters obtained from the blood level studies can be compared with those obtained from the urinary excretion studies. The rat was anesthetized with ether for less than 1 min for intravenous injection of a fixed dose of the compound contained in 2 ml of isotonic solution. Each injection time was accurately noted.

Only one blood sample was obtained from a given rat upon its decapitation at an appropriate time following administration of the intravenous dose of the compound. The blood samples, which were obtained over 1–100 min for benzoylformic acid and over 1–65 min for the rest of the compounds, were collected in 50-ml beakers previously coated with heparin to prevent coagulation of blood. Each beaker was coated with 0.1 ml (10 units) of heparin. The blood samples were analyzed for the compound on the same day they were collected. The pharmacokinetics of I were studied at the three intravenous dose levels (166.65[5], 249.80, and 333.33 μmoles/kg). The pharmacokinetics of II (152.45 μmoles/kg)[5], III (140.5 μmoles/kg)[5], IV (165.35 μmoles/kg)[5], V (149.6 μmoles/kg)[5], VI (138.25 μmoles/kg)[5], or VII (128.1 μmoles/kg)[5] were studied at a single intravenous dose level. Each compound was injected as its sodium salt.

GLC Analysis—Depending on the anticipated concentration of the compound in a blood sample, an appropriate volume of blood (1–5 ml) was transferred to a 150-ml beaker. The proteins and blood cells were precipitated with a dropwise addition of 5 *N* HCl, with continuous stirring for 10 min with a magnetic stirrer. To extract the compounds from this blood sample into ether, 25 ml of ether was added to the blood sample and stirring was continued for another 15 min. The ethereal layer was then quantitatively transferred to a 60-ml separator, and it was extracted with 15–20 ml of 5 *N* sodium hydroxide solution to recover completely the compound in the alkaline aqueous phase as its sodium salt; the ethereal layer was discarded.

The residue of each precipitated blood sample remaining in the 150-ml beaker after the first ether extraction was further extracted with two additional 20-ml volumes of ether for I and its *para*-alkylated homologs and with three additional 20-ml volumes of ether for IV and its *para*-alkylated homologs. The compound was recovered from these ethereal phases using the alkaline solution employed in the first extraction. The alkaline solution was then acidified with 5 *N* HCl and extracted twice with ether for I and its *para*-alkylated homologs and three times for IV and its *para*-alkylated homologs, using 30 ml of ether each time.

The ethereal layer was collected in a 100-ml beaker and the ether was evaporated by transferring the ethereal layer in portions to a 20-ml graduated tube. The ether was evaporated from the test tube on a water bath maintained at 42°. The residue of the compound thus obtained in the test tube was treated with sufficient amount of ethereal diazomethane to convert the compound to its methyl ester. Excess ether and diazomethane were removed from the tube on a water bath at 42°. A sufficient quantity of absolute methanol was added to the residue to dissolve the compound and to adjust the volume to 1 ml. The methanolic solution thus prepared was ready for GLC analysis.

An appropriate volume (generally 20 μl) of the methanolic solution was injected onto the GLC column. The conditions employed for the GLC analysis and the column used are described in Table I.

To determine accurately the amount of a compound (*i.e.*, I or one of its homologs or IV or one of its homologs) present in the blood samples, a calibration curve for the compound was prepared in the following manner. The solutions of the compound were prepared in the blood obtained from generally three rats, which were not previously treated with any compound. To each 2-ml volume of blood, a known quantity of the compound was added. Then each solution was treated to obtain the methyl ester of the compound according to the procedure described previously. The known quantities of the compound added to 2-ml blood volumes were those obtained from the stock solution prepared on the same day for injecting the rats.

The calibration curve for the compound was also prepared in this manner by using 5 ml of blood, instead of 2 ml, to determine the influence of blood volume on the quantitative recovery of the compound (Fig. 1). The area under each chromatogram was calculated by the trapezoidal rule and plotted against the corresponding amount of the compound (Fig. 1). With reference to such a calibration curve, prepared separately for each study, the amount of the compound present in each blood sample was calculated.

VII	5% E.G.S.[a]	165°	210°	40	12.2

[a] Ethylene glycol succinate on Diatoport S (80–100 mesh) packed in a 1.2-m (4-ft) long and 0.6-cm (0.25-in.) diameter copper column. [b] GE-SE 30 silicone gum rubber on Diatoport S (80–100 mesh) packed in a 1.2-m (4-ft) long and 0.6-cm (0.25-in.) diameter copper column.

Determination of Dissociation Constants and Apparent Partition Coefficients of Compounds and Their Binding to Whole Rat Blood as well as Plasma Proteins—These determinations for I and its *para*-alkylated homologs were carried out by the methods previously described for IV and its several homologs (9–12).

RESULTS

Selection of Compounds—Selection of the compounds for the present study was based on the following ideal properties:

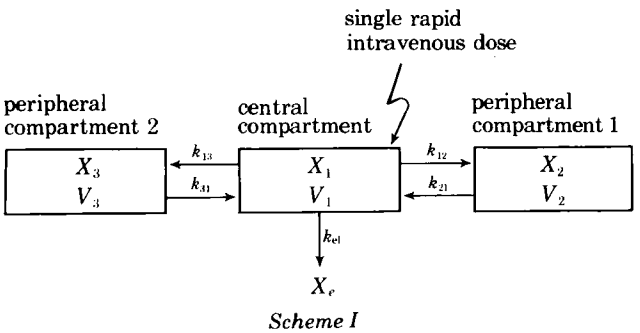
1. From the overall urinary recovery (Table II) of the administered intravenous doses of I–III, it was demonstrated that virtually 100% of the administered dose of each compound was recovered in the unchanged form, indicating negligible metabolism in rats. The fact that the intravenous dose of IV–VII is also completely recovered in the urine in the unchanged form was already reported (9–12).

2. The pKa values determined for I, II, and III are 3.2, 3.3, and 3.3, respectively; those reported for IV, V, VI, and VII are 3.3, 3.4, 3.4, and 3.6, respectively. Therefore, these compounds should remain in the ionized form in the biological fluids.

3. The partition coefficients ($C_{organic}/C_{buffer}$) determined for these compounds, according to the procedure previously described (9), were zero. Therefore, it was assumed that the reabsorption of the compounds in the renal tubules is negligible.

4. From the equilibrium dialysis studies, it was noted that at the equilibrium concentrations of 1.07 mg/4 ml of I, 0.51 mg/4 ml of II, and 1.03 mg/4 ml of III in the blood as well as in plasma, the extent of binding observed was 13.5, 4, and 4%, respectively. If, as generally believed (15), the plasma protein–drug complex is assumed to dissociate rapidly at the secretion site, the effect of 13.5% binding of I to plasma proteins can be expected to exert no pronounced effect on the biological half-life of the compound. Therefore, for practical purposes, this extent of binding of I as well as of II and III was considered negligible. The binding of IV–VII to plasma proteins also is negligible (9–12).

Determination of Pharmacokinetic Parameters—*Pharmacokinetics of I–III*—The pharmacokinetics of I were studied at three intravenous doses to determine if there were any apparent dose-dependent kinetics in the 166.65–333.33-μmole/kg dosage range. The typical blood level data obtained are presented in Fig. 2. Feathering of the semilogarithmic plots of the data obtained at each dose indicated that the decline in blood levels of the compound can best be described to occur triexponentially rather than biexponentially (Fig. 3). Therefore, these data were analyzed according to the three-compartment open model (Scheme I) with elimination occurring from the central compartment. The elimination process consisted of only urinary excretion, as demonstrated from the overall urinary excretion studies.



Scheme I

Table II—Overall Urinary Excretion Recovery Observed following Intravenous Administration of I–III to Rats

Compound	Dose per Rat, mg	Number of Studies	Intact Compound Recovered, mg

In Scheme I, X_1, X_2, and X_3 are the amounts of the compound in the central compartment, peripheral compartment 1, and peripheral compartment 2, respectively, at time t; V_1, V_2, and V_3 are the apparent volumes of the central compartment, peripheral compartment 1, and peripheral compartment 2, respectively; X_e is the cumulative amount of the compound excreted in the urine up to time t; k_{el} is the apparent first-order rate constant of elimination of the compound; and k_{12}, k_{21}, k_{13}, and k_{31} are the apparent first-order rate constants for the transfer of the compound from one compartment to the other.

The general solution for the three-compartment open model was described (16) as:

$$C_b = C_1e^{-\alpha t} + C_2e^{-\beta t} + C_3e^{-\gamma t} \qquad \text{(Eq. 1)}$$

where C_b is the concentration of the compound in the blood at time t. The blood data were plotted on semilogarithmic paper (Fig. 2), and preliminary estimates for the intercepts (C_1, C_2, and C_3) and slopes ($-\alpha/2.303$, $-\beta/2.303$, and $-\gamma/2.303$) were obtained by using appropriate equations (16).

By using these initial estimates, the blood level data were fitted to a three-compartment open model according to the NONLIN least-squares program (17). The excellent fit of the data was indicated by the high coefficient of determination and the correlation

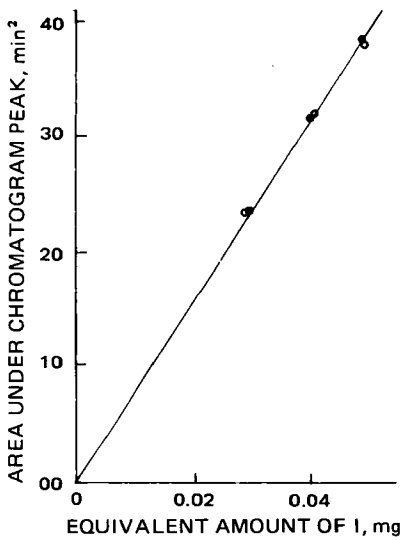

Figure 1—*Standard curve prepared for I contained in 2 (●) and 5 (○) ml of blood, indicating negligible influence of blood volume on the recovery of the compound from the blood.*

Table III—Pharmacokinetic Parameters Estimated and Derived for the Three-Compartment Open Model by Nonlinear Least-Squares Fitting (NONLIN) of Whole Blood Concentration Data Obtained for I in Rats

Pharmacokinetic Parameters	Intravenous Dose (166.65 μmoles/kg)	Intravenous Dose (249.80 μmoles/kg)	Intravenous Dose (333.33 μmoles/kg)	Average for Three Studies

coefficient (Table III). The volumes of the central compartment, peripheral compartment 1, and peripheral compartment 2 were calculated, using appropriate equations. The volume of the central compartment (V_1) refers to the volume of the blood and interstitial fluids that are readily accessible to the compound, and V_2 and V_3 refer to the volumes constituted by different tissue fluids.

To determine if I shows any apparent dose-dependent kinetics in the dosage range used, the blood level data of each dose were treated according to the superposition method (18). Accordingly, plots of C_b/intravenous dose *versus* time were prepared for the blood level data obtained at each dosage level. As can be seen in Fig. 3, no apparent dose-dependent kinetics are observed. Therefore, to facilitate the interpretation of the data in the later sections, the appropriate pharmacokinetic parameters obtained at these three dosage levels were averaged (Table III).

The pharmacokinetics of II and III each were studied at only one intravenous dose level (25 mg/kg); there was no specific need to determine their dose-dependent kinetics for this study. Examination of the blood level data obtained for these compounds (Fig. 4) indicated that their disappearance from the blood occurred monoexponentially. Therefore, these data were analyzed according to the one-compartment open model (Scheme II). The elimination process of the compound consisted of urinary excretion only, as demonstrated from the overall urinary excretion studies (Table II).

In Scheme II, X_1 is the amount of the compound in the body at time t, X_e is the cumulative amount of the compound excreted in the urine up to time t, k_{el} is an apparent first-order rate constant for elimination of the compound, and V_1 is an apparent volume of

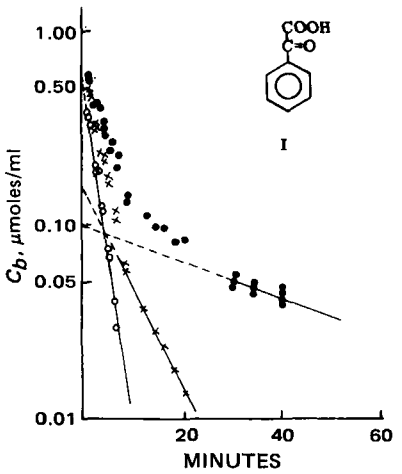

Figure 2—*Plot showing triexponential decline of blood levels of I following administration of a 166.65-μmoles/kg iv dose per rat. Figure 3—*Superposition plot of C_b/intravenous dose versus time, indicating the apparent absence of dose-dependent kinetics for I in the dosage range of 166.65–333.33 μmoles/kg in rats. Key: ○, 166.65-μmoles/kg iv dose; □, 249.80-μmoles/kg iv dose; and △, 333.33-μmoles/kg iv dose.*

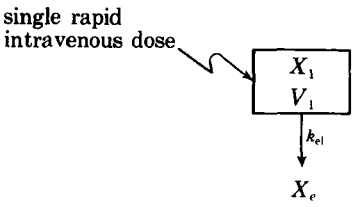

Scheme II

distribution for the compound in the body. The blood level data were treated according to the following equation:

$$\log C_b = \log C_b^0 - k_{el}t/2.303 \qquad \text{(Eq. 2)}$$

where C_b is the concentration of the compound at time t, and C_b^0 is the concentration of the compound at zero time. The values of C_b^0 for these compounds were determined from the intercepts obtained by extrapolating the respective least-squares straight lines to zero time (Fig. 4). The volumes of distribution and the biological half-lives were calculated according to the equations V_d = intravenous dose/C_b^0 and $t_{1/2} = 0.693/k_{el}$. The pharmacokinetic parameters determined are recorded in Table IV.

Pharmacokinetics of IV–VII—Examination of the data obtained for IV (Fig. 5) indicated that the disappearance of the compound from the blood occurs biexponentially. Therefore, these data were treated according to the two-compartment open model (Scheme III), with elimination occurring from the central compartment. The elimination process for the compound consisted of urinary excretion only, as demonstrated by Randinitis *et al.* (9).

In Scheme III, X_1 and X_2 are the amounts of the compounds in the central compartment and the peripheral compartment, respectively, at time t; X_e is the cumulative amount of the compound excreted in the urine up to time t; V_1 and V_2 are the apparent volumes of the central compartment and the peripheral compartment, respectively; k_{el} is the apparent first-order rate constant of elimination of the compound; and k_{12} and k_{21} are the apparent first-order rate constants for the transfer of the compound from one compartment into another. The general solution of this system gives the following equation:

$$C_b = C_1e^{-\alpha t} + C_2e^{-\beta t} \qquad \text{(Eq. 3)}$$

where C_b is the concentration of the compound in the blood at time t. Preliminary estimates for the intercepts (C_1 and C_2) and slopes ($-\alpha/2.303$ and $-\beta/2.303$) were obtained by feathering the semilogarithmic plot (Fig. 5). The initial estimates for k_{12}, k_{21}, and k_{el} were obtained using the usual equations (19). By using these initial estimates, the blood level data were fitted to a two-compartment open model according to the NONLIN least-squares program (17). The estimated and derived parameters are presented in Table V. The excellent fit of the data is indicated by the high coefficient of determination and the correlation coefficient (Table V). The volumes of the central compartment (V_1) and the peripheral compartment (V_2) were calculated from V_1 = intravenous dose/C_b^0 and $V_2 = (k_{12}/k_{21})V_1$, respectively (19). The fraction of the dose of the compounds, $f_c = \beta/k_{el}$, and the $t_{1/2\beta} = 0.693/\beta$ values were calculated.

The data obtained for V–VII are presented in Fig. 6. Examination of the blood level data for each compound revealed that the decline in the blood levels of the compounds also occurs biexponentially, as was noted for IV. Therefore, these data were analyzed according to the two-compartment open model system and the initial estimates were determined. By using the initial estimates, the blood level data were fitted to a two-compartment open model according to the NONLIN least-squares program (17). The estimated and derived parameters are presented in Table V. The excellent fit of the data is indicated by the high coefficient of determination and the correlation coefficient (Table V).

DISCUSSION

Effect of Substitution of Alkyl Groups in the *para*-Position of IV on Their Distribution Pharmacokinetic Parameters—To determine the effect of alkyl group substitution on the distribution pharmacokinetic parameters of IV and its *para*-alkylated homologs, the parameters appropriate for evaluation are V_1, V_2, and k_{12}/k_{21}. Examination of the data presented in Table V reveals a certain trend in the magnitudes of these parameters which relate to the influence of the alkyl groups.

Comparison of V_1 *and* V_2—In general, the volume of the central compartment (V_1) for IV appears to be greater than that for its *para*-alkylated homologs, although the V_1 for VII may be considered very similar to that for IV. The apparent volume of the peripheral compartment (V_2) for IV is greater than that for each of its homologs. Substitution of a methyl group or an ethyl group resulted in a sharp decrease (by a factor of almost 4.5–5) in the volume of distribution of the peripheral compartment, whereas sub-

[a] The number in parentheses refers to the standard deviation of the corresponding parameter.

stitution of an isopropyl group resulted in a decrease in the volume of the peripheral compartment by a factor of 2.

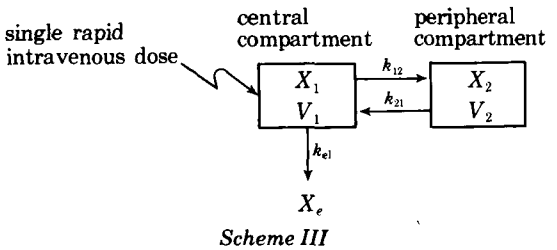
It is generally believed that the peripheral compartment consists of less moderately or poorly perfused tissues such as fatty tissues. Therefore, it is argued that if the peripheral compartment in which these compounds are distributed does consist of poorly perfused fatty tissues, then the *para*-alkylated compounds, because of their lipophilic alkyl groups, should distribute into the peripheral compartment to a greater extent than does IV, and each should consequently exhibit higher values of V_2 than those observed for IV. This, however, was not the case in the present study.

Furthermore, since IV and its *para*-alkylated homologs have pKa values in the 3.3–3.8 range, all of these compounds should remain in the systemic body fluids in the anionic form and are, consequently, least soluble in the fatty tissues or poorly perfused tissues. Therefore, it is believed that, for the compounds under discussion, the peripheral compartment consists of moderately perfused tissues and the rate of diffusion of each *para*-alkylated homolog into such tissues is significantly lower than that of IV.

Comparison of Ratios of k_{12}/k_{21}—Although the individual distribution rate constants, k_{12} and k_{21}, are calculated in the present study, it is considered desirable to compare the ratios of these rate constants (k_{12}/k_{21}), rather than the individual rate constants, to determine the effect of alkyl groups of the homologs of IV on their distribution characteristics. The reason for this approach is that one cannot be certain if the values of the forward or backward distribution rate constants are absolute since these rate constants are the result of various diffusion steps involved in a given compartment and these rate constants are calculated from the hybrid parameters of α and β.

The appropriateness of this approach is illustrated by the fact that when the distribution rate constants k_{12} = 0.993 hr^{-1} and k_{21} = 1.99 hr^{-1} determined by Wagner *et al.* (20) for spectinomycin were recalculated for the data by Pfeffer (21), using a different computer program, the values obtained were k_{12} = 0.160 hr^{-1} and k_{21} = 0.345 hr^{-1}. Although the values of k_{12} and k_{21} determined by Wagner *et al.* (20) did not agree with those determined by Pfeffer (21), their ratios of k_{12}/k_{21} were very similar. Likewise, while the values of the distribution rate constants reported for ^{3}H-alphaprodine (22) in the same dog are k_{12} = 0.097 min^{-1} and k_{21} = 0.042 min^{-1} at a 1-mg/kg iv dose, the values reported for these constants are k_{12} = 0.059 min^{-1} and k_{21} = 0.028 min^{-1} at a 2-mg/kg iv dose, indicating the possible differences that can exist in the individual values of the distribution rate constants determined at different doses. However, when the ratios of k_{12}/k_{21} are considered for these two doses, the values are very similar. As seen in Table V, the ratio k_{12}/k_{21} obtained for IV in the present study is almost 3–4 times greater than the ratios for its homologs.

To account for (*a*) the lower values of V_2 noted for V–VII than for IV, (*b*) the slightly lower values of V_1 noted for V and VI than for IV or VII, and (*c*) the lower k_{12}/k_{21} ratios noted for V–VII than for IV, it is desirable that the general structure of biological membranes and the mechanisms for transmembrane transport of solutes be considered. Although the biological membranes are composed mainly of phospholipids and proteins, the proportions of these building blocks are not identical for membranes of all organs.



Scheme III

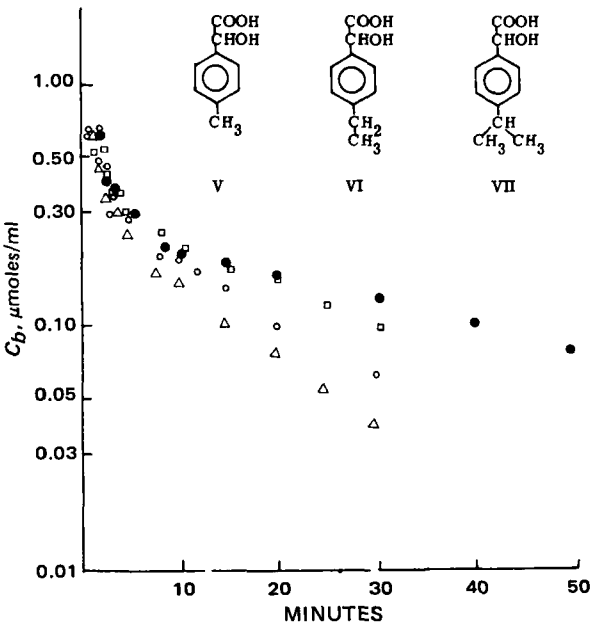


Figure 6—*Plot showing biexponential decline of blood levels for* para*-alkylated homologs of IV. Key:* ●, *IV;* △, *V;* ○, *VI; and* □, *VII.*

For instance, Aschworth and Green (23) showed that the amounts of phospholipids in the red blood cell ghost, liver plasma, muscle sarcolema, and mitochondrial membrane of liver and mitochondrial membranes of muscles of rats are approximately 61, 42, 28, and 11 mg/100 mg of proteins, respectively. Furthermore, they reported that the membranes of the microsomal liver fractions I, II, and III of rats contain 30, 80, and 35 mg of phospholipids/100 mg of protein, respectively.

For transmembrane transport of solutes, several mechanisms (8) have been proposed including: (*a*) diffusion of permeant molecules by dissolution in the membrane; (*b*) diffusion of permeant molecules through aqueous pores lined with polar portions of the proteins and possibly phospholipids; (*c*) carrier-mediated transport, which may include protein and phospholipid as carriers; and (*d*) active transport, which may involve enzymes and adenosine triphosphatase. Therefore, depending upon the organ of permeation and the mechanism of transport of solute through the membrane of the organ, differences in the rates of diffusion of the compounds of a homologous series can be expected.

Although several studies described the transport of organic nonelectrolytes and the ions of inorganic electrolytes through the membranes of many body tissues or organs, the transmembrane transport of organic electrolytes (ionized forms of acids and bases) has been studied mainly through the renal tubular membrane. Previous studies (9–13) showed that a carrier mechanism is involved in the renal tubular transport of IV and its homologs and that the affinity of VI and D-(−)-*p*-*n*-propylmandelic acid for the carrier is greater than that of IV.

In the present study, however, the transport of V–VII from the central compartment into the peripheral compartment decreased with an increase in the chain length of the homologs, as evidenced by the decrease in the k_{12}/k_{21} ratios. Therefore, it may be inferred that the transport of these compounds from the central compartment into the peripheral compartment does not involve a carrier mechanism. Furthermore, since the molecules of IV and its homologs are completely ionized in the systemic body fluids, the solubilities of the compounds in the lipoidal membranes can be considered negligible.

It is generally believed that the ions dissolve in the membrane by interacting with the oppositely charged constituents of the membrane, and if they are transported across the membrane, they do so because the membrane constituent(s) serves as carrier(s). Although the carrier mechanism for the transmembrane transport for IV and its homologs is discounted, as discussed here, it seems possible to explain the transport of these compounds between the central and peripheral compartments by considering the aqueous pore mechanism, especially in view of the magnitudes of the ratios of their distribution rate constants. The diffusion of organic nonelectrolytes through plasma membranes was shown (24, 25) to be governed by their ability to hydrogen bond with membrane components in addition to their lipid solubilities and molecular size. The larger molecular size and greater extent of hydrogen bonding of the permeant molecules decrease their rate of diffusion through the aqueous pores. Since the lining of these aqueous pores is composed of proteins and phospholipids, the diffusion rates of IV and its homologs, with their polar or ionic groups exposed to the aqueous phase of the pores, from one compartment into another may be influenced by their interaction with the ionic or polar portions of the proteins or phospholipids of the pores through electrostatic interaction, hydrogen bonding, and hydrophobic bonding.

In view of these considerations, it seems possible to explain why the volume of the peripheral compartment and the rates of diffusion of V–VII through the aqueous pores are lower than those of IV. It is reasonable to expect that, because of the presence of alkyl groups, neither the charge densities of V–VII nor the hydrogen bonding ability of the hydroxy groups present in their side chains is going to be different from those of IV. Therefore, the lower k_{12}/k_{21} ratios of distribution constants observed for V–VII, as compared to the ratio for IV, are attributed to the presence of alkyl groups. The lower rates of diffusion of the homologs from the central compartment to the peripheral compartment need not be attributed to the molecular size of these molecules, since the homologs of nonelectrolytes, with molecular weights above 140, have increased rates of membrane permeability with an increase in their molecular weights (24).

It is fairly well established that the structure of water within the membrane, including that in the aqueous pore, is much different than the bulk of water, since icebergs are formed by the water molecules present within the membrane in association with the nonpolar portions of phospholipids and/or protein (26, 27). Therefore, if the interactions between the permeant molecules and the protein or phospholipid molecules of the aqueous pores occur through electrostatic forces and/or hydrogen bonding, the nonpolar portions of the permeant molecules and the stationary receptor site(s) of the aqueous pores (proteins and/or phospholipids) may interact through hydrophobic bonding, thus releasing the water molecules associated with the nonpolar portions of these interactants and giving rise to increases in entropy. The association of these reactants then would be stronger, as shown previously in model copolymer system studies (28, 29). This would then result in a decrease in the rate of diffusion of V–VII and, consequently, in a decrease in the volume of the peripheral compartment.

The difference observed between V_2 values of V and VI cannot be ascertained in view of how these values were calculated in the present study; therefore, these values may be considered to be similar. However, the difference between the V_2 values of V and VII appears to be substantial. In view of the mechanism suggested for the transmembrane transport of these organic anions and the role that hydrophobic bonding (between the permeant organic anions and the constituents of the lining of the aqueous membrane pores) plays in reducing the rate of transmembrane transport, the higher V_2 observed for VII (higher even than for V) can be attributed to its branched group, which apparently may not form as strong a hydrophobic bond as does V, since the isopropyl group may not allow close contact of the phenyl group with the hydrophobic portion of the receptor protein or phospholipid of the aqueous pore lining.

As pointed out previously, the V_1 noted for V and VI is somewhat (about 15–20%) lower than that for IV. In view of the fact (discussed in Ref. 30) that, in the presence of a renal tubular inhibitor (DL-tropic acid), the V_1 for IV or VII decreased but that for V or VI remained unchanged, it seems possible to explain the lower V_1 observed for V or VI in terms of the heteroporosity of the membranes. It is known that the membrane pores of a given organ are heteroporous, with their pores ranging in size from 8 to 320 Å; the majority of the pores have a pore diameter of 70–120 Å (31–33). When considering the diameter of the molecule of IV and its homologs, especially when they are hydrated, it seems reasonable to expect that only one molecule of any of these compounds could pass at a time through those pores, which are about 8 Å in diameter. The percentage of small size (8 Å diameter) pores in a membrane of a given organ is apparently not reported in the literature; but if it is assumed that the pores of this size constitute a significant population of the total pores, it is conceivable that molecules showing greater intermolecular interactions with constituents of the pore lining would not be able to occupy the same volume of distribution in a given organ as would similar size molecules exhibiting less intermolecular interactions. Therefore, it is believed that V and VI probably show greater interactions with the aqueous pore lining through hydrophobic bonding than do IV and VII. Consequently, the V_1 for V or VI can be expected to be smaller than that for IV or VII.

Comparison of Effect of Carbonyl Group of I with Effect of Alcoholic Hydroxy Group of IV—The striking effect of the carbonyl group of I, as compared to that of the hydroxy group of IV, becomes apparent from the fact that the disappearance of I from the rat blood is describable by a three-compartment open model whereas that of IV is describable by a two-compartment open model, even though the biological half-lives of the compounds determined from their respective predominantly elimination phases are very similar. One possible explanation for this difference follows.

The rate of diffusion of the molecules of IV through the aqueous pores of tissue membranes, which constitute the peripheral compartment, can be expected to be different due to the differences in the chemical composition of the lining of the pores of different tissues. Apparently, however, such differences in the rates of diffusion do not exist so as to distinguish the various tissues of the peripheral compartment into more than one peripheral compartment. However, the differences in the rates of diffusion of the molecules of I through the aqueous pores of the peripheral compartment tissues may vary widely because they have less ability to hydrogen bond, as compared to those of IV; therefore, the various tissues of the peripheral compartment become kinetically distinguishable as two peripheral compartments. The reason for expect-

ing the molecules of I to show these differences is that the chemical composition of proteins and phospholipids of the membranes of all tissue organs (34) and, therefore, of their aqueous pore lining is not identical. It is conceivable, therefore, that the molecules of I, which have one less potential or a weaker site for hydrogen bonding than the molecules of IV, could show relatively greater hydrogen bonding with the constituents of the lining of pores of the one tissue organ than with the constituents of the lining of pores of other tissue organs of the peripheral compartments.

On this basis, those organs whose aqueous pores exhibit stronger hydrogen bonding with the molecules of I would constitute the peripheral compartment that would have a smaller apparent volume of distribution; organs whose aqueous pores exhibit weaker hydrogen bonding with the molecules of I would constitute the peripheral compartment that would have a larger apparent volume of distribution. The former peripheral compartment may be designated as peripheral compartment 1 with volume V_2, and the latter peripheral compartment may be designated as peripheral compartment 2 with volume V_3. As stated previously, if the differences in the extent of hydrogen bonding of IV with the constituents of the aqueous pores of these peripheral compartments are not sufficiently large, these peripheral compartments would then be kinetically describable as a single peripheral compartment for IV.

It is observed that the volume of the central compartment for I is larger than that for IV, and the volume of its peripheral compartments ($V_2 + V_3$) is smaller than that for the molecules of IV. In connection with the transport of these molecules through the aqueous pores, it seems possible that I is able to equilibrate into part of the compartment that serves as a peripheral compartment of IV somewhat more readily than does IV, thus resulting in a larger volume of the central compartment. Also, since the volume of the peripheral compartment is in no sense an absolute value of the actual volume but rather a mathematically manipulated value, the lower volume of the peripheral compartments ($V_2 + V_3$) for I may possibly be explained on the basis that I probably interacts with the biopolymers of the intracellular fluids of the tissue cells of the peripheral compartments, thereby restricting its diffusion into only a limited region of the tissues of the peripheral compartments. The reason for speculating about the interaction of I with the intracellular biopolymers is based on the observation that I is bound to plasma protein to the extent of 13–15% while IV shows no binding to plasma proteins (9). The binding of drugs to tissue proteins, such as nucleic acids and DNA, is reported in the literature (34).

Effect of Substitution of Alkyl Groups in the *para*-Position of I—Since the blood level data for I can be described by a three-compartment open model, the revelation that the blood level data for II and III can be described by a one-compartment open model demonstrated a dramatic effect of alkyl groups on the distribution of these compounds in rats.

Among IV–VII, although the effect of *para*-alkyl groups is not seen in terms of reducing the two-compartment open model for IV to a one-compartment open model for V–VII, the dramatic effect of the alkyl groups in terms of a substantial decrease in the volume of the peripheral compartment is observed (Table V). However, as pointed out later, blood level data for D-(−)-*p*-*n*-propylmandelic acid are indeed describable by a one-compartment open model (13), thereby demonstrating the effect of the propyl group in reducing the volume of distribution of the peripheral compartment to zero, as observed for II and III. Clearly, for the *para*-alkylated homologs of I and IV, the apparent effect of the alkyl groups is to diminish the volume of the peripheral compartment, but the disappearance of a kinetically describable peripheral compartment remains a function of the size of the peripheral compartment for the parent compounds.

Accordingly, if the volume of the peripheral compartment is relatively large for the parent compound, the peripheral compartment may not become kinetically indistinguishable for the short alkyl chain *para*-alkylated homologs as seen for V–VII. However, if the volume of the peripheral compartment is relatively small for the parent compound, it may become kinetically indistinguishable, even for the short alkyl chain *para*-alkylated homologs as noted for II and III. As explained in the case of the homologs of IV, the effect of alkyl groups in restricting the distribution of the compound to the central compartment is a consequence of the decreased rate of diffusion of the compounds due to the strengthened interaction (through hydrophobic bonding) of the permeant molecules with the proteins and/or phospholipids of the lining of the aqueous pores of the tissue organs.

The volume of the central compartment noted for II is slightly greater than that for I. This slightly higher volume may be due to incorporation of that volume of the peripheral compartment that is not kinetically distinguishable because of its highly reduced size. It is believed that, since the rate of diffusion of II from the central compartment into the peripheral compartment is considerably reduced, the amount of the compound distributed into the peripheral compartment is relatively small, and the system cannot be kinetically described either as a two-compartment open model or a three-compartment open model.

If the pattern observed for I and its homologs with respect to their volumes of the central compartment is considered, the volume of the central compartment for III would be anticipated at 225–250 ml, which is the range of the volume of the central compartment observed for I and II. However, the volume of the central compartment noted for III is only about 125 ml. A study is under consideration to determine the possible reason for this finding.

Comparison of Effect of Branched Alkyl Group (Isopropyl) against Straight Chain Alkyl Group (Propyl)—The kinetics of disappearance of D-(−)-*p*-*n*-propylmandelic acid (VIII), which also possesses the "ideal properties," from the blood has been studied in rats (13). The pharmacokinetics of this compound are describable by a one-compartment open model, and its apparent volume of distribution is 220 ml. The dramatic effect of hydrophobic bonding in reducing the rate of transmembrane transport through aqueous membrane pores is readily seen with VIII, as with II and III. Clearly, the propyl group of this compound is able to form a substantially stronger hydrophobic bond with constituents of the membrane pores, thus restricting the compound mainly in the central compartment of distribution.

Although the total volume of distribution (one-compartment open model) observed for VIII is 20% larger than that observed for the central compartment (two-compartment open model) of VII, the volume of distribution of the central compartment for VIII may not be larger than that observed for VII or for that matter for IV–VI. It is believed that, since the rate of diffusion of VIII from the central compartment into the peripheral compartment is considerably reduced, the amount of the compound distributed into the peripheral compartment is relatively small and the system cannot be kinetically described as a two-compartment open model.

The influence of the geometrical factor relating to the extent of surface contact area between the permeating molecule and the membrane was illustrated by Diamond and Wright (25). They showed that the branched nonelectrolytes such as isobutyramide and isovaleramide exhibited less permeability in several epithelia than did their corresponding straight chain isomers butyramide and valeramide. This observation is considered to be very striking because the partition coefficients of the straight chain isomers are noted to be lower than those of the branched isomers and, in water, the diffusion coefficients of butyramide and isobutyramide are similar (35). The possible explanation for this observation is that the area of close contact with surrounding molecules decreases with increased branching, so the van der Waals forces between the permeating molecule and the membrane are weakened. This explanation suggests that the selectivity is determined by the types of interactions in the membrane interior which, in the case of these molecules, implies that the rate-limiting step is diffusion through the membrane and not transition from aqueous solution to the membrane phase (35).

In the case of the isomers of organic nonelectrolytes, the isomers containing branched alkyl groups showed less permeability into the epithelial membrane than did the corresponding isomers containing straight chain alkyl groups (25); in the case of organic electrolytes of the present study, the isomer containing a branched alkyl group (VII) showed a greater rate of permeability through the aqueous pores of membranes than did the corresponding isomer containing a straight chain alkyl group (VIII). If, indeed, the major pathway for the transfer of VII and VIII anions from the central body compartment into the peripheral body compartment was through the membrane (possibly *via* a "carrier" mechanism), the pharmacokinetics of VIII would probably have been describable according to the two-compartment open model, with V_2 greater than that noted for VII and possibly IV. Therefore, this observation is supportive of the aqueous pore mechanism suggested for transmembrane transport of I, IV, and some of its *para*-alkylated

homologs between central and peripheral body compartments.

Mechanistic Evaluation of Modifications of Distribution Pharmacokinetic Parameters of Model Organic Anions in Presence of a Model Renal Tubular Secretion Inhibitor in Rats

YASHWANT M. AMIN * and JANARDAN B. NAGWEKAR ˣ

Abstract □ The effects of DL-tropic acid (VIII) on the distribution pharmacokinetic parameters of the model compounds benzoylformic acid (I), *p*-methylbenzoylformic acid (II), *p*-ethylbenzoylformic acid (III), D-(−)-mandelic acid (IV), D-(−)-*p*-methylmandelic acid (V), D-(−)-*p*-ethylmandelic acid (VI), and D-(−)-*p*-isopropylmandelic acid (VII) were studied in rats. Since VIII is a competitive inhibitor of renal tubular secretion of I–VII and since all of these compounds (I–VIII) are negligibly bound to plasma proteins and are neither metabolized nor reabsorbed from the renal tubules, they were considered as model compounds. Therefore, changes observed in the values of the distribution pharmacokinetic parameters of I–VII were attributed to the influence of VIII on the transmembrane transport of the compounds between body compartments in rats. The decrease in the apparent volumes of the central compartments for I, IV, and VII, the increase in the apparent volumes of the peripheral compartments for IV–VII, the absence of change in the volumes of the central or peripheral compartments for the other compounds, and the increase in the ratios of the rate constants of the transfer of compounds from one compartment into another for I and IV–VII were explained in terms of the "aqueous pore" mechanism for the transmembrane transport of the anions of the compounds as well as the heteroporosity of the tissue membranes.

Keyphrases □ Pharmacokinetics—distribution parameters, mechanistic evaluation of modifications, model organic anions in presence of model renal tubular secretion inhibitor, rats □ Distribution—pharmacokinetic parameters, mechanistic evaluation, model organic anions in presence of model renal tubular secretion inhibitor, rats □ Transport—mechanistic evaluation of modifications of distribution pharmacokinetic parameters, model organic anions in presence of model renal tubular secretion inhibitor, rats

It was recently shown (1, 2) that a renal tubular secretion inhibitor such as probenecid increases the blood levels of penicillins not only by depressing their renal tubular secretion but also by decreasing the volumes of body central compartments for the drugs. The reason suggested (2) to account for the decrease in the volume of distribution was that the presence of probenecid caused an increase in the plasma protein binding of these antibiotics and/or limited their penetration or distribution into certain body compartments. It was further speculated that the higher rate constant of metabolism noted for the antibiotics in the presence of probenecid was due to the decrease in the apparent volume of distribution, which resulted in presenting a larger fraction of the drug at the site of metabolism.

If a drug is subjected simultaneously to metabolism, protein binding, and renal tubular secretion, it is difficult to isolate the effect of the renal tubular secretion inhibitor on its distribution pharmacokinetic parameters, especially if the renal tubular inhibitor can displace the drug from its protein binding sites or interfere with its metabolism. Therefore, if one intends to determine specifically the effect of the renal tubular secretion inhibitor on the distribution pharmacokinetic parameters of substrate compounds, it is advantageous to have compounds and their renal tubular secretion inhibitor that are neither bound to plasma proteins, metabolized, nor reabsorbed from the renal tubules. In addition, they should be completely recovered in the urine.

Since benzoylformic acid, D-(−)-mandelic acid, and their respective *para*-alkylated homologs possess such desirable properties (3–7) and DL-tropic acid, which is also a homolog of D-(−)-mandelic acid and possesses these ideal properties, is a competitive renal tubular secretion inhibitor of D-(−)-mandelic acid and its *para*-alkylated homologs (3–6) and of benzoylformic acid and its *para*-alkylated homologs (8), the purpose of this study was to determine in rats the effect of DL-tropic acid (VIII) on the distribution pharmacokinetic parameters of benzoylformic acid (I), *p*-methylbenzoylformic acid (II), *p*-ethylbenzoyl-

formic acid (III), D-(−)-mandelic acid (IV), D-(−)-*p*-methylmandelic acid (V), D-(−)-*p*-ethylmandelic acid (VI), and D-(−)-*p*-isopropylmandelic acid (VII).

Furthermore, since the pKa values of these compounds are in the 3.2–4.2 range, these compounds are expected to remain in the systemic body fluids only in the anionic form. Consequently, any changes observed in the values of the distribution pharmacokinetic parameters of these anions in the presence of VIII (anionic) can be attributed to the influence of VIII on the transmembrane transport of these compounds between the body compartments in rats. As discussed previously (7), the distribution pharmacokinetic parameters considered for the compounds exhibiting a multicompartment open-model system are the apparent volumes of the central compartment (V_1), the apparent volumes of the peripheral compartments (V_2 and V_3), and the ratios of the apparent first-order rate constants of transport of compounds from one compartment into another. For those compounds that follow the one-compartment open model, the apparent volume of distribution (V_d) is considered.

It is anticipated that, in light of the mechanism suggested (7) for reversible transmembrane transport between the central and peripheral compartments, it

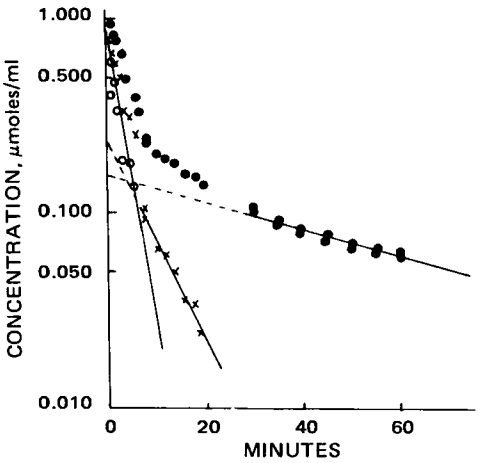

Figure 3—*Plot showing triexponential decline of blood levels of I following the administration of a 249.8-μmoles/kg iv dose per rat in the presence of a simultaneously administered 3012-μmoles/kg dose of VIII. is possible to rationalize mechanistically the effect(s) of VIII that may be observed on the distribution pharmacokinetic parameters of I–VII.

EXPERIMENTAL

Materials—Compounds I–VII were the same as described previously (7). In addition, DL-tropic acid[1], mp 117–119°, was used.

Methodology—The methodology followed was described previously (7), except that 2 ml of the intravenous solution, containing an appropriate dose of one of the seven substrate compounds (I–VII), also contained 3012 μmoles/kg of VIII. Compound VIII served as a renal tubular secretion inhibitor of the substrate compounds.

The intravenous doses of the substrate compounds administered were 165.65[2], 249.8, and 333.33 μmoles/kg for I; 152.45 μmoles/kg[2] for II; 140.5 μmoles/kg[2] for III; 164.35 μmoles/kg[2] for IV; 149.6 μmoles/kg[2] for V; 138.25 μmoles/kg[2] for VI; and 128.1 μmoles/kg[2] for VII. Each compound (I–VIII) was injected as its sodium salt. The fact that a 3012-μmoles/kg iv dose[3] of VIII completely inhibits renal tubular secretion of I–III (7) and IV–VII (3–6) has been demonstrated already.

GLC Analysis—The equipment and procedure used to analyze I–VIII gas chromatographically in blood were the same as those described previously (7).

Binding of I to Whole Rat Blood and Plasma Proteins in Presence of VIII—The equilibrium dialysis procedure used for determining the binding of I to whole rat blood and plasma proteins was the same as that described previously (3–6), except that, along with 2 mg of I, the 4 ml of blood or plasma contained 40 mg of VIII. Since the binding of the other model compounds was considered negligible, no binding of those compounds was studied in the presence of VIII.

RESULTS AND DISCUSSION

Effect of VIII on Distribution Pharmacokinetic Parameters of I and IV and Their Respective Homologs—The blood level data obtained for the compounds in this study are presented in Figs. 1 and 2, along with those reported previously (7) for the same compounds in the absence of VIII. As illustrated in Figs. 3 and 4 for I and IV, respectively, the observed kinetic pattern of disappearance of each compound from the blood was the same as that noted in the absence of VIII. Initial estimates for the phar-

[a] Average of pharmacokinetic parameters determined for the data obtained at each dosage level study. The coefficients of determination (r^2) for the data at 166.65-, 249.80-, and 333.33-μmoles/kg doses were 0.997, 0.996, and 0.993, respectively; the correlation coefficients were 0.997, 0.997, and 0.994, respectively.

macokinetic parameters were obtained by use of appropriate equations as discussed previously. The data were found to fit very well to a three-compartment open model for I, to a two-compartment open model for IV and its *para*-alkylated homologs, and to a one-compartment open model for II and III, as indicated by the coefficients of determinations and correlation coefficients (Tables I–III).

The comparative plots (Figs. 1 and 2) of concentration *versus* time for these compounds showed that VIII elevated the blood levels of each substrate compound, as expected. The comparative data concerning the distribution pharmacokinetic parameters for I–VII, both in the absence and presence of VIII, are presented in Tables IV and V. As noted (7) in the absence of VIII, no apparent dose-dependent pharmacokinetics were observed for I in the intravenous dosage range of 165.65–333.33 μmoles/kg in the presence of VIII (Fig. 5).

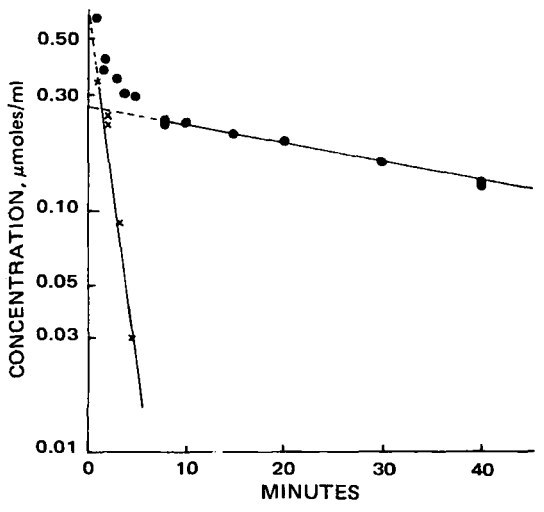

Figure 4—*Plot showing biexponential decline of blood levels of IV following the administration of a 164.35-μmoles/kg iv dose per rat in the presence of a simultaneously administered 3012-μmoles/kg dose of VIII. Effect on IV and Its *para*-Alkylated Homologs—A comparison of the distribution pharmacokinetic parameter data (Table IV) for IV and its *para*-alkylated homologs shows that the volumes of the peripheral compartments and the ratios of k_{12}/k_{21} increased in the presence of a large dose of VIII. Furthermore, while the apparent volume of the central compartment slightly decreased (about 15–20%) for IV and VII, it remained practically unchanged for V and VI. These effects of VIII may be explained in terms of the aqueous pore diffusion mechanism previously advocated (7) for the transmembrane transport of these compounds.

It is reasonable to expect that VIII (pKa = 4.2), which is also a homolog of IV, should follow the same pathway for its transmembrane transport between the body compartments as do IV and its *para*-alkylated homologs. To facilitate comparison, the pharmacokinetics of VIII were studied following administration of 150.45 μmoles/kg iv. The blood level data obtained are presented in Fig. 6; the disappearance of the compound from the blood is also describable by a two-compartment open model. The initial estimates of the appropriate pharmacokinetic parameters of the compound were obtained and used to refine the values after fitting the data according to the two-compartment open model, using the NONLIN least-squares program (Table VI).

[a] Data obtained from Ref. 7.

Since the molecules of VIII are expected to follow the same pathway for their transport from the central compartment to the peripheral compartment, it is conceivable that these molecules would compete for the same sites of adsorption in the aqueous pore lining as do IV and its *para*-alkylated homologs, especially when a large dose of VIII is administered along with a much smaller dose of each substrate compound. In this event, it is not unlikely that the substrate molecules of IV or any of its homologs would find less resistance for their transport through the aqueous pores and, consequently, exhibit higher values not only of the volumes of peripheral compartments but also of the ratios of the distribution rate constants (k_{12}/k_{21}). Another factor that may be expected to contribute to the increased volume of the peripheral compartment is the increase in the $t_{1/2\beta}$ (Table III), which would tend to favor an increase in time to allow further distribution or penetration of the compound into the peripheral compartment.

The decrease in the volume of the central compartment for IV and VII in the presence of VIII may be explained on the basis of the heteroporosity of the membrane of the tissues of the central compartment (7). As pointed out previously (7), a substantial percentage of the total pores of these membranes may be about 8 Å in diameter, which probably would allow passage of only one molecule at a time through a pore. Therefore, when a large excess of the molecules of VIII are present in the central compartment, these molecules would predominantly occupy the small size pores and prevent access to the substrate molecules of IV or any of its *para*-alkylated homologs, thus diminishing the volume of the central compartment for the substrate compound. Since the molecules of V and VI are indicated to have little or no access through the small

size pores previously mentioned, the volume of the central compartment for these compounds in the presence of an excessively large number of molecules of VIII can be expected to remain unchanged.

Effect on I—Comparison of the distribution pharmacokinetic parameter data (Table V) for I in the presence of VIII shows that the volume of the central compartment, the volume of peripheral compartment 1 (V_2), and the volume of peripheral compartment 2 (V_3) decreased, increased, and practically remained unchanged, respectively. The decrease in the volume of the central compartment for I can be explained on the same basis (*i.e.*, heteroporosity of the membranes of the tissues of the central compartment) as the decrease in the volume of the central compartment for IV and VII. Accordingly, when present in excessively large numbers in the central compartment, the molecules of VIII would predominantly occupy the small size pores of the membranes of the tissues of the central compartment and prevent access to the molecules of the substrate compound, I, thereby diminishing V_1 for I. The decrease in the volume of the central compartment in the case of I (20%) is similar to that noted in the case of IV (18%).

Although, in the presence of VIII, V_2 for I substantially increased and V_3 slightly decreased, the total volume ($V_2 + V_3$) of the peripheral compartments remained practically unchanged (Table V). The rationalization for these observations follows. In the preceding paper (7), it was indicated that the binding of I with the biopolymers of the intracellular fluids of the tissues of the peripheral compartments restricts its diffusion into only limited regions of the tissues of the peripheral compartments as compared to that of IV. Even when the concentration of VIII was several times greater than that of I, it did not affect the binding of I to plasma proteins, as determined from *in vitro* equilibrium dialysis studies, thus leading to the assumption that VIII does not interfere *in vivo* with the binding of I to the biopolymers of intracellular fluid of the tissues of the peripheral compartments. Therefore, it may not be too surprising that the total volume ($V_2 + V_3$) of the peripheral compartments for I remained practically unchanged in the presence of VIII.

However, in accordance with the other idea proposed previously (7), that the two peripheral compartments are identified for I because of the differences in the extent of hydrogen bonding of its molecules with the constituents (proteins and/or phospholipids) of the aqueous pores of membranes of the tissues of the peripheral compartments, the diffusion of molecules of I through the aqueous pores may be affected to different degrees in the presence of the molecules of VIII to reflect a substantial increase in V_2 and a very slight decrease (which may even be discounted as being within experimental error) in V_3 for I, as noted in this study. The apparent increase in V_2 may also be attributed to the increased $t_{1/2\gamma}$ of I in the presence of VIII.

The fact that the ratios of the distribution rate constants (k_{12}/k_{21} and k_{13}/k_{31}) observed for I increased in the presence of VIII also supports the interpretation (made earlier in connection with the increase in k_{12}/k_{21} value of IV) that the substrate molecules of I find less resistance for their transport through the larger aqueous pores in the presence of a large excess of the molecules of VIII.

Table VII—Distribution Pharmacokinetic Parameters Obtained for I in Rats in the Absence and Presence of VIII

	II		III	
Pharmacokinetic Parameter	VIII Absent[a]	VIII Present	VIII Absent[a]	VIII Present
V_d, ml/kg	247.8	248.0	123.5	124.2

[a] Data obtained from Ref. 7.

Effect on II and III—The volume of distribution of II as well as III remained unchanged in the presence of VIII (Table VII). This finding suggested that the diffusion of these *para*-alkylated compounds through the small size aqueous membrane pores is not involved, as was inferred in the case of V and VI, the *para*-alkylated (methyl and ethyl) homologs of IV. This finding also confirmed that the V_d of III is indeed as low as 125 ml/kg, as noted previously (7).

The increase in the biological half-lives of these compounds did not tend to increase their V_d, as was implicated with the compounds following a two- or three-compartment open model. This finding suggests that, in the case of compounds (organic anions) whose distribution is primarily restricted to well-perfused tissues, the increase in their residence time in the body (because of their increased biological half-lives) brought about by the renal tubular secretion inhibitor would probably not increase their V_d.

CONCLUSIONS

It is recognized that a majority of drugs do not possess the ideal properties described here for the model compounds; most drugs are metabolized, bound to plasma proteins, may or may not be secreted or reabsorbed in the renal tubules, or may remain in the systemic body fluids partially or completely ionized or unionized. It is also recognized that the renal tubular secretion inhibitor of substrate drugs may or may not interfere with these processes of the substrate drugs. However, in the event that differences are observed in the distribution pharmacokinetic parameters of a drug in the presence of its renal tubular secretion inhibitor, it is desirable to know what factors are primarily responsible for such differences. Unless one is cognizant of all possible effects each factor can produce, the task of proposing mechanisms to account for the changes observed becomes difficult and highly speculative.

The literature survey indicated that either no deliberate efforts have been made to determine the effect of renal tubular secretion inhibitors on the distribution pharmacokinetic parameters of the substrate compounds or, if such efforts have been made, the reasons offered have remained highly speculative. Therefore, it is extremely desirable to build up a body of knowledge, based on model studies where the effect of each factor is exclusively determined, which will allow more realistic speculation. Although the compounds employed in the study are not used as drugs, except for D-(−)-mandelic acid, they served as model compounds to reveal not only features involved in the transmembrane transport process of organic anions but also to illustrate the influence of a renal tubular secretion inhibitor on the distribution pharmacokinetic parameters of these substrate organic anions.

The essential features revealed for the compounds exhibiting multicompartment open-model systems are that: (*a*) the organic anions most probably diffuse through the aqueous pores of the membranes; (*b*) the permeating molecules are subjected to electrostatic forces, hydrogen bonding, and hydrophobic bonding in the aqueous pores; and (*c*) the heteroporosity of the membranes may influence the volume of a given body compartment. The feature revealed by the compounds that followed a one-compartment open model was that the volume of distribution of the substrate organic anions would not necessarily change in the presence of their renal tubular secretion inhibitor.

It is hoped that the insight gained into the pharmacokinetic be-

havior of the model organic anions employed in this study will provide further understanding, not only of the design and modification of drug molecules but also of the effects of the competitive renal tubular secretion inhibitor on the distribution pharmacokinetic parameters of the substrate compounds.

Behavior of Erythrocytes in Ternary Solvent Systems

SHIAO-HUAN KU and DONALD E. CADWALLADER ˣ

Abstract □ The effect of ternary solvent systems on erythrocytes was investigated. Hemolysis experiments were run at 37° in solutions containing various amounts of water, two nonaqueous solvents, and 0.9% sodium chloride. The nonaqueous solvents were propylene glycol, polyethylene glycol 400, dimethyl sulfoxide, dimethylformamide, and tetramethylurea. Ternary diagrams based on the critical hemolytic compositions of the various ternary systems are presented.

Keyphrases □ Erythrocytes—behavior in ternary solvent systems, ternary diagrams, critical hemolytic compositions □ Solvents—effect of ternary solvent systems on erythrocytes, ternary diagrams, critical hemolytic compositions □ Blood—behavior of erythrocytes in ternary solvent systems, ternary diagrams, critical hemolytic compositions □ Intravenous preparations—behavior of erythrocytes in ternary solvent systems

To prepare a safe and efficacious injection, it is sometimes necessary to employ a mixed solvent system consisting of water and a nonaqueous solvent. The behavior of rabbit and human erythrocytes in aqueous solutions of propylene glycol and liquid polyethylene glycol (1–3) and the behavior of human erythrocytes in aqueous solutions of dimethyl sulfoxide, liquid amides, tetramethylurea systems, and monohydric alcohols (4–7) were reported in previous papers in this series.

Binary solvent systems are not the only systems that can be used for intravenous preparations. Since aqueous solutions containing two or more nonaqueous solvents might be necessary to prepare a suitable solution, the effects of some ternary solvent systems on red blood cells were studied. Experiments were conducted to determine the behavior of human erythrocytes in systems containing two nonaqueous solvents in 0.9% aqueous saline.

The nonaqueous solvents selected were propylene glycol, polyethylene glycol 400, dimethyl sulfoxide, dimethylformamide, and tetramethylurea. Critical hemolytic concentrations were determined for the various ternary solvent systems, and the data were used to construct ternary diagrams depicting the various concentrations of water and two nonaqueous solvents, mixed together as ternary solvent blends, which are compatible with human red cells.

EXPERIMENTAL

Materials—Propylene glycol[1] USP, polyethylene glycol 400[2] (average mol. wt. 380–420), tetramethylurea[3], and reagent grades of dimethylformamide[4] and sodium chloride[2] were used.

Preparation of Solutions—All solvent systems were volume-

To prepare a safe and efficacious injection, it is sometimes necessary to employ a mixed solvent system consisting of water and a nonaqueous solvent. The behavior of rabbit and human erythrocytes in aqueous solutions of propylene glycol and liquid polyethylene glycol (1–3) and the behavior of human erythrocytes in aqueous solutions of dimethyl sulfoxide, liquid amides, tetramethylurea systems, and monohydric alcohols (4–7) were reported in previous papers in this series.

Binary solvent systems are not the only systems that can be used for intravenous preparations. Since aqueous solutions containing two or more nonaqueous solvents might be necessary to prepare a suitable solution, the effects of some ternary solvent systems on red blood cells were studied. Experiments were conducted to determine the behavior of human erythrocytes in systems containing two nonaqueous solvents in 0.9% aqueous saline.

The nonaqueous solvents selected were propylene glycol, polyethylene glycol 400, dimethyl sulfoxide, dimethylformamide, and tetramethylurea. Critical hemolytic concentrations were determined for the various ternary solvent systems, and the data were used to construct ternary diagrams depicting the various concentrations of water and two nonaqueous solvents, mixed together as ternary solvent blends, which are compatible with human red cells.

EXPERIMENTAL

Materials—Propylene glycol[1] USP, polyethylene glycol 400[2] (average mol. wt. 380–420), tetramethylurea[3], and reagent grades of dimethylformamide[4] and sodium chloride[2] were used.

Preparation of Solutions—All solvent systems were volume-

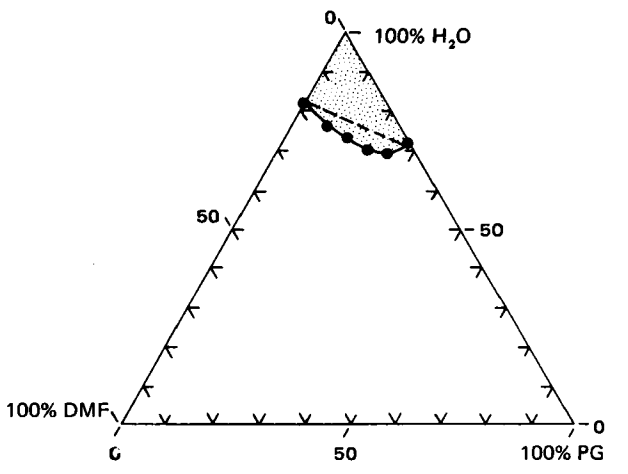

Figure 4—*Ternary diagram for aqueous propylene glycol (PG)–dimethylformamide (DMF) solutions containing 0.9% sodium chloride at 37°.*

in-volume percentage preparations, and each ternary system contained 0.9% (w/v) sodium chloride (0.15 *M*). Necessary dilutions were made from stock solutions, and distilled water was used to prepare all solutions.

Collection of Blood—Blood samples were obtained from the forearm veins of several 20–25-year-old Caucasian and Oriental subjects. Fresh blood samples were used. Approximately 10 ml of blood was obtained from each donor and placed in a 50-ml round-bottom flask containing 10–15 glass beads. The flask was rotated gently for about 5 min to separate the fibrin, and then the blood was decanted into a 50-ml conical flask and aerated by swirling the flask gently for about 5 min.

Quantitative Determination of Percent Hemolysis—In each experiment, the hemolytic method was used to determine the degree of hemolysis of erythrocytes in the various solvent systems. This quantitative method is based on the fact that a hypotonic solution liberates oxyhemoglobin in direct proportion to the number of cells hemolyzed.

Into each of two test tubes was transferred 5 ml of the standard sodium chloride solution (0.32, 0.34, . . ., 0.46, and 0.48%) or 5 ml of the mixed solvent systems. The standard sodium chloride solutions were used to ensure the osmotic normalcy of each blood sample. After the test tubes were brought to a constant temperature in a water bath (37 ± 0.5°), 0.05 ml of blood was pipetted into each tube. Each tube was shaken on a vibratory mixer to ensure thorough mixing and allowed to remain at 37° for 45 min. The tubes were centrifuged at approximately 2500 rpm, and the light absorbance of the supernatant liquid was measured using a photoelectric colorimeter[5] equipped with a No. 54 filter.

To find the percent hemolysis, these absorbance readings were divided by the absorbance readings for 0.05 ml of blood in 5 ml of distilled water (standard for 100% hemolysis) and multiplied by 100. A blank, made by placing 0.05 ml of blood in 5 ml of 0.9% sodium chloride solution, was used to cancel any light absorbance inherent in the blood sample. Both the standard and the blank were subjected to the same conditions of standing at 37° for 45 min followed by centrifuging (2500 rpm for 5–10 min).

Construction of Ternary Diagram—A ternary phase diagram can be constructed when three liquid components are involved in a solution at a fixed temperature. In the current studies, one apex of the triangle represents 100% of water, and each of the other two apexes represents 100% of a different nonaqueous component. The side of the triangle opposite each apex represents zero percentage of that particular component.

The points in the ternary diagram are the experimental values, and each point represents the average of at least two experiments using different blood samples. The points were connected to give an experimental curve for the particular ternary solvent system. The region within each curve (shaded area) defines the compositions of ternary solvent systems in which human red cells do not hemolyze (<5% hemolysis) under the experimental conditions. The region outside the curve describes the solvent compositions

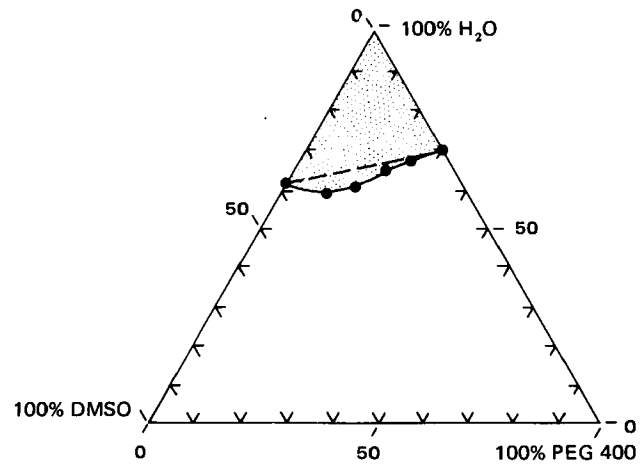

Figure 3—*Ternary diagram for aqueous polyethylene glycol 400 (PEG 400)–dimethyl sulfoxide (DMSO) solutions containing 0.9% sodium chloride at 37°.*

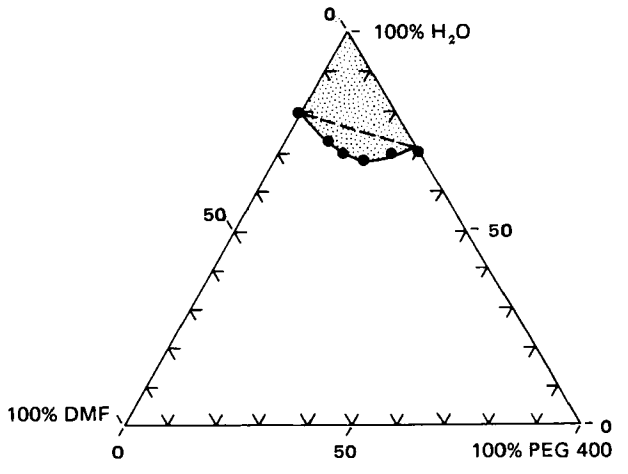

Figure 5—*Ternary diagram for aqueous polyethylene glycol 400 (PEG 400)–dimethylformamide (DMF) solutions containing 0.9% sodium chloride at 37°.*

[5] Klett–Summerson.

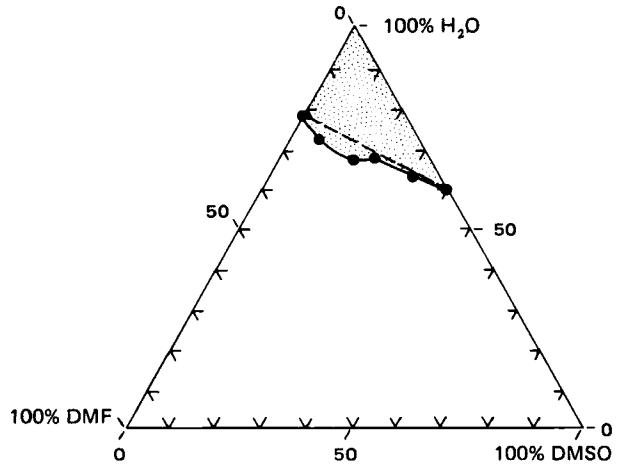

Figure 6—*Ternary diagram for aqueous dimethyl sulfoxide (DMSO)–dimethylformamide (DMF) solutions containing 0.9% sodium chloride at 37°.*

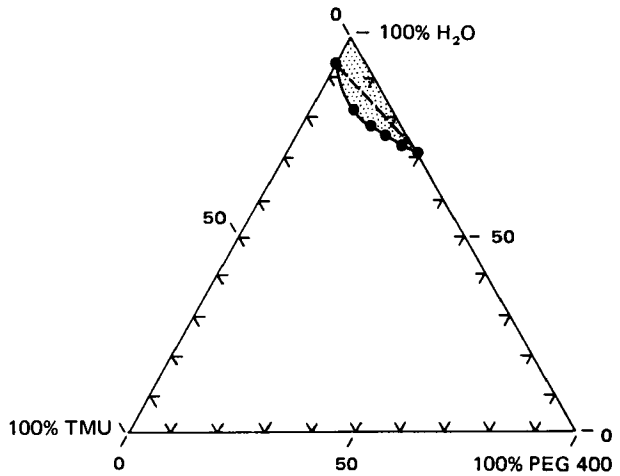

Figure 8—*Ternary diagram for aqueous polyethylene glycol 400 (PEG 400)–tetramethylurea (TMU) solutions containing 0.9% sodium chloride at 37°.*

where hemolysis and/or discoloration and precipitation were not prevented.

Each ternary diagram has a tie-line (dashed line) connecting the critical concentrations of the two nonaqueous solvents. If the hemolytic effect of each individual component is strictly an additive property of the solvent, this tie-line should represent the theoretical curve delineating nonhemolytic from hemolytic compositions.

RESULTS AND DISCUSSION

Binary Solvent Systems—Experiments were carried out to determine the critical hemolytic concentration of the individual nonaqueous solvents in 0.9% saline solution. These data were utilized for the baseline points in the construction of the individual ternary diagrams. The critical hemolytic concentrations (% v/v) of the solvents were: propylene glycol, 30%; polyethylene glycol 400, 31%; dimethyl sulfoxide, 38%; dimethylformamide, 20%; and tetramethylurea, 8%. Each critical concentration is the average of four experiments with different blood samples and is in good agreement with the data reported previously (2–6).

Ternary Solvent Systems—To determine the effect of ternary solvent systems on erythrocytes, hemolysis experiments were run at 37° in solutions containing various amounts of water, two nonaqueous solvents, and 0.9% sodium chloride. Ternary diagrams showing the critical concentrations of each ternary solvent system are shown in Figs. 1–10. These curves were constructed as described under *Experimental*, utilizing the experimental data. In each diagram, the experimental curve separates the nonhemolytic from the hemolytic compositions of the ternary systems. The transition from nonhemolytic to hemolytic concentrations was very abrupt.

All ternary solvent systems had experimental curves that were convex with reference to the theoretical tie-lines and penetrated into higher nonaqueous solvent concentration areas. This finding indicated that one or both of the nonaqueous components in the solvent system contributed somewhat to the tonicity of the extracellular solvent. Since there was no radical departure of the experimental curves from the theoretical tie-lines, the hemolytic effect of the nonaqueous combinations apparently was essentially dependent on their total concentration in solution and did not depend on one solvent being at or near its critical concentration.

The most convex curves were obtained for ternary systems containing polyethylene glycol 400 (Figs. 1, 3, 5, and 8), while the least deviation from the theoretical tie-line was observed for the aqueous dimethylformamide–tetramethylurea system (Fig. 10). The results indicated that the hemolytic effect of the aqueous dimethylformamide–tetramethylurea system was additive, since the experimental curve was very similar to the theoretical tie-line. The relatively greater convex experimental curves of the ternary systems containing polyethylene glycol 400 indicated that these systems offered more protection to red cells than did solvent systems without polyethylene glycol 400.

Previous workers (3) reported that polyethylene glycol 400 has the ability to contribute to the tonicity of extracellular solutions, and they calculated a hemolytic i value (isotonic coefficient) of 0.6

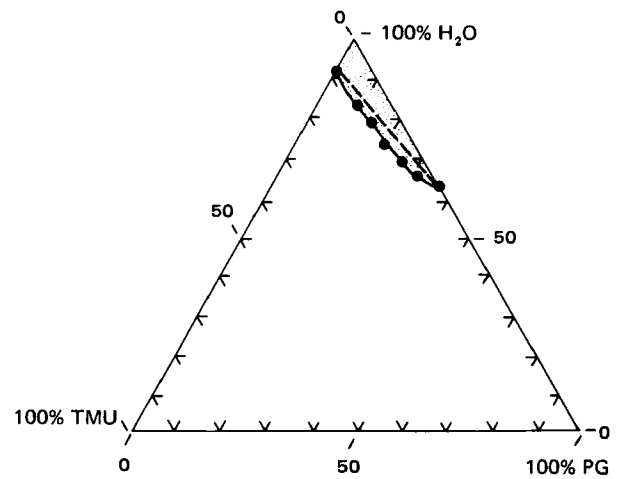

Figure 7—*Ternary diagram for aqueous propylene glycol (PG)–tetramethylurea (TMU) solutions containing 0.9% sodium chloride at 37°.*

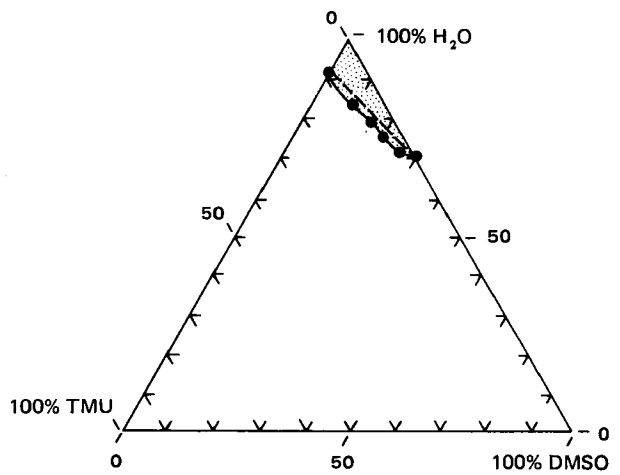

Figure 9—*Ternary diagram for aqueous dimethyl sulfoxide (DMSO)–tetramethylurea (TMU) solutions containing 0.9% sodium chloride at 37°.*

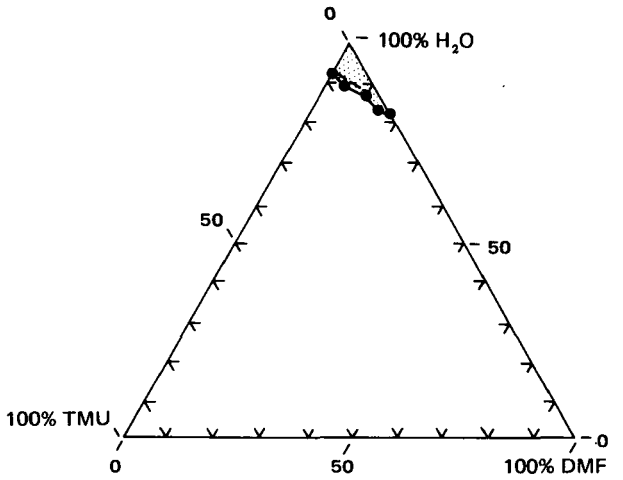

Figure 10—*Ternary diagram for aqueous dimethylformamide (DMF)–tetramethylurea (TMU) solutions containing 0.9% sodium chloride at 37°.*

for this compound. All other solvents have been reported to offer very little protection to red blood cells from hemolysis at all concentrations (1, 4–6). Therefore, the convex deviation from the theoretical tie-line can be explained by the fact that polyethylene glycol 400 contributed to the tonicity of the ternary solvent by virtue of its intrinsic property of incomplete penetration into the red blood cell.

The components of ternary solvent systems not containing polyethylene glycol 400 do contribute to the tonicity of the system but to a lesser degree than the polyethylene glycol 400 systems. Hemolytic isotonic coefficients (i values) were reported previously for sodium chloride in all solvents used in this study (1, 4–6). These i values for sodium chloride in aqueous solutions containing approximately one-half the critical hemolytic concentrations of the solvents were 1.71 for 4% tetramethylurea (6), 1.90 for 10% dimethylformamide (5), 1.95 for 15% propylene glycol (1), and 2.10 for 20% dimethyl sulfoxide (4).

When the isotonic coefficients are used as an indicator of the individual solvent's contribution to the tonicity of extracellular solutions, tetramethylurea would have the least contribution and dimethyl sulfoxide the most. Therefore, according to these hemolytic i values, the aqueous tetramethylurea–dimethylformamide system (average i value 1.80) should contribute very little, if at all, to the extracellular tonicity and should display little deviation from the theoretical tie-line. The experimental data (Fig. 10) are in agreement with this explanation.

The experimental data for the other systems also concur with this explanation, since the rank order of the average sodium chloride i values of the two nonaqueous components in a particular ternary system was approximately the same as the rank order of the degree of deviation of the experimental curves from their theoretical tie-lines. The rank order for the amount of deviation from the theoretical tie-line was propylene glycol–dimethyl sulfoxide (i = 2.03) > dimethylformamide–dimethyl sulfoxide (i = 2.00) > dimethylformamide–propylene glycol (i = 1.93) = tetramethylurea–dimethyl sulfoxide (i = 1.92) > tetramethylurea–propylene glycol (i = 1.83) > tetramethylurea–dimethylformamide (i = 1.80).

Abstract □ *Duboisia* samples were analyzed for scopolamine and hyoscyamine using GLC, by a slope ratio method, and by methods employing homatropine, tetraphenylethylene, and phenylacetyltropine as internal standards. Limits of precision were determined by the inverse prediction method. Phenylacetyltropine was the preferred internal standard. The alkaloids were silanized with either hexamethyldisilazane or *N,O*-bis(trimethylsilyl)acetamide to prevent dehydration to the apo forms. Samples from a commercial bale of *Duboisia myoporoides* were assayed. The alkaloid content varied considerably, depending on the sample position within the bale.

Keyphrases □ *Duboisia myoporoides* and *Duboisia leichhardtii*—GLC analysis for scopolamine and hyoscyamine, slope ratio method □ Scopolamine and hyoscyamine—GLC determination in *Duboisia* samples, slope ratio method □ Phenylacetyltropine—internal standard in GLC analysis of scopolamine and hyoscyamine in *Duboisia* samples

Two species of *Duboisia, Duboisia leichhardtii* and *Duboisia myoporoides,* are commercial sources of the mydriatic tropane alkaloid scopolamine, 1000 tons being grown annually. They are cultivated together with their hybrids, and it was essential that an accurate analytical method for the major alkaloids, scopolamine and hyoscyamine, be established for cultivation trials. The assay is complicated by the wide spectrum of tropane alkaloids the genus offers (Table I). Coulson and Griffin (1) found that aerial parts of

Analysis of *Duboisia myoporoides* R. Br. and *Duboisia leichhardtii* F. Muell.

W. J. GRIFFIN [x], H. P. BRAND, and J. G. DARE

Abstract □ *Duboisia* samples were analyzed for scopolamine and hyoscyamine using GLC, by a slope ratio method, and by methods employing homatropine, tetraphenylethylene, and phenylacetyltropine as internal standards. Limits of precision were determined by the inverse prediction method. Phenylacetyltropine was the preferred internal standard. The alkaloids were silanized with either hexamethyldisilazane or *N,O*-bis(trimethylsilyl)acetamide to prevent dehydration to the apo forms. Samples from a commercial bale of *Duboisia myoporoides* were assayed. The alkaloid content varied considerably, depending on the sample position within the bale.

Keyphrases □ *Duboisia myoporoides* and *Duboisia leichhardtii*—GLC analysis for scopolamine and hyoscyamine, slope ratio method □ Scopolamine and hyoscyamine—GLC determination in *Duboisia* samples, slope ratio method □ Phenylacetyltropine—internal standard in GLC analysis of scopolamine and hyoscyamine in *Duboisia* samples

Two species of *Duboisia, Duboisia leichhardtii* and *Duboisia myoporoides,* are commercial sources of the mydriatic tropane alkaloid scopolamine, 1000 tons being grown annually. They are cultivated together with their hybrids, and it was essential that an accurate analytical method for the major alkaloids, scopolamine and hyoscyamine, be established for cultivation trials. The assay is complicated by the wide spectrum of tropane alkaloids the genus offers (Table I). Coulson and Griffin (1) found that aerial parts of

D. myoporoides contain 12 different tropane alkaloids. The complex nature is complemented by the reported presence of the pyridine alkaloids, nicotine and anabasine (2).

Various analytical procedures for the assessment of scopolamine and hyoscyamine have been published. Solomon *et al.* (3) were the first to apply GLC to the quantitation of scopolamine and atropine in plant powders. A standard linear regression line was established of quantity *versus* peak area. For the nine results quoted, the amounts estimated differed from the actual amounts by as much as 27.5%, although five differed by less than 4%. On-column decomposition of the alkaloids to their apo forms also occurred.

An assay procedure was described for unit dose quantities of scopolamine, using homatropine as an internal standard (4, 5). The amounts estimated differed from the stated actual amount by as much as 14%. The use of tetraphenylethylene as an internal standard was described (6).

This paper reports the use of phenylacetyltropine as an internal standard and gives a critical appraisal of various assays. Where estimations from a known regression were made, predicted inverse tolerance limits were obtained according to Williams (7).

EXPERIMENTAL[1]

Materials—The carrier gas was helium. Dual columns of Pyrex glass (150 cm × 4 mm i.d.) were packed with acid-washed, silanized Chromosorb W (80–100 mesh) containing 1.5% SE-30. The silanized support material was coated with a trace of polyethylene glycol 4000 and then with SE-30 according to the method of Street (8). The packing was held by a small plug of silanized glass wool.

All solvents were fractionally distilled, and the chemicals used were of analytical reagent grade. Plant material was dried at 50° and then milled[2] to a moderately coarse powder (BP). Hyoscyamine base[3], scopolamine hydrobromide[3], homatropine[3], hexamethyldisilazane[4], *N,O*-bis(trimethylsilyl)acetamide[5], and tetraphenylethylene[6] were obtained commercially. Phenylacetyltropine was prepared by chemical synthesis.

Slope Ratio Assay—The column temperature was 194° with an injection port heater set at 244°. The gas inlet pressure was 28 psi and gave a flow rate of 190 ml/min. The output was attenuated ×2000 to a 10-mv recorder with a chart speed of 20 mm/min. Peak areas were measured by the peak height–peak width method (9).

Solutions were prepared by dissolving scopolamine in pyridine containing 5% hexamethyldisilazane on the day before use. By forming the trimethylsilyl derivative, on-column decomposition to the apo form was avoided and symmetrical peaks with no tailing were obtained. Both the standard and unknown preparations were injected on the column in five replicates using two separate volumes, 10 and 20 μl, to simplify the statistical evaluation.

Several assays (A–C) were performed in which the exact milligrams per milliliter content of scopolamine was known in both the standard and the unknown but in which the strength of the unknown solution was not disclosed to the analyst until after the assay was completed. A commercial sample of *Duboisia* (D), previously assayed by a titrimetric method (10), was analyzed. Other samples of *Duboisia* (E–H) fortified with increasing amounts of scopolamine were assayed similarly (Table II).

A 10-g sample of coarsely powdered *D. leichhardtii*[7] leaves, mixed with 1 g of calcium hydroxide, was moistened with 10 ml of distilled water (or, in later experiments, water containing a known quantity of scopolamine hydrobromide). After 30 min to allow a thorough penetration of alkali, the mixture was exhaustively extracted by repeated maceration with cold ether (3 × 150 ml). The combined ether extracts, after concentration to 100 ml, were extracted with 0.5 *N* hydrochloric acid (2 × 100 ml), and the combined acidic extracts were basified with excess ammonium hydroxide solution (wt./ml 0.88).

The alkaloid bases were extracted with chloroform (3 × 150 ml), and the combined chloroform extracts were evaporated under reduced pressure. The residue was taken up in pyridine containing 5% hexamethyldisilazane. The solution was quantitatively transferred to a 50-ml volumetric flask, and the volume was adjusted with more solvent.

Internal Standard Assay—The column temperature was 235° with an injection port heater set at 285°. The gas inlet pressure was 15 psi and gave a flow rate of 60 ml/min. The output was attenuated ×5000 to a 10-mv integrating recorder.

Regression Line Investigation for Phenylacetyltropine and Tetraphenylethylene—Standard solutions of scopolamine hydrobromide (0.125 g/50 ml of water), phenylacetyltropine picrate (0.125 g/50 ml of chloroform), hyoscyamine (0.075 g/50 ml of chloroform), and tetraphenylethylene (0.125 g/50 ml of chloroform) were prepared. One milliliter of the phenylacetyltropine solution was added to 16 separators using a buret[8]. To every separator were added measured volumes of the scopolamine and hyoscyamine solutions (4 × 0.5, 4 × 1, 4 × 1.5, and 4 × 2 ml), so that each separator contained identical volumes of the two solutions.

The volumes of organic and aqueous phases in each separator were adjusted to 3 and 2 ml, respectively, by appropriate addition, if necessary, of chloroform and water. The extraction then was continued as follows. Approximately 1 ml of ammonium hydroxide solution (wt./ml 0.88) was added, and the two phases were shaken together. The chloroform layer was run off into a stoppered test tube, and the aqueous layer was reextracted with chloroform (2 × 2 ml). To the combined chloroform extracts was added 1 ml of the tetraphenylethylene standard solution, and the extract was evaporated under a stream of nitrogen. The residue was taken up in 1 ml of anhydrous pyridine, and 0.30 ml of hexamethyldisilazane was added. After 8 hr, 10 μl of the silanized extract was subjected to GLC analysis.

Regression Line Investigation for Homatropine—Standard solutions of scopolamine hydrobromide (0.254 g/100 ml of water), hyoscyamine (0.156 g/100 ml of chloroform), and homatropine (0.200 g/100 ml of chloroform) were prepared. Extracts were prepared as described previously with the omission of the standard solutions of phenylacetyltropine and tetraphenylethylene, the inclusion of homatropine as the internal standard, and the replacement of hexamethyldisilazane by *N,O*-bis(trimethylsilyl)acetamide as the silanizing agent.

Table I—GLC Retention Times of *Duboisia* Alkaloids[a]

Alkaloids	A[b]	B[c]
Tetraphenylethylene[d]	1.27	1.30
Scopolamine	1.0	1.0
Hyoscyamine	0.73	0.69
Norhyoscyamine	0.74	0.69
Homatropine[d]	0.53	0.47
Meteloidine[e]	0.37	0.31
Phenylacetyltropine[d]	0.36	0.27
Valeroidine	0.18	0.13
Tigloidine	0.15	0.10
Valtropine	0.12	0.07
Butropine	0.09	0.05
Anabasine	0.09	0.05
Nicotine	0.07	0.03
Acetyltropine	0.06	0.03

[a] Actual retention time = (A) × 15 min and (B) × 32.8 min. All alkaloids were treated with hexamethyldisilazane. [b] Column temperature was 233°, column pressure was 15 psi, and flow rate was 60 ml/min. [c] Column temperature was 194°, column pressure was 28 psi, and flow rate was 190 ml/min. [d] Internal standards. [e] A tropane alkaloid not isolated from *Duboisia*.

[1] A Pye series 104 gas chromatograph fitted with dual flame-ionization detectors and a Rikadenki 10-mv integrating recorder were used.

Table III—Regression Equations for Internal Standard Assays[a]

Internal Standard	Scopolamine	Hyoscyamine
Phenylacetyltropine (0.0025 g picrate)	$y = 0.817529x - 0.153925$	$y = 0.80385x - 0.130925$
Tetraphenylethylene (0.0025 g)	$y = 0.267702x - 0.0722498$	$y = 0.29095x - 0.082875$
Homatropine (0.0020 g)	$y = 0.834662x - 0.057589$	$y = 0.71885x - 0.026988$

[a] x = weight of scopolamine or hyoscyamine expressed in milligrams; y = ratio of integrated areas of scopolamine or hyoscyamine *versus* internal standard.

Extraction and Assay—A 10-g sample of coarsely powdered *D. leichhardtii* leaves, mixed with 1 g of calcium hydroxide, was moistened with 10 ml of distilled water. After 30 min to allow a thorough penetration of alkali, the mixture was exhaustively extracted by repeated maceration with cold ether (3 × 150 ml). On evaporation, the combined ether extracts gave a residue which was taken up in chloroform and the volume was adjusted to 25 ml. A suitable quantity (1, 2, or 4 ml) was pipetted into a separator, and 1 ml of either homatropine or phenylacetyltropine solution was added. The volume was adjusted to 5 ml if necessary with chloroform.

The chloroform extract was shaken with 0.5 *N* hydrochloric acid (1 × 5 and 1 × 3 ml), and 1 ml of ammonium hydroxide solution (wt./ml 0.88) was added to the combined acidic extract, which was extracted with chloroform (1 × 5, 1 × 3, and 1 × 2 ml). Then the chloroform extracts were combined. One milliliter of tetraphenylethylene was added if required as an internal standard. The chloroform was removed under a stream of nitrogen, the residue was dissolved in 1 ml of anhydrous pyridine, and 0.3 ml of either hexamethyldisilazane or *N,O*-bis(trimethylsilyl)acetamide was added according to the internal standard employed. After 8 hr, a 10-μl sample was subjected to GLC analysis.

Phenylacetyltropine—Atropine sulfate (5 g) was refluxed with barium hydroxide (6 g) in distilled water (200 ml) for 2 hr. After cooling, excess 2 *N* sulfuric acid was added and the barium sulfate so formed was filtered off. The filtrate was extracted with ether (2 × 150 ml) to remove tropic acid. The aqueous fraction was made alkaline with excess ammonium hydroxide solution (wt./ml 0.88) and extracted with chloroform (4 × 100 ml).

The chloroform extracts were combined and gave tropine (2 g, 95% yield) after evaporation under reduced pressure. Tropine (1 g) was added to phenylacetyl chloride (20 ml), and the mixture was heated for 2 hr on a water bath. The reaction mixture was diluted with 80 ml of distilled water and made acidic with 2 *N* sulfuric acid. Phenylacetic acid was removed by ether extraction (2 × 100 ml). The aqueous residue was made alkaline with the addition of excess ammonium hydroxide solution (wt./ml 0.88) and extracted with chloroform (3 × 100 ml). Evaporation of the combined chloroform extracts gave phenylacetyltropine which, when neutralized with 0.2 *N* sulfuric acid and treated with a saturated aqueous solution of sodium picrate, gave phenylacetyltropine picrate (2.5 g, 72% yield), mp 166°.

Anal.—Calc. for $C_{16}H_{21}NO_2 \cdot C_6H_3N_3O_7$: C, 54.1; H, 4.9; N, 11.5. Found: C, 54.4; H, 5.1; N, 11.2.

Sampling from a Bale of Duboisia *Leaf*—One bale (175 × 150 × 100 cm, approximately 175 kg) of commercial *D. myoporoides* leaves[9] was subdivided into 11 vertical layers (A–K). Then each layer was divided into 16 lots, distributed horizontally in a 4 × 4 square so that the horizontal position of each lot could be identified. From these, four lots were selected at random, namely E5, F9, G2, and J12. Each lot was subdivided into 16 samples. Four samples were selected randomly from each lot and annotated such that E5/15 indicates Layer E, Lot 5, Sample 15. Each sample was analyzed with four replicates, using phenylacetyltropine as the internal standard.

RESULTS AND DISCUSSION

Slope Ratio Assay—Two injection volumes of a standard solution, *S* (10 and 20 μl), and two identical volumes of an unknown solution, *U*, are injected into the gas chromatograph. If the two regression lines of the responses to *S* and *U* intersect at the origin, then the ratio of the concentrations of the two solutions is equal to the ratio of the slopes of the regression lines. By using the appropriate experimental design and tests of significance, an estimate of confidence limits may be calculated from internal evidence in the assay. The statistical methods used were fully discussed by Finney (11).

For Assays A, B, and C, the analyst was presented with two solutions, labeled standard and unknown. The three standards were of different concentrations, but in each case the unknown was actually a sample of one solution. Thus, the analyst was unknowingly assaying the same preparation; but since the standards differed for each assay, the slope ratios in each case were different. Individual assays showed some error, varying from −0.62 to +1.8% (Table II). Each assay provided its own limits of precision, but in one instance the true concentration was just outside the limits. Confidence limits in Assays E, F, G, and H, in which varying amounts of scopolamine were added as the hydrobromide to powdered *D. leichhardtii*

[9] The bale was supplied by G. R. Davies, Hornsby, N.S.W. A voucher specimen, annotated BRI 179202, was lodged with the Queensland Herbarium.

Table IV—Predicted x Values and Tolerance Limits Determined from Regression Equations of the Internal Standard Assay Using y Values at the Mean, Upper, and Lower Parts of the Regression Line

Internal Standard	Assay for	y Value Observed	Mean of	Predicted x Value	Limits, $p = 0.95$
Phenylacetyltropine	Scopolamine	4.09	1	5.19	4.61–5.77 (±0.58, ±11.2%)
		4.09	4	5.19	4.85–5.50 (±0.31, ±6%)
		1.30	1	1.78	1.16–2.38 (±0.60, ±33%)
		1.30	4	1.78	1.31–2.25 (±0.47, ±25%)
		7.0	1	8.75	8.15–9.37 (±0.62, ±7.1%)
		7.0	4	8.75	8.40–9.12 (±0.37, ±4.2%)
Phenylacetyltropine	Hyoscyamine	3.48	1	4.5	3.97–5.02 (±0.52, ±11.2%)
		3.48	4	4.5	4.22–4.77 (±0.27, ±6.2%)
		1.1	1	1.53	0.97–2.06 (±0.53, ±35%)
		1.1	4	1.53	1.20–1.84 (±0.31, ±20%)
		6.0	1	7.63	7.10–8.18 (±0.55, ±7.3%)
		6.0	4	7.63	7.31–7.96 (±0.33, ±4.4%)
Tetraphenylethylene	Scopolamine	1.085	1	4.32	4.03–4.62 (±0.30, ±6.1%)
		1.085	4	4.32	4.16–4.48 (±0.16, ±3.6%)
		0.4	1	1.76	1.45–2.06 (±0.30, ±17%)
		0.4	4	1.76	1.57–1.94 (±0.18, ±13%)
		1.8	1	7	6.68–7.30 (±0.30, ±4.4%)
		1.8	4	7	8.81–7.18 (±0.18, ±2.7%)
Tetraphenylethylene	Hyoscyamine	1.01	1	3.75	3.35–4.15 (±0.40, ±10%)
		1.01	4	3.75	3.53–3.96 (±0.21, ±5.8%)
		0.4	1	1.66	1.23–2.07 (±0.41, ±24%)
		0.4	4	1.66	1.40–1.90 (±0.24, ±11%)
		1.8	1	6.47	6.04–6.91 (±0.44, ±6.8%)
		1.8	4	6.47	6.21–6.74 (±0.27, ±4.3%)
Homatropine	Scopolamine	0.98	1	1.25	1.03–1.46 (±0.21, ±17%)
		0.98	4	1.25	1.13–1.36 (±0.11, ±9.2%)
		0.4	1	0.55	0.32–0.76 (±0.21, ±39%)
		0.4	4	0.55	0.41–0.67 (±0.12, ±23%)
		1.6	1	1.98	1.77–2.21 (±0.23, ±11%)
		1.6	4	1.98	1.85–2.10 (±0.12, ±7.0%)
Homatropine	Hyoscyamine	0.87	1	1.25	1.10–1.39 (±0.14, ±11%)
		0.87	4	1.25	1.17–1.32 (±0.07, ±6.2%)
		0.30	1	0.45	0.30–0.60 (±0.15, ±33%)
		0.30	4	0.45	0.35–0.54 (±0.09, ±19%)
		1.50	1	2.12	1.97–2.28 (±0.16, ±7.3%)
		1.50	4	2.12	2.03–2.22 (±0.10, ±4.6%)

leaves, were greater than in previous assays because they included errors incurred in the additional extraction stage.

If Assay E is assumed to be exact, errors varied from +0.05 to +2.05%. Thus, the slope ratio method appears to provide a valuable and accurate quantitative assay for scopolamine.

Internal Standard Assay—Analysis of the results gave six regression equations for values of x (milligrams of scopolamine or hyoscyamine) and of y (ratio of integrated areas of alkaloid *versus* internal standard) (Table III). Silanization of the alkaloid mixture was essential to prevent dehydration to the apo derivatives. Of the internal standards employed, homatropine suffered the disadvantage that it underwent silanization with difficulty. Hexamethyldisilazane would not cause the silanization to go to completion, and a more active agent was necessary [*N,O*-bis(trimethylsilyl)-acetamide]. Internal standards such as homatropine and phenylacetyltropine are superior to tetraphenylethylene, since they are introduced into the assay during the extraction stage so that any losses during extraction are reflected in the confidence limits. The results demonstrate that of the three internal standards, phenylacetyltropine and tetraphenylethylene are the standards of choice.

If it is important that the confidence limits be close, for example to deduce whether two samples are different or if one is superior to the other, then replicate determinations will vastly narrow them. Such an occasion may arise in the selection of trees for cultivation trials. In the results (Table IV), x values are quoted at the mean of y and also at values of y at the lower and upper limits of the regression line. Greater accuracy can be achieved by adjusting the experiment so that the regression line in and around the mean is employed during the assay.

The assay for hyoscyamine also includes norhyoscyamine since both alkaloids have similar retention times. Norhyoscyamine has been isolated as a minor alkaloidal component of *D. myoporoides* (1) and *D. leichhardtii* (12). This does not detract from the value of the assay since samples of *Duboisia* for commercial purposes are estimated on their scopolamine content alone.

Commercial *Duboisia* consignments are obtained from both cultivated and natural sources. In the past, *D. leichhardtii* was the most cultivated of the two species. Cultivation of the genus was hampered by the poor germination of *Duboisia* seed, and most plantations were derived from naturally set seedlings. Hills *et al.* (13) found considerable variations in alkaloid type and yield in natural stands of *Duboisia*, suggesting the existence of chemical varieties. Thus, consignments of *Duboisia*, whether cultivated or naturally obtained, are unlikely to be homogeneous in alkaloid content.

Samples were selected randomly from a bale of *D. myoporoides*, which formed part of a commercial consignment obtained from natural sources. There was a threefold variation in the scopola-

Table V—Analysis of Samples of *D. myoporoides* Leaves Obtained from a Commercial Bale

Solubilization and Stabilization of the Cytotoxic Agent Coralyne

M. J. CHO [*§], A. J. REPTA [*x], C. C. CHENG [‡], K. Y. ZEE-CHENG [‡], T. HIGUCHI [*], and I. H. PITMAN [*]

Abstract □ Kinetic studies were carried out on the ring opening of the quaternary nitrogen cation, coralynium ion (I), to yield 6′-acetylpapaverine (III), on the cyclization of III to yield I, and on a photochemical reaction undergone by I in aqueous solutions exposed to visible light. From the results, it was concluded that: (*a*) I and III are in facile equilibrium in aqueous solution but appreciable amounts of III do not exist in dilute solutions with pH values below 10; (*b*) the photochemical reaction of I in water (presumably a photohydration) can be reversed by lyophilization, by heating, and by increasing the pH of solutions to values greater than 12; (*c*) the photochemical reaction of I can be inhibited by protecting the aqueous solutions from visible light, and the rate in the presence of light can be reduced by increasing the concentration of I in the solution; and (*d*) although the chloride and sulfoacetate salts of I react identically and have similar solubilities in water, it is possible to prepare more concentrated and, hence, more stable solutions of the sulfoacetate salt by including sodium hydroxide in the solvent. The solubility of coralyne chloride remains about the same in dilute sodium hydroxide as in water.

Keyphrases □ Coralyne salts—photohydration, ring cleavage, pH dependence of solubility, stabilization, formation of 6′-acetylpapaverine □ Cytotoxic agents—coralyne salts, solubilization and stabilization, photohydration, pH dependence, formation of 6′-acetylpapaverine □ 6′-Acetylpapaverine—kinetics of formation from coralynium ion, cyclization □ Solubility—coralyne chloride and sulfoacetate, pH dependence

Coralyne chloride (I*a*) is a berbinium salt possessing antileukemic activity against both the P-388 and L-1210 strains (1, 2). However, the clinical evaluation of I*a* has been hampered by the relatively high expected dose of 1-2 g[1] together with the rather low aqueous solubility of about 5 mg/ml and a report[2] that solutions of the drug stored under different conditions or for varying times exhibited altered spectral characteristics relative to freshly prepared solutions.

This study was undertaken to determine the stability of coralynium ion (I) in aqueous solution with respect to chemical transformation. Previous reports led to the expectation that the most likely degradation pathways would be a ring opening to yield 6′-acetylpapaverine (III) (3) and a covalent hydration reaction (4). Although these reactions were postulated, no quantitative information about reaction rates was reported.

An investigation into the chemical stability and solubility of coralyne sulfoacetate (I*b*), isolated as the initial product in a general synthesis of I (1), suggests that I*b* may be a better coralynium salt to use in liquid dosage forms than I*a*.

EXPERIMENTAL

Materials—Coralyne chloride[3] and coralyne sulfoacetate[4] were provided by the National Cancer Institute and used without further purification. The IR spectrum of coralyne chloride used was identical to the reported spectrum[2]. Coralyne sulfoacetate has an extra absorption band at 1720 cm^{-1} due to the carbonyl group in the anionic part. 6′-Acetylpapaverine was prepared, following the

procedure given by Schneider and Schroeter (3), from coralyne chloride.

Water was double distilled, with the second distillation being from acid–permanganate solution in an all-glass still. Indoor light was from an ordinary fluorescent bulb[5], and the photohydration was carried out about 1.5 m (5 ft) from such lights. Deoxygenated water was obtained by bubbling double-distilled water with nitrogen gas passed through a pyrogallol solution in concentrated sodium hydroxide. Commercially available borosilicate glass containers were used except where otherwise specified.

Kinetic Experiments—Formation of 6′-acetylpapaverine from coralyne was followed by the absorbance change at 297 nm on a UV spectrophotometer[6]. The reaction was carried out in such a way that, after rapid mixing with sodium hydroxide solution in an optical cell, a coralyne chloride concentration of 1.64×10^{-5} *M* and a coralyne sulfoacetate concentration of 1.82×10^{-5} *M* were obtained. Whenever the half-life of the reaction was shorter than 10 sec, a stopped-flow spectrophotometer[7] was used. In this case, a 1:1 volume ratio of coralyne solution to sodium hydroxide solution was adopted. A temperature of 25.0 ± 0.5° was maintained during the reaction. Ionic strength was not controlled, since no significant primary salt effect was observed when the final ionic strength of the solution, which was 0.5 *M* in sodium hydroxide, was adjusted to 1.0 *M* with sodium sulfate.

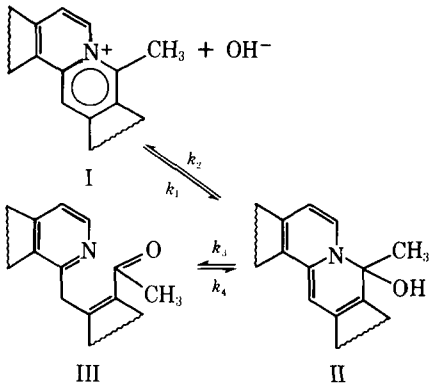

Scheme I

The aromatization reaction of 6′-acetylpapaverine was followed in a similar manner. A concentrated solution, freshly prepared in chloroform, was used as a stock solution (~6 mg/ml). After about 3.5 μl of this stock solution was directly transferred into an optical cell through a microsyringe, the solvent was evaporated by nitrogen gas, the residue was rapidly dissolved in the appropriate buffer solutions, and the absorbance change at 297 nm was followed on a spectrophotometer. Since the reaction was extremely slow in 0.1 *N* HCl (Table I), sometimes a concentrated stock solution (~6 mg/ml) prepared in 0.1 *N* HCl was used in the kinetic experiments. Temperature and the final ionic strength were maintained at 25.0 ± 0.1° and 0.1 *M*, respectively.

Solubility Studies—The solubility of Ia and Ib in aqueous media was determined as follows. About 100 mg of either Ia or Ib was placed into separate 4-dram screw-capped vials. To each vial was added about 5 ml of distilled water. The tightly closed vials were wrapped in aluminum foil and attached to a rotating shaft in a water bath thermostated at 25 ± 0.1°. The samples were allowed to equilibrate for 7 days.

The solubility of Ib in various concentrations of sodium hydroxide was determined similarly. To a series of vials were added successively increasing amounts of Ib and 5 ml of increasingly concentrated aqueous sodium hydroxide solution. In a typical series of vials, the composition of the contents of each vial relative to the added amounts of Ib and the concentration of the sodium hydroxide solution, respectively, were as follows: vial I, ~125 mg, 0.02 *M*; vial II, ~200 mg, 0.04 *M*; vial III, 275 mg, 0.06 *M*; and vial IV, 350 mg, 0.08 *M*.

The vials were tightly closed and equilibrated as already described. Equilibration was complete after about 30 hr. Following equilibration, samples of the various solutions were withdrawn using a filter[8] and the filtrate was analyzed.

Analysis of Coralyne Chloride and Coralyne Sulfoacetate in Solution—The determination of the concentration of the coralyne salts in solution was carried out spectrophotometrically. The UV spectra of both compounds were qualitatively identical in solutions of anhydrous methanol and in 1% water–methanol. Beer's law plots were constructed for each salt in anhydrous methanol at λ_{max} = 312 nm. The molar absorptivity of the two compounds differed slightly. The experimental values determined from Beer's law plots were $\epsilon_{312} = 5.3 \times 10^4$ liters/mole cm for Ia and $\epsilon_{312} = 5.85 \times 10^{-4}$ liter/mole cm for Ib. This difference in absorptivities may be due to the presence of greater amounts of water in Ia (up to 10%)[9] as compared to Ib (0–2% water)[10].

Filtered aliquots of the aqueous coralyne solutions were suitably diluted (100-fold or more) with anhydrous methanol. The absorbance was then measured at 312 nm in a 1-cm cell, and the concentration was calculated utilizing the molar absorptivity value obtained for the particular salt being analyzed.

Methanol was used as the solvent for the analysis to prevent photohydration, which would have occurred rapidly in dilute aqueous solutions.

RESULTS AND DISCUSSION

Stability of Ia and Ib in Solutions Protected from Light—The UV spectra of aqueous solutions of *Ia* and *Ib* that had pH values below 10 and were completely protected from light (*e.g.*, stored in stoppered flasks wrapped in aluminum foil) did not change more than ±2% at any wavelength during 48 hr. The spectra of these two solutions were identical and were similar to the spectrum of *Ia* in methanol.

When the pH values of solutions of *Ia* and *Ib* were above 12, spectral changes occurred in a manner suggesting that coralynium ion was being converted into one or more products. An isosbestic point was maintained at 253 nm during these changes. Figure 1 displays the spectra measured at several times after the mixing of 0.6 ml of a 1×10^{-4} *M* solution of *Ia* in acetonitrile (a solvent in which *Ia* appeared to be stable for several days) with 3.0 ml of 1×10^{-1} *M* NaOH.

It was reported previously (3) that coralynium ion (I) is converted into 6′-acetylpapaverine (III) in alkaline solutions. Hence, it is believed that the spectral changes observed in solutions of *Ia* and *Ib* at pH > 12 were caused by the conversion of I to III. The results of studies (5) on the ring opening of other ring systems containing a quaternary nitrogen atom led to the conclusion that the reactions shown in Scheme I are probably involved in the conversion of I to III.

Compound III, formed by the reactions of *Ia* and *Ib* in solutions at pH ≥ 12, reverted to coralynium ion when the pH value of the solutions was reduced to values below 11. The spectral changes observed during the reaction for the conversion of III to I were precisely the reverse of those shown in Fig. 1, and the isosbestic point maintained during the closure reaction was at the same wavelength (253 nm) as that observed during the conversion of I to III in solutions with pH > 12. These spectral data represent evidence that the reactions observed at pH < 11 were the reverse of the reactions of *Ia* in more alkaline solutions.

Furthermore, a precipitate obtained 24 hr after III (5 mg/ml) was dissolved in 0.1 *N* HCl had an identical IR spectrum (measured in a KBr disk) and NMR spectrum (when dissolved in trifluoroethanol) to those of an authentic sample of *Ia*. It has recently been observed (2) that the pharmacological activities of *Ia* and III are similar. This observation is consistent with the postulates that I and III are rapidly interconvertable in solution and that III would be rapidly converted to I at physiological pH.

When the initial concentration of sodium hydroxide, $[NaOH]_0$, was at least five times greater than the initial concentration of *Ia* or *Ib*, the conversion of I to III was a first-order process. Pseudo-first-order rate constants, k^0_{obs}, for this reaction sequence were calculated from the slopes of linear plots of log $(A_t - A_\infty)$ against time. Values of k^0_{obs} are shown plotted against $[NaOH]_0$ in Fig. 2.

The conversion of III to I in aqueous buffers was also a first-order process, and values of a pseudo-first-order rate constant, k^c_{obs}, were calculated from the slopes of linear plots of log $(A_t - A_\infty)$ against time. Values of k^c_{obs} at several different pH values, together with the buffer systems, are listed in Table I. No attempt

was made to evaluate buffer-independent rate constants or general-acid and general-base catalysis constants.

The facts that pure first-order kinetics were observed during both the conversion of I to III and the reverse reactions and that the same isosbestic point was maintained during the forward and reverse reactions strongly suggest that no significant concentrations of an intermediate (*i.e.*, the carbinolamine, II) accumulated during either the forward or the reverse reactions. Therefore, an identity relating k^0_{obs} and k^c_{obs} values to the microscopic rate constants in Scheme I can be arrived at by using a steady-state treatment. An identity that should apply at any pH value where species III exists primarily as a neutral molecule is:

$$k^0_{obs} = k^c_{obs} = \frac{k_1 k_3}{(k_2 + k_3)}[OH^-] + \frac{k_2 k_4}{(k_2 + k_3)} \qquad \text{(Eq. 1)}$$

Values of the slope and intercept of the plot of k^0_{obs} against $[NaOH]_0$ indicate that $k_1k_3/(k_2 + k_3) = 0.1\ M^{-1}$ sec^{-1} and $k_2k_4/(k_2 + k_3) \ll 10^{-2}$ sec^{-1}. Values of k^c_{obs} calculated from experiments in which the pH values were varied between 6 and 11 (*i.e.*, where $[H^+]$ and $[OH^-]$ varied by 10^5) only differed from one another by a factor of about 20. Hence, it appears that under these conditions the term $k_1k_3[OH^-]/(k_2 + k_3) \ll k_2k_4/(k_2 + k_3)$.

The relatively small change observed in k^c_{obs} values was perhaps caused by the different general acids and general bases in each reaction system. If this conclusion is correct, the value of the buffer-independent term, $k_2k_4/(k_2 + k_3)$, is likely to be no greater than $\sim 3.5 \times 10^{-4}$ unit, which is the smallest value of k^c_{obs} observed throughout this pH range (Table I). The decrease in the value of k^c_{obs} that occurred when the pH value was reduced from 6 to 3 was most likely caused by protonation of the nitrogen atom of 6′-acetylpapaverine. The conjugate acid of III would be expected to have a pKa value similar to that of isoquinoline, 5.4 (6). Protonation of III would be expected to reduce its rate of cyclization to yield II and would thus reduce the apparent value of k_4.

It can be concluded that $k_1k_3/k_2k_4 = [III]/[I][OH^-] \simeq 10^{-1}/3 \times 10^{-4} \simeq 3 \times 10^2\ M^{-1}$. Hence, at pH < 11, [III]/[I] < 0.3; at pH ~ 6, [III]/[I] would be of the order of 10^{-5}. Thus, the interconversion of I and III occurs relatively rapidly in solution and only an insignificant fraction of the total alkaloid persists as III in solutions with pH values ≤10.

Photochemical Reactions of Ia and Ib—It has been suggested (4) that I becomes covalently hydrated in aqueous solution. This conclusion was based on similarities between the UV spectra of freshly prepared aqueous coralyne solutions and solutions of coralyne salts in anhydrous solvents, such as acetonitrile and methanol, and the differences between these spectra and that of an aged aqueous solution. The reversibility of the hydration reaction was established from the fact that lyophilization of aged solutions of *Ia* or *Ib* yielded residues which, on redissolution in methanol, produced solutions with UV and NMR spectra identical to those obtained from freshly prepared solutions of the authentic salts.

In the present study, the reactions that occur in aqueous solutions of *Ia* and *Ib* at pH values where no appreciable amounts of III are formed were investigated and the following additional information is reported.

1. The reaction of I that has been referred to as a covalent hydration reaction is a photochemical reaction and appeared to occur as a result of exposure of solutions of I to visible light. Hence, whereas the UV spectra of solutions of *Ia* and *Ib* in water do not change appreciably during 24 hr if the solutions are completely

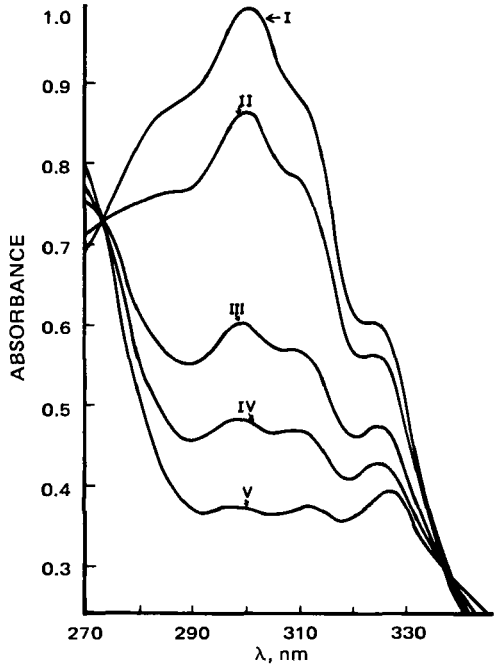

Figure 3—*Spectral changes for an aqueous solution of Ia (~2 × 10^{-5} M) exposed to fluorescent laboratory light for various periods. Key: I, 0 min (freshly prepared solution); II, 15 min; III, 60 min; IV, 180 min; and V, 2 days (no further spectral changes occurred).*

protected from light, they do change rapidly upon exposure to sunlight or normal laboratory illumination in either open or closed glass vessels.

Figure 3 displays the spectrum of a freshly prepared solution of I*a* in water and the spectra measured after various periods of exposure of the solutions to normal laboratory illumination. If a solution that had been exposed to illumination for any length of time was then protected from light (*e.g.*, by storing it in an amber glass container or in a container painted black or wrapped with aluminum foil), its spectrum underwent no further changes during the protection period.

The rate and nature of spectral changes upon illumination were the same in solutions of I*a* and I*b* stored in either borosilicate glass or quartz containers. Because the materials of the former type of container absorb UV light whereas those of the latter type transmit UV light, it seems highly probable that the visible range of radiant energy is involved in the photochemical reaction. Thus, it is

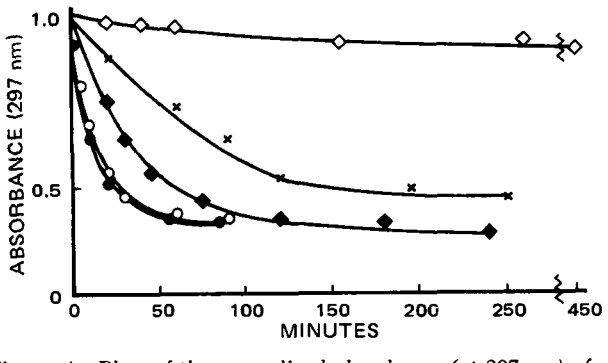

Figure 4—*Plots of the normalized absorbance (at 297 nm) of solutions of I*b versus *the time of exposure to normal laboratory light. The studies were conducted at room temperature (about 19–22°). The initial concentrations of I*b *in the solutions were: ◇, 2.15 × 10^{-3} M; ×, 2.15 × 10^{-4} M; ♦, 7.54 × 10^{-5} M; ○, 1.08 × 10^{-5} M; and ●, 7.10 × 10^{-6} M. Normalization was achieved by multiplying measured absorbances at 297 nm by a factor that took into account differences in the initial concentration and the path length of the cell. The initial absorbance of a 2.15 × 10^{-5} M solution of I*b *in a 1-cm cell was 0.984.*

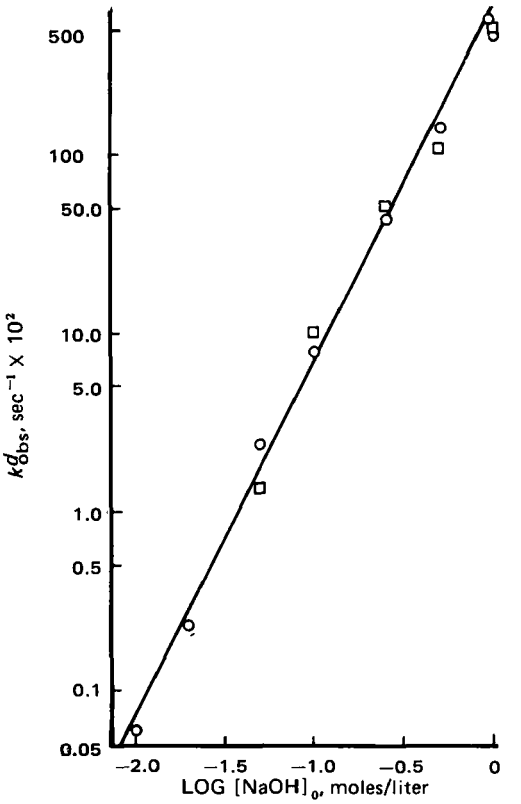

Figure 5—*Logarithmic plot of observed first-order rate constants for the conversion of the postulated photohydrate to I as a function of sodium hydroxide concentration. T = 25°. Identical results were obtained with I*a *(○) and I*b *(□).*

necessary to exclude light to prevent the reaction from occurring.

2. The rate of spectral changes during illumination was not affected by the presence of dissolved oxygen in the solutions. This fact was established by comparing the rates of spectral changes in illuminated solutions of I*a* in water that had been saturated with either oxygen or nitrogen. It can be concluded from this result that oxygen is not involved in the photochemical reaction. Furthermore, oxygen is a quencher of many photochemical reactions involving triplet-state excited molecules (T^1). Hence, the fact that the rate of the photochemical reaction of I is insensitive to oxygen concentrations suggests that it involves single-state (S^1) rather than triplet-state (T^1) excited molecules. A similar conclusion was drawn (7) about the photohydration of uracil, because the rate of this reaction was also insensitive to oxygen concentrations.

3. The rate of photohydration reaction was the same in 0.1 *N* HCl as it was in water. This result suggests that the rate-determining step involves a reaction between an excited form of the coralynium ion (presumable S^1 species) and undissociated water molecules rather than hydroxide ions or hydrogen ions.

4. The apparent rate of the photohydration reaction decreased as the initial concentration of I in the solution was increased. This result can be seen in Fig. 4, where plots of the absorbance (at 297 nm) of different solutions of I*b* against time of exposure to laboratory illumination are displayed.

In a typical experiment, 10–12 identical volumetric flasks (25 ml), wrapped with aluminum foil, were filled with a solution of I*b* in water. This operation was performed in a photographic darkroom where no appreciable photochemical reaction occurred. The flasks were then placed on an illuminated laboratory bench and the aluminum foil was removed. At various time intervals, a flask was selected at random and the UV absorbance of its solution at 297 nm was measured in a 0.2-, 1.0-, or 5.0-cm cell or an appropriate dilution was made in a darkroom and the absorbance then was measured. The absorbance data were normalized so that they could be conveniently presented on a single graph.

No simple rate law could be derived to account for the absorbance changes as a function of time. This observation suggests that the distribution of light energy is not uniform throughout the reac-

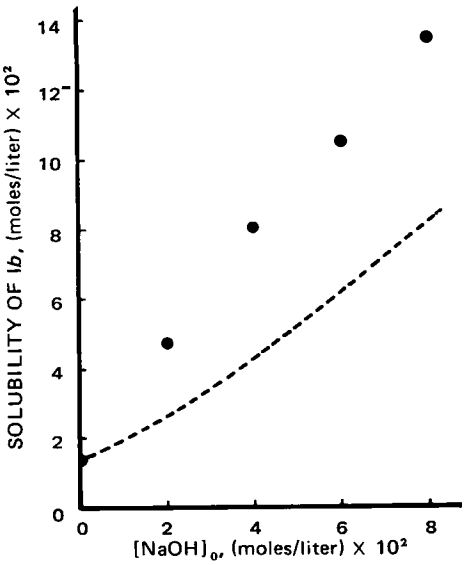

Figure 6—*Plot of aqueous solubility of Ib as a function of added sodium hydroxide, [NaOH]₀. The points represent the experimental results. The dashed line represents the curve calculated using Eq. 6 and a value of* $K_{sp}^{Ib} = 1.72 \times 10^{-4}$ M²; T = 25°.

tion solutions, a phenomenon that is commonly encountered in photochemical reactions where the excited-state molecules have only a very short lifetime (8). However, the results clearly indicate that the apparent rate of the photochemical reaction decreases as the concentration of I increases. Further confirmation of this fact comes from the observation that rapid dilution with water of a saturated solution of Ia, which had been stored in a flask on a laboratory bench for 2 months, yielded a solution that had a UV spectrum identical to that of a freshly prepared solution of Ia.

It was reported (4) that the presumed hydration of I can be reversed by lyophilization of solutions or by dilution of solutions of the hydrate with methanol. Two other methods of causing a reversal of the hydration reaction have become apparent as a result of this work. In the first case, when a 10^{-4} *M* solution of Ia, which had been illuminated with laboratory light for several weeks, was refluxed for 1 hr and then cooled in the dark, its spectrum was almost the same as that of a freshly prepared solution of Ia.

In the second case, if a solution of Ia in water was exposed to light for several weeks and was then made alkaline to pH > 12, its spectrum rapidly changed from that of the hydrate to one that was very similar to the spectrum of Ia. This spectrum then changed in the manner that has been attributed to the conversion of I to III. Since an isosbestic point is maintained at 253 nm during the conversion of I to III and the absorbance of I and its hydrate at 253 nm differ significantly, the kinetics of conversion of the hydrate to I could be studied by measuring absorbance changes at this wavelength. The reaction appeared to be first order in the concentration of the hydrate, and pseudo-first-order rate constants, k_{obs}^{d}, were calculated from the slopes of linear plots of log $(A_t - A_\infty)$ against time.

As can be seen from the logarithmic plot of k_{obs}^{d} against $[NaOH]_0$ in Fig. 5, the rate of this reaction had a second-order dependence on hydroxide-ion concentrations. An explanation of this result cannot be offered at this time. Dehydration reactions of photohydrates of molecules such as uracil have been reported (9) to be first order with respect to hydroxide-ion concentration, but we are unaware of any dehydration reactions that have been shown to be second order with respect to this reactant. This result may cast some doubt on whether the product of the photochemical reaction is indeed a photohydrate.

This study did not yield additional evidence as to the structure of the product; its characterization rests on the observations that it only forms in water and not in anhydrous methanol or acetonitrile and that it is readily converted into I by lyophilization, by heating, or by making the solution alkaline.

Irrespective of the exact nature of the product of the photochemical reaction of I, the reaction can be prevented by completely protecting the aqueous solutions from visible light and the rate in the presence of light can be greatly reduced by increasing the concentration of I in the solution. These facts, together with the ability to reverse the photochemical reaction through lyophilization, are extremely important in the ultimate development of formulations for parenteral solutions of I.

Solubility of Ia and Ib—It was desirable to identify a method for obtaining more concentrated solutions of I to facilitate the intravenous administration of the cytotoxic agent, especially in view of the data in Fig. 4 indicating the apparent increase in chemical stability achieved through increased concentration.

The solubility of Ia and Ib in water at 25° was determined to be about 4.5 and 6.5 mg/ml, respectively. It had been shown[1] that the solubility of Ia was no greater in weakly alkaline aqueous media than in distilled water, as expected for such a compound. The solubility of Ib as a function of added sodium hydroxide is shown in Fig. 6. It is obvious that the apparent solubility of Ib is greatly increased by the presence of added sodium hydroxide. Qualitatively, this solubility behavior of Ib was expected, since the sulfoacetate anion (in contrast to Cl^-) is an acid and would be ionized by the added hydroxide ion. This behavior can be expressed mathematically as follows.

The apparent solubility product (K_{sp}) for Ib is given by:

$$K_{sp}^{Ib} = [I][(HO_2C—CH_2—SO_3)^-] \quad \text{(Eq. 2)}$$

Because $(HO_2C—CH_2—SO_3)^-$ is a weak acid, it would react with each added hydroxide ion according to Scheme II:

$$(HO_2C—CH_2—SO_3)^- + (OH)^- \rightarrow (O_2C—CH_2—SO_3)^{-2} + H_2O$$

Scheme II

and:

$$[NaOH]_0 \simeq [(O_2C—CH_2—SO_3)^{-2}] \quad \text{(Eq. 3)}$$

As long as the only solid phase in the system is Ib, the following identities must be obeyed:

$$[I] = [(HO_2—C—CH_2—SO_3)^-] + [(O_2C—CH_2—SO_3)^{-2}] \quad \text{(Eq. 4)}$$

$$[I] = [(HO_2C—CH_2—SO_3)^-] + [NaOH]_0 \quad \text{(Eq. 5)}$$

Substituting Eq. 5 into Eq. 2 and solving for [I] lead to:

$$[I] = \{[NaOH]_0 + ([NaOH]_0^2 + 4K_{sp}^{Ib})^{1/2}\}/2 \quad \text{(Eq. 6)}$$

The dashed line in Fig. 6 was calculated using Eq. 6 and a K_{sp}^{Ib} value that was calculated from the identity:

$$K_{sp}^{Ib} = [I]_{sat}^2 \quad \text{(Eq. 7)}$$

where $[I]_{sat}$ ($= 1.31 \times 10^{-2}$ *M*) is the solubility of Ib in water at 25°.

There are at least two possible explanations for the fact that the actual solubility of Ib was higher in aqueous sodium hydroxide than was predicted using Eq. 6. First, no allowance was made for the fact that the K_{sp}^{Ib} value would change as the ionic strength of the solution increased. The solubility of Ib and the concentration of the dianionic species $(O_2C—CH_2—SO_3)^{-2}$ obviously increased as the initial concentration of sodium hydroxide was increased. Therefore, the ionic strength of the solution increased, and such an increase probably would be expected to increase the value of K_{sp}^{Ib} (10).

Second, there is a strong possibility that I dimerizes or forms higher order complexes in solution. The occurrence of this phenomenon might also be expected to lead to an increase in the apparent solubility of the salt. Although this latter phenomenon was not investigated further, related quaternary nitrogen-containing ring systems such as acridines do form dimers and higher order complexes in aqueous solution (11).

The important result of this solubility study is that much more concentrated solutions of I can be formed by dissolving Ib (or, presumably, other salts of I and the anions of polyprotic acids) *in* aqueous alkaline solutions than can be prepared using Ia. Moreover, the salt Ib is the initial product obtained by a general synthesis of I (1).

Application of Results—These results have been useful in the development of a formulation of I which obviates the problems that had previously limited the clinical evaluation of the cytotoxic

coralyne salts. This formulation is presently being utilized and is prepared by dissolving Ib in sufficient aqueous sodium hydroxide to yield a final concentration of 25 mg/ml (calculated on the basis of Ib) at pH ~ 6.5. The solution obtained is sterile filtered, frozen, and lyophilized. The lyophilized product is stable, and reconstitution as a solution is easily accomplished upon the addition of water. Such a formulation affords good solubility and stability with respect to I and appears to be completely suitable for intravenous use.

Micelle Formation and Its Relationship to Solubility Behavior of 2-Butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl Ketone Hydrochloride

LOUIS J. RAVIN ˣ, ELIE G. SHAMI ‡, and ELISABETH S. RATTIE

Abstract □ Micelle formation by 2-butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl ketone hydrochloride was studied by conductance measurements. The CMC was approximately 0.05% and was independent of temperature between 20 and 50°. The heat of formation for the micelle was calculated to be 6.9 kcal/mole. The unusual solubility behavior of the compound was attributed to its ability to form micelles. Ultracentrifuge studies indicate the molecular weight of the micelle to be approximately 100,000. Anions such as chloride, sulfate, acetate, tartrate, and citrate significantly affect the equilibrium solubility of the compound. NMR spectroscopic data indicate that the solubility behavior, in part, is related to an effect on the CMC of the compound by the anionic environment.

Keyphrases □ 2-Butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl ketone hydrochloride—micelle formation, relationship to solubility □ Solubility—2-butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl ketone hydrochloride, micelle formation □ Micelles—2-butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl ketone hydrochloride, relationship to solubility

It was reported previously (1, 2) that 2-butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl ketone hydrochloride[1] (I) was capable of existing in the micellar state and that surfactants such as polysorbate 80, sodium lauryl sulfate, and cetyldimethylbenzylammonium chloride had a pronounced effect on its equilibrium solubility. This paper reports the results of studies on the micellar behavior of I, its relationship to the solubility characteristics, and the effect of various anions on its equilibrium solubility.

EXPERIMENTAL

Materials—Ultrapure water[2] was used. All other chemicals were of analytical reagent grade quality.

Equipment—A recording spectrophotometer[3] was used for UV absorption measurements. A conductivity bridge[4] and a conductivity cell[5] were used in the conductance experiments.

Equilibrium Solubility Studies—*Effect of Temperature*—Approximately 200 mg of I was added to screw-capped vials containing 15 ml of water. The vials were rotated for 24 hr at 20, 25, 30, 35, 40, 45, and 60°. The contents of the vials were filtered through syringes fitted with Swinney filter adapters containing a

I

0.45-μm filter disk[6]. The resulting clear solutions were diluted with anhydrous methanol and assayed for I using a recording spectrophotometer.

Effect of Various Salt Solutions—Approximately 200 mg of I was added to screw-capped vials containing 15 ml of salt solutions of known concentrations. The vials were rotated for 24 hr at 30°. The contents of the vials were filtered as previously stated. The resulting solutions were diluted with anhydrous methanol and assayed for I.

Determination of Critical Micelle Concentration (CMC)—The CMC for I was determined by conductance measurements. A series of solutions of various concentrations was prepared and equilibrated at 20, 25, 30, 37, 45, and 50°. Conductance measurements were made on the solutions. The CMC was determined from a plot of equivalent conductance *versus* square root of concentration, using the point of intersection of the straight-line segments of the curve as the CMC value.

Ultracentrifuge[7] Studies—The ultracentrifuge studies were conducted using the sedimentation equilibrium method (3). Samples containing 4.6, 3.5, and 1.5% of I were prepared. To effect solution, it was necessary to dissolve the drug at temperatures in excess of 60°. When cooled, I remained in solution. The samples were centrifuged at 38,000 rpm. Photographs were taken at intervals of 0, 15, 30, 47, 64, and 147 min to follow the movement of the front.

NMR Studies—The NMR spectrum of a solution of I (0.15% in 0.02% sodium sulfate solution) was run in deuterium oxide at 25 and 60°.

RESULTS

CMC—The CMC for I in aqueous solution was approximately 0.05%. Figure 1 shows a plot of the equivalent conductance *versus* the square root of concentration. The CMC was independent of temperature between 20 and 50°.

Effect of Temperature on Equilibrium Solubility—The equilibrium solubility of I in water at 25° was approximately 5.1×10^{-4} mole/liter, and showed a dramatic temperature dependency. Figure 2 shows a typical van't Hoff plot, illustrating the temperature dependency on solubility. The solubility increased gradually up to about 35°; the heat of formation for the micelle was calculated to be 6.9 kcal/mole. At 35°, there was a sharp increase in the solubility, apparently due to the appearance of a new species in solution. The concentration of I in solution at the inflection point corresponded to the CMC value determined by conductance measurements. The calculated apparent heat of formation for the micelle is high when compared to reported values (4). In the 35–60° range, the solubility remained temperature dependent. A sample

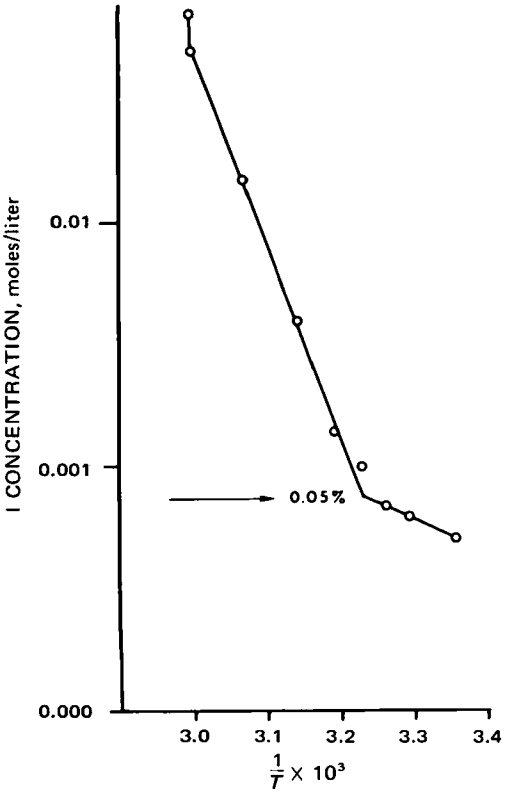

Figure 2—*Typical van't Hoff-type plot illustrating the effect of temperature on the aqueous solubility of I.*

equilibrated at 40° for 48 hr had a solubility of 1.4×10^{-3} mole/liter; however, when this solution was brought to 25° and equilibrated for 48 hr, the solubility approximated the value previously determined. Thus, in this temperature range, the solubility was reversible. However, above 60°, complete solution of the excess compound was achieved.

This solution remained clear after shock-cooling and crystal seeding to induce crystallization and formed a metastable micellar solution. Subsequent dilutions of this metastable solution remained clear until the effective concentration on dilution approached the CMC. Below this concentration, the compound precipitated from solution.

Determination of Micelle Molecular Weight—To characterize the system further, sedimentation equilibrium studies were conducted to determine the approximate size and molecular weight of the micelle. Figure 3 shows a series of ultracentrifuge patterns, illustrating the approach to sedimentation equilibrium for a 4.6% solution of I. The character of the curves suggests that the system is heterogeneous. The distance the front moved with time was determined, and a plot of the log of this distance against time is shown in Fig. 4. The slope of the line was determined and

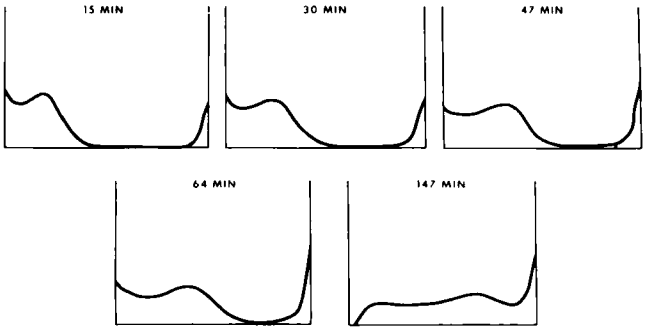

Figure 3—*Representative ultracentrifuge patterns illustrating the approach to sedimentation equilibrium for a micellar solution of I.*

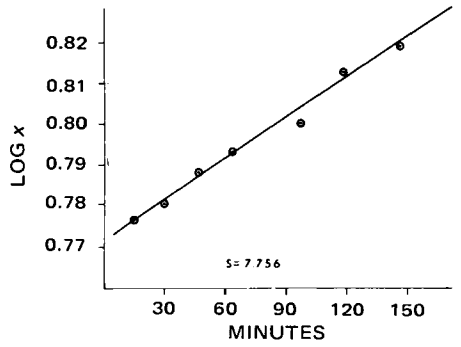

Figure 4—*Determination of sedimentation coefficient from a plot of log* x (*distance of boundary to axis of rotation*) versus *time for a micellar solution of I.*

used in the following equation to calculate the apparent sedimentation coefficient:

$$S = \frac{2.303\ d\ \log x/dt}{60(\omega)} \qquad \text{(Eq. 1)}$$

where S = sedimentation coefficient, and ω = angular velocity.

A sedimentation coefficient of 7.756 was calculated for the system. When utilizing this value and extrapolating from a plot for protein compounds in the literature (5), it appears that the micelle is composed of approximately 150 monomeric units having a molecular weight in excess of 100,000.

Effect of Various Anions—Previously it was reported that chloride ion depressed the solubility of I (2); therefore, it was decided to investigate the effect of some commonly used buffer salts on the equilibrium solubility. Figure 5 illustrates the effect of citrate and tartrate ions on the equilibrium solubility of I. The solubility increases rapidly and then suddenly decreases to a constant value below the equilibrium solubility previously determined.

The pH of these solutions ranged from 4.3 to 5.4. To eliminate the possible effect of pH with increasing salt concentrations, several neutral sulfate salts were studied. The pH of these solutions remained relatively constant at pH 4.3. The effect of these salts on the solubility of I is shown in Fig. 6. Again there are a sharp increase and the sudden drop to a constant value.

Another anion, acetate, was utilized in the solubility studies. The pH of these solutions ranged from 4.0 to 4.7. The effect (Fig. 7) was similar to that previously observed with the chloride ion (2). The solubility was depressed by the addition of increasing amounts of acetate ions. Apparently, the effect on solubility was not due to an ionic strength effect. When solubility was plotted as a function of increasing normality, these data were superimposable.

The possibility of interconversion of the hydrochloride salt to

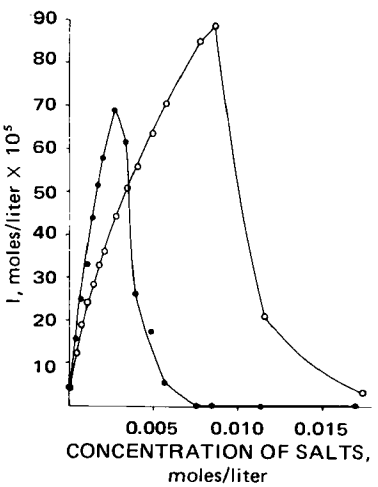

Figure 5—*Plot showing the effect of sodium citrate* (●) *and sodium tartrate* (○) *on the equilibrium solubility of I.*

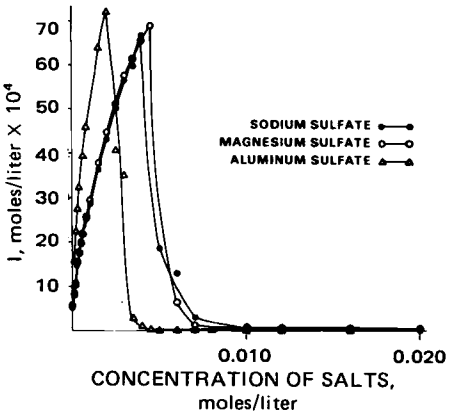

Figure 6—*Plot showing the effect of various sulfate salts on the equilibrium solubility of I.*

the citrate salt being responsible for the solubility behavior was considered. The citrate salt of I was prepared. The equilibrium solubility of this salt at 25° was 9.1×10^{-5} mole/liter, which is not in agreement with the solubility values achieved during the studies with the citrate ion.

NMR Spectroscopy—It was previously reported that the NMR spectrum of I in micellar solution had broad resolution bands at 25°; however, when the temperature was increased, the resolution became sharp and reached a maximum at 60° (1). The conclusions were that the micellar system was completely disrupted at 60° and that the resulting spectrum was of the monomer of I.

To explain the dramatic increase in solubility, a solution isolated from the sulfate solubility studies was investigated using this technique. This solution showed behavior similar to that of the micellar solution. At 25°, there was no apparent resolution. However, when the temperature was raised to 60°, the resolution bands became sharper (Fig. 8). Apparently, the various ions exert an effect on the equilibrium solubility of I by affecting its CMC. The NMR data confirm this observation. This finding is not surprising since ionic environment has been shown to affect CMC values (6, 7).

CONCLUSION

The pharmaceutical importance of this study is apparent, and the implications of equilibrium solubility and dissolution rate to drug availability in a dosage form are obvious. When formulating this drug, the development pharmacist must exercise extreme care in the selection of the proper excipients and/or buffer systems and also in the concentration of these ingredients. A study of this type points out that a thorough understanding of the physical–chemical behavior of complex drug molecules is extremely important.

Solvolysis of a Substituted Imidazoline, Mazindol

H. V. MAULDING[x], P. TURI, D. GROSSMAN*, and J. P. NAZARENO

Abstract □ Hydrolysis of mazindol to form 2-(2-aminoethyl)-3-(*p*-chlorophenyl)-3-hydroxyphthalimidine was followed spectrophotometrically in aqueous solutions at temperatures between 37 and 70°, pH values up to 7.6, and an ionic strength of 0.2. The effects of acetate, formate, and phosphate buffers as well as ionic strength on the observed rate constants were investigated. An interesting nonlinear dependency of the k_{obs} with buffer concentration was noted. The velocity constants declined with increasing hydrogen-ion concentration; the log k–pH profile and rate law are given along with other relevant data.

Keyphrases □ Solvolysis—mazindol, a substituted imidazoline, pH values up to 7.6 □ Mazindol—solvolysis in aqueous solutions, pH up to 7.6

The chemical stability of organic medicinal agents from the viewpoint of the finished dosage forms and the kinetic aspects of the pertinent drugs are of great interest.

The transformation of the nonphenethylamine anorexigenic, mazindol[1] [5-(*p*-chlorophenyl)-2,5-dihydro-3*H*-imidazo[2,1-*a*]isoindol-5-ol] (I), to its hydrolysis product, 2-(2-aminoethyl)-3-(*p*-cholorophenyl)-3-hydroxyphthalimidine (II), was practically quantitative under the conditions employed as monitored by spectrophotometric and TLC methods. The process is somewhat analogous to the hydrolysis of 1,3-diphenyl-2-imidazolinium chloride recently reported (1).

EXPERIMENTAL

Kinetic Studies—A stock solution was prepared by dissolving 90 mg (3.16×10^{-4} mole) of I in 5 ml of 0.1 *N* HCl, and water was added to 50 ml. Two-milliliter aliquots were added to 200-ml volumetric flasks, equilibrated at various temperatures, containing 198 ml of the acidic or buffer solution. Ten-milliliter samples were withdrawn periodically and scanned[2] from 210 to 350 nm. The absorbance readings at 272 ± 1 nm were used to evaluate the rate of conversion of I to II.

A stock solution of II containing 95.5 mg (3.16×10^{-4} mole) in 50 ml of 0.01 *N* HCl was prepared. Two-milliliter aliquots were added to 198 ml of acidic or buffer solution previously equilibrated at various temperatures. Samples (10 ml) were taken periodically, and their UV spectra were scanned from 210 to 350 nm to monitor possible degradation of II.

Preparation of II from I—Two grams of I was refluxed in 100 ml of 48% aqueous ethanol for 2 hr until the solution became almost clear. The solvent was removed *in vacuo*. The resultant white solid dissolved in 50 ml of benzene with heating. Petroleum ether was added until the point of slight turbidity, and the compound was allowed to crystallize overnight at room temperature. The yield after two recrystallizations was 1.5 g (71%) of II, mp 170–171°.

Determination of pKa Values—A stock solution of 6.3×10^{-3} *M* I was prepared and added to 0.01 *M* tromethamine buffers (pH 7.8, 8.0, 8.2, and 8.4) along with 0.1 *N* HCl and 0.09 *N* NaOH to give a final concentration of 6.3×10^{-5} *M*. The samples were quickly read[2] at 272 nm. The pKa was calculated to be 8.55 ± 0.05 by the procedure of Albert and Sergeant (2).

Compound II (151.4 mg, 0.005 *M*) was dissolved in 95 ml of boiled water with the aid of 5 ml of 0.1 *N* HCl. The solution was titrated with 0.5-ml increments of 0.1 *N* KOH, giving a pKa value of 8.53 ± 0.05 at 25° (2).

Solvolysis of a Substituted Imidazoline, Mazindol

H. V. MAULDING[x], P. TURI, D. GROSSMAN*, and J. P. NAZARENO

Abstract □ Hydrolysis of mazindol to form 2-(2-aminoethyl)-3-(*p*-chlorophenyl)-3-hydroxyphthalimidine was followed spectrophotometrically in aqueous solutions at temperatures between 37 and 70°, pH values up to 7.6, and an ionic strength of 0.2. The effects of acetate, formate, and phosphate buffers as well as ionic strength on the observed rate constants were investigated. An interesting nonlinear dependency of the k_{obs} with buffer concentration was noted. The velocity constants declined with increasing hydrogen-ion concentration; the log k–pH profile and rate law are given along with other relevant data.

Keyphrases □ Solvolysis—mazindol, a substituted imidazoline, pH values up to 7.6 □ Mazindol—solvolysis in aqueous solutions, pH up to 7.6

The chemical stability of organic medicinal agents from the viewpoint of the finished dosage forms and the kinetic aspects of the pertinent drugs are of great interest.

The transformation of the nonphenethylamine anorexigenic, mazindol[1] [5-(*p*-chlorophenyl)-2,5-dihydro-3*H*-imidazo[2,1-*a*]isoindol-5-ol] (I), to its hydrolysis product, 2-(2-aminoethyl)-3-(*p*-cholorophenyl)-3-hydroxyphthalimidine (II), was practically quantitative under the conditions employed as monitored by spectrophotometric and TLC methods. The process is somewhat analogous to the hydrolysis of 1,3-diphenyl-2-imidazolinium chloride recently reported (1).

EXPERIMENTAL

Kinetic Studies—A stock solution was prepared by dissolving 90 mg (3.16×10^{-4} mole) of I in 5 ml of 0.1 *N* HCl, and water was added to 50 ml. Two-milliliter aliquots were added to 200-ml volumetric flasks, equilibrated at various temperatures, containing 198 ml of the acidic or buffer solution. Ten-milliliter samples were withdrawn periodically and scanned[2] from 210 to 350 nm. The absorbance readings at 272 ± 1 nm were used to evaluate the rate of conversion of I to II.

A stock solution of II containing 95.5 mg (3.16×10^{-4} mole) in 50 ml of 0.01 *N* HCl was prepared. Two-milliliter aliquots were added to 198 ml of acidic or buffer solution previously equilibrated at various temperatures. Samples (10 ml) were taken periodically, and their UV spectra were scanned from 210 to 350 nm to monitor possible degradation of II.

Preparation of II from I—Two grams of I was refluxed in 100 ml of 48% aqueous ethanol for 2 hr until the solution became almost clear. The solvent was removed *in vacuo*. The resultant white solid dissolved in 50 ml of benzene with heating. Petroleum ether was added until the point of slight turbidity, and the compound was allowed to crystallize overnight at room temperature. The yield after two recrystallizations was 1.5 g (71%) of II, mp 170–171°.

Determination of pKa Values—A stock solution of 6.3×10^{-3} *M* I was prepared and added to 0.01 *M* tromethamine buffers (pH 7.8, 8.0, 8.2, and 8.4) along with 0.1 *N* HCl and 0.09 *N* NaOH to give a final concentration of 6.3×10^{-5} *M*. The samples were quickly read[2] at 272 nm. The pKa was calculated to be 8.55 ± 0.05 by the procedure of Albert and Sergeant (2).

Compound II (151.4 mg, 0.005 *M*) was dissolved in 95 ml of boiled water with the aid of 5 ml of 0.1 *N* HCl. The solution was titrated with 0.5-ml increments of 0.1 *N* KOH, giving a pKa value of 8.53 ± 0.05 at 25° (2).

[a] The reaction was followed by loss of absorbance at 272 nm and studied for at least two half-lives. Rate constants were reproducible within 15%. The pH values were measured at the specified temperatures (ionic strength 0.2). [b] Supplementary values for rate constants listed are as follows [pH and k (hr^{-1})]: At 37°: 7.62, 0.75; 7.1, 0.33; 6.65, 0.124; and 6.0, 0.051. At 55°: 6.67, 0.88; 6.64, 0.59; 6.5, 0.35; 6.0, 0.22; 5.85, 0.150; 6.67, 0.80; 6.61, 0.77; 6.5, 0.68; and 6.4, 0.51. At 60.5°: 6.8, 1.66. At 70° (run at formate-ion concentration of 0.08 *M* and ionic strength 0.2): 5.0, 0.22; 4.50, 0.15, 0.16; and 4.0, 0.14. [c] Some k_{obs} values deviate somewhat from those listed in Fig. 3. This is likely a consequence of slight pH deviations in the pH 6–7.2 region, which result in large changes in the k_{obs} at these pH values where the slope of the log k_{obs}–pH profile is +1. These experiments were run by different operators in different months, *etc.*, so other factors may also come into play. [d] Phosphate buffers were prepared according to Ref. 8, except the pH 6.00 buffer which was made from 0.115 *M* NaH_2PO_4 and 0.028 *M* Na_2HPO_4 and the pH 6.35 buffer which was adjusted with sodium hydroxide. [e] Acetate and formate buffers were produced from 8 g of sodium hydroxide, sufficient acid, and dilution with water to give the appropriate pH in 1 liter of solution.

All pH measurements were carried out on a pH meter[3] standardized with phthalate and borate buffers at the specified temperatures (2).

TLC—The solvent system utilized was chloroform–ethanol–ammonia (80:20:1). Silica gel GF plates were spotted with 20 μl of solution containing 25–50 μg of I and/or II. The walls of the tank were lined with filter paper saturated with solvent. The product (II) and reactant (I) showed R_f values of 0.8 and 0.9, respectively, by this method when the plates were dried and visualized under shortwave UV light.

RESULTS AND DISCUSSION

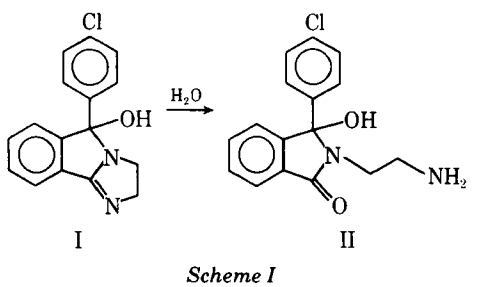
The solvolysis of I was studied between pH 0.3 and 7.2. The phthalimidine reaction product (II) was preparatively made from I (Scheme I) and was compared with an authentic sample of II[4]; they were found to be identical by NMR, mass, IR, and UV spectra, microanalysis, and melting-point determination.

Compound II was produced in almost quantitative yields from I by a first-order process. At higher acidities (below pH 2.6), the reaction was followed for at least 300 hr and exhibited pseudo-first-order kinetics for that time. Only I and II were discernible by TLC and UV spectrophotometry under the conditions examined.

The observed first-order rate constants were calculated from the expression:

$$\log (A_t - A_\infty) = \log (A_0 - A_\infty) - k_{obs}t/2.303 \qquad \text{(Eq. 1)}$$

where A_t, A_0, and A_∞ are absorbances at times t, zero, and infinity, respectively; k_{obs} is the observed or pseudo-first-order rate constant in hours^{-1}; and t is time in hours. Absorbance disappearance was followed at 272 ± 1 nm, with the hydrolysis product (II) and reactant (I) possessing molar absorptivities of 2.37×10^3 and 14.00×10^3 liters/mole cm, respectively. The absorbances for a given concentration of I and II were practically invariant over the pH scale studied (up to about pH 7.6).



Scheme I

Compound II did not degrade further under the conditions employed except after 500 hr in 0.1 *N* HCl at 70°; a slight change in UV spectra was seen along with a third trace spot on the TLC plates. Figure 1 illustrates data obtained for the decomposition of I at various pH values at 55°. Table I shows typical results from which the rate–pH profile was constructed (Fig. 2).

Hydroxide-Ion Catalysis—The right-hand portion of the rate–pH profile in Fig. 2, above pH 6, has a slope of about 1. This result is partially the consequence of hydroxide-ion attack on the imidaz-

oline (I) in solution and may be written:

$$-d(I)_{tot}/dt = k_{obs}I_{tot} = k'_{OH^-}[OH^-][IH^+] + k_{OH^-}[OH^-][I] \quad \text{(Eq. 2)}$$

or:

$$k_{obs} = k'_{OH^-}[OH^-]f_{IH^+} + k_{OH^-}[OH^-]f_I \quad \text{(Eq. 3)}$$

where I plus IH^+ is the total compound in solution as neutral and protonated species, and k'_{OH^-} and k_{OH^-} are bimolecular rate constants for attack of hydroxide ion on the protonated fraction, f_{IH^+}, and the neutral fraction, f_I, respectively. The expression may be given as:

$$k_{obs} = k'_{OH^-}[OH^-]\frac{[H^+]}{[H^+] + K_{a_1}} + k_{OH^-}[OH^-]\frac{K_{a_1}}{K_a + [H^+]} \quad \text{(Eq. 4)}$$

At a pH above 7.6, the neutral molecule precipitated from aqueous solution. This precipitation, as well as a high reaction velocity, precluded study in these ranges. In the absence of other catalytic agents, *i.e.*, buffers, the k_{obs} of Eqs. 1–6 is actually the k_0 in Eq. 7.

The second term in the right-hand side of Eq. 4 may be omitted when $[H^+] \gg K_a$; $K_a/(K_a + [H^+]) \sim 0$. The resultant equation is written in the logarithmic form when $[H^+] \gg K_a$ in the usual manner:

$$\log k_{obs} = \log k'_{OH^-} + \log K_w - \log [H^+] \quad \text{(Eq. 5)}$$

or:

$$\log k_{obs} = \log k'_{OH^-} - pKw + pH \quad \text{(Eq. 6)}$$

In the range below 7.25 (about 1.30 units below the pKa), a plot of the log of the observed rate constant *versus* pH should give a straight line with a slope of 1 and an intercept of $\log k'_{OH^-} - pKw$.

Buffer Effects—Equations 4–6 hold in the absence of other catalytic species; however, a specific increment of the observed rate constant may be assigned to phosphate buffer catalysis at and above pH 5.7 (Fig. 2). The catalytic constants for $H_2PO_4^-$ and HPO_4^{-2} may be defined in the following manner, as mentioned by Notari and Caiola (3):

$$k_{obs} = k'_{H_2PO_4^-}[H_2PO_4^-] + k_{HPO_4^{-2}}[HPO_4^{-2}] + k_0 \quad \text{(Eq. 7)}$$

The k_0 is composed primarily of $k'_{OH^-}[OH^-]$ as stated in Eq. 4. Equation 7 may be written as:

$$k_{obs} = \{k_{H_2PO_4^-}(R) + k_{HPO_4^{-2}}[HPO_4^{-2}] + k_0 \quad \text{(Eq. 8)}$$

where $R = [H_2PO_4^-]/[HPO_4^{-2}]$ and is invariant at a given pH. Thus, a plot of k_{obs} *versus* $[HPO_4^{-2}]$ with the pH constant gives:

$$\text{slope} = k_{H_2PO_4^-}(R) + k_{HPO_4^{-2}} \quad \text{(Eq. 9)}$$

A plot of the slopes of Eq. 8 at three or more pH values against the R values should yield a straight line with slope $k_{H_2PO_4^-}$ and a y intercept, $k_{HPO_4^{-2}}$, as expressed in Eq. 9.

The value for $k_{HPO_4^{-2}}$ at 55° was calculated using Eqs. 8 and 9 and found to be 6.8 liters/mole hr, with $k_{H_2PO_4^-}$ being negligible. The constants for $k_{HPO_4^{-2}}$ catalysis (liters per mole hour) at other

Table II—Catalytic Constants[a] for Solvolysis of Mazindol in Aqueous Solution at Various Temperatures[b]

Constant	70°	55°	45°	37°
k'_{OH^-}	4.6×10^6	2.1×10^6	1.1×10^6	8.1×10^5
k''_{OH^-}	9×10^8	4.2×10^8	$(2.45 \times 10^8)^c$	$(1.55 \times 10^8)^c$
k''_{H_2O}	1.5×10^{-4}	6.5×10^{-5}	$(3.6 \times 10^{-5})^d$	$(2.2 \times 10^{-5})^d$
$k_{HPO_4^{-2}}$	18.0	6.8	2.6	1.5
$k_{CH_3COO^-}[CH_3COO^-]$	—	0.03	—	—

[a] Constants were calculated in liters per mole hour, except $k_{CH_3COO^-}[CH_3COO^-]$ which was estimated from data in Fig. 4 and k''_{H_2O} which was estimated in hours^{-1}. [b] Other pertinent values are: pKa_1, 8.55 (spectrometric determination at 25°), and pKa'_2, 2.9 (kinetic determination at 55°). [c] Determined by extrapolation of the Arrhenius equation. [d] Estimated from Eq. 12.

temperatures were: 37°, 1.5; 45°, 2.6; and 70°, 18.0 (Table II). Figure 3 shows an example of the utilization of Eq. 8 where the observed first-order constant is graphed on the ordinate and the $[HPO_4^{-2}]$ is graphed on the abscissa.

It is evident that the log k–pH profile, where $f_{IH^+} = 1$, in the phosphate buffer region may be adequately described in the following terms:

$$k_{obs} = k'_{OH^-}[OH^-] + k_{HPO_4^{-2}}[HPO_4^{-2}] \qquad \text{(Eq. 10)}$$

The k'_{OH^-} may be determined from Eq. 10 and/or the y intercepts in Fig. 3 by division of that value by the hydroxide-ion concentration at that temperature. The k'_{OH^-} values (liters per mole hour) were: 70°, 4.6×10^6; 55°, 2.1×10^6; 45°, 1.1×10^6; and 37°, 8.1×10^5 (Table II).

In the acetate and formate buffer range (pH 2.7–5.4) a nonlinear dependency of rate constants on conjugate base existed contrary to the expected straight lines (Fig. 4). This phenomenon was encountered by Martin *et al.* (4) in the *S*- to *N*-acetyl transfer of *S*-acetyl-β-mercaptoethylamine and was further investigated by Barnett and Jencks (5). These investigators predicted a sequence containing a catalyzed rate-determining step at low acetate and formate concentrations, followed by an uncatalyzed rate-determining step at higher buffer concentrations. Notari *et al.* (6) observed the same occurrence in the general-acid-catalyzed deamination of arabinosylcytosine.

With the imidazoline (I), the increments attributable to acetate and formate catalysis exhibited this nonlinear dependency. No attempt was made to dissect the function into constants. The amount contributed by hydroxide ion in the region, pH 2.6–5.0, may be estimated by extrapolation of acetate- and formate-ion concentrations to zero. These amounts at 55° (Fig. 4) were 0.012, 0.022, 0.033, and 0.046 hr^{-1} for pH values 2.6, 4.0, 4.5, and 5.0, respectively, and were the result of specific base (hydroxide-ion) catalysis. These values should be composed of two components: (*a*) k'_{OH^-}, and (*b*) k''_{OH^-}, which is indicative of hydroxide-ion reaction with a diprotonated species.

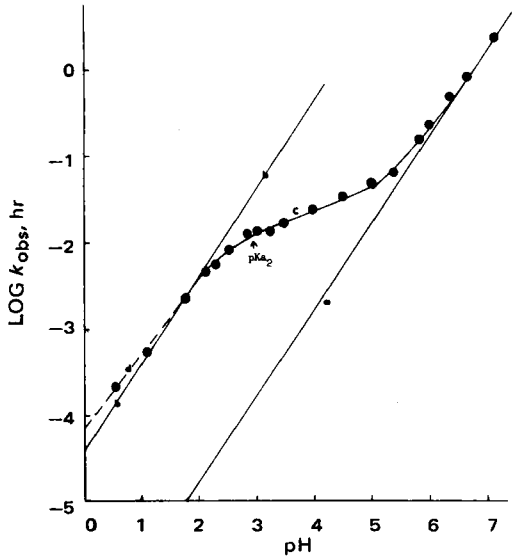

Figure 5—*Synthesis of the log* k–*pH profile for the solvolysis of mazindol at 55° (ionic strength 0.2). Line a represents hydroxide-ion attack on monoprotonated mazindol,* $k'_{OH^-}[OH^-]$, *while line b describes hydroxide-ion reaction with diprotonated mazindol,* $k''_{OH^-}[OH^-]$. *Line c is a summation of the two functions, where* $K_{a2} = 1.26 \times 10^{-3}$ M. *Line d is a summation of line b plus the increment added by water hydrolysis of the substrate as given in Eq. 11. The solid dots represent the experimental data points extrapolated to zero buffer concentration.*

Log *k*–pH Profile—Table III lists rate constants and half-life times for hydrolysis of I under acidic conditions.

The curvature of the real data points in Fig. 5 indicate the likelihood of a second pKa. The predisposition of the velocity constants to increase as the pH rises point toward specific hydroxide-ion catalysis of both mono- and diprotonated species. Due to the prevalence of buffer catalysis in the acidic region, reaction with water might be considered since the two frequently occur concomitantly.

At low pH values, pH < 2, one may write an equation of the type:

$$k_{obs} \approx k_0 = (k''_{OH^-}[OH^-] + k''_{H_2O})f_{IH_2^{+2}} \qquad \text{(Eq. 11)}$$

which simplifies when $f_{IH_2^{+2}} \approx 1$ to:

$$k_{obs} = k''_{OH^-}[OH^-] + k''_{H_2O} \qquad \text{(Eq. 12)}$$

explaining the results of Fig. 5. Thus, a plot of k_{obs} *versus* $[OH^-]$ at low pH values, *i.e.*, between 0 and 2, should yield a straight line of slope k''_{OH^-} and intercept k''_{H_2O}. The k''_{OH^-} values are listed in Table II along with results at 37 and 45° obtained by extrapolation of the Arrhenius plot.

Line b of Fig. 5 was derived from the function $k''_{OH^-}[OH^-]$, while line d is a combination of the function plus the increment attributable to k''_{H_2O}. The k''_{H_2O} values of 1.5×10^{-4} (70°) and 6.5×10^{-5} (55°) in hours^{-1} (Table II) were calculated from Eq. 12.

These findings support the thought that two principal kinetic

[a] Reactions were followed by loss of absorbance at 272 nm and monitored for at least 300 hr. Ionic strength was made to 0.2 with sodium chloride where possible. [b] Solutions were made from 0.05 *M* $NaH_2PO_4 \cdot H_2O$ with phosphoric acid added to give the proper pH. No evidence of phosphoric acid or phosphorus acid catalysis was noted.

Table IV—Effect of Ionic Strength (μ) on Observed First-Order Velocity Constants for Hydrolysis of Mazindol in Aqueous Solution (6.32×10^{-5} *M*) in Acetate and Phosphate Buffers at 55°

Buffer[a]	pH[b]	$\mu^{1/2}$	μ	k, hr^{-1}
Phosphate	6.67	0.10	0.01	0.862
Phosphate	6.67	0.224	0.05	0.802
Phosphate	6.67	0.447	0.20	0.715
Phosphate	6.67	0.707	0.50	0.675
Phosphate	6.67	1.0	1.0	0.595
Acetate	4.5	0.10	0.01	0.045
Acetate	4.5	0.224	0.05	0.040
Acetate	4.5	0.447	0.20	0.036
Acetate	4.5	0.707	0.50	0.029
Acetate	4.5	1.0	1.0	0.024

[a] Reaction solutions (200 ml) were prepared by taking 10 ml of acetate or phosphate buffer (μ = 0.2) with addition of sodium chloride to bring the solutions up to the stated ionic strengths. Phosphate buffers were prepared according to the specifications of Ref. 8. Acetate buffers were made by adding acetic acid to 8 g of sodium hydroxide to give the proper pH and dilution to 1 liter with water. [b] Due to the extreme effect of pH on rate constants of pH 6.67 phosphate buffer, a small amount of 1 *N* NaOH had to be added to the solutions containing larger amounts of sodium chloride. The most added was 0.2 ml of 1.0 *N* NaOH to adjust pH to 6.67.

factors work at pH < 2: (*a*) spontaneous decomposition, and (*b*) hydroxide-ion attack on some polyprotonated form of I.

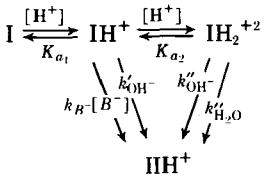
Figure 5 contains a second diagonal line of slope 1, line a, which signifies hydroxide-ion reaction with the monoprotonated molecule, $k'_{OH^-}[OH^-]$, from Eq. 4 (Table II). Once the bimolecular rate constants for attack of hydroxide ion on monoprotonated and diprotonated imidazoline were determined, the K_{a_2} could be estimated (Eq. 13) by means of data fitting to meet experimental results. The intermediate area between lines a and b, line c, is a combination of the two functions $k'_{OH^-}[OH^-]$ and $k''_{OH^-}[OH^-]$, with K_a 1.26×10^{-3}, pKa 2.9, being used for analysis of the data. A small contribution was made by the k''_{H_2O}, but it may be neglected above pH2.0.

The k''_{OH^-} values of 9×10^8 (70°) and 4.2×10^8 (55°) liters/mole hr were evaluated from the data in Table III by means of Eqs. 11 and 12. These values are more than two orders of magnitude above the k'_{OH^-} values for similar temperatures, which were 4.6×10^6 and 2.1×10^6 liters/mole hr, respectively. Results of this type may be expected for the reaction of hydroxide ion with IH_2^{+2}, because the constants should be considerably larger than those for the reaction of OH^- with IH^+.

Figure 5 illustrates the theoretical log k_0–pH profile, using the relationship:

$$k_0 = k'_{OH^-}[OH^-]\frac{[H^+]}{[H^+]+K_{a_1}} + (k''_{OH^-}[OH^-] + k''_{H_2O})\frac{[H^+]}{[H^+]+K_{a_2}} \quad \text{(Eq. 13)}$$

Ionic Strength Effects—The perturbation of the observed first-order velocity constants by addition of neutral salts at constant pH values are shown in Table IV. These results imply reaction of a negative and positive ion at pH 6.67 and 4.5. This finding



Scheme II—Schematic diagram for the solvolysis of mazindol and its protonated forms, IH^+ and IH_2^{+2}, to produce 2-(2-aminoethyl)-3-(p-chlorophenyl)-3-hydroxyphthalimidine (II) in its protonated form, IIH^+. (The possibility exists of diprotonated II, but it was not noted by the experimental methods utilized.) Both molecules primarily protonated (95+%) under the conditions investigated.

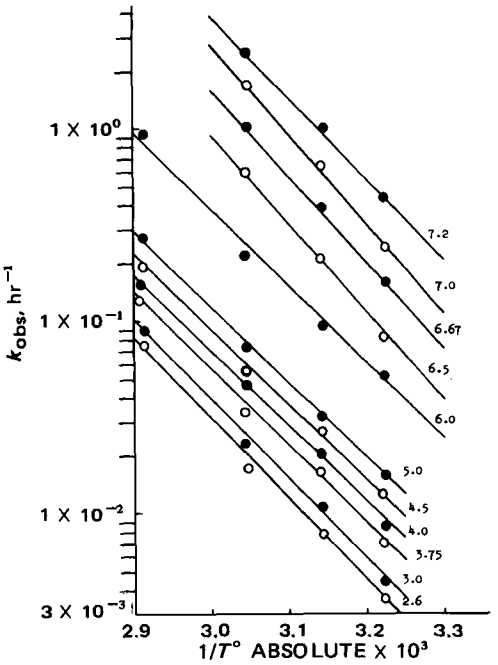


Figure 6—*Typical Arrhenius plots for hydrolysis of mazindol in aqueous media at the indicated pH values.*

cannot be considered conclusive since the Debye–Hückel theory and Brønsted–Bjerrum equation are valid for solutions below 0.01 *M* of 1:1 electrolytes (7).

Dependency of Reaction Rate on Temperature—The Arrhenius parameters for solvolysis of I were determined from the slopes and intercepts of plots of log k_{obs} *versus* the reciprocal of the absolute temperature in accordance with the equation:

$$\log k_{obs} = \log P - E_a/2.303RT \quad \text{(Eq. 14)}$$

with R being 1.987 cal deg^{-1} $mole^{-1}$. The results for several pH values are illustrated in Fig. 6. The apparent energies of activation between pH 6 and 7.2 were 20.9–22.3 kcal/mole, while those in the acetate and formate buffers varied between 17.9 and 21.1 kcal/mole. The k'_{OH^-} values give a E_a equal to 11.35 kcal/mole; $k_{HPO_4^{-2}}$ was found to have 20.9 kcal/mole as the activation energy.

SUMMARY

Mazindol (I) hydrolyzes in aqueous solution to yield a phthalimidine product (II) in practically quantitative amounts.

The solvolysis possibly proceeds through a tetrahedral intermediate similar to that suggested by Robinson (1). The intermediate should show a diminution of absorbance if it has an appreciable lifetime. This phenomenon was not encountered under the conditions studied.

The process is a relatively facile transformation at moderate temperatures in neutral media, which leads to II as a simple hydrolytic product. This transformation is an instance where the velocity constants vary directly with pH, signifying hydroxide-ion catalysis over the entire range. Negligible acid catalysis was encountered, but both general-base and water catalysis were manifest. The observed or apparent rate constant may be reasonably well described between pH 7.6 and zero by the following relationship:

$$k_{obs} = k'_{OH^-}[OH^-]\frac{[H^+]}{[H^+]+K_{a_1}} + (k''_{OH^-}[OH^-] + k''_{H_2O})\frac{[H^+]}{[H^+]+K_{a_2}} + k_B[B^-][I_{tot}] \quad \text{(Eq. 15)}$$

with $k_B[B^-]$ indicative of species in HPO_4^{-2}, acetate, and formate. Acetate and formate must be estimated due to a nonlinear dependency of the rate constant on the concentration of conjugate base. At higher acidities, the reaction rate is mainly dependent upon hydroxide-ion concentration and water attack on the diprotonated molecule in solution.

Arrhenius parameters are given and may allow prediction of shelflife as well as stability in biological media at various temperatures and conditions. Salt effects are also discussed and point toward reaction between two oppositely charged ions. A diagram of the entire process is shown in Scheme II.

Isolation and Identification of Three New Flavones from *Achillea millefolium* L.

A. J. FALK *§, S. J. SMOLENSKI ‡, L. BAUER *, and C. L. BELL *ˣ

Abstract □ Column chromatography on silica gel of a petroleum ether extract of the flowering heads of *Achillea millefolium* L. allowed three flavones to be separated and identified. Spectral studies (PMR, mass spectrometry, and UV) and a comparison with data for compounds reported in the literature established the flavones as 5-hydroxy-3,6,7,4′-tetramethoxyflavone, artemetin, and casticin. These compounds have not been reported previously as constituents of *A. millefolium*.

Keyphrases □ Flavones—chromatographic separation and spectral identification from *Achillea millefolium* □ *Achillea millefolium*—chromatographic isolation and spectral identification of flavone components □ Medicinal plants—*Achillea millefolium*, isolation and identification of flavone components

Achillea millefolium L. (Compositae), commonly known as yarrow, grows abundantly throughout America and Europe (1). The plant has been a popular medicinal remedy, having been known to Dioscorides (2), and has been recommended for use as a tonic, a stomachic, a hemostatic, an antispasmodic, an antihemorrhoidal, an emmenagogue, an antiseptic, and an anthelmintic (3).

Chemical investigations of the plant have been numerous, extending back for more than 200 years (4, 5). One class of compounds that has received considerable attention is the flavonoids; they have been proposed as the cause of the spasmolytic activity of *A. millefolium*. Horhammer (6) examined a number of flavones and extracts of different plants for antispasmotic activity and showed *A. millefolium* to be the most active plant. He found that the plant contained apigenin and luteolin-7-glycosides. These flavones, as well as caffeic acid, were found also by Michaluk (7), and the presence of caffeic acid was more recently verified (8). In 1964, luteolin-7-glucoside was isolated from *A. millefolium* and synthesized (9). More recently, the presence of isorhamnetin was reported (10).

The present work yielded three polymethoxy flavones not previously reported as constituents of this plant.

EXPERIMENTAL

Plant Material—The flowering heads of *A. millefolium* were harvested in June 1970 at the University of Illinois Drug and Horticultural Experimental Station, Downers Grove, Ill. The seeds of wild growing *A. millefolium* were collected in the Bemis Woods, McHenry County, Ill., and were planted in a greenhouse at the Station. Shoots were transplanted from one generation to the next to assure that material of the same species was maintained. Only the inflorescence of the plant was used and was harvested at the time of opening of the flowers. The plant was identified as *A. millefolium* by chromosome count[1].

Extraction—One kilogram, 500 g at a time, of air-dried, coarsely ground plant material was extracted in a soxhlet extractor. Each 500-g portion was extracted for 24 hr with 3400 ml of petroleum ether, the extract was removed, 2500 ml of fresh solvent was added, and the extraction was continued for an additional 48 hr. All solvents were combined, and an insoluble precipitate, F1, was filtered off and set aside. The filtrate was condensed by evaporation to 1500 ml and again filtered, yielding another precipitate, F2.

The precipitate F1 was crystallized from ligroin, and the filtrate was combined with F2. The crystals were triturated with ether, and the filtrate again was added to F2. Finally, the crystals were recrystallized from chloroform–ether to yield 3.75 g of achillin, a sesquiterpene lactone previously isolated from this plant (11), and this filtrate was combined with F2.

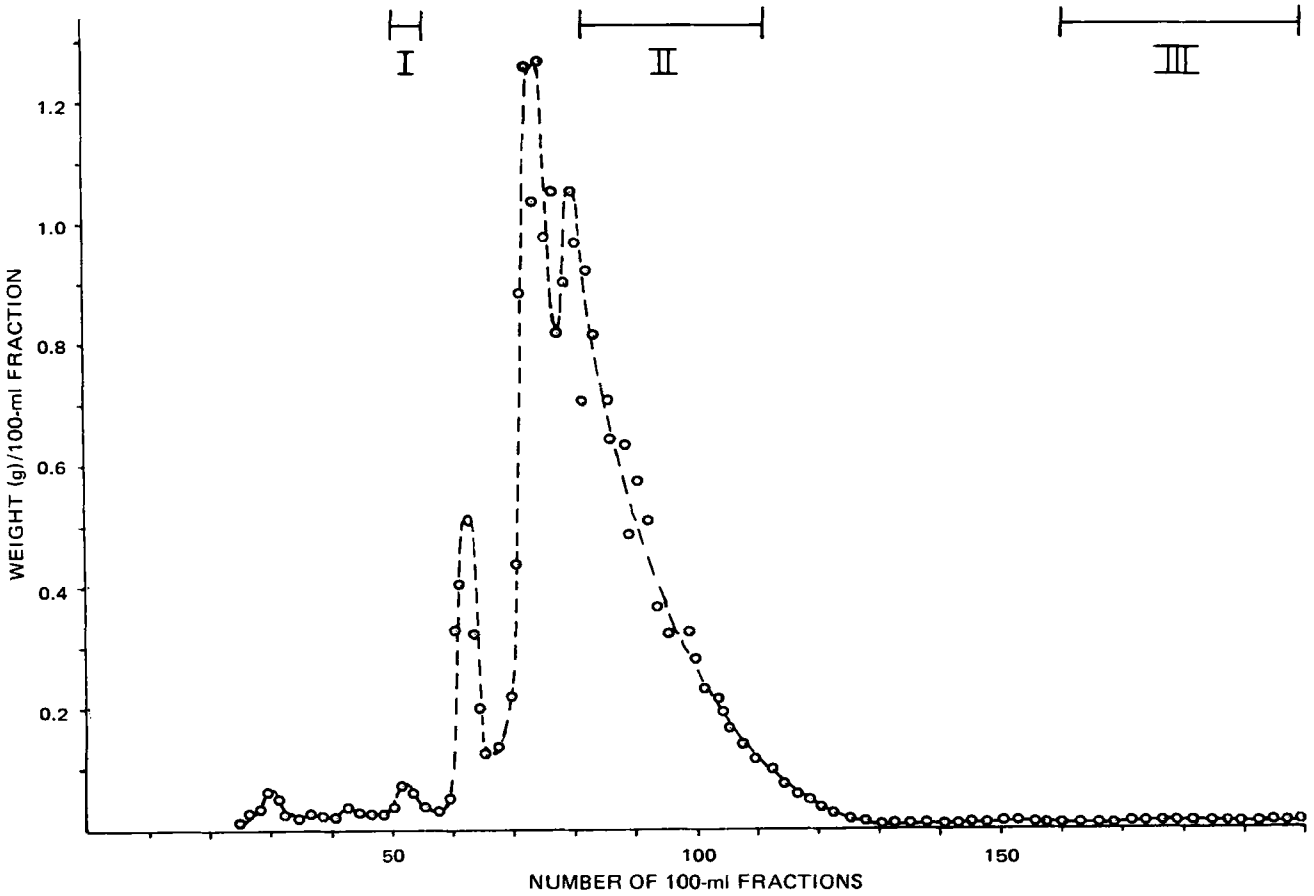

Figure 1—*Residue weights* versus *column fraction number for chromatographic separation on silica gel.*

Fraction F2, containing the flavonoids, was evaporated to dryness *in vacuo* (36.4 g). The fraction was chromatographed on a silica gel[2] column prepared by first activating the silica (1800 g) at 120° for 24 hr and then deactivating with 10% distilled water before preparing a 30% slurry in benzene–ethyl acetate (9:1). The column was allowed to settle for 24 hr before being charged, resulting in a column having the dimensions of 80 × 8 cm.

The fraction was dissolved in a minimum of eluent, benzene–ethyl acetate (9:1), and chromatographed. Two hundred column fractions of 100 ml each were collected, each was evaporated to dryness, and the residue weight was determined. A plot of the residue weight *versus* fraction number is shown in Fig. 1.

Isolation of 5-Hydroxy-3,6,7,4′-tetramethoxyflavone (I)—Column fractions 50–56 (Fig. 1) were combined and evaporated to dryness *in vacuo* (0.31 g). The residue was crystallized from ether, yielding the flavone I as pale-yellow crystals (0.142 g), mp 168–170° [lit. (12) mp 169–171°]; PMR[3] (deuterochloroform with tetramethylsilane as the internal reference), ppm (δ): 3.87 (s, 3), 3.90 (s, 3), 3.92 (s, 3), 3.95 (s, 3), 6.49 (s, 1), 7.01–8.07 (m[A_2B_2], 4), and 12.60 (s, 1). UV[4] spectra in methanol and with various reagents are given in Table I. The mass spectrum[5] of I is given in Fig. 2.

Isolation of Artemetin (II)—As indicated in Fig. 1, fractions 78–109 were combined and evaporated to dryness *in vacuo*, yielding 11.84 g of residue. This residue consisted primarily of achillin, as shown by TLC and spectral data, with one minor component (<5%). This mixture was rechromatographed, using 300 g of basic alumina (deactivated with 5% water) on a 3 × 31-cm column, and eluted with 875 ml of chloroform–acetone (1:1) to remove the achillin. The column was then eluted with 625 ml of 1-butanol–acetic acid–water (4:1:1) to remove the flavone.

After evaporation to dryness *in vacuo*, a powdery residue of the compound and alumina remained. To remove the alumina, 200 ml of benzene was added and the mixture was extracted twice with 200-ml portions of 0.1 *N* HCl. The aqueous layer was extracted twice with 200-ml portions of benzene, and the benzene layer was finally separated and evaporated to dryness *in vacuo*, leaving an orange residue. Recrystallization was from benzene–petroleum ether to yield a yellow-orange solid (0.070 g), mp 159–160° [lit. (13) mp 161.5°].

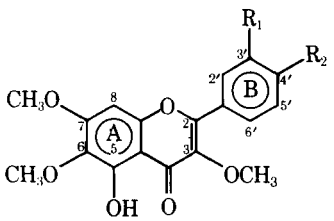
3.87 (s, 3), 3.92 (s, 3), 3.95 (s, 3), 3.98 (s, 3), 6.49 (s, 1), 6.95 (d, 1, J = 9.6 Hz), 7.65 (d, 1), 7.69 (dd, 1, J = 9.6 Hz, J = 2.0 Hz), 12.58 (s, 1), and 5.76 (s, 1). UV[4] spectra in methanol and with various reagents are given in Table I. The mass spectrum[5] of III is shown in Fig. 4.

RESULTS AND DISCUSSION

Three flavonoids were isolated from the petroleum ether extract of the inflorescence of *A. millefolium* and proved to be 5-hydroxy-3,6,7,4′-tetramethoxyflavone (I), artemetin (II), and casticin (III).

Compound I was purified by column chromatography and identified by its physical and spectral properties. The mass spectrum showed both a parent peak at *m/e* 358 (base peak) and a large P − 1 fragment ion, characteristic of flavones, at *m/e* 357.

A prominent ion at *m/e* 343, representing a methyl loss from the parent ion, and a peak at *m/e* 339, attributed to the loss of water from the P − 1 fragment, also were observed. An expected ion in flavone spectra arising from a retro Diels–Alder fragmentation of the heterocyclic ring was not observed, and its absence was explained by the substitution at the 3-position on the flavone nucleus (17). This conclusion was corroborated by the similarity in the mass spectra of the other isolated flavones, which also bear a substituent at the 3-position. Stabilization of the heterocyclic ring by the loss of a methyl radical to produce an oxonium ion (IV) probably occurred in each instance to produce a stable even-electron ion.



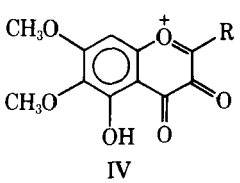
I: $R_1 = H$, $R_2 = OCH_3$
II: $R_1 = R_2 = OCH_3$
III: $R_1 = OH$, $R_2 = OCH_3$

The IR spectrum[6] revealed two strong absorptions at 1650 and 1600 cm^{-1}, indicating an α,β-unsaturated ketone with extended conjugation (18).

The 60-MHz PMR spectrum contained four singlets (3H each), indicating four methoxy groups at δ 3.87, 3.90, 3.92, and 3.95. The singlet at δ 6.49 (1H) represented an isolated aromatic proton (8-position), and the A_2B_2 pattern at δ 7.01 (2H) and 8.07 (2H) indicated a *para*-substituted phenyl group. The remaining downfield singlet (1H) at δ 12.60 was highly characteristic of a C-5 phenolic hydroxy proton hydrogen bonded to the pyrone carbonyl (19).

From these spectral data, a monohydroxy tetramethoxyflavone with a molecular formula of $C_{19}H_{18}O_7$ was concluded. While the PMR spectrum gave some information on the substitution pattern on the flavone nucleus, the precise arrangement of substituents was verified by the method of Mabry *et al.* (14) by observing the effect of a series of reagents on the UV spectrum in methanol.

The UV maximum observed in methanol was indicative of a flavone with oxygen substitution in the A ring. The bathochromic shift noted upon addition of sodium methoxide indicated that a hydroxy group was present but not on the 3- or 4′-position. The spectrum in the presence of aluminum chloride fixed the hydroxy substituent at the 5-position, and the addition of hydrochloric acid



IV

[6] Perkin-Elmer models 337 and 700 spectrophotometers. Solution spectra were obtained in deuterochloroform, using 0.15-mm KBr cells.

to the previous solution caused a shift of 20 nm, considered diagnostic of a 5-hydroxyflavone having a methoxy group on the adjacent 6-position.

These deductions, coupled with the PMR pattern reported, fixed the position of all but two methoxy groups with permissible ring sites limited to the 3-, 7-, and 8-positions. Chemical shift data fixed the substituents at the 3- and 7-positions, since the singlet at δ 6.49 was characteristic of a C-8 proton with a nonhydroxy substituent at the 7-position (14). Furthermore, the chemical shifts observed for the B ring protons were consistent with an oxygenated 3-position (14, 20).

The structure assignment of 5-hydroxy-3,6,7,4′-tetramethoxyflavone was verified by a comparison with literature data, since the compound had been isolated from *Dodonaea labulata* (20) and synthesized by Quijano *et al.* (12).

The flavone II was more readily identified, since its PMR and UV spectra appeared in the literature (13, 14). The mass spectrum (Fig. 3) exhibited a molecular ion at *m/e* 388 and the same lossess of 1 and 15 mass units observed for I. In addition, a peak at *m/e* 369 corresponded to the water loss from the P − 1 fragment ion mentioned previously. A 220-MHz PMR spectrum[7] and the series of six UV spectra (using the reagents shown in Table I) were identical with those published for artemetin (5-hydroxy-3,6,7,3′,4′-pentamethoxyflavone) (13, 14).

The third flavonoid, III, exhibited spectral characteristics similar to I and II. The 60-MHz PMR spectrum revealed four methoxy groups and signals due to four aromatic protons. The aromatic proton region of the spectrum was virtually identical (chemical shift difference <0.04 ppm) to that obtained for II. A somewhat broadened singlet at δ 5.76 (1H) could be assigned to another hydroxy group in addition to the distinctive C-5 hydroxy proton with the characteristic low-field resonance at δ 12.58.

A comparison of the mass spectra of II and III indicated a mass difference equivalent to replacing one methoxy group in II by a hydroxy group to give a molecular ion at *m/e* 374. The characteristic fragment ions were the same as observed for the other two flavones. Based on the mass spectra and PMR data, III was concluded to be a dihydroxytetramethoxyflavone.

In the manner previously described, the UV spectra in methanol with various reagents were used to determine the positions of substituent groups (Table I). The methanol spectrum exhibited a maximum at 351 nm, well within the region expected for a flavone with a methoxy group at the 3-position, and two maxima in the 250–275-nm region, indicative of 3′,4′-oxygenated flavones. Addition of sodium methoxide to the methanol solution resulted in a 34-nm bathochromic shift from 351 to 385 nm and a decrease in intensity. These results eliminated the possibility of a hydroxy group at the 4′-position (14).

The addition of sodium acetate or sodium acetate–boric acid produced no changes in the UV spectrum from that obtained in methanol alone and indicated the absence of a hydroxy group at the 3-, 7-, or 4′-position. The aluminum chloride and aluminum chloride–hydrochloric acid treatments verified, as before, a C-5 hydroxy group with an adjacent methoxy group at C-6.

The similarities in the PMR spectrum with that of artemetin and the UV spectral behavior described indicated that III was 5,3′-dihydroxy-3,6,7,4′-tetramethoxyflavone (casticin). Physical properties verified the assignment, since casticin was isolated previously from *Vitex agnus castus* (15) and was synthesized by Horhammer *et al.* (16). The isolation of these three flavones, new to *A. millefolium*, was repeated, following the same procedure, on a larger scale (4 kg of plant material) to obtain sufficient material for biological testing.

Quantitative GLC Determination of Pentylenetetrazol in Biological Fluids

H. W. JUN ˣ, W. B. ITURRIAN, J. T. STEWART, and B. H. LEE

Abstract □ A quantitative, sensitive, and specific GLC method was developed for the determination of pentylenetetrazol in water, plasma, and urine. The assay involves a single extraction of the sample into chloroform followed by centrifugation, evaporation, and chromatography. The method for pentylenetetrazol is reproducible, and the sensitivity limit of the assay is 0.5 μg of pentylenetetrazol/ml of biological fluid using a 2-ml sample. This method has a sensitivity sufficient to detect human plasma levels after therapeutic clinical doses and was successfully applied to monitor complete plasma level profiles of this drug in dogs. The data indicate that this drug is very rapidly absorbed following an oral dose, and the half-life of the drug in plasma is approximately 1 hr.

Keyphrases □ Pentylenetetrazol—GLC analysis in plasma and urine □ CNS stimulants—pentylenetetrazol, GLC analysis in biological fluids □ GLC—analysis, pentylenetetrazol in plasma and urine

Pentylenetetrazol[1] is being used for various clinical purposes in humans and animals. The main use in humans is as a central nervous system (CNS) stimulant for the therapeutic management of chronic mental depression in geriatric patients. Although several GC methods (1–3) and other techniques (4, 5) have been described for the determination of pentylenetetrazol in biological samples, complete blood level profiles of this drug have not been reported. One reported GC method (3) involves extraction of pentylenetetrazol from aqueous samples with ether or benzene. However, its usefulness in quantitative determinations of the drug in plasma samples was limited by low extraction recoveries and inadequate reproducibility.

To evaluate the absorption and elimination of this drug in the body, a sensitive and specific method of drug analysis was needed. This report describes a sensitive and specific GLC method for the quantitative determination of pentylenetetrazol in biological fluids.

EXPERIMENTAL

Chemicals—Pentylenetetrazol[1] and the calibration marker, hexamethylenamine[2], were used as received. Spectrophotometric grade chloroform[3] and absolute ethanol[4] USP were employed.

Instrumentation—Chromatographic determinations were made with a gas chromatograph[5] equipped with a dual flame-ionization detector and a recorder[6]. The chromatographic column was a 0.3-cm (0.125-in.) o.d. stainless steel column, 1.8 m (6 ft) in length, packed with 10% UC-W98 on Diatoport S (80–100 mesh)[7].

Table I—Partition Coefficients of Pentylenetetrazol between Water and Various Organic Solvents at 22°

Organic Solvents	Partition Coefficient[a], Solvent Drug Concentration/ Water Drug Concentration
Ether	0.11
Carbon tetrachloride	0.25
n-Octanol	1.37
Benzene	2.25
Chloroform	23.4

[a] Each value is an average of three experiments.

The column was conditioned for 24 hr at the operating settings after each chromatographic determination. The operating conditions were: column oven temperature, 195°; injection tube temperature, 250°; and detector block temperature, 255°. Compressed nitrogen was used as a carrier gas at the flow rate of 60 ml/min. The flow rates of hydrogen and compressed air were maintained for optimal results.

Extraction Procedure—Place a 2-ml plasma or urine sample in a Teflon-lined screw-capped centrifuge tube (15 ml) and add 12 ml of water-saturated chloroform. When more than a 2-ml sample is used, the volume of chloroform is at least six times greater than the volume of the sample. The sample is then extracted by mixing for at least 5 hr in a rotating apparatus[8], followed by centrifugation at 2000 rpm for 10 min.

About 8 ml of the filtered chloroform layer is transferred to a centrifuge tube and evaporated to dryness in a water bath at 80°. The wall of the centrifuge tube is washed down with 0.5 ml of anhydrous ether, followed by complete evaporation at room temperature. The residue is then redissolved in 10–20 μl of ethanol containing hexamethylenamine (1-μg/μl solution). One microliter of ethanol, containing an unknown amount of pentylenetetrazol and 1 μg of hexamethylenamine, is injected into the chromatograph. Hexamethylenamine is used as a calibration marker due to its stability, solubility, and adequate retention time.

Standard Calibration Curve for Pentylenetetrazol Standards—Known quantities of pentylenetetrazol are dissolved in ethanol containing hexamethylenamine (1 μg/μl) to obtain pentylenetetrazol concentrations over a 0.2–4.0-μg/μl range. When 1-μl aliquots of these standard solutions are injected into the column, the samples contain varying amounts of pentylenetetrazol per microgram of the calibration marker. The calibration curve is then obtained by plotting the known concentrations of pentylenetetrazol against the corresponding peak height ratios. The peak height ratios are obtained by dividing the peak height due to the hexamethylenamine calibration marker into the peak height of the pentylenetetrazol standard.

Calibration Curve of Pentylenetetrazol Standards Analyzed in Human Plasma—Known amounts of pentylenetetrazol (5–30 μg) are added to 2-ml aliquots of control human plasma, and the drug is then extracted in the same manner as described in *Extraction Procedure*. After evaporation of the solvent extracts, the residues are dissolved in 10-μl aliquots of ethanol containing 1 μg/μl of hexamethylenamine. Following the injection of 1 μl of each sample into the chromatograph, a calibration curve for pentylenetetrazol standards analyzed in plasma is made as previously described.

[8] Menold, Lester, Pa.

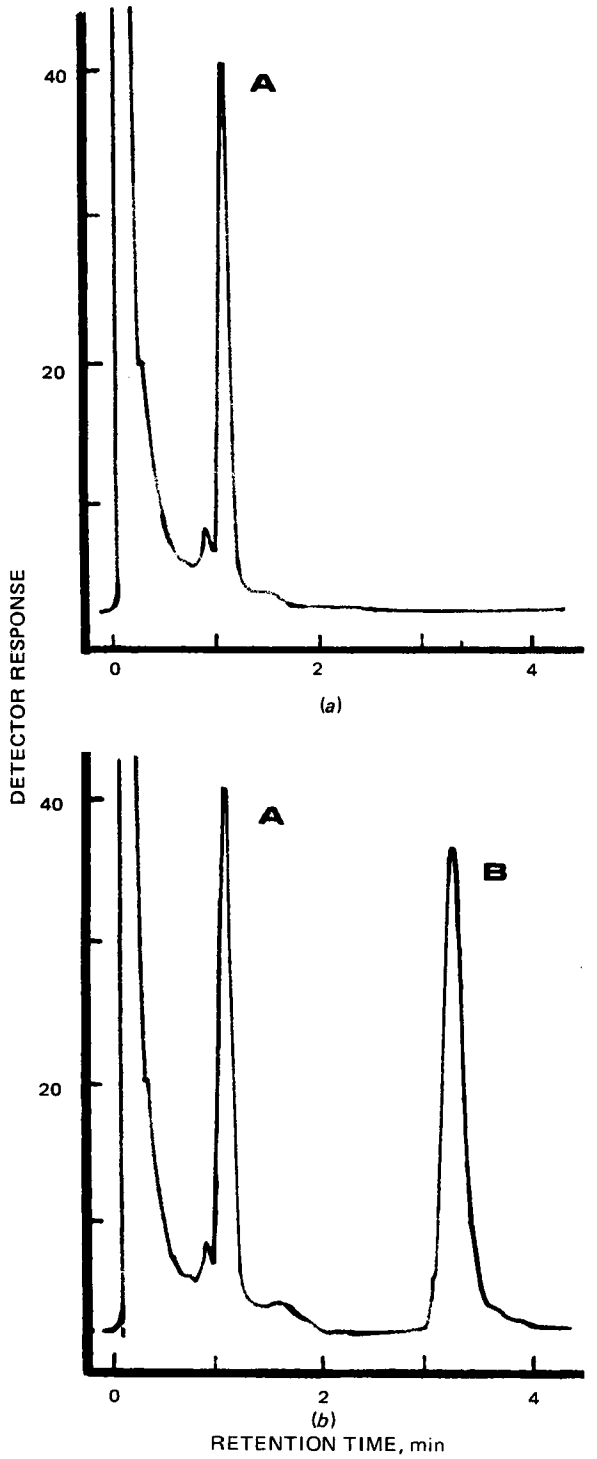

Figure 1—*Gas–liquid chromatograms of:* (a) *dog plasma extracts of control plasma and* (b) *plasma extract containing pentylenetetrazol. Key: A, hexamethylenamine; and B, pentylenetetrazol.*

Drug Recovery Studies—Known quantities of pentylenetetrazol (2–30 μg) were added to 2 ml of dog control plasma. The samples were thoroughly mixed and processed in the same manner as the unknown samples. The pentylenetetrazol in each sample was determined chromatographically by injecting a 1-μl aliquot of the ethanol containing the dissolved residue into the column and measuring the peak height ratios.

Calculations—The concentration of pentylenetetrazol (micrograms per milliliter) in unknown plasma or urine samples is determined as follows:

$$\text{drug concentration (micrograms per milliliter)} = \frac{\text{slope of calibration curve} \times \text{peak height ratio} \times \text{microliters of ethanolic solution} \times \text{milliliters of chloroform used for extraction}}{\text{milliliters of chloroform taken for evaporation} \times \text{milliliters of plasma or urine sample}} \quad \text{(Eq. 1)}$$

Drug Partition Studies—To determine the best solvent for the extraction of pentylenetetrazol from biological samples, the partition properties of this drug between water and various organic solvents were determined at room temperature. Ten milliliters of pentylenetetrazol in water (10 mg/ml) and an equal volume of a water-saturated organic solvent were mixed in a centrifuge tube with a Teflon-lined screw-cap by a rotating apparatus for 20 hr. After equilibrium, 5 mg of hexamethylenamine was dissolved in 5 ml of the aqueous layer, and 1 μl of this solution was directly injected into the chromatograph. Peak height ratios were measured for the determination of pentylenetetrazol in each water layer. The partition coefficients are expressed as the ratio of the drug concentration in the organic layer to the drug concentration in the water.

Drug Plasma Level Studies—To demonstrate the utility of this method, the pentylenetetrazol dose (15 mg/kg) was intravenously administered to one dog (11 kg) and orally administered to another dog (9 kg). Blood samples (4 ml) were withdrawn from the cephalic vein of the front leg using a heparinized in-dwelling catheter at various time intervals after dosing. Blood samples were centrifuged, and the plasma was transferred for extraction. During the experiment, dogs were anesthetized with pentobarbital sodium. Urine samples were collected for the chromatographic examination.

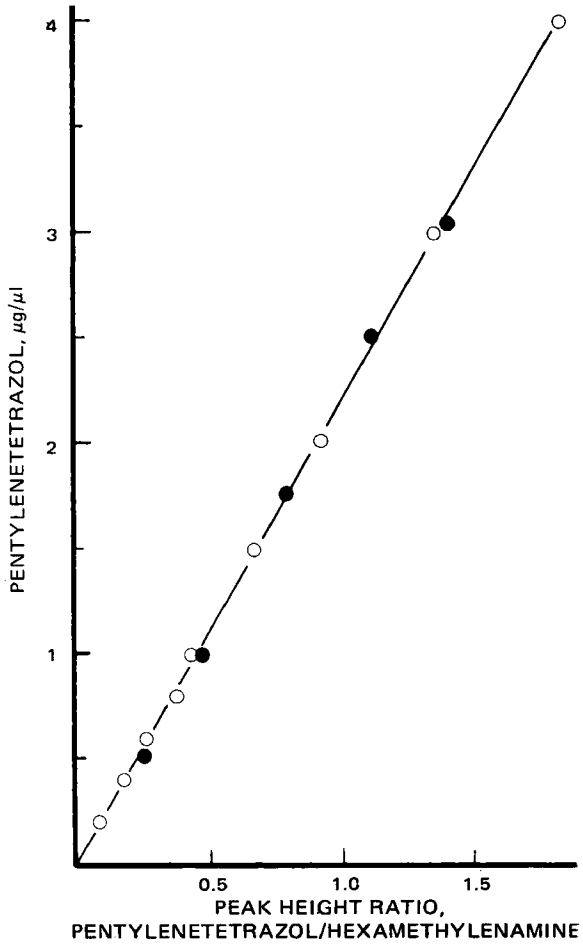

Figure 2—*Standard calibration curve for pentylenetetrazol to the calibration marker in ethanol (○), and for pentylenetetrazol extracted from human plasma (●).*

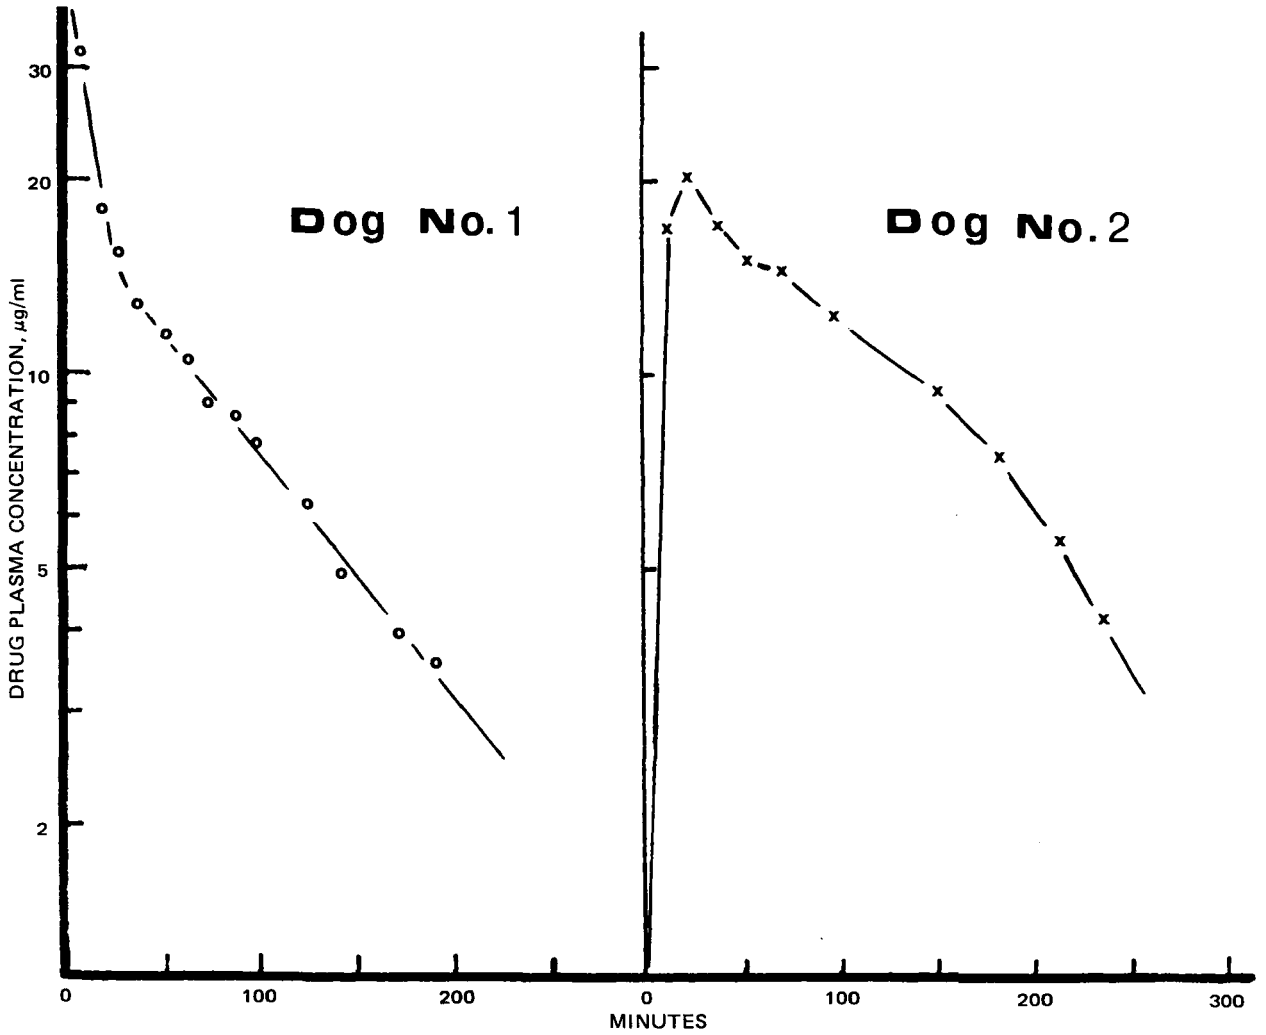

Figure 3—*Plasma concentrations of pentylenetrazol following the rapid intravenous administration of a 15-mg/kg dose in Dog 1 (11 kg) and following the oral administration of a 15-mg/kg dose in Dog 2 (9 kg).*

Human blood samples were obtained from three patients (57–68 years of age) regularly taking pentylenetetrazol tablets. This experiment was performed to test the sensitivity of the proposed technique for detecting drug plasma levels in patients after subconvulsive therapeutic doses.

RESULTS AND DISCUSSION

Drug Partition Studies—Since pentylenetetrazol has a high solubility in water as well as in most organic solvents, it was necessary to determine the partition properties of this compound (Table I). The large partition coefficient of pentylenetetrazol in the chloroform layer led to the use of chloroform in the extraction. The partition coefficient of this drug in chloroform is about 200 times greater than in ether, although these two solvents have similar dielectric constants (6). This difference may be due to the formation of a molecular interaction between pentylenetetrazol and chloroform. After equilibrium, the concentration of pentylenetetrazol in the water layer was determined by direct injection of an aliquot of the aqueous phase into the chromatograph and determination of the peak height ratio of the drug to the calibration marker.

Table II—Recoveries of Pentylenetetrazol Standards Added to Control Biological Fluids of the Dog

Pentylenetetrazol Added, μg/ml		Recovery of Pentylenetetrazol[a], %	
		Plasma	Urine
1		105.0	96.0
2		105.0	—
3		96.7	103.0
5		98.0	—
7		107.1	102.5
9		105.6	98.0
11		98.2	—
13		—	96.5
15		93.4	95.1
	Mean	101.1	98.5
	± *SD*	5.1	3.4

[a] Each percent recovery of pentylenetetrazol represents the results from a single sample subjected to the complete pentylenetetrazol analytical method.

Chromatography—Figure 1 shows typical chromatograms for a control plasma extract in which the calibration marker was added and for a pentylenetetrazol standard added to a control plasma sample and analyzed by this procedure using the calibration marker. Both peaks are sharp and symmetrical, and the chromatographic time for each determination is relatively short. Analysis of many control samples of plasma showed no interfering peaks with retention times similar to pentylenetetrazol (3.2 min) or hexamethylenamine (1.1 min).

Calibration Curves—As shown in Fig. 2, a linear relationship exists for known concentrations of pentylenetetrazol over a 0.2–4-μg/μl range when plotted against the corresponding peak ratios. An identical linear line is also obtained for the analysis of drug standards added to control samples by plotting the concentrations of pentylenetetrazol added to control plasma samples against the peak height ratio as described under *Experimental*. This correlation indicates a high efficiency of extraction and reproducibility of the analytical method for pentylenetetrazol.

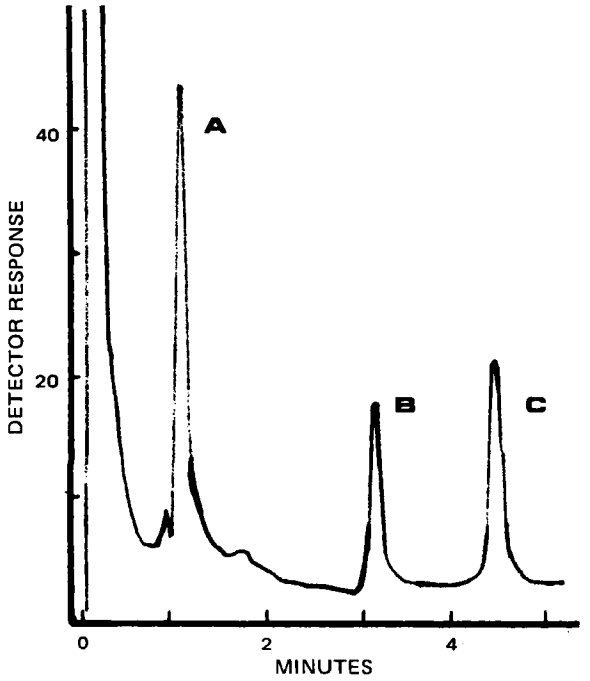

Figure 4—*Gas–liquid chromatogram of dog plasma extracts. Key: A, calibration marker; B, pentylenetetrazol; and C, unidentified metabolite.*

Drug Recovery—Results for recovery experiments of pentylenetetrazol standards added to control dog plasma and urine are shown in Table II. The data indicate that recovery of the drug from dog plasma is essentially quantitative in the 1–15-μg/ml range using a 2-ml plasma sample (mean ± *SD* = 101.1 ± 5.1%). Actual concentrations of the drug in dog plasma samples were also in this concentration range.

The average recovery of the drug added to control dog urine (2 ml) was 98.5 ± 3.4%. Because of its high partition property into chloroform, almost complete recovery of the drug was achieved after a single extraction process. The mean recoveries of the drug from control human plasma (95.8 ± 4.4%) and urine samples (97.0 ± 3.9%) were also quantitative.

Drug Plasma Level Studies—The described analytical method for pentylenetetrazol was used in the determination of plasma levels of pentylenetetrazol in dogs following rapid intravenous and oral administrations of a 15-mg/kg dose. Plasma profiles after the rapid intravenous injection (Fig. 3) indicate the applicability of the two-compartment pharmacokinetic model proposed previously (7, 8). The half-life of the drug in the plasma of one dog (male, 11 kg) was about 1 hr.

The drug plasma levels after oral administration of the aqueous solution (135 mg in 20 ml of water) to the other dog (female, 9 kg) indicate that GI absorption of this drug was very rapid and efficient. After the maximal drug peak, which occurred in the plasma at about 25 min (Fig. 3), the plasma levels declined slowly and then more rapidly. The initial slow decline was due to the simultaneous absorption and elimination process.

Table III—Plasma Concentrations of Pentylenetetrazol in Human Plasma Samples

Subject	Dose, mg	Sample Time, hr Postdose	Concentration, μg/ml
A	100	3	1.86
B	100	5	1.45
C	100	1.25	3.1

Detection of Pentylenetetrazol in Human Plasma—Human plasma samples were obtained from three patients given therapeutic oral doses of the drug. These plasma samples (4 ml) were then analyzed by the described method (Table III). The chromatographic results indicate that the method is sufficiently sensitive to detect the plasma levels of pentylenetetrazol after therapeutic doses of the drug.

Detection of Unidentified Metabolite—During a chromatographic analysis of plasma extracts from drug-treated dogs, a new peak due to a drug metabolite with a retention time of 4.5 min was consistently observed (Fig. 4). The size of the peak due to the metabolite in the plasma reached a maximum after about 1 hr and decreased slowly thereafter. Analysis of urine samples for the drug also showed the peak due to the metabolite at the identical retention time (4.5 min). No peak with this retention time was seen in the control plasma or urine samples. Extensive metabolism of this drug was previously reported (4, 9).

Enterohepatic Circulation of Tetracycline in Rats

JOSEPH ADIR

Abstract □ The absorption of tetracycline hydrochloride excreted in the bile of rats was evaluated using the *in situ* intestinal preparation. For comparative purposes, the absorption of the drug from an aqueous solution having the same pH as that of the bile was also determined. After 4 hr, the amounts of tetracycline absorbed from the bile and aqueous solutions were 72.92 and 77.34%, respectively. There was no significant difference in the amount of drug accumulated in the gut tissue. The disappearance of the drug from the intestinal lumen was biexponential, and the kinetic parameters appeared to be similar. It was concluded that tetracycline excreted in the bile is readily absorbed from the rat intestine. Accordingly, biliary excretion does not seem to account for a significant elimination of this antibiotic from the body.

Keyphrases □ Tetracycline—intestinal absorption from bile and aqueous solutions, elimination, rats □ Absorption—intestinal, tetracycline from bile and aqueous solutions, rats □ Excretion, biliary—role in tetracycline elimination, rats □ Biliary elimination—tetracycline, rats

Studies on the disposition of tetracycline in humans and animals indicate that 50–70% of the dose is eliminated unchanged in the urine after both intravenous and oral administrations (1–5). Since no significant metabolism of tetracycline has been observed (6), excretion *via* the bile is presumed to be the other route of elimination (7–10). The observed high levels of tetracycline in the bile (11–13) and the detection of high percentages of the administered dose in feces (3, 4, 14) supported this notion.

Recently, von Wittenau and Twomey (8) reported that doxycycline excreted in dog feces could not be totally extracted by the same solvent system employed to extract the unchanged drug from other fecal excreta. Accordingly, it was speculated that the positively charged doxycycline may form a complex with the negatively charged bile salts and that this complex is unavailable for reabsorption from the intestine (8).

The purposes of this investigation were to determine whether tetracycline excreted in the bile is reabsorbed from the small intestine and, eventually, to delineate the role of biliary excretion in the overall elimination of this drug from the body.

EXPERIMENTAL

Chemicals—^{3}H-7-Tetracycline hydrochloride powder was obtained commercially in a sealed borosilicate glass container[1]. The radioactive material (specific activity of 2.9 mCi/mg) was dissolved in methanol and stored at −20°. Nonlabeled tetracycline hydrochloride was used as obtained[2]. Anhydrotetracycline was synthesized according to the method of McCormick *et al.* (15), and 4-epitetracycline was synthesized according to the method of Simmons *et al.* (16).

Purity of Samples—The radiolabeled tetracycline was claimed by the manufacturer to be 98% pure according to TLC analysis on silica gel developed in 10% citric acid solution saturated with *n*-butanol and by paper chromatography on Whatman P20 cellulose phosphate cation paper in 0.1% NH_4Cl. To ascertain this purity, TLC purity and UV absorption of both labeled and nonlabeled materials were determined. Glass plates, 20 × 20 cm, were coated with a 0.25-mm layer of a slurry composed of 50 g of Kieselguhr G[3] and a mixture of 95 ml of 0.1 *M* edetate sodium in distilled water and 5 ml of 20% (v/v) polyethylene glycol 400 in glycerol (17). After air drying, the plates were developed in methyl ethyl ketone saturated with citric acid–phosphate buffer at pH 4.7 (17).

Twenty-five microliters of the methanolic solution of the labeled tetracycline was spotted and developed. After drying in air, the different spots were located by fluorescence under long wavelength UV light. The spots were identified by comparing their R_f values with those observed with methanolic solutions of tetracycline, anhydrotetracycline, and 4-epitetracycline. The plates were then radioscanned, and the area under the peaks was determined by the cut-and-weigh method.

UV absorption wavelengths were determined by scanning[4] a methanolic solution of each compound. The concentration of anhydrotetracycline was determined by absorption at 391 nm. Tetracycline was quantitated by the difference in absorption at 357 and 391 nm, using an equation reported previously (18). 4-Epitetracycline could not be quantitated by UV absorption.

Biliary Excretion Studies—Male Sprague–Dawley rats, 380–510 g, were anesthetized with urethan (1.3 g/kg im). A midline abdominal incision was made, and the common bile duct was cannulated with polyethylene (PE 10) tubing. After a steady flow of bile was observed, a 10-mg/kg dose of tetracycline (specific activity of 34.7 μCi/mg) was injected in the femoral vein over 5 min. The injectable dose was freshly prepared by evaporating the methanol from the tritiated tetracycline solution and adding nonlabeled aqueous drug solution to yield the desired specific activity.

The exteriorized bile was collected under a gentle stream of nitrogen in covered dark vials to avoid decomposition of its constituents. After 8–15 hr of collection, the bile solution was frozen and then mixed with bile collected from other rats treated in a similar way (total of six rats). The pH of the pooled bile from rats was determined, and an aliquot was used for qualitative and quantitative analyses. No attempt was made to calculate the percent of dose excreted in the bile of individual rats.

***In Situ* Absorption Studies**—Overnight fasted, male Sprague–Dawley rats, 280–380 g, were used. After urethan anesthesia, an abdominal midline incision was made. An 80–100-cm segment of the small intestine was isolated and cannulated with Tygon tubing about 2 cm distal to the common bile duct junction and proximal to the cecal end. The loop was washed thoroughly with 0.9% NaCl at 37° to remove any residual food and flushed with a mixture of 95% oxygen and 5% carbon dioxide to expel excess saline solution. Each cannula was attached to a 20-ml syringe to allow sampling of the loop content.

Five milliliters of the pooled bile solution was introduced, and a 0.1-ml aliquot was removed at 10-min intervals for the 1st hr, every 15 min for the 2nd hr, and every 30 min for the next 2 hr. Sampling was alternated between the two syringes. The volume loss due to water absorption from the drug solution was replenished with distilled water, adjusted to the same pH as the bile solution (8.75). At the end of the experiment, the intestinal segment was excised and its length was measured. It then was homogenized and incubated with a tissue solubilizer[5], and an aliquot was used for quantitative analysis. The *in situ* intestinal preparation was similar to that reported previously (19).

For comparative purposes, the absorption of tetracycline from

Table I—Quantitative Analysis of Tetracycline in the Bile and Aqueous Solutions

Solution	R_f[a]	Composition, % Labeled: Radioscanning	Labeled: UV Absorption	Nonlabeled, UV Absorption
Aqueous				
Unknown	0.09 (0.0)	0.9	N.D.[b]	N.D.
4-Epitetracycline	0.24 (0.26)	2.5	N.D.	N.D.
Tetracycline	0.56 (0.62)	89.1	75.6[c]	84.4[c]
Anhydrotetracycline	0.98 (1.00)	7.2	10.4[d]	N.P.[e]
Bile				
Unknown[f]	0.03	94.9	N.D.	N.D.
Anhydrotetracycline	0.98	5.1	N.D.	N.D.

[a] R_f values given in parentheses were reported by Lanman *et al.* (20). [b] N.D. = not determined. [c] Calculated by the equation of Pernarowski *et al.* (18). [d] Determined from Beer's law plot of anhydrotetracycline solutions. [e] N.P. = not present. [f] See text for explanation.

an aqueous solution having a pH and specific activity similar to the bile solution was determined as already described.

Partition Coefficient Studies—The partitioning characteristics of the bile and aqueous solutions of tetracycline were determined by mixing equal volumes of either solution and isoamyl alcohol in a shaker[6] at 37°. The partition coefficient is defined as the equilibrium ratio of radioactivity of the isoamyl alcohol phase to that of the test solution.

Assay—The level of radioactivity in the bile and aqueous and tissue homogenate samples was quantitated in 15 ml of a scintillation counting solution consisting of 0.1 g of 1,4-bis[2-(5-phenyloxazolyl)]benzene, 5.5 g of 2,5-diphenyloxazole, and 250 ml of octoxynol[7] and diluted to 1 liter with toluene. The counting[8] efficiency of each sample was determined by the internal standard method using tritiated toluene.

RESULTS

Table I shows the composition of the tetracycline samples. In spite of the presence of some degradation products, the composition of the labeled and nonlabeled samples was similar. About 85–90% of the sample was present as pure tetracycline according to radioscanning and UV absorption analyses. However, analysis of the bile solution indicated that the major portion of radioactivity (95%) was attributed to an unknown species which remained at the origin of the thin-layer chromatogram. Further disparity between the properties of the bile and aqueous solutions is indicated by the partition coefficients. The partition coefficient of the bile solution (0.573) was more than twice that of the aqueous solution (0.213), as indicated by the equilibrium ratio of the radioactivity of the isoamyl alcohol phase to that of the test solution.

The results of the *in situ* absorption studies of tetracycline from the bile and aqueous solutions are shown in Table II. A negligible percent of the dose initially introduced in the intestinal loop accumulated in the gut wall. Furthermore, there was no statistical difference in the amount of drug found in the gut walls between the bile (2.24%) and aqueous (2.44%) solutions. Accordingly, the disappearance of the drug from the intestinal lumen could be construed to indicate its absorption into the systemic circulation. On the average, 72.92% of the drug in the bile solution was absorbed compared with 77.34% absorbed from the aqueous solution. The difference in the percent absorbed was statistically significant ($p < 0.05$).

Figure 1 shows the time course of the disappearance of tetracycline from the rat intestinal lumen expressed as the ratio of the amount of drug present at a given time to the amount introduced at zero time. Only the values obtained at and beyond the 75-min sample were statistically greater ($p < 0.05$) for the bile than for the aqueous tetracycline solutions. However, the disappearance of the drug from both solutions was rapid initially. On the average, 40–50% of the initial dose disappeared from the lumen during the first 0.5-hr.

DISCUSSION

The report by Lanman *et al.* (20) on the purity of tritiated tetracycline hydrochloride samples available commercially instigated a thorough examination of the purity of the samples used in the present study. These workers found that two commercially available radioactive samples contained only 50–60% pure tetracycline hydrochloride; the rest consisted of the degradation products, anhydrotetracycline and 4-epitetracycline. Another marketed sample consisted mainly of anhydrotetracycline (20).

It is obvious that the presence of substantial quantities of the degradation products of tracers could lead to serious misinterpretations. Usually, these tracers are mixed with nonlabeled, chemically pure materials which may behave differently in the biological system. Therefore, it was essential to verify the purity of the labeled tetracycline, although the sample employed in the present study was obtained from a different source than the samples tested by Lanman *et al.* (20). The findings of the present study indicate that both the labeled and nonlabeled samples contained 85–90% pure tetracycline.

Analysis of the tetracycline bile solution showed that except for one spot corresponding to anhydrotetracycline, 95% of the radioactivity remained at the origin. Therefore, the tetracycline compounds existed in a polar form which could not migrate in the solvent system employed in the development of the thin-layer plates. It is possible that this polar form is a complexation product of the charged tetracycline species and bile constituents. Similar inference was made by von Wittenau and Twomey (8) with respect to the extraction of oxytetracycline from dog fecal excreta. On the other hand, this complex appears to possess a greater lipid solubility than the uncomplexed drug, as indicated by its greater tendency to partition into the isoamyl alcohol from the test solution. Further investigations are needed to characterize more fully the properties of this complex.

Although the difference between the amount of tetracycline absorbed from the bile and aqueous solutions is statistically signifi-

Table III—Kinetic Parameters of the Disappearance of Tetracycline in the Bile and Aqueous Solutions from the Rat Intestine[a]

Solution	A	α, min^{-1}	B	β, min^{-1}

p[b]	<0.01	>0.95	>0.2	>0.95

[a] The ratios of the amount of tetracycline at a given time to the amount initially introduced were fitted to Eq. 1 (see text). [b] Unpaired t test.

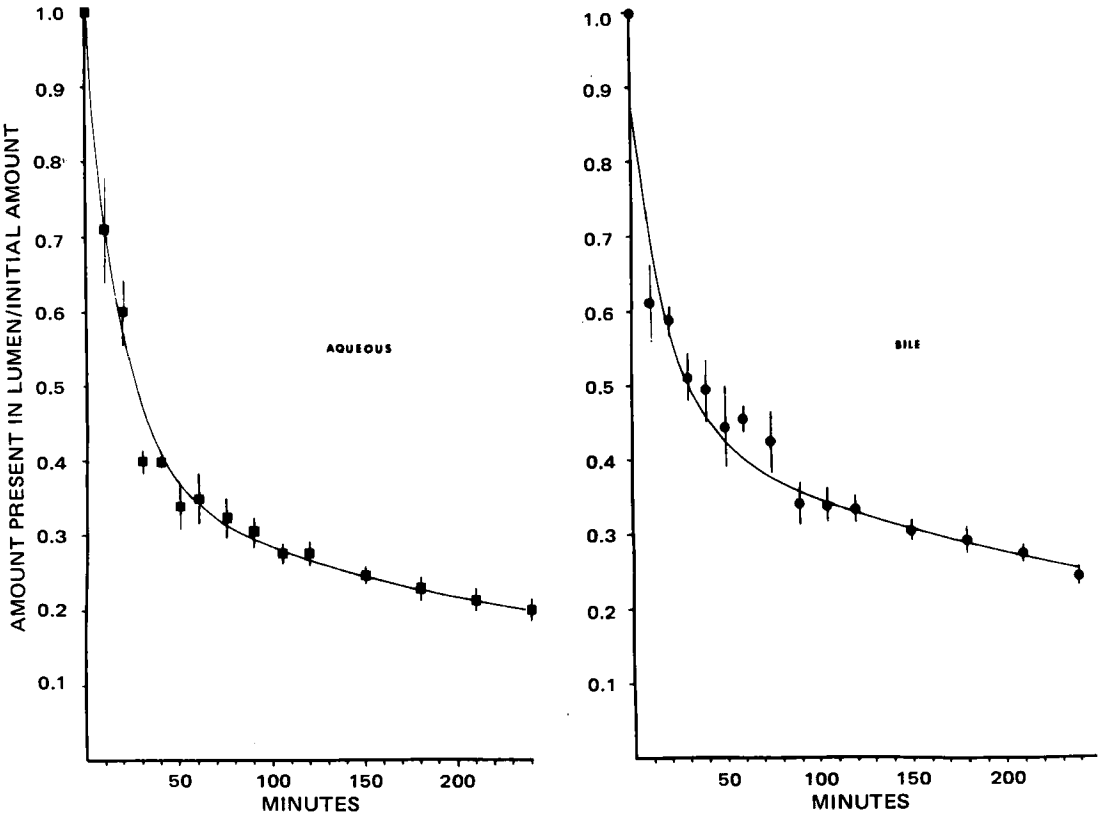

Figure 1—*Disappearance of tetracycline hydrochloride in the bile and aqueous solutions from the rat intestine as a function of time. The ordinates represent the ratio of the amount of the drug present at a given time to the amount introduced initially. Each point represents the mean of five rats, and vertical lines indicate the standard error of the mean. The continuous curves denote computer-fitted lines to the mean data.*

cant (Table II), it may not be biologically important unless it is accompanied by a similar difference in the rate of absorption of the drug from the two solutions. The time course of the disappearance of tetracycline from the rat intestinal lumen was plotted on semilogarithmic graph paper and found to be biphasic. Accordingly, data of each rat were fitted to the following biexponential equation using the SAAM 25 digital program (21):

$$R = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where R is the ratio of amount of radioactivity present at a given time, t, to the amount initially introduced; α and β are the rate constants (minutes^{-1}) characterizing the rapid and more slowly declining phases, respectively; and A and B are constant coefficients, the sum of which represents the value of R at $t = 0$. The derived kinetic parameters are listed in Table III. It is clear that there are no statistical differences between the kinetic parameters B, α, and β whereas the value of A is significantly less for the bile solution than for the aqueous solution ($p < 0.01$). This may be explained by the greater tendency of the former to partition onto the gut wall, as indicated by its higher partition coefficient compared to the aqueous solution.

The findings of this investigation raise questions regarding the other routes of elimination of tetracycline in addition to excretion in urine. In a well-designed study, von Wittenau *et al.* (22) demonstrated that diffusion of doxycycline from the blood into the lumen of the small intestine and its ultimate excretion in feces constitute the other major route of elimination of this antibiotic in the rat. Other investigators detected tetracycline in the lower intestinal lumen of mice at various times after the intravenous administration of the drug (23, 24). Pindell *et al.* (25) demonstrated that tetracycline is rapidly absorbed from the duodenum but that negligible absorption takes place from the colon.

It is quite possible, therefore, that because of the poor absorption from the lower intestine and colon, tetracycline excreted into these areas is eventually eliminated in the feces. In fact, the biphasic disappearance of tetracycline from the isolated loop observed in the present study may be explained by the back-diffusion of drug absorbed from the duodenum and jejunum into the lower small intestine. The intestinal segment used in this investigation was sufficiently long to include the major portion of the ileum.

Complexation in Formulation of Parenteral Solutions: Solubilization of the Cytotoxic Agent Hexamethylmelamine by Complexation with Gentisic Acid Species

BO KREILGÅRD *, T. HIGUCHI ‡, and A. J. REPTA ˣ

Abstract □ The apparent solubility of hexamethylmelamine in aqueous solutions suitable for intravenous use was increased by complexation with gentisic acid. Studies were carried out in the pH 0–8 range. Unprotonated hexamethylmelamine did not form complexes with the gentisate ion, while the hexamethylmelammonium ion appeared to form several different complexes with both the gentisate ion and gentisic acid. Two different solid complexes were isolated and characterized. The solubility increases observed at pH 3.5–5.0 are described by mathematical relationships involving the stability constants of some postulated complex species. From these results, suitable formulations for use as parenteral solutions are proposed. The increase in the apparent aqueous solubility of hexamethylmelamine in such formulations may range from five- to 90-fold, depending upon the pH and total gentisate-ion concentrations.

Keyphrases □ Complexation—hexamethylmelamine–gentisic acid species, pH 0–8, effect on solubility □ Solubilization—hexamethylmelamine by complexation with gentisic acid species, pH 0–8, intravenous formulations □ Cytotoxic agents—hexamethylmelamine, solubilization by complexation with gentisic acid species, intravenous formulations □ Hexamethylmelamine—solubilization by complexation with gentisic acid species, intravenous formulations □ Triazine derivatives—hexamethylmelamine, solubilization by complexation with gentisic acid species, intravenous formulations

Hexamethylmelamine[1], a cytotoxic triazine, was evaluated in extensive phase I and II clinical trials (1). Although the efficacy is not particularly striking in any tumor type, clinical interest in hexamethylmelamine continues in view of its consistent, although low, response rate in several tumors including bronchogenic carcinoma (2, 3).

In phase I and II trials, hexamethylmelamine was given by the oral route (1), and GI side effects such as nausea and vomiting were encountered in such studies (4, 5). To avoid such problems, an intravenous dosage form was developed. Because of the weakly basic nature of the drug and its low aqueous solubility (<0.1 mg/ml), the only parenteral formulation used was an aqueous hydrochloric acid solution (pH ~2) of the drug[2]. The clinical use of this solution has been restricted by the occurrence of thrombophlebitis and local irritation. To determine whether these untoward reactions at the injection site are inherently due to hexamethylmelamine or to the very acidic formulation, a less acidic (pH > 3) formulation of hexamethylmelamine at a concentration of 2–5 mg/ml was desired[2].

Previous experience with the complexation tendencies of various hydroxybenzoic acids with substances exhibiting characteristics akin to those of hexamethylmelamine (6–9) suggested that the apparent solubility of this drug probably could be increased through complexation. Such complexation necessitated the identification and use of a suitable ligand. Preliminary studies with gentisic acid as the ligand demonstrated a significant increase in the apparent solubility of hexamethylmelamine.

This report describes the qualitative and quantitative nature of the interactions of hexamethylmelamine with gentisic acid species, with particular attention being paid to those pH and concentration condi-

tions that might normally be encountered in the formulation and use of an intravenous solution.

EXPERIMENTAL

Chemicals—Hexamethylmelamine was used as received[3], mp 171–173° [lit. (10) mp 172–174°]. Titrations with perchloric acid in acetic acid showed the molecular weight to be 210 ± 0.5 (theoretical 210.3). TLC [silica gel F-254 and benzene–acetone–formic acid (8:4:1)] indicated that the material was homogeneous when 100 μg was spotted and visualized by iodine vapor and UV light at 254 nm.

Gentisic acid[4], mp 204–205° [lit. (9, 11) mp 205°] was also found to be homogeneous by TLC using the same conditions. Analysis of gentisic acid, using the USP (12) assay for benzoic acid, indicated a purity >99.5%. All other chemicals were of analytical reagent grade and were used without further purification. The water used was distilled from aqueous acidified potassium permanganate solutions and stored in Pyrex glass containers.

Solubility Studies—The experimental method used was described in detail previously (13). In the studies at pH 3.5–5.0, equal volumes of a stock solution of the ligand were pipetted into the 15-ml screw-capped vials containing 210 mg of hexamethylmelamine (1.00×10^{-3} mole). Then different amounts of a solution of either 0.1 or 1 *N* hydrochloric acid were added, and the solution in each vial was brought to a constant final volume of 10 ml with water.

Ligand stock solutions of the desired concentration and pH were prepared by dissolving the necessary quantity of gentisic acid and sodium bicarbonate in water. In the preparation of these stock solutions, ~0.1% sodium bisulfite was included to minimize oxidation of the ligand. The addition of sodium bisulfite did not appear to influence the complexation reaction quantitatively compared to studies in which the solutions were deoxygenated by flushing with nitrogen gas.

Solubility equilibrium was obtained by fixing the sealed vials to a rotating shaft in a water bath thermostated at 25.0 ± 0.1°. The contents of the vials were allowed to equilibrate until no further changes in the concentration of the species in solution were detectable. After 20 hr or more, samples corresponding to the ascending portion of the phase diagram were at equilibrium; samples corresponding to the remaining portion of the phase diagrams achieved equilibrium after 42 hr or more. To avoid oxidation of gentisate, no samples were allowed to equilibrate for more than 72 hr.

Following equilibration, the contents of the vials were filtered through sintered-glass filters. The pH of each solution was measured[5] at 25°, and the total concentrations of the hexamethylmelamine and gentisic acid species were determined.

Since the system was highly pH dependent and since changes in pH occurred when precipitation of the complex took place, it was necessary to run a series of experiments covering the desired pH range (pH 3.5–5) for each concentration of ligand used. As an example, Table I shows experimental results at a gentisate-ion concentration of 0.44 *M*. In Group A samples, the increasing amounts of hydrochloric acid added caused a decrease in pH and an increase in dissolved hexamethylmelamine. This relationship was typical and to be expected when no precipitation of complex took place. However, when a solid complex precipitated, no significant changes in pH occurred with the incremental increase in the volume of hydrochloric acid solution added (Group B). During this precipitation of the complex, the concentration of hexamethylmelamine appeared to be constant while the concentration of gentisic acid species gradually decreased.

With the Group C samples, further addition of hydrochloric acid caused a decrease in pH as well as in the concentrations of substrate and ligand because the supply of excess solid substrate had been exhausted by the precipitation of the complex (in those samples represented by Group B).

The composition of all solutions was plotted against pH, and the concentrations of substrate and ligand at each particular pH value were read. Table I illustrates that no definite value for the concentration of hexamethylmelamine could be obtained at pH 4.5 in this particular experiment. Similar studies were carried out to obtain phase solubility diagrams in the pH 3.5–5.0 range.

	2.0	3.54	8.1	0.263
	2.2	3.34	6.5	0.267

[a] Hexamethylmelamine (210 mg, 1.0×10^{-3} mole) was added to each sample, and the total volume of the aqueous phase was 10 ml. See *Experimental* section for detailed explanation.

In studies done at pH > 7, increments of the stock solution of the ligand were pipetted into the vials, sodium bicarbonate (1 *N*) was added to bring the pH in the final solution to pH > 7, and water was added to a final volume of 10 ml. Otherwise, the procedure was as already described.

For studies done in highly acidic solutions, gentisic acid was used as the substrate due to the high solubility of hexamethylmelamine in strongly acidic media. The gentisic acid (231 mg, 1.5×10^{-3} mole) was combined with aliquots of a solution of hexamethylmelamine in 1 *N* hydrochloric acid, and the final liquid volume was adjusted to 10 ml with 1 *N* hydrochloric acid. The remainder of the procedure was as already described.

The influence of ionic strength on the aqueous solubility of hexamethylmelamine was determined at 25°. Distilled water was adjusted to pH 9–10 with aqueous sodium bicarbonate (1 *N*), and the ionic strength was adjusted to the desired value with sodium chloride. Such solutions were equilibrated with excess solid hexamethylmelamine for 20 hr, after which the concentration of dissolved hexamethylmelamine remained constant. Some results are shown in Table II, and the solubility of hexamethylmelamine at zero ionic strength was estimated by extrapolation to be 4.15×10^{-4} *M* at 25.0°.

Analytical Procedure—Hexamethylmelamine and gentisate in aqueous solutions were analyzed by measuring the absorbances[6], at 228 and 322 nm, of solutions diluted to the required extent with sodium borate (10^{-2} *M*) in methanol–water (1:4). Since hexamethylmelamine did not absorb at 322 nm, the concentration of gentisate could be calculated directly from the absorbance of the solution at 322 nm and an independently determined value of $\epsilon_{322} = 3850\ M^{-1}\ cm^{-1}$ for gentisate in the described solvent system.

The calculation of hexamethylmelamine was not quite as straightforward as anticipated due to a small and varying degree of oxidation of gentisate, which occurred during the preparation of the gentisate stock solutions (involving the neutralization of gentisic acid by addition of alkali). This oxidation caused the absorbance values for gentisate at 228 nm to vary by about 2–5% from the value predicted using the molar absorptivity value of $\epsilon_{228} = 7240\ M^{-1}\ cm^{-1}$. This value was obtained using solutions prepared by dissolving gentisic acid directly into the sodium borate–methanol–water system already described.

Table II—Influence of Ionic Strength (μ) on the Acid Dissociation Constants of Hexamethylmelamine, pKa_M, and Gentisic Acid, pKa_G, and on the Solubility of Hexamethylmelamine Base, $[HM]_0$ ($T = 25°$)

μ	pKa_M	pKa_G	$[HM]_0$, $M \times 10^4$
0	4.92[a]	2.95[a]	4.15[b]
0.05	4.97	2.87	4.09
0.10	5.02	2.82	3.94
0.50	5.15	2.66	2.86
1.00	5.20	2.57	1.89

[a] Obtained by calculations as described in the *Experimental* section. [b] Value at zero ionic strength was obtained by extrapolation.

Such oxidation of gentisate did not affect the absorption at 322 nm and, once prepared, the absorbance spectrum of any particular stock solution did not change over a period of more than a week. Therefore, it was possible to obviate the problem by measuring the absorbance values at 322 (A'_{322}) and 228 (A'_{228}) nm for the particular gentisate stock solution used in the samples to be analyzed. A value R ($= A'_{228}/A'_{322}$) was then calculated and used in estimating the concentration of hexamethylmelamine in the samples according to the expression:

$$[\text{hexamethylmelamine}] = [A_{228} - (RA_{322})]/\epsilon_{228,HM} \quad \text{(Eq. 1)}$$

where A_{228} and A_{322} are the values of the absorbances in the sample being analyzed, and $\epsilon_{228,HM}$ (=50,700 M^{-1} cm^{-1}) is the molar absorptivity of hexamethylmelamine at 228 nm.

All reported absorptivity values were obtained from appropriate Beer–Lambert-type plots.

Ionization Constants—The acid dissociation constant, pKa_M, for the hexamethylmelammonium ion was determined at various ionic strengths by a solubility technique which involved measuring the apparent solubility of hexamethylmelamine at several pH values (14) (Table II). When utilizing the Debye–Hückel equation (15), correction of the results obtained at $\mu \leq 0.1$ yielded the value $pKa_M = 4.92$ at zero ionic strength. The corresponding constant for gentisic acid, pKa_G, was determined by potentiometric titrations (14) at 25.0° (Table II). Again using the Debye–Hückel equation (15), the value of pKa_G at zero ionic strength was determined to be 2.95, which agrees with the literature value of 2.97 (16).

Isolation and Characterization of Complexes—Complexes were isolated during the solubility studies at pH 3.5 and 4.0. Immediately after separation by filtration, the crystalline complexes were washed twice with 5 ml of cold water and then dried *in vacuo* at room temperature. Samples of the dry solid were dissolved in methanol, and the ratio of total hexamethylmelamine and gentisate species was determined by UV spectrophotometry as already described. The alkaline equivalent weights of these solids was obtained by nonaqueous potentiometric titration with perchloric acid (0.01 N) in acetic acid. The acidic equivalent weights were determined by titration with aqueous sodium hydroxide (0.5 N) (Table III).

At pH < 0.5, the solid complex was isolated during the solubility studies from solutions with an initial concentration of 0.08 M hexamethylmelammonium chloride. Since the complex dissolved very rapidly when washed with water, it could not be washed free of hydrochloric acid. UV spectrophotometric determination showed it to contain 0.68 mole of hexamethylmelammonium ion/mole of gentisic acid, which closely agrees with a stoichiometry of 3:2.

RESULTS AND DISCUSSION

Phase Solubility Studies—The complexation of hexamethylmelamine and gentisic acid was studied at 25° by the solubility method in the pH 0–8 range. The apparent solubility of hexamethylmelamine at a pH between 7 and 8 did not change measurably with increasing amounts of gentisate ion (0–0.5 M). This finding indicated that the hexamethylmelamine base and gentisate ion did not appreciably associate.

In hydrochloric acid (1 N) solutions at 25°, gentisic acid and hexamethylmelammonium ion did interact appreciably. As shown in Fig. 1, the solubility of the substrate (gentisic acid) was increased by addition of the ligand at concentrations up to about 0.01 M. The slope of the ascending part of the diagram is approximately 2, indicating formation of a soluble 2:1 (or higher order) gentisic acid–hexamethylmelammonium-ion complex (13). At concentrations of ligand >0.01 M, a solid complex precipitated. Based on the length of the plateau region (13), the stoichiometry of the solid gentisic acid–hexamethylmelammonium-ion complex was calculated to be 3:2. This stoichiometric value was supported both by the data obtained from analysis of the isolated solid complex and by calculations utilizing the data for the descending part of the phase solubility diagram (13), which corresponds to the precipitation of the complex.

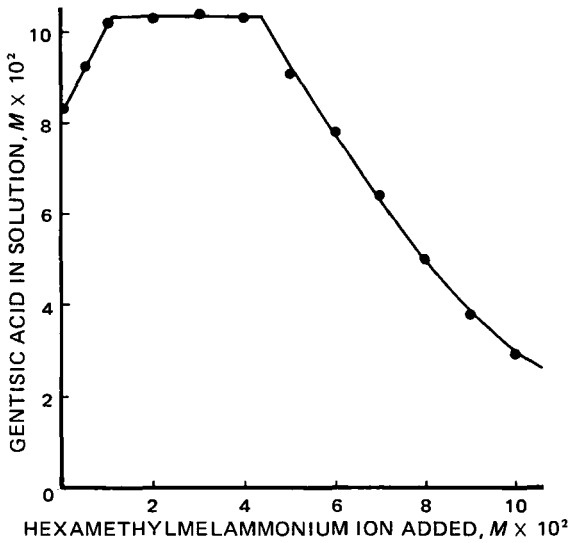

Figure 1—*Solubility of gentisic acid in 1 N hydrochloric acid at 25° as a function of hexamethylmelammonium ion added.*

Similar solubility studies were carried out at 25° and pH values between 3.5 and 5.0, where both the charged and uncharged species of the compounds are present. In this range, control of pH was difficult since the substrate and ligand had electrolytic character and the association as soluble or insoluble complexes caused changes in pH. Therefore, experiments were done covering the whole pH range at each ligand concentration. In such studies, hexamethylmelamine was used as the substrate.

The results at pH 3.5 and 4.0 are shown in Fig. 2, and those obtained at 4.5 and 5.0 are presented in Fig. 3. In all four phase diagrams, the solubility of total hexamethylmelamine increased as increasing amounts of ligand were added. At pH 3.5 and 4.0, a solid complex was precipitated, as indicated by the plateau regions in Fig. 2; at pH 5.0, no complex precipitated. At pH 4.5 and a ligand concentration >0.425 M, a precipitate was also observed, but the concentration data obtained from the solution phase in such samples appeared to be quite scattered and were not reproducible. The cause and nature of these results were not examined further.

Inspection of the data in Fig. 2 demonstrated some unusually sharp changes in concentration of substrate as a function of added ligand at both pH 3.5 and 4.0. To determine whether such abrupt changes were due to supersaturation, 10-ml samples (pH 3.5) of 210 mg of hexamethylmelamine (10^{-3} M) and gentisate concentrations of 0.04–0.07 M were allowed to equilibrate for 1 day. Then, as an aid to nucleation, glass wool and some crystals of the complex isolated at pH 3.5 were introduced and the samples were again kept at 25°.

Supersaturation appeared to be responsible for high substrate concentrations in solution only at ligand concentrations above ~0.065 M. At ligand concentrations below ~0.065 M, the concentration of hexamethylmelamine species did not change as a function of time from ~1 to 7 days, although the substrate concentrations were significantly higher than those at the plateau region. While these studies at pH 3.5 did not elucidate the causes for the sharp changes in substrate concentrations observed at pH 3.5 and 4.0, such variations may be due to small changes in the pH values of the solutions resulting from the precipitation of the complex (as exemplified in Table I and discussed in *Experimental*).

Analytical data for the solid precipitates isolated at pH 3.5 and 4.0 (Table III) strongly indicated that a 1:1:1 gentisic acid–hexamethylmelammonium-ion–gentisate-ion complex was the solid phase in both cases. A plot of the concentration of the ligand added *versus* the ligand in solution (17) verified the 1:2 ratio between gentisic acid species and hexamethylmelamine species.

An interesting observation was made during isolation of this 1:1:1 complex. When the complex was isolated from a sample containing 0.1% sodium bisulfite, the solid complex had a pronounced yellow color. However, if retardation of oxidation was accomplished by expelling the molecular oxygen by bubbling nitrogen gas through the solution, the solid complex obtained was almost white. In both cases, the solutions themselves were colorless. Analysis of the complexes obtained under the different conditions did not show any significant differences in the chemical composition, and the reason for difference in color of the solids has not been explained (Table III).

Estimation of Stability Constants—To use the data obtained for descriptive and predictive purposes, attempts were made to define the formation of complexes and the corresponding increase in the apparent solubility of hexamethylmelamine at different pH values in terms of stability constants.

Since no complexation appeared to occur between free hexamethylmelamine and gentisate ion, as indicated by the studies at pH ≥ 7, only complexes between the hexamethylmelammonium ion and gentisic acid and/or gentisate were considered. At pH 5.0, only a very small fraction of the total gentisate added was present as gentisic acid. The distinct curvature of the solubility diagram indicates formation of complexes of higher order with respect to the gentisate ion. The assumption was made that the increase in apparent solubility of hexamethylmelamine was due mainly to the formation of two complexes, ($HMH^+ \cdot G^-$) and [$HMH^+ \cdot (G^-)_2$][7]. The stability constants for each complex, expressed in terms of the concentration of the various species, are given by Eqs. 2 and 3:

$$K_1 = \frac{[HMH^+ \cdot G^-]}{[HMH^+][G^-]} \qquad \text{(Eq. 2)}$$

$$K_2 = \frac{[HMH^+ \cdot (G^-)_2]}{[HMH^+ \cdot G^-][G^-]} \qquad \text{(Eq. 3)}$$

Calculations (8) made on the basis of these equations did not adequately describe the results obtained in the pH 3.5–5.0 range. Although not isolated at pH 4.5 and 5.0, the solid complex found at pH 3.5 and 4.0 having the composition ($GH \cdot HMH^+ \cdot G^-$) was expected also to be involved in the equilibrium at pH 4.5 and 5.0. Therefore, a stability constant, K_3, was included and may be defined as:

$$K_3 = \frac{[GH \cdot HMH^+ \cdot G^-]}{[HMH^+ \cdot G^-][GH]} \qquad \text{(Eq. 4)}$$

However, calculations based on the involvement of the three complexes defined in terms of K_1, K_2, and K_3 still did not correlate well with the experimental data. Therefore, it was necessary to consider other equilibria to fit the data.

If it is assumed that in highly acidic solvents, the increased solubility seen at low concentrations of ligands (Fig. 1) was primarily due to formation of a 2:1 complex, [$(GH)_2 \cdot HMH^+$], and if it is also assumed that the 2:1 complex forms by association of a 1:1 complex and excess ligand, it is necessary to consider two additional complexes, ($HMH^+ \cdot GH$) and [$HMH^+ \cdot (GH)_2$]. The stability constants for these species may be defined as:

$$K_4 = \frac{[HMH^+ \cdot GH]}{[HMH^+][GH]} \qquad \text{(Eq. 5)}$$

and:

$$K_5 = \frac{[HMH^+ \cdot (GH)_2]}{[HMH^+ \cdot GH][GH]} \qquad \text{(Eq. 6)}$$

The mass balance equations are:

$$[HM]_t = [HM] + [HMH^+] + [HMH^+ \cdot G^-] + [HMH^+ \cdot (G^-)_2] + [GH \cdot HMH^+ \cdot G^-] + [HMH^+ \cdot GH] + [HMH^+ \cdot (GH)_2] \qquad \text{(Eq. 7)}$$

[7] HM = hexamethylmelamine, HMH^+ = hexamethylmelammonium ion, GH = gentisic acid, and G^- = gentisate ion.

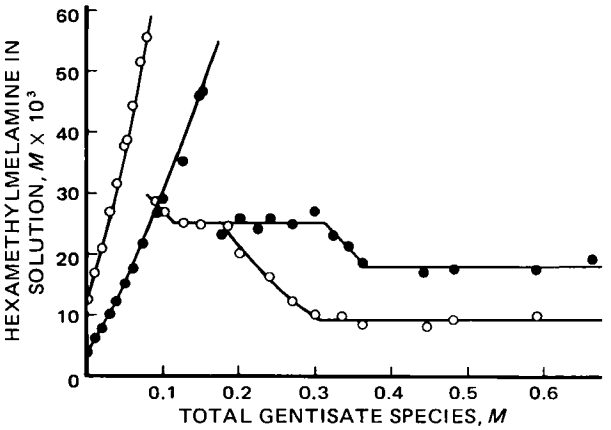

Figure 2—*Solubility of hexamethylmelamine in aqueous solution at pH 3.5 (○) and pH 4.0 (●) at 25° as a function of gentisic acid species added. The ascending part of the curves are calculated from Eq. 7.*

and:

$$[GH]_t = [GH] + [G^-] + [HMH^+ \cdot G^-] + 2[HMH^+ \cdot (G^-)_2] + 2[GH \cdot HMH^+ \cdot G^-] + [HMH^+ \cdot GH] + 2[HMH^+ \cdot (GH)_2] \qquad \text{(Eq. 8)}$$

where $[HM]_t$ is the total concentration of hexamethylmelamine species, and $[GH]_t$ is the total concentration of gentisate species added.

The concentration of uncomplexed hexamethylmelamine species is calculated (18) from:

$$[HM] + [HMH^+] = [HM]_0\left(1 + \frac{(H^+)}{K_{aM}}\right) \qquad \text{(Eq. 9)}$$

where $[HM]_0$ is the solubility of hexamethylmelamine at each particular ionic strength (Table II).

In all calculations, corrections were made for the effect of ionic strength on the solubility of hexamethylmelamine and the values of pK_{aM} and pK_{aG}.

The reportedly (11) weak binding between gentisic acid and gentisate ion was not taken into account, since calculations showed it to have no significant influence (≤5%) on the stability constants reported here.

Estimates of the values of K_1 and K_2 were obtained based on the reasonable assumption that only negligible amounts of gentisic

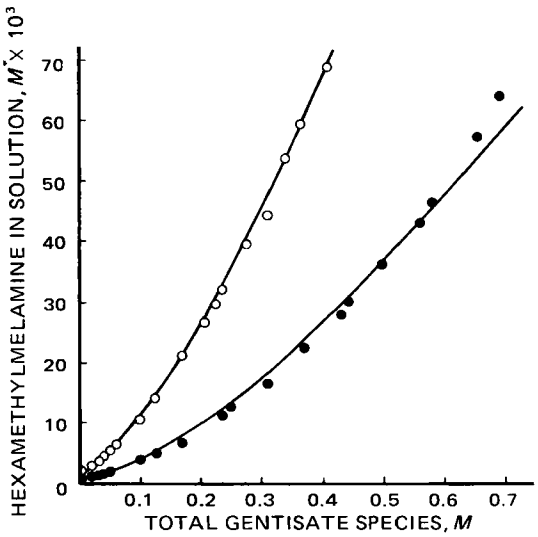

Figure 3—*Solubility of hexamethylmelamine in aqueous solution at pH 4.5 (○) and pH 5.0 (●) at 25° as a function of gentisic acid species added. The solid curves are calculated from Eq. 7.*

Table III—Results of Analysis of Some Solid Hexamethylmelamine–Gentisic Acid Complexes

Complex Isolated at	Melting Point	Ratio HM/GH[a]	Acidic Equivalent Weight[b]	Alkaline Equivalent Weight[c]	Elemental Analysis, %		
					C	H	N
pH 3.5[d]	134–135°	1:2.02	258	515	53.21	5.87	16.36
pH 4.0[d]	134–135°	1:2.09	259	512	53.43	5.77	16.54
pH 4.0[e]	130–134°	1:2.09	257	512	53.63	5.88	16.53
Theoretical[f]	—	1:2.00	259	518	53.58	5.83	16.21

[a] The ratio of hexamethylmelamine (HM) species to total gentisic acid (GH) species was determined by UV spectrophotometry. [b] Determined by titration with 0.5 *N* sodium hydroxide. [c] Determined by titration with 0.01 *N* perchloric acid in acetic acid. [d] Solution contained 0.1% sodium bisulfite. [e] Solution was flushed with nitrogen. [f] Calculated for a 1:1:1 gentisic acid–hexamethylmelammonium ion–gentisate-ion complex.

acid were present at pH 5.0. The values obtained for K_1 and K_2, as calculated by a previously described method (8), were 48 and 7.3 M^{-1}, respectively.

To calculate $[HM]_t$ from Eq. 6, the free ligand concentration, $[G^-]$, must be known. By combining Eqs. 2–6 and 8 and solving for $[G^-]$, Eq. 10 was obtained:

$$[G^-] = [-\alpha + (\alpha^2 + 8[GH]_t\beta)^{1/2}]/4\beta \quad \text{(Eq. 10)}$$

where:

$$\alpha = 1 + K_1[HMH^+] + [H^+](1 + K_4[HMH^+])/K_{aG} \quad \text{(Eq. 11)}$$

and:

$$\beta = K_1K_2[HMH^+] + [H^+][HMH^+](K_1K_3 + K_4K_5[H^+]/K_{aG})/K_{aG} \quad \text{(Eq. 12)}$$

By using the values of K_1 and K_2 already mentioned and varying the values of K_3, K_4, and K_5, values of $[HM]_t$ that best fit the experimental results were calculated[8]. Values of $K_3 = 150\ M^{-1}$, $K_4 = 200\ M^{-1}$, and $K_5 = 50\ M^{-1}$ gave a good correlation between the experimental points and the calculated curve (solid line) shown in Figs. 2 and 3. Only the curve related to pH 5.0 shows a significant deviation between the calculated curve and the experimental results, particularly at ligand concentrations above 0.6 *M*. The deviation probably was due to formation of other soluble complexes of higher order in gentisic acid or gentisate ion than those considered.

The relatively large number of stability constants considered here should be regarded only as empirical parameters that adequately describe the observed increase in the apparent solubility of hexamethylmelamine in the presence of gentisic acid in the pH 3.5–5.0 range. They should not be interpreted as evidence that all such postulated associations actually occur or that other complexes do not exist.

The fact that the hexamethylmelammonium ion associated strongly with the gentisate ion while the corresponding base apparently does not appear to associate is attributed to the difference in resonance structure occurring when the triazine ring is protonated. In the case of gentisic acid and gentisate ion, however, the charge on the gentisate ion is not conjugated with the aromatic ring and no great change in the charge distribution of the aromatic binding site would be expected. Therefore, it seems reasonable that both gentisic acid and gentisate ion would form complexes with hexamethylmelammonium ion as observed.

The importance of a charge transfer reaction between hexamethylmelamine cation and gentisate anion is probably negligible, since such interactions may occur only to a very small extent between organic species in aqueous solution (19).

If plane-to-plane orientation occurs, as has been suggested in the case of 1:1 complexes (19, 20), it seems reasonable to assume that the solid complex isolated at pH 3.5 and 4.0 has a gentisate-ion molecule and a gentisic acid molecule on either side of the hexamethylmelammonium ion. Since this complex is electrically neutral, it is not unreasonable that the solubility of this particular species would be relatively low and precipitation could be expected.

Formulation—From the data discussed, it is apparent that the interactions between the various gentisic acid and hexamethylmelamine species are somewhat complex and highly dependent on pH and system composition. However, the use of gentisic acid species as a ligand clearly resulted in increases in the apparent solubility of hexamethylmelamine. Such increases range from approximately fivefold at pH 3.5 to at least approximately 90-fold at pH 5.0. Thus, physically stable solutions with concentrations of ≥5 mg of hexamethylmelamine/ml can be prepared at pH ≥ 3.5.

Solutions containing 5 mg/ml of drug (pH 3.5; gentisic acid, 6 mg/ml) and 10 mg/ml of drug (pH 4.5; gentisic acid, 54 mg/ml) were prepared and lyophilized[9]. Such preparations were readily reconstituted and appeared to be suitable for use in the clinical testing of hexamethylmelamine. Lyophilization of the solutions was considered desirable to avoid the possible oxidation of gentisic acid species in aqueous solution. In the pH 3.5 preparation, about one-half of the amount of hexamethylmelamine was present as a complex; in the pH 4.5 preparation, more than 95% of the drug was complexed.

The systems described in Figs. 2 and 3 allow for appreciable choice in the composition of a formulation. However, if one chooses a high pH value, the formulation will necessarily require greater concentrations of gentisate species to obtain a given dose of hexamethylmelamine.

Upon administration of such described parenteral solutions, a very rapid release of hexamethylmelamine will occur due to dilution of the sample as well as change in pH to a value of ~7.4 at which no complexation occurs.

SUMMARY AND CONCLUSIONS

The present study demonstrated the practical use of complexation in the formulation of the cytotoxic agent, hexamethylmelamine, as a product potentially suitable for intravenous use. Where the desired objectives of the formulation can be realized through the use of complexation, it is a very useful and attractive method, particularly where a reversible alteration of the physical and/or chemical properties of a drug substance is desired to improve drug delivery. Since complexation is a reversible phenomenon and the equilibrium is shifted by concentration changes, it is obvious that upon dissolution of a solid complex or dilution of a solution containing complexed species, the complexed molecules will dissociate and provide rapid release of the free drug. In view of these rather unusual drug delivery advantages, complexation may well be included when defining prodrug approaches.

However, the application of complexation to the solubilization of drugs is somewhat limited, since complexation between organic molecules generally results in apparent solubility increases of only an order of magnitude or less and this increase is often not sufficient. Another important problem is that it is often difficult to identify suitable ligands which will associate appreciably with the given substrate.

Amino Acid Analogs III: New Syntheses of Monomethyl- and Monophenylglutamic Acids

HERMAN GERSHON ˣ, RAULO PARMEGIANI, VINCENT R. GIANNASIO, and IRA S. KRULL

Abstract □ Glutamic acid analogs containing 3- and 4-methyl and 2-, 3-, and 4-phenyl substituents were prepared. The 3- and 4-methyl- and 3- and 4-phenylglutamic acids did not inhibit *Plasmodium berghei* and were nontoxic to the host (mice) at 640 mg/kg. The five analogs in addition to 2-methylglutamic acid were inactive against *Lactobacillus casei* at 1000 μg/ml in a defined medium; against *Escherichia coli*, only 2-methylglutamic acid caused 27% inhibition at 10,000 μg/ml. All six analogs failed to inhibit *Aspergillus niger, Aspergillus oryzae, Trichoderma viride*, and *Myrothecium verrucaria* in a defined medium below 10,000 μg/ml.

Keyphrases □ Glutamic acid analogs—syntheses, inhibition of plasmodia, bacteria, and fungi, toxicity in mice, potential antimalarial activity □ Antimalarial agents, potential—syntheses of methyl- and phenylglutamic acids

As a result of an interest in synthesizing potential antimalarial agents, it became necessary to prepare quantities of 3- and 4-methyl- and 3- and 4-phenylglutamic acids. The four glutamic acid analogs were reported previously (1–4).

DISCUSSION

3-Methylglutamic acid (IIIa) was obtained by reacting crotonaldehyde with ethyl acetamidomalonate by means of a Michael condensation, followed by oxidation of the aldehyde function (I) with permanganate and hydrolysis of the oxidation product (II) with acid. The preparation of 4-methylglutamic acid (IIIb) was based on condensing methacrolein with ethyl acetamidomalonate, oxidizing, and hydrolyzing the products, as for 3-methylglutamic acid. 3-Phenylglutamic acid (IIIc) was obtained in a similar manner, by a Michael condensation of cinnamaldehyde with ethyl acetamidomalonate followed by oxidation and hydrolysis.

For the preparation of 4-phenylglutamic acid (V), tropic acid was made into the acid chloride by means of thionyl chloride which, in turn, was esterified with ethanol. Ethyl tropate was subsequently converted to ethyl 3-bromo-2-phenylpropionate with phosphorus tribromide, and the bromo compound was condensed with ethyl acetamidomalonate. Upon hydrolysis of the condensation product with acid, 4-phenylglutamic acid was obtained. Scheme I indicates the preparation of IIIa–IIIc, and Scheme II indicates the preparation of V.

Since it was desired to carry out microbiological and other testing on the three monomethyl- and three monophenylglutamic acids, 2-methyl- and 2-phenylglutamic acids were also required. The synthesis of 2-phenylglutamic acid was reported previously, but it cyclized spontaneously to 2-phenylpyroglutamic acid (5). For the present study, benzoylpropionic acid was treated with ammonium carbonate and potassium cyanide, according to the method of Henze and Speer (6), to form the hydantoin (VI). Compound VI was hydrolyzed to 2-phenylglutamic acid (VII) by successive treatments with sodium hydroxide and hydrochloric acid (Scheme III). This preparation of 2-phenylglutamic acid did not cyclize spontaneously at room temperature. 2-Methylglutamic acid was commercially available. IR spectra of the six glutamic acid analogs appear in Figs. 1 and 2.

3-Methyl-, 4-methyl-, 3-phenyl-, and 4-phenylglutamic acids were screened against *Plasmodium berghei* in mice[1]. These com-

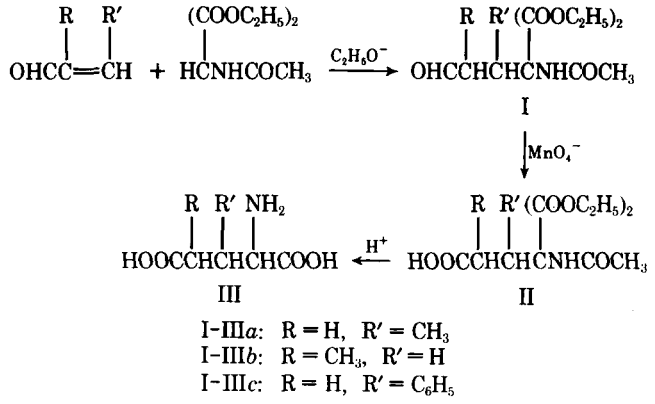
3-Methyl-, 4-methyl-, 3-phenyl-, and 4-phenylglutamic acids were screened against *Plasmodium berghei* in mice[1]. These com-

[1] Testing done at the Rane Laboratory, University of Miami, Miami, Fla.



Scheme I

pounds at 640 mg/kg, the highest level administered, were both inactive to the *Plasmodium* and nontoxic to the host.

Since the bacterial cell wall of many species is known to contain D-glutamic acid (7–9), it was of interest to determine whether the substituted glutamic acids would inhibit bacterial growth, presumably by preventing the incorporation of D-glutamic acid into the bacterial wall. It was previously reported that when *Lactobacillus plantarum*, a glutamic acid-requiring mutant, was grown in a medium containing sufficient L-glutamic acid to afford half-maximal growth and the three monomethylglutamic acids were incorporated into the medium individually up to a molar ratio of 186:1, only 4-methylglutamic acid caused any inhibition of growth (10%) (10).

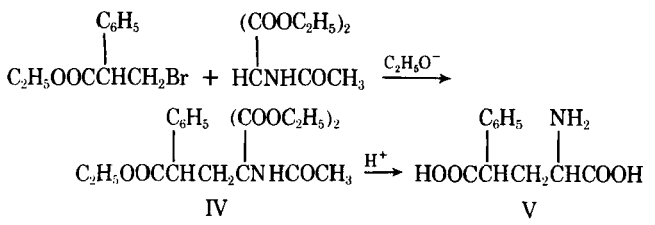
A test of the compounds against *Lactobacillus casei* (ATCC 9595), a second glutamic acid-requiring mutant, was carried out. Glutamic acid assay medium[2] enriched with 20 μg/ml of L-glutamic acid hydrochloride, allowed 85% of the optimal growth. No inhibition of the organism was observed when 1000 μg/ml of each of the six glutamic acid analogs was added to the assay medium. All six glutamic acid analogs were tested against *Escherichia coli* (ATCC 9723) in the medium of Davis and Mingioli (11). Only 2-methylglutamic acid inhibited the growth of the organism (27%) at a level of 10,000 μg/ml. All of these glutamic acid analogs also failed to inhibit four fungi, *Aspergillus niger* (ATCC 6275), *Aspergillus oryzae* (ATCC 1101), *Trichoderma viride* (ATCC 8678), and *Myrothecium verrucaria* (ATCC 9095), in Czapek–Dox agar[2] at pH 5.6 and 7.0 at 10,000 μg/ml, the highest level tested.

EXPERIMENTAL[3]

Ethyl 2-Acetamido-2-carbethoxy-3-methyl-5-oxovalerate (Ia)—This compound was prepared as reported previously (12), yielding 95%, mp 91–92°. An analytical sample was crystallized from ethanol, mp 95° [lit. (12) mp 88–89°].

Anal.—Calc. for $C_{13}H_{21}NO_6$: C, 54.35; H, 7.37; N, 4.88. Found: C, 54.15; H, 7.42; N, 4.90.

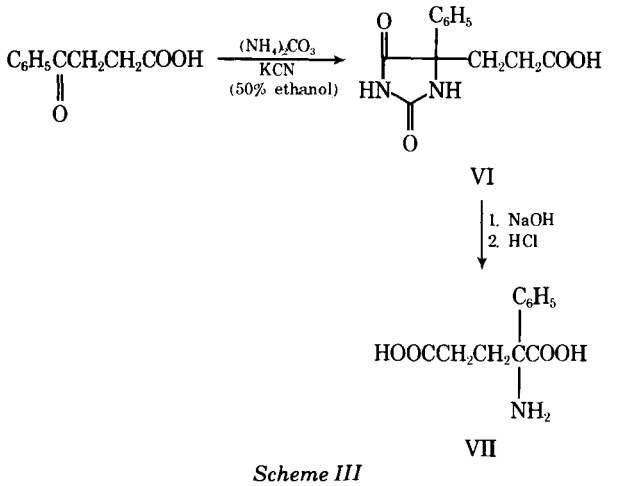
Ethyl 2-Acetamido-2-carbethoxy-3-methylglutarate (IIa)—Compound Ia (28.8 g, 0.1 mole) was dissolved in 380 ml of water at 70–75°. Potassium permanganate (22.5 g, 0.14 mole), dissolved in 450 ml of water, was added over 2 hr. The mixture was stirred for an additional 2 hr at 70–75°. The manganese dioxide was removed



Scheme II

[2] Difco.

[3] Melting points were taken in a Thomas-Hoover melting-point apparatus and are uncorrected. IR spectra were obtained with a Perkin-Elmer model 221 spectrophotometer. 3-Benzoylpropionic acid, tropic acid, and 2-methylglutamic acid were obtained commercially



Scheme III

by filtration, and the filtrate was decolorized with a small quantity of sodium thiosulfate and refiltered. After acidification with dilute sulfuric acid, the solution was extracted with 5 × 100 ml of methylene chloride. The combined washings were backwashed with 50 ml of water and dried (sodium sulfate). The solid obtained upon evaporation of the solvent was crystallized from ether, yielding 15.5 g (56%), mp 100–103°. An analytical sample was crystallized from ether, mp 102–103°.

Anal.—Calc. for $C_{13}H_{21}NO_7$: C, 51.48; H, 6.98; N, 4.62. Found: C, 51.65; H, 7.12; N, 4.53.

DL-3-Methyl-DL-glutamic Acid (IIIa)—Compound IIa (28.4 g, 0.1 mole) was heated under reflux with 285 ml of concentrated hydrochloric acid overnight. The excess acid was removed by flash evaporation, and the syrupy residue was diluted to 50 ml with water and adjusted to pH 3.2 with pyridine. Three volumes of ethanol was added to the solution, and the mixture was refrigerated at −10° overnight. The product was removed by filtration, washed with ethanol, and dried at 70° overnight, yielding 12.1 g (75%), mp 164° dec. [lit. (1) mp 164° dec.].

Ethyl 2-Acetamido-2-carbethoxy-4-methyl-5-oxovalerate (Ib)—Compound Ib was prepared from methacrolein (technical grade contained 90% methacrolein and 10% acetic acid) and ethyl acetamidomalonate (12), and additional sodium was used to neutralize the acetic acid. The ethanol solution was evaporated to near dryness in a rotary evaporator, and the residue was dissolved in chloroform, washed free of salts (water), dried (sodium sulfate), and taken to dryness in the evaporator. The product was obtained as a syrup in 98% yield (12). An analytical sample was prepared by drying under vacuum overnight.

Anal.—Calc. for $C_{13}H_{21}NO_6$: C, 54.35; H, 7.37; N, 4.88. Found: C, 54.06; H, 7.31; N, 4.95.

Ethyl 2-Acetamido-2-carbethoxy-4-methylglutarate (IIb)—Compound IIb was prepared from the aldehyde by oxidation with potassium permanganate in the same manner as IIa. The yield was 43%, mp 121.5–122.5°. An analytical sample was crystallized from ether, mp 125.5–126°.

Anal.—Calc. for $C_{13}H_{21}NO_7$: C, 51.48; H, 6.98; N, 4.62. Found: C, 51.68; H, 6.75; N, 4.72.

DL-4-Methyl-DL-glutamic Acid (IIIb)—Compound IIIb was prepared by hydrolysis of IIb with concentrated hydrochloric acid in the same manner as IIIa. The yield was 66%, mp 152° dec. An analytical sample was crystallized from aqueous acetone, mp 160.5° dec. [lit. (13) mp 154–155°].

Anal.—Calc. for $C_6H_{11}NO_4$: C, 44.72; H, 6.88; N, 8.69. Found: C, 45.06; H, 6.83; N, 8.56.

Ethyl 2-Acetamido-2-carbethoxy-5-oxo-3-phenylvalerate (Ic)—Compound Ic was prepared from cinnamaldehyde and ethyl acetamidomalonate in the same manner as Ia. The yield was 84%, mp 95–96°. An analytical sample was crystallized from ethanol, mp 96.5–97.5°.

Anal.—Calc. for $C_{18}H_{23}NO_6$: C, 61.88; H, 6.64; N, 4.01. Found: C, 62.02; H, 6.62; N, 4.00.

Ethyl 2-Acetamido-2-carbethoxy-3-phenylglutarate (IIc)—Compound Ic was oxidized to IIc with potassium permanganate in the same manner as Ia, except that the product crystallized from the filtrate upon acidification. It was obtained by filtration,

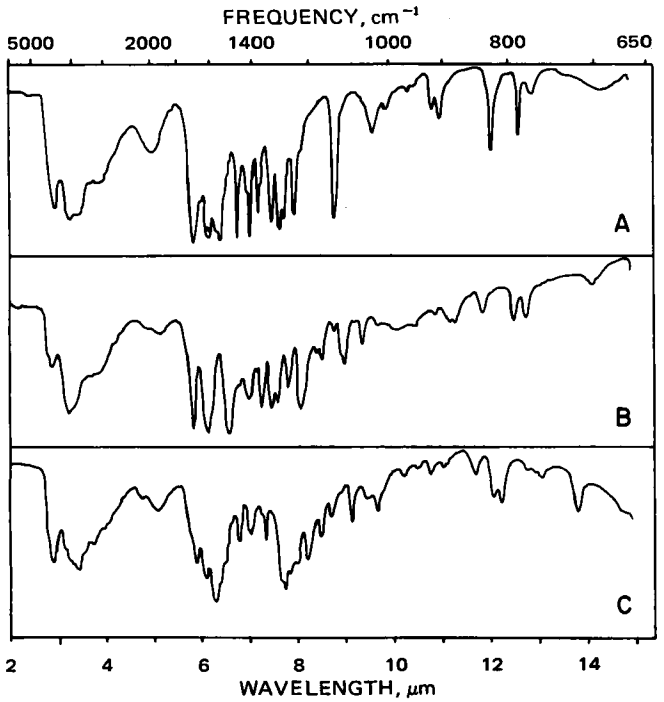


Figure 1—*IR spectra in KBr of DL-2-methylglutamic acid (A), DL-3-methyl-DL-glutamic acid (B), and DL-4-methyl-DL-glutamic acid (C).*

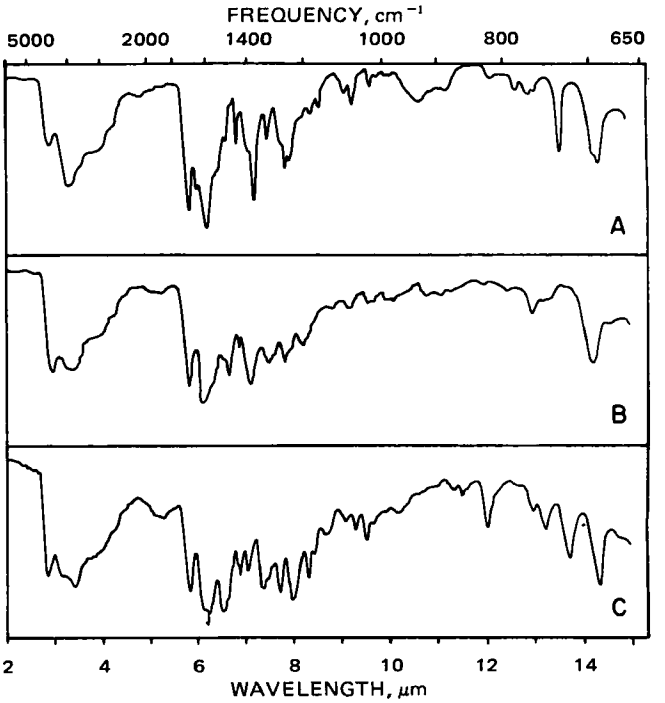

Figure 2—*IR spectra in KBr of DL-2-phenylglutamic acid (A), DL-3-phenyl-DL-glutamic acid (B), and DL-4-phenyl-DL-glutamic acid (C).*

washed free of salts with water, and dried at 70° overnight, mp 179–180° (56%). An analytical sample was crystallized from water, mp 180–180.5°.

Anal.—Calc. for $C_{18}H_{23}NO_7$: C, 59.17; H, 6.34; N, 3.83. Found: C, 59.33; H, 6.29; N, 3.87.

DL-3-Phenyl-DL-glutamic Acid (IIIc)—Compound IIIc was prepared by hydrolysis of IIc with concentrated hydrochloric acid in the same manner as IIIa. The yield was 89%, mp 179–180° dec. An analytical sample was crystallized from aqueous acetone, mp 187–189° dec. [lit. (3) mp 175° dec.].

Anal.—Calc. for $C_{11}H_{13}NO_4$: C, 59.19; H, 5.87; N, 6.27. Found: C, 59.59; H, 6.03; N, 6.01.

Ethyl Tropate—Tropic acid (500 g, 3.0 moles) was heated with thionyl chloride (1300 ml) under reflux with stirring and exclusion of moisture for 4 hr. The excess thionyl chloride was removed by flash evaporation, and the residue was heated with 2 liters of ethanol under reflux with stirring overnight. The alcohol was removed by flash evaporation, and the residue was distilled under vacuum. The yield of product was 524 g (90%), bp 120–124° (2 mm) [lit. (4) bp 152–154° (12 mm)].

Ethyl 3-Bromo-2-phenylpropionate—To ethyl tropate (194 g, 1.0 mole) in 200 ml of dry chloroform was added 100 g (0.36 mole) of phosphorus tribromide dropwise with stirring; the temperature was kept between −5 and 10°. The reaction mixture was stirred overnight and allowed to come to room temperature. It was again cooled to 0°, added slowly with stirring to a slurry of ice and water, extracted with chloroform, and washed twice with sodium bicarbonate followed by water. The chloroform layer was separated, dried (sodium sulfate), and freed of solvent by flash evaporation. The residue was distilled under vacuum, yielding 206 g (80%), bp 97–100° (0.5 mm) [lit. (4) bp 102° (0.5 mm)].

Ethyl 2-Acetamido-2-carbethoxy-4-phenylglutarate (IV)—To a solution of 4.5 g (0.196 g-atom) of sodium in 500 ml of anhydrous ethanol was added ethyl acetamidomalonate (42.5 g, 0.196 mole). A solution of ethyl 3-bromo-2-phenylpropionate (47.6 g, 0.196 mole) in 100 ml of dry ethanol was added dropwise with agitation. Upon completion of addition of the bromo compound, the mixture was kept under reflux with stirring overnight. The salts were removed by filtration, and the solvent was flash evaporated. The residue was dissolved in chloroform, washed twice (water), and dried (sodium sulfate). After evaporation of the solvent, the residue was dissolved in isopropanol and kept at −15° for several days. A yield of 67 g (85%) was obtained, mp 68–70°. An analytical sample was crystallized from isopropanol, mp 68.5–70° [lit. (4) mp 95°].

Anal.—Calc. for $C_{20}H_{27}NO_7$: C, 61.06; H, 6.92; N, 3.56. Found: C, 61.18; H, 6.91; N, 3.53.

DL-4-Phenyl-DL-glutamic Acid (V)—Compound IV (32.0 g, 0.081 mole) was heated under reflux in 320 ml of concentrated hydrochloric acid overnight, and excess acid was removed in a rotary evaporator. The residue was brought to pH 3.2 with pyridine and diluted with two volumes of ethanol. After refrigeration for several hours, the product was obtained by filtration, washed free of chloride with ethanol, and dried at 70° overnight. The yield of compound was 14.8 g (81%), mp 170–171° dec.

After recrystallization from aqueous acetone followed by vacuum drying at room temperature, the compound melted at 177–179° dec. Upon further heating, the material solidified and remelted at 203–204° (pyroacid). Additional recrystallizations yielded products of higher melting points. All possessed the same retention time by GC (trimethylsilyl derivative on 1% Apiezon column) [lit. (4) no melting point reported].

Anal.—Calc. for $C_{11}H_{13}NO_4$: C, 59.19; H, 5.87; N, 6.27. Found: C, 59.35; H, 5.61; N, 6.20.

5-Phenyl-5-(2-carboxyethyl)hydantoin (VI)—A solution of 3-benzoylpropionic acid (100 g, 0.56 mole), ammonium carbonate (215 g, 2.24 moles), and potassium cyanide (72.8 g, 1.12 moles) in 1400 ml of 50% aqueous ethanol was kept at 60° for 2 hr. After the solution was cooled in an ice bath for several hours, the product crystallized and was removed by filtration, washed with a small volume of cold water, and dried at 100° under vacuum overnight. The yield was 131 g (94%), mp 214–215°. An analytical sample was crystallized from water, mp 215.5–216.5°.

Anal.—Calc. for $C_{12}H_{12}N_2O_4$: C, 58.06; H, 4.87; N, 11.28; O, 25.78. Found: C, 57.98; H, 5.05; N, 11.12; O, 25.98.

DL-2-Phenylglutamic Acid (VII)—A solution of 10 g (0.04 mole) of VI and 2.5 g (0.06 mole) of sodium hydroxide in 100 ml of water was kept at 160° in a stainless steel bomb for 16 hr. The bomb was cooled, and the solution was removed and boiled for 5 min to remove free ammonia, brought to pH 4 with acetic acid, and again boiled for 5 min to remove carbon dioxide. It was then passed through an ion-exchange resin[4] column (acidic) to remove sodium ions.

[4] Amberlite IR-120.

The column was washed with 1500 ml of hot water, the effluent was brought to near dryness by flash evaporation, and the residue was heated under reflux for 2.5 hr with 50 ml of concentrated hydrochloric acid. The hydrochloric acid was removed in a rotary evaporator, and the residual solution was dissolved in a small volume of water, decolorized with carbon, and adjusted to pH 3.1 with pyridine; then three volumes of ethanol was added.

After cooling at −15° overnight, the crystalline product was removed by filtration, washed with ethanol followed by ether, and dried at 70° overnight. The yield was 4.3 g (48%), mp 162–164°. On further heating, the melt solidified and remelted at 202–203° (2-phenylpyroglutamic acid). The analytical sample was crystallized from aqueous ethanol, mp 166–167° [lit. (5) mp 170°]; with further heating, the melting point was 205–206° [lit. (5) mp 207°].

Anal.—Calc. for $C_{11}H_{14}NO_4$: C, 59.19; H, 5.87; N, 6.27; O, 28.67. Found: C, 59.36; H, 5.95; N, 6.14; O, 28.89.

Inhibitory Effect of Dioctyl Sodium Sulfosuccinate on Trypsin Activity

GURCHARAN S. JODHKA, M. WAFIK GOUDA [x], RUSTEM S. MEDORA, and SAID A. KHALIL [x]

Abstract □ The inhibitory effect of dioctyl sodium sulfosuccinate on the proteolytic activity of trypsin was investigated over the pH 6–8 range. The antitryptic activity was determined using two different substrates: casein and *N*,α-benzoyl-DL-arginine-*p*-nitroanilide hydrochloride. The mechanistic studies revealed the substrate–inhibitor interaction to be the overall major mechanism of inhibition. This interaction was shown to involve substrate depletion, probably involving some primary sites of the natural substrate casein. Some inhibition was also shown to be due to an interaction between the enzyme and the inhibitor molecules. The interactions of the inhibitor with the enzyme and the substrate were irreversible. The possible therapeutic significance of the inhibitory effect of the surfactant is discussed.

Keyphrases □ Dioctyl sodium sulfosuccinate—trypsin inhibition, pH 6–8, two different substrates, therapeutic significance □ Trypsin—inhibition by dioctyl sodium sulfosuccinate, pH 6–8, two different substrates, therapeutic significance □ Enzyme inhibition—trypsin by dioctyl sodium sulfosuccinate, pH 6–8, two different substrates, therapeutic significance

The theories on the role of proteolytic enzymes in physiological and pathological states in humans and animals have been the topic of great controversy. The old belief that these enzymes catalyze protein synthesis no longer exists, yet it would be equally unjustified to restrict the role of body proteinases to a few processes such as cleavage of food proteins, mobilization of tissue proteins, and protein degradation usually associated with physiological wear and various traumas. In fact, it is now evident that these enzymes play a causative or adjunctive role in some disease processes such as inflammation, thromboembolic disorders, complement-dependent immune reactions, peptic and duodenal ulcers, and pancreatitis and even in some syndromes of malignant carcinomas (1).

Trypsin and kallikrein, which are present in the body tissues and fluids, are capable of releasing pharmacologically active plasma kinins (2). These proteolytic enzymes play an indirect but significant role in such important conditions as hypertension, shock, certain pains, changed capillary permeability, edema, and leucocyte migration. In the light of this knowledge, the proteinase inhibitors, both synthetic and natural, have gained new theoretical and practical importance (3). Recent attempts have been made to synthesize some active-site-oriented inhibitors as well as to improve their inhibitory activity (4–6). Also, it is reported that proteolytic enzymes are inhibited by agents such as sodium lauryl sulfate (7) and some sulfated polysaccharides (8).

Dioctyl sodium sulfosuccinate is an anionic surfactant, widely used medicinally as a fecal softener. The effect of this surfactant on drug absorption through membranes of varying complexities has been re-

The theories on the role of proteolytic enzymes in physiological and pathological states in humans and animals have been the topic of great controversy. The old belief that these enzymes catalyze protein synthesis no longer exists, yet it would be equally unjustified to restrict the role of body proteinases to a few processes such as cleavage of food proteins, mobilization of tissue proteins, and protein degradation usually associated with physiological wear and various traumas. In fact, it is now evident that these enzymes play a causative or adjunctive role in some disease processes such as inflammation, thromboembolic disorders, complement-dependent immune reactions, peptic and duodenal ulcers, and pancreatitis and even in some syndromes of malignant carcinomas (1).

Trypsin and kallikrein, which are present in the body tissues and fluids, are capable of releasing pharmacologically active plasma kinins (2). These proteolytic enzymes play an indirect but significant role in such important conditions as hypertension, shock, certain pains, changed capillary permeability, edema, and leucocyte migration. In the light of this knowledge, the proteinase inhibitors, both synthetic and natural, have gained new theoretical and practical importance (3). Recent attempts have been made to synthesize some active-site-oriented inhibitors as well as to improve their inhibitory activity (4–6). Also, it is reported that proteolytic enzymes are inhibited by agents such as sodium lauryl sulfate (7) and some sulfated polysaccharides (8).

Dioctyl sodium sulfosuccinate is an anionic surfactant, widely used medicinally as a fecal softener. The effect of this surfactant on drug absorption through membranes of varying complexities has been re-

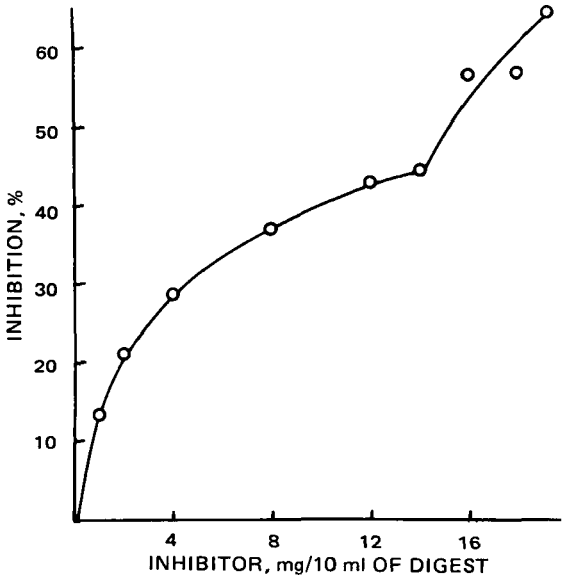

Figure 1—*Effect of various inhibitor concentrations on the percentage inhibition at pH 7.6. Ten milliliters of digest contained 10 μg of enzyme and 50 mg of substrate.*

ported (9–11), as has the absorption of dioctyl sodium sulfosuccinate into the systemic circulation (12). These findings and the similarity of the chemical nature of this surfactant to some proteolytic inhibitors such as sodium lauryl sulfate and sulfated polysaccharides led to this investigation of the inhibitory effect of dioctyl sodium sulfosuccinate on tryptic activity.

EXPERIMENTAL

Materials—Trypsin[1], casein[2], *N*,α-benzoyl-DL-arginine-*p*-nitroanilide hydrochloride[3], dioctyl sodium sulfosuccinate[4], and tromethamine[5] were obtained commercially. All other chemicals used were either USP or reagent grade.

Methods for Antitryptic Activity—*Method I*—Sørensen phosphate buffers (0.1 *M*) of various pH values were used. A fresh 1% casein (I) solution was prepared by suspending 1.0 g of casein in 100 ml of buffer and heating the suspension in a boiling water bath for 15 min. Enzyme (II) solutions of various concentrations, ranging between 10 and 50 μg/ml, were prepared by first dissolving 10 mg of trypsin in 10 ml of 0.001 *M* HCl and then diluting with the appropriate buffers. Various inhibitor (III) solutions were prepared by dissolving required amounts of the inhibitor in the buffers at the appropriate pH.

The assay was carried out using a modification of Kunitz's procedure (13). All solutions were freshly prepared and mixed at room temperature before incubation. The final volume of the digestion mixture was kept at 10 ml in all cases. In this method, two different mixing procedures were followed.

In one mixing procedure, inhibitor was added to the enzyme before digestion. One milliliter of enzyme solution was pipetted into flasks followed by 1 ml of the inhibitor solution. Five milliliters of the substrate solution was then added to each flask at 30-sec intervals. All flasks were incubated in a water bath metabolic shaker[6] maintained at 37° for 1 hr. Samples were shaken at 200 rpm throughout the digestion period. At the end of the incubation period, 3 ml of 10% trichloroacetic acid was added to each flask, in the same order, and the flasks were allowed to stand at room temperature for 10 min. Blanks were prepared in the same way as samples except that the casein solution was added after the addition of trichloroacetic acid.

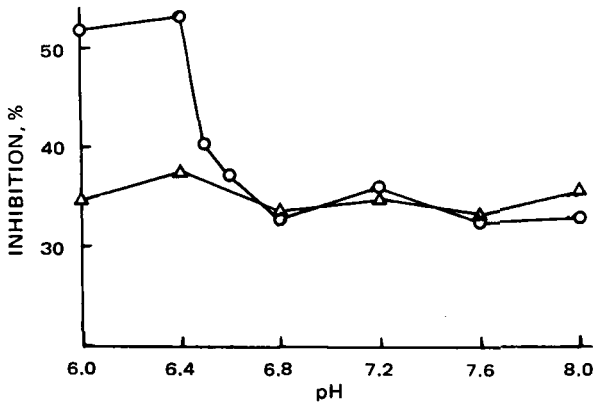

Figure 2—*Effect of pH and mixing orders on percentage inhibition. Ten milliliters of digest contained 20 μg of enzyme, 50 mg of substrate, and 10 mg of inhibitor. Key: O, inhibitor added to enzyme first; and Δ, inhibitor added to substrate first.*

Both samples and blanks were then centrifuged[7] at 8000 rpm for 20 min, and the supernates were filtered[8]. The absorbance of each filtrate was read[9] at 280 nm against the respective blank. Controls were run simultaneously for every inhibition experiment. The controls differed from the samples in having inhibitor solution replaced by equivalent amounts of buffers.

The absorbance values were used as measures of reaction velocities in the kinetic studies. The inhibition (i) equals $[1 - (v_i/v)]$, where v_i and v represent digestion velocities with and without the inhibitor, respectively. Percentage inhibition values were calculated from i values.

The other mixing procedure for digestion was the same as already described, except that the inhibitor solution was added to the substrate first and mixed, followed by addition of enzyme.

Method II—*N*,α-Benzoyl-DL-arginine-*p*-nitroanilide hydrochloride solution (10^{-3} *M*) was prepared as described by Erlanger *et al.* (14). Various concentrations of enzyme and inhibitor solu-

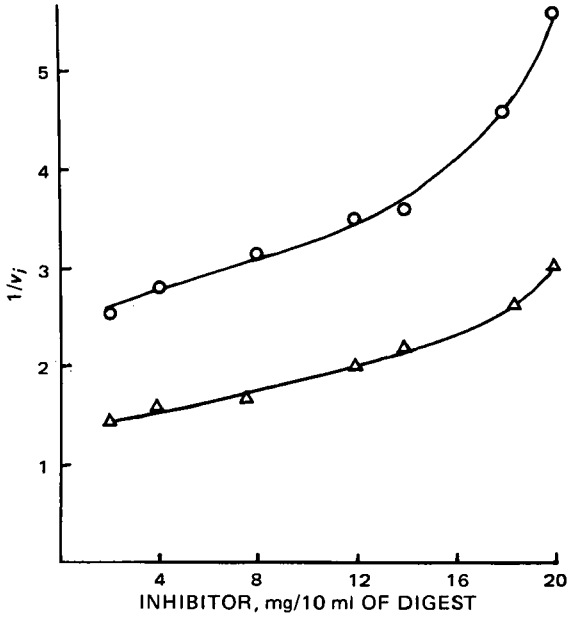

Figure 4—*Plots of $1/v_i$ against III for dioctyl sodium sulfosuccinate at pH 7.6. Key: O, 10 ml of digest contained 10 μg of enzyme and 50 mg of substrate; and Δ, 10 ml of digest contained 20 μg of enzyme and 50 mg of substrate.*

tions were prepared as described in Method I, except that the buffers used were 0.05 *M* tromethamine at various pH values. An amidase assay procedure was used with a few modifications (14). The final volume of the reaction mixture was 8 ml in each case. Incubation of the samples was done at 37° for 300 sec, and the reaction was stopped by adding 1 ml of 30% acetic acid to each flask.

All incubation mixtures were centrifuged and then filtered as described in Method I. Blanks and controls were prepared in the same manner as described in Method I. The absorbance of the filtrates of both samples and blanks was recorded[10] at 410 nm against distilled water. Differences between the absorbance of samples and blanks represent the proteolytic activity. Inhibition values (i) and the percentage inhibitions were calculated as already described. Different orders of mixing were carried out according to the two procedures used in Method I.

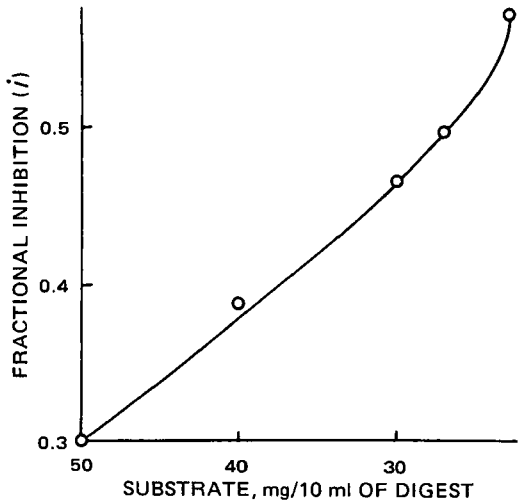

Figure 5—*Plot of* i *against I for dioctyl sodium sulfosuccinate at pH 7.6. Ten milliliters of digest contained 20 μg of enzyme and 10 mg of inhibitor.*

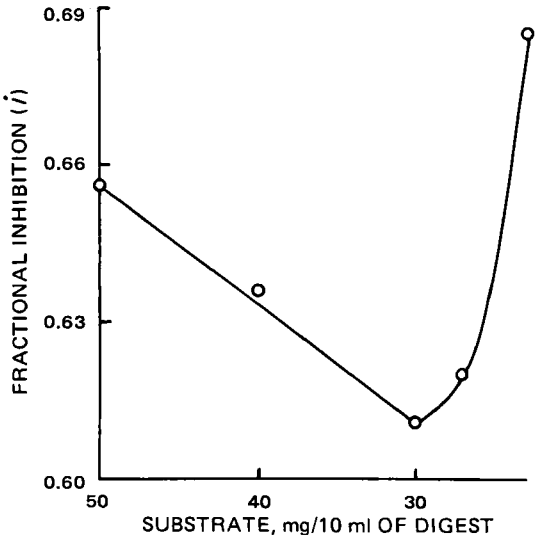

Figure 6—*Plot of* i *against I for dioctyl sodium sulfosuccinate at pH 6.4. Ten milliliters of digest contained 20 μg of enzyme and 10 mg of inhibitor.*

Preincubation Studies—In the preincubation studies the inhibitor was allowed to react for an additional 15 min either with the enzyme or with the substrate before digestion was started. The controls were also preincubated for the same period. Digestion was carried out according to both procedures described under *Method I*.

Dialysis Studies—To find out whether the interaction of inhibitor toward substrate and enzyme is reversible or irreversible, dialysis studies were carried out at pH 6.4 and 7.6. Regenerated cellulose dialysis tubings[11] were cut into pieces of 15–23 cm (6–9 in.) and thoroughly washed with distilled water. The tubings were then immersed in 500 ml of 10 m*M* edetate sodium solution and heated at 70–80° for 2 hr. Then the tubings were allowed to cool, washed again thoroughly with double-distilled water, and stored in distilled water at 2–4°. Prior to use, the tubings were soaked in an appropriate buffer for 18–24 hr.

The inhibitor was added to the enzyme or substrate, and the reaction was allowed to proceed at 37° for 60 min in a metabolic shaker at 200 rpm. A portion of the mixture was then assayed for tryptic activity using Method I, and the rest of the mixture was put in a preconditioned dialysis tubing sac. The sac was immersed in 1000 or 2000 ml of 0.1 *M* phosphate buffer of appropriate pH, and dialysis was carried out at 4° for 96 hr. The external buffer was replaced every 24 hr during the dialysis period, at the end of which the contents were again assayed for their tryptic activity. A control dialysis experiment was run simultaneously in the same way, except that the inhibitor solution was replaced by an equivalent amount of buffer solution. Percentage inhibition values before and after dialysis were calculated as already described.

All experiments were performed at least in duplicate.

RESULTS AND DISCUSSION

The inhibitory effect of dioctyl sodium sulfosuccinate on tryptic activity was studied at various inhibitor concentrations using Method I. Percentage inhibition was plotted against inhibitor concentration (Fig. 1). In all studies, the inhibitor was added to the enzyme first, except for the data of Fig. 2 in which case both mixing procedures were used. The biphasic plot in Fig. 1 can be explained as due to the saturation of either the enzyme or the substrate with the inhibitor at the point of inflection.

The effect of pH and mixing orders on the percentage inhibition was also studied using Method I (Fig. 2). Figure 2 shows that when the inhibitor was added to the substrate first, the percentage inhi-

[11] No. 20, 1.6 cm (0.62 in.) in flat width, for trypsin dialysis and No. 36, 2.85 cm (1.1 in.) in diameter, for casein dialysis were used. Average pore size was 24 Å. Van-Waters and Rogers, Inc., San Francisco, Calif.

Table I—Irreversible Binding of the Inhibitor to Enzyme and Substrate[a]

pH	Component Bound to the Inhibitor before Dialysis	Amount of the Components in 10 ml of Digestion Mixture			Inhibition, %	
		Enzyme, μg	Substrate, mg	Inhibitor, mg	Before Dialysis	After Dialysis
6.4	Trypsin	10	50	1.0	100.0	100.0
	Trypsin	10	50	0.1	65.0	57.5
	Trypsin	20	50	0.1	94.4	95.0
	Casein	20	50	10.0	42.0	38.0
7.6	Trypsin	10	50	1.0	65.6	67.6
	Casein	20	50	10.0	36.7	34.3

[a] Casein.

bition remained reasonably constant throughout the pH range studied. When the inhibitor was added to the enzyme first, the resulting percentage inhibition was significantly higher ($p < 0.001$ as determined by the Student t test for unpaired data) at pH <6.5. This marked difference in inhibition pattern below pH 6.5 will be discussed later.

Using casein as the substrate, double reciprocal plots in the presence of the inhibitor at both pH 6.4 and 7.6 (Fig. 3) and plots of $1/v_i$ against III at pH 7.6 (Fig. 4) indicate the substrate–inhibitor interaction as the major mechanism of inhibition (15). When using the data of Figs. 3 and 4, plots of I/v_i against I, v_i against v_i/I, and $1/i$ against 1/III also yielded curves typical of substrate–inhibitor interaction (16).

Plots of fractional inhibition (i) against I at pH 7.6 (Fig. 5) and 6.4 (Fig. 6), with the data of Fig. 3, suggest that the enzyme–inhibitor interaction as well as the substrate–inhibitor interaction also contributes to the overall inhibition. This contribution seems to be least at pH 7.6 (Fig. 5) and most at pH 6.4 (Fig. 6). This apparent increased involvement of the enzyme with the inhibitor as a consequence of a change in pH can be well explained by the fact that dioctyl sodium sulfosuccinate is a molecule carrying a net negative charge and that trypsin possesses an isoelectric point in the vicinity of pH 7 (17). Therefore, increased amount of inhibition below pH 6.5 is expected. This explains the increased inhibition below pH 6.5 observed in Fig. 2. Also, the biphasic curve of percentage inhibition against the inhibitor concentration (Fig. 1) can be explained on the basis of a dual mechanism of inhibition involving both the substrate and the enzyme.

A double reciprocal plot (Fig. 7) also was made using a synthetic substrate (Method II), and the mechanism of inhibition seems to be similar to the one observed when casein was used as the substrate. This similarity in mechanisms when two different substrates were used indicates that the interaction between the inhibitor and casein molecules involves some primary sites of the natural protein.

A general inhibitory mechanism involving a substrate can be further distinguished into three basic mechanisms by plotting III against $i/(1 - i)$ (18). These mechanisms are: (a) substrate depletion, (b) inhibition of the enzyme by a substrate–inhibitor complex, and (c) combination of both mechanisms. The shapes of such plots (Fig. 8) for dioctyl sodium sulfosuccinate at pH 7.6, using casein as a substrate, are typical of substrate depletion. Similar plots showing substrate depletion as the basic mechanism were also obtained using different substrate and enzyme concentrations. The results of the dialysis studies (Table I) indicate that dioctyl sodium sulfosuccinate binds both casein and trypsin irreversibly at both pH 6.4 and 7.6.

Preincubation studies (Table II) show that preincubation of the substrate with the inhibitor has no significant effect on the inhibition. Preincubation of the enzyme with the inhibitor prior to digestion seems to increase the percentage inhibition at almost all substrate–inhibitor ratios. These results suggest that, besides the substrate–inhibitor interaction, the enzyme–inhibitor interaction is a part of the overall mechanism of inhibition at pH 7.6. This finding is in good agreement with what has already been concluded from the mechanistic studies.

The effect of various mixing orders on percentage inhibition was also studied using the synthetic substrate. Results were similar to those obtained with casein.

The effect of various shaking rates was investigated using casein as the substrate. The degree of inhibition was unaltered at various shaking speeds ranging between 0 and 200 rpm.

Pancreatitis can be regarded as a chemical autolytic process, the pathogenesis of which is well documented from postmortem, operative, and experimental studies (19). The exact mechanism of the pathological process has yet to be established. However, evidence supports the central role of trypsin in the pathogenesis of the disease (1, 3, 20). It is then apparent that means of controlling the undesirable hypertryptic activity at the site of disease could serve as an approach to alleviate the disease. The present inhibitory studies with dioctyl sodium sulfosuccinate and the recent finding that this compound is absorbed into the systemic circulation (12) suggest a possible use of this medicinal surfactant in pancreatitis. The interaction of dioctyl sodium sulfosuccinate with casein

suggests the possibility of a similar interaction between the inhibitor molecule and the polysaccharide proteins at the site of inflammation. Such an interaction *in vivo* may prove to be useful in protecting the site from necrosis and erosion (21).

These inhibitory studies with dioctyl sodium sulfosuccinate also suggest that possible drug interactions may arise with this compound in situations and conditions where concomitant use of proteolytic enzymes such as trypsin and chymotrypsin is desirable. Drug interactions are also possible with drug esters such as penamecillin and chloramphenicol palmitate and certain *N*-acylated drugs when given orally along with dioctyl sodium sulfosuccinate. Such drugs are usually acted upon by proteinases in the GI tract resulting in changed chemical and/or pharmacological activity. These drug interactions may be difficult to recognize, particularly when dioctyl sodium sulfosuccinate is used as an excipient for the formulation of any drug being used simultaneously.

Determination of Mercury-Containing Pharmaceuticals by Vapor Phase Atomic Absorption Spectroscopy

RICHARD D. THOMPSON ˣ and TERRY J. HOFFMANN

Abstract □ A procedure was developed for the determination of mercurials of pharmaceutical interest. Protic acid cleavage of the compound was followed by reduction of the resulting mercuric ion and vapor phase atomic absorption spectroscopy. This procedure was applied to 11 different mercurial compounds in various pharmaceutical preparations and offers excellent sensitivity with respect to presently used compendial assays. Comparative analytical data between this procedure and compendial methodology are presented.

Keyphrases □ Mercurials—determination by vapor phase atomic absorption spectroscopy, compared to compendial methods □ Atomic absorption spectroscopy, vapor phase—determination, mercury-containing pharmaceuticals, compared to compendial methods

Pharmaceutical compounds containing the element mercury, either organically combined or as the inorganic form, have found widespread medicinal use as diuretics, anti-infectives, and bacteriostatic agents. Mercury-containing pharmaceuticals have been analyzed by numerous analytical approaches. Many presently used procedures (1–3) involve conversion of mercurial mercury to mercuric ion followed by classical thiocyanate titrimetry or precipitation of the insoluble mercuric sulfide and gravimetric measurement. Theimer and Arnow (4) applied the thiocyanate titration procedure to injectable organomercurial diuretics.

A titration procedure similar in sensitivity to the official methods involves the acetolysis of the compound in the presence of methylamine hydrochloride followed by nonaqueous titration of the liberated strong base with perchloric acid (5). A more sensitive and convenient approach, utilizing coulometric titration of mercuric ion with electrogenerated sulfhydryl reagent, was developed (6) and applied to marketed dosage forms. Mercaptomerin sodium, which contains a mercury–sulfur bond, could not be analyzed by this method. However, the determination can be carried out in the presence of chloride ion, a species incompatible with both thiocyanate titration and acetolysis procedures.

Direct current polarography has been used to analyze thimerosal (7, 8). Unsubstituted phenylmercuric compounds and mersalyl and meralluride were investigated also (8).

More recently, several sensitive instrumental approaches have been used in mercurial compound analysis. The principle of isotopic exchange utilizing ^{203}Hg was employed in the determination of 13 different mercurials of pharmaceutical or agricultural interest, including three commercial preparations (9). Margosis and Tanner (10) applied neutron activation analysis to the determination of seven different organomercurial compounds, three in pharmaceutical dosage forms. Their results, obtained from the ^{197}Hg- and ^{203}Hg-induced radioactivity, were compared to those obtained by X-ray fluorescence and atomic absorption techniques. The X-ray fluorescence results generally were lower than those achieved with the neutron activation procedure; the atomic absorption results obtained by direct and vapor phase techniques, although incomplete, generally were higher. The poor correlation obtained with the vapor phase technique was attributed to the possible presence of volatile aromatic-type compounds.

The introduction of atomic absorption spectroscopy as a sensitive and specific means for metal analysis has resulted in numerous applications for the determination of mercury, primarily from the environmental impact of the presence of this element (11–13). To date, only a few studies have employed this approach in the analysis of mercury-containing pharmaceuticals. Leaton (14) described a direct atomic absorption procedure for mercuric iodide in ointments, and similar methodology for the direct analysis of phenylmercuric nitrate in ophthalmic preparations was proposed (15). More recently, vapor phase atomic absorption was applied to the analysis of mercurial bacteriostatic agents (16, 17), including phenylmercuric acetate, phenylmercuric nitrate, and thimerosal (17).

The purpose of this study was to determine the feasibility of vapor phase atomic absorption spectroscopy for the analysis of mercurial compounds of pharmaceutical interest and their commercial preparations. The described procedure is convenient, sensitive, and accurate with respect to the official methods.

EXPERIMENTAL

The developed procedure is based on "protodemercuration" of the mercurial compound with hydrochloric acid or a hydrochloric acid–nitric acid mixture under various heating conditions followed by reduction of the resulting mercuric ion to elemental mercury with subsequent detection and quantitation by vapor phase (*e.g.*, flameless, cold vapor) atomic absorption spectroscopy. The final determinative step is in accordance with the reduction procedure of Hatch and Ott (18) as modified by Munns and Holland (19).

Table I—Analysis of Mercurial Compounds[a]

Compound	Heating Condition[b]	Atomic Absorption Method		Official Method	
		Recovery, %	Range, %	Recovery, %	Range, %
Thimerosal	C	100.1	0.2	100.0[c]	0.0

[a] Mean of duplicate determinations. [b] See *Experimental*. [c] NF XIII. [d] NF XI. [e] USP XVIII. [f] NF XII.

Eleven mercurial compounds and the respective commercial preparations representing six different types of products were analyzed using the proposed methodology.

Apparatus—An atomic absorption spectrophotometer[1] equipped with a mercury hollow cathode lamp[2], a hydrogen continuum lamp[2] to provide background correction capability, and a cylindrical flow-through cell (2.1-cm i.d. × 10.0-cm) with quartz windows was used. Absorbance measurements were monitored with a 0–100-mv strip-chart recorder[3]. Mercury analysis was performed under the following conditions: wavelength, 253.7 nm; hollow cathode lamp current, 3 mamp; scale, 0.5; circulating pump flow rate, 4.8 liters/min; slit width, 160 μm; and chart speed, 2.5 cm (1 in.)/min.

The reduction apparatus was essentially as described previously (19) with the following modifications. The reduction vessel consisted of a 250-ml two-necked distilling flask with a vertical side neck and ⅋ 24/40 joints. The reducing solution was added *via* a 100-ml cylindrical separator attached to the side neck of the reduction vessel. All connections within the system were of Tygon tubing (5.0-mm i.d.).

Glassware was thoroughly rinsed with hot nitric acid (50% v/v) followed by distilled water prior to use. Dilutions of samples, pure compounds, and mercury standards were carried out in the presence of hydrochloric acid to minimize adsorption of mercuric ion on glassware surfaces.

Materials and Reagents—Powdered portions of thimerosal[4], mersalyl[5], meralluride[6], mercaptomerin sodium[7], phenylmercuric acetate[8], chlormerodrin[6], merbromin[9], nitromersol[10], phenylmercuric nitrate[11], yellow mercuric oxide[12], and ammoniated mercury[12] (mercury amide chloride) were used. Pharmaceutical preparations containing each mercurial compound were obtained through commercial sources. Crystalline mercuric chloride[12] prepared in an acidic medium was employed as the standard mercury solution. All other chemicals and reagents were reagent grade, commercially available materials and were used without further purification.

Standard Mercury Solution—A standard stock solution was prepared by dissolving 0.1354 g of crystalline mercuric chloride in 1 *N* HCl and diluting to 100.0 ml with the same solvent. This solution was prepared fresh on a biweekly basis. Suitable dilutions were prepared in 0.05 *N* HCl to provide a working standard solution having a concentration of 0.25 μg of mercury/ml. These dilutions were carried out daily and just prior to the quantitative reduction step.

General Procedure—Accurately weighed portions of solid materials or measured aliquots of the liquid forms representing the various mercurial compounds or respective products were treated under one of the following heating conditions with occasional swirling of the mixture:

A. Heated for 1 hr on a steam bath with 75 ml of concentrated hydrochloric acid in a 1-liter volumetric flask.

B. Boiled gently for 25 min on a hotplate with 75 ml of concentrated hydrochloric acid in a 300-ml erlenmeyer flask containing five glass beads and fitted with a 6.5-cm diameter powder funnel. Care was taken to prevent the solution from going to dryness by addition of 5–10 ml of the acid when necessary.

C. Heated for 1 hr on a steam bath with 75 ml of diluted hydrochloric acid–nitric acid mixture[13] in a 1-liter volumetric flask.

D. Heated for 15 min on a steam bath with 80 ml of dilute hydrochloric acid (10% v/v) in a 1-liter volumetric flask.

The required heating condition for each mercurial compound and the respective commercial preparation is noted in Table I. Upon completion of the heating step, the 1-liter flask and contents were cooled under tap water to room temperature and the acidic solution was diluted to volume with distilled water. When heating condition B was employed, the cooled acidic solution was quantitatively transferred to a 1-liter volumetric flask with distilled water and diluted to volume.

Further dilutions were prepared with 0.05 *N* HCl to provide an assay solution having a final concentration of approximately 0.25 μg of mercury/ml. Three milliliters of this assay solution was transferred to the reduction vessel, and the published procedure (19) was followed. The system was normally equilibrated with several standard determinations prior to the reduction of sample aliquots. A reagent blank consisting of the appropriate acid solution was carried through the entire procedure in a similar manner to the samples. Quantitation was accomplished by direct comparison of the sample absorbance value to the absorbance obtained with 3.0 ml of the working standard solution of mercury.

Bulk Drug Substances or Reference Compounds—An accurately weighed portion of the powdered material, equivalent to 60 mg of mercury, was taken for analysis. After completion of the appropriate heating step and dilution of the acid solution to 1 liter with distilled water, an assay solution was prepared by further dilution of 2.0 ml to 500.0 ml with 0.05 *N* HCl. A 3.0-ml aliquot of the assay solution was transferred to the reduction vessel for quantitative purposes.

Commercial Preparations—The quantities of mercury taken for the analysis of the various products are given in Table II. The amount of mercury present in the sample portions ranged from 2.5 to 82.5 mg, depending on the particular formulation with the exception of the product containing phenylmercuric nitrate[14]. Therefore, specified dilutions are not given due to the diversity in concentrations of mercury in the preparations.

Tablets and Gels—An accurately weighed portion of a powdered tablet composite or well-mixed gel preparation was taken for the analysis. The general procedure was followed.

Solutions and Tinctures—An accurately measured aliquot was evaporated to dryness under a current of air on a steam bath, the

Ammoniated mercury	Ointment	10%[g]	80	103.6	0.6	102.5	0.0

[a] Mean of duplicate determinations. [b] See Table I. [c] Label claim: 39 mg of mercury in organic combination and 48 mg of theophylline/ml. [d] Product assayed by the NF XIII procedure for phenylmercuric acetate; 250.0 ml was evaporated to dryness on a steambath and the NF XIII procedure was followed beginning with "add 15 ml. water, and 5 ml. of formic acid." [e] Official method not available. [f] Twice the NF strength. [g] Twice the USP strength.

required acid was added, and heating condition A, B, or C was followed (*General Procedure*).

Injectables—An accurately measured aliquot was taken directly for the analysis as described under *General Procedure*.

Ointments—An accurately weighed portion of the well-mixed product was transferred to a 125-ml separator and dispersed by shaking with 50 ml of ether. The ethereal dispersion was extracted four times with 20-ml volumes of dilute hydrochloric acid (10% v/v), and the acidic extracts were drained into a 1-liter volumetric flask. The general procedure was followed, beginning with heating condition D. This condition was employed to facilitate the removal of the residual ether present.

Calculations—The amount in milligrams of the mercurial compound present in the weighed portion or aliquot was calculated in the following manner:

$$\text{mg} = \frac{A_u}{A_s} \times C \times D \times \frac{E}{200.59} \times \frac{1\text{ mg}}{1000\ \mu\text{g}} \qquad \text{(Eq. 1)}$$

where A_u and A_s represent the absorbance values obtained for the reduced sample and standard aliquots, respectively (corrected for any reagent blank absorbance); C is the concentration in micrograms of mercury per milliliter in the final diluted mercuric chloride standard solution; D is the appropriate dilution factor; E is the molecular weight of the mercurial compound; and the value[15] 200.59 represents the atomic weight of mercury. Calculation of the quantity of the mercurial compound per dosage unit or labeled amount was achieved by introduction of the appropriate factors into Eq. 1.

Linearity—Under the assay conditions described, a linear relationship between absorbance and micrograms of mercury was obtained over a 0–1.4-μg range. A quantity of mercury equal to 0.75 μg was selected for the reduction step of the general procedure.

Official Methods—For comparative purposes, each pure compound and pharmaceutical preparation, except the product containing phenylmercuric nitrate, was assayed in duplicate by compendial methodology (1, 2).

RESULTS AND DISCUSSION

Preliminary experiments were conducted to determine the most suitable acid medium for the protolysis of the mercurial compounds in this study, since several different chemical bonds associated with mercury were apparent. Adaptation of a sulfuric acid–nitric acid digestion medium utilized for marine products (19) proved to be both time consuming and cumbersome. Modification of similar procedures (11, 12) under nonreflux conditions with respect to time and temperature was also investigated, but the results obtained were erratic due to the possible loss of mercury from volatilization. Evidence regarding volatility losses of mercury employing such digestion procedures for the total destruction of organic material was reported previously (11, 20).

It was concluded from these initial experiments that a heating step under acidic conditions was necessary to effect cleavage of mercury from the compounds in most cases. The inorganic mercurials, yellow mercuric oxide and ammoniated mercury, were easily cleaved at room temperature; compounds such as phenylmercuric acetate and mercaptomerin sodium containing the mercury–carbon and mercury–sulfur bond, respectively, required more drastic reaction conditions. Organomercurial compounds such as mersalyl and meralluride containing the mercury–nitrogen linkage were intermediate with respect to ease of cleavage. These observations were in agreement with the relative stabilities of such bonds discussed by Makarova and Nesmeyanov (21).

The use of hydrochloric acid to facilitate the cleavage of mercury–carbon bonds in addition to mercury in combination with oxygen or nitrogen has been described (6). The importance of bond type associated with mercury in analytical studies has also been noted (5). A study of the protolysis of the mercury–carbon bond with concentrated hydrochloric acid has been carried out (22). Based on these reported observations, hydrochloric acid was investigated for use as a protolytic solvent under varying time and temperature conditions to cleave mercury from the compounds considered in this study. Many difficulties associated with the total digestion procedures were overcome with hydrochloric acid. Moreover, total mercury could be successfully determined using hydrochloric acid for all compounds with the exception of mercaptomerin sodium and thimerosal, both of which contain the mercury–sulfur bond. The mercury present in these two compounds was effectively cleaved by a hydrochloric acid–nitric acid medium.

The results obtained for the bulk drug substances and reference compounds by both the described atomic absorption procedure and official methodology are summarized in Table I. The comparative data based on the amount of mercury found illustrate that the correlation between these two procedures is very good.

The comparative results for the analysis of the mercurial compounds in the pharmaceutical preparations by the atomic absorption and official procedures are presented in Table II. The atomic absorption procedure produced slightly different results for the product containing chlormerodrin, in which the mean percent of declared was 4.6% lower with the atomic absorption procedure.

[15] Twice this value was employed for the calculation of phenylmercuric nitrate, an equimolar combination of phenylmercuric nitrate and phenylmercuric hydroxide having an assigned molecular weight of 634.40.

The reason for this difference is not readily apparent from the limited analytical data available. In addition, mean differences of 2.6 and 3.0% of the percent of the declared amount were obtained for the products containing thimerosal and phenylmercuric acetate, respectively.

The product containing phenylmercuric nitrate, which gave a mean value of 77.4% of the declared amount by the atomic absorption procedure, could not be analyzed by adaptation of official methodology due to the low concentration of this ingredient. Additional atomic absorption analysis of this product utilizing heating condition C gave a mean value of 78.5% of the declared amount. Approximately 13 months after the initial analyses were performed, the product was reassayed by both the proposed atomic absorption method and a total digestion procedure (19). The results obtained from single determinations were 60.7 and 60.8% of the declared amount, respectively. These observations provide corroborative evidence that adsorption of this compound by the container material (polyethylene in this case) may occur over an extended period (16). A simulated preparation of the product was formulated in this laboratory and subjected to atomic absorption analysis utilizing heating condition B. The mean recovery for the phenylmercuric nitrate based on duplicate results was 99.6% with a range of 0.8%.

An orange precipitate was formed during the protolysis of the merbromin reference standard, which, upon isolation and total digestion under reflux conditions (19), revealed the absence of mercury. The product containing merbromin showed a similar precipitate during this stage of the analysis.

Recovery experiments employing heating condition B (hotplate) with mercuric chloride standards representing quantities of mercury in the range encountered with the commercial preparations yielded values between 98.7 and 100.4%. This finding indicated that loss of mercury due to volatilization was negligible.

At the sensitivity level employed in the atomic absorption procedure, the use of the background correction mode indicated the absence of interferences due to nonspecific absorption.

In general, the results obtained indicate the overall applicability of the described atomic absorption procedure or modifications thereof to the analysis of various mercurial compounds present in bulk form, as reference compounds, or in pharmaceutical mixtures. The method also should be adaptable to products containing *o*-hydroxyphenylmercuric chloride and various other preparations containing thimerosal.

GLC Determination of Hexadiphane in Pharmaceutical Preparations

SALVATORE MARDENTE [x] and FRANCO De MARCHI

Abstract □ A specific, rapid, and sensitive GLC method for purity control of hexadiphane and its determination in pharmaceutical preparations is described. The method utilizes an extraction of the free base, followed by GLC on a 0.5% OV-17 column at isothermal temperature for 6 min and then the temperature was programmed. Results from this method and from a titrimetric method were compared, and no significant differences were found.

Keyphrases □ Hexadiphane—GLC analysis in pharmaceutical formulations □ GLC—analysis, hexadiphane in pharmaceutical formulations

Hexadiphane, 1,1-diphenyl-3-hexamethyleneiminopropane (I), is a papaverine-like compound with weak anticholinergic effects. It is widely employed as an antispasmodic (1–5).

Quantitative determination of hexadiphane is essentially based on the chemistry of the imine moiety. The methods employed are those used for basic nitrogen compounds, primarily titration in nonaqueous

The reason for this difference is not readily apparent from the limited analytical data available. In addition, mean differences of 2.6 and 3.0% of the percent of the declared amount were obtained for the products containing thimerosal and phenylmercuric acetate, respectively.

The product containing phenylmercuric nitrate, which gave a mean value of 77.4% of the declared amount by the atomic absorption procedure, could not be analyzed by adaptation of official methodology due to the low concentration of this ingredient. solvents or with anionic surfactants and determination with picric acid (trinitrophenol), silicotungstic acid, tetraphenylboron, reineckate, and acid dyes (6). Such methods offer accuracy and precision and many are listed in the current pharmacopeias. However, they lack specificity and often require long and complicated separations.

Several GLC methods have been proposed for the determination of basic nitrogen compounds. Greenwood and Guppy (7) extensively reviewed the relevant literature. The GLC technique offers greater specificity, rapidity, and simplicity than do "classical" methods, with no loss of precision or accuracy.

The need for specificity and rapidity in the hexadiphane determination is great because the compound, which is obtained by decyanation of 1,1-diphenyl-3-hexamethyleneiminobutyronitrile (II), must be checked during the reaction to make sure that a quantitative reaction has occurred.

This paper describes a rapid quantitative GLC method for the determination of hexadiphane in pharmaceutical preparations. The preparations examined included a liquid form for oral use[1], a combination with oxazepam hemisuccinate in hard gelatin capsules[2], and a combination with digestive enzymes and dimethylpolysiloxane in coated tablets[3]. With the two solid forms, the analysis was carried out on specially prepared mixtures containing all components of the preparations.

The results were compared with those observed following titration with an anionic surfactant (0.01 *M* sodium lauryl sulfate).

EXPERIMENTAL

Equipment and Materials—The following were used: a gas chromatograph[4], dual column, equipped with flame-ionization detectors; a recorder[5]; a stainless steel column, 2 m × 2 mm i.d., packed with 0.5% methyl phenyl silicone (OV-17) on Gas Chrom Q, 80–100 mesh; a 10-μl syringe[6]; hexadiphane hydrochloride[7], hexadiphane maleate[7], and diphenylpyraline hydrochloride, pure to GLC analysis and at least 99.5% pure to titration in nonaqueous

solvents; daily-distilled ether; carbon disulfide, analytical grade; ether-washed anhydrous sodium sulfate; 0.1 *N* hydrochloric acid; and 1 *N* sodium hydroxide.

Operating Conditions—The column was conditioned by heating at 250° for 1 hr with carrier gas flow, then at 300° for 4 hr without carrier gas flow, and finally at 250° for 18 hr with carrier gas flow.

The operational parameters were: column temperature, 190°, isothermally for 6 min and then programmed to 250° at a heating rate of 22°/min; injection port temperature, 300°; detector temperature, 280°; carrier gas, nitrogen at 35 ml/min; hydrogen, 25 ml/min; air, 0.5 kg/cm^2; and attenuation, 10 × 128.

Hexadiphane Standard Solution—About 25 mg of hexadiphane hydrochloride, accurately weighed, was dissolved in water and diluted to 100 ml in a volumetric flask.

Internal Standard Solution—About 16 mg of diphenylpyraline hydrochloride, accurately weighed, was dissolved in water and diluted to 100 ml in a volumetric flask.

Correction Factor and Calibration Curve—Two milliliters of the hexadiphane standard solution and 2 ml of the internal standard solution were pipetted into a 30-ml stoppered centrifuge tube, made basic with 1–2 drops of 1 *N* sodium hydroxide, and extracted with two portions of ether (10 and 5 ml) with shaking for 5 min. After decantation or centrifugation, as necessary, the ether solution was removed by aspiration and filtered on anhydrous sodium sulfate into a conical bottom 20-ml tube.

The ether was evaporated in a current of nitrogen, and the residue was dissolved in 0.2 ml of carbon disulfide. About 2 μl of the solution was injected into the gas chromatograph. This operation was repeated at least three times. The correction factor was calculated as follows:

$$f = \frac{H_d C_h}{H_h C_d} \qquad \text{(Eq. 1)}$$

where f = correction factor, H_d = height of the diphenylpyraline peak, H_h = height of the hexadiphane peak, C_d = diphenylpyraline hydrochloride concentration, and C_h = hexadiphane hydrochloride concentration.

The linearity of the response was checked by keeping constant the concentration of the internal standard (0.16 mg/ml) and varying the hexadiphane concentration (0.05–0.6 mg/ml). The calibration curve was made by plotting the hexadiphane/diphenylpyraline peak height ratio against the amount of hexadiphane.

Procedure—For the liquid preparation, virtually the same procedure as described for the determination of f was followed. A solution equivalent to 400 μg of hexadiphane hydrochloride and 2 ml of the internal standard solution were pipetted into a 30-ml stoppered centrifuge tube and extracted with two portions of ether (10 and 5 ml). The ether was then discarded. This extraction was

Table II—Assay Results of the Hexadiphane–Oxazepam Hemisuccinate Combination (Hexadiphane Maleate, 3.2 mg/Capsule)

Analysis Number	Titrimetric Method		GLC Method	
	Found, mg	Recovered, %	Found, mg	Recovered, %
1	3.26	101.9	3.24	101.2
2	3.22	100.6	3.12	97.5

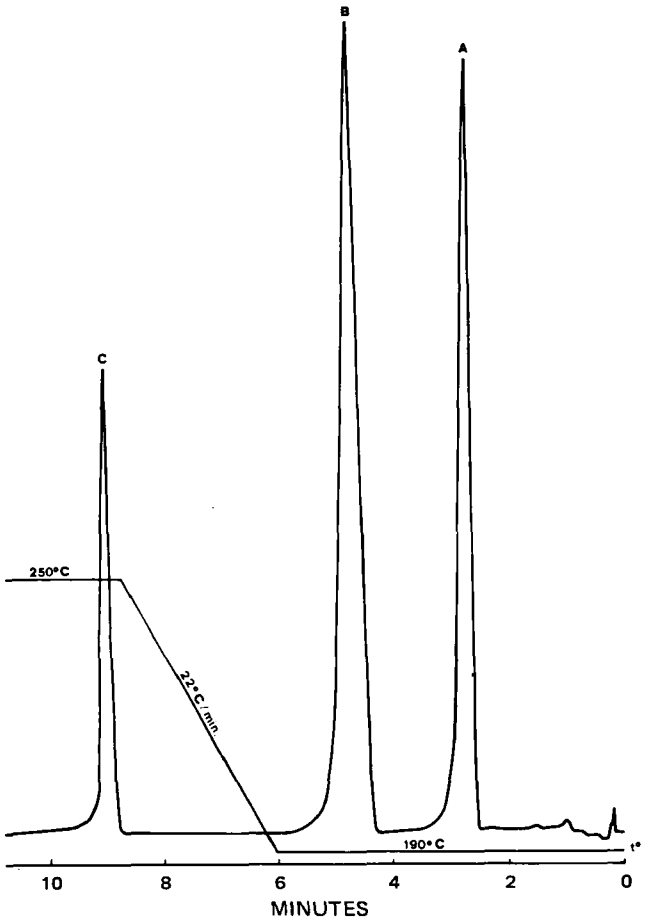

Figure 1—*Typical chromatogram. Key: A, diphenylpyraline; B, hexadiphane; and C, 1,1-diphenyl-3-hexamethyleneiminobutyronitrile.*

adopted to remove ether-soluble substances which might interfere in the analysis. After alkalinization with 1 *N* sodium hydroxide, the procedure was the same as that employed for determining *f*.

The solid products were finely pulverized. An accurately weighed quantity of powder equivalent to about 4 mg of hexadiphane hydrochloride or 6 mg of hexadiphane maleate was transferred into a 50-ml volumetric flask, and about 40 ml of 0.1 *N* hydrochloric acid was added. After heating at 70–80° and shaking for 30 min, the solution was allowed to cool. It then was brought to volume with 0.1 *N* hydrochloric acid, thoroughly mixed, and centrifuged. Five milliliters of this solution and 2 ml of the internal standard solution were pipetted into a 30-ml stoppered centrifuge tube, and the procedure described for the liquid preparation was then followed. The amount of hexadiphane hydrochloride in the sample analyzed was determined by:

$$\text{hexadiphane hydrochloride} = \frac{H_h C_d}{H_d} f \qquad \text{(Eq. 2)}$$

The value was multiplied by 1.241 to obtain the corresponding hexadiphane maleate content.

RESULTS AND DISCUSSION

The liquid preparation and the combination with oxazepam hemisuccinate were assayed by titration with sodium lauryl sulfate and GLC. Since there was no interference from other basic nitrogen compounds, the titration was possible without additional separations.

Direct titration could not be done on the combination with digestive enzymes because of the complexity of the formulation. Only GLC analysis was performed.

The GLC results (Tables I–III) show that the method is sufficiently accurate and precise for use in the analysis of pharmaceutical preparations. Although the standard deviation of the GLC results is higher than that of the titrimetric results, the *t* test for the means and the *F* test for the variances (Tables I and II) indicate no significant difference at the 5% level.

GLC analysis, however, is preferable because of its simplicity, rapidity, and selectivity; as shown in Fig. 1, there is sharp separation of hexadiphane from its precursor II. In the absence of additional separations, the presence of this precursor would not have been revealed by titration and other chemical methods.

These features make the GLC method suitable for routine checks and those carried out during synthesis and manufacture as well as for purity checks.

Carbon disulfide was chosen as the solvent because of its relatively low response with the flame-ionization detector.

Diffusion Model for Fluidized-Bed Drying

M. A. ZOGLIO ˣ, W. H. STRENG, and J. T. CARSTENSEN *

Abstract □ A sucrose–lactose–starch granulation was used to study particulate motion and attrition in a fluid bed dryer. There is some classification of material in the dryer as drying proceeds; fine particles are dried faster and become less dense, and the less dry but denser large particles show some (although not great) accumulation tendencies in the lower central area. Unlike countercurrent rotary drying, fluid bed drying cannot be accounted for by water diffusion inside the granule as the rate-limiting step. In its place, a model of external water vapor diffusion is proposed and is supported by vapor–concentration curves and by the linear dependence of the rate constants on the linear air velocities. The dried granulation exhibits the same trend as does countercurrent dried material in that larger particles have higher moisture contents than do smaller particles. Quantitative relationships between content of moisture and size were developed and are supported by experimental data. The granulation, upon storage, does not equilibrate, indicating that this type of water distribution is a problem in batch process granulations as well as in the earlier reported case of granulations for continuous production.

Keyphrases □ Drying—fluid bed dryer, diffusion model, sucrose–lactose–starch granulation, rate-limiting step, relationships between moisture and size □ Diffusion—model for fluidized-bed drying, moisture and size relationships, rate-limiting step □ Fluid bed drying—diffusion model, moisture and size relationships, rate-limiting step, equations

Drying of granulations has traditionally been performed by tray drying, and the factors involved have been classified as a dynamic balance between the rate of moisture movement from inside the solid to the surface and the evaporation of moisture from the surface (1, 2). It has been shown (3) that the drying rate is controlled by the film thickness of the vapor above the bed and that there is no difference fundamentally between the heat balances involved in fluidized drying and those involved in tray drying (4). In countercurrent rotary dryers, the rate-determining step is diffusion of moisture *in* the granule (5). An investigation of the *basic* mass transfer balance in a fluidized bed at fluidizing air velocities was the primary purpose of the study reported here.

The general phenomena involved in fluid bed drying are described in various texts; the text by Vanecek *et al.* (6) will be referred to frequently. Fluidization occurs between an incipient fluidizing velocity and is limited at the higher end by an entrainment velocity beyond which conveyance takes place. The linear velocity of the air in the bed is different from that in the ducts. The velocity between the particles is referred to as interstitial velocity; the velocity in the free cross section, *i.e.*, in the ducts, is denoted as superficial velocity.

One purpose of this study was to determine whether particulate fluidization or aggregative fluidization takes place. In the former case, the bed is uniform throughout; in the latter case, it is not. The solids motion in the bed is somehow controlled by the fact that bubbles are created at the distributor. Not only the bubbles but also their wakes contribute to the solids motion (7). Bubbles do not mix in a horizontal plane, but they coalesce whenever a bubble is less than one bubble diameter behind another in a vertical path (8). Therefore, bubble size is less above the distributor than higher up in the bed.

Several "freezing" techniques were described in investigations of mixing, such as the one by Abrahami and Resnick (9). Essentially, it is shown that mixing will occur beyond the incipient fluidization velocity. The actual mixing patterns in a fluid bed dryer were described by Schugerl (10).

In a mixture of two particle sizes, it was shown that when one fraction (f_1) is abundant there is a tendency for accumulation of the coarse fraction above the distributor (11).

The temperature of the material being dried is frequently uniform throughout the bed, except for a small range immediately above the distributor (12). It is not possible to obtain a countercurrent arrangement of the streams of the material and drying medium in a fluid bed dryer (6). Therefore, one would not expect that the drying mechanism reported in countercurrent drying (5) would apply to fluid bed drying.

Although attempts to quantitate the stream lines in a fluidized bed have been made (6), no previous studies reported particle-size distributions and classifications (or lack of classifications) in fluid bed dryers. It was observed in continuous rotary drying (5) that the moisture content of various screen fractions of a continuously dried granulation differs in the sense that the coarse particles contain more moisture than the fines. It was speculated that this fact would be of no consequence in batch operations, since the particles would, presumably, equilibrate. This latter point was investigated in this study.

EXPERIMENTAL

Granulations were made of the following formula: 17.55 kg of lactose USP, 11.43 kg of sucrose (containing 3% starch), 4.20 kg of starch USP, 0.0093 kg of yellow FD&C No. 6, and 0.0045 kg of red FD&C No. 2. The lactose, sucrose, and 4.05 kg of starch were mixed for 5 min in a mixer[1] at a speed of 140 rpm. A starch suspension was made of 150 g of starch in 300 ml of water. The dyes were dissolved in 2700 ml of water and heated to boiling; then the starch suspension was added to make approximately 3 liters of dye starch

[1] Littleford-Lodige model FM-100, 3.3 ft³ capacity, Littleford Brothers, Inc., Cincinnati, OH 45202

paste. One-fourth of this paste was added to the powder blend in the mixer, and blending was carried out for 30 sec; the next one-fourth was then added and so on until all of the paste had been added.

The wet granules (5.0 kg) were screened through a No. 4 stainless steel hand screen and placed in the basket of a fluid bed dryer[2]. The fluid bed dryer was equipped with a velocity meter[3] of the Pitot-tube type with wet and dry bulb thermometers in inlet and outlet ducts. The position of the Pitot-tube was (as recommended by the manufacturer) positioned on linear portions of the duct work. The velocity could be varied by a conventional damper system. The ranges of velocity were such that no fluidization took place below 396 m (1300 ft)/min air velocity; above 823 m (2700 ft)/min air velocity, air conveyance would start. The range used was 396–815 m (1300–2675 ft)/min. The inlet temperature was 43°, and the exit temperature was 30°.

The heat capacity of the granulation was determined by calorimetric means. A Dewar flask, equipped with a rubber stopper and a Beckmann thermometer, was placed in a 20° constant-temperature bath along with 250 ml of heptane. When the temperature was equilibrated, the heptane was transferred to the Dewar flask. Then 100 g of granulation was heated to 30° by equilibrating it for 6 hr in a glass container in a 30° constant-temperature bath. It was then transferred to the Dewar flask, and the temperature increase was recorded. The calorimetric constant (80 cal/degree) was determined by water calibration. The heat capacity is 0.45 cal/g/degree of dry weight.

THEORETICAL

It will be assumed that the drying chamber is cylindrical (although in actuality it is slightly conical) with a cross section of A cm^2 and height of l cm. When fluidized, the bed has a void fraction (in the conventional sense) of ϵ and a solid fraction of $(1 - \epsilon)$. The free cross-sectional area (7) is then, on the average, $A\epsilon$. The granulation is polydisperse, containing fraction f_1 of particles with "diameter" a_1, f_2 with "diameter" a_2, and so on. The assumption is made that the particle is spherical.

In a small section of the cylinder of length dx, the total solids volume is $A\,dx(1 - \epsilon)$. The volume of particles of diameter a_i in the section is $A\,dx(1 - \epsilon)f_i$. There are, hence, $A\,dx(1 - \epsilon)f_i/(\pi a_i^3/6)$ particles of diameter a_i, each having a surface of πa_i^2, so that the total solids area in the section of length dx is then given by:

$$O = A\,dx(1 - \epsilon)\sum_{i=1}^{n} f_i \frac{6}{a_i} \qquad \text{(Eq. 1)}$$

The drying, as shown in Fig. 1, is governed by diffusion of water vapor from the solid surface (where the gaseous concentration is q^* in grams of water per cubic centimeter of dry air) to the bulk of the air stream where the water content at position x is q_x in grams of water per cubic centimeter of dry air. The interface where the water vapor concentration has just dropped to q_x is h cm from the granule surface and is referred to here as the "film." By way of Fick's first law applied to the length of this film, when a linear concentration gradient is assumed (8), the rate of moisture given off at time t and position x from the solids to the air stream is:

$$\frac{D}{h}(q^* - q_x)A(1 - \epsilon)\sum_{i=1}^{n}(f_i 6/a_i)\,dx = \gamma(q^* - q_x)A\,dx \qquad \text{(Eq. 2)}$$

where:

$$\gamma = \frac{D}{h}(1 - \epsilon)\sum_{i=1}^{n}(f_i 6/a_i) \qquad \text{(Eq. 3)}$$

and D is the diffusion coefficient for the water vapor in the gas stream.

The total moisture content of the solids is denoted m_0 and m at times zero and t sec, respectively. The moisture loss rate of the total solids mass is obtained by integrating Eq. 2 between the limits zero and l, *i.e.*:

$$-\frac{dm}{dt} = \gamma A\int_0^l (q^* - q_x)\,dx \qquad \text{(Eq. 4)}$$

If the relative humidity ($100q_x/q^*$) gradient is constant, then:

$$q_x = q_0 + \frac{q_l - q_0}{l}x \qquad \text{(Eq. 5)}$$

where $100q_l/q^* = \text{RH}$ is the relative humidity of the exit air. The average water vapor concentration, q, is:

$$q = (q_l + q_0)/2 \qquad \text{(Eq. 6)}$$

Combining Eqs. 5 and 6 with Eq. 4 yields:

$$-\frac{dm}{dt} = \gamma A\{(q^* - q_0)l - [\tfrac{1}{2}(q_l - q_0)/l]\,l^2\} =$$

$$\gamma Al[q^* - \tfrac{1}{2}(q_l + q_0)] = \gamma Al(q^* - q) \qquad \text{(Eq. 7)}$$

When the system is considered to be a suspension with a solids volume of $lA(1 - \epsilon)$ and an air volume of $lA\epsilon$, the increase in average concentration of water vapor in the gas is the amount of water given up by the solids divided by the gas volume $[-(dm/dt)/(\epsilon lA)]$ minus the amount lost in the gas stream, *i.e.*, the difference between incoming and outgoing moisture quantities[4] $[vA\epsilon(q_l - q_0)]$ divided by the gas volume, *i.e.*:

$$\frac{dq}{dt} = \frac{1}{\epsilon lA}\frac{dm}{dt} - \frac{vA\epsilon}{\epsilon lA}(q_l - q_0) \qquad \text{(Eq. 8)}$$

where v is the linear velocity of the air. Inserting Eqs. 7 and 6 into Eq. 8 now yields:

$$\frac{dq}{dt} = \frac{\gamma}{\epsilon}(q^* - q) - \frac{2v}{l}(q_l - q_0) = \alpha(q - \beta q^* - \sigma q_0) \qquad \text{(Eq. 9a)}$$

where:

$$\alpha = -\left(\frac{\gamma}{\epsilon} + \frac{2v}{l}\right) < 0 \qquad \text{(Eq. 9b)}$$

$$\beta = \frac{(\gamma/\epsilon)}{(\gamma/\epsilon) + (2v/l)} \qquad \text{(Eq. 9c)}$$

$$\sigma = \frac{(2v/l)}{(\gamma/\epsilon) + (2v/l)} \qquad \text{(Eq. 9d)}$$

It is noted that $\alpha + \sigma = 1$. Integration of Eq. 9a yields:

$$\ln(q - \beta q^* - \sigma q_0) = \alpha t + I \qquad \text{(Eq. 10)}$$

where I is an integration constant to be determined by initial conditions. Boundary conditions dictate that when t becomes infinite, the term under the logarithm sign approaches zero; *i.e.*, since q then approaches q_0:

$$q_0 - \beta q^* - \sigma q_0 = 0 \qquad \beta = (1 - \sigma)q_0/q^* \qquad \text{(Eq. 11a)}$$

Inserting Eq. 11a into Eq. 10 then gives:

$$\ln(q - q_0) = \alpha t + I \qquad \text{(Eq. 11b)}$$

where I is an integration constant. The value of I can be obtained from initial conditions; here the inlet air has a moisture content of q_0 and a (saturated) content of q^* at the outlet, so that initially $q = (q_0 + q^*)/2$, which, inserted in Eq. 11b, yields:

$$\ln[(q_0 + q^*)/2 - q_0] = 0 + I \qquad \text{(Eq. 11c)}$$

so that $I = \ln[(q^* - q_0)/2]$. The complete equation may be written:

$$\ln[(q_l - q_0)/2 - q_0)] = \alpha t + \ln[(q^* - q_0)/2] \qquad \text{(Eq. 12a)}$$

or:

$$\log(\text{RH} - \text{RH}_0) = (\alpha/2.3)t + \log(100 - \text{RH}_0) \qquad \text{(Eq. 12b)}$$

where $\alpha < 0$. Data plotted according to Eq. 12b (Fig. 2) show that this equation is obeyed at all air velocities tested. It is noted that:

$$-\alpha = \frac{\gamma}{\epsilon} + \frac{2v}{l} \qquad \text{(Eq. 13)}$$

so that the negative slopes in Fig. 2 multiplied by 2.3 should be linearly related to the linear velocity, as demonstrated in Fig. 3.

[3] Catalog No. 102AV, Dwyer Instruments Inc., Michigan City, IN 46360

[4] It is noted that q_0 and RH_0 are equal to the values in the outlet at infinite time.

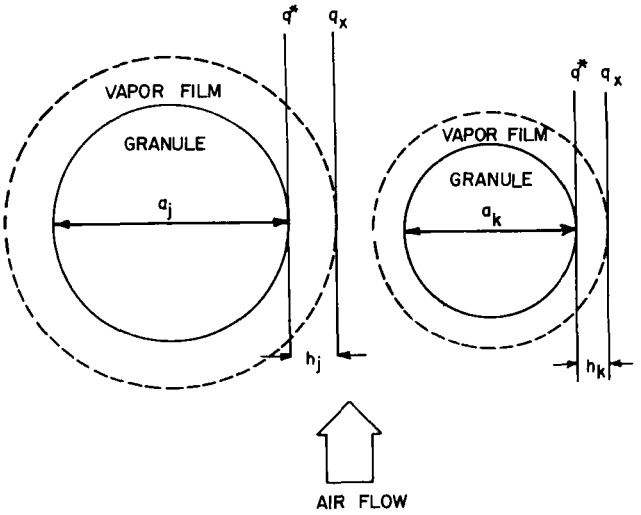

Figure 1—*Particles of diameter* a_j *and* a_k *and film thicknesses* h_j *and* h_k.

If it is assumed that all sieve fractions start with the same moisture content and level off at about 0.04 g of water/g of dry solid, then the moisture loss rates may be estimated from Table I. In particular, at any given time, according to Eqs. 3 and 7:

$$(dm_i/dt)_{t=t'} = D(1-\epsilon)(6f_i/a_ih_i)Al(q^* - q_{t'}) \quad \text{(Eq. 14)}$$

Data from $t = 1.25$ min calculated from Table I are shown graphically in Fig. 4.

According to hydrodynamic theory (8), diffusion in turbulent flow occurs through a film of thickness h, which is related to the Reynolds number (Re) by an exponential relation, *i.e.*, $h = (\omega)Re^{-(\zeta-1)}$. Here, $Re = v(a/\nu)$, where v is the velocity of the stream flowing past the body, a is the characteristic dimension of the body, and ν is the kinematic viscosity of the stream. Therefore, it follows that Eq. 14 will take the form:

$$\log[-(dm_i/dt)_{t=t'}] = (\zeta - 2)\log a_i + \log\left[D(1-\epsilon)(6f_i)Al(q^* - q_{t'})\left(\frac{1}{\omega}\right)\right] + (\zeta - 1)\log(v/\nu) \quad \text{(Eq. 15)}$$

Figure 4 shows that Eq. 15 is obeyed, the value of $(\zeta - 2)$ being -0.40. Hence, $\zeta = 1.6$ and $h = (\omega)Re^{-0.6}$. This result is close to the usual hydrodynamic postulate that the sorbed "film" of fluid (or gas) is inversely proportional to the square root of the velocity (13). This should not be construed as implying quantitative proof of the proposed model, but the adherence to Eq. 15 lends credence to the proposed view.

RESULTS AND DISCUSSION

The granulation from a 15-min drying experiment, conducted in the manner described, was sampled from the top (2–3 cm deep) in a zone at the center in a circle with radius 7.6 cm (3 in.), then in a zone 7.6–15.4 cm (3–6 in.) from the center, and then in a zone more than 15.4 cm (6 in.) from the center. The samples were subjected to a sieve analysis through a nest of standard U.S. screens, and the various screen fractions were subjected to a Karl Fischer moisture analysis (Table II).

The screen analysis is fairly independent of the zone, and the moisture analysis shows that the coarse material is somewhat moister than the fine material. Apparently, there is a slight tendency for a larger proportion of the coarse fraction to be positioned at the center of the distributor; this so-called immobile zone has a minimal effect on the general particle distribution. Initially, the wet granules (prior to drying) contain 97.5% (w/w) of granules coarser than 60 mesh; these granules contain 9.5% moisture. The 2.5% material finer than 60 mesh is slightly drier (6.4%).

The next experiment utilized a 5-min drying time. The dried granulation was mixed in a large plastic bag, and the material was subjected to sieve analysis. The experiment was then repeated for 15, 30, and 45 min (Table III). Table III shows that the particle-size distribution stays fairly constant throughout the drying and that the formula is resistant to the possible abrasion in the fluidizing motion.

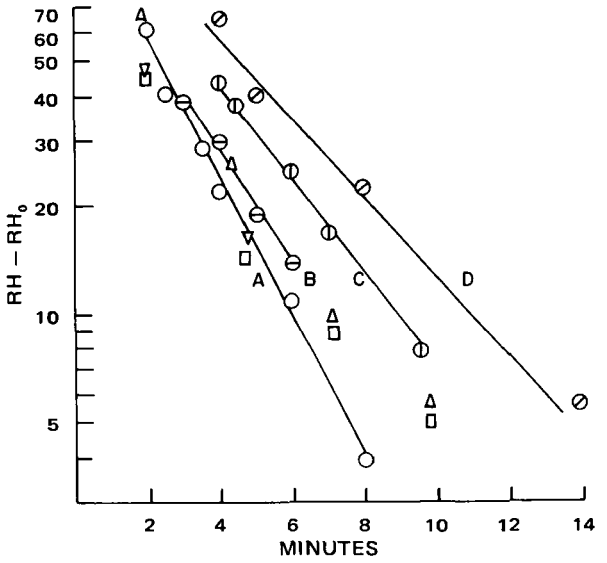

Figure 2—*Relative humidity of outlet air minus relative humidity of ambient air* ($RH - RH_0$) *plotted in semilogarithmic fashion versus time. Least-squares fit slopes are: A (470 cm/sec),* -0.186 min^{-1}; *B (460 cm/sec),* -0.155 min^{-1}; *C (407 cm/sec),* -0.130 min^{-1}; *and D (274 cm/sec),* -0.114 min^{-1}. *Key:* △, *37° (460 cm/sec);* ▽, *30° (460 cm/sec); and* □, *25° (460 cm/sec).*

Moisture assays by Karl Fischer titration were performed on various fractions from the experiments (Table I). Table I illustrates the increased drying time necessary to bring the larger granules to moisture levels comparable to those achieved rapidly by the smaller graules. A sample was dried for 2.5 min and blended and screened as described. Samples of the various fractions were assayed for moisture; the remainder of the batch was reblended and placed in a plastic bag in a sealed fiber drum for 2 days. Screening, sampling, assay, blending, and restorage were repeated twice. Inspection of Table IV shows that equilibration of the tested formula does *not* occur subsequent to drying and that the previous observation (5) that the uneven distribution of moisture could be a problem in continuous processes is apparently also true for batch processing.

A series of runs was then performed in which the linear velocity of the air was varied; the temperatures of the incoming air and the temperatures of the exit air were monitored to permit calculation of the relative humidities of inlet and outlet streams at all times (Fig. 2).

The process that dominates continuous rotary drying, as found by Pitkin and Carstensen (5), dictates (as detailed in the *Appen-*

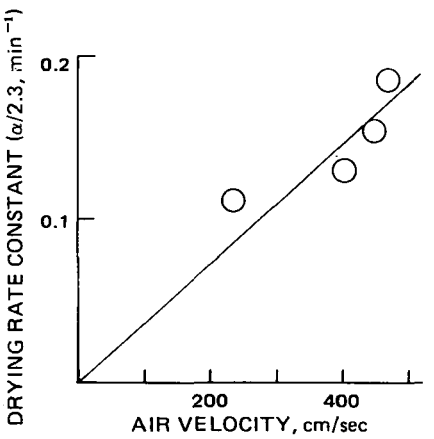

Figure 3—*Negative slopes from Fig. 2 plotted versus linear velocities.*

dix) that the drying curve be of the form:

$$\log(RH - RH_0) = (\alpha'/2.3)t + \beta' \qquad \text{(Eq. 16)}$$

where RH is the relative humidity in the outlet air, RH_0 is the relative humidity of the inlet air, and α' is independent of air velocity. As seen in Fig. 3, α (Eq. 12*b*) *is* dependent on air velocity and the rate-limiting step here cannot be moisture movement within the granule.

SUMMARY

Fluid bed drying is governed by external diffusion because:

1. Equation 12*b* predicts a found dependency on interstitial velocity but no temperature dependence. The lack of temperature dependence is shown in Fig. 2.
2. Data demonstrate a dependence on particle size predicted by external diffusion (Eq. 15) but not internal diffusion (Eq. A7).
3. The dependence of drying on velocity is identical to that expected from hydrodynamic film theory.

With dried granules, the larger the moisture content the larger is the granule. The granules do *not* equilibrate on storage.

APPENDIX

If, as shown schematically in Fig. 1, the air flow is Q cm³ of dry air/sec and the dry bulb temperature, T, of the stream is constant, and if the air contains, on entry, q_0 g of water/cm³ of dry air, then the relative humidity (RH) of the incoming air will be $(q_0/q^*)100$, where q^* denotes the saturation amount of moisture per cubic centimeter of dry air at $T_0°$. The air mass "gains" $-dm/dt$ g of water/sec, where m is the moisture content of the granulation and where m_0 is the initial moisture content of the granulation. In time element dt, therefore, $Q\,dt$ cm³ of air gain $(-dm)$ g of water, so that, at time t:

$$RH/100 = [q_0 - (dm/Q\,dt)]/q^* = (RH_0/100) - (1/Qq^*)\,dm/dt \qquad \text{(Eq. A1)}$$

Pitkin and Carstensen (5) showed that for a monodisperse fraction of a granulation:

$$m = m_0(6/\pi^2)\sum_{j=1}^{\infty}(1/j^2)\exp(-j^2t/k) \qquad \text{(Eq. A2)}$$

where $k = a^2/(4\pi^2D)$.

As before, if there is a fraction f_1 of particles with diameter a_1, f_2 with diameter a_2, *etc.*, then:

$$m = \sum_{k=1}^{\infty}\sum_{j=1}^{\infty} f_k m_0(6/\pi^2)(1/j^2)\exp[(j^2 4\pi^2 Dt)/a_k{}^2] \qquad \text{(Eq. A3)}$$

Differentiating yields:

$$-dm/dt = -m_0(6/\pi^2)\sum_{k=1}^{\infty}\sum_{j=1}^{\infty} f_k 4\pi^2 D/(a_k{}^2) \times \exp(-j^2 4\pi^2\, Dt/a_k{}^2) \qquad \text{(Eq. A4)}$$

This equation, inserted in Eq. A1, yields:

$$(RH - RH_0)/100 = (m_0/Qq^*)\sum_{k=1}^{\infty}\sum_{j=1}^{\infty} f_k 24D/(a_k{}^2) \times \exp(-j^2\pi^2\, Dt/a_k{}^2) \qquad \text{(Eq. A5)}$$

Table IV—Screen Analysis and Moisture Contents of Drum-Stored Granulation

Screen Fraction	Percent (w/w)				Moisture Content, %			
	Initial	2 Days	3 Days	5 Days	Initial	2 Days	3 Days	5 Days
+20	59	57	57	57	8.9	8.5	8.4	8.2
−20/+40	12	13	12	12	6.9	7.7	6.9	7.4
−40/+60	10	15	13	19	6.4	6.6	5.7	6.6
−60/+80	7	10	12	9	5.4	5.6	5.8	5.8
−80/+100	4	3	4	1	5.0	4.1	4.4	4.0
−100/pan	8	2	2	2	4.5	3.6	4.1	3.9

If there is a predominance of a fine fraction (size a_1, fraction f_1) where $j = 1$ and $k = 1$, then at reasonably high t Eq. A5 has one predominant term. It then simplifies to:

$$(RH - RH_0)/100 = (f_1 m_0/Qq^*)(24D/a_1^2) \exp(-4\pi^2 Dt/a_1^2) \quad \text{(Eq. A6)}$$

and hence:

$$\log(RH - RH_0) = -[4\pi^2 D/(2.3a_1^2)]t + \log(100C_0 24D)/(Qq^* a_1^2) f_1 \quad \text{(Eq. A7)}$$

RH_0 is the relative humidity of the incoming air (*not* RH at time zero). According to Eq. A7, $t \to \infty$ implies that $RH \to RH_0$ in conformity with the physical picture presented. Hence, at conditions *other* than times strictly close to time zero, Eq. A7 predicts that the log of the term $(RH - RH_0)$ is linear with time. Figure 2 shows this to be so. However, the slope in Eq. A7 is independent of air velocity.

The efficiency of the dryer is calculated conventionally (6) as follows. Five kilograms of 10.22% initial moisture and 4% final moisture loses 511 − 187 = 324 g water, so that 324 × 0.582 = 199 kcal is employed for evaporation. The bed in the process is heated 5°, *i.e.*, 0.45 × 4.489 × 5 = 10 kcal is used. Drying time is 15 min. The amount of heat given up is enthalpy of air at entry minus enthalpy at exit. The entry air is 43°, 10% RH; the exit air is 30° and the RH (Fig. 2) is estimated as follows. From Fig. 2 (slope A), $RH(t)$ from 0 to 15 min was measured and found to be 516 RH-minutes so that the average RH is:

$$RH = \frac{1}{15}\int_0^{15} RH(t)\,dt = \frac{516}{15} = 35\%\ RH \quad \text{(Eq. A8)}$$

The enthalpy of the outgoing air is found from a psychrometric chart to be 13 + 0.35(43 − 13) = 23.5 Btu/lb dry air, and the enthalpy of the incoming air is 18 + 0.10(82 − 18) = 24.4 Btu/lb dry air so the difference is 0.9 Btu/lb dry air. One pound of dry air at 110°F is found from the psychrometric chart to occupy 14.5 ft^3, so the enthalpy difference is 0.9/14.5 = 0.062 Btu/ft^3. The superficial air flow is 2500 ft/min through a 0.166-ft^2 duct for 115 min; *i.e.*, 2500 × 0.166 × 15 = 6225 ft^3. Hence, the heat expended is 6225 × 0.062 = 386 Btu = 386 × 0.817 = 315 kcal, so the efficiency of the dryer is (199 + 10) 0.100/315 = 64%.

Spectrofluorometric Determination of the Antibiotic Lasalocid in Blood

M. A. BROOKS *x, L. D'ARCONTE *, J. A. F. de SILVA *, G. CHEN ‡, and C. CROWLEY ‡

Abstract □ A spectrofluorometric assay was developed for the determination of the antibiotic lasalocid in dog blood, based on the intrinsic fluorescence of the compound in ethyl acetate. The assay can measure "total" levels of drug and any metabolites present. The specificity of the assay was verified by TLC separation of the dog blood extract, which indicated the presence of only intact drug. The overall recovery (±*SD*) of lasalocid was 62.0 ± 3.6% in the concentration range of 1.0–10 μg of compound/ml of dog blood. The sensitivity of the assay is 0.5 μg/ml. The assay was applied to the determination of blood levels of lasalocid in the dog following the intravenous administration of a 5-mg/kg dose.

Keyphrases □ Lasalocid—spectrophotofluorometric analysis in blood after intravenous administration, dogs □ Spectrophotofluorometry—analysis, lasalocid in dog blood

The isolation of the antibiotic lasalocid[1] (I) was first reported in 1951 (1), and it is presently under investigation as an anticoccidial agent in chicks (2). Studies pertaining to the structure elucidation (3–5) and the biosynthesis (6–8) of the compound were reported. Other investigations have dealt with chemical transformations and their effects on antibacterial activity (9), nitration (10), and pyrolytic cleavage (11).

Analytical investigations of lasalocid include GLC determination of the compound in fermentation broths (12), in which the compound is pyrolyzed in the injection port to two naphthols (III[2] and IV[3]) and a retroaldol ketone (II[4]). The ketone is used for quantitation employing a flame-ionization detector. Bioautographical procedures also were reported for the measurement of the antibiotic in tissues of chickens following administration at the 0.0075% level (13).

The compound shows strong optical activity in the presence of several amines and monovalent and divalent metals (14, 15). This activity was reported in terms of circular dichroic absorption (14, 15) and fluorescence emission (15) of the complexed compound. A spectrofluorometric assay to measure lasalocid in finished feeds and premixes also was reported (16). The assay involves extraction of the drug into ethyl acetate from the premixes and finished feeds, followed by a differential spectrofluorometric measurement of lasalocid.

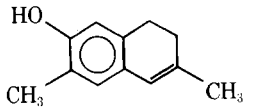
III



IV

The present work employs several modifications of the previously reported spectrofluorometric assay (16) in order to measure lasalocid in blood. The assay is based on the intrinsic fluorescence of the compound in ethyl acetate and has a sensitivity limit of 500 ng/ml. The assay measures "total" levels of the drug and any metabolites present. The specificity of the assay was verified by TLC separation of the dog blood extract, which indicated the presence of only intact drug. The method was applied to the determination of blood levels of the drug in the dog following intravenous administration of a 5-mg/kg dose.

EXPERIMENTAL

Instrument—A spectrofluorophotometer[5] equipped with a selected high energy output dc xenon arc energy source and a high sensitivity (>10 lumen rating) photomultiplier[6] was used. The 10-nm slit arrangement was used in all four positions, and the instrument was adjusted for maximum energy output using a Pyrex reference rod. Spectra were obtained on an *X–Y* recorder[7].

Standard Solutions—Prepare a stock solution (Solution A) of lasalocid (I) ($C_{34}H_{53}NaO_8$, mol. wt. = 612.78, pKa 5.13), by dissolving 10 mg of I in 100 ml of methanol. Make a 1:10 dilution of this

[1] 6-[7(*R*)-[5(*S*)- Ethyl-5-[5(*R*)-ethyltetrahydro-5-hydroxy-6(*S*)- methyl-2*H*- pyran-2(*R*)-yl]tetrahydro -3(*S*)-methyl- 2(*S*)- furanyl]- 4(*S*)-hydroxy-3(*R*),5(*S*)-dimethyl-6-oxononyl]-2-hydroxy-3-methylbenzoic acid. Lasalocid is also designated as X-537A in the literature.

stock solution in methanol to yield a working solution (Solution B) containing 10 μg/ml; suitable aliquots of Solution B are added to blood as internal standards.

Reagents—The reagents used were of analytical reagent grade (ACS) purity and included saturated tribasic sodium phosphate (Na_3PO_4) (pH 12.3), ethanol–0.1 *N* NaOH (80:20, spray reagent), anhydrous ether[8], benzene[9], methanol[9], and ethyl acetate[10].

Analysis in Blood—Into a 50-ml centrifuge tube, add 1 ml of sample and then mix[11] for about 5 sec. Add 1 ml of ethanol, stopper, and mix well again for about 5 sec, making sure that all of the sample has been in contact with the alcohol; then place in a water bath at about 70° for 5 min for protein precipitation.

Allow the samples to cool to room temperature. Add 5 ml of saturated tribasic sodium phosphate solution (pH 12.3), and mix[11] well to ensure that the coagulated sample is uniformly suspended in the mixture. Add 20 ml of ether, mix again for 5 sec, and place in a reciprocating shaker for 20 min. Centrifuge at 2400–2600 rpm for about 5 min.

Transfer an 18-ml aliquot of the ether extract into a clean 50-ml tube and evaporate to dryness. Reconstitute by the addition of 200 μl of ether, stopper, and mix[11] well. To the ether solution, add 10 ml of ethyl acetate (spectral grade); then mix well and measure the fluorescence of the solution in a 1-cm path quartz cell at 415 nm with excitation at 310 nm. Along with the unknowns, run internal standards of 0.5, 1.0, 2.0, 5.0, and 10.0 μg of I (0.05, 0.10, 0.20, 0.50, and 1.0 ml of Solution B, respectively, evaporated to dryness under nitrogen) in blood taken preferably from the same dog prior to medication or from a pooled control source.

TLC Analysis of Blood Extracts—The specificity of the fluorometric assay in blood can be verified as follows. Following fluorometric analysis, evaporate the ethyl acetate solution to dryness and dissolve the residue in 100 μl of ether. Transfer the extract quantitatively onto a 20 × 20-cm 60-μm silica gel chromatoplate[12]. Rinse each tube with an additional 50 μl of ether and transfer to the TLC plate to effect a quantitative transfer.

Develop the plate for 15 cm ascending in a vapor-saturated tank using benzene–methanol (90:10). Air dry the plate, spray it lightly with a mixture of ethanol–0.1 *N* sodium hydroxide (80:20), and heat in an oven at 100° for 15 min. The parent drug (I, $R_f \simeq 0.32$) is identified by reference to the R_f of 10 μg of authentic standard run alongside the sample extract as a blue fluorescent spot seen under short- and longwave UV irradiation characteristic of salicylate-like fluorescence. These zones turn yellow upon standing and exposure to the atmosphere.

Calculations—All fluorescence readings [(*TM*) = transmittance (*T*) × meter multiplier factor (*M*)] are corrected for blank readings and for any dilutions made. Unknown concentrations are interpolated from the internal standard curve or from direct comparison with one of the internal standards. The percent recovery of the assay is calculated based on the comparison of (*TM*/μg/ml) values of the internal and external standards (corrected for aliquots taken).

The percentage recovery should be calculated routinely as a check on analytical precision and reproducibility.

Recovery and Sensitivity Limits—The assay has an overall recovery (±*SD*) of 62.0 ± 3.6% in the range of 1.0–10 μg of I/ml of dog blood. The sensitivity limit of the assay is 0.5 μg of I/ml of blood. At the 0.5-μg/ml level, the recovery is approximately 15% lower than that in the 1.0–10-μg/ml range (Table I).

RESULTS AND DISCUSSION

The UV absorption spectrum of lasalocid shows a major band at 305 nm with an absorbance (*A*/μg/ml) ≃0.008 in ethyl acetate, indicating a potential sensitivity limit of about 10–20 μg/ml of blood. Because of this poor sensitivity, a spectrophotometric assay was not attempted and the development of a spectrofluorometric assay based on a reported method (16) was undertaken.

The compound exhibits moderate fluorescence emission at 415 nm (*TM*/μg/ml = 498) in ethyl acetate with an excitation maximum at 310 nm (Fig. 1). The fluorescence of the compound is linear with concentration over the range of 0.04–20 μg of I/ml of ethyl

5	2.7	3.8
24	0.4	0.4

acetate (Fig. 2). The overall sensitivity limit of the assay, 0.5 μg of I/ml of sample, is restricted by interferences from the sample extract of the dog blood.

The ether residues of the sample extracts contain a yellow-colored coextracted biological impurity, which necessitates the addition of 200 μl of ether to effect its solution in ethyl acetate. This impurity imparts a distinct yellow color to the ethyl acetate solution used for spectrofluorometric measurement and produces fluorescence quenching to the extent of about 10%. Therefore, the samples and internal standards must be measured in the same volume of ethyl acetate.

Back-extraction of the samples, using a variety of acidic and basic aqueous solutions to effect better cleanup, was unsuccessful. Contact with solutions below pH 11 resulted in a shift of the excitation and emission maxima to 320 and 370 nm, respectively, with a corresponding decrease in overall fluorescence yield. Washing with strongly alkaline solutions also decreased the overall sensitivity.

Application of the pyrolysis flame-ionization GLC (12) was not successful due to the presence of many coextracted impurities that interfered with the measurement of the analytical retroaldol ketone (II) peak.

The spectrofluorometric assay presented is more rapid than the bioautographical assay (13), but it is not as sensitive. In the bioautographical assay, larger volumes of samples can be extracted. This same assay procedure is applicable to urine samples with recoveries ($\pm SD$) of 80.5 ± 4.2% in the concentration range of 1.0–10.0 μg/ml.

APPLICATIONS

Blood levels were determined in a male dog by the spectrofluorometric assay following intravenous administration of 5 mg of lasalocid/kg (Table II). A peak blood level of 15.8 μg of I/ml was obtained at 5 min and declined to 0.4 μg of I/ml at 24 hr.

These same samples were also analyzed by the bioautographical assay (13), and satisfactory correlation was found between the two assays. Examination of the ethyl acetate solutions by TLC following fluorometric analysis did not reveal the presence of other fluorescent zones due to possible metabolites (after spraying with ethanol–sodium hydroxide) that may interfere with the specificity or accuracy of the fluorometric assay. This finding does not, however, preclude the presence of nonfluorescent UV-absorbing metabolites that are extractable under the same conditions.

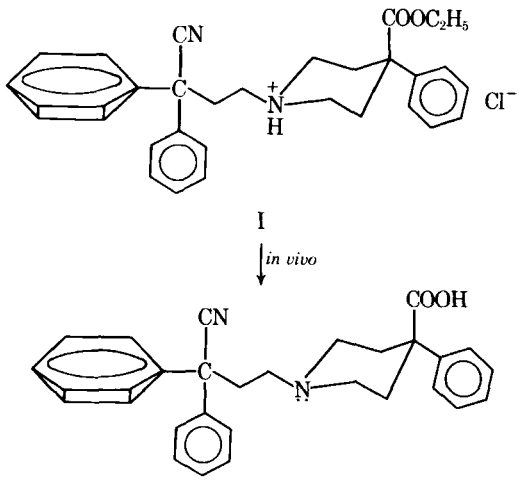
In Vitro Adsorption of Diphenoxylate Hydrochloride on Activated Charcoal and Its Relationship to Pharmacological Effects of Drug *In Vivo* I

DILIP R. SANVORDEKER ˣ **and ESAM Z. DAJANI**

Abstract □ The adsorption of diphenoxylate hydrochloride, a potent antidiarrheal agent, on activated charcoal powder was studied *in vitro*. Langmuir adsorption isotherms were established at pH 4 and 7, and the maximum adsorption capacity of charcoal for this drug was estimated using these values. Activated charcoal modified the bioavailability of diphenoxylate hydrochloride *in vivo*. The antipropulsive action of diphenoxylate in the mouse was strongly inhibited in the presence of activated charcoal. A comparative evaluation of charcoal and chromium oxide used as inert, nonabsorbable markers revealed that chromium oxide may be the marker of choice in GI transit studies in laboratory animals since it does not influence the bioavailability of diphenoxylate hydrochloride.

Keyphrases □ Diphenoxylate hydrochloride—adsorption on activated charcoal and chromium oxide, effect on bioavailability □ Bioavailability—diphenoxylate hydrochloride, effect of activated charcoal and chromium oxide □ Adsorption—diphenoxylate hydrochloride on charcoal and chromium oxide, pH 4 and 7 Langmuir isotherms

It has been established that the presence of a solid adsorbent, such as activated charcoal, interferes with the drug absorption process, resulting in a decrease in bioavailability of some drugs (1–5). Such an interference in the systemic availability of a drug is brought about by its adsorption on the activated surface of the solid adsorbent, thus preventing the adsorbed fraction of the drug from permeating through the GI mucosa into the bloodstream. In general, under *in vitro* experimental conditions the drug adsorption phenomenon exhibits Langmuir adsorption isotherm characteristics (4–8). Indeed, this principle of surface adsorption has found clinical usefulness in the management of acute toxicity in drug overdosing of pediatric as well as adult patients (9).



Scheme I

Diphenoxylate hydrochloride (I), a potent antidiarrheal agent, has been shown to be clinically effective for the management of severe diarrhea (10). In pediatric use, however, there is a persistent concern about the overdosage of this drug given in combination with atropine sulfate (11, 12). One aspect of this problem is the rapid absorption of the drug as manifested by possible enterohepatic circulation of diphenoxylic acid (II), the major metabolite (Scheme I), from the lower intestinal tract (13).

It was of interest, therefore, to explore the possibility of altering the *in vitro* availability of diphenoxylate hydrochloride (I) in the presence of activated charcoal powder and to assess its relationship to the pharmacological activity of this drug *in vivo*. This report presents the results of these investigations and their clinical implications in the management of overdosage problems related to this drug.

EXPERIMENTAL

Materials—All reagents used were analytical grade. Diphenoxylate hydrochloride[1] was tested for its structure identity and purity prior to use. Activated charcoal powder[2], chromium oxide[3], methylcellulose[4], and absolute alcohol[5] were used as supplied.

Methods—All *in vitro* adsorption studies were conducted at 25°. Studies with activated charcoal were conducted at pH 2, 4, and 7 with a 0.2% solution of diphenoxylate hydrochloride in hydroalcoholic mixtures (50:50 v/v). Accurately weighed amounts of activated charcoal powder, 0.02–1 g, were transferred to 25-ml test tubes with screw caps. After 25 ml of a 0.2% solution of diphenoxylate hydrochloride was added to each test tube, the charcoal suspensions were continuously mixed[6] for 20 hr. The suspensions were then rapidly centrifuged, and the clear supernatant liquid was assayed spectrophotometrically at 258 nm[7].

Appropriate control solutions were also run and assayed to ensure control over experimental conditions. The amount of diphenoxylate hydrochloride adsorbed on the charcoal was determined on the basis of a previously established standard curve. Studies with chromium oxide were conducted in a similar manner with the adsorbent at 0.5 and 1.0 g in suspension with a 0.2% solution of diphenoxylate hydrochloride and the blank solvent. The following *in vivo* studies were performed.

GI Transit Time in Mice—The method used was adapted from previous studies (14, 15). In these experiments, the extent of GI propulsion was measured with the aid of nonabsorbable and visually identifiable markers such as charcoal. Six male Charles River mice, 20–25 g, were fasted in screen-bottom cages with water supplied *ad libitum* for 24 hr prior to the test. The animals were orally pretreated with logarithmically graded doses (0.3–18 mg/kg) of diphenoxylate hydrochloride in a 0.5% solution of methylcellulose in water. The total volume of the suspension administered to

Table I—Effect of Charcoal on the Antipropulsive Activity of Diphenoxylate Hydrochloride in the Mouse

Treatment Condition	$ED_{50} \pm SE$, mg/kg po	Relative Potency
Diphenoxylate hydrochloride administered 30 min prior to charcoal	3.12 ± 1.29	1.0
Diphenoxylate hydrochloride and charcoal administered simultaneously	14.77 ± 6.59	0.22 ± 0.14[a]

[a] Statistically significant at $p = 0.02$ level.

these animals was kept constant at 10 ml/kg. The control group received the same volume of 0.5% methylcellulose solution.

Thirty minutes after drug administration, the animals were given a single 0.2-ml dose of a 10% suspension of activated charcoal powder in 1% methylcellulose solution. The animals were sacrified 3.5 hr later, and the cecum was examined for the presence or absence of charcoal on an all-or-none basis. In 95% of all control animals, charcoal was present in the cecum. Antidiarrheal drugs, such as diphenoxylate hydrochloride, interfere with the GI propulsive activity, so the presence or absence of charcoal in the cecum provides a measure for the pharmacological response to these drugs. Consequently, the median effective dose (ED_{50}) can then be calculated by using the logistic method of Berkson (16).

In a second experiment, logarithmically graded doses (4.6–46.0 mg/kg) of diphenoxylate hydrochloride mixed with charcoal powder in methylcellulose solutions were administered to the animals; the extent of charcoal translocation also was evaluated in a similar manner. The relative potencies for the two experiments were calculated using the logistic method of Berkson (16).

Effect of Chromium Oxide as a Marker on Antipropulsive Activity of Diphenoxylate Hydrochloride in Mice—In this study, the antipropulsive activity of diphenoxylate hydrochloride was evaluated using a second nonabsorbable and visually identifiable marker, chromium oxide. The experimental design was essentially the same as described previously. Aqueous solutions of methylcellulose (0.5%) were used to prepare 10% suspensions of charcoal or chromium oxide. Thirty minutes after the administration of diphenoxylate hydrochloride as a suspension in 0.5% methylcellulose, the animals were given a single 0.2-ml dose of the marker preparation. The animals were sacrificed 3.5 hr later, and the presence or absence of the marker in the cecum was evaluated on an all-or-none basis.

Chromium oxide	0.68 ± 0.18	6.07 ± 2.97[a]

[a] Statistically significant at $p < 0.05$.

RESULTS AND DISCUSSION

Figure 1 illustrates the Langmuir adsorption isotherm for the uptake of diphenoxylate hydrochloride by activated charcoal powder suspended in pH 4 and 7 solutions. The reciprocal of the slope of the two lines (A and B) gives the maximum binding capacity of charcoal at the given pH. A twofold increase in the binding capacity was observed for diphenoxylate hydrochloride at pH 7 as compared to pH 4 solutions. No significant difference in the extent of drug adsorption was observed between pH 2 and 4 solutions.

These data indicate that the nonionized species of diphenoxylate hydrochloride (pKa = 4.4) is more preferably adsorbed than its ionized species in solution. The lipophilic moieties (phenyl and piperidyl) of this drug probably promote drug adsorption through hydrophobic interaction with the activated surface of the charcoal particles. Such a possibility is consistent with previous findings on the nature of the activated carbon surface (7, 17). Furthermore, the lipophilic nature of diphenoxylate hydrochloride, as evidenced by its partition coefficient[8] ($PC_{CHCl_3-H_2O} \geq 68.5$) supports the occurrence of such an interaction between diphenoxylate hydrochloride and activated charcoal. Under given experimental conditions, the maximum adsorption capacity of charcoal was estimated at 200 and 416 mg/g of charcoal in suspension at pH 4 and 7, respectively.

To assess whether charcoal modifies the pharmacological activity of diphenoxylate hydrochloride *in vivo*, GI transit studies of the drug with and without activated charcoal were carried out in the mice. Table I illustrates the effect of charcoal on the antipropulsive activity of diphenoxylate hydrochloride in the mouse; coadministration of the two compounds significantly affected the potency of diphenoxylate hydrochloride as a constipating agent. In the presence of activated charcoal, there was a fourfold decrease in the relative potency of diphenoxylate hydrochloride. These results strongly suggest that the adsorption of diphenoxylate to activated charcoal can occur *in vivo*, resulting in a modification of the antipropulsive activity of this drug.

In view of these findings, it was of interest to examine whether a different marker, such as chromium oxide, which shares with charcoal the property of being pharmacologically inert, can affect the observed antipropulsive activity of diphenoxylate hydrochloride. Furthermore, investigations on sterol balance in humans (18) have provided ample evidence that chromium oxide exhibits superior performance as an inert, nonabsorbable marker for GI transit studies. *In vitro* studies showed that a 2–4% suspension of chromium oxide adsorbs diphenoxylate hydrochloride only to the extent of 10–18%, whereas activated charcoal at the same level in suspension adsorbs virtually all drug in solution.

As evident from Table II, the quantitative response of diphenoxylate hydrochloride was strongly influenced by the choice of the marker in the mouse studies. With chromium oxide, diphenoxylate hydrochloride showed a sixfold increase in its relative potency as compared to charcoal used conventionally to screen for antipropulsive activity of antidiarrheal agents. The important implication of these findings is that charcoal may not provide the desired "inert" nature as a marker since it can modify the apparent pharmacological activity of antidiarrheal agents such as diphenoxylate hydrochloride.

The clinical implications of these adsorption studies are obvious when one considers the maximum adsorption capacity of activated charcoal for diphenoxylate hydrochloride. Although the use of activated charcoal for the management of accidental overdosage of

[8] The partition coefficient was estimated on the basis of saturation solubility of this drug in the two solvents.

diphenoxylate hydrochloride has been suggested previously, the present studies provide *in vitro* as well as *in vivo* evidence to support the possibility that activated charcoal may significantly modify the bioavailability of this drug.

Electron-Capture GLC Determination of Timolol in Human Plasma and Urine

D. J. TOCCO [x], F. A. deLUNA, and A. E. W. DUNCAN

Abstract □ A GLC procedure was developed for measuring nanogram quantities of timolol in plasma and urine. The unchanged drug was extracted into heptane–4% isoamyl alcohol from alkalinized plasma or urine, together with a homolog of timolol which served as the internal standard. The compounds were subsequently back-extracted into 0.1 *N* HCl and then into chloroform following adjustment of the acid phase to an alkaline pH. The compounds in the chloroform extract were derivatized with heptafluorobutyrylimidazole to form the diheptafluorobutyryl derivatives; these were quantitated by electron-capture GLC. Recovery of timolol added to normal plasma and urine was quantitative and reproducible, and no interfering substances were observed in normal biological samples. The method is capable of measuring concentrations as low as 2 ng/ml in plasma or 20 ng/ml in urine. After a 10-mg oral dose of ^{14}C-timolol, peak plasma levels of approximately 30 ng/ml were observed in 1–2 hr.

Keyphrases □ Timolol—extraction, derivatization, GLC analysis, biological fluids □ Adrenergics—timolol, extraction, derivatization, GLC analysis, biological fluids □ GLC—analysis, timolol, biological fluids

Timolol maleate, (−)-1-(*tert*-butylamino)-3-[(4-morpholino-1,2,5-thiadiazol-3-yl)oxy]-2-propanol maleate, is a new β-adrenergic receptor blocking agent (1). More recently, it was shown to reduce the frequency of anginal episodes and thus have a place in the treatment of angina pectoris (2). When administered orally to rats and dogs, the compound is several times more potent than propranolol in blocking isoproterenol-induced cardiac acceleration (3). Its activity in humans also has been demonstrated (4, 5).

This report is concerned with the determination of timolol in biological fluids. In view of the small therapeutic doses used (generally 5–15 mg po), a sensitive as well as a specific analytical method is required. The procedure involves extraction of the compound from biological fluids followed by derivatization to form the diheptafluorobutyryl analog and determination by electron-capture GLC. The procedure is capable of quantitating timolol in concentrations as little as 2 ng/ml in plasma and 20 ng/ml in urine. Accordingly, the method should prove useful in clinical applications where quantitation and diagnostic confirmation are necessary.

EXPERIMENTAL

Reagents—Pesticide quality *n*-heptane[1] was used without further purification. Reagent grade isoamyl alcohol[2] was glass distilled prior to use. Methylene chloride[3], reagent grade, was washed successively with 1 *N* HCl, 1 *N* NaOH, and three times with water and then glass distilled. Distilled, deionized water was used in the preparation of 0.1 *N* HCl and 2.0 *N* NaOH. Heptafluorobutyrylimidazole[4], in 1-ml ampuls stored under nitrogen, was diluted 1:10 with pesticide quality ethyl acetate[5] immediately before use. Timolol (I) was used as the maleate salt, and desmethyltimolol, 1-isopropylamino-3-[(4-morpholino-1,2,5-thiadiazol-3-yl)oxy]-2-propanol hydrochloride (II) served as the internal standard. All concentrations were expressed in terms of the free base.

Apparatus—Samples were analyzed on a gas chromatograph[6]

diphenoxylate hydrochloride has been suggested previously, the present studies provide *in vitro* as well as *in vivo* evidence to support the possibility that activated charcoal may significantly modify the bioavailability of this drug.

Electron-Capture GLC Determination of Timolol in Human Plasma and Urine

D. J. TOCCO [x], F. A. deLUNA, and A. E. W. DUNCAN

Abstract □ A GLC procedure was developed for measuring nanogram quantities of timolol in plasma and urine. The unchanged drug was extracted into heptane–4% isoamyl alcohol from alkalinized plasma or urine, together with a homolog of timolol which served as the internal standard. The compounds were subsequently back-extracted into 0.1 *N* HCl and then into chloroform following adjustment of the acid phase to an alkaline pH. The compounds in the chloroform extract were derivatized with heptafluorobutyrylimidazole to form the diheptafluorobutyryl derivatives; these were quantitated by electron-capture GLC. Recovery of timolol added to normal plasma and urine was quantitative and reproducible, and no interfering substances were observed in normal biological samples. The method is capable of measuring concentrations as low as 2 ng/ml in plasma or 20 ng/ml in urine. After a 10-mg oral dose of ^{14}C-timolol, peak plasma levels of approximately 30 ng/ml were observed in 1–2 hr.

Keyphrases □ Timolol—extraction, derivatization, GLC analysis, biological fluids □ Adrenergics—timolol, extraction, derivatization, GLC analysis, biological fluids □ GLC—analysis, timolol, biological fluids

Timolol maleate, (−)-1-(*tert*-butylamino)-3-[(4-morpholino-1,2,5-thiadiazol-3-yl)oxy]-2-propanol maleate, is a new β-adrenergic receptor blocking agent (1). More recently, it was shown to reduce the frequency of anginal episodes and thus have a place in the treatment of angina pectoris (2). When administered orally to rats and dogs, the compound is several times more potent than propranolol in blocking isoproterenol-induced cardiac acceleration (3). Its activity in humans also has been demonstrated (4, 5).

This report is concerned with the determination of timolol in biological fluids. In view of the small therapeutic doses used (generally 5–15 mg po), a sensitive as well as a specific analytical method is required. The procedure involves extraction of the compound from biological fluids followed by derivatization to form the diheptafluorobutyryl analog and determination by electron-capture GLC. The procedure is capable of quantitating timolol in concentrations as little as 2 ng/ml in plasma and 20 ng/ml in urine. Accordingly, the method should prove useful in clinical applications where quantitation and diagnostic confirmation are necessary.

EXPERIMENTAL

Reagents—Pesticide quality *n*-heptane[1] was used without further purification. Reagent grade isoamyl alcohol[2] was glass distilled prior to use. Methylene chloride[3], reagent grade, was washed successively with 1 *N* HCl, 1 *N* NaOH, and three times with water and then glass distilled. Distilled, deionized water was used in the preparation of 0.1 *N* HCl and 2.0 *N* NaOH. Heptafluorobutyrylimidazole[4], in 1-ml ampuls stored under nitrogen, was diluted 1:10 with pesticide quality ethyl acetate[5] immediately before use. Table I—Recovery of Timolol from Human Plasma

Timolol Added, ng/ml	Found, ng/ml	Percent Recovery, Mean ± *SD*
50	49.0 ± 4.0	98 ± 7
40	38.0 ± 5.0	95 ± 12
20	18.0 ± 2.0	90 ± 9
10	8.5 ± 2.0	85 ± 18
5	5.7 ± 0.9	120 ± 18
2	1.9 ± 0.8	95 ± 40

equipped with a ^{63}Ni (2 mCi) electron-capture detector and a 1.83-m × 0.64-cm (6-ft × 0.25-in.) column packed with 1% OV-17 on Gas Chrom Q[7] (80–100 mesh). The instrument was operated isothermally with oven, detector, and injection port temperatures maintained at 185, 300, and 250°, respectively; the carrier gas (helium) and the purge gas (10% methane in argon) were each maintained at 75 ml/min. The pulse mode of voltage was used with a pulse interval of 50 μsec. Gas lines were fitted with filters containing molecular sieve 4A.

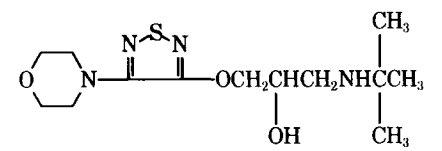
Procedure—In a 30-ml glass-stoppered centrifuge tube were placed 1.0 ml of plasma or 0.1 ml of urine, 0.1 ml of desmethyltimolol internal standard (stock solution, 500 ng/ml of water), 0.1 ml of 1.0 *N* NaOH, and 10 ml of heptane–4% isoamyl alcohol. The mixture was shaken mechanically for 10 min and centrifuged. In a clean 13-ml glass-stoppered centrifuge tube were placed 1.0 ml of 0.1 *N* HCl and 8.0 ml of the organic phase.

After the tube was shaken for 10 min and centrifuged, the organic phase was discarded by aspiration and the aqueous phase was washed three times with 10 ml of *n*-heptane to remove traces of the isoamyl alcohol. To the aqueous phase were added 0.2 ml of 2 *N* NaOH and 5.0 ml of methylene chloride. The samples were shaken for 10 min and centrifuged. The aqueous phase was carefully aspirated, and 4.0 ml of the organic phase was added to a clean 13-ml glass-stoppered tube. The contents were evaporated to dryness in a 60° water bath under a stream of nitrogen.

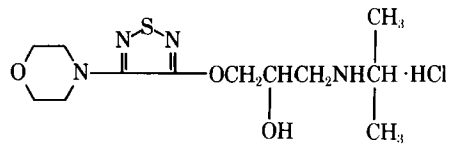
The residue was dissolved in 0.1 ml of the heptafluorobutyrylimidazole–ethyl acetate reagent, and the stoppered tube was immersed in a boiling water bath for 1 hr. The tubes were cooled to room temperature, 3.0 ml of *n*-heptane plus 1.0 ml of 0.1 *N* HCl was added, and the tubes were then shaken for 10 min. After centrifugation, 2.0 ml of the *n*-heptane phase was transferred to a clean 13-ml conical centrifuge tube and the contents were evaporated to dryness at 60° using a stream of nitrogen.

The residue was dissolved in 0.1 ml of *n*-heptane, and 1–5 μl was chromatographed. The retention times of derivatized timolol and derivatized internal standard were 7.6 and 6.0 min, respectively. GC–mass spectrometric methods showed that the products of acylation of these compounds are the diheptafluorobutyryl derivatives[8].

Peak heights for derivatized timolol and internal standard were measured to the nearest millimeter. A standard curve was constructed by analysis of samples of control plasma containing known quantities of timolol and internal standard. The ratio obtained by dividing the timolol peak height by the internal standard peak height was plotted against the concentration of timolol in



I



II

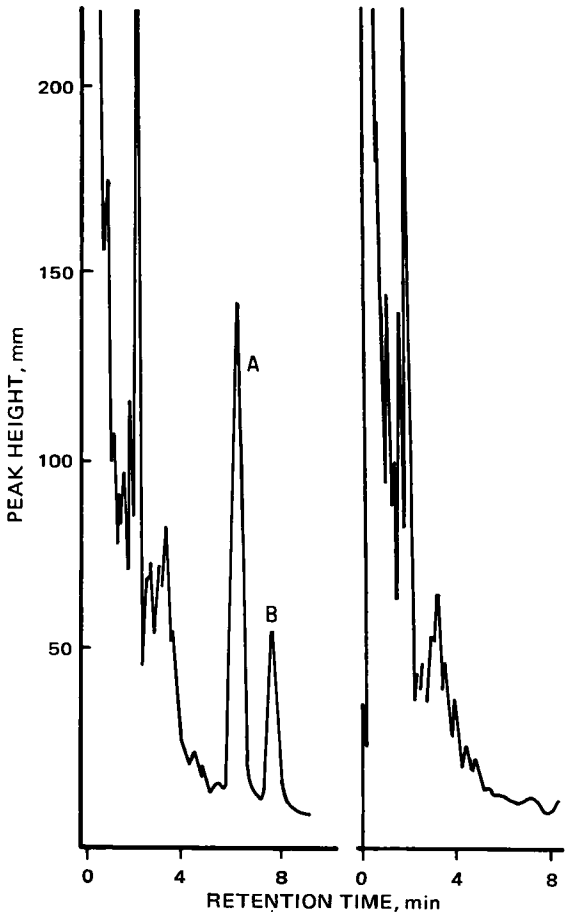


Figure 1—*Gas–liquid chromatograms (electron-capture detector) of human plasma extracts. Left: 50 ng of desmethyltimolol (A) and 20 ng of timolol (B) added to 1.0 ml of plasma. Right: control human plasma.*

nanograms per milliliter of plasma or urine. The line that best fit the data was drawn through the experimental points and the origin. Concentrations of timolol in biological samples were determined by interpolation from the standard curve.

Timolol in Human Plasma—Three healthy human subjects were given a single oral dose (either a tablet or solution) containing 10 mg of ^{14}C-timolol in which both carbons of the thiadiazole ring were labeled. Fourteen days later, the same subjects were given a second 10-mg dose in a simple crossover design. Blood was collected in heparinized containers at intervals during 24 hr following each dose, and plasma was separated by centrifugation and frozen until assayed.

"Apparent timolol" in plasma was determined by measuring the radioactivity in the heptane–4% isoamyl alcohol extract of plasma. Aliquots (0.5 ml) were evaporated to dryness in counting vials. The samples were counted in 16 ml of a toluene medium containing 2-(4′-*tert*-butylphenyl)-5-(4″-biphenylyl)-1,3,4-oxadiazole (8 g/liter), 2-(4-biphenylyl)-6-phenylbenzoxazole (0.5 g/liter), and solubilizer[9] (125 ml/liter).

At least 5000 total counts were made on all samples[10]. The counting efficiency was determined by external standardization and corrected for a background counting rate of approximately 40 cpm.

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram obtained when plasma was assayed by the electron-capture procedure. In this sample, 50 ng of internal standard (peak A) and 20 ng of timolol (peak B)

[7] Applied Science Laboratories.

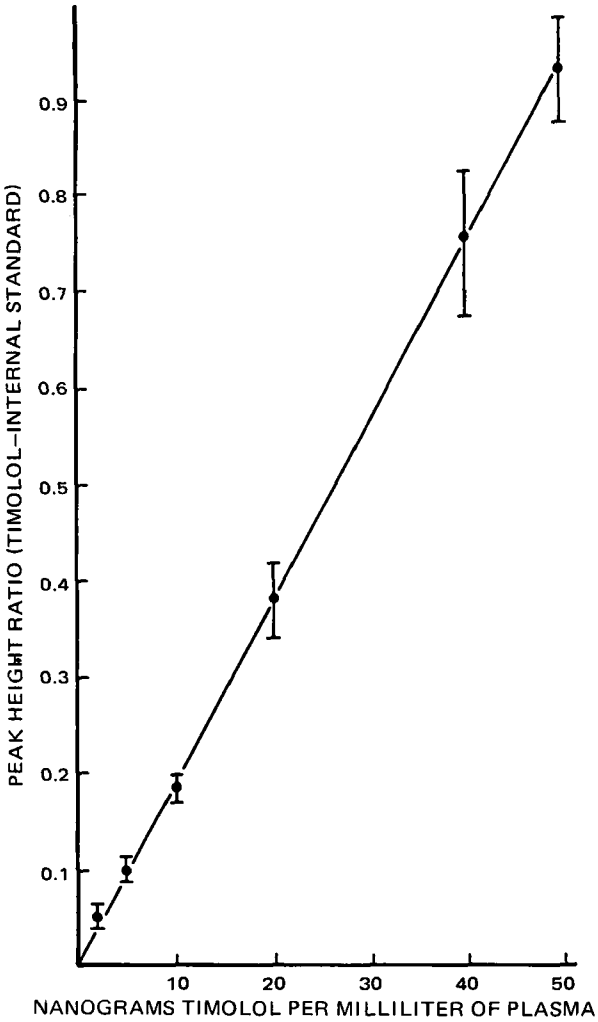

Figure 2—*Calibration curve showing the relationship between the peak height ratio of the diheptafluorobutyryl derivatives of timolol and desmethyltimolol and the amount of timolol in plasma. Each point represents the mean ± SD for four determinations.*

were added to 1.0 ml of human plasma and carried through the procedure. This concentration of timolol gave a peak height of approximately 50 mm (32 pamp) at a range setting of 10 and an attenuation of 16. Blank plasma samples assayed in the same manner gave no interfering peaks on the chromatogram.

Quadruplicate samples, containing 2.0–50 ng of timolol/ml of plasma, were adequately recovered (Table I). The concentrations found were equal to 98 ± 22% (*SD*) of the actual values. A calibration curve prepared from these data indicates that the peak height ratios of timolol–internal standard were linear when plotted against the concentration of timolol, and the curve passed through the origin (Fig. 2). The lower limit of sensitivity was 2.0 ng/ml, and the upper limit of linearity was at least 50 ng/ml.

Plasma levels of timolol were determined in six human subjects over 24 hr following a single oral 10-mg dose of ^{14}C-timolol (Table II). Apparent timolol, *i.e.*, radioactive equivalents of timolol that were extracted by heptane–4% isoamyl alcohol, showed reasonably

Table II—Mean Plasma Levels of Timolol in Six Human Subjects after a Single Oral 10-mg Dose of ^{14}C-Timolol[a]

Time after Dose, hr	Timolol in Plasma, ng/ml ± *SD*		Ratio of Apparent Timolol–Timolol
	"Apparent Timolol"[b]	Timolol

[a] Timolol labeled with ^{14}C in both carbons of the thiadiazole ring had a specific activity of 3996 dpm/μg. [b] The radioactive equivalents of timolol, expressed as nanograms per milliliter, that were extracted from plasma during the analytical procedure for timolol.

good agreement with the timolol concentration as measured by the electron-capture procedure. The ratio of apparent timolol–timolol was 1.11 ± 0.24 (mean ± *SD*). Peak plasma levels of 31 ng/ml occurred at 2 hr after drug administration. The half-life of the drug in plasma was approximately 3 hr.

The electron-capture method was applied to numerous samples of urine as well as plasma. Electrophoretograms of human urine have shown that timolol is the only drug-related base in the urine[11]. Hence, the method is presumed to be specific for determining the intact compound in plasma and urine. In humans, 10–20% of an oral 10-mg dose of timolol was excreted unchanged. Frequently the concentration of drug in the urine was between 500 and 2000 ng/ml. Therefore, to avoid unnecessary dilution at the end of the assay, a smaller aliquot (0.1 ml of urine) should be processed at the beginning. As with plasma, blank urine samples gave no interfering peaks on the chromatogram.

Synthesis of *dl*-4ξ-(2-Carboxyethyl)-*cis*-hexahydropyrrolo-[3,4-*d*]imidazol-2-one (Bisnorazabiotin)

HENRY C. WORMSER ˣ **and HANLEY N. ABRAMSON**

Abstract □ Bisnorazabiotin was synthesized in a six-step sequence from 1,5-dioxo-2-carbethoxypyrrolizidine. It is anticipated that the molecule will serve as a cofactor for biotin-requiring enzymes.

Keyphrases □ Biotin analog—synthesis of *dl*-4ξ-(2-carboxyethyl)-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (bisnorazabiotin), IR, UV, and NMR spectra □ Bisnorazabiotin—synthesis of biotin analog *dl*-4ξ-(2-carboxyethyl)-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one, IR, UV, and NMR spectral analyses

Previous articles (1–3) reported the synthesis of several analogs of biotin (I) prepared as potential cofactors for biotin-dependent enzymes. The synthesis of bisnorazabiotin, utilizing a slightly modified synthetic approach, is reported here.

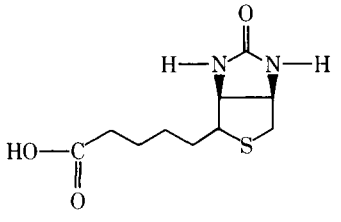
DISCUSSION

The starting point in this sequence (Scheme I) is 1,5-dioxo-2-carbethoxypyrrolizidine (II), prepared in high yield by a modification of the procedure of Gensler and Wu (4). Conversion of II to the enamine (III) was accomplished with ammonium formate in hot isopropanol. When methanol or ethanol was the solvent for this amination, the yield of enamine was considerably lower and TLC of the crude mixtures revealed the presence of an additional product of lesser polarity than either II or III.

Column chromatography of the product obtained from the amination of II in ethanol gave a 30% yield of a compound characterized as ethyl *N*-(2-carbethoxyethyl)-5-oxopyrrolidine-2-carboxylate (IV*b*) (5). The latter actually represents a reverse Dieckmann product of II. Since each stage of the Dieckmann condensation is completely reversible, the reverse reaction has been frequently used to convert β-ketoesters to open chain dicarboxylates (6–10). Under normal circumstances, a small amount of alkoxide in alcoholic solvent is sufficient to bring about the transformation. Although ammonium formate in alcohol is not a particularly basic medium, a minute amount of alkoxide might conceivably form, due to the ionization of the salt, catalyzing the reverse Dieckmann reaction.

When methanol was used as solvent, a 40% yield of methyl *N*-(2-carboxyethyl)-5-oxo-2-pyrrolidinecarboxylate (IV*a*) was obtained. A close examination of the same reaction in isopropanol failed to reveal a reverse Dieckmann product, probably indicating steric hindrance to the approach of isopropoxide anion. Treatment of III with acetic anhydride gave a crystalline enamine acetate (V) in 89% yield. Compound V should be used soon after its preparation or stored under an inert atmosphere, since exposure to air leads to the formation of the pyrrole (VI) (1, 3).

Reduction of V to *cis*-VII was effected catalytically in the presence of platinum in a Parr shaker. Conversion of VII to the tricyclic IX was carried out through the intermediacy of a hydrazide and the Curtius rearrangement of the corresponding acyl azide. Hydrolysis of the lactam ring of IX with aqueous base gave the desired amino acid (X).



I

EXPERIMENTAL[1]

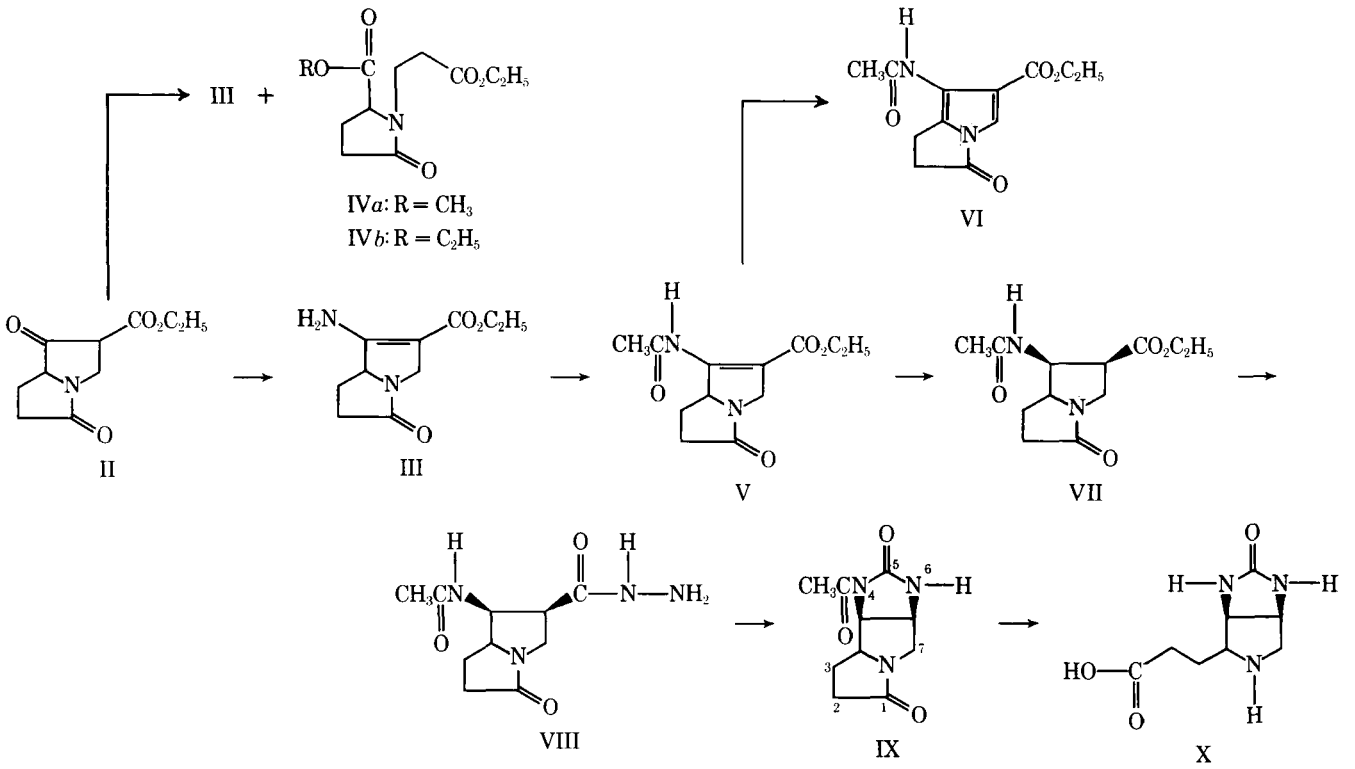
1,5-Dioxo-2-carbethoxypyrrolizidine (II) (4)—A solution of ethyl *N*-(2-carbethoxyethyl)-5-oxopyrrolidine-2-carboxylate (5) (51.46 g, 0.20 mole) in 250 ml of dry benzene was treated with sodium (4.8 g, 0.21 mole) and refluxed for 30 hr. The glassy, brown sodium enolate was filtered and dried (48.32 g, 100%). The free enol ester was released by adding the powdered enolate salt to a stirring slurry of chipped ice, concentrated hydrochloric acid, and chloroform. The chloroform solution was separated, and the aqueous phase was extracted with several portions of fresh chloroform. The combined chloroform extracts were washed with water and dried (magnesium sulfate). Evaporation of the solvent afforded 41.3 g of oily product, which showed one spot on TLC (30% methanol in ether) and gave a purple color with ferric chloride solution; IR: λ_{max} (chloroform) 5.63, 5.76, 5.87, and 6.13 μm.

Reaction of II with Ammonium Formate—*In Isopropanol*—A solution of 21.12 g (0.10 mole) of II and 12.6 g (0.20 mole) of ammonium formate in 150 ml of isopropanol was refluxed for 4 hr. The solvent was removed *in vacuo*, and the residue was partitioned between water and chloroform. The organic layer was washed with water, dried (magnesium sulfate), and concentrated to yield 20.6 g (98%) of 1-amino-5-oxo-2-carbethoxypyrrolizid-1-ene (III) as a light-brown oil. TLC on silica gel GF_{254} (10% methanol in ether) showed primarily one spot. Preparative TLC on silica gel $PF_{254+366}$, as well as column chromatography on silica gel, failed to afford a crystalline product; IR: λ_{max} (chloroform) 2.84, 2.95, 5.93, and 6.12 μm; UV: λ_{max} (ethanol) 274.5 nm; NMR: δ 1.28 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.00–2.80 (4H, m, $-CH_2CH_2$), 4.22 (2H, q, $-OCH_2CH_3$, J = 7 Hz), and 5.97 (2H, s, $-NH_2$).

In Methanol—A mixture of 4.23 g (0.02 mole) of II and 2.5 g (0.04 mole) of ammonium formate in 50 ml of methanol was stirred at room temperature for 48 hr and then refluxed for 1 hr. The separation, as described for isopropanol, gave 3.66 g of a dark-brown oil. TLC (10% methanol in ether) showed primarily two spots, with the lower R_f compound corresponding to III. The crude oil was chromatographed on 50 g of silica gel, eluting with progressively increasing concentrations of chloroform in benzene (200-ml fractions). Fractions 6–13 afforded a yellow oil (1.96 g, 40%), which proved homogeneous by TLC on silica gel G (2% methanol in ether). Fractions 17–19 afforded 1.46 g (34.7%) of a light-brown oil; IR, UV, and NMR data were identical to those of the product obtained using isopropanol (III). The less polar oil was distilled and afforded a pale-yellow oil (bp 148–149° at 0.23 mm); IR: λ_{max} (chloroform) 5.75 and 5.90 μm; NMR: δ 1.27 (3H, t, $-OCH_2CH_3$, J = 7 Hz), 2.62 [2H, t, ring $-CH_2C(=O)-$, J = 7 Hz], and 4.17 (4H, q, $-OCH_2CH_3$, J = 7 Hz); $[\alpha]_D^{25}$ 0°.

Anal.—Calc. for $C_{11}H_{17}NO_5$: C, 54.31; H, 7.04; N, 5.76. Found: C, 54.36; H, 7.06; N, 5.80.

[1] Melting points were taken on a Fisher-Johns melting-point stage and a Thomas-Hoover melting-point apparatus and are uncorrected. UV absorption spectra were determined in 95% ethanol on a Beckman recording spectrophotometer (model DK2A). IR absorption spectra were recorded on Beckman recording spectrophotometers (models 8 and 33). NMR spectra were determined in deuteriochloroform, using tetramethylsilane as the reference standard, on a Varian EM 360 spectrometer. Microanalyses were carried out by Spang Microanalytical Laboratory, Ann Arbor, Mich. TLC was carried out with silica gel G, silica gel GF_{254}, or silica gel $PF_{254+366}$. Column chromatography was performed with silica gel 60 (particle size 0.063–0.200 mm).



Scheme I

On this basis, the less polar oily product was identified as methyl *N*-(2-carbethoxyethyl)-5-oxo-2-pyrrolidine-2-carboxylate (IV*a*).

In Ethanol—A mixture of 6.24 g (0.03 mole) of II, 3.5 g (0.056 mole) of ammonium formate, and 95% ethanol (100 ml) was stirred for 48 hr at room temperature. The reaction mixture was refluxed for 1 hr, and the usual workup afforded 6.10 g of a dark-brown oil. TLC of this material was quite similar to that of the crude product obtained using methanol. The crude oil was chromatographed on 75 g of silica gel using the same elution scheme as described for the methanol method. Fractions 8–10 gave a yellow oil (2.3 g, 30%), homogeneous on TLC (2% methanol in ether; 5% methanol in ether). Distillation gave a colorless oil (bp 143–145° at 0.2 mm); IR: λ_{max} (chloroform) 5.77 and 5.92 μm; NMR: δ 1.26 (3H, t, —OCH_2CH_3, J = 7 Hz), 1.32 (3H, t, —OCH_2CH_3, J = 7 Hz), 2.61 [2H, t, ring —$CH_2C(=O)$—, J = 7 Hz], 4.16 (2H, q, —OCH_2CH_3, J = 7 Hz), and 4.26 (2H, q, —OCH_2CH_3, J = 7 Hz). This product was characterized as ethyl *N*-(2-carbethoxyethyl)-5-oxopyrrolidine-2-carboxylate (IV*b*) on the basis of superimposability of spectral data. Fractions 15–17 by TLC gave homogeneous III as a yellow oil (2.85 g, 45%).

1-Acetamido-5-oxo-2-carbethoxypyrrolizid-1-ene (V)—A solution of 12.6 g (0.05 mole) of III in 150 ml of acetic anhydride was heated on an oil bath at 90–100° for 3 hr. The excess acetic anhydride was removed under vacuum to give 13.4 g of a dark-brown oil, which crystallized upon standing at room temperature for several days. Recrystallization from ether gave colorless crystals (11.2 g, 89%), mp 123–126°. Two additional recrystallizations from ether gave the analytical sample, mp 127–129°; IR: λ_{max} (chloroform) 3.01, 5.87, 5.95, and 6.13 μm; UV: λ_{max} (ethanol) 274 nm (ε = 23,300); NMR: δ 1.31 (3H, t, —OCH_2CH_3, J = 7 Hz), 2.18 [3H, s, N—(C=O)CH_3], 2.00–2.90 (4H, m, —CH_2CH_2—), 4.26 (2H, q, —OCH_2CH_3, J = 7 Hz), and 5.25 (1H, s, NH).

Anal.—Calc. for $C_{12}H_{16}N_2O_4$: C, 57.13; H, 6.39; N, 11.10. Found: C, 57.10; H, 6.40; N, 11.06.

1-Acetamido-5-oxo-2-carbethoxy-6,7-dihydro-5*H*-pyrrolizine (VI)—A thin film of V (0.25 g, 1.0 mmole) on a watchglass was allowed to remain at room temperature while exposed to the air for 5 weeks. TLC on silica gel GF_{254} (10% methanol in ether) showed the appearance of a new spot with a higher R_f than V and very little remaining starting material. Crystallization from ether gave colorless crystals, mp 108–110°; IR: λ_{max} (chloroform) 2.96, 3.14, 5.68, and 5.92 μm; UV: λ_{max} (ethanol) 240 nm (ε = 31,300); NMR: δ 1.37 (3H, t, —OCH_2CH_3, J = 7 Hz), 2.17 [3H, s, NC(=O)CH_3], 4.37 (2H, q, —OCH_2CH_3, J = 7 Hz), 7.54 (1H, s, =CH), and 9.06 (1H, s, NH).

Anal.—Calc. for $C_{12}H_{14}N_2O_4$: C, 57.59; H, 5.64; N, 11.19. Found: C, 57.53; H, 5.79; N, 11.21.

1-Acetamido-5-oxo-2-carbethoxypyrrolizidine (VII)—Compound V (0.85 g, 3.37 mmoles), dissolved in 50 ml of absolute ethanol, was hydrogenated at 60 psi in a Parr shaker over platinum (100 mg of platinum oxide). The catalyst was filtered, and the ethanol was evaporated *in vacuo*, affording a colorless viscous oil (0.84 g, 98%). TLC on silica gel G (10% methanol in ether) showed disappearance of V and a new spot of lower R_f; IR: λ_{max} (chloroform) 2.91, 5.85, and 5.97 μm; NMR: δ 1.30 (3H, t, —OCH_2CH_3, J = 7 Hz), 2.02 [3H, s, NC(=O)CH_3], 4.24 (2H, q, —OCH_2CH_3, J = 7 Hz), and 6.85 (1H, d, NH, J = 7 Hz). All attempts to crystallize the compound failed.

6-Acetyldecahydroimidazo[4,5-*a*]pyrrolizine-1,5-dione (IX)—Compound VII (5.4 g, 0.021 mole), dissolved in 100 ml of absolute ethanol, was treated with 10 ml of hydrazine hydrate and kept at room temperature for 6 hr. The excess reagent and solvent were removed *in vacuo*, and the oily residue was subjected to vacuum for an additional 24 hr. A foamy, hygroscopic residue was obtained (5.14 g). This hydrazide, dissolved in 70 ml of 20% hydrochloric acid, was cooled to 3° and treated dropwise with sodium nitrite (2.53 g, 0.037 mole) in 10 ml of water, keeping the temperature near 0°. The reaction mixture was extracted with ethyl acetate (5 × 50 ml), the combined fractions were dried (magnesium sulfate), and the ethyl acetate solution was refluxed for 3 hr. Evaporation of the solvent gave a yellow oil, which crystallized upon the addition of 95% ethanol (3.2 g, 68%), mp 250–254°. Two recrystallizations from ethanol gave the analytical sample, mp 253–254°; IR: λ_{max} (mineral oil) 3.01, 3.13, 5.75, 5.93, and 6.01 μm.

Anal.—Calc. for $C_{10}H_{13}N_3O_3$: C, 53.81; H, 5.87; N, 18.82. Found: C, 53.75; H, 5.80; N, 18.79.

***dl*-4ξ-(2-Carboxyethyl)-*cis*-hexahydropyrrolo[3,4-*d*]imidazol-2-one (X)**—A suspension of IX (0.095 g, 0.43 mmole) in 3 ml of 10% sodium hydroxide was heated at 120° in a sealed tube. The colorless solution was evaporated to dryness, and the residual powder was neutralized with ethanolic hydrogen chloride. The crystalline product obtained (mp 174–176°, resolidifies at 177°, and then mp 252–254°) was recrystallized from aqueous ethanol. TLC on silica gel G in the following systems showed the product to be ho-

mogeneous: *n*-butanol–acetic acid–water (3:1:1), 95% ethanol–water (7:3), *n*-propanol–34% ammonia (7:3), 95% ethanol–34% ammonia (7:3), and *n*-propanol–water (1:1). One additional recrystallization from aqueous ethanol gave the analytical sample (mp 178–180°, resolidifies, and then mp 253–255°); IR: λ_{max} (mineral oil) 2.86, 2.91, and 5.92 μm.

Anal.—Calc. for $C_8H_{13}N_3O_3 \cdot H_2O$: C, 44.23; H, 6.96; N, 19.34. Found: C, 44.30; H, 7.00; N, 19.44.

Sodium Chloride Equivalents, Cryoscopic Properties, and Hemolytic Effects of Certain Medicinals in Aqueous Solution III: Supplemental Values

CURTIS SAPP [*], MICHAEL LORD [*], and E. ROY HAMMARLUND [x]

Abstract □ A supplemental table of sodium chloride equivalents and freezing-point depressions at various concentrations for 44 different substances in aqueous solution is presented. Also given in the table is the isosmotic concentration of each material that can form such a solution. The degree of hemolysis of human erythrocytes was determined in 24 different isosmotic solutions, and the data are presented in a table to supplement the previously published values. Eleven isosmotic solutions prevented hemolysis, and 13 others failed to prevent hemolysis.

Keyphrases □ Sodium chloride equivalents—data for 44 drugs □ Cryoscopic properties—data for 44 drugs □ Hemolytic effects—data for 44 drugs □ Drug substances—sodium chloride equivalents, cryoscopic properties, and hemolytic effects determined for 44 drugs

The sodium chloride equivalents and freezing-point depressions for 456 substances in aqueous solution were determined experimentally and reported previously (1–4). Furthermore, the degree of hemolysis of fresh human erythrocytes in certain aqueous isosmotic solutions was determined using the hemolytic method (3–5).

The objectives of the current investigation were to study, using the same methods, some additional available substances not included in the earlier cryoscopic and hemolytic investigations and to present these data in suitable tables to supplement the previous data.

EXPERIMENTAL

Cryoscopic Measurements—The method used for the measurements of the freezing points of the solutions was the same as that already reported; all freezing-point data were obtained with a cryoscopic osmometer (4).

The freezing-point measurements were corrected for the amount of disengaged ice, and −0.52° was used as the comparative freezing point for aqueous 0.9% reagent grade sodium chloride solution, which is isotonic and isosmotic with blood and tears. The materials studied were of the official grade of purity or better, and the grade of purity of the donated specialty preparations complied with the manufacturer's specifications.

Hemolysis of Human Erythrocytes—Colorimetric hemoglobin determinations were made to indicate the degree of hemolysis for solutions that could be made isosmotic. The method, utilizing a 45-min incubation period of erythrocytes in the isosmotic solution followed by centrifugation of the erythrocytes and ghosts and determination of absorbance *versus* a standard at 520 nm in a colorimeter, was reported previously in detail (3–5).

RESULTS AND DISCUSSION

Table I lists the sodium chloride equivalents and freezing-point depressions at various concentrations for the 44 currently studied substances. To use these data, one should employ the sodium chloride equivalent that represents the concentration nearest to the desired final concentration of medicinal substance used. Because of general interest in the colligative properties of medicinal solutions, the freezing-point depressions and sodium chloride equivalents are included for several substances that are not necessarily used as isotonic or isosmotic solutions. The sodium chloride equivalents and isosmotic concentrations are reported to the nearest 0.01.

The percent of hemolysis found for the 24 compounds studied is listed in Table II in addition to the isosmotic concentration used for each and the solution's approximate pH. For solutions that developed a color or cloudiness upon the addition of blood, the proportional decrease in the volume of the packed, nonhemolyzed centrifuged erythrocytes was estimated visually. Any noticeable change in appearance of the erythrocytes or the solution is referred to in the footnotes for Table II. Of the compounds studied, 11 isosmotic solutions prevented hemolysis of human erythrocytes and 13 failed to prevent hemolysis.

A compilation of the 293 substances whose isosmotic solutions were studied using the same hemolytic method in this laboratory

mogeneous: *n*-butanol–acetic acid–water (3:1:1), 95% ethanol–water (7:3), *n*-propanol–34% ammonia (7:3), 95% ethanol–34% ammonia (7:3), and *n*-propanol–water (1:1). [a] Top value is sodium chloride equivalent, and bottom value is freezing-point depression. [b] Isosmotic concentration, % w/v. [c] Solution foams readily.

shows that 136 failed to prevent hemolysis while 157 prevented hemolysis completely. One must be careful not to equate isotonicity and isosmoticity without knowledge of the corresponding data whenever a biological membrane is being utilized. This aspect was discussed in detail previously (2, 4–8).

Earlier reports in the series contained data on substances that foamed in aqueous solution and apparently aggregated above certain critical concentrations. These critical concentrations can be determined readily from the abrupt change in their cryoscopic graphs (3, 4, 9). The following behaved in this manner: benzethonium chloride, chlorpheniramine maleate, chlorpromazine hydrochloride, bromodiphenhydramine hydrochloride, dexchlorpheniramine maleate, dibucaine hydrochloride, fluphenazine hydrochloride, hydroxyzine hydrochloride, methotrimeprazine hydrochloride, pramoxine hydrochloride, pyrilamine maleate, nafcillin sodium, tetracaine hydrochloride, and valethamate bromide. Later, Altwood (10) studied micelle formation of some antihistamines in aqueous solution with a light-scattering photometer and reported their critical micelle concentrations (CMC), micellar weights, and aggregation numbers, which agreed well with our cryoscopic data.

Because of interest in the apparent aggregation of some substances in aqueous solution, the authors were especially looking for this characteristic discontinuity in the cryoscopic graphs from any of the 44 new compounds in this study, but none behaved in this manner. Triflupromazine hydrochloride was the only one whose graph even slightly suggested the possibility of any aggregation in solution. Its graph showed a slight discontinuity at a concentration of 0.019 *M* and approximately −0.05°, which corresponded to an apparent aggregation number of six. However, the discontinuity in the graph was not as distinct as it was with all of the before-mentioned substances.

A sufficient number of compounds demonstrated that they tend to aggregate in solution to suggest that this interfacial phenomenon may play a role in drug action by affecting biological activity. Associations taking place in the complex biological medium undoubtedly affect the thermodynamic activity of a given drug at the molecular level and, therefore, warrant increased study.

Table II—Hemolysis of Erythrocytes in Isosmotic Solutions

Substances	Isosmotic Concentration, % w/v	Hemolysis, %	Approximate pH
Acetylcysteine	4.58	100[a]	2.0
Alphaprodine hydrochloride	4.98	100	5.3
Anileridine hydrochloride	5.13	12	2.6
Arginine glutamate	5.37	0	6.9
Bupivacaine hydrochloride	5.38	83	6.8
Butabarbital sodium	3.33	0	6.8
Carbenicillin disodium	4.40	0	6.6
Chloroquine phosphate	7.15	0	4.3

Binding of Bile Acids to Cholestyramine at Gastric pH Conditions

SIEGFRIED LINDENBAUM ˣ and TAKERU HIGUCHI

Abstract □ The binding of bile salts to cholestyramine was studied under varying conditions of pH and added electrolyte. The taurine-conjugated bile salts were strongly absorbed by the anion-exchange resin at low pH and in the presence of chloride anions. Glycocholic acid binding was very weak at low pH but increased strongly with increasing pH. The presence of chloride ions strongly decreased the amount of glycocholate bound by the anion-exchange resin.

Keyphrases □ Bile acids—binding to cholestyramine at gastric pH □ Cholestyramine—binding of bile acids at gastric pH □ Binding—bile acids to cholestyramine at gastric pH

Recently published evidence shows that the reflux of the duodenal contents into the stomach is frequently the cause of gastric ulcers (1) and gastritis (2). It has been shown that bile salts disrupt the mucosal barrier and render it permeable to hydrogen ions (3, 4). The name "bile reflux gastritis" has been applied to this condition (2).

Cholestyramine resin has been used in recent clinical trials to reduce the intragastric bile salt content (1, 2, 5).

It is not clear, however, from these studies whether the cholestryamine significantly binds bile salts in the stomach or whether the anion-exchange resin acts chiefly to bind bile acids in the intestine, thereby generally reducing the circulating bile acid pool.

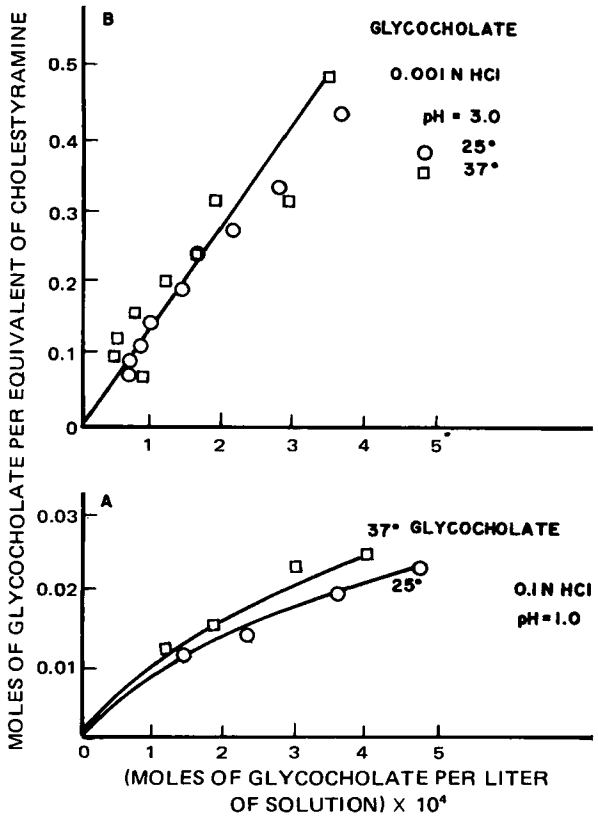

Figure 1—*Isotherms for the binding of glycocholate to cholestyramine at pH 1.0 (A) and 3.0 (B).*

Table I—Binding of Bile Salts by Cholestyramine

Bile Salt	pH	Ionic Strength	Millimoles per Gram of Resin	Grams Bound per Gram of Resin[a]
Glycocholic acid	1.0	0.1	0.08	0.039
	3.0	0.001	2.1	1.00
	3.1	0.1	0.1	0.048
	4.2	0.1	0.26	0.125
Taurocholic acid	1.0	0.1	0.50	0.269
Taurodeoxycholic acid	1.0	0.1	3.63	1.89

[a] The equilibrium concentration of bile salt in the aqueous solution is 4×10^{-4} *M* in each case.

Cholestyramine resin has been shown to be effective in lowering serum cholesterol levels by removing bile salts from the intestine and increasing their fecal elimination (6, 7). The increased fecal loss of bile salts due to binding by the anion-exchange resin leads to increased metabolism of cholesterol to replace the lost bile acids.

Under the relatively high pH conditions prevailing in the small intestine, both *in vitro* (8, 9) and *in vivo* (6, 7) studies showed that bile acids are bound by cholestyramine resin. Since the glycine-conjugated bile acids are weak acids (glycocholic acid, pKa = 3.95; glycodeoxycholic acid, pKa = 4.89) (10), they will be only slightly ionized at the low pH of the stomach and their binding by the anion-exchange resin consequently decreased. The taurine-conjugated bile acids are much stronger acids; even at low gastric pH, a significant fraction of the bile acid will be in the ionized form.

The pH of the stomach will, however, significantly determine the extent of bile acid binding since approximately 75% of the bile acid in adult human bile is glycine conjugated (11).

The objective of this study was to determine quantitatively the binding of bile acids by cholestyramine at acid pH conditions.

EXPERIMENTAL

Glycocholic acid[1], sodium taurodeoxycholate[2], sodium taurocholate, and cholestyramine resin[3] USP were used as received. All other chemicals were reagent grade. The ion-exchange capacity of the resin was determined by argentometric titration of the chloride ions released from the resin in the presence of excess potassium ni-

trate in aqueous solution. The capacity was 3.59 mEq/g. Bile acid analyses were performed spectrophotometrically using the method of Eriksson and Sjovall (12).

Ion-exchange adsorption isotherms were measured by shaking the aqueous bile acid solutions with samples of cholestyramine resin in a constant-temperature bath. Preliminary experiments indicated that overnight shaking was sufficient to attain equilibrium. The solutions were filtered, and the bile acid content of the supernatant liquid was determined. The amount of bile acid absorbed by the ion-exchange resin was calculated as the difference between the amount initially in solution and the amount in solution after equilibration.

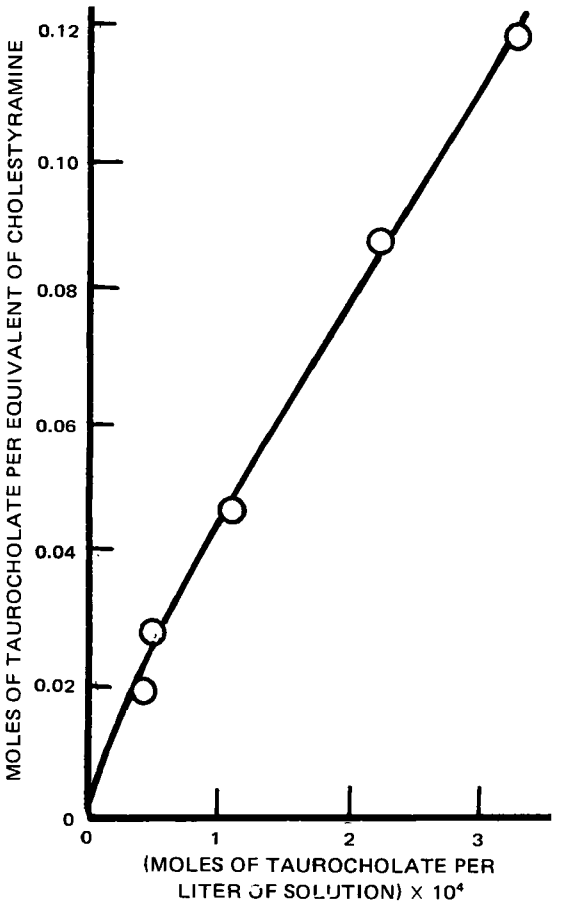

Figure 3—*Isotherms for the binding of taurocholate to cholestyramine at pH 1.0 and 25° in 0.1* N *HCl.*

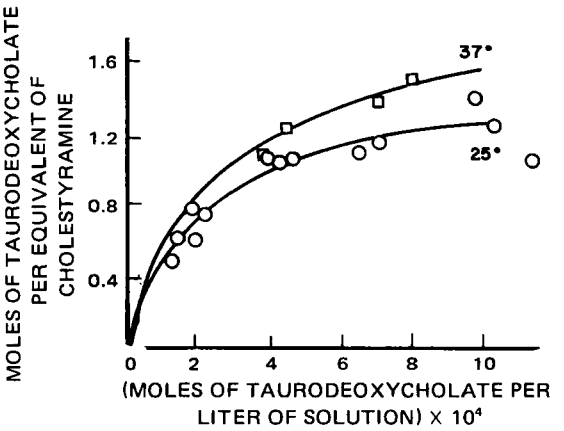

Figure 4—*Isotherms for the binding of taurodeoxycholate to cholestyramine at pH 1.0 in 0.1* N *HCl.*

RESULTS AND DISCUSSION

Ion-exchange isotherms for the distribution of bile salts between cholestyramine resin and aqueous bile salt solution are given in Figs. 1–4. Glycocholate (Fig. 1A) is only slightly absorbed from 0.1 *N* HCl. The binding is weak because the glycocholic acid is only slightly ionized at pH 1.0 and there is competition for the exchange sites by chloride ions. Previous studies of anion-exchange binding of bile salts at higher pH showed that chloride ions compete strongly for the resin anion-exchange sites (9). The isotherms also show that binding is stronger at higher temperature. This result indicates that the enthalpy change for the reaction shown in Scheme I:

$$RCl + A^- \rightleftharpoons RA + Cl^-$$

Scheme I

(where RCl represents cholestyramine resin in the chloride form) is positive, suggesting that the binding of glycocholate ion to ion-exchange resin is caused partly by a hydrophobic interaction between the glycocholate ion and the resin matrix. The interaction between the resin and the glycocholate ion is facilitated by the release of "structured" water surrounding the bile acid anion (13, 14). The temperature effect also may possibly be due in part to a decrease in pKa with increasing temperature.

Much stronger binding of glycocholic acid by the resin is found at pH 3.0 and reduced ionic strength (Fig. 1B). At this pH, more glycocholic acid is in the ionized form and the main interaction with the cholestyramine is probably coulombic. No difference is obtained in the adsorption isotherm between 25 and 37°, suggesting that the hydrophobic contribution is small.

The effect of pH alone on the ion-exchange binding of glycocholic acid is demonstrated better with the data given in Fig. 2. These isotherms at constant ionic strength show that there is a large increase in ion-exchange binding when the pH is increased from 3 to 4. This result suggests that the binding of glycine-conjugated bile acids may be considerably improved by increasing the pH in the gastric lumen.

Taurocholate (Fig. 3) is strongly bound by the resin even at low pH and in competition with 0.1 *M* chloride-ion concentration. Binding of taurodeoxycholate is much stronger and also shows a strong positive temperature dependence. Since taurodeoxycholic acid is a dihydroxy bile acid, it is considerably less polar (more hydrophobic) than the trihydroxy acids and is, therefore, more subject to hydrophobic binding forces.

Further evidence that hydrophobic binding predominates in this case is that the binding capacity for taurodeoxycholic acid, as seen from the ordinate of Fig. 4, exceeds 1.0. Therefore, more than 1 mole of bile acid anion is adsorbed per equivalent of exchange site, suggesting that the hydrophobic resin matrix plays an important role in the binding process.

The effects of pH and added electrolyte on the binding of bile salts by cholestyramine are summarized in Table I. In calculating the amount of bile salt bound per gram of resin, it is assumed that the equilibrium aqueous concentration of bile salt is 4×10^{-4} *M*.

The taurine-conjugated acids are strongly bound even at low pH and in the presence of 0.1 *M* chloride. The glycocholic acid binding is strongly pH dependent, and effective binding is only obtained at low pH in the absence of competing chloride ion. However, previous work (9) showed that much more glycocholate is bound by cholestyramine at higher pH (5.4–6.8), even in the presence of 0.15 *M* sodium chloride or sodium carbonate. Under these conditions, the glycocholate is present almost entirely in the dissociated anionic form.

Tumor-Inhibitory Agent from *Montezuma speciosissima* (Malvaceae)

S. D. JOLAD, R. M. WIEDHOPF, and J. R. COLEˣ

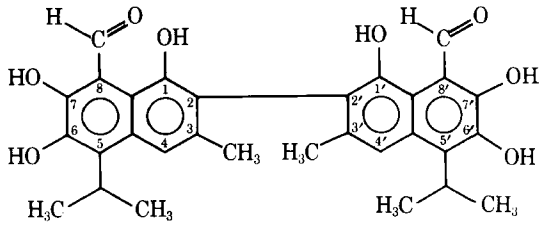
Abstract □ The petroleum ether extract of *Montezuma speciosissima* Sesse and Moc. demonstrated tumor-inhibiting properties in the P-388 lymphocytic leukemia test system (3PS). The constituent responsible for this activity was shown to be a symmetrically substituted 2,2′-dinaphthol, identified as gossypol ($C_{30}H_{30}O_8$).

Keyphrases □ *Montezuma speciosissima*—extract, PMR, UV, IR, and mass spectra, gossypol isolated □ Gossypol—isolated from *Montezuma speciosissima*, PMR, UV, IR, and mass spectra, tumor inhibitory activity □ Tumor inhibition—gossypol, isolated from *Montezuma speciosissima*, PMR, UV, IR, and mass spectra

As a result of the continuing search for plants yielding tumor-inhibiting constituents, it was found that the petroleum ether extract of the woody stems and stem barks of *Montezuma speciosissima* Sesse and Moc. (Malvaceae)[1] showed inhibitory activity toward the P-388 lymphocytic leukemia test system (3PS)[2].

DISCUSSION

The ether-soluble portion of the petroleum ether extract, after mild alkali extraction followed by careful acidification, gave a product which, when subjected to silica gel column chromatography, yielded a brilliant golden-yellow compound. This compound was characterized as 1,1′,6,6′,7,7′-hexahydroxy-5,5′-diisopropyl-3,3′-dimethyl[2,2′-binaphthalene]-8,8′-dicarboxaldehyde, identical to gossypol (I) in all respects. This identity was demonstrated by



I

means of its melting point, mixed melting point, elemental analysis, PMR, mass spectrometry, and comparison of UV and IR spectra with authentic sample spectra. Gossypol, the principal yellow pigment of cottonseed, was isolated first by Marchlewski (1) and then synthesized by Edwards (2). The structure of gossypol has been extensively studied by various workers (3).

The petroleum ether extract demonstrated activity of 131% test/control (T/C) at 50 mg/kg, 136% T/C at 25 mg/kg, and 125% T/C at 16 mg/kg. Gossypol demonstrated activity of 150% T/C at 10 mg/kg and 129% T/C at 5 mg/kg in the 3PS test system. Activity in the 3PS system is defined as an increase in the survival of treated animals over that of controls resulting in a T/C ≥ 125% (4).

EXPERIMENTAL[3]

The woody stems and stem barks (10 kg) of *M. speciosissima* were ground and extracted exhaustively in a Lloyd-type extractor with petroleum ether. After removal of the solvent in air, the residue (69 g) was repeatedly extracted with ether and filtered. The

[1] Identification was confirmed by Dr. Robert E. Perdue, Medicinal Plant Resource Laboratory, Plant Genetics and Germ Plasm Institute, Beltsville, Md. A reference specimen was deposited in that herbarium. The plant was collected in Puerto Rico in February 1972.

[1] Identification was confirmed by Dr. Robert E. Perdue, Medicinal Plant Resource Laboratory, Plant Genetics and Germ Plasm Institute, Beltsville, Md. A reference specimen was deposited in that herbarium. The plant was collected in Puerto Rico in February 1972.

[2] Of the Division of Cancer Treatment, National Cancer institute, National Institutes of Health, Bethesda, Md.

[3] Carbon and hydrogen analyses were performed by Chemalytics, Inc., Tempe, Ariz. PMR, IR, and mass spectra were determined using a Varian T-60 spectrometer, a Beckman IR-33, and a Hitachi Perkin-Elmer double-focusing spectrometer (model RMU-6E), respectively. The melting points were determined on a Kofler hot-stage apparatus and are uncorrected.

combined ether solution (about 2.5 liters) was subjected to mild alkali extraction (5% aqueous sodium carbonate). The alkaline phase was carefully neutralized with 10% aqueous hydrochloric acid, extracted with ether, and dried, and the solvent was removed *in vacuo*.

The resulting product (26 g) was then subjected to silica gel (130 g) column chromatography. The column was eluted with hexane–ether (4:1) followed by ether, acetone, and methanol. Fractions from the hexane–ether eluate, which showed two spots on TLC, were combined, and the solvent was removed *in vacuo*. The residue was treated with an excess of acetone, stirred, and filtered. The filtrate, on concentration *in vacuo*, gave a buff-colored precipitate, which was removed by filtration. On further concentration followed by cooling, the filtrate gave tiny yellow needles of gossypol, which were collected by filtration. More crystals were obtained from the mother liquor by repeating this step.

Crystallization from methylene chloride–petroleum ether yielded pure gossypol in long brilliant golden-yellow needles, mp 178–180°; this melting point was not depressed by mixing with an authentic sample[4]. Several melting points have been reported for gossypol: 184° (5), 199° (6), and 214° (7); gossypol exists in three crystalline modifications, each with a characteristic melting point.

All spectra obtained by UV, IR, PMR, and mass spectrometry agreed with literature data (8–10).

[4] The authors are grateful to the Division of Drug Research and Development, National Cancer Institute, Bethesda, Md., for providing an authentic sample.

Isolation of Lysergide (LSD) with Agarose-Bound Antibodies to Lysergic Acid

Keyphrases □ Lysergide—isolation, agarose-bound antibodies to lysergic acid, column chromatography □ Antibodies—lysergide binding, coupled to agarose, isolation of lysergide

To the Editor:

Several research groups (1–3) have obtained antiserums specific to lysergide (D-lysergic acid diethylamide, LSD). These antiserums have been useful in the development of sensitive and specific radioimmunoassay procedures for lysergide in plasma and urine (2, 3).

We have now succeeded in purifying lysergide-binding antibodies from sheep antiserum, utilizing affinity chromatographic (4) columns prepared by covalent binding of D-lysergic acid to a suitable derivative of beaded agarose. Purified specific antibodies are themselves coupled to beaded agarose and subsequently utilized for the selective absorption of lysergide from solution. Elution of lysergide from the column is readily achieved.

D-Lysergic acid (I) was readily coupled to the long chain hydrazide derivative of beaded agarose (II) (5) (Scheme I). To 10 g of II was added 40 mg of D-lysergic acid dissolved in 32 ml of saline–phosphate buffer (0.15 *N* NaCl and 0.01 *M* phosphate, pH 7.4) containing 5% ethanol. Then 50 mg of water-soluble carbodiimide reagent (III) was added, and the pH was adjusted to 5.50. After stirring for 24 hr, the agarose was washed thoroughly with buffer and made up to a final volume of 20 ml. The washings were analyzed for uncoupled D-lysergic acid by UV absorbance at 308 nm and the resultant affinity adsorbent (IV) was calculated to contain 2.5 μmoles (0.67 mg) of D-lysergic acid/g.

To a column of IV (1.5 ml, 0.5 × 15 cm, packed in pH 7.4 buffer) was added 1.0 ml of undiluted lysergide antiserum obtained from sheep after immunization with a lysergic acid–human serum albumin conjugate (3). [This antiserum (10 μl) showed the ability to bind 50% of 1 ng of tritium-labeled lysergide at a dilution of 1:1000 (3).] One hour was allowed for equilibration prior to elution from the column. Both protein absorbance (280 nm) and ability to bind tritiated lysergide in the radioimmunoassay system were monitored.

combined ether solution (about 2.5 liters) was subjected to mild alkali extraction (5% aqueous sodium carbonate). The alkaline phase was carefully neutralized with 10% aqueous hydrochloric acid, extracted with ether, and dried, and the solvent was removed *in vacuo*.

The resulting product (26 g) was then subjected to silica gel (130 g) column chromatography. The column was eluted with hexane–ether (4:1) followed by ether, acetone, and methanol. Fractions from the hexane–ether eluate, which showed two spots on TLC, were combined, and the solvent was removed *in vacuo*. The residue was treated with an excess of acetone, stirred, and filtered. The filtrate, on concentration *in vacuo*, gave a buff-colored precipitate, which was removed by filtration. On further concentration followed by cooling, the filtrate gave tiny yellow needles of gossypol, which were collected by filtration. More crystals were obtained from the mother liquor by repeating this step.

Crystallization from methylene chloride–petroleum ether yielded pure gossypol in long brilliant golden-yellow needles, mp 178–180°; this melting point was not depressed by mixing with an authentic sample[4]. Several melting points have been reported for gossypol: 184° (5), 199° (6), and 214° (7); gossypol exists in three crystalline modifications, each with a characteristic melting point.

All spectra obtained by UV, IR, PMR, and mass spectrometry agreed with literature data (8–10).

[4] The authors are grateful to the Division of Drug Research and Development, National Cancer Institute, Bethesda, Md., for providing an authentic sample.

Isolation of Lysergide (LSD) with Agarose-Bound Antibodies to Lysergic Acid

Keyphrases □ Lysergide—isolation, agarose-bound antibodies to lysergic acid, column chromatography □ Antibodies—lysergide binding, coupled to agarose, isolation of lysergide

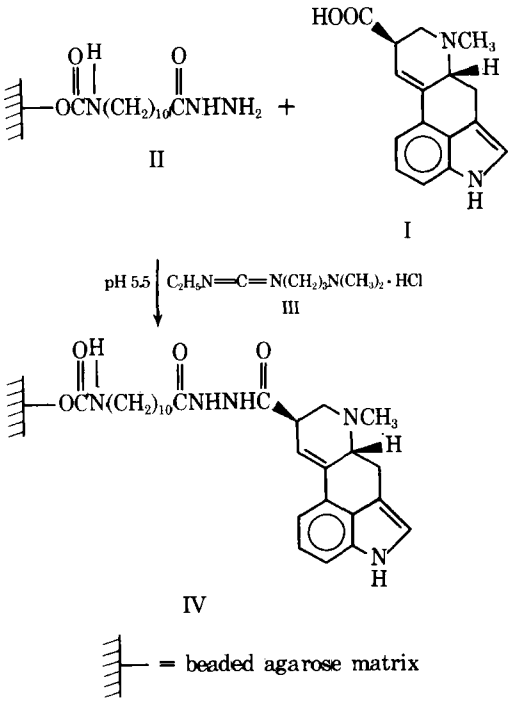
To the Editor:

Several research groups (1–3) have obtained antiserums specific to lysergide (D-lysergic acid diethylamide, LSD). These antiserums have been useful in the development of sensitive and specific radioimmunoassay procedures for lysergide in plasma and urine (2, 3).

We have now succeeded in purifying lysergide-binding antibodies from sheep antiserum, utilizing affinity chromatographic (4) columns prepared by covalent binding of D-lysergic acid to a suitable derivative of beaded agarose. Purified specific antibodies are themselves coupled to beaded agarose and subsequently utilized for the selective absorption of lysergide from solution. Elution of lysergide from the column is readily achieved.

D-Lysergic acid (I) was readily coupled to the long chain hydrazide derivative of beaded agarose (II) (5) (Scheme I). To 10 g of II was added 40 mg of D-lysergic acid dissolved in 32 ml of saline–phosphate buffer (0.15 *N* NaCl and 0.01 *M* phosphate, pH 7.4) containing 5% ethanol. Then 50 mg of water-soluble carbodiimide reagent (III) was added, and the pH was adjusted to 5.50. After stirring for 24 hr, the agarose was washed thoroughly with buffer and made up to a final volume of 20 ml. The washings were analyzed for uncoupled D-lysergic acid by UV absorbance at 308 nm and the resultant affinity adsorbent (IV) was calculated to contain 2.5 μmoles (0.67 mg) of D-lysergic acid/g.

To a column of IV (1.5 ml, 0.5 × 15 cm, packed in pH 7.4 buffer) was added 1.0 ml of undiluted lysergide antiserum obtained from sheep after immunization with a lysergic acid–human serum albumin conjugate (3). [This antiserum (10 μl) showed the ability to bind 50% of 1 ng of tritium-labeled lysergide at a dilution of 1:1000 (3).] One hour was allowed for equilibration prior to elution from the column. Both protein absorbance (280 nm) and ability to bind tritiated lysergide in the radioimmunoassay system were monitored.



Scheme I—Coupling of D-lysergic acid (I) to long chain hydrazide derivative of agarose (II)

The results (Fig. 1) show that the lysergide antibody was indeed retained; it could be eluted by the use of 0.1 *M* acetic acid, 0.01 *N* HCl, 6 *M* guanidine, lysergic acid, or lysergide. Fractions eluted with acid were neutralized with sodium hydroxide to pH 7.4 (phenol red) immediately upon collection. Other protein components of the serum, with no lysergide-binding ability, passed through the column in early fractions. In several experiments, it was determined that the protein content of the lysergide binding effluent was approximately 0.9 mg of protein/ml of original antiserum (6.0 nmoles/ml). As shown in Fig. 1, about two-thirds of this amount was eluted from the column with dilute hydrochloric acid; the remaining third required the use of 6 *M* guanidine hydrochloride (later removed by dialysis).

Microzone electrophoresis studies on material from fraction 11 (Fig. 1) indicated the presence of a faint band in the γ-globulin region and the absence of other protein bands characteristic of the whole antiserum components. This material was employed in subsequent studies.

For coupling of the agarose–hydrazide derivative (II) to the specific lysergide antibody, the hydrazide was first activated by conversion to the corresponding azide with nitrous acid (5). Three grams of the cold, freshly activated, azide derivative was then added to a cold solution of a mixture of 0.3 mg of antilysergide and 5 mg of bovine serum albumin carrier in phosphate buffer (pH 7.4). After 20 hr, the mixture was filtered and washed well with buffer. As a control preparation, 5 mg of bovine serum albumin alone was coupled to II under identical conditions. From subsequent calculations, it was determined that the coupled antilysergide content of the agarose was about 4.7×10^{-5} μmole/ml of agarose (sufficient

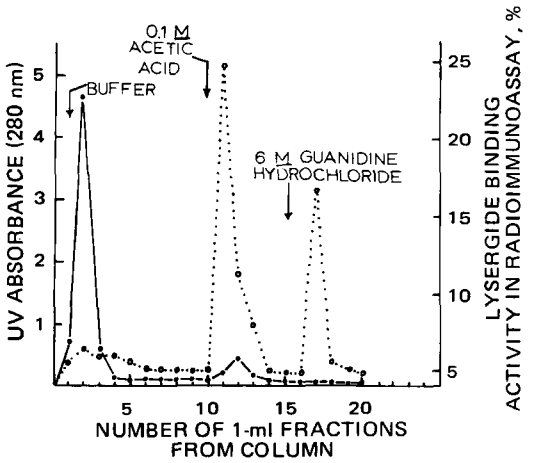


Figure 1—*Selective adsorption of specific lysergide antibodies from sheep antiserum by means of D-lysergic acid immobilized on beaded agarose (IV). Curve A (solid line) indicates protein retention by the affinity column as measured by UV spectral analysis of effluent fractions. About 8% of the protein was specifically retained. Curve B (dotted line) indicates that the major portion of the immunochemical binding ability of the effluent was contained in the fractions eluted with acid or guanidine hydrochloride. Bovine serum albumin (0.5%) was added to the elution buffer for stabilization of the antibody activity.*

to bind 30 ng of lysergide, with each divalent antibody binding 2 moles of lysergide).

To determine the selective retention of lysergide by the column, tritiated lysergide of specific activity 1.9 Ci/mmole was employed[1]. The radioactive lysergide (1 or 5 ng in a typical run) was placed in 1.0 ml of buffer on the column of adsorbent (1.5 ml as before) and allowed to equilibrate for 1 hr. Elution was accomplished with buffer or 0.01 *N* hydrochloric acid (Fig. 2). One-milliliter effluent fractions were counted *via* scintillation counting techniques, and the quantities of lysergide in each fraction were calculated.

Under these conditions, typical results indicated 64% retention of 1 ng of lysergide and 79% retention

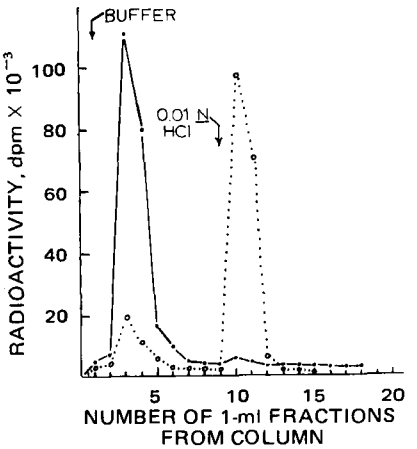

Figure 2—*Selective removal of tritiated lysergide from buffer by insolubilized antibodies. Curve A (solid line) indicates bovine serum albumin coupled to the matrix. Curve B (dotted line) indicates bovine serum albumin plus antibody coupled to the matrix.*

of a 5-ng sample. Retained material was eluted from the column with 0.01 N hydrochloric acid. Under identical conditions, the column composed of coupled bovine serum albumin alone retained less than 1% of the radioactive material. Essentially identical results were obtained when ^{3}H-lysergide was added initially to the columns in pooled human plasma or human urine rather than buffer. Columns appeared to be equally effective upon at least one reuse after washing thoroughly with 0.01 N hydrochloric acid and then buffer.

Upon further quantitation and development, and perhaps with the use of a more specific antibody of higher titer, the described techniques might be utilized to advantage in conjunction with quantitative radioimmunoassay determinations of lysergide, either to isolate selectively very small quantities of lysergide far below the current sensitivity capabilities or to separate lysergide from tissue homogenates which may contain materials that render present assay methods inexact. Such methodology may be of importance in the study of lysergide levels in the brain and other organs.

Determination of Protein Binding Parameters in Systems Involving Interaction between Sites

Keyphrases □ Protein binding—determination of parameters in systems involving interaction between sites, evaluation of method □ Binding, protein—parameters, interaction between sites, evaluation of method □ 1-Anilinonaphthalene-8-sulfonate—discussion of binding parameters

To the Editor:

A recent report by Ma *et al.* (1) utilized a log Q *versus* $\bar{\upsilon}$ plot to determine the protein binding parameters of 1-anilinonaphthalene-8-sulfonate in systems where interactions between binding sites were assumed to be occurring. As a result of this study, it is our feeling that the basic concepts underlying such systems and the application of the log Q *versus* $\bar{\upsilon}$ plot (2) to them should be reviewed. The intent of this communication is to ensure the proper use of the log Q *versus* $\bar{\upsilon}$ treatment by investigators encountering binding behavior similar to that reported by Ma *et al.* (1) for the interaction of 1-anilinonaphthalene-8-sulfonate with serum albumin.

The log Q *versus* $\bar{\upsilon}$ method applies to systems involving interactions between binding sites when n (number of) binding sites are initially all equivalent insofar as the binding of a drug molecule is concerned. As soon as one such molecule is bound, however, the affinity constant for a subsequent molecule's binding to a neighboring site is altered. The binding of successive molecules further alters the affinity constant for a remaining unoccupied site. Thus, in the case of n sites, the intrinsic binding constants $K_1, K_2, \ldots, K_n$ are not equal but may progressively increase or decrease. To calculate affinity constants under such conditions, a function Q is used:

$$Q = \bar{\upsilon}/(n - \bar{\upsilon})[D] \qquad \text{(Eq. 1)}$$

where $\bar{\upsilon}$ is the number of moles of drug bound per mole of protein at a free drug concentration $[D]$, with n representing the number of binding sites possible (2). A plot of log Q *versus* $\bar{\upsilon}$ is made, and the limiting values at $[D] \rightarrow 0$ and $[D] \rightarrow \infty$ give K_1 and K_n, respectively. Also, the limiting slopes, $d \ln Q/d\bar{\upsilon}$, at $\bar{\upsilon} \rightarrow 0$ and $\bar{\upsilon} \rightarrow n$ give $(n - 1)(K_2 - K_1)/nK_1$ and $(n - 1)(K_n - K_{n-1})/nK_{n-1}$, respectively (2). The log Q *versus* $\bar{\upsilon}$ plot is generally appropriate when K values are close (ratio of largest to smallest much less than 1000).

In using the log Q *versus* $\bar{\upsilon}$ plot, it should be noted that Eq. 1 implies that the value of n must be known or at least inferred with confidence in order to make a determination of the intrinsic binding constants. Ma *et al.* (1) suggested that n can be determined as that assumed value that best provides a linear log Q *versus* $\bar{\upsilon}$ plot. This usage is not proper, because the semilogarithmic plot need not approach linearity even when the value for n is known. As indicated by Eq. 1, the relationship between log Q and $\bar{\upsilon}$ is strictly linear only when the n binding constants are independent and equivalent. In such a situation, Q obviously is independent of free drug concentration and, indeed, is equal to the intrinsic binding constant. Thus, with independent and equivalent sites, a plot of log Q *versus* $\bar{\upsilon}$ is linear with a slope of zero.

When the binding sites are not independent, *i.e.*, when there is enhanced or inhibited binding of a small molecule to an available site, two situations may arise. In one case, the ratio of intrinsic binding constants, $K_{(s+1)}/K_{(s)}$, is a constant independent of s for all values of s from 1 to n (2). The constant ratio may be greater or less than unity, depending on whether interactions result in facilitated or inhibited binding. In the other system, the ratio of binding constants, $K_{(s+1)}/K_{(s)}$, is not constant for all values of s from 1 to n. Both systems will be considered.

In the first case, where a constant ratio of binding constants is present, a log Q *versus* $\bar{\upsilon}$ plot may have a region of linearity but the plot would not be expected

Determination of Protein Binding Parameters in Systems Involving Interaction between Sites

Keyphrases □ Protein binding—determination of parameters in systems involving interaction between sites, evaluation of method □ Binding, protein—parameters, interaction between sites, evaluation of method □ 1-Anilinonaphthalene-8-sulfonate—discussion of binding parameters

To the Editor:

A recent report by Ma *et al.* (1) utilized a log Q *versus* $\bar{\upsilon}$ plot to determine the protein binding parameters of 1-anilinonaphthalene-8-sulfonate in systems where interactions between binding sites were assumed to be occurring. As a result of this study, it is our feeling that the basic concepts underlying such systems and the application of the log Q *versus* $\bar{\upsilon}$ plot (2) to them should be reviewed. The intent of this communication is to ensure the proper use of the log Q *versus* $\bar{\upsilon}$ treatment by investigators encountering binding behavior similar to that reported by Ma *et al.* (1) for the interaction of 1-anilinonaphthalene-8-sulfonate with serum albumin.

The log Q *versus* $\bar{\upsilon}$ method applies to systems involving interactions between binding sites when n (number of) binding sites are initially all equivalent insofar as the binding of a drug molecule is concerned. As soon as one such molecule is bound, however, the affinity constant for a subsequent molecule's binding to a neighboring site is altered. The binding of successive molecules further alters the affinity constant for a remaining unoccupied site. Thus, in the case of n sites, the intrinsic binding constants $K_1, K_2, \ldots, K_n$ are not equal but may progressively increase or decrease. To calculate affinity constants under such conditions, a function Q is used:

$$Q = \bar{\upsilon}/(n - \bar{\upsilon})[D] \qquad \text{(Eq. 1)}$$

where $\bar{\upsilon}$ is the number of moles of drug bound per mole of protein at a free drug concentration $[D]$, with n representing the number of binding sites possible (2). A plot of log Q *versus* $\bar{\upsilon}$ is made, and the limiting values at $[D] \rightarrow 0$ and $[D] \rightarrow \infty$ give K_1 and K_n, respectively. Also, the limiting slopes, $d \ln Q/d\bar{\upsilon}$, at $\bar{\upsilon} \rightarrow 0$ and $\bar{\upsilon} \rightarrow n$ give $(n - 1)(K_2 - K_1)/nK_1$ and $(n - 1)(K_n - K_{n-1})/nK_{n-1}$, respectively (2). The log Q *versus* $\bar{\upsilon}$ plot is generally appropriate when K values are close (ratio of largest to smallest much less than 1000).

In using the log Q *versus* $\bar{\upsilon}$ plot, it should be noted that Eq. 1 implies that the value of n must be known or at least inferred with confidence in order to make a determination of the intrinsic binding constants. Ma *et al.* (1) suggested that n can be determined as that assumed value that best provides a linear log Q *versus* $\bar{\upsilon}$ plot. This usage is not proper, because the semilogarithmic plot need not approach linearity even when the value for n is known. As indicated by Eq. 1, the relationship between log Q and $\bar{\upsilon}$ is strictly linear only when the n binding constants are independent and equivalent. In such a situation, Q obviously is independent of free drug concentration and, indeed, is equal to the intrinsic binding constant. Thus, with independent and equivalent sites, a plot of log Q *versus* $\bar{\upsilon}$ is linear with a slope of zero.

When the binding sites are not independent, *i.e.*, when there is enhanced or inhibited binding of a small molecule to an available site, two situations may arise. In one case, the ratio of intrinsic binding constants, $K_{(s+1)}/K_{(s)}$, is a constant independent of s for all values of s from 1 to n (2). The constant ratio may be greater or less than unity, depending on whether interactions result in facilitated or inhibited binding. In the other system, the ratio of binding constants, $K_{(s+1)}/K_{(s)}$, is not constant for all values of s from 1 to n. Both systems will be considered.

In the first case, where a constant ratio of binding constants is present, a log Q *versus* $\bar{\upsilon}$ plot may have a region of linearity but the plot would not be expected

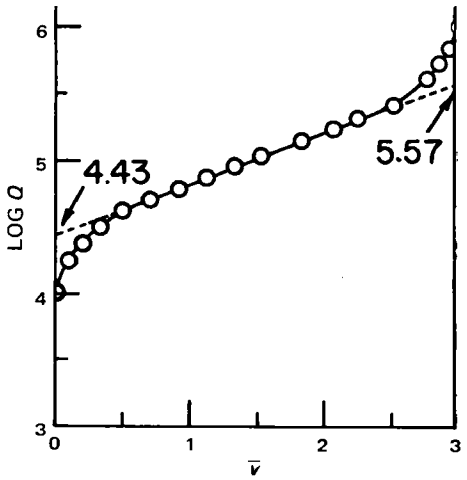

Figure 1—*Relationship between log* Q *and* $\bar{v}$ *for the binding of a hypothetical drug where* n = 3 *with increasing affinity constants of* $K_1 = 10^4$, $K_2 = 10^5$, *and* $K_3 = 10^6$.

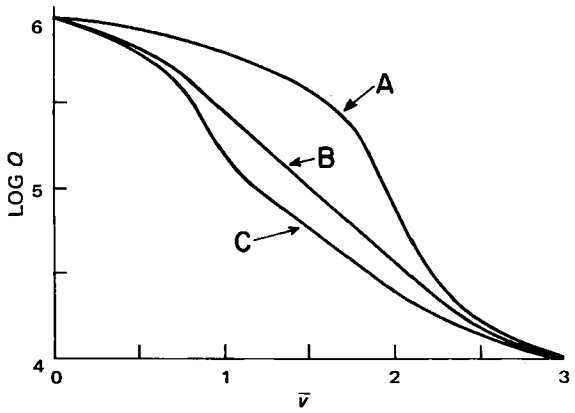

Figure 2—*Relationship between log* Q *and* $\bar{v}$ *for the binding of hypothetical drugs where* n = 3 *in all cases. The affinity constants used were: in A,* $K_1 = 10^6$, $K_2 = 5 \times 10^5$, *and* $K_3 = 10^4$; *in B,* $K_1 = 10^6$, $K_2 = 10^5$, *and* $K_3 = 10^4$; *and in C,* $K_1 = 10^6$, $K_2 = 5 \times 10^4$, *and* $K_3 = 10^4$.

to be linear over the entire $\bar{v}$ range. As discussed by Edsall *et al.* (2) and as depicted by the hypothetical data in Fig. 1, Eq. 1 does not predict a linear semilogarithmic relationship.

The data in Fig. 1 were generated by assuming three dependent sites where a constant ratio of binding constants of 10 occurs. The constants used were $K_1 = 10^4$, $K_2 = 10^5$, and $K_3 = 10^6$. Figure 1 does show, however, that linearity may be found over a large range of $\bar{v}$ (0.5–2.5 in this hypothetical case). It is evident that, in accordance with Eq. 1, curvature in a log Q *versus* $\bar{v}$ plot should not be used to indicate that an erroneous selection of the n value was made. When linearity is found over a large range of $\bar{v}$ values, the interpretation should be that the linearity is a consequence of the unique and constant ratio among the intrinsic binding constants.

In a system where the ratio of affinity constants, $K_{(s+1)}/K_{(s)}$, is not constant for all values of s from 1 to n, curvature and even breaks in a log Q *versus* $\bar{v}$ plot are to be expected, depending on the relationship and magnitude of the differences between the intrinsic binding constants. As an example, Fig. 2 shows the relationship between log Q and $\bar{v}$ for three hypothetical systems. In these systems, $n = 3$ and, as opposed to Fig. 1, inhibited binding is assumed upon successive site occupation. For curve B of Fig. 2, a constant ratio of affinity constants was used ($K_1 = 10^6$, $K_2 = 10^5$, and $K_3 = 10^4$). This curve is included only for comparison. In curve A, where the assumed constants were $K_1 = 10^6$, $K_2 = 5 \times 10^5$, and $K_3 = 10^4$, the ratio K_2/K_1 is 25 times that of K_3/K_2. An expected marked curvature is found in this case. In curve C, where $K_1 = 10^6$, $K_2 = 5 \times 10^4$, and $K_3 = 10^4$, the ratio K_3/K_2 is four times larger than the ratio K_2/K_1. Deviations from linearity are apparent in this hypothetical system also, but it might be interpreted as approximately linear for the $\bar{v}$ region between 1 and 2.

In each curve in Fig. 2, nonlinearity is again a consequence of the relationship between the intrinsic binding constants and not solely dependent on the value for n. Thus, the use of the log Q *versus* $\bar{v}$ treatment of binding data depends on knowing or reasonably estimating the number of binding sites. Figure 2 demonstrates that linearity in a log Q *versus* $\bar{v}$ plot should not be used to determine n as was suggested by Ma *et al.* (1).

One other consideration should be pointed out with respect to analyzing a system where a constant ratio of binding constants is found. It is not correct to extrapolate the linear portion of a log Q *versus* $\bar{v}$ plot to $\bar{v} = 0$ and $\bar{v} = n$, where $[D] \rightarrow 0$ and $[D] \rightarrow \infty$, to determine K_1 and K_n, respectively, as was done by Ma *et al.* (1). At best, such extrapolated values should be used as gross first estimates of the binding constants. Significant errors in affinity constants may be introduced by simply extrapolating the linear region of the relationship as opposed to extrapolating limiting data. Theory dictates that the extrapolated limiting data determine K_1 and K_n.

To use the method properly, data collected in these extremes must be accurate. Figure 1 illustrates the inaccuracy introduced when an extrapolation of the linear portion of the log Q *versus* $\bar{v}$ plot is used to determine K_1 and K_n. Hypothetical data are used in this figure where the ratios K_2/K_1 and K_3/K_2 are equal. The experimental data collected in regions where limiting slopes and intercepts are characterized are subject to large experimental error, regardless of whether or not a constant ratio of affinity constants is operative. Therefore, Edsall and Wyman (3) recommended that extrapolated values using limiting data be used as first estimates of affinity constants which may be used to calculate an expected curve. If the calculated curve significantly differs from the observed, new affinity constants are estimated and the curve fitting is continued until reliable constants are found.

Protein binding systems analogous to those of 1-anilinonaphthalene-8-sulfonate are certainly possible, and it may be proper to interpret and analyze them by assuming that interactions of the type invoked by Ma *et al.* (1) do take place. It is our hope that this communication will clarify the factors that make such an analysis correct and complete.

Group Contribution Data Obtained by Ion-Pair Extraction of Prostaglandin B_2 with Aliphatic Amines

Keyphrases □ Ion-pair extraction—prostaglandin B_2 with aliphatic amines, methylene group contribution, partition coefficients □ Partition coefficients—ion-pair extraction of prostaglandin B_2 with aliphatic amines, methylene group contribution □ Prostaglandin B_2—ion-pair extraction with aliphatic amines, methylene group contribution, partition coefficients

To the Editor:

The concept of ion-pairs (1) is significant in various areas including chemistry, organic synthesis (2), solvolytic reactions (3), partition chromatography (4–6), pharmaceutical analysis (7–10), and facilitated absorption of quaternary ammonium compounds in the GI lumen (11). Also, systematic studies on the ion-pair extraction successfully yielded functional group contributions to the thermodynamic parameters involved in transferring a given molecule from one phase to another (12, 13). Although our original study (14) was initiated to explore the practical utility of ion-pair formation of prostaglandins in all of these aspects, the present communication is specifically concerned with the free energy of transferring a methylene group from water to chloroform as determined by the ion-pair extraction process.

The importance of the lipophilicity of a drug molecule in the structure–activity relationship has been recognized and, consequently, great effort has been directed toward developing some means by which the partition coefficient of a drug molecule between oil (or lipophilic biological membrane) and aqueous systems can be predicted accurately (13, 15–17). Presently, the most popular way to achieve this goal appears to be the group contribution approach, in which the partition coefficient of a molecule is considered as the sum of the contribution of each functional group present in the molecule. Experimentally, an accurate measurement of the partition coefficient becomes very difficult as the value becomes either too large or too small.

Since the apparent partition coefficient of acidic or basic compounds depends not only upon the pH of the aqueous layer but also upon the type and the concentration of the counterions, by adjusting these factors it is possible to control the partition coefficient so that it is experimentally measurable. For a given charged solute, if the structural changes in a series of counterions are far removed from the electrostatically interacting charged portions of the molecules, it can be assumed that the change in the partition coefficient observed is independent of the electrostatic interaction and that the change solely reflects the structural modification of the counterions.

We determined the ion-pair extraction coefficient (K) of prostaglandin B_2 (I) with 10 simple aliphatic amines ranging from n-propyl- to n-dodecylamine at 25°:

$$K = \frac{\{A^-BH^+\}}{[A^-]\{BH^+\}} \qquad \text{(Eq. 1)}$$

The partition system consisted of chloroform presaturated with water and tromethamine buffer (pH 8 and ionic strength 0.1 M) also presaturated with chloroform. Throughout the paper, prostaglandin B_2, amines, and ion-pair are represented as AH, B, and A^-BH^+, respectively. The braces { } and brackets [ ] indicate the molar concentrations of a given species in chloroform and aqueous buffer, respectively. Since, in most cases, the system is very dilute with respect to prostaglandin B_2 and amines, the molar concentrations are assumed to be equal to thermodynamic activities.

Simple algebraic manipulation of Eq. 1 yields:

$$P_{obs} = K[BH^+] + P_{app} \qquad \text{(Eq. 2)}$$

where:

$$P_{obs} = \frac{\{A^-BH^+\} + \{AH\}}{[A^-] + [AH]} \qquad \text{(Eq. 3)}$$

and:

$$P_{app} = \frac{\{AH\}}{[AH] + [A^-]} \qquad \text{(Eq. 4)}$$

In deriving Eq. 2, it was assumed that ion-pairs do not exist in aqueous solutions, not only because the dielectric constant of water is extremely high but also because the concentrations of prostaglandin B_2 and amines in aqueous solutions are low. The dissociation constant of ion-pairs in an organic solvent of low dielectric constant is usually in the order of from 10^{-4} to 10^{-7} M (12, 18). Therefore, in our study, it was assumed that no significant dissociation takes place in chloroform. Moreover, at pH 8 the concentrations of neutral species of our acid and bases (*i.e.*, AH and B) are in the order of 0.1% of the total concentrations, because the pKa values of prostaglandin B_2 and

Group Contribution Data Obtained by Ion-Pair Extraction of Prostaglandin B_2 with Aliphatic Amines

Keyphrases □ Ion-pair extraction—prostaglandin B_2 with aliphatic amines, methylene group contribution, partition coefficients □ Partition coefficients—ion-pair extraction of prostaglandin B_2 with aliphatic amines, methylene group contribution □ Prostaglandin B_2—ion-pair extraction with aliphatic amines, methylene group contribution, partition coefficients

To the Editor:

The concept of ion-pairs (1) is significant in various areas including chemistry, organic synthesis (2), solvolytic reactions (3), partition chromatography (4–6), pharmaceutical analysis (7–10), and facilitated absorption of quaternary ammonium compounds in the GI lumen (11). Also, systematic studies on the ion-pair extraction successfully yielded functional group contributions to the thermodynamic parameters involved in transferring a given molecule from one phase to another (12, 13). Although our original study (14) was initiated to explore the practical utility of ion-pair formation of prostaglandins in all of these aspects, the present communication is specifically concerned with the free energy of transferring a methylene group from water to chloroform as determined by the ion-pair extraction process.

The importance of the lipophilicity of a drug molecule in the structure–activity relationship has been recognized and, consequently, great effort has been directed toward developing some means by which the partition coefficient of a drug molecule between oil (or lipophilic biological membrane) and aqueous systems can be predicted accurately (13, 15–17). Presently, the most popular way to achieve this goal appears to be the group contribution approach, in which the partition coefficient of a molecule is considered as the sum of the contribution of each functional group present in the molecule. Experimentally, an accurate measurement of the partition coefficient becomes very difficult as the value becomes either too large or too small.

Since the apparent partition coefficient of acidic or basic compounds depends not only upon the pH of the aqueous layer but also upon the type and the concentration of the counterions, by adjusting these factors it is possible to control the partition coefficient so that it is experimentally measurable. For a given charged solute, if the structural changes in a series of counterions are far removed from the electrostatically interacting charged portions of the molecules, it can be assumed that the change in the partition coefficient observed is independent of the electrostatic interaction and that the change solely reflects the structural modification of the counterions.

We determined the ion-pair extraction coefficient (K) of prostaglandin B_2 (I) with 10 simple aliphatic amines ranging from n-propyl- to n-dodecylamine at 25°:

$$K = \frac{\{A^-BH^+\}}{[A^-]\{BH^+\}} \qquad \text{(Eq. 1)}$$

The partition system consisted of chloroform presaturated with water and tromethamine buffer (pH 8 and ionic strength 0.1 M) also presaturated with chloroform. Throughout the paper, prostaglandin B_2, amines, and ion-pair are represented as AH, B, and A^-BH^+, respectively. The braces { } and brackets [ ] indicate the molar concentrations of a given species in chloroform and aqueous buffer, respectively. Since, in most cases, the system is very dilute with respect to prostaglandin B_2 and amines, the molar concentrations are assumed to be equal to thermodynamic activities.

Simple algebraic manipulation of Eq. 1 yields:

$$P_{obs} = K[BH^+] + P_{app} \qquad \text{(Eq. 2)}$$

where:

$$P_{obs} = \frac{\{A^-BH^+\} + \{AH\}}{[A^-] + [AH]} \qquad \text{(Eq. 3)}$$

and:

$$P_{app} = \frac{\{AH\}}{[AH] + [A^-]} \qquad \text{(Eq. 4)}$$

In deriving Eq. 2, it was assumed that ion-pairs do not exist in aqueous solutions, not only because the dielectric constant of water is extremely high but also because the concentrations of prostaglandin B_2 and amines in aqueous solutions are low. The dissociation constant of ion-pairs in an organic solvent of low dielectric constant is usually in the order of from 10^{-4} to 10^{-7} M (12, 18). Therefore, in our study, it was assumed that no significant dissociation takes place in chloroform. Moreover, at pH 8 the concentrations of neutral species of our acid and bases (*i.e.*, AH and B) are in the order of 0.1% of the total concentrations, because the pKa values of prostaglandin B_2 and

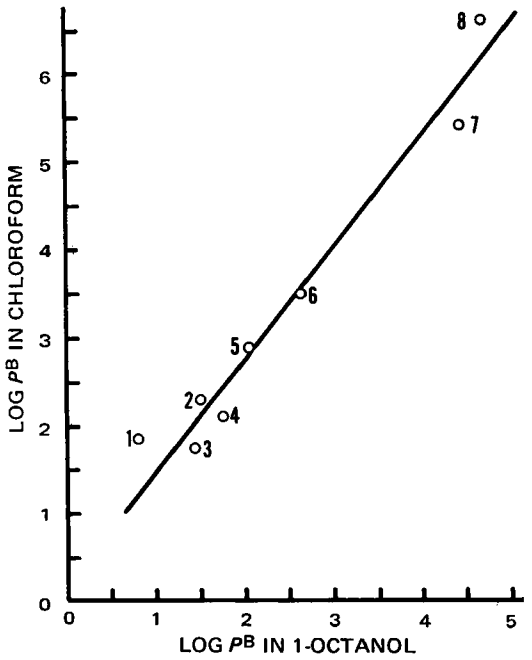

Figure 1—*Relationship between the intrinsic partition coefficient* (P^B) *of aliphatic amines between chloroform and water and that of the same amines between 1-octanol and water at 25°. The straight line is log* $P^B_{CHCl_3}$ = *1.276 log* P^B_{oct} + *0.171. Amines are: 1,* n-*butyl; 2,* n-*hexyl; 3, triethyl; 4, dipropyl; 5,* n-*heptyl; 6, dibutyl; 7, tributyl; and 8, dihexyl.*

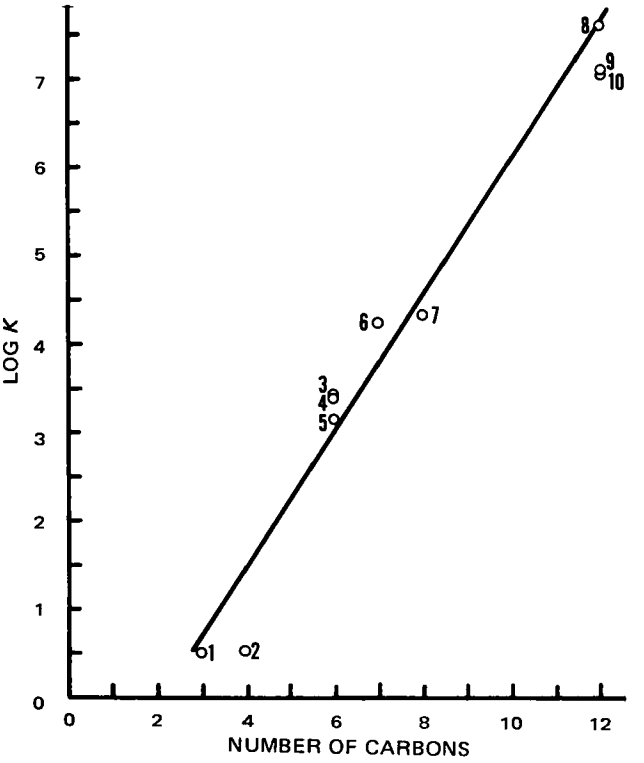

Figure 2—*Logarithm of the ion-pair extraction coefficient* (K) *for prostaglandin* B_2*–amine pairs at 25° as a function of carbon numbers in the amines. The slope of the straight line is 0.77. Amines are: 1,* n-*propyl; 2,* n-*butyl; 3, triethyl; 4, dipropyl; 5,* n-*hexyl; 6,* n-*heptyl; 7, dibutyl; 8,* n-*dodecyl; 9, dihexyl; and 10, tributyl.*

amines employed are approximately 5 (14) and 11, respectively. Equation 2 predicts a linear relationship between P_{obs} and [BH^+].

The values of P_{obs} were determined by spectrophotometrically measuring the total concentrations of prostaglandin B_2 ($\epsilon_{280} \sim 2.50 \times 10^4$ in water) both in chloroform and aqueous layers at distribution equilibrium for at least five different amine concentrations. To reduce the experimental errors in determining P_{obs}, from 1:1 to 1:20 phase volume ratios were employed. We found it very difficult to measure [BH^+] accurately at equilibrium, because in most cases [BH^+] was extremely low. Therefore, we calculated [BH^+] from the independently determined apparent partition coefficients of amines at pH 8, the initial concentrations of amines, [A^-] measured at equilibrium in the presence of amines, P_{obs}, and the known phase volume ratio. The entire calculation procedure was described elsewhere (14).

The apparent partition coefficients of amines at pH 8 were obtained by dividing {B} at equilibrium by the amine concentrations in the aqueous layer. The former was determined by nonaqueous titration (19), and the latter was obtained by subtracting {B} from the known initial concentration of the amine in chloroform. Experimental data, when plotted following Eq. 2, invariably showed negative deviations from the linearity as [BH^+] increased, presumably due to the premicellar aggregation of the amines in the aqueous layers. Therefore, the initial slopes were measured as the values of K.

Determination of the apparent partition coefficient of amines at pH 8 not only allowed us to calculate [BH^+] in Eq. 2 at distribution equilibrium but also resulted in an independent measurement of methylene group contribution. The intrinsic partition coefficients of the amines were calculated from the apparent partition coefficients determined at pH 8 and the known pKa values of amines (20). The pKa values at ionic strength 0.1 M were obtained from the so-called thermodynamic pKa values (pKa°) by correcting the activity coefficient of ionic species using the Davies equation (21); pKa at ionic strength 0.1 M = pKa° + 0.224. The pKa° values of dihexyl- and n-dodecylamine, which were not available in the literature, were assumed to be the same as those of dibutyl- and n-heptylamine, respectively.

The intrinsic partition coefficients of amines thus obtained were linearly correlated with those for the 1-octanol–water system (15), as shown in Fig. 1. The slope, intercept, and correlation coefficient are 1.27, 0.20, and 0.978, respectively, in excellent agreement with the relationship reported in the literature (22). Since the methylene group contribution to the partition coefficient for a 1-octanol–water system is 0.50 in terms of a logarithmic scale (*i.e.*, π_{CH_2} = 0.50) (15), the linear relationship shown in Fig. 1 strongly implies that the methylene group contribution to the partition coefficient for a chloroform–water system is 0.5 × 1.27 = 0.64. This value is again in good agreement with the value reported in the literature (13, 23, 24).

When the logarithms of the intrinsic partition coefficients of amines we obtained were plotted

against the carbon number, a slope of 0.64 was obtained for a series of primary amines. As expected, secondary and tertiary amines showed somewhat smaller partition coefficients than the primary amines of the same carbon number.

On the other hand, when the logarithms of K were plotted against the carbon number of the amines (Fig. 2), a slope of 0.77 was obtained. The discrepancy between the methylene group contribution obtained by the ion-pair extraction studies (0.77) and that obtained by the measurement of the intrinsic partition coefficient (0.64) was small but significant and deserves further comment. The ion-pair extraction coefficient defined by Eq. 1 is an overall equilibrium constant for the formation as well as the partition of ion-pairs:

$$K_1 = \frac{[A^-BH^+]}{[A^-][BH^+]} \qquad \text{(Eq. 5)}$$

$$K_2 = \frac{\{A^-BH^+\}}{[A^-BH^+]} \qquad \text{(Eq. 6)}$$

$$K = K_1K_2 \quad \text{or} \quad \log K = \log K_1 + \log K_2 \qquad \text{(Eq. 7)}$$

According to Eq. 5, ion-pairs are formed in the aqueous phase. In reality, this formation most likely would occur at the interface. No matter where the ion-pairs are formed, the separation of K into K_1 and K_2 shown in Eq. 7 should be valid. As shown in Eq. 7, for the slope shown in Fig. 2 truly to represent K_2 and ultimately the methylene group contribution, K_1 must be constant regardless of the amine employed. The fact that we obtained 0.77 for the methylene group contribution from ion-pair extraction studies and 0.64 from ordinary partition experiments strongly suggests that, at least in certain cases, the group contribution data obtained from ion-pair studies may not be generally the same as obtained in straightforward partition experiments.

In the present study, as the amine becomes more hydrophobic, the equilibrium constant for the ion-pair formation (K_1) appears to increase at a rate of $\Delta \log K_1/CH_2 = 0.13$. It is to be seen in the future whether such a deviation, intrinsically derived from the assumption that the change in the ion-pair extraction coefficient (ΔK) is independent of the electrostatic interaction, is universal or not.

Plastic Containers for Pharmaceuticals—Testing and Control. By JACK COOPER. World Health Organization, Geneva 27, Switzerland (WHO Offset Publication No. 4), 1974. 204 pp. 22 × 28 cm. Price SW. fr. 32, $12.80.

Packaging of pharmaceuticals in plastic containers has increased at an unprecedented rate. Testing and control procedures are needed for the pharmaceutical industry. During revision of the second edition of the *International Pharmacopoeia*, the World Health Organization recognized the importance of general monographs on this subject and it was at their request that Mr. Cooper prepared this comprehensive report. Mr. Cooper's experiences with the sorption of preservatives by rubber closures are well documented. As Chairman of a Commission for the Standardization of Regulatory Requirements for Plastic Containers set up by Fédération Internationale Pharmaceutique, he is cognizant of the potential problems in the use of plastics in pharmacy. He has done an excellent job of compiling his information.

In Sections I to V, physical–chemical properties of the most important plastics (polyethylene, polypropylene, polyvinyl chloride, and celluloids) used in packaging drugs are considered. Possible difficulties in the use of plastic containers for drugs are loss of product ingredients to the plastic (sorption), loss of plastic ingredients to the product (desorption), transport of water vapor or gases across the plastic wall (permeation), drug loss through radiation (photodegradation), and change in physical properties of the container by contact with the product (polymer modification). The nature and the means of dealing with these issues are succinctly described and illustrated with published work. The author points out that most of the materials causing drug–plastic interactions are preservatives, and that any significant drug loss is adequately identified by the comprehensive stability programs used by the pharmaceutical industry. Section VI describes the implications of these problems in some of the main dosage forms such as parenterals, ophthalmics, topical preparations, solid dosage forms, and oral liquids.

Sections VII and VIII cover pharmacopoeial regulatory requirements from seven countries, and standards issued by institutions or industries from four countries. The greater part of the book consists of 24 attachments that enlarge on the material found in these chapters. Mr. Cooper also discusses the possibility of establishing international standards.

The report is highly recommended as an addition to industrial quality control and stability laboratories and libraries.

Comparative Pharmacology, Vol. 1. Edited by M. J. MICHELSON. Pergamon Press Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. 517 pp. 24 × 16 cm.

Dr. Michelson has performed an excellent job in editing the book *Comparative Pharmacology, Vol. 1,* and the choice of international authors for the preparation of this book is excellent. The comparative pharmacology of acetylcholine in various phyla is well presented and represents one of the best comparative treatises that I have seen. The chapter on the structure and mutual disposition of cholinoreceptors and changes in their disposition in the course of evolution, by Dr. Michelson, is exceptionally well presented.

In addition, Chapter 3, on the comparative pharmacology of catecholamines, by Dr. Goteborg and Dr. Malmo, provides a readily usable review and compilation of the comparative pharmacology of the catecholamines in both invertebrates and vertebrates. Each of the contributors to this book has provided excellent bibliographies to allow the reader to obtain an in-depth knowledge of the comparative pharmacology of the neurotransmitters acetylcholine and catecholamines.

Terpenoids and Steroids, Vol. 4. Senior Reporter, K. H. OVERTON. Specialist Periodical Reports, The Chemical Society, Burlington House, London WIV OBN, England, 1974. 608 pp. 15 × 22 cm. Price £18.50. (Orders should be addressed to The Publication Sales Officer, The Chemical Society, Blackhorse Road, Letchworth, Herts., SG6 IHN, England)

This is the fourth volume on terpenoids and steroids in a valuable series first published 4 years ago. The aim of the various series of Specialist Periodical Reports is to provide systematic, comprehensive, and critical review coverage of progress in the major areas of chemical research. The various series are being published annually or biennially on such topics as Foreign Compound Metabolism in Mammals; Biosynthesis; The Alkaloids; Carbohydrate Chemistry; Amino-acids, Peptides and Proteins; and Photochemistry.

This volume does not contain a subject index but is organized in a systematic manner which facilitates finding any information being sought. The six pages in the Table of Contents outline this volume in detail. The chapters are divided into many sections which are identified in boldface type in the text as well as in the Table of Contents. These sections are further divided into subsections. Chapter titles are found at the top of every second page of the text. There is an author index which is helpful to those following the research of a given individual.

This review is illustrated with drawings of over 2400 chemical structures. It is documented with 2100 references which are listed at the bottom of the first page of each chapter where used.

Part I, which covers the terpenoids, is divided into chapters which include Monoterpenoids; Sesquiterpenoids; Diterpenoids; Sesterterpenoids; Triterpenoids; Carotenoids and Polyterpenoids; and Biosynthesis of Terpenoids and Steroids. Of special interest is the identification and referencing of over 150 recent reviews covering 1968–1973. The chapter on sesterterpenoids deserves special attention since it contains an excellent review of the literature published on this class of terpenoids beginning with the first report published in 1965.

Part II, which covers steroids, includes three large chapters. The chapter on steroid properties and reactions is divided into sections based upon more common functional groups, a section on compounds of nitrogen and sulfur, and sections on such important subjects as molecular rearrangements, functionalization at nonactivated positions, and photochemical reactions.

The chapter on microbiological reactions with steroids provides a comprehensive account of research published since this subject was last reviewed in this series in 1967. Subject matter in this chapter is organized according to types of transformations and presented under headings which include hydroxylation reactions; hydroxy-steroid–oxo-steroid interconversions; dehydrogenation and the reductions of carbon–carbon double bonds; olefinic bond isomerization; esterase, amidase and hydrolase reactions; reactions involving heteroatoms; and steroid degradation reactions.

In this reviewer's opinion, the "frosting on the cake" is the last chapter entitled "Steroid Conformations from X-Ray Analysis Data." The authors have utilized data from their laboratory at Rijksuniversiteit, Leiden as well as from research literature, part of which they recalculated. The authors were thus able to recalculate equilibrium geometries and analyze the effects of functional groups and configurations upon these geometries of steroids. The

He has done an excellent job of compiling his information.

In Sections I to V, physical–chemical properties of the most important plastics (polyethylene, polypropylene, polyvinyl chloride, and celluloids) used in packaging drugs are considered. Possible difficulties in the use of plastic containers for drugs are loss of product ingredients to the plastic (sorption), loss of plastic ingredients to the product (desorption), transport of water vapor or gases across the plastic wall (permeation), drug loss through radiation (photodegradation), and change in physical properties of the container by contact with the product (polymer modification). The nature and the means of dealing with these issues are succinctly described and illustrated with published work. The author points out that most of the materials causing drug–plastic interactions are preservatives, and that any significant drug loss is adequately identified by the comprehensive stability programs used by the pharmaceutical industry. Section VI describes the implications of these problems in some of the main dosage forms such as parenterals, ophthalmics, topical preparations, solid dosage forms, and oral liquids.

Sections VII and VIII cover pharmacopoeial regulatory requirements from seven countries, and standards issued by institutions or industries from four countries. The greater part of the book consists of 24 attachments that enlarge on the material found in these chapters. Mr. Cooper also discusses the possibility of establishing international standards.

The report is highly recommended as an addition to industrial quality control and stability laboratories and libraries.

Comparative Pharmacology, Vol. 1. Edited by M. J. MICHELSON. Pergamon Press Inc., Maxwell House, Fairview Park, Elmsford, NY 10523, 1973. 517 pp. 24 × 16 cm.

Dr. Michelson has performed an excellent job in editing the book *Comparative Pharmacology, Vol. 1,* and the choice of international authors for the preparation of this book is excellent. The comparative pharmacology of acetylcholine in various phyla is well presented and represents one of the best comparative treatises that I have seen. The chapter on the structure and mutual disposition of cholinoreceptors and changes in their disposition in the course of evolution, by Dr. Michelson, is exceptionally well presented.

In addition, Chapter 3, on the comparative pharmacology of catecholamines, by Dr. Goteborg and Dr. Malmo, provides a readily usable review and compilation of the comparative pharmacology of the catecholamines in both invertebrates and vertebrates. Each of the contributors to this book has provided excellent bibliographies to allow the reader to obtain an in-depth knowledge of the comparative pharmacology of the neurotransmitters acetylcholine and catecholamines.

Terpenoids and Steroids, Vol. 4. Senior Reporter, K. H. OVERTON. Specialist Periodical Reports, The Chemical Society, Burlington House, London WIV OBN, England, 1974. 608 pp. 15 × 22 cm. Price £18.50. (Orders should be addressed to The Publication Sales Officer, The Chemical Society, Blackhorse Road, Letchworth, Herts., SG6 IHN, England)

This is the fourth volume on terpenoids and steroids in a valuable series first published 4 years ago. The aim of the various series of Specialist Periodical Reports is to provide systematic, comprehensive, and critical review coverage of progress in the major areas of chemical research. The various series are being published annually or biennially on such topics as Foreign Compound Metabolism in Mammals; Biosynthesis; The Alkaloids; Carbohydrate Chemistry; Amino-acids, Peptides and Proteins; and Photochemistry.

This volume does not contain a subject index but is organized in a systematic manner which facilitates finding any information being sought. The six pages in the Table of Contents outline this volume in detail. The chapters are divided into many sections which are identified in boldface type in the text as well as in the Table of Contents. These sections are further divided into subsections. Chapter titles are found at the top of every second page of the text. There is an author index which is helpful to those following the research of a given individual.

This review is illustrated with drawings of over 2400 chemical structures. It is documented with 2100 references which are listed at the bottom of the first page of each chapter where used.

Part I, which covers the terpenoids, is divided into chapters which include Monoterpenoids; Sesquiterpenoids; Diterpenoids; Sesterterpenoids; Triterpenoids; Carotenoids and Polyterpenoids; and Biosynthesis of Terpenoids and Steroids. Of special interest is the identification and referencing of over 150 recent reviews covering 1968–1973. The chapter on sesterterpenoids deserves special attention since it contains an excellent review of the literature published on this class of terpenoids beginning with the first report published in 1965.

Part II, which covers steroids, includes three large chapters. The chapter on steroid properties and reactions is divided into sections based upon more common functional groups, a section on compounds of nitrogen and sulfur, and sections on such important subjects as molecular rearrangements, functionalization at nonactivated positions, and photochemical reactions.

The chapter on microbiological reactions with steroids provides a comprehensive account of research published since this subject was last reviewed in this series in 1967. Subject matter in this chapter is organized according to types of transformations and presented under headings which include hydroxylation reactions; hydroxy-steroid–oxo-steroid interconversions; dehydrogenation and the reductions of carbon–carbon double bonds; olefinic bond isomerization; esterase, amidase and hydrolase reactions; reactions involving heteroatoms; and steroid degradation reactions.

In this reviewer's opinion, the "frosting on the cake" is the last chapter entitled "Steroid Conformations from X-Ray Analysis Data." The authors have utilized data from their laboratory at Rijksuniversiteit, Leiden as well as from research literature, part of which they recalculated. The authors were thus able to recalculate equilibrium geometries and analyze the effects of functional groups and configurations upon these geometries of steroids. The

section entitled "Biological Activity at the Molecular Level" would be of special interest to pharmaceutical scientists.

The chapter on steroid synthesis, which had been included in previous volumes of this series, was not included. A 2-year review of this subject will appear in Volume 5.

It is a credit to the editor and 15 reporters preparing this volume that it is so well written and organized. Everyone interested in the chemistry of terpenoids and/or steroids should have access to this volume and others in the series. They would be a great time saver and a source of many new ideas. I highly recommend this series.

Pharmacy Practice: Social and Behavioral Aspects. Edited by A. I. WERTHEIMER and M. C. SMITH. University Park Press, Baltimore, MD 21202, 1974. xv + 556 pp. 16 × 24 cm. Price $15.50.

The main purpose of this excellent collection is also the greatest drawback to its broad-scale usefulness as a college text. It identifies and satisfies a need for a text presenting abstracts from the literature of the social and behavioral sciences in relation to pharmacy practice. The intended audience is the pharmacy student and the pharmacy practitioner (hopefully, including the administrator and scientist, as well as the community and institutional practitioner). Unfortunately, we are disappointed with the book as an undergraduate text primarily because it does provide abstracts exclusively related to the social and behavioral sciences. The lack of substantial material related to the marketing of pharmaceuticals probably limits its use in survey courses in pharmacy administration.

Each of the 12 chapters begins with a 1-page statement of the issues to be addressed and a summary of the major points to follow. An original contribution, ranging in length from nine to nineteen pages follows (except in the last chapter). Each chapter contains several well-chosen abstracts from the literature.

The organization of the book provides areas of overlapping coverage. For example, we find the stages of becoming a patient (symptom recognition, *etc.*) treated in both the chapter on "Discerning the Role of the Patient" and the chapter on "The Patient's Search for Care." Such duplication is, however, not as frequent as one might expect in a book which covers a wide range of interrelated subjects prepared by many authors.

The selection of the authors for the original contributions represents an excellent selection of experts, well known and well respected for their work in the social sciences of pharmacy and health care. The quality and relevance of the original contributions vary, possibly related to the assignment of subject matter. For example, the chapter, "The Patient and the Prescribed Regimen," while interesting (dealing with patient compliance) seemed out of place in a book dealing with major issues of pharmacy and health care, such as "The Health Professions" or "Drugs and Drug Use." This is not to minimize the importance of studies on patient compliance, but merely to indicate they seemed overly emphasized considering the general tone of the book.

Similarly the quality of the abstracts following the original contributions varied. Space priorities sometimes seemed amiss. In the chapter "The Health Care System," the 10-page original contribution is followed by a 15-page "abstract." A short abstract in the book consisted of only thirteen lines, which made the desired point but in a way which caused one to say, "Prove it."

Overall, the quality of the book more than compensates for its relatively minor shortcomings. It is a very thorough review of the relevant literature in the field. It is highly recommended for the pharmacy student (although its status as a required text would probably require many supplemental readings in most introductory pharmacy administration courses). While technically thorough, the book is not written in "social science talk" so that it can be readily understood by the pharmacist without training in sociology or psychology. The information contained in the book should be of significant value and interest to the pharmacy practitioner (as defined above) and reading the book will be time well spent, even for the non-social scientist.

ACHIEVING THE FULL VIEWPOINT

As this is written, a young girl lies in a hospital in New Jersey, her very existence being sustained by a battery of complex machines and instruments. We use the word "existence," rather than "life," because depending upon one's definition of life, it can be argued that medical technology is just maintaining isolated physiological processes and that, in fact, she is already dead.

The controversy that swirls about this girl is both heartrending and complex. Some physicians agree that her brain function has been irreversibly destroyed, but nonetheless contend that on legal, liability, or ethical grounds they are prohibited from unplugging the apparatus that maintains her artificial existence. Even the theologians appear to be split, with opinions divided as to where the limit lies concerning our obligation to maintain human life.

Our purpose here is not to offer any opinion on this most unfortunate case. Hopefully, it will have been resolved long before this journal reaches our readers.

We do, however, feel that it drives home the need for broad-based input in reaching decisions on many matters and issues facing society. We recently heard a clergyman comment upon the case mentioned above, and he pointed out that this question could not have even arisen twenty years ago because the technology did not exist at that time. We now have technology available that presents us with options never before known. This is true whether the subject is heart transplants, or environmental protection, or child-proof containers.

Each of these questions involves a multiplicity of issues and of viewpoints. If a complex medical decision arises, it is no longer adequate or satisfactory to create a panel consisting solely of physicians for purposes of reaching a decision. Other health-care practitioners must be included, as well as persons who reflect other considerations such as the moral and legal aspects.

Many corporations are beginning to recognize this fact and are broadening their boards of directors. Formerly, banks were run exclusively by bankers, industries by industrialists, and so on. Slowly, but surely, this is changing. And contrary to initial expectations, inclusion of these nonspecialists appears to have been beneficial to the dynamic growth and financial health of the corporations involved.

Presently, there is a movement toward expansion or reorganization of the state boards which regulate the respective professions. The intent again is to broaden the makeup of these groups in order to provide a cross section of backgrounds and input. If we subscribe to the belief that a profession exists to serve the public, then it would seem to follow that the public should have at least some voice in how that profession is regulated and, most importantly, should be in a position to ascertain that the particular regulatory body is regulating on behalf of the public rather than in the self-interests of that profession.

Even the Food and Drug Administration has been routinely including a consumer representative and an industry representative on each of its recently appointed advisory panels.

And finally, scientists, too, need to recognize that their actions and decisions are subject to reasonable review, scrutiny, and question. "Scientific freedom" is limited by the same constraints as the exercise of other "freedoms." And nowhere in science is the need for broadened input of viewpoint more evident than in the matter of grant review and approval.

Two years ago, our column was titled "Peer Review under Fire" and discussed the unhappiness then prevalent with the National Institutes of Health and related federal government grant programs. Rather than improve, this situation has deteriorated further during the interim. In our opinion, the prognosis for peer review as it presently operates remains dismal at best, unless there is a prompt reorganization of the system to involve participation by nonscientists.

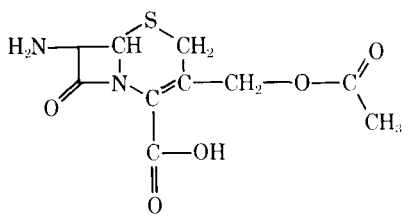
Cephalosporins are a series of compounds containing the 7-aminocephalosporanic acid [7-amino-3-(hydroxymethyl)-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid acetate] nucleus (I). Although cephalosporin C was one of the original and active members of the series, being derived from the fermentation products of *Cephalosporium acremonium*, it has not proved to be useful clinically. However, I has been used as the basis for the synthesis of various derivatives (II–XII). An excellent review of the history, isolation, synthesis, analysis, and physicochemical properties of cephalosporins was published (1). The purpose of this work is to review the pharmacokinetics and clinical use of cephalosporin antibiotics.

PHARMACOLOGY AND PHARMACOKINETICS

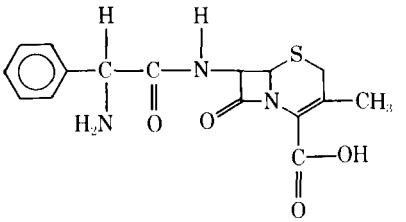
Cephalexin—Cephalexin, 7-(D-2-amino-2-phenylacetamido) - 3 - methyl - 8 -oxo-5-thia-1-azabicyclo-[4.2.0]oct-2-ene-2-carboxylic acid (II), is an orally active semisynthetic derivative of I with a spectrum of activity against both Gram-positive and Gram-negative bacteria. It has relatively low solubility in water; *i.e.*, 1–2 mg was dissolved in 1 ml of water at 37° (2). At pH 2 and 8, the solubility was increased to approximately 120 and 100 mg/ml, respectively (2). The increase in solubility as a function of pH is due to the zwitterionic nature of the drug. Cephalexin is very unstable at physiological pH (3), showing the presence of decomposition products within 20 min of solution in water. It shows less deterioration at low pH. However, the drug is most stable at pH 4.5, its isoelectric point, and may be kept frozen when dissolved in biological fluids for long periods ($t_{1/2}$ > 90 days) (2).

Studies of the protein binding of cephalexin showed that, in concentrations usually found in therapy, less than 10% of the total drug was bound to human plasma proteins (2). At a total cephalexin concentration of 3.2 μg/ml, 6% of the total drug was in the protein-bound state (2). Cephalexin is removed from the body solely by the processes of glomerular filtration and excretion in the kidney tubules.

Cephalexin is advocated for the treatment of infections of the upper and lower respiratory tract, genitourinary system, skin and soft tissue, and bones and joints and for certain other infections due to susceptible organisms. An excellent review of its antibacterial, pharmacological, and therapeutic properties was presented (4). Blood concentrations of the drug, after the usual therapeutic dose, are high enough to be bactericidal against most susceptible organisms (5).



I



II: cephalexin

Absorption—The oral and intramuscular absorption of cephalexin in normal human subjects has been studied (2, 5–19). After oral administration, absorption was rapid and complete, with peak levels being reached within 1 hr (2, 14). The time to reach peak levels may vary between individuals after administration of the drug in capsule form. This finding can be attributed to a lag time in the absorption process due to dosage form effects. Following a 500-mg dose given as a 5% suspension, cephalexin appeared in the serum in 9 min compared with 38 min when given in capsule form (14).

The peak height is dose dependent, usually reaching a level of 18 μg/ml after a 500-mg dose (14, 20). Single doses of 125, 250, 500, and 1000 mg in 12 fasting subjects produced average peak levels of 4.5, 9, 18, and 32 μg/ml, respectively, at 1 hr (20). Some investigators (6, 10, 17, 19, 21) found peak blood levels that were slightly lower than those reported by others (5, 7, 8, 13, 20, 22). Lower peak values may be related to the time food is ingested.

When cephalexin is administered with food, there is a delay in the onset of absorption, a lower peak, and a prolongation of blood levels (14, 20). A total of 82% of a 500-mg dose was found in the urine when the patients were fasting compared to 73% when the dose was taken with food, indicating that the total amount of drug absorbed was not appreciably altered (20). Similarly, a 1-g dose of cephalexin resulted in a peak serum level of approximately 31 μg/ml in fasted subjects but only 20.9 μg/ml after a standard meal (11). The peak time was increased to 2 hr after administration. Similar results were also reported (23). Apparently, small amounts of food do not significantly affect the absorption process (17, 24).

Absorption and excretion of cephalexin are delayed and peak serum levels are less in newborns and infants in the first 6 months of life. Peak serum levels occurred after 3 hr in these patients, 2 hr in infants 9–12 months in age, and 1 hr in children older than 1 year (25–29). Food, *i.e.*, milk, had the same effect in the infant as did food in the adult; *i.e.*, lower peak levels occurred at later times (26).

The influence of disease on cephalexin absorption is variable. In children (18–20 months) with a malabsorption syndrome, a reduction was reported in the excretion of unchanged cephalexin (28). With a dose of 50 mg/kg, however, effective blood levels were

reached but did not peak until 4 hr postadministration. In another study, absorption was significantly impaired in one of three patients with pernicious anemia and obstructive jaundice (30). Reports of impaired absorption due to infectious diseases are lacking with the exception of the report of decreased plasma levels with a prolonged peak time in patients with severely impaired kidney function (creatinine clearance of 0–2.5 ml/min) (18).

Distribution—Cephalexin is widely distributed in body tissues. The only tissues in which concentrations of the drug were higher than in serum were the kidneys and liver (31, 32). Significant levels of the drug in animals also were demonstrated in other tissues, including lung, spleen, fat, heart muscle, and bone. In humans, levels in the appendix, stomach, gallbladder, omentum, peritoneum, and vein and tumor tissues were lower than in serum following an oral dose of 0.5 or 1.0 g (33). Bile levels were lower than serum levels after a dose of 0.5 or 1.0 g of cephalexin (34, 35). Peak levels of 0.3–32.0 μg/ml were observed at 2–3 hr. Probenecid administration significantly increased biliary levels of the antibiotic, probably due to interference with renal excretion producing higher blood levels. Low tissue levels (<1 μg/ml) were found in the gallbladder wall suspension of two patients.

Low levels of the drug in saliva were reported (36, 37). Detectable levels in the aqueous humor at 1 hr and peak levels of 0.75–2.0 μg/ml at 2–3 hr after an oral dose of 2 g were reported (38). These concentrations occurred whenever the serum level exceeded 10 μg/ml.

Cephalexin does not appear to penetrate into the cerebrospinal fluid in significant amounts in the absence of meningeal inflammation (28, 30, 39).

The appearance of cephalexin in the serum and exudate of normal and leukemic patients was studied (40). After a 500-mg oral dose, peak serum levels (12 μg/ml) were obtained at approximately 1.5 hr. Exudate levels reached a peak of 5 μg/ml within the same period and appeared to decline at a slow rate. After 4 hr, the level declined to approximately 3.5 μg/ml, illustrating that cephalexin rapidly appears in skin exudates, with a half-life of elimination from that fluid of approximately 4 hr.

In leukemic patients, distribution into skin exudate was decreased. The ratio of the mean exudate level, expressed as a percent of the serum level, between normal and leukemic patients was 210, 17, and 3.2 after 1, 2, and 3 hr postadministration, respectively. The data suggest that the volume of distribution of the antibiotic may be changed in the leukemic patient. It is not clear if this result is due to the disease state or to the influence of antineoplastic drug therapy.

Metabolism and Excretion—Cephalexin is not metabolized in the body and is rapidly excreted unchanged, principally by the kidney, although small amounts are also excreted in the bile. Studies with labeled ^{14}C-cephalexin in rats and mice showed that the drug is not metabolized and is eliminated unchanged *via* the kidney (41). In rats, 84% of an orally administered dose appeared in the urine after 24 hr, with 77% appearing in the first 4 hr. Fifteen percent was recovered in the feces and was attributed to biliary excretion. In humans, cephalexin does not undergo enzymatic metabolism (42). Excretion of cephalexin in the urine occurs partly through glomerular filtration (66%) and partly by tubular secretion (33%) (24).

The renal clearance of cephalexin was calculated to be 210 ml/min/1.73 m^2, with 72.2% of the total plasma clearance of the drug being accounted for by renal clearance (43). The ratio between the renal and plasma clearances was 1.69, indicating a significant (28%) nonrenal excretion of cephalexin. Since no metabolite of cephalexin has been found (2), it is difficult to account for the apparent nonrenal excretion. Kirby and Regamey (44) reported values of 252 ± 5 and 248 ± 11 ml/min/1.73 m^2 for renal and serum clearances, respectively. When these values are considered, it can be seen that the entire dose can be accounted for through renal excretion. Other values reported for the plasma clearance of cephalexin are 260 and 376 ml/min (8, 11).

The administration of probenecid shortly before or simultaneously with cephalexin enhances both the peak serum concentration and the duration of activity of the antibiotic in the serum (6, 11, 17, 20). The administration of 500 mg of probenecid with 1 g of cephalexin caused an increase in the mean peak serum level of 79% over the mean peak serum level achieved with a similar dose without probenecid (*i.e.*, an increase from 20.9 to 36.7 μg/ml) (11). Levels at 6 hr were also increased, ranging from 4.5 to 9.7 μg/ml (mean of 7.1 μg/ml). Similar findings also were reported (7, 20, 45).

In subjects with normal renal function, cephalexin had a serum half-life of approximately 0.6–2.1 hr after oral administration (2, 7, 8, 10, 12, 14, 16, 18, 19, 39, 42–47), with a mean and standard deviation of 1.2 ± 0.47 hr. In fasting subjects, the mean serum half-life was 49.5 min, but this value increased to 76.5 min in subjects who received cephalexin with food (11). This latter value probably was due to the half-life being calculated during the time when both absorption and elimination were occurring simultaneously. The serum half-life following oral administration is prolonged in neonates and infants. A half-life of approximately 5 hr in newborn infants and of 2.5 hr in infants 3–12 months of age was demonstrated (27, 29).

Due to its extremely short half-life and long dosing interval (4–6 hr), little accumulation of cephalexin in the serum of patients with normal renal function has been observed (24, 48). Blood level curves and urinary excretion values following doses of 250 or 500 mg of cephalexin every 6 hr were unchanged after 1, 3, and 5 days (20). Similarly, the blood level curves and mean urinary recovery values in six subjects after 1-g doses every 6 hr were not significantly different from those following a single dose (11). Some accumulation was noted by O'Callaghan *et al.* (14), who found that both peak concentration and the length of time the serum levels exceeded 12.5 μg/ml

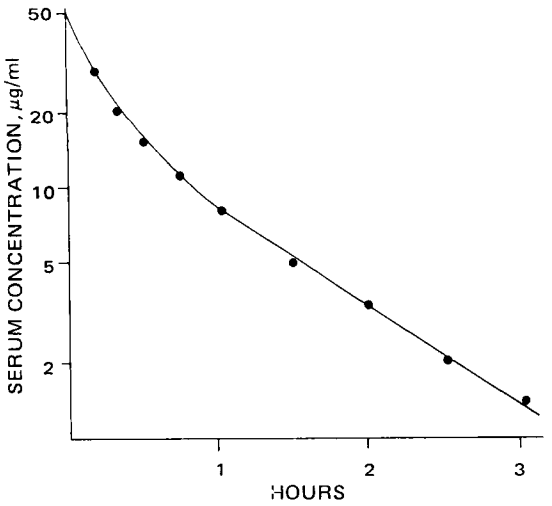


Figure 1—*Serum levels for cephalexin administered intravenously (rate constants for data generation from Table I).*

were significantly increased after the fifth 1-g dose (every 6 hr). These increases did not occur after doses of 500 mg, which is to be expected for a drug with a short half-life and relatively long dosing interval.

Between 82 and 100% of an orally administered dose appeared in the urine after 250- and 500-mg doses of cephalexin (13, 50). However, urinary recoveries of 29–89% were reported in patients with urinary tract infections (49). Urinary levels of the antibiotic are, therefore, high, and peak levels in the urine may be more than 100 times higher than in the serum. Thornhill *et al.* (17) found mean urinary concentrations in a 6-hr period of 830 μg/ml and 1.1 mg/ml after 250 and 500 mg of cephalexin, respectively. Mean urinary concentrations of 2.3 and 5.0 mg/ml were observed in the first 1–2-hr period following administration of 0.5 and 1.0 g of cephalexin, respectively (24). Similar results also were observed (6, 20).

The clearance of cephalexin is prolonged in the presence of renal dysfunction, resulting in higher and more sustained serum levels; *i.e.*, an increase in the serum half-life occurs as renal function decreases (18, 19, 39, 51–55). Serum half-lives of 7.7, 10.8, and 13.9 hr were observed in subjects with creatinine clearances of 13.5, 9.2, and 4 ml/min, respectively (19). No significant increase was found in the serum half-life in patients with creatinine clearances of 45 ml/min; but when kidney function fell below one-fourth of normal, *i.e.*, creatinine clearance of less than 30 ml/min, the half-life increased significantly (55). Similarly, only moderate increases were noted in plasma half-lives when the creatinine clearance was between 10 and 40 ml/min, but a rapid increase was noted thereafter when the value fell below 10 ml/min (52).

Peak serum levels after single oral doses of 500 mg of cephalexin were reached in 1–2 hr, with appreciable levels still present at 12–24 hr (53). In patients with a creatinine clearance of less than 3 ml/min, however, the peak serum levels occurred at 4–8 hr, and levels of 5 and 6 μg/ml were still present at 48 and 60 hr, respectively. Detectable levels were present for 72–90 hr. A delay in the time to reach the peak serum level occurred in patients with severe renal failure (18, 51). Repeated administration of the drug in patients with renal impairment led to accumulation (18, 19).

Urinary excretion of cephalexin is inversely related to the serum half-life and directly related to the creatinine clearance. Less than 5% of a single dose of cephalexin was excreted within 24 hr in patients with creatinine clearances of less than 2.5 ml/min (18). The urinary excretion of cephalexin at 6, 24, and 48 hr after a 500-mg dose was 7.5, 23, and 37%, respectively (51). Satisfactory antibacterial levels were attained. Satisfactory urine levels were found in patients with creatinine clearances of 3 ml/min (56); however, in another report (19), acceptable levels were not achieved if the creatinine clearance was less than 9 ml/min.

Hemodialysis resulted in a fourfold decrease in serum levels within 7 hr (54). Similarly, a fivefold reduction in half-life was reported when hemodialysis was employed for 12 hr (18, 53). Peritoneal dialysis resulted in a twofold decrease in serum levels after 7 hr (54). Bennett *et al.* (57) described an adjusted dosage regimen as a guide in treating patients with various degrees of renal failure.

Pharmacokinetic Considerations—When the available literature blood level data after intravenous administration of cephalexin are carefully examined (Fig. 1), it appears that the drug follows a two-compartment open model (Scheme I). All investigators analyzed their data using a one-compartment open model. This model may lead to errors in the calculation of the volume of distribution and the elimination and absorption rate constants (58, 59). A reevaluation of selected literature data is shown in Tables I and II. The half-lives reported using a one-compartment open model analysis are equivalent to the half-life of the β-phase. The value of the half-life of the distributive (α) phase was 0.15 hr. Therefore, to describe completely the time course of the drug in plasma, it is necessary to remove at least two or three blood samples within the first 45 min after administration.

Cephalexin, which is only 6% protein bound in the therapeutic range, is distributed widely within plasma water and some extracellular water. The volume of the central compartment using a two-compartment open model analysis is 10.8 liters. In contrast, the volume of distribution of cefazolin (V), another cephalosporin antibiotic, is approximately 4 liters. Cefazolin, being 90% protein bound, is distributed mainly in the plasma water. When the volume of distribution found for cephalexin is compared to that of

[a] Analysis of data using a two-compartment open model (Scheme I).

cefazolin, the effect of protein binding on the volume of distribution of a drug is evident.

The volume of the tissue compartment into which cephalexin distributes can be found by using Eq. 1:

$$V_t = \frac{K_{12}}{K_{21}} V_c \qquad \text{(Eq. 1)}$$

where K_{12}, K_{21}, V_c, and V_t are defined in Scheme I. The volume of the tissue compartment using this formula is 7.6 liters. This value gives a total volume of distribution within the body of 18.4 liters, a value that is usually reported as Vd_{ss}, the volume of distribution at steady state.

The current literature contains only two references to values of the volume of distribution of cephalexin. A value of 15 ± 2.3 liters was found (43) after a 3-hr intravenous infusion. The formula used was:

$$Vd = \frac{i}{(p)(K_{el} \times 10^3)} \qquad \text{(Eq. 2)}$$

where i is the infusion rate, p is the concentration of cephalexin in the plasma at steady state, and K_{el} is the elimination rate constant for cephalexin. The value of K_{el} was determined by using a log-linear regression on the postdistribution portion of the blood level *versus* time curve after infusion. The value of K_{el} obtained in this manner is analogous to the value of beta obtained from a two-compartment open model analysis. Therefore, the value determined by the use of Eq. 2 is equivalent to the value of Vd_β, the volume that can be determined during the β-phase in a two-compartment open model.

The value of Vd_β shown in Tables I and II when the data were analyzed with a two-compartment open model is approximately 23 liters, which is significantly greater than the reported value of 15 liters (43). The reason for the difference becomes clear when Eq. 2 is examined. If the value of K_{el} were too large, it would cause the value of the volume of distribution calculated by this formula to be too small. One factor that could cause the value of K_{el} to be very large would be the method by which it was obtained. Since it has been shown that cephalexin follows two-compartment open model kinetics, it follows that after infusion is terminated, the resultant curve will have an α- (distributive) phase and a β- (disposition or elimination) phase. Therefore, use of the entire curve after infusion instead of the late postinfusion curve results in an overestimation of the value of K_{el}.

The effect of using this method of analysis of two-compartment open model data is apparent if Fig. 2 is examined. A shortening of the half-life with an increased value of the rate constant is the result of the incorrect analysis of serum level data. deMaine and Kirby (43) reported a relatively short half-life (0.61 hr) for cephalexin. It is difficult, however, to determine if α-phase data were utilized in their determination.

A value of 37 liters (range of 26–53 liters) was reported for cephalexin after intramuscular administration (8). This volume of distribution was determined using:

$$Vd = \frac{\text{dose}}{(AUC)(K_{el})} \qquad \text{(Eq. 3)}$$

where AUC represents the area under the plasma level *versus* time curve from time zero to time infinity. Since the value of K_{el} is analogous to the value of beta used in the two-compartment open model, the volume found by the use of this equation is equal to the value of Vd_β.

The value of 37 liters (8) is much larger than the value of Vd_β determined using the two-compartment open model. The overestimation (8) is attributable to

[a] Analysis of data using a two-compartment open model (Scheme I).

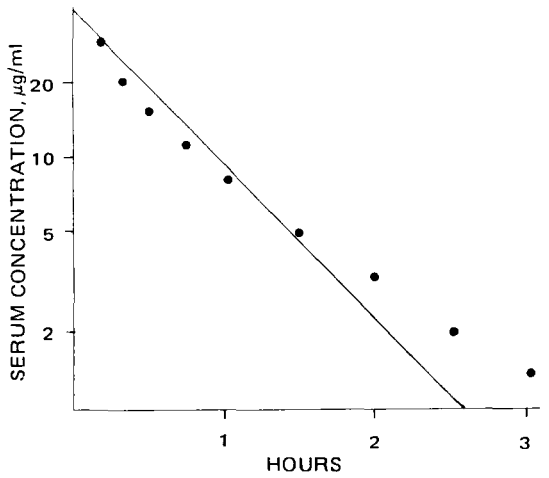

Figure 2—*Log-linear regression on biphasic data.*

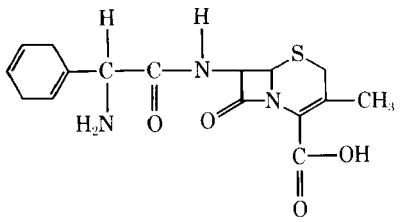
an underestimation of the value of K_{el}. It appears that these investigators overestimated the half-life of cephalexin (1.1–2.3 hr) due to the fact that absorption and elimination occurred during the entire sampling time. In studies where the absorptive processes are allowed to vary due to improper fasting or precipitation at the site of muscular injection, the apparent absorption rate constant might be smaller and the $t_{1/2}$ for elimination might appear longer than expected. These phenomena could explain the wide range of elimination half-lives reported in the oral studies.

Use of the one-compartment open model to fit cephalexin data results in errors in the volume of distribution term. Since the therapeutic range of the drug is high, the use of the larger *Vd* (extrapolated) term as a one-compartment open model volume of distribution will not compromise the efficacy of cephalexin therapy since the normal dose results in blood levels that are usually well above the minimum inhibitory concentration (MIC). Since the half-life of cephalexin is short compared to the normal dosing interval (6 hr), drug accumulation is negligible and errors in calculation of the absorption rate constant are not significant. It appears that routine pharmacokinetic analysis of cephalexin could be accomplished using the one-compartment open model treatment without introducing serious error, provided the $t_{1/2}$ was determined correctly from intravenous data, *i.e.*, after the distributive phase and the volume terms are properly interpreted.

Cephradine—Cephradine, 7-[D-2-amino-2-(1,4-cyclohexadien-1-yl)acetamido]-3-methyl-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid monohydrate (III), is a semisynthetic cephalosporin



III: cephradine

used orally, intramuscularly, and intravenously. The structure of cephradine is similar to that of cephalexin, the only difference being in the six-membered ring. Cephalexin has three double bonds forming an aromatic system while cephradine has two double bonds in the same ring. The antibacterial activity of cephradine is similar to that of cephalexin (60).

Cephradine is a white crystalline powder with a molecular weight of 349.4 (61). The synthesis of cephradine has been discussed (62). Cephradine is freely soluble in aqueous solvents. It is a zwitterion, containing both an alkaline amino group and an acidic carboxyl group. In the pH range of 3–7, cephradine exists as an internal salt (63). Cephradine is stable for 24 hr at 25° within the pH range of 2–8. Since it is stable in acidic media, there is little loss of activity in the gastric fluid; losses of less than 7% have been reported (64).

Cephradine is weakly bound to human serum proteins. In one study (63), the drug was less than 20% bound to the serum proteins. At a serum concentration of 10–12 μg/ml, 6% of the total drug was in the protein-bound complex. Another study (65) found that at a total concentration of 10 μg/ml, 28% of the drug was in the protein-bound state; at a total concentration of 100 μg/ml, 30% of the drug was in the protein-bound state. This study also showed that the addition of serum to cephradine decreased antibiotic activity. Another study (61) showed that the protein binding of cephradine varied from 8 to 20%, depending on the concentration of the drug. However, a study by Gadebusch *et al.* (64) found no change in the MIC of cephradine toward either *Staphylococcus aureus* or *Escherichia coli* after the addition of human serum.

Absorption—Cephradine has been administered orally, intramuscularly, and intravenously and is well absorbed using these routes. This large degree of absorption is evidenced by recoveries of approximately 100% of the administered dose in the urine (63, 66–69). In one study (63), tritiated cephradine was administered orally to human subjects in the form of a 250-mg capsule. Urine and feces were collected and assayed for the drug; 92% of the drug was present in the urine at the end of 24 hr, while minimal amounts were present in the feces at the end of 72 hr. These findings are evidence for the claim that cephradine is well absorbed orally and apparently not excreted in the bile.

After oral administration of cephradine, the time of peak serum concentration was at 1 hr with peak concentration in the serum ranging from 6 to 7 μg/ml after a 250-mg capsule (63, 68, 69). After the administration of 500 mg of cephradine in the form of two 250-mg capsules, peak serum levels were in the range of 11–18 μg/ml (60, 63, 66–68). After the administration of 500 mg of cephradine as an oral suspension, a peak serum concentration of 19.5 μg/ml was found at 0.5 hr (68). When human subjects were given 1 g of cephradine, the peak levels ranged from 15 to 24 μg/ml (60, 68).

After the administration of 1 g im, a peak level of 10.4 μg/ml at 2 hr was attained (63). While the peak

concentration of cephradine after intramuscular injection was lower than that after oral administration, the areas under the curve were identical. One advantage of the intramuscular route over the oral route was that the concentration of the antibiotic in the serum was below 1 μg/ml at 4 hr after oral administration while the concentration after intramuscular administration was 6.8 μg/ml (63).

One study (66) found that the rate of absorption after oral administration was influenced by the presence of food but that the extent of absorption was not affected. Serum levels at 30 min after administration were 7.9 μg/ml for nonfasting volunteers and 15.8 μg/ml for fasted volunteers. However, peak levels were not significantly different; values of 19.2 and 18.3 μg/ml were found for nonfasting and fasted volunteers, respectively.

After intravenous administration of cephradine, the peak levels are reached immediately. In one study, a serum concentration of 56 μg/ml at 7 min after injection was attained after administration of 1 g (70). In another study (63), the administration of 1 and 0.5 g of cephradine intravenously gave levels of 86.3 and 46.0 μg/ml, respectively, 5 min after injection. When cephradine was given as an intravenous constant infusion (0.166 g/hr), a steady-state level of 4.8 μg/ml was attained after 3 hr (70).

Distribution—In a study performed with mice (71), cephradine was widely distributed throughout the body. In this study, 50 mg/kg of tritiated cephradine was administered orally to mice and tissue levels were determined as a function of time. The levels in the stomach, small intestine, and kidneys were all above 100 μg/g of tissue. The liver had a level of more than 50 μg/g of tissue at 1 hr after administration. Almost all other body tissues had levels above 1 μg/g of tissue. The levels found in the brain were 0.8–2.2 μg/g of tissue in the 24-hr period of the study.

The tissue levels of cephradine in humans after oral dosing were examined (67). The level in lung tissue 6 hr after administration of 500 mg po was 0.46 μg/g of tissue (serum level was 0.58 μg/ml). Three hours after dosing, adipose tissue levels of 0.46–0.56 μg/g of tissue were found (serum level was 0.31–0.60 μg/ml). Cephradine levels for various other tissues were also given (67). The volume of distribution of cephradine was reported to be 21 liters/1.73 m^2 (72).

Metabolism and Excretion—A study in mice and dogs using paper chromatographic techniques showed that no metabolites of cephradine could be found in the urine (71, 73). A study in humans also could not find any metabolites of cephradine (63).

When 500 mg of cephradine was administered orally to subjects having cholecystolithiasis (67), the levels of cephradine in the bile ranged from 2.2 to 41.0 μg/ml at 3–7.5 hr after administration.

The major route for the elimination of cephradine is renal excretion. Cephradine is removed from the body by the processes of glomerular filtration and tubular secretion (63). A study (61) in which probenecid was coadministered with cephradine resulted in a prolonged half-life and elevated serum levels.

The recovery of unchanged cephradine in the urine ranged from 78.3 to 95.9% (63, 66–68). The urinary concentration of cephradine in the first 2 hr after administration of 500 mg was between 1.1 and 3.2 mg/ml (63, 66, 68).

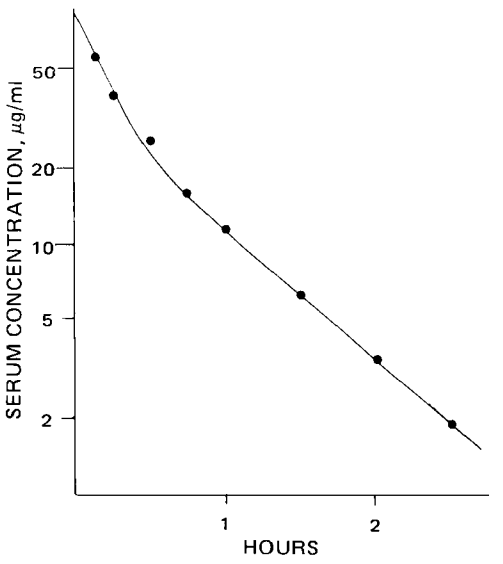


Figure 3—*Serum levels for cephradine administered intravenously (rate constants for data generation from Table III).*

The half-lives of elimination of cephradine were 32 min (70) after intravenous administration, 40–50 min after intramuscular administration (63), and 42 min after oral administration (68). These studies were performed in patients having normal kidney function. During a constant infusion, patients having a creatinine clearance of 125 ml/min had serum and renal clearances of cephradine of 435 and 367 ml/min, respectively (72).

In another study (74), 500 mg of cephradine was administered orally to patients with impaired kidney function. The time required to excrete 90% of the administered cephradine was 24 hr in normal patients. Individuals having impaired kidney function required much longer to excrete a similar amount of the drug.

Pharmacokinetic Considerations—Little work has been performed on the pharmacokinetics of cephradine in subjects with normal and impaired kidney function. Further study is necessary to elucidate these parameters.

A plot of cephradine serum concentration *versus* time (Fig. 3) indicates a biexponential decay. Therefore, fitting of the data for cephradine should be performed using a two-compartment open model. The effects of using a one-compartment open model analysis when a two-compartment open model is indicated were discussed previously.

When the data for intravenous cephradine were fit to a two-compartment open model, the half-life was approximately 45 min. The values of the parameters obtained are listed in Table III.

The volume of distribution was 22 liters, compared to 21 liters/1.73 m^2 reported previously (72). A value of 17 ± 3.9 liters/1.73 m^2 also was reported (61).

The pharmacokinetics of cephradine probably will

[a] Analysis of data using a two-compartment open model (Scheme I). [b] Literature values.

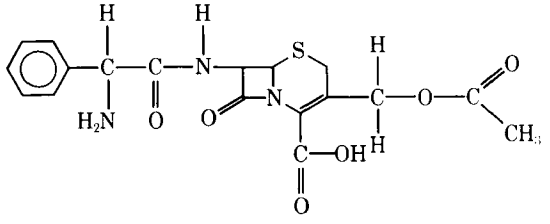
be similar to those found for cephalexin due to the similarity of their structures. The protein binding of these two compounds is not significantly different, so the volume of distributions should be similar, as was found in the reanalysis of literature data (Table III).

Cephaloglycin—Cephaloglycin, 7-(2-amino-2-phenylacetamido)-3-(hydroxymethyl)-8-oxo-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid, acetate (ester) (IV), is a zwitterion of 7-(D-α-aminophenylacetamido)cephalosporanic acid and exhibits an antibacterial spectrum similar to that of other cephalosporins. It is water soluble [8 mg/ml at 25° (75)] and orally absorbed, and it is indicated for use in treating bacterial infections of the urinary tract (76). The stability of cephaloglycin is dependent on pH, degrading very rapidly in alkaline media and remaining stable under acid conditions (77, 78). The decomposition rate is 6–8%/hr in aqueous solution at pH 7.0, but at pH 4.5 the rate is less than 1%/hr (75).

Cephaloglycin exhibits moderate protein binding. Wick (79) found a decrease of 24% in antibacterial activity when the drug was in the presence of human serum as compared to buffer.

Absorption—Several investigators reported mean peak blood serum activity after a 500-mg dose in the range of 0.9–2.0 μg/ml (48, 80–85). Peak concentrations of 0.6–0.8 μg/ml were reported (83, 86), but in another study no serum levels could be detected (87). A concentration of 2.2–3.0 μg/ml was found after a 500-mg dose (48). The activity in serum is due in part to the parent compound but largely to the deacetylated metabolite (78).

Food was reported not to interfere with cephaloglycin absorption (84); however, another study (6) found decreased peak levels after a meal. Urinary recovery was also decreased. Prolonged serum activity was reported when the drug was administered with



IV: cephaloglycin

food as compared to the fasting state (84). Peak concentrations occurred 2 hr after administration (84, 86). Peak concentrations were found 1 hr after administration to fasting patients and 2 hr after administration to nonfasting individuals (6). Similar results were obtained in children 1–15 years old (88).

Peak heights were compared after oral and intramuscular doses of the drug (48). Only 25% of the orally administered dose was assumed to be absorbed.

Distribution—The antibacterial activity in the bile of rats and mice exceeded that in the circulating blood, but only 0.04–0.23% of a 200-mg/kg dose was recovered in the bile during a 24-hr period. The antibacterial activity in the tissues of mice was determined 4 hr after an oral dose of 200 mg/kg (89). The concentrations of drug in liver and kidney were 1.9 and 3.2 times greater than in the serum, respectively. Other tissues such as lung, spleen, and heart and skeletal muscle had approximately 40% of the activity of the serum. Rat liver levels were similar to blood levels after administration of 100 mg/kg of cephaloglycin, but lung and spleen levels were slightly lower and kidney levels were much higher (90).

Metabolism—Esterases can remove the acetyl group from the C-3 methyl position of I to yield desacetyl cephalosporins (91). Carefully controlled studies, by microbiological assay procedures and chromatographic techniques, showed that 2–10% of the antibiotic activity of serum and urine specimens from humans receiving cephaloglycin is due to the parent compound. The remainder of the biological activity (90–98%) is due to the active metabolite desacetylcephaloglycin (78, 92–94). The metabolite had approximately equal activity against staphylococci but was about fourfold less active against other Gram-positive cocci and Gram-negative bacilli (94).

Excretion—Cephaloglycin and its metabolite are excreted in the urine. A half-life of 2.2 μg/ml/hr was reported (85), but it is not clear how this value was obtained. Other data (6) suggest a half-life for microbiological activity of approximately 1.5 hr.

Several studies (6, 48, 82) found 25% of the orally administered activity in the urine. Stein *et al.* (85) recovered 18% of a 500-mg dose. Most recovered activity was due to the desacetyl metabolite (48, 78, 93, 94). Urine concentrations expressed as antibacterial activity after a 500-mg dose varied from 76 to 330 μg/ml. Somewhat lower (18–255 μg/ml) results were reported (86), as were ranges of 18–750 μg/ml (83) and 70–900 μg/ml (95). It was reported that probenecid increased the serum concentration of the antibacterial activity (6). However, other studies reported no increase in serum concentrations with probenecid, but the duration of assayable activity was prolonged (82, 84).

Disease, except decreasing kidney function, does not appear to affect the pharmacokinetics of this drug. An increase in the half-life of the drug was observed with decreasing renal function (85). Significant prolongation of serum half-life occurred when creatinine clearances fell below 20 ml/min. Adequate urine concentrations in all but anuric patients were observed after a 500-mg dose (85). Hemodialysis did

not appreciably affect the elimination of the drug in anuric patients (85). Peritoneal dialysis caused a 40% decrease in blood levels within 6 hr (83).

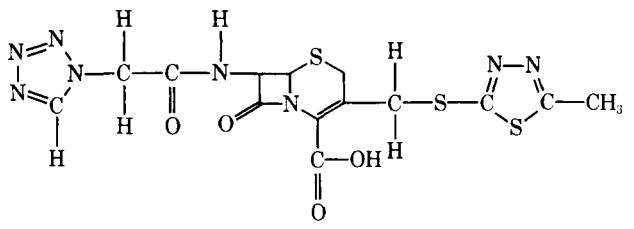
Pharmacokinetic Considerations—The data reported do not allow an accurate estimation of the pharmacokinetic parameters of this drug. Human metabolism of cephaloglycin has not been extensively studied, and blood level data obtained *via* microbiological assay do not yield accurate pharmacokinetic constants; instead, apparent constants are obtained based upon the total activity of the drug and its metabolite.

Since this drug yields poorer blood levels, has a similar spectrum, and does not yield superior urinary levels as compared to cephalexin, no clear advantage for its use is evident. From a pharmacokinetic view, cephaloglycin has many disadvantages compared to cephalexin and should be abandoned in favor of the latter drug. For practical purposes, cephaloglycin is an uninteresting drug, and further pharmacokinetic analysis is not warranted.

Cefazolin—Cefazolin, 3-{[(5-methyl-1,3,4-thiadiazol-2-yl)thio]methyl}-8-oxo-7-[2-(1*H*-tetrazol-1-yl)-acetamido]-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid (V), is a semisynthetic cephalosporin used parenterally. Its synthesis was described previously (96). Cefazolin is a broad spectrum antibiotic, active against most strains of Gram-positive and Gram-negative bacteria (97). It is active against *S. aureus, E. coli, Klebsiella pneumoniae,* and *Proteus mirabilis.*

The free acid form of cefazolin is insoluble in water, becomes more soluble as the pH increases, and reaches a maximum solubility between pH 5 and 6 (98). Cefazolin is available commercially as the sodium salt with a molecular weight of 476.5 (99). In the sodium salt form, cefazolin is highly soluble in aqueous solvents, slightly soluble in methanol, and practically insoluble in acetone, benzene, chloroform, and ethanol (96, 100). The pH of a reconstituted solution and region of maximum stability of cefazolin sodium lies between 4.6 and 6.0 when in an aqueous medium. In a more acidic or alkaline medium, cefazolin is hydrolyzed to products that possess little or no antibacterial activity (98, 99, 101). The pKa of cefazolin in an aqueous solution (23.8 mg of cefazolin sodium in 5.0 ml of water) was 2.3 (99).

The solid lyophilized powder of cefazolin was stable for 1 year when stored at 0–15°, with 92–95% of the original activity remaining when assayed microbiologically (96). The product information brochure (98) states that the lyophilized powder is stable for 2 years at room temperature. Various reports of the



V: cefazolin

stability of the reconstituted aqueous solutions of cefazolin sodium have been published (96, 97, 101, 102). These studies found that the drug is stable at 25° and below, with approximately 90% of the original activity remaining after 72–120 hr (96, 97). Cefazolin is less stable at 37°, and a net loss of 20% of the original activity was found after 72 hr (97). A complete survey of the stability of cefazolin, in which the effects of various diluents and temperatures were studied, is available (101).

Cefazolin is highly bound to human plasma proteins. Investigations using the equilibrium dialysis technique found values of 73% (103), 81% (104), and 84% (105, 106) of the total drug being bound to plasma proteins in normal patients. Values of 74% (107) and 86% (44, 108) were found when the ultrafiltration technique was used to analyze the plasma samples. In one study, the effect of total drug concentration on serum protein binding was studied (105). The binding to serum protein varied from 80 to 90% in the normal therapeutic range of cefazolin. The effect of protein binding on antibiotic activity is unclear, but one study (102) showed that the presence of human serum caused a decrease in antimicrobial activity of 41–48% as compared to a cefazolin solution made in buffer.

Absorption—Cefazolin is not absorbed orally, so it is only administered intramuscularly and intravenously. Cefazolin is well absorbed when administered intramuscularly, as evidenced by urinary recoveries of approximately 100% of the administered dose. The time of peak concentration after intramuscular administration was usually within 45 min to 1 hr after administration (44, 103–126). However, in several cases, the time of peak serum concentration appeared as late as 2 hr after administration (127, 128).

The peak concentration of cefazolin after an intramuscular injection of 250 mg ranged from 12.3 to 30.0 μg/ml (104, 117, 119). After an intramuscular injection of 500 mg, peak levels ranged from 11.0 to 70.0 μg/ml (44, 103, 104, 106–109, 111, 112, 114, 115, 117, 119–121, 124–126, 128, 129); after administration of 1 g of cefazolin, peak levels of 38.8–75.7 μg/ml were found. In one study where 2 g of cefazolin was administered, levels of 111.0 μg/ml were attained; 3 g of cefazolin and 1 g of probenecid resulted in a level of 200.0 μg/ml (123).

Distribution—Rats were injected intramuscularly with ^{14}C-labeled cefazolin, and the tissue concentrations were determined using radioactive and microbiological assays (98, 117, 120, 126, 130, 131). The concentration of cefazolin was very high in the kidneys, lungs, and liver. Peak levels reported (120) for these organs were 68.64, 19.52, and 22.41 μg/g of tissue, respectively. The concentration of cefazolin found in the serum at the time of peak tissue levels was 77.60 μg/ml; levels of 14.42 μg/g of heart tissue, 1.05 μg/g of brain tissue, and 5.10 μg/g of spleen tissue were also found.

In one study where synovial fluid levels of cefazolin were measured in humans (113), the levels of cefazolin found were similar to the levels of cefazolin found in the blood. After an intramuscular injection of 1.0

g, peak serum levels of 65 μg/ml were attained. The synovial fluid level at that time was approximately 75 μg/ml. Cerebrospinal fluid concentrations in human volunteers also were measured (120). In this study, intravenous doses of 10 mg/kg were given and the cerebrospinal fluid and serum levels were determined as a function of time. The serum levels varied from 40 μg/ml at 30 min after injection to 9 μg/ml at 4 hr after injection. However, the cerebrospinal fluid levels remained constant at 4 μg/ml throughout the entire study.

Studies performed on mucous membranes (132) in patients with chronic sinusitus found that the levels of cefazolin were 1.5 and 3.5 μg/g of tissue after a 250- and 500-mg intramuscular dose, respectively. The tissue used was the mucus membrane removed from the maxillary sinus. In other studies performed by these same authors, doses of 250 and 500 mg of cefazolin were administered to patients with tonsillar hypertrophy. The tissue levels attained were 3.4 and 7.6 μg/g of tissue, respectively.

Metabolism and Excretion—The metabolism of cefazolin is a very insignificant process in the elimination of the drug. Various studies using chromatographic separation techniques found that no microbiologically active metabolites were present in the urine of rats or humans (102, 117, 131). In studies where ^{14}C-cefazolin was injected intramuscularly into rats, two metabolites of cefazolin were present in the bile and one metabolite was present in the urine (122). These metabolites accounted for a small fraction of the original dose. Some metabolites were recovered in the urine and the bile (131), but the amounts recovered were very small. Another similar study found no cefazolin metabolites (120).

The bile of normal patients and patients with gallbladder and bile duct impairments was examined for cefazolin content after systemic administration of the drug (113, 121, 133). In one study (113), cefazolin was infused intravenously at a rate of 500 mg/hr for 1 hr and then at a rate of 250 mg/hr for 2 hr. During the steady state, the serum concentration of cefazolin was 50 μg/ml and the concentration of cefazolin in the bile was 12.2 μg/ml. Cefazolin biliary excretion was 0.104 ml/min/1.73 m^2. Other studies performed using patients with normal bile duct and gallbladder function found a biliary concentration twice that of the serum concentration of cefazolin (121); bile levels seven times those found in serum were observed in one study (133).

In diseased patients having a gallbladder or bile duct dysfunction, without obstruction of the bile duct, the levels in the bile were at least twice, and sometimes as high as seven times, those of the serum. These patients had cholelithiasis, cholecystitis, and a nonobstructed cystic duct. The levels found in the gallbladder tissue were similar to those found in the bile. In patients with an obstructed cystic duct, the levels of cefazolin in the bile were below those found in the serum (133).

The recovery of cefazolin in the bile of rats given 20-mg/kg im or sc doses of cefazolin was as high as 20% of the original administered dose (117). Thus, considering the high levels of drug appearing in the bile, cefazolin may be effectively used to treat infections in the bile duct or gallbladder.

Cefazolin is eliminated from the body mainly through renal excretion. Urinary recovery studies (44, 70, 98, 99, 104–109, 111, 113–118, 121, 127, 134) showed that essentially 100% of the administered dose can be accounted for as unchanged drug in the urine. The serum and renal clearances for cefazolin were reported to be 62 ± 6 and 64 ± 6 ml/min, respectively (44). Since these values are not significantly different, it can be concluded that the renal route of elimination is responsible for removal of a major percentage of the drug.

The mechanisms responsible for the elimination of cefazolin are glomerular filtration and tubular secretion. This elimination was first postulated by Regamey *et al.* (108) by comparing the creatinine clearance, a measure of glomerular filtration, to the clearance of cefazolin. The mechanisms involved in the elimination of cefazolin were further elucidated when probenecid was administered concurrently with the antibiotic (44, 114, 123). In all of these studies, a prolonged half-life and elevated serum levels characteristic of the competitive inhibition of the tubular secretion of cefazolin were found.

Numerous pharmacokinetic studies have been performed using patients with normal kidney function (44, 70, 98, 99, 103–122, 127, 128, 134, 135) and impaired kidney function (98, 99, 103, 105, 106, 109, 111, 114, 122, 128, 136). The range of half-lives reported for cefazolin after intravenous administration is 69–108 min (44, 70, 99, 108, 127, 134), with an average of 88 min. After intramuscular administration, the values of the reported half-lives range from 96 to 153 min (44, 99, 104, 105, 109, 114, 127, 134), with an average of 121 min.

In one study where multiple dosing of cefazolin was investigated, a half-life of 124 min was found after the first dose and a value of 88 min was found after a series of multiple doses (106). The reason for this change of half-life after a series of intramuscular multiple doses is unclear, but the explanation reported was that cefazolin-metabolizing enzymes were produced (106). However, since cefazolin has not been shown to be appreciably metabolized, this explanation does not seem plausible.

The renal and total body clearances of cefazolin have been studied (44, 70, 105, 106, 108, 113, 114, 128, 130). The plasma clearance found in one study was 61.5 ± 6.1 ml/min and the renal clearance was 64.6 ± 6.0 ml/min after either intravenous or intramuscular administration (44). Values of 50 ml/min (106, 128), 61.2 ml/min (105), 78.0 ml/min (130), 81.8 ml/min (113), and 83.6 ml/min (70) have been reported for renal clearance.

When probenecid was administered concurrently with cefazolin, higher levels and a prolonged half-life were found as compared to the administration of cefazolin without probenecid (123). Cefazolin was administered at a dose of 2 g intramuscularly to human volunteers. When cefazolin was administered with probenecid, peak levels of about 140 μg/ml were at-

tained. When cefazolin was administered alone, the peak level attained was about 110 μg/ml. There was a significant difference in the serum levels attained at the end of 12 hr when the two levels were compared. At that time, the cefazolin serum levels were less than 40 μg/ml with, and 10 μg/ml without, the coadministration of probenecid. Therefore, concurrent administration of cefazolin and probenecid resulted in levels above the MIC of many susceptible bacterial organisms for a prolonged period. In this study, equal cefazolin serum levels were attained when 3 g of the drug was administered concurrently with probenecid compared to the administration of 2 g of cefazolin and 1 g of probenecid. Increased serum levels and prolonged half-lives were obtained in other studies (44, 114).

Since cefazolin is eliminated from the body primarily by renal excretion, a longer half-life and a higher serum level result in a patient with impaired kidney function. The effect of kidney function on the pharmacokinetics of cefazolin has been investigated (98, 99, 103, 105, 106, 109, 111, 114, 122, 128, 136). In one study (114), normal volunteers and patients with varying degrees of renal impairment (creatinine clearance of 0–47 ml/min) were given 500-mg intramuscular doses of cefazolin. The peak levels achieved in the patients with normal kidney function ranged from 44.0 to 70.0 μg/ml at 30–60 min after injection. The peak levels attained in the patients with kidney failure ranged from 42.0 to 81.5 μg/ml at 30–120 min after drug administration. The half-life of cefazolin in the normal patients ranged from 1.37 to 1.96 hr, with a mean value of 1.60 hr. In the patients with renal impairment, the half-life ranged from 4.84 hr in a patient with a renal clearance of 47.2 ml/min to 69.2 hr in an anuric patient.

A similar study (128) found that as creatinine clearance decreased, the half-life increased. Czerwinski *et al.* (128) stated that: "in patients with serum creatinine concentrations less than 2.5 mg/dl or creatinine clearances greater than 25 ml/min modification of cefazolin dosage is not necessary since urinary excretion is rapid and exponentially related to plasma concentration. In patients with more severe renal impairment, modification of dosage is necessary to prevent accumulation." This observation was based on the fact that the plasma half-life of cefazolin does not significantly change until the creatinine clearance falls below 25 ml/min. Below 25 ml/min, the half-life of cefazolin increased rapidly (128).

In this study (128), the effect of renal function on the volume of distribution, total serum protein, and serum albumin was examined. No significant differences in total serum protein existed in normal patients as compared to patients with varying degrees of renal dysfunction. However, the volume of distribution in normal patients was much less than that of patients having severe renal impairment. In patients having normal kidney function, the volume of distribution was 13.52 ± 3.70% of body weight. Values of 13.62 ± 4.06 and 16.53 ± 2.62% of body weight were found in patients with moderate kidney function and severe impairment, respectively.

In a study in which cefazolin was administered to patients with varying degrees of renal dysfunction, patients with lower creatinine clearances generally bound cefazolin to plasma proteins to a lower extent than patients with higher creatinine clearance (105). Since there is a lower degree of protein binding in the patients with poor kidney function, this increase in the volume of distribution is expected.

In patients with renal impairment, the reported urinary recovery of cefazolin was less than that of normal patients. Patients with normal kidney function excreted 81.47 ± 6.80% of the dose in 24 hr, with almost 55% of the dose excreted in the first 6 hr (128). In patients with moderate impairment (creatinine clearance of 47–69 ml/min), 36% was excreted in the first 6 hr, with a total 24-hr cumulative excretion of 68.14 ± 6.08% of the original dose. In patients with severe renal impairment (creatinine clearance of 5–21 ml/min), 5.9% of the dose was excreted in the first 6 hr, with a total of 22.08 ± 14.13% of the dose excreted in 24 hr. Urinary concentrations remained relatively high in patients having normal kidney function and only moderate impairment; urinary concentrations of 698 ± 216 and 638 ± 245 μg/ml were reported for the first 6 hr, respectively. However, in patients with severe impairment, the urinary concentration was 58 ± 85 μg/ml in the first 6 hr.

In another study (109), levels in the urine somewhat higher than those previously reported (128) were found. In patients having normal kidney function, levels of 1.5 ± 0.2 mg/ml were attained in the first 4 hr. In patients having moderately impaired kidney function (creatinine clearance of 56–80 ml/min), levels of 1.9 ± 0.6 mg/ml were reached. In patients with severe kidney impairment, a mean value of 368 ± 199 μg/ml was attained. However, even in patients having severely impaired kidney function, the urinary concentrations were above the MIC for many organisms. Cefazolin is known to be an effective antibiotic for the treatment of urinary infections (129).

The effect of hemodialysis on the pharmacokinetics of cefazolin has been investigated (105, 109, 122, 128, 136). Four patients received 500 mg of cefazolin intramuscularly about 2 hr before undergoing hemodialysis (128). The half-life of cefazolin during dialysis was 9.3 ± 2.5 hr, which represents a 33% decrease in the half-life (39.14 ± 18.07 hr) between dialysis periods.

In another study (122), 1 g of cefazolin was injected intravenously before dialysis was started. Between dialyses, the serum cefazolin levels were 89.8 ± 28.5 μg/ml at 15 min after administration and 61.6 ± 25.3 μg/ml after 8 hr. The half-life was 32.7 ± 9.3 hr. During dialysis, the serum concentration of cefazolin was 84.3 ± 20.7 μg/ml at 15 min after administration and fell to 31.6 ± 6.0 μg/ml at 8 hr. The half-life was reduced to 6.9 ± 2.3 hr during the dialysis period. The hemodialysis extraction percentage was 23% (122).

During dialysis, little difference existed between the concentration of cefazolin in the arterial plasma and venous plasma (136). In one study where the effect of peritoneal dialysis was investigated (109), it

Table IV—Pharmacokinetic Parameters for Cefazolin Administered Intravenously (Literature Data)[a]

[a] Analysis of data using a two-compartment open model (Scheme I). [b] Literature values.

was found that this procedure had a less dramatic effect on decreasing the half-life of cefazolin. The half-life of the drug before the dialysis was not given, but the half-lives found after dialysis were 20.3 and 46 hr.

Use in Children and Infants—The use of cefazolin in pediatrics has been discussed (110, 124, 135, 137, 138). In one study (124) in which 25 mg/kg of cefazolin was injected into a neonate, peak levels of 35 μg/ml were attained in the serum. At the end of 12 hr, the serum level was 10.7 μg/ml. It was reported that 41.5% of the dose was excreted in the urine within the first 24 hr.

After a 6.25-mg/kg dose of cefazolin in children (ages not given), the concentration of cefazolin in the urine was 850 μg/ml (135). After a dose of 10.0–12.5 mg/kg, the concentration in the urine was 1425 μg/ml. Another study (137) found similar results with newborn babies; however, in premature infants, the 7-hr urinary recovery was 61.5% as compared to the 7-hr urinary recovery of 41.4% in newborn babies.

The concentration of cefazolin in the mothers' milk was reported to be very low (124, 275). The levels in the umbilical cord after an injection of 500 mg into the mother before delivery was between 5 and 7 μg/ml 15 min after injection (124). Levels in newborns were not reported.

Pharmacokinetic Considerations—All studies of the pharmacokinetics of cefazolin, except two (70, 139), were performed using a one-compartment open model. As can be seen in Fig. 4, the resultant plot appears to be biexponential and the two-compartment open model analysis (70, 139) appears to describe more appropriately the pharmacokinetics of this drug than do other published studies. Use of the two-compartment open model analysis of cephalosporin data was discussed in the section on cephalexin.

The pharmacokinetic parameters obtained when the literature data were analyzed using a two-compartment open model appear in Table IV. Other reported values (70, 139) also appear in this table for comparison.

The half-life of cefazolin when analyzed by a two-compartment open model is approximately 1.8 hr. This value is not significantly different from the reported values of 1.5 and 1.95 hr for cefazolin after intravenous and intramuscular administration, respectively.

Cefazolin, being over 80% bound at therapeutic concentrations, has a relatively small volume of distribution. The volume of the central compartment, found when literature data were analyzed using a two-compartment open model, was 4.4 liters. This value approximates the volume of the plasma water. In one report (70), the volume of distribution (15 liters) was found by using a constant-infusion one-compartment open model. This volume represents a Vd_{β} of a two-compartment open model, and its significance was discussed under *Cephalexin*.

A volume of distribution of 10 liters after an intravenous infusion was found by using Eq. 3 and is analogous to Vd_{β} (44). It is not significantly different from the term shown in Table IV.

The volume of distribution after intramuscular administration of cefazolin was approximately 12.2% of body weight (105); thus the volume of distribution would be 8.5 liters in a 70-kg human. This value was calculated by fitting the blood levels of cefazolin to a one-compartment open model. Therefore, the volume found in this analysis is analogous to the two-compartment Vd_{ext}. This number is not appreciably different from the two-compartment Vd_{ext} (Table IV).

A value of 13.2% of body weight was reported for

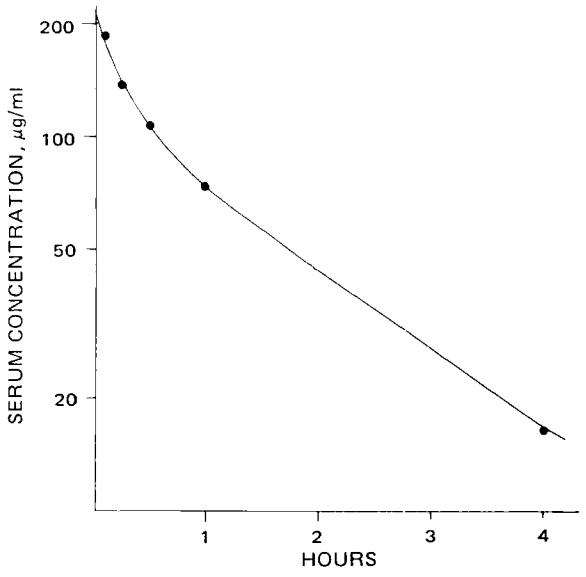

Figure 4—*Serum levels for cefazolin administered intravenously (rate constants for data generation from Table IV).*

the volume of distribution of cefazolin after intramuscular administration (128). The method used was to extrapolate the log-linear portion of the serum level curve to the y axis. The y intercept would erroneously be called $C_p{}^0$, and the volume of distribution is then dose/$C_p{}^0$. However, this intercept is actually $(C_p{}^0k_a)/(k_a - K)$, where K and k_a are the overall one-compartment open model elimination and absorption rate constants, respectively. Therefore, the value of this intercept was not correctly evaluated, and the volume obtained is incorrect.

The value for the renal clearance of cefazolin when analyzed by a two-compartment open model is 71.8 ml/min. This value is similar to the values reported with a one-compartment open model analysis. Reported values range from 61.5 to 81.8 ml/min (108, 113).

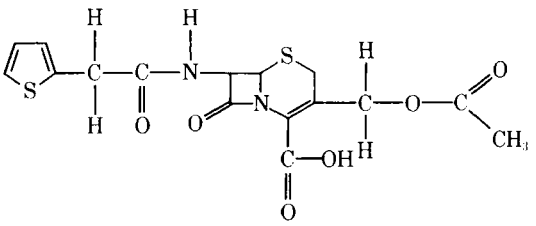
The normal dosage for patients with normal kidney function is 0.5–1.0 g every 12 hr (99). Since 12 hr is approximately six half-lives, over 98% of the drug has left the body. Since cefazolin has a wide therapeutic range and since accumulation does not take place due to the short half-life and long dosing interval, the use of one-compartment open model kinetics for this drug as well as for cephalexin will not seriously affect data analysis.

Cephalothin—Cephalothin, 3-(hydroxymethyl)-8-oxo-7- [2-(2-thienyl)acetamido]-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylate acetate (ester) (VI), is a semisynthetic cephalosporin and is available as the sodium salt for intravenous or intramuscular administration. The molecular weight of cephalothin sodium is 418.4. The synthesis of cephalothin has been discussed (139). It is moderately soluble in aqueous media, *i.e.*, up to 300 mg of cephalothin sodium may be dissolved in 1 ml of water. The pH of an aqueous solution of cephalothin sodium is 5.2; however, the activity of cephalothin is not altered by a variation of pH from 4 to 7.5 (153). It is active against both Gram-negative and Gram-positive bacteria, including such strains as *Diplococcus pneumoniae, S. aureus,* and *E. coli* (140).

In one study of the stability of cephalothin (141), the drug was stable for 12 days when stored at −15° in either serum or pH 6 phosphate buffer. When stored at 4°, 10% of the original activity was lost in 48 hr and 40% was lost by the end of the 12th day. When cephalothin was stored in serum at room temperature, only 13% of the original activity remained after 2 days. However, the drug in the phosphate buffer lost only 15% of its original activity after 12 days when stored at room temperature. Other studies of cephalothin stability have been reported (142, 143).

With the ultrafiltration technique, cephalothin was found to be 65% protein bound to human serum proteins (44, 105, 108, 144). In one study (141), cephalothin was about 60% less active against a test organism when in serum as compared to phosphate buffer.

Absorption—Cephalothin is not absorbed when administered orally (140). When 500 mg of cephalothin was administered orally, there was no detectable antibacterial activity in the serum between 1 and 4 hr (140). The recovery of cephalothin in the urine



VI: cephalothin

ranged from 4.3 to 11.3% of the administered dose. These results were confirmed in another study (145).

Cephalothin is well absorbed following intramuscular administration. After an intramuscular dose of 500 mg, peak levels of 6.3–8.0 μg/ml were attained. When the dose was increased to 1 g, peak levels of 15.0–20.0 μg/ml were attained (140, 141, 145–148). Peak levels were obtained approximately 0.5–1 hr after administration. When probenecid was administered concurrently with intramuscular cephalothin, peak levels of 20.2 and 33.0 μg/ml were attained after 500-mg and 1.0-g doses, respectively.

Peak levels after intravenous administration of 1 g of cephalothin as a single intravenous dose ranged from 30 to 60 μg/ml at 15 min after injection (149–153). After an intravenous infusion of 1 g over 15 min, levels of 10.22 μg/ml were attained (149). When cephalothin was administered intraperitoneally, a serum level of 4.45 μg/ml was attained 1 hr after dosing (149).

Sheng *et al.* (160) studied the serum concentrations of cephalothin after intramuscular administration of 12.5 mg/kg to infants and children. In newborn infants (1.5 hr–8 days old), peak levels of 25 μg/ml were attained 30 min after injection. In older infants and children, levels of 14.72 μg/ml were attained 0.5 hr after injection.

Distribution—When cephalothin was administered on a dosage schedule of 2 g every 4 hr intramuscularly, the levels of cephalothin were high in the heart, liver, and kidneys. A concentration of 640 μg/ml was found in the heart blood, with a corresponding level of 201 μg/g of tissue in the myocardium of the heart (153). The level of the drug in the kidneys was 548 μg/g of tissue in the renal cortex, and it was 63 μg/g of tissue in the liver (153). Brain cortex levels were reported to be 11 μg/g of tissue.

In a study of the penetration of cephalothin into the spinal fluid, levels of 0.16 and 0.31 μg/ml were attained at 30–60 min after an intravenous injection of 2 g to patients with meningitis or nervous system inflammation (155). In patients not having meningitis, the concentrations of cephalothin were below the limits of the assay (0.16 μg/ml) and could not be detected. A spinal fluid level of 11.7 μg/ml (serum concentration of 15.9 μg/ml) was found 2 hr after administration of 1 g intramuscularly (140).

At 1 hr after injection of 1 g of cephalothin intravenously, the level of cephalothin in pleural fluid was 70.6 μg/ml; at 2 hr, the level was 40.8 μg/ml (140). A level of 12.6 μg/ml in synovial fluid 20 min after injection of 1 g of cephalothin intravenously also was reported (150). Distribution of the drug into the

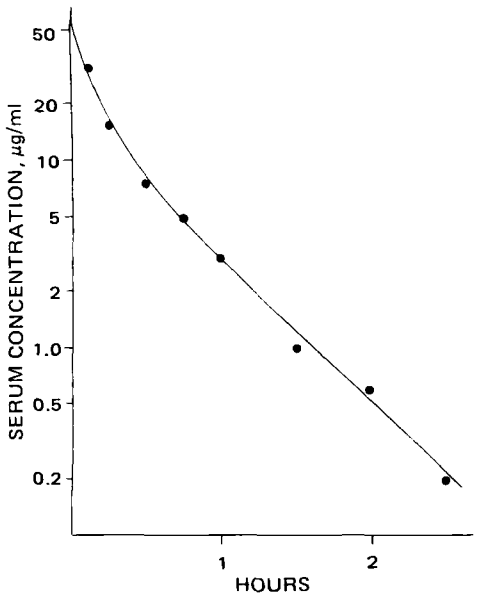


Figure 5—*Serum levels for cephalothin administered intravenously (rate constants for data generation from Table V).*

aqueous humor of the eye was reported (152). In this study, 1 g of cephalothin was administered intravenously and an aqueous humor level of 0.48 μg/ml 0.5 hr after administration was found. Ascitic fluid levels of 2.6–4.0 μg/ml after intravenous administration of 1 g of cephalothin were reported (149).

Many studies have appeared concerning the placental transfer of cephalothin (156–160, 275). Cephalothin is transferred rapidly from the maternal blood supply to the fetus (156, 157, 275). Concentrations of 30.2 and 12.5 μg/ml were found in the mother and fetus after an intravenous injection of cephalothin (156). The drug appeared in the amniotic fluid within 15 min after administration. The concentration of cephalothin in the mother's milk was reported to be very low (275).

Metabolism—Cephalothin is rapidly metabolized in the body to desacetylcephalothin. The site of the desacetylation of cephalothin is speculated to be within the liver and kidneys (161). It is possible to separate the unchanged drug from its metabolite by use of chromatographic techniques (162). One study found that 33% of the recovered urinary antibiotic activity is due to the metabolite (161).

Wick (163) studied the antibacterial activity of desacetylcephalothin against various strains of bacteria. He found that while the metabolite was active against many forms of bacteria, it was less effective than the unchanged drug. The levels of the metabolite in the urine of mice were almost twice those of the unchanged drug.

The time course of desacetylcephalothin appearance was studied in a patient with chronic renal failure after a 1-g iv dose (42). Appreciable metabolite production did not occur until approximately 2 hr after dosing. A differential microbiological assay was apparently used, but the procedure was not discussed in detail. Examination of the data indicates that the metabolite was assayed in the presence of greater than 100 times the concentration of the parent compound. Due to the lack of experimental detail and the technical difficulties of such an analysis, it is not possible to assess the meaning of these findings.

Excretion—The biliary excretion of cephalothin was studied in humans by injecting 1 g of cephalothin intravenously and collecting bile and serum (164). The peak levels of cephalothin in the bile ranged from 0.4 to 42.0 μg/ml. The time of the peak concentration was between 1 and 3 hr. In the first 3 hr after administration, the levels in the bile were generally above 1 μg/ml. In duodenal juice collected by intubation from patients with normal kidney function, the levels of cephalothin ranged from 4.6 to 6.5 μg/ml. In patients with renal insufficiency, the levels in duodenal juice were slightly elevated, with maximum levels between 10 and 16 μg/ml. This increase in biliary levels was due to the elevated serum concentration attributed to poor kidney function. Therapeutic levels were found in only 2.4% of the subjects in one study (276).

The half-life of cephalothin in patients with normal kidney function was reported to be between 0.47 and 0.85 hr (44, 105, 108, 141, 165–167). After an intramuscular dose of 1 g, levels of 800 and 2500 μg/ml were found in the urine (48, 140, 145, 168).

Cephalothin is excreted through the processes of tubular secretion and glomerular filtration, as is apparent by the increase in plasma levels after the coadministration of probenecid (140, 146). Serum levels of 33.0 μg/ml, almost double those in individuals not given probenecid, were reported after administration of 1.0 g of cephalothin and probenecid (140). The reported renal clearance was 274 ml/min, and the total body clearance of cephalothin was 472 ml/min (108). Therefore, 58% was removed from the body by renal processes. The rest was removed by metabolism.

Since cephalothin is metabolized *in vivo*, the total recovery of unchanged drug does not equal the amount of administered drug. In one study (131), approximately 52% of the initial dose was recovered in the urine after 24 hr; other recoveries ranged from 50 to 70% (140, 141).

The half-life of cephalothin is increased in patients with impaired renal function (169). The half-life of cephalothin increased to 18 hr in patients with creatinine clearance less than 5 ml/min (165). The half-life of cephalothin increased from 0.5 hr in a normal patient to 2.9 hr in a patient with a creatinine clearance of 5 ml/min (166). The serum half-life of cephalothin only increased moderately even in a patient with severe kidney dysfunction (103). In another study (42), a uremic patient was given 1 g of cephalothin intravenously. The half-life of cephalothin was about 2 hr. The levels of the metabolite, desacetylcephalothin, increased over the first 12 hr and then declined, with the half-life of the metabolite being about 8 hr.

Cephalothin is removed from the body during both hemodialysis and peritoneal dialysis (148, 170). The half-life of cephalothin was reported to be 3.3 hr during dialysis (170). The half-life of cephalothin during the nondialysis periods was not given. Perkins *et al.* (148) found that 24% of cephalothin was removed

Table V—"Apparent" Pharmacokinetic Parameters for Cephalothin Administered Intravenously (Literature Data)[a]

[a] Analysis of data using a two-compartment open model (Scheme I). [b] Literature values.

from the body during peritoneal dialysis.

Pharmacokinetic Considerations—If the serum levels of cephalothin after intravenous administration are plotted on a semilogarithmic axis (Fig. 5), the resultant plot appears to be biexponential. However, since cephalothin is metabolized, it is possible that the two-compartment open model is not appropriate and the kinetics should be described by a model with a provision for a saturable metabolic process.

A complicating factor in the analysis of cephalothin is that the reported serum concentrations of the drug do not represent actual concentrations of cephalothin but the total combined antibiotic activities of cephalothin and desacetylcephalothin. In addition, the standard curves used in microbiological analysis are constructed using pure drug and a particular microorganism. The sensitivity of these microorganisms to the parent compound and the metabolite are dissimilar.

As drug blood levels decline, a change in the proportion of free drug to metabolite occurs as a function of time. The measured zone sizes, therefore, do not represent a simple log-linear relationship with concentration since the sensitivity of the microorganism to the combined "antimicrobial agents" is apparently changing as a consequence of an altered parent compound to metabolite ratio. In addition, if one uses a different microorganism with different sensitivity to these drugs, one would expect the assay results to yield somewhat altered "apparent concentrations."

It is, therefore, not possible to analyze the published data pharmacokinetically, since the calculated rate constants are artifactual. Since this drug is widely used and considerable blood level data have been published and widely quoted, a two-compartment open model analysis of literature data is provided in Table V for the sake of completeness and comparison. These data should not be interpreted to represent actual pharmacokinetic parameters.

Cephaloridine—Cephaloridine, 1-[[2-carboxy-8-oxo-7-[2-(2-thienyl)acetamido]-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl]methyl]pyridinium hydroxide inner salt (VII), has a qualitative spectrum of antibacterial activity almost identical to that described for cephalothin, although there are differences in the degree of activity against specific bacterial genera (103, 116, 144, 167, 171–182).

When the acetoxy group of cephalothin is replaced with pyridine, the resulting compound, cephaloridine, is more stable both *in vitro* and *in vivo* (77, 142, 143, 183, 184).

Cephaloridine was reported to be 15% (79) and 8–31% (185) protein bound in human serum. Other reports give protein binding values within this range; however, most values appear to be less than 20% (42, 167, 186).

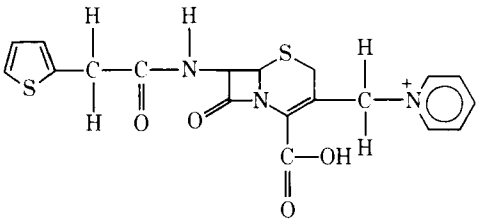
Absorption—Cephaloridine is readily absorbed after intramuscular injection and poorly absorbed from the GI tract (86, 173). A 250-mg intramuscular dose gave a peak serum concentration of about 15 μg/ml (103, 187), while 500-mg and 1-g doses gave peak blood levels of approximately 30 and 40 μg/ml, respectively (103, 188). Slightly lower levels also were reported (48, 108, 116, 126, 173, 179, 186, 189).

After intramuscular administration to children 2 months to 14 years of age, peak serum concentrations (approximately 45 min after administration) were 7, 16, and 32 μg/ml after a 50-, 100-, and 200-mg/kg dose, respectively (190). Similar results were reported in another study (275).

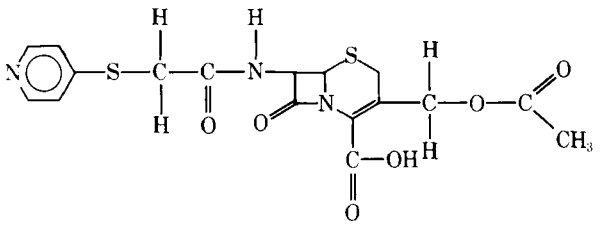
Distribution—Biliary excretion was found to be a minor pathway of elimination. A biliary concentration of 10 μg/ml was found when the serum concentration was 24 μg/ml (189, 191).

Cephaloridine concentrations in the spinal fluid of patients with uninfected meninges were 6–12% of those in the blood and serum (188, 189, 192, 193). However, poor penetration of the drug into the cerebrospinal fluid was reported (194).

Cephaloridine concentrations of about 12 μg/ml were found in fresh wounds 1 hr after a 15-mg/kg intravenous dose (185). The antibiotic levels decreased as the wound age increased.



VII: cephaloridine



VIII: cephapirin

Cephaloridine was found to diffuse into peritoneal and pleural fluids (193, 195). The drug distributed well into the liver, spleen, stomach wall, and lung but was found in a much smaller amount in the cerebral cortex (189).

Cephaloridine injected subconjunctivally was found to penetrate aqueous humor and subretinal fluid effectively (196, 197). Low but effective subretinal levels were reported (198).

Records (199) was unable to detect antibacterial activity in the aqueous humor after a 1-g dose of cephaloridine. However, levels of 7–28 μg/ml were found in the secondary aqueous humor which refills the eye following aspiration of the primary fluid.

Prakash *et al.* (200) injected 1 g of cephaloridine intramuscularly every 12 hr for two doses to 60 women undergoing amniotomy for induction of labor to study the absorption and transfer of the antibiotic to the fetus as protection against intrapartum infections. The drug provided inhibitory concentrations in maternal serum, amniotic fluid, and umbilical cord blood. Similar results were found in another study (275).

Metabolism and Excretion—Urine specimens, both animal and human, which were examined by chromatographic and bioautographic techniques, showed that no other microbiologically active metabolites were present and that cephaloridine was excreted unchanged in the urine (183, 201).

Renal excretion of this drug is considered to be largely the result of glomerular filtration, but a 1.2-fold increase in cephaloridine serum concentration was found after probenecid administration (173, 179, 202, 203) and appears to indicate some tubular secretion. Excretion was found to be pH dependent, *i.e.*, increasing with decreasing pH (277).

Kidney disease resulting in impaired kidney function results in increased serum half-lives up to 23 hr (54, 105, 167, 189, 192, 203–207). The relationship between renal function and biological half-life was discussed (192).

Hemodialysis reduced the serum half-life in uremic patients to 3–5 hr (105, 167, 189, 204). An extraction ratio of 0.23–0.35 was reported (148, 192). Peritoneal dialysis resulted in a daily loss of 125–500 mg of drug from the body.

Urinary concentrations of 150 μg/ml or greater after a 0.5- or 1-g dose were maintained in all but anuric patients (192).

Urinary recovery after intramuscular and intravenous dosing was 60–80% (44, 116, 126, 172, 173, 179, 186, 187). Several investigations found 85% of a 500-mg dose in the urine (44, 105, 108).

Renal clearances were reported to be 146–280 ml/min (108, 173). A plasma clearance of 167 ml/min/1.73 m^2 and a renal clearance of 125 ml/min/1.73 m^2 were reported, indicating that approximately 75% of the drug was removed from the body by the kidneys (44, 108).

A serum half-life of approximately 1.1–1.5 hr was reported for cephaloridine (108, 126, 166, 167, 192, 205); however, a value of 48 min also was found (173). The volume of distribution was 16 liters (108).

Pharmacokinetic Considerations—Extensive pharmacokinetic analysis of literature data is not possible for this drug, since appropriate intravenous data have not been published. Most studies performed with cephaloridine involved intramuscular administration and were not designed for pharmacokinetic analysis. This drug is primarily administered *via* the intramuscular route.

Since its physicochemical properties are not significantly different from the other cephalosporins, the pharmacokinetics of this drug should be similar to those of the other cephalosporins; *i.e.*, its time course in the body is biexponential. Like the other cephalosporins, its half-life (1 hr) is short in relation to the normal dosing interval (6 hr), so the pharmacokinetics of this drug can be described adequately by a one-compartment open model.

Cephapirin—Cephapirin, 3-(hydroxymethyl)-8-oxo-7-[2-(4-pyridylthio)acetamido]-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylate acetate (ester) (VIII), is a semisynthetic cephalosporin for parenteral use. It is derived from 7-aminocephalosporanic acid. Cephapirin has a spectrum of antimicrobial activity similar to that of cephalothin (208). Cephapirin is effective against Gram-positive bacteria. Except for two strains of *Staphylococcus epidermidis* and *S. aureus*, cephapirin is effective at concentrations of 3.1 μg/ml or less against all susceptible strains of Gram-positive bacteria. Gram-negative bacteria were found to be less sensitive to the effects of the drug (208).

The sodium salt of cephapirin is extremely soluble in water; at 25°, the solubility is greater than 500 mg/ml (209). The pH of a reconstituted solution of cephapirin (sodium salt) is between 5.7 and 7.3 (209). Cephapirin is stable at 25° when reconstituted in most commonly used parenteral solutions. When reconstituted in sterile water, only 6% of the initial activity of the drug is lost in a 24-hr period. A complete study of the stability of cephapirin has been published (209).

Cephapirin is 44–50% bound to human plasma proteins (210). The addition of cephapirin to serum had little effect in lowering the MIC of this drug to *S. aureus* (208).

Absorption—Since cephapirin is not absorbed orally, it is only administered through the intramuscular and intravenous routes. Cephapirin seems to be relatively well absorbed after intramuscular injection. In one study in which 1 g of cephapirin was administered intramuscularly, peak levels in the serum of 24.2 μg/ml were attained at 0.5 hr after injection (211). Peak levels of cephapirin after intramuscular

administration of 0.5- and 1.0-g doses were 8 and 15 μg/ml, respectively (210). Peak levels were attained between 0.5 and 1 hr after administration.

After intravenous administration, a level of 72.6 μg/ml was reported at 0.5 hr after injection (211). These levels fell to 6.06 μg/ml at 1 hr after administration. Another study (210) found much lower levels after intravenous administration of 1.0 g of cephapirin. A peak level of about 15 μg/ml was attained.

Excretion and Metabolism—Cephapirin is metabolized to desacetylcephapirin *in vivo* (212). Approximately 41% of the recovered antibiotic is in the desacetylcephapirin form. Desacetylcephapirin was approximately 54% as potent as the unchanged drug against *S. lutea* (212).

Cephapirin is eliminated from the body largely through renal processes. Less than 1% of the original dose was recovered in the bile (210).

After an intravenous dose of 1 g, urinary levels of 2560 ± 503 μg/ml were found. Recoveries after 1-g intravenous and intramuscular doses were 72 ± 7.5 and 54 ± 18.6%, respectively (211).

The reported half-lives of cephapirin after intravenous and intramuscular administrations to normal volunteers were 21 and 47 min, respectively (211).

Since the elimination of cephapirin is largely due to renal excretion, the half-life of cephapirin is extended in patients with renal dysfunction. A study using azotemic patients found that the serum half-life of cephapirin was 95.9 min (212). These patients were not undergoing any form of dialysis treatment during the study. The average creatinine clearance was 12.6 ml/min. These patients excreted 19.5% of the initial dose in the urine.

The effect of dialysis on the half-life of cephapirin was studied, and the half-life in patients undergoing dialysis was about 107 min (212). Dialysis removed 22.8% of the dose.

A review of the use of cephapirin in children was prepared (213). Intramuscular injections of 20 mg/kg produced peak levels of 14.5 μg/ml, and injections of 12.5 mg/kg produced peak levels of 7.6 μg/ml. The antibiotic concentration in the urine after an intramuscular dose of 20.0 mg/kg was 1600 μg/ml. This recovery was 53% of the initial dose.

Pharmacokinetic Considerations—A very limited number of studies report serum levels of cephapirin (211, 214). Due to the paucity of information, plus the fact that the drug is metabolized and assayed microbiologically, it is difficult to discuss the pharmacokinetics of cephapirin. Only one study (211) described the pharmacokinetics of this drug. The reported half-life was 21 min after intravenous injection. This value was probably calculated by a log-linear regression using all points. Graphical estimation of the terminal portion of the curve, however, results in a half-life of approximately 42 min.

These data (211) are shown in Fig. 6. It can be seen that the curve appears to be biexponential. For the sake of completeness, the data were fitted to a two-compartment open model (Table VI). The half-life of the β-phase is about 45 min, almost twice that reported but identical to that obtained from the terminal portion of Fig. 6. The rate constants in Table VI should be considered to be apparent due to the fact that the drug is metabolized to a less active compound and assayed *via* a microbiological procedure. A more detailed discussion appears in the *Cephalothin* section.

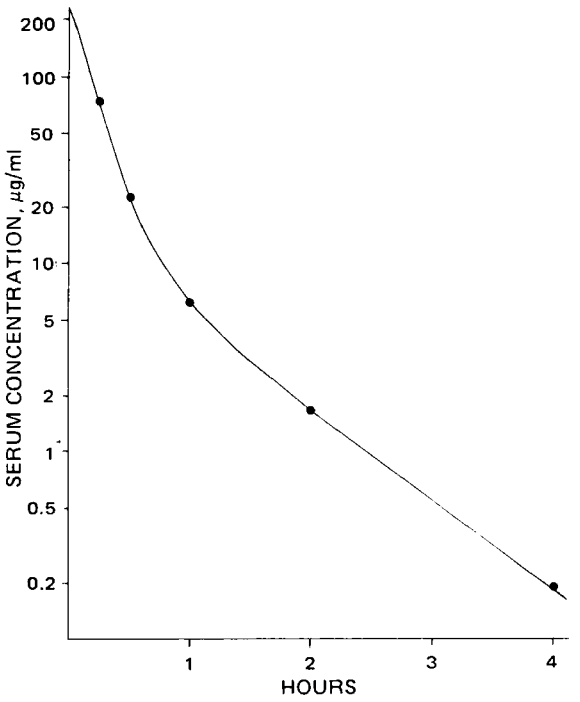


Figure 6—*Serum levels for cephapirin administered intravenously (rate constants for data generation from Table VI).*

Cephacetrile—Cephacetrile, 7-(2-cyanoacetamido) - 3 -(hydroxymethyl)-8-oxo-5-thia-1-azabicyclo-[4.2.0]oct-2-ene-2-carboxylate acetate (ester) (IX), is a bactericidal drug whose mode of action is similar to the β-lactam antibiotics (215). It is less active than cephaloridine against penicillin-susceptible strains of *S. aureus* but is more active than cephaloridine or cephalexin against β-lactamase-producing strains. Cephalothin is more active in this regard than cephacetrile. Cephacetrile was reported to be relatively stable to β-lactamase degradation (180). It is also less active than cephaloridine and more active than ceph-

alothin against certain Gram-negative organisms (215). Similar results were reported in other studies (216–219). Cephacetrile was 33–36% bound to serum (215, 220). A binding range of 23–34% also was reported (221). Metabolism of the drug appears to be negligible based on chromatographic work (215, 220). It also appears to be less nephrotoxic than cephaloridine (222–224).

Absorption—Cephacetrile is absorbed after intramuscular injection. In one study, peak serum concentrations of 22.7 μg/ml were achieved 1 hr after administration of a 1-g dose and declined to an average of 1.65 μg/ml 4 hr after dosing (225). Similar results were reported (226), but some lower peak levels also have been found (221, 227, 228). Peak levels of 17.1 μg/ml at 30 min after injection were reported (229).

Dvoracek *et al.* (228) used a one-compartment open model to fit their data and found an intramuscular absorption half-life of 0.3 hr. This value was one-fifth the elimination half-life of 1.4 hr. This drug apparently is rapidly absorbed without a significant lag time (221, 228). Patients with decreased renal function exhibited prolonged peak times (229).

Distribution—Distribution to duodenal juice was low after a 1-g intramuscular injection (227). The maximal concentrations ranged from 1.0 to 3.1 μg/ml and were attained at the 1st and 2nd hr after administration. Higher levels (2.9–7.0 μg/ml) were reported in patients with renal failure (227).

Cephacetrile was administered to healthy pregnant women during labor by intravenous infusion and multiple bolus dosing (230). Maternal serum and amniotic fluid concentrations were determined as a function of time, and cord serum concentrations were determined after delivery. In the maternal serum, a mean steady state of 30 μg/ml was obtained. Cord serum and amniotic fluid concentrations reached 14 and 8–9 μg/ml, respectively, after intravenous administration and 19 and 22–25 μg/ml, respectively, after intramuscular administration. Maurice *et al.* (221) reported cerebrospinal fluid, fetal cord, amniotic fluid, bone, and prostatic tissue levels.

Excretion—Peak bile levels were observed between 1 and 4 hr after a 1-g intramuscular dose of the drug in cholecystectomized subjects (227, 231). The biliary concentration was low, with the peak concentration ranging from 1.0 to 6.8 μg/ml. In normal patients, the 1-hr peak concentrations were 14.7–19.4 μg/ml (227, 231).

Cephacetrile was reported to be 60–100% excreted in the urine (215, 220–222, 225, 226, 228, 229, 232–234).

The renal and plasma clearances of this drug were found to be approximately 230–240 ml/min (228). A plasma and renal clearance of 361 ml/min/1.73 m^2 was reported (226), which is further evidence that the drug is not significantly metabolized (228, 233, 235).

The serum half-life was reported to range between 0.5 and 1.5 hr (215, 220, 221, 226, 227, 229, 235, 236).

The pharmacokinetics of this drug were analyzed using a two-compartment open model (228). A β-phase half-life of 1.2 hr was found after intravenous injection. The rate constants are shown in Table VII. The intramuscular data were analyzed *via* a one-compartment open model, and a half-life of 1.4 hr was found.

Altered renal function was accompanied by a drop in the urinary elimination of the drug (219, 221, 222, 226–228, 231, 233–235, 237). In patients with renal failure, the serum concentrations of the antibiotic rose significantly (40.6 ± 8.1 μg/ml) 1 hr after injection (227). An increase in the half-life from 2.2 to 30 hr was noted (221, 226, 227, 229, 231, 233–238), depending on the severity of the renal function.

The relationships between renal function and the drug's half-life of elimination from the body have been studied (221, 231, 233–237, 239). Suggested doses in the case of renal insufficiency have been recommended (221, 229, 234, 240).

Hemodialysis in one study reduced the serum half-life by a factor of eight, with a mean extraction ratio of 32% (236). Fillastre *et al.* (229) found a twofold de-

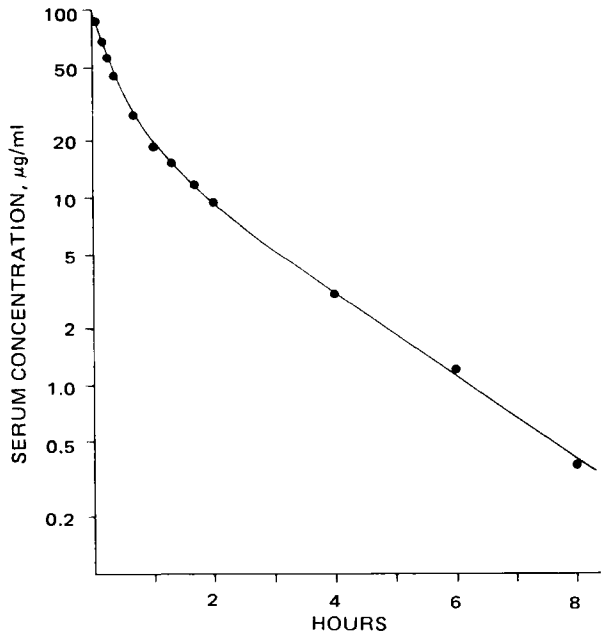

Figure 7—*Serum levels for cephacetrile administered intravenously (rate constants for data generation from Table VII).*

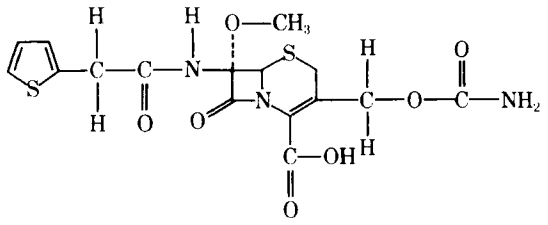
crease in serum levels compared to controls, with an extraction percentage of 27–33%. Similar results also were reported (226).

Evidence was presented that cephacetrile is actively secreted by the kidney and that probenecid can compete for the secretory route (233).

Pharmacokinetic Considerations—As with other cephalosporins, cephacetrile appears to follow two-compartment open model kinetics (Fig. 7). Investigators, with one exception (228), analyzed their data *via* a one-compartment open model. Shown in Table VII are the pharmacokinetic parameters obtained by analyzing literature data according to a two-compartment open model (220, 221, 228, 232, 236, 241). The analysis by Dvoracek *et al.* (228) is included for comparison and is similar to the other studies shown in Table VII. The half-life of the β-phase is within the range of reported values. Dvoracek *et al.* (228) reported a value of 9542 ml as the volume of the tissue compartment. The sum of $V_c + V_t$ is Vd_{ss} and is equal to 18,763 ml, in agreement with the Vd_{ss} values calculated using data from other studies (Table VII). The only other volume of distribution term reported was 0.3–0.5 liter/kg or 21,000–35,000 ml (221). The method of calculation was not clear, but the graphical data suggest that the reported value was actually Vd_{ext}.

In spite of the good fits of cephacetrile data using a two-compartment open model, little practical advantage is gained with this type of analysis for the reasons stated in the *Cephalexin* section.

Cefoxitin—Cefoxitin, 3-(hydroxymethyl)-7-methoxy-8-oxo-7-[2-(2-thienyl)acetamido]-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid carbamate (ester) (X), is a semisynthetic cephamycin antibiotic (243). The 7-methoxylated cephalosporins possess marked resistance to the action of β-lactamases from Gram-positive and Gram-negative organisms (244). Of the Gram-negative microorganisms generally susceptible to cephalothin, *i.e.*, *E. coli*, *P. mirabilis*, and *Klebsiella*, cefoxitin was significantly more active than cephalothin (243, 245). The Gram-positive microorganisms, on the other hand, were less susceptible to cefoxitin than to cephalothin (243, 245).



X: cefoxitin

Cefoxitin does not appear to be orally absorbed; however, the drug appears rapidly in the blood after intramuscular injection (246). After 0.5- and 1.0-g doses, approximately 90% was recovered in the urine. After a 2-g iv dose, 99% was recovered in the urine, indicating that no extrarenal excretion occurred. Probenecid was found to affect the elimination of cefoxitin in mice (245), suggesting that this drug is eliminated *via* glomerular filtration as well as tubular secretion. This finding was also reported in humans (247). The drug was also found to be widely distributed in soft tissue (245).

The biological half-life of cefoxitin was calculated to be 45 min (246) compared to 25 min for cephalothin. The serum concentration *versus* time curve (Fig. 8) for this drug, as well as other cephalosporins, appears to exhibit biphasic decay. Analysis of the data of Kosmidis *et al.* (246) *via* a two-compartment open model analysis is shown in Table VIII. Since a paucity of published data exists concerning this antibiotic, it is not possible to draw further conclusions relative to its pharmacokinetic characteristics. The main advantage of this drug seems to be its resistance to degradation by β-lactamases.

Cephanone—Cephanone, 3-(5-methyl-1,3,4-thiadiazol-2-ylthiomethyl)-7-[2-(3-sydnone)acetamido]-

[a] Analysis of data using a two-compartment open model (Scheme I).

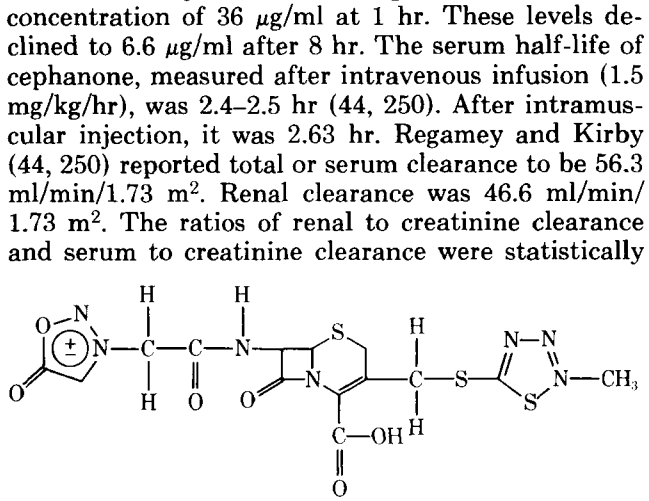
3-cephem-4-carboxylic acid (XI), is a semisynthetic cephalosporin derivative with an antibacterial spectrum similar to that of cephalothin (44, 248, 249). This drug was withdrawn from clinical trials due to suspected carcinogenicity, but it is included in this review for the sake of completeness. The drug is 86–88% protein bound (44, 250) and is relatively stable to β-lactamase degradation (180).

The average drug concentration in serum 0.5 hr after intramuscular administration of 1 g of cephanone was reported to be 38 μg/ml (249). Peak concentrations were attained at 1 hr. After 6 hr, the blood level declined to 22.1 μg/ml; after 12 hr, the blood level was still relatively high: 5.3 μg/ml. This level exceeds the MIC for most susceptible organisms (249). The half-life was 174 min; however, after intravenous administration, the half-life was 126 min, indicating that intramuscular administration does not provide, as with cefazolin and cephalexin, a pure elimination phase. After a 1-g iv injection, the blood levels ranged from 81.2 to 8 μg/ml after 8 hr. At 12 hr postadministration, drug levels were not detectable (249).

Regamey and Kirby (250), however, found higher blood levels after both intramuscular and intravenous injections. After intravenous administration of 250 mg of cephanone, a peak serum concentration of 31.9 μg/ml was present at the end of the 1st hr. An intramuscular injection of 500 mg resulted in a peak concentration of 36 μg/ml at 1 hr. These levels declined to 6.6 μg/ml after 8 hr. The serum half-life of cephanone, measured after intravenous infusion (1.5 mg/kg/hr), was 2.4–2.5 hr (44, 250). After intramuscular injection, it was 2.63 hr. Regamey and Kirby (44, 250) reported total or serum clearance to be 56.3 ml/min/1.73 m^2. Renal clearance was 46.6 ml/min/1.73 m^2. The ratios of renal to creatinine clearance and serum to creatinine clearance were statistically



XI: cephanone

identical, *i.e.*, 0.40–0.47. These ratios suggest that cephanone leaves the body chiefly through the kidneys.

The volume of distribution was reported to be 12 liters/1.73 m^2 (44) and 13.6 liters (250). These values were obtained after constant infusion and are analogous to the Vd_β of a two-compartment open model analysis.

Urinary excretion of cephanone appears to be high; however, variable results were reported (249). During a 24-hr period, all of a 1-g intravenous dose was excreted, but only 38% was found in the urine after a 500-mg injection. Intramuscular injection resulted in 50% of the administered (1-g) dose being excreted in the urine. Urinary drug concentrations were high. After administration of 1 g intramuscularly or intravenously, urine concentrations were 1.7 and 5.0 mg/ml, respectively, after 8 hr.

Regamey and Kirby (250) found 92% of a 500-mg im dose excreted in the urine. Similar results were obtained after intravenous infusion. Urine concentrations of cephanone were 900, 200, and 20 μg/ml in collections 0–4, 4–8, and 8–24 hr after administration, respectively.

After intravenous administration, the decline in cephanone serum levels appears to be biexponential (Fig. 9). It was possible to fit these data using a two-compartment open model analysis (Table IX). It can be seen that the half-life of the β-phase is in reasonable agreement with the literature using a one-compartment open model analysis. The volume of distribution terms are relatively low, probably due to the high degree (86–88%) of protein binding. This partially contributes to the relatively high blood levels seen with this drug. The large degree of protein binding probably results in the high and prolonged serum levels of cephanone.

Cefamandole—Cefamandole, 7-D-mandelamido-3-[[(1-methyl-1*H*-tetrazol-5-yl)thio]methyl]-8-oxo-5-thio-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid (XII), is a semisynthetic cephalosporin intended for parenteral use. The sodium salt has a molecular weight of 484.5. The spectrum of antibacterial activity is similar to that of other cephalosporins (251).

Since cefamandole is one of the newest cephalosporins, no pharmacokinetic studies have appeared.

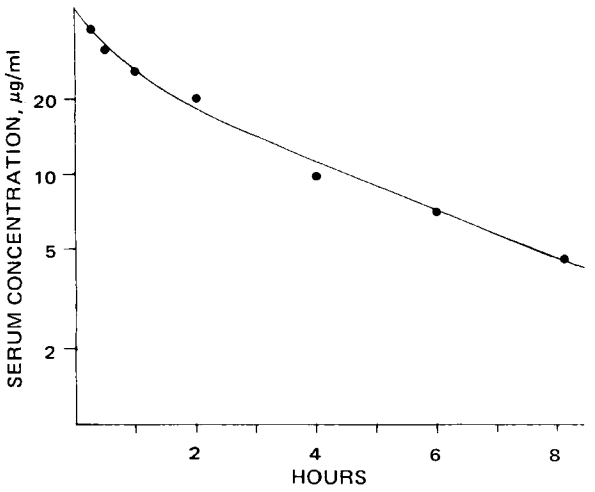


Figure 9—*Serum levels for cephanone administered intravenously (rate constants for data generation from Table IX).*

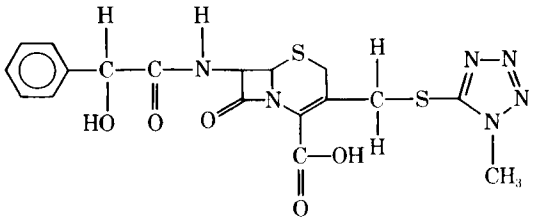
CLINICAL USE

Appropriate antibiotic usage requires an accurate knowledge of the antimicrobial susceptibility pattern of the drug to be given, sound clinical reasoning as to why the drug is being given, and knowledge of whether it will reach the site of the pathogen in adequate concentrations without producing serious side effects. This portion of the review is an attempt to provide an overview of the appropriate clinical use of cephalosporin antibiotics from the standpoint of an infectious disease physician.

General Considerations for Cephalosporin Administration—Cephalosporins are usually effective for infection from Gram-positive bacteria such as staphylococci (*S. aureus* and *S. epidermidis*), group A *Streptococcus*, anaerobic streptococci, and *Streptococcus pneumoniae* ("pneumococcus") and from Gram-negative organisms such as *E. coli*, *P. mirabilis*, *Hemophilus* species, and *K. pneumoniae*. However, once one of these bacteria has been identified as the causative organism of an infectious disease process, usually other antibiotic agents are preferable, either because of a greater degree of microbiological activity or because of a smaller likelihood of producing a suprainfection. For instance, the antibiotic of choice for group A *Streptococcus*, the "pneumococcus," nonpenicillinase-producing staphylococci, and anaerobic streptococci is penicillin G; ampicillin is the preferred antibiotic for *Hemophilus* infection and often has equal or greater activity toward *E. coli* and *P. mirabilis*; and oxacillin is a more logical choice for penicillinase-producing *S. aureus*. Cephalosporins have a greater degree of activity against *S. epidermidis* (about 80–85% sensitive to oxacillin, almost all sensitive to cephalosporins); but if a strain is sensitive to oxacillin, it is a better drug to give because of its narrower spectrum as compared to a cephalosporin.



XII: cefamandole

It is only with respect to *Klebsiella* that cephalosporins are clearly more active than ampicillin, penicillin G, or oxacillin. Although more strains of *Klebsiella* are sensitive to aminoglycosides, such as gentamicin and kanamycin, one usually prefers a cephalosporin in a situation where an isolate is sensitive to both classes of antibiotics due to the greater potential toxicity of the aminoglycosides.

The enterococci, indole-positive *Proteus*, *Enterobacter* species, *Serratia*, *Pseudomonas*, *Herellea*, and *Citrobacter* are usually resistant to cephalosporins.

The cephalosporin popularity stems mainly from their reasonably broad antimicrobial coverage, their relatively low incidence of serious adverse drug reactions, the small frequency of cross-reaction in patients with a history of penicillin hypersensitivity, and their common usage to prevent the development of infection following surgical procedures involving the insertion of prosthetic devices such as vascular grafts, artificial heart valves, and orthopedic hardware.

Appropriate Use of Cephalosporins by Parenteral Route—*Prevention of Infection on Prosthetic Devices*—Few subjects create more lively debate than the use of antibiotics for prophylactic purposes. As seen by Jawetz (252), there is no place for prophylactic antibiotics unless the prophylaxis is directed against one particular or small group of microorganisms.

All other attempts at more general prophylaxis with antibiotics usually have been unsuccessful. Chemoprophylaxis has never proven significant in reducing the likelihood of a patient developing an infection in clinical situations where multiple organisms may invade, as is the case in most GI surgical procedures, pancreatitis, or the insertion of an in-dwelling bladder catheter. In fact, general prophylaxis has often been detrimental by favoring colonization and infection by microbes resistant to the antibiotic given. Since most compromised hosts, such as patients with leukemia or lymphoma, develop infection from organisms on their skin or from their genitourinary tract, and since it is impossible to sterilize the entire patient, antibiotic prophylaxis has also been of no value in these cases.

In view of these comments, it would be logical to administer a cephalosporin antibiotic only in clinical situations where one can predict the likely pathogen with a high degree of certainty and the particular pathogen is easily eradicated by this type of antibiotic. The administration of a cephalosporin to prevent infection following the insertion of artificial material (*e.g.*, prosthetic heart valves, Dacron or Teflon artificial grafts, and orthopedic hardware) follows this dictum, since after the placement of these foreign bodies about 90% of the infections develop from a single group of organisms, namely staphylococci, either coagulase negative (*S. epidermidis*) or coagulase pos-

itive (*S. aureus*). As already mentioned, cephalosporin antibiotics are usually active against all types of staphylococci whereas the isoxazole antibiotics, such as oxacillin, are usually ineffective against 15–20% of coagulase-negative staphylococci. Because of this situation, cephalosporins have emerged as the most appropriate agents to use in the prevention of infections on prosthetic material.

Some clinical situations represent "gray zones" in prophylactic antibiotic usage because more than one organism, but usually not more than five, may produce the infection. An open comminuted fracture represents a situation where infection commonly occurs from a relatively small number of microbes. Traumatic wound infections above the waist are often from skin bacteria, such as *S. aureus* or group A *Streptococcus*, while those below the waist are usually caused not only by these common skin microbes but also by *E. coli* and *P. mirabilis* (indole-negative *Proteus*), probably derived from bacterial "fallout" from the GI tract. As a result, oxacillin, which exhibits its activity against these Gram-positive bacteria, and cephalosporins, which are bactericidal toward both these Gram-positive and Gram-negative organisms, are the logical choices for prophylaxis against wound infection above and below the waist, respectively.

Two major problems have developed with the use of cephalosporins for prophylaxis. One is that they are often administered too long, even in appropriate situations, and the other is that they are often given illogically in clinical problems such as bowel surgery where they can be detrimental by the replacement of susceptible organisms with resistant ones.

Various investigators have demonstrated clearly that maximum protection from infection from a surgical procedure occurs only if adequate tissue levels are present at the time of the surgical procedure (253) and that the continuation of antibiotics beyond the operative period has no value. This situation was nicely illustrated in a study where a single dose of cephalothin administered immediately prior to the insertion of prosthetic heart valves was as effective in the prevention of infection as was the use of additional dosages after the operation (254).

The tendency of physicians to be reluctant to discontinue completely antibiotics by the intravenous route after they no longer are necessary has been a traditional problem with all antibiotics, particularly with the use of cephalosporins for prophylaxis. For instance, it is quite common for a surgeon to administer a cephalosporin in a ritualistic sequence: first intravenously, then intramuscularly, and finally orally for 1 to many weeks following an operative procedure. In fact, one often wonders why the physician does not go next to the intradermal or intraocular route! Unfortunately, this gradual weaning process has been a major reason for the increase in cost for this class of antibiotics, because it not only increases the amount of antibiotic administered but also enhances the chances of toxic drug reactions or superinfection, resulting in greater morbidity and prolonged hospital stay.

Therapy of Lung Infections Acquired in the Community—If the sepsis appears to be from a pulmonary infection produced by bacteria acquired from outside the hospital, and especially if the patient has a history of chronic lung or other debilitating disease, a cephalosporin antibiotic seems to be the wisest choice. The usual pathogens in this setting are *K. pneumoniae*, *Strep. pneumoniae*, *Hemophilus influenzae*, *S. aureus*, and group A *Streptococcus* organisms and are almost always sensitive to this antimicrobial agent if given in adequate dosage. There is some hesitancy about relying on ampicillin or penicillin alone, since most *Klebsiella* organisms and many staphylococci are resistant to both penicillin and ampicillin (about 80% of the *S. aureus* acquired outside the hospital now produces penicillinase).

It usually is possible to use penicillin or ampicillin as the sole antibiotic only in healthy patients with mild respiratory infections, since the physician can usually exclude the *Staphylococcus* or *Klebsiella* organism in such a clinical setting because these organisms almost always produce very serious disease.

Therapy of Lung Infections Acquired in Hospitals—Pulmonary infection acquired in a hospital setting is a difficult clinical problem because of the rapid colonization of the upper respiratory tract by common as well as bizarre bacteria. In a recent epidemiological survey (255) (Table X), 10.7 and 15.3% of the hospital-acquired pneumonias were produced by *Pseudomonas aeruginosa* and *K. pneumoniae*, respectively, followed in decreasing frequency by *E. coli* (10.6%), *Strep. pneumoniae* (9.5%), *Enterobacter* species (8.0%), and *S. aureus* (6.6%). Thus, in patients who develop hospital-acquired pneumonias, a combination of a cephalosporin and gentamicin appears to make sense, since it affords a more clinically proven coverage against *S. aureus* and *Klebsiella* than may be obtained with gentamicin and ampicillin. Moreover, the *Bacteroides* species usually involved in hospital-acquired pneumonias come from the upper respiratory tract where they are usually sensitive to cephalosporins.

Although most strains of *S. aureus* are susceptible to gentamicin *in vitro*, there is extremely little clinical experience for the use of this antibiotic in patients with overwhelming staphylococcal disease. Moreover, the enterococcus is rarely, if ever, involved

Table X—Major Organisms Associated with Suspected Hospital-Acquired Pneumonia from October 1970 to October 1973

Organism	Number	Percent
Klebsiella pneumoniae	138	15.3
Pseudomonas aeruginosa	97	10.7
Escherichia coli	96	10.6
Streptococcus pneumoniae	86	9.5
Enterobacter species	73	8.0
Staphylococcus aureus	60	6.6
Proteus species	45	4.9
Serratia species	17	1.9
Candida	17	1.9
Herellea	14	1.5
Citrobacter	3	0.3
Enterococcus	1	0.1
Other organisms	256	28.3
Total	903	100.0

in producing pneumonia; hence, the absence of coverage for this organism with the combination of a cephalosporin and gentamicin is of no great concern. For instance, in a review of hospital-acquired pneumonias at Hartford Hospital (255), from 1970 to 1973 there was only a single equivocal case of pulmonary infection caused by the enterococcus (Table X).

Inappropriate Use of Cephalosporins by Parenteral Route—*Treatment of Central Nervous System Infections*—Although cephalothin is often an effective antibiotic in many types of infection, especially pulmonary infections, its poor penetration into the cerebrospinal fluid is often not appreciated. In humans without meningitis, no detectable levels of this antibiotic were achieved after the intravenous administration of cephalothin, whereas even in patients with meningitis, low levels of 0.16–0.31 μg/ml were obtained (155). After the rapid intravenous infusion of 2–4 g of cephalothin in 14 patients, either as a single dose or at 4–6-hr intervals for several days and, in one case, for 3 weeks, Lerner (256) found cerebrospinal cephalothin levels of 0.155–25 μg/ml only in patients with cerebrospinal fluid protein content in excess of 50 mg/100 ml. When the protein concentration was less than 50 mg/100 ml, no measurable drug activity could be found in the cerebrospinal fluid.

Brown *et al.* (257) treated 12 patients with meningococcal meningitis with intravenous cephalothin at a dosage of 100–200 mg/kg/day. Clinical results were variable, and they concluded that this antibiotic could not be recommended as an effective alternative to penicillin or ampicillin. Mangi *et al.* (258) recently summarized eight cases of meningitis that developed during cephalothin therapy from organisms sensitive to this antibiotic, indicating dramatically its poor penetration into the cerebrospinal fluid.

Empirical Therapy of Infections from the Genitourinary or GI Tract—Since infection derived from the genitourinary and GI tracts are also usually from Gram-negative organisms with a wide variety of antimicrobial susceptibility patterns, the antibiotic "coverage" must be very broad. Combination of ampicillin and gentamicin meets this requirement better than a cephalosporin with gentamicin. Gentamicin sulfate is an aminoglycoside which has *in vitro* activity against practically all important Gram-negative and Gram-positive bacteria including *Ps. aeruginosa*, *Serratia marcescens*, and *S. aureus*. This antibiotic, however, is usually not effective against *Strep. pneumoniae*, group D *Streptococcus* (enterococcus), and anaerobes such as *Bacteroides* species. By adding ampicillin, protection also is created against the group D *Streptococcus* and *Strep. pneumoniae*, but there is only moderate defense against *Bacteroides*.

There is usually no need for antibiotic coverage of anaerobes, *Strep. pneumoniae*, group A *Streptococcus*, and *S. aureus* in the urinary tract, since these organisms are essentially of no clinical importance in this area. Thus, since cephalosporins have little activity against group D *Streptococcus*, and since ampicillin has a high degree of activity against this organism, the latter antibiotic seems to be the more appropriate drug to combine with gentamicin, especially when the suspected source of the bacteremia is from the urinary tract, an area where the enterococcus commonly resides.

Table XI—Organisms Isolated from Blood in Patients with Bacteremia *Definitely* Related to Urinary Tract Instrumentation

Organism	Number of Cases	Cephalosporin Activity[a]
Escherichia coli	9	±
Enterococcus	4	—
Enterobacter species	3	—
Proteus mirabilis	3	+
Proteus vulgaris	2	—
Citrobacter freundii	2	—
Proteus morganii	1	—
Klebsiella species	1	+
Serratia marcescens	1	—
Pseudomonas aeruginosa	1	—
Total	27	

[a] + = high degree of activity, ± = moderate activity, and — = no activity.

Table XI records the organisms that were definitely involved in bacteremia following urinary tract manipulation from 1970 to 1973 (255). Until these epidemiological data were shown to physicians, particularly to urologists, it was customary to administer a cephalosporin as a sole antibiotic in patients who suddenly became septic following instrumentation of the urinary tract. As can be seen from this table, over half of the organisms were not covered by this antibiotic; a combination of gentamicin and ampicillin would have provided appropriate protection against all of these pathogens.

Table XII (255) shows the 10 most common organisms producing bacteremias on a general surgical service during the same period. It is again apparent that over half of the organisms would not have been covered if a cephalosporin was used as the only antibiotic.

Additional Therapeutic and Economic Considerations in Selection of Cephalosporins for Parenteral Administration—From an inspection of Table XIII and Fig. 10, it is apparent that cephalothin and cephapirin are very similar from a pharmacokinetic standpoint. After the administration of 1 g of either antibiotic, results from sequential determinations of blood levels are very similar. Moreover,

Table XII—"Top Ten" Bacteremias in General Surgery (1970–1973)

Organism	Number of Isolates	Cephalosporin Activity[a]
Escherichia coli	23	±
Pseudomonas	12	—
Bacteroides	12	—
Klebsiella	11	+
Staphylococcus aureus	8	+
Enterococcus	7	—
Proteus indole +	6	—
Proteus indole —	5	+
Enterobacter	4	—
Serratia	3	—
Total	91	

[a] + = high degree of activity, ± = moderate activity, and — = no activity.

Table XIII—Comparison of Pharmacokinetic Parameters of Cephalosporin Antibiotics

Parameter	Cephalexin[a]	Cephradine	Cephaloglycin[a]	Cefazolin	Cephalothin	Cephaloridine	Cephapirin	Cephacetrile	Cefoxitin	Cephanone
Serum clearance, ml/min	248 ± 11	435	—	62 ± 6	472	167	—	230—240	—	56.3
Renal clearance, ml/min	252 ± 5	367	—	64 ± 6	274	125	—	230—240	—	46.6
Renal excretion (24 hr), %	80—100	79—96	18—25	100	52	75	41	60—100	90—100	92
Half-life, hr	0.9	0.8	1.5	1.8	0.6	0.6—1.5	0.7	1.3	0.67	2.8

[a] Oral administration.

cephapirin shares essentially the same antibacterial spectrum (208) as cephalothin with similar therapeutic results from infections such as pneumoniae (259, 260), septicemia, empyema, osteomyelitis, soft tissue infections, and urinary tract infections (148, 213, 261, 262). Adding even further to the similarities is the conversion of both antibiotics to a desacetyl metabolite, which results in appreciable loss of antibiotic activity (263).

A double-blind study (264) comparing the phlebitis produced by cephapirin and cephalothin showed that neither the incidence nor the degree of phlebitis was significantly different with the two drugs. Although cephalothin and cephapirin are not generic equivalents, there appears to be no reason why these antibiotics cannot be considered equivalent, making it acceptable and safe for a patient receiving 1 g of cephalothin to be given 1 g of cephapirin in its place or vice versa.

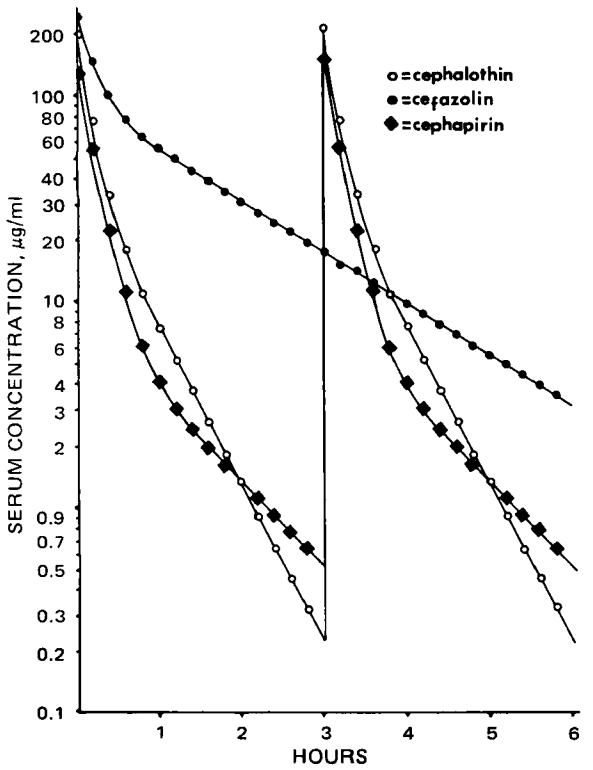

Figure 10—*Comparison of serum levels after intravenous administration of a single 1-g dose of cefazolin* versus *1 g of cephalothin or cephapirin every 3 hr (rate constants for data generation reported in Tables IV–VI).*

Cephaloridine has little justification for use in clinical medicine any longer since it is the only parenteral cephalosporin associated with significant nephrotoxicity (265–268) in humans and has no greater therapeutic effectiveness than any of the other three available cephalosporins for use by the parenteral route. With the recent availability of cefazolin, the logic for the continued usage of cephaloridine has been reduced even further.

Of the cephalosporins presently available for administration by the parenteral route, cefazolin is the preferred agent on both a therapeutic and economic basis. This impression is based on the following reasoning:

1. Cefazolin provides serum levels two to three times as high as cephalothin or cephapirin (see pharmacological and pharmacokinetic sections) (Table XIII and Fig. 10).

2. Biliary tract excretion of cephalosporins in humans is highest with cefazolin (approximately 17, 7, and 1 μg/ml for cefazolin, cephaloridine, and cephalothin, respectively) (269).

3. Cefazolin can be given comfortably and safely by either the intravenous or intramuscular route. In a dosage greater than 0.5 g, cephalothin is poorly tolerated.

4. Unlike cephalothin or cephapirin, cefazolin is not metabolized into a less active compound (see sections on pharmacology and pharmacokinetics).

5. Clinical studies demonstrated that cefazolin has therapeutic effectiveness at least as adequate as cephalothin and cephapirin (44).

6. Toxicology studies in animals and clinical experience with cefazolin in humans indicate that it is as safe as cephapirin and cephalothin (110, 274).

7. Cefazolin has the longest half-life of all cephalosporins (cephalothin, 0.6 hr; cephapirin, 0.7 hr; cephaloridine, 0.6–1.5 hr; and cefazolin, 1.8 hr). As a result, it can be administered less frequently (Table XIII).

8. Since cefazolin can be given less frequently and in a smaller total daily dosage (approximately half as frequently and/or half the number of grams), appreciable reduction in pharmacy cost can be predicted.

9. The microbiological activity of cefazolin is essentially similar to that of cephalothin and cephapirin except for its slightly greater activity against *E. coli* and *Enterobacter* species (111, 270).

10. To increase the economic savings for both the hospital and the patient, advantage should be taken of cefazolin's ability to be administered without appreciable discomfort by the intramuscular route. Such administration will reduce the cost of intravenous administration and lessen the demands on the intravenous therapist. The levels achieved by 1 g of cefazolin by the intramuscular route are high; peak levels in 1 hr are about 70 μg/ml, with appreciable levels (8–10 μg/ml) still present at 8 hr. These levels are certainly adequate since most Gram-positive bacteria such as *S. epidermidis, S. aureus,* the pneumococcus, and group A *Streptococcus* require less than 2–3 μg/ml, and the average MIC of cefazolin for Gram-negative bacteria such as *E. coli, P. mirabilis, Salmonella* species, *K. pneumoniae, H. influenzae,* and *Shigella* species are 1.6, 6.2, 4.0, 2.0, 4.0, and 8.0 μg/ml, respectively (104).

11. More frequent use of intramuscular medication will reduce the incidence of hospital deaths associated with bacteremia from prolonged in-dwelling intravenous polyethylene catheters.

12. Cefazolin is manufactured by two different pharmaceutical companies, allowing for competitive bidding.

In brief, cefazolin appears to combine the best features of cephalothin, cephapirin, and cephaloridine.

Cephalosporins for Oral Administration—Cephalexin, cephradine, and cephaloglycin are semisynthetic analogs of cephalosporin C that can be administered by the oral route. Their antibacterial spectrum *in vitro* is very similar to the parenteral cephalosporins; as expected, the enterococci, indole-positive *Proteus, Enterobacter, Serratia,* and *Pseudomonas* organisms are usually resistant. These oral agents often have less activity against staphylococci than any of the parenteral cephalosporins or the penicillinase-resistant penicillins. Cephalexin and cephradine have become the favorite oral cephalosporins since, in contrast to cephaloglycin which is relatively poorly absorbed from the GI tract and produces effective concentrations only in the urine (271), they are well absorbed and result in adequate antibiotic levels throughout most of the body (68, 79, 272).

Although cephalexin and cephradine have been used successfully in many infections of the respiratory tract, soft tissue, and urinary tract (63, 273), there is no evidence that their results are any better in the treatment of these illnesses from organisms that are sensitive to much cheaper oral drugs such as penicillin, ampicillin, oxacillin, dicloxacillin, or erythromycin. Their main use probably should be in the followup management of patients who are initially treated with parenteral cephalosporins or in the initial treatment of patients who have infections of the urinary tract from organisms (usually *Klebsiella)* resistant to other oral antibiotics or of patients with a history of penicillin hypersensitivity.

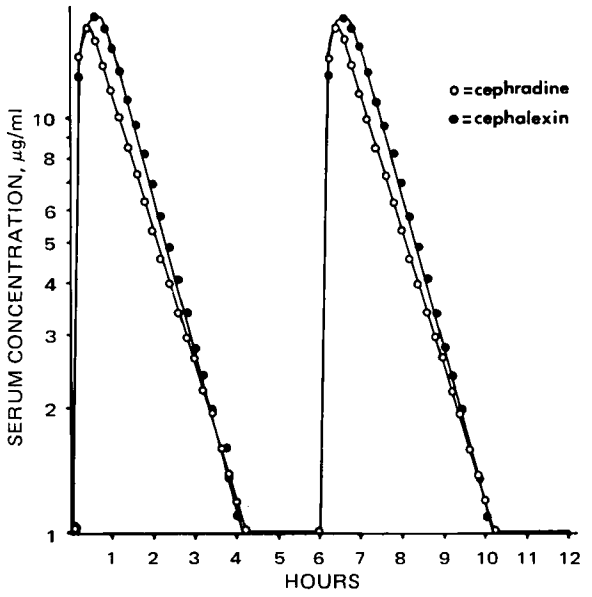

Figure 11—*Serum concentration of cephradine and cephalexin after 500 mg of each drug by the oral route (rate constants for data generation reported in Tables II and III).*

Cephalexin and cephradine, although different drugs, can also be considered similar in terms of pharmacokinetics and therapeutic equivalence (66) and can be interchanged in a fashion analogous to cephalothin and cephapirin. Figure 11 depicts the almost identical serum levels of cephradine and cephalexin following the administration of 500 mg of each drug. Moreover, inasmuch as cephradine and cephalexin are produced by different pharmaceutical companies, competitive bidding should result in a significant reduction in cost for the hospital and patient.

Conclusion—In brief, an explosion in the number of commercially available cephalosporins has occurred as the potential market for the sale of this class of antimicrobial agents has grown appreciably. To prevent excessively high hospital pharmacy cost with the resultant increase in the cost of a patient's hospital stay, the present cephalosporins and each new one that appears—which will be numerous—must not be automatically looked upon as "unique" antibiotics, even though they are not exact generic equivalents. The important issue is whether they are equivalent from pharmacokinetic and therapeutic standpoints, since the former determines the mode of administration and the likelihood of an adverse drug reaction, while the latter decides whether a patient will survive an infectious disease process.

Inhibition of Drug Metabolism by Hydroxylated Metabolites: Cross-Inhibition and Specificity

DAVID M. SODA and GERHARD LEVY ˣ

Abstract □ Inhibition of drug metabolism was studied in adult male Sprague–Dawley rats. A hydroxylated metabolite of phenylbutazone (oxyphenbutazone) inhibited the elimination of phenytoin, which is metabolized by oxidative pathways. The biotransformation of a relatively polar and only slightly plasma protein-bound drug, antipyrine, was subject to product inhibition by a hydroxylated metabolite, 4-hydroxyantipyrine. Neither oxyphenbutazone nor 4-hydroxyantipyrine measurably affected the elimination kinetics or metabolic fate of a drug (sulfanilamide) that is not metabolized by oxidative pathways.

Keyphrases □ Metabolism—oxyphenbutazone, phenytoin, antipyrine, sulfanilamide, effect of hydroxylated metabolites, rats □ Oxyphenbutazone—effect on metabolism of phenytoin and sulfanilamide, rats □ Antipyrine—biotransformation, effect of 4-hydroxyantipyrine, rats □ Sulfanilamide—biotransformation, effect of oxyphenbutazone and 4-hydroxyantipyrine, rats □ Phenytoin—biotransformation, effect of oxyphenbutazone, rats □ 4-Hydroxyantipyrine—effect on metabolism of antipyrine and sulfanilamide, rats

Several studies have shown that the hydroxylated metabolites of certain drugs can inhibit the biotransformation of their precursors. Such inhibitory effects were demonstrated *in vitro* with 5-(*p*-hydroxyphenyl)-5-phenylhydantoin (hydroxyphenytoin) and 2-hydroxydesmethylimipramine (1, 2), the metabolites of phenytoin and desipramine, respectively. *In vivo* studies revealed the inhibitory effect of injected hydroxyphenytoin and oxyphenbutazone on the elimination of phenytoin and phenylbutazone, respectively (3, 4). Accumulation of endogenously formed hydroxyphenytoin in the body by blocking its glucuronidation also has caused inhibition of phenytoin elimination (5). Computer simulations indicate that product inhibition may account for the dose-dependent change in the half-life of some drugs (6).

More recently, it was shown *in vitro* that the hydroxylated metabolite of one drug can inhibit the biotransformation of another drug. Such cross-inhibition was reported for the following metabolite–drug systems: hydroxyphenytoin–phenylbutazone (7), oxyphenbutazone–phenytoin (7), hydroxyphenytoin–hexobarbital (8), hydroxyphenytoin–ethylmorphine (8), hydroxyphenytoin–zoxazolamine (9), and hydroxyphenytoin–aniline (9). It also has been shown that hydroxyphenytoin prolongs hexobarbital sleeping time in mice (8) and zoxazolamine paralysis time in rats (9), but there has been no direct pharmacokinetic demonstration of cross-product inhibition *in vivo*.

The purposes of this investigation were to determine: (*a*) if a product inhibitory effect can be demonstrated for a relatively hydrophilic and negligibly protein-bound drug (antipyrine), (*b*) if hydroxylated metabolites with a demonstrated inhibitory effect on the biotransformation of their precursors can affect the elimination of a drug metabolized by other than oxidative pathways (sulfanilamide), and (*c*) if the hydroxylated metabolite of one drug (oxyphenbutazone) can inhibit the *in vivo* elimination of another drug metabolized by oxidative pathways (phenytoin).

EXPERIMENTAL

All studies were performed on male Sprague–Dawley rats[1], 300–450 g. A two-piece cannula of silicone rubber–polyethylene was implanted in the right jugular vein under light ether anesthesia (3, 10), 3 days before the first experiment. Crossover experiments were carried out 2 weeks after the first experiment. Blood samples were obtained through one outlet of a three-way stopcock after withdrawal of 0.5 ml of blood (which was subsequently reinjected) to ensure against artifacts due to sample dilution by heparin or blood trapped in the cannula (3).

4-Hydroxyantipyrine–Antipyrine Experiments—Three rats received 4-hydroxyantipyrine[2], 100 mg/kg iv, 30 min before an intravenous injection of ^{14}C-antipyrine, 70 mg/kg, and additional doses of 4-hydroxyantipyrine, 50 mg/kg, every 45 min during the experiment. The hydroxylated metabolite was dissolved in a small volume of 1.2 *M* NaOH, which was diluted immediately with 0.2 *M* phosphate buffer, pH 7.4, to yield a 100-mg/ml solution of pH

9.5–10. This solution was injected slowly (3–5 min) to prevent irritation and precipitation. Three control animals received the solvent only. Crossover studies were performed on all six rats. The antipyrine injection solution was prepared by adding 5 μCi of ^{14}C-antipyrine, 12.1 mg/mCi labeled in the *N*-methyl position[3], to 0.5 ml of a 70-mg/ml antipyrine[2] solution in water.

Blood samples (0.5 ml) were obtained at 0.5, 1.0, 2.0, 3.0, 4.5, and 6.0 hr after antipyrine injection. A 200-μl portion of plasma with 0.05 ml of 1 *M* NaOH was extracted with 2 ml of chloroform by shaking on a reciprocating shaker (200 cpm) for 10 min. The phases were separated by centrifugation at 400×*g* for 5 min, and the aqueous phase was removed by aspiration. A 1.8-ml portion of the chloroform phase was evaporated to dryness in 2-ml vials[4] under nitrogen at room temperature. The sides of the vessel were washed twice with chloroform which was also evaporated.

The residue was redissolved in 50 μl of chloroform and applied to a TLC plate of silica gel G with fluorescent indicator F-254[5], which had been activated (1 hr at 100°) immediately before use. The vial was rinsed twice with 20-μl portions of chloroform, which were also applied on the plate. In addition to the plasma extracts, a chloroform solution of "cold" antipyrine was spotted as an R_f reference. The plate was developed immediately with chloroform–ethanol (9:1) for 45–60 min in a chamber which had been equilibrated with the solvent system (11).

The spots on the dried plate were visualized under UV light,

scraped off, and placed into vials containing 10 ml of scintillation fluid for subsequent counting in a spectrometer with an external standard. Recovery of antipyrine from spiked samples was 88 ± 3.7% (mean ± *SD*) and was not affected by the presence of 4-hydroxyantipyrine and its metabolite(s) (plasma from rats given 4-hydroxyantipyrine).

4-Hydroxyantipyrine–Sulfanilamide and Oxyphenbutazone–Sulfanilamide Experiments—Crossover studies were carried out on four rats for each of the two hydroxylated metabolites. The same dosage schedules used in the other experiments were used in this study. A control blood sample (for determination of blank value) was obtained immediately before injection of sulfanilamide, 20 mg/kg iv. A solution of the latter was prepared by dissolving 100 mg in 0.5 ml of 1 *M* NaOH, adjusting the pH to 8 with hydrochloric acid, and adding water to yield 5 ml.

Blood samples (0.5 ml) were obtained at 1, 2, 3, 4, 5, and 6 hr after sulfanilamide injection. The animals were housed individually in plastic metabolism cages for 2 days. Sulfanilamide in plasma and urine and sulfanilamide metabolites in urine were assayed by a modification of the Bratton–Marshall method (12). Two hundred microliters of plasma was shaken with 1 ml of 15% trichloroacetic acid and 0.5 ml of concentrated hydrochloric acid for 3 min. The precipitated proteins were separated by centrifugation at 400×*g*. To 1 ml of the supernate was added 0.1 ml of 0.2% sodium nitrite solution. After 15 min, 0.1 ml of 10% ammonium sulfamate solution was added. Five minutes later, 0.1 ml of 0.1% naphthylethylenediamine dihydrochloride solution was added; after 20 min, the absorbance was determined at 545 nm, using microcells.

Assays of urine were carried out with 2 ml of appropriately diluted urine to which 5 ml of 15% trichloroacetic acid and 1 ml of concentrated hydrochloric acid had been added. Sulfanilamide metabolites were assayed by determining the difference between the concentration of total and unmetabolized drug. Total sulfonamide was determined after hydrolysis of the urine–trichloroacetic

Table IV—Effect of Oxyphenbutazone and 4-Hydroxyantipyrine on the Metabolic Fate of Sulfanilamide in Rats

Experiment	Recovery in 48-hr Urine, % of Dose[a]: Sulfanilamide	Recovery in 48-hr Urine, % of Dose[a]: Metabolites
Oxyphenbutazone		
Without	22.4 ± 3.4	46.4 ± 5.4
With	25.8 ± 4.7[b]	49.9 ± 3.6[b]
4-Hydroxyantipyrine		
Without	23.9 ± 3.6	45.5 ± 7.7
With	25.2 ± 8.2[b]	46.3 ± 1.9[b]

[a] Mean ± *SD* for four animals in each group. [b] Not statistically significantly different from control value.

acid–hydrochloric acid mixture at 100° for 1 hr. Reference curves were based on absorbance data obtained with solutions of known sulfanilamide concentrations in plasma and water. Recovery of drug from spiked plasma samples from rats given 4-hydroxyantipyrine or oxyphenbutazone did not differ from the recovery from plasma of unmedicated animals.

Oxyphenbutazone–Phenytoin Experiments—Oxyphenbutazone[6], 80 mg/kg, was given intraperitoneally to 15 of 29 rats 1 hr before intravenous injection of ^{14}C-phenytoin, 10 mg/kg. A 40-mg/kg dose of oxyphenbutazone was administered 3 hr after the first dose of that drug. The control rats received only solvent instead of oxyphenbutazone. Six of the 29 rats were studied in crossover fashion.

Blood samples (~250 μl) were obtained at 10, 20, 40, 60, 80, 100, 120, 150, 180, and 210 min after phenytoin injection. Preparation of the injection solutions and analytical methodology were described previously (3, 4).

Plasma Protein Binding of Antipyrine—Plasma from unmedicated rats, with antipyrine added to yield concentrations from 7.4 to 74 μg/ml, was dialyzed at 37° for 3 hr against isotonic sodium phosphate buffer solution, pH 7.4, in dialysis cells separated by a cellophane membrane. Preliminary studies showed that dialysis equilibrium is attained in less than 3 hr under the experimental conditions.

Pharmacokinetic Analysis—Half-life values were obtained from the slope of the terminal linear portion of individual plots of the logarithm of drug concentration *versus* time, fitted to the data by the method of least squares.

RESULTS

The results of the crossover study of the effect of 4-hydroxyantipyrine on the elimination of antipyrine are summarized in Table I; a typical example of the detailed data is shown in Fig. 1. Treatment with 4-hydroxyantipyrine resulted in an almost fourfold increase in the average half-life of antipyrine.

Protein binding of antipyrine in rat plasma was 13.1 ± 1.5% (mean ± *SD*, n = 23), with no apparent concentration dependence in the 7.4–74-μg/ml range.

Table V—Effect of Oxyphenbutazone on the Elimination of Phenytoin in Rats

Type of Comparison	Half-Life ($t_{½\beta}$)[a], min: Control	Half-Life ($t_{½\beta}$)[a], min: With Oxyphenbutazone	Statistical Significance of Difference (p Value)
14 animals in control group, 15 in oxyphenbutazone group	57 ± 37	147 ± 93	<0.005[b]
Six animals in crossover study	47 ± 24	109 ± 97	<0.05[c]

[a] Mean ± *SD*. [b] Student t test. [c] Sign test for paired data.

Crossover experiments with and without 4-hydroxyantipyrine showed that this compound had no apparent effect on the elimination kinetics of sulfanilamide (Table II and Fig. 2). The same lack of effect was found when the plasma half-life of sulfanilamide was determined with and without oxyphenbutazone (Table III and Fig. 3). Neither 4-hydroxyantipyrine nor oxyphenbutazone had any apparent effect on the metabolic fate of sulfanilamide, as reflected by the composition of urinary excretion products (Table IV).

The results of the study of the effect of oxyphenbutazone on the elimination of phenytoin are summarized in Table V; detailed data obtained in crossover experiments on one animal are shown in Fig. 4 as a typical example. Administration of oxyphenbutazone with phenytoin caused an approximately 2.5-fold average increase in the plasma half-life of the latter. There was a strong (r = 0.95) and statistically significant (p < 0.005) positive correlation between the individual half-life values of phenytoin in control and oxyphenbutazone experiments in the group of six rats used for crossover studies.

DISCUSSION

The results of this investigation demonstrate directly *in vivo* that the hydroxylated metabolite of one drug can inhibit the elimination of another drug metabolized by an oxidative pathway. On the other hand, neither of the two hydroxylated metabolites with demonstrated inhibitory activity on oxidative biotransformation had any effect on the elimination of sulfanilamide, which is removed from the body mainly by acetylation and glucuronidation (*i.e.*, nonoxidative processes) and renal excretion (13). These results are consistent with the *in vitro* observations of others, which

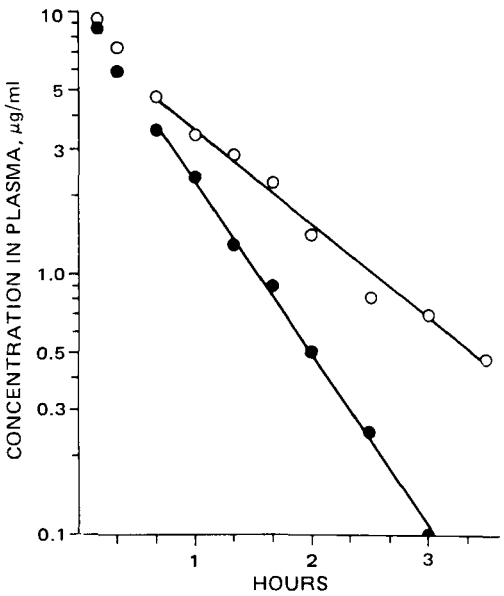

Figure 4—*Effect of oxyphenbutazone on the elimination of phenytoin, 10 mg/kg iv, in Rat 13-IV. Key:* ●, *control experiment; and* ○, *with oxyphenbutazone, 80 mg/kg, at −1 hr and 40 mg/kg at +2 hr relative to the time of phenytoin injection.*

suggested that product inhibition (including cross-product inhibition) of drug biotransformation processes may be due to an interaction of the inhibitory agents with cytochrome P-450 (8, 14). Specifically, a competition between the hydroxylated metabolite and the drug for binding sites on cytochrome P-450 was suggested (14).

The observation of product inhibition in the elimination of antipyrine is of particular interest because this drug differs from the others studied so far in that it is very hydrophilic and negligibly bound to plasma proteins. The metabolite 4-hydroxyantipyrine may be a potentially useful inhibitor of drug elimination in human drug therapy (analogous to the use of probenecid as an inhibitor of renal excretion of drugs). However, since its biological half-life in humans is very short[7], it may be most useful as an inhibitor of "first-pass" metabolism. This possibility remains to be explored.

Solid-State Decomposition of *para*-Substituted Salicylic Acids

PAKDEE POTHISIRI and J. T. CARSTENSEN [x]

Abstract □ A series of *para*-substituted salicylic acids, all crystallizing monoclinically and decomposing by decarboxylation, were shown to adhere to Bawn-type kinetics, and the decomposition rate constants were shown to adhere approximately to a Hammett-type relation. The value of the reaction parameter was −8. Both *para*-substituted salicylic and benzoic acids occur as dimers in the crystalline state. The mechanism whereby the latter decomposes is speculated to be intermolecular in the sense that the substituent from one dimer interacts with the carboxyl group of a neighboring dimer. In the same sense of the word, the substituted salicylic acids decompose by an intramolecular mechanism, *i.e.*, within the dimer unit.

Keyphrases □ Salicylic acids, *para*-substituted—decomposition in the solid state, intramolecular mechanism, Bawn kinetics, Hammett relation □ Solid-state decomposition—*para*-substituted salicylic acids, intramolecular mechanism, Bawn kinetics, Hammett relation □ Decomposition—solid state, *para*-substituted salicylic acids, intramolecular mechanism, Bawn kinetics, Hammett relation

The theory of the kinetics of solid-state decomposition, where a solid decomposes into a liquid and a gas, was developed by Bawn (1); experimental data supporting the theory were reported by Carstensen and Musa (2). In this type of reaction, there are (at least) two parallel decomposition paths: (*a*) the solid itself decomposes *via* a first-order decay route with rate constant k_s in reciprocal time units, and (*b*) the compound saturates the liquid decomposition layer and here decomposes in solution with a rate constant k_l in reciprocal time units. It is assumed that the reaction products do not participate actively in the decomposition in any other way than supplying the liquid vehicle in which part of the overall reaction takes place.

BACKGROUND

As long as there is solid present, the fraction decomposed, x, will accelerate exponentially as shown in Fig. 1; as time progresses, there will be an increasing amount of liquid phase and a decreasing amount of solid phase present. At time t_S, the last solid compound disappears and the solubility, S (moles per mole), of the compound in its decomposition product can be determined from the fraction decomposed, x_S, at time t_S. At times later than t_S, the decomposition will be a conventional first-order decomposition with the shape denoted by BC in Fig. 1, so the overall curve (ABC in Fig. 1) will be of the frequently reported sigmoid shape.

One assumption made is the first-order decomposition in the solid phase; this point has been justified both theoretically and ex-

suggested that product inhibition (including cross-product inhibition) of drug biotransformation processes may be due to an interaction of the inhibitory agents with cytochrome P-450 (8, 14). Specifically, a competition between the hydroxylated metabolite and the drug for binding sites on cytochrome P-450 was suggested (14).

The observation of product inhibition in the elimination of antipyrine is of particular interest because this drug differs from the others studied so far in that it is very hydrophilic and negligibly bound to plasma proteins. The metabolite 4-hydroxyantipyrine may be a potentially useful inhibitor of drug elimination in human drug therapy (analogous to the use of probenecid as an inhibitor of renal excretion of drugs). However, since its biological half-life in humans is very short[7], it may be most useful as an inhibitor of "first-pass" metabolism. This possibility remains to be explored.

Solid-State Decomposition of *para*-Substituted Salicylic Acids

PAKDEE POTHISIRI and J. T. CARSTENSEN [x]

Abstract □ A series of *para*-substituted salicylic acids, all crystallizing monoclinically and decomposing by decarboxylation, were shown to adhere to Bawn-type kinetics, and the decomposition rate constants were shown to adhere approximately to a Hammett-type relation. The value of the reaction parameter was −8. Both *para*-substituted salicylic and benzoic acids occur as dimers in the crystalline state. The mechanism whereby the latter decomposes is speculated to be intermolecular in the sense that the substituent from one dimer interacts with the carboxyl group of a neighboring dimer. In the same sense of the word, the substituted salicylic acids decompose by an intramolecular mechanism, *i.e.*, within the dimer unit.

Keyphrases □ Salicylic acids, *para*-substituted—decomposition in the solid state, intramolecular mechanism, Bawn kinetics, Hammett relation □ Solid-state decomposition—*para*-substituted salicylic acids, intramolecular mechanism, Bawn kinetics, Hammett relation □ Decomposition—solid state, *para*-substituted salicylic acids, intramolecular mechanism, Bawn kinetics, Hammett relation

The theory of the kinetics of solid-state decomposition, where a solid decomposes into a liquid and a gas, was developed by Bawn (1); experimental data supporting the theory were reported by Carstensen and Musa (2). In this type of reaction, there are (at least) two parallel decomposition paths: (*a*) the solid itself decomposes *via* a first-order decay route with rate constant k_s in reciprocal time units, and (*b*) the compound saturates the liquid decomposition layer and here decomposes in solution with a rate constant k_l in reciprocal time units. It is assumed that the reaction products do not participate actively in the decomposition in any other way than supplying the liquid vehicle in which part of the overall reaction takes place.

BACKGROUND

As long as there is solid present, the fraction decomposed, x, will accelerate exponentially as shown in Fig. 1; as time progresses, there will be an increasing amount of liquid phase and a decreasing amount of solid phase present. At time t_S, the last solid compound disappears and the solubility, S (moles per mole), of the compound in its decomposition product can be determined from the fraction decomposed, x_S, at time t_S. At times later than t_S, the decomposition will be a conventional first-order decomposition with the shape denoted by BC in Fig. 1, so the overall curve (ABC in Fig. 1) will be of the frequently reported sigmoid shape.

One assumption made is the first-order decomposition in the solid phase; this point has been justified both theoretically and ex-

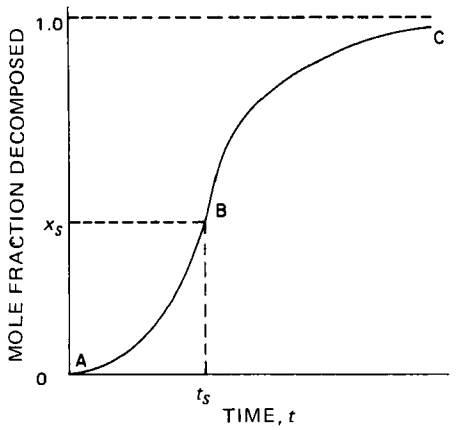

Figure 1—*Typical sigmoid-shaped curve for fraction decomposed in a solid as a function of time, when the solid decomposition produces a gas and a liquid. AB is the acceleratory period where both parent solid and liquid decomposition products are present, and BC is the part of the curve where only the liquid phase is present. The time scale is linear.*

perimentally by the authors (3). The assumption that the liquid reaction product is inert has been justified by consistency checks of the values of k_l obtained from the AB and BC portions of the curve in the case of substituted benzoic acids (2).

For a series of *para*-substituted benzoic acids, Carstensen and Musa (2) showed that the substituent σ-values have to be more negative than −0.3 for the compound to decompose below its melting point. Although the log k_s *versus* σ plot did not give a good linear fit, the correlation coefficient was high (0.9) and the reaction parameter, ρ, was positive. There have been other attempts reported in the literature to tie in reaction rates with substituent σ-values in solid-state reactions. Clark (4–6) found no such effect in a series of malonic acids, and Dorko *et al.* (7, 8) found no systematic correlation in decomposition reactions of tosylates. On the other hand, Meyers *et al.* (9) studied the reaction of benzoic acid derivatives with their salts at elevated temperatures under vacuum and obtained a systematic relation between the reactivities and the substituent σ-values of the compounds.

The aim of the study reported here was to determine whether a chemical substituent effect exists for k_s in a Bawn-type decomposition. A series of *para*-substituted salicylic acids was chosen because they were found experimentally to crystallize in the same crystal system (monoclinic) and they exhibited a clean decarboxylation decomposition without side reactions. These compounds, furthermore, have been studied in solution in quinoline (10, 11); in such solutions, they exhibited a linear free energy relationship for substituents with σ-values of less than +0.3.

EXPERIMENTAL

Samples[1] of *p*-dimethylaminosalicylic acid, *p*-diethylaminosalicylic acid, *p*-hydroxysalicylic acid, and *p*-ethoxysalicylic acid were purified by recrystallization from anhydrous methanol. The crystals were reduced by grinding in a porcelain mortar and pestle to a particle size of 8–10 μm as measured by permeamitry[2]. Sample preparation and gas analysis methods were as described elsewhere (2, 3). As in the quoted cases dealing with *para*-substituted benzoic acids, the volatility of the compounds prohibits the use of conventional vacuum setups (12) since they would cause sublimation of the compound from the heated reaction site to the cooler analysis portion of the apparatus. Therefore, the break-seal technique described by Carstensen and Musa (2) was used; sample sizes were 300 mg.

The amount of decomposition was monitored by the number of moles of gas produced. The remaining solid was titrated and the amount of titer lost was shown to equal the number of moles of gas evolved, so the reactions are stoichiometric and of the form: $XC_6H_3(OH)COOH \rightarrow XC_6H_4OH + CO_2$. Since the compounds tested are somewhat volatile at the temperatures used in the study, their vapor pressures were determined as described elsewhere, as were the gas phase decomposition rate constants (2). The value of t_S was determined (to within 15 min) by visual observation of the break-seal tubes in each kinetic run.

The σ-values for one compound, *p*-diethylaminosalicylic acid, is

unreported in the literature. The pKa value of each compound was determined potentiometrically according to the method of Albert and Sergeant (13).

RESULTS AND DISCUSSION

All of the compounds exhibited decomposition curves of the type shown in Fig. 1; the decomposition curves for *p*-ethoxysalicylic acid are shown in Fig. 2. The results from the vapor pressure determinations are shown in Fig. 3. The linearity gives some assurance (although it does not guarantee) that the compounds do not undergo polymorphic transformation in the temperature range studied. The decomposition rate of the compounds in the gaseous state was of such a magnitude that it would contribute less than 1% of the total decomposition in an ordinary solid run; in the following discussion, it is assumed that vapor phase decomposition can be neglected.

As mentioned, the solubility of the *para*-substituted salicylic acids in their corresponding *meta*-substituted phenols can be determined by removing the break-seal tube at the time of complete

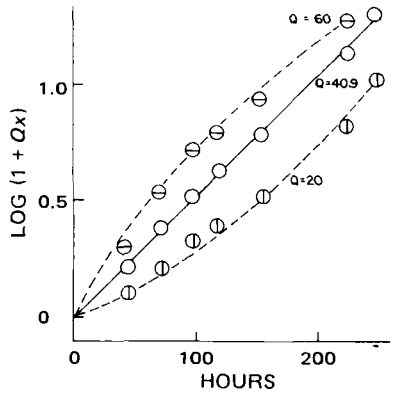

Figure 5—*Plot of ln [1 + Qx] versus time (Eq. 1) for varying values of* Q. *The data relate to the solid-state decomposition of* p-*ethoxysalicylic acid at 399°K.*

liquefaction, t_S, and determining the mole fraction, x_S, decomposed. The solubility is then determined as $S = (1 - x_S)/x_S$ moles per mole. The solubilities are shown in Fig. 4, and the fact that log S is linear in $(1/T)$ is an indication (although no guarantee) that no polymorphic transformation takes place in the temperature range of the kinetic study.

The pKa values determined are shown in Table I, as are a series of reported σ-values for the substituents in question. The last column, denoted pKa (H) − pKa (X), is the difference between the pKa of the unsubstituted salicylic acid and the pKa of the X-substituted salicylic acid. The σ-value for the diethylamino substituent based on the pK value of the diethylaminobenzoic acid (6.19) appears to be of an abnormally high negative value. Since values of pKa (X) − pKa (H) for the salicylic acid series in the case of ethoxy, hydroxyl, and dimethylamino substituents are identical to reported σ-values, the value of pKa (H) − pKa (X) for diethylaminosalicylic acid was used in this study as was the σ-value for the diethylamino substituent.

If a solid decomposes into 1 mole of gas and 1 mole of a liquid decomposition product, then the mole fraction decomposed, x, is given by (1–3, 18, 19):

$$\ln [1 + Qx] = Qk_s t \qquad \text{(Eq. 1)}$$

[a] $k_s = Ze^{-Ea/RT}$. [b] $k_l = Z_l e^{-Ea'/RT}$.

where:

$$Q = k_l S - k_s S - k_s \qquad \text{(Eq. 2)}$$

Q is found by iteration and is the value which in Eq. 1 imparts linearity to the data. The data in Fig. 5 are data from Fig. 2 plotted in the form of Eq. 1. Knowing Q allows calculation of k_s from the best slope, and then knowing S allows calculation of k_l from Eq. 2. The value of k_l can also be obtained from the part of the decomposition curve beyond the inflection point ($t > t_S$), and k_l values found in the latter fashion agree with the former to within ±25%. Values of k_s and k_l (from Eq. 2) are plotted logarithmically *versus* reciprocal temperature in Figs. 6 and 7; the Arrhenius relationship holds well in both cases.

Gomes (20) reported that there is an inherent difficulty in assigning thermodynamic parameters to data from solid-state reactions. This difficulty is primarily due to the facts that such reactions frequently are dictated and controlled by physical phenomena (*e.g.*, strain and diffusion) and that the solid-state reaction rate constants are not comparable to conventional constants in solution kinetics. In topochemical reactions, for instance, rate constants have dimensions of square centimeters per second where square root laws pertain (21, 22). In contrast, the k_s in this study is of a usual first-order dimension; the data are summarized in Table II. The k_s values[3] are plotted *versus* σ-substituent values in Fig. 8. There appears to be good linearity, and the general correlations imply that the reactions are controlled by chemical factors rather than (or in addition to) physical factors. That the liquid layer may preferentially dissolve a solid at points of strain has been suggested (3) and may minimize the physical factors in a Bawn-type reaction.

As seen in Fig. 8, the trend in a series of *para*-substituted benzoic acids is opposite in sign to that of *para*-substituted salicylic acids. The explanation for this result is sought in the crystallographic arrangement of the two series. Pothisiri (19) described the molecular packing arrangement in crystals of *p*-aminosalicylic acid, *p*-hydroxysalicylic acid, and *p*-aminobenzoic acid (Figs. 9 and 10). *p*-Aminobenzoic acid is built up in dimeric units; hydrogen bonding through the hydrogen of the carboxyl group with the carbonyl oxygen of the neighboring molecule forms links between

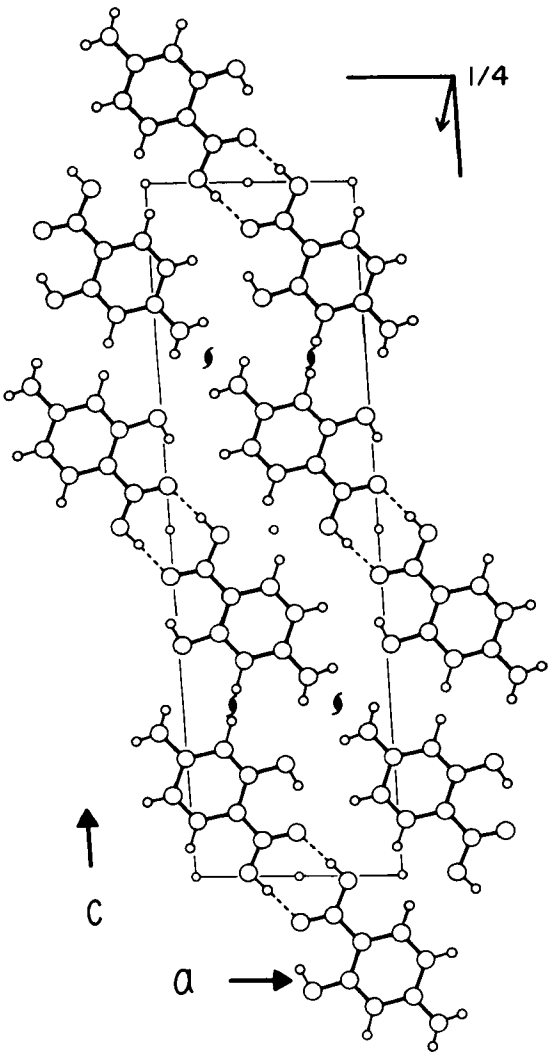

Figure 9—*Packing diagram of* p-*aminosalicylic acid in the [010] projection.*

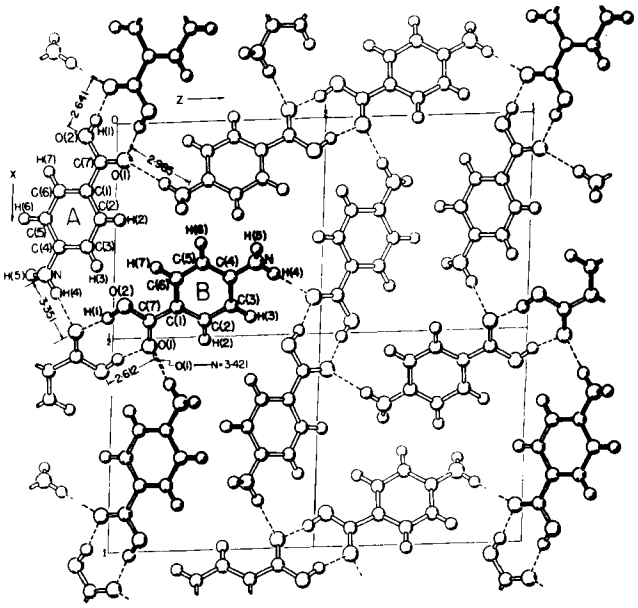

Figure 10—*Packing diagram of* p-*aminobenzoic acid in the [010] projection.*

[3] The k_l values were not plotted in this fashion, since each point corresponds to a different solvent.

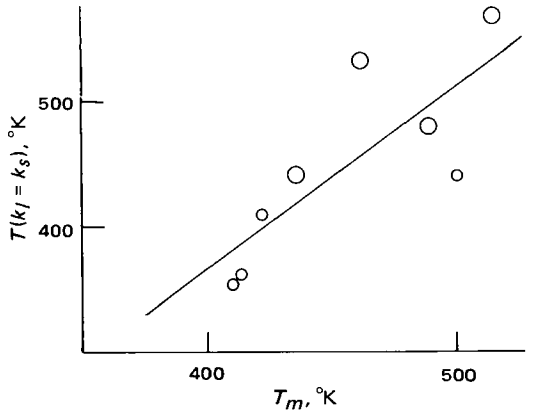

Figure 11—*Plot of the temperature where liquid and solid decomposition rate constants are equal* versus *the melting temperature.*

dimers. The arrangement is such, however, that there is a fairly close proximity (2.985 Å, Fig. 10) between the substituent X of one dimer pair and one carboxyl group of the neighboring pair.

In the case of substituted salicylic acids, however, Fig. 9 shows that the molecular unit is a dimer through hydrogen bonding between carboxyl groups and that a relatively strong intramolecular hydrogen bond exists between the hydroxyl group in the 2-position and the carboxyl oxygen atom. Pothisiri (19) showed that the O(3)—H(2) . . . O(2) distance is 2.610 Å and that there is no hydrogen bonding between the *para*-substituent from one molecule to the carboxyl oxygen of a neighboring molecule (dimer). Therefore, one explanation to the opposite signs of the reaction parameters would be that the *para*-substituted benzoic acid series decomposes *via* an intermolecular mechanism in the sense that there is an interaction between the substituent from one dimer pair with the carboxyl group of a neighboring dimer whereas, in the same sense of the word, compounds in the substituted salicylic series decompose *via* an intramolecular route.

No attempt was made here to seek further substantiation; the proposal should not be construed as a model but rather as a feasible explanation. Several kinetic characteristics (ρ, $\Delta S^{\ddagger}$, and E_a[4]) are of larger magnitude than in solution kinetics. Moreover, some points in the data treatment are not unambiguously resolved; there is, for instance, the possibility of a finite volume of activation which (since the pressure changes during the reaction) could change k_l and k_s as the reaction progresses. Furthermore, although the k_l values from the three-phase part of the curve equal those from the two-phase part[5] to within ±25%, the solution kinetics still could be carbon dioxide dependent, and this may influence the calculated k_s values. The sorting out of such parameters will have to await the results of a systematic kinetic study of *para*-substituted salicylic acids in their corresponding *meta*-substituted phenols at various carbon dioxide pressures.

[4] $\Delta S^{\ddagger}$ is the entropy of activation; it can be calculated from the data in Table II. It is based on a different standard state (moles per mole) than is customary in solution kinetics.

[5] During the latter part of the decomposition, only the liquid and gas phase are present.

The data in Table II allow calculation of the temperatures where k_l and k_s are equal. Such a calculation was performed on the *para*-substituted benzoic acid data reported by Carstensen and Musa (2). When these temperatures are plotted *versus* melting point, a straight line (with correlation coefficient of 0.9) results (Fig. 11). The general significance of this relation (and whether it will extend to other series of compounds) is left undiscussed here.

Kinetics and Mechanisms of Drug Action on Microorganisms XXII: Effects of Aminosidine with and without Organism Pretreatment with Bacteriostatic Agents

EDWARD R. GARRETT ˣ and JOHN K. LEWIS

Abstract □ *Escherichia coli* generation in the logarithmic growth phase was inhibited in peptone broth USP at pH 7.0 without kill below 3.0 μg/ml of aminosidine. Above this value, the logarithms of the number of viables of the drug-treated culture ultimately decreased linearly with time and the slopes of these plots were independent of concentration. A concentration-dependent lag in the time of attainment of the cidal action was observed, and the extent of this lag was related to the ease of emergence of resistant organisms. The minimal concentration for cidal action increased with increasing concentrations of nutrients and with decreasing pH. Pretreatment of the cultures with novobiocin and tetracycline lessened the minimum bactericidal concentration of aminosidine whereas chloramphenicol pretreatment increased it. Tetracycline pretreatment inhibited the emergence of aminosidine-resistant organisms.

Keyphrases □ Aminosidine—kinetics and mechanisms of action, microorganisms, with and without pretreatment □ Antibiotics—aminosidine, kinetics and mechanisms of action, microorganisms, with and without pretreatment □ *Escherichia coli*—kinetics and mechanisms of aminosidine action, with and without pretreatment

Aminosidine is an oligosaccharide antibiotic isolated from *Streptomyces chrestomyceticus* (1). Structural studies indicated that the major component of aminosidine is identical with that of paromomycin and that aminosidine belongs to the neomycin group of aminoglycoside antibiotics (2). The nature of aminosidine or paromomycin activity indicates that it is closely related to streptomycin in its mode of action (3) in causing misreading of messenger-RNA. The bactericidal action may be due primarily to an irreversible binding to the ribosomes (3, 4).

The purpose of this work was to study the effects of aminosidine on a balanced growth culture of *Escherichia coli* as part of ongoing research into the kinetics and mechanisms of antibiotic action on microbial generation (5–7).

EXPERIMENTAL

Bacterial Cultures—The test organism, *Escherichia coli* (ATCC 12407) (5, 6), and the antibiotic medium 3[1] rehydrated to peptone broth USP (6) were as described previously. Studies were also conducted at twice and half the normal nutrient composition. The pH of the autoclaved medium, normally 7.0, was adjusted between 6.1 and 7.8 with sterile filtered 1 *N* HCl and 1 *N* NaOH for studies on pH effects

An aliquot (10 ml) of culture medium was inoculated from a fresh agar slant, and the culture generated for 15 hr at 37.5°. An aliquot (0.5 ml) was then diluted into 49.5 ml of fresh culture medium and generated to 2×10^7 *E. coli*/ml. An aliquot (0.5 ml) of this culture was treated similarly, and an aliquot of this final culture was diluted 100-fold into bulk broth. The suspension was dispensed by a sterile 49.5-ml pouring head into separate, sterile, loosely capped conical culture flasks maintained at 37.5 ± 0.01° in a constant-temperature water bath equipped with a shaker. After 25 min, when the organisms were in the logarithmic growth phase, 0.50 ml of an appropriate stock solution of antibiotic was added. In addition, the antibacterial effects of aminosidine[2] were studied at various inoculum concentrations of organisms.

The generation of viable and total *E. coli* as affected by aminosidine sulfate[2] concentrations was monitored by previously described methods (5–7); typical examples are shown in Figs. 1 and 2. Similar studies were conducted with paromomycin sulfate[3].

Bacterial Resistance to Aminosidine Action—Cultures of resistant organisms were prepared by overnight growth in the presence of 4.0, 5.0, and 6.0 μg/ml of aminosidine. Aliquots (0.5 ml) were diluted 100-fold with drug-free medium and subcultured twice at 1×10^7 organisms/ml. The presumed resistant organisms, inoculated at 1×10^5 organisms/ml in the logarithmic growth phase, were permitted to grow in fresh medium. At 60 min, drug concentrations ranging from 3.5 to 6.0 μg/ml were effected in different flasks and the generation rates were monitored. The various flasks were filtered at 1×10^9 organisms/ml, and the filtrates were stored at 4° for 17 hr. They then were inoculated with logarithmically generating naive organisms at 37.5°, and the generation rates were monitored.

Aminosidine Combinations with Bacteriostatic Agents—The effects on generation rates of aminosidine combinations with growth-inhibiting concentrations of the bacteriostatic chloramphenicol[4], tetracycline[5], or novobiocin[6] at pH 7.00 were studied by adding aminosidine subsequent to the establishment of drug-affected steady-state generation rates with one of the former.

Cell Size Distribution—The size–frequency distributions and total counts of the generating organisms in the presence of aminosidine were recorded with time using a pulse height analyzer[7]. This instrument had been calibrated with 1.305-μm diameter polytoluene latex beads.

Aminosidine pKa Values—Nitrogen-purged aminosidine sulfate solutions (10 ml containing 3 mg), to which a measured quantity of 1 *N* HCl had been added, were potentiometrically titrated[8] with 0.10 *N* NaOH. Volumes without drug and treated similarly were also titrated.

RESULTS AND DISCUSSION

Effect of Aminosidine on Microbial Generation—The numbers of *E. coli* as a function of time as affected by various concentrations of aminosidine are plotted semilogarithmically in Figs. 1 and 2. At bactericidal concentrations, the action of the drug demonstrated an initial lag period with a subsequent increasing diminution of generation rate. The numbers of viables tended to increase to a maximum and then decrease to approach an apparent first-order rate of dying, $k_{app} = -5.36 \times 10^{-4}$/sec at 37.5°, which was independent of drug concentration above the minimum necessary to exercise killing action. However, there was a relationship between the time required to achieve this first-order process of dying and drug concentration in the medium (Figs. 1 and 3), which

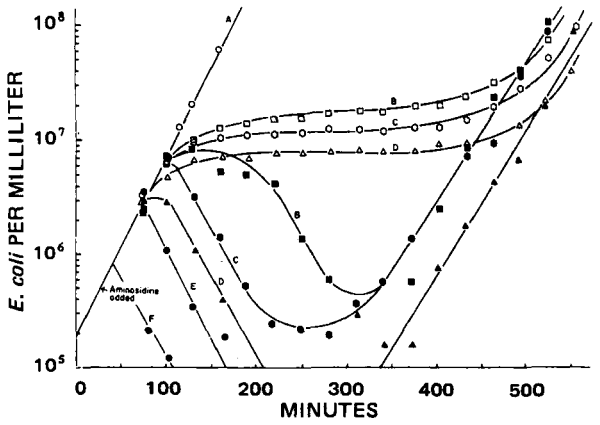

Figure 1—*Drug-affected death rates of* E. coli *in the presence of aminosidine sulfate at pH 7.00 in peptone broth USP. Open symbols are total counts, and solid symbols are viable counts. Key: A, 0.0 μg/ml; B, 4.0 μg/ml; C, 4.5 μg/ml; D, 5.0 μg/ml; E, 5.5 μg/ml; and F, 15 μg/ml.*

can be assigned to concentration-dependent processes of rates of drug permeation into the cell and reaction with receptor sites.

The fact that, after a definitive period of organism kill, there is a subsequent generation of viable organisms (Fig. 1) indicates: (*a*) development of drug-resistant organisms, (*b*) drug degradation in the culture with time, or (*c*) production of antagonists by the culture. The inoculation of fresh medium with these filtered organisms demonstrated generation rates ($k_o = 5.80 \times 10^{-4}$/sec) equivalent to those of naive organisms in the absence of drug, even at drug concentrations more than twice the minimum inhibitory concentrations for these organisms. When the filtrates of these cultures were inoculated with naive organisms, the action of aminosidine was the same as when equivalent amounts of fresh drug were added to fresh cultures.

It was concluded that negligible aminosidine degradation or antagonist production occurred *in situ* and that the later generation of organisms in the presence of bactericidal concentrations of drug was due to the production of resistants. The fact that extrapolation of the semilogarithmic plots for the generation of these resistant organisms (Fig. 1) gave different intercepts for the same inoculum size implied that resistant organisms developed during the generation observed in the presence of drug prior to the establishment of the first-order rate of kill. The longer the time at the lower bactericidal concentrations to obtain this maximum kill rate, the greater was the rate of production of resistant organisms.

Studies on aminosidine-affected microbial generation conducted at drug concentrations below the minimum (3.0 μg/ml) necessary to effect killing of *E. coli* at pH 7.0 demonstrated inhibition of generation rates with no significant kill. The evidence was the coincidence of viable and total counts of organism with time in these dose ranges.

There was a significant difference in the minimum concentration necessary to effect killing at pH 7.0 with various nutrient concentrations of medium. At twice the normal concentration of the nutrient medium, the value was 14 μg/ml but diminished to less than 3.0 μg/ml at half the normal nutrient concentration. This finding is strong evidence for antibiotic binding to the constituents of the medium.

Size distribution plots indicated that at the low drug concentrations studied, the mean size of the organisms decreased from 1.5 to 0.75 μm^3 as the population of the culture approached 1×10^8 *E. coli*/ml. This finding is consistent with the size distribution data observed for drug-free cultures.

At the higher aminosidine sulfate concentrations (*e.g.*, 15 μg/ml), which correspond to the plasma concentrations reached in humans under the recommended therapeutic regimen (8), the mean size remained the same after drug addition but the dispersion increased.

The organism appears to have an ability (Fig. 2) to survive with lessened generation rate until a critical concentration of aminosidine is reached in its biophase, at which time and concentration the process of dying becomes irreversible.

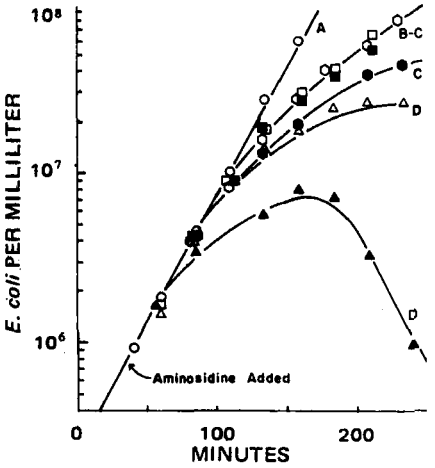

Figure 2—*Drug-affected generation of* E. coli *in the presence of aminosidine at pH 7.00 in peptone broth USP. Open symbols are total counts, and solid symbols are viable counts. Key: A, 0.0 μg/ml; B, 2.75 μg/ml; C, 3.0 μg/ml; and D, 3.25 μg/ml.*

There was no significant difference between the aminosidine- and paromomycin-affected generation curves for *E. coli* for all drug concentrations at pH 7.0 in the normal medium.

pH Effects of Aminosidine Action—Decreasing the pH of the culture medium from 7.8 to 6.1, which had no effect (9) on the generation rate of *E. coli*, increased the time necessary to reach the aminosidine-affected first-order rate of dying (Fig. 3) and increased the minimum concentrations of aminosidine necessary for observation of death from 3.0 to 12 μg/ml. The rate of death at bactericidal concentrations of aminosidine was independent of pH. These facts imply that the degree of protonation of the polyamine aminosidine decreases its rate of permeation into the cell, which may be dependent on the concentrations of species that are least ionized.

Analysis of the potentiometric titration curve (Fig. 4) of aminosidine by the difference method of Parke and Davis (10) permitted estimation of the pKa′ values for each of the five amino groups: 5.47, 6.24, 7.17, 8.15, and 9.07. These pKa′ values were estimated from the pH values at the midpoints of the five equal segments of the difference in titer necessary to achieve the same pH value for 10 ml of the aminosidine solution (0.300 mg/ml) and an equal volume of blank solution. The stoichiometric titer demonstrated that the active aminosidine was 706 μg/mg of the aminosidine sulfate used, which was within 5% of the estimated purity by the manufacturer's microbial assay.

Effects of Aminosidine Combinations with Bacteriostatic

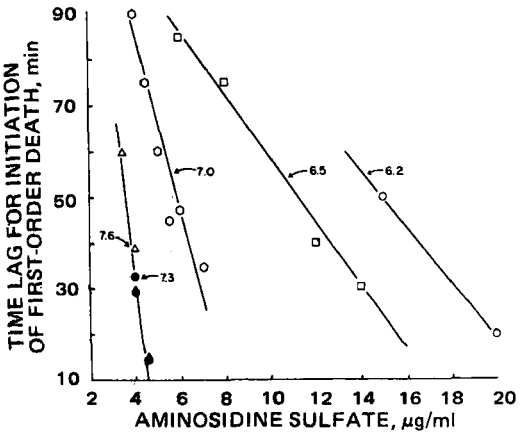

Figure 3—*Dependence of time lag to achieve first-order decay of* E. coli *on aminosidine concentrations. The lag was estimated from the intersection of the extrapolated linear segment of the decreasing log (numbers of organisms) against time with the semilogarithmic plot of the generation of organisms in the absence of drug. Curves are labeled with pH values of the medium.*

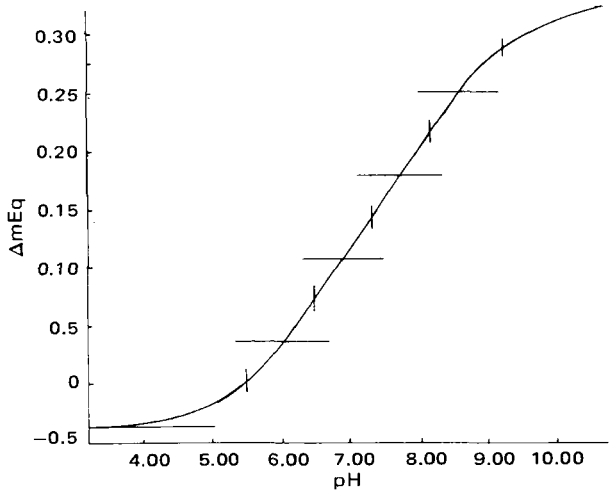

Figure 4—*Plots of the difference in milliequivalents of titer, ΔmEq, necessary to achieve a given pH for 10 ml of 0.300 mg/ml of aminosidine and an equal volume of blank solution against pH. The designated values are apparent pKa′ values at midpoints of five equal segments of the stoichiometric titer.*

Agents—The curves labeled A in Figs. 5–7 represent the generation rate of *E. coli* in the absence of any drug. The curves labeled B represent the action of the bacteriostatic agent alone. The curves labeled C, D, *etc.*, represent the action of aminosidine in combination with that same amount of bacteriostatic agent. The amount of aminosidine increased in the alphabetical order of the labeled curves. The minimum concentration for the ultimate killing rate of aminosidine alone on *E. coli* was 3.5 μg/ml, but it diminished to 1.0 μg/ml in the presence of 90 μg/ml of novobiocin (Fig. 5) and to 2.5 μg/ml in the presence of 0.3 μg/ml of tetracycline (Fig. 6); these combinations may be considered synergistic.

Only in the tetracycline case did combinations with 2.5, 3.0, and 3.5 μg/ml of tetracycline not show the development of resistant organisms on the following day. However, concentrations as high as 4.5 μg/ml of aminosidine in the presence of 1.98 μg/ml of chloramphenicol had less significant effects on *E. coli* generation (Fig. 7), and even this combination demonstrated the ultimate emergence of resistant organisms.

Rationalizations of Aminosidine Action—A toxicity model, similar to that proposed by Jusko (11), can rationalize the ultimate first-order dependency of the aminosidine-affected death rate, $-dN/dt$ (Fig. 1).

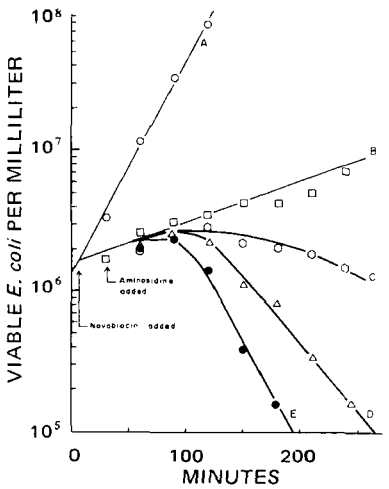

Figure 5—*Generation curves for combinations of aminosidine sulfate and 90 μg/ml of novobiocin. Curve A is for the control culture, and curve B is for novobiocin alone. Curves C, D, and E are for novobiocin combinations with 0.5, 1.0, and 2.0 μg/ml of aminosidine sulfate, respectively. All showed the development of drug-resistant* E. coli *on the following day.*

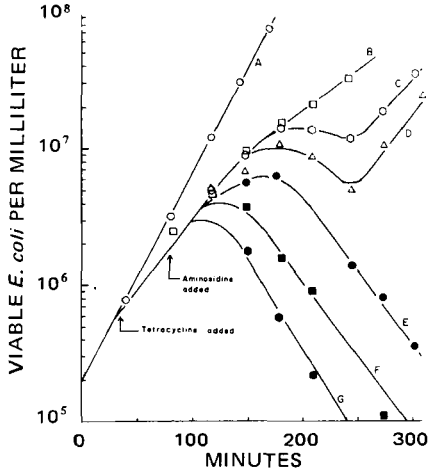

Figure 6—*Generation curves for combinations of aminosidine sulfate and 0.3 μg/ml of tetracycline hydrochloride. Curve A is for the control culture, and curve B is for tetracycline hydrochloride alone. Curves C, D, E, F, and G are for tetracycline hydrochloride combinations with 1.0, 2.0, 2.5, 3.0, and 3.5 μg/ml of aminosidine sulfate, respectively. The cultures of curves E, F, and G showed no subsequent development of resistant organisms.*

If the number of organisms dying per unit of time is proportional both to the net degree of complete inhibition, ΔI, of the biological or metabolic action necessary for organism survival and to the number of organisms, N, then:

$$-dN/dt = k_D(\Delta I)N = k_D(I - I_m)N \qquad \text{(Eq. 1)}$$

when $I > I_m$. The net degree of complete inhibition, ΔI, is a finite value when the degree of inhibition, I, exceeds a minimum value, I_m, below which the repair or homeostatic capacity of an individual organism permits the biological processes to continue at a level that maintains survival. If I is less than I_m, $-dN/dt = 0$ in the absence of generation.

These postulates include the premises that the repair capacity in every individual organism is the same and that a larger net degree of inhibition results in death in a shorter time than a smaller net degree of inhibition. The inhibitory process eventually results in the critical depletion of some biologically necessary product or effect, and thus death results ultimately in all organisms where $I > I_m$.

It follows that for $I > I_m$:

$$\int_{N_{t_1}}^{N} dN/N = \int_{t_1}^{t} k_D(I - I_m)dt \qquad \text{(Eq. 2)}$$

where N_{t_1} is the number of organisms alive at time t_1, and N is the number of organisms alive at time t. Thus:

$$\ln N/N_{t_1} = -\int_{t_1}^{t} k_D(I - I_m)dt \qquad \text{(Eq. 3)}$$

and the fraction, f_A, of organisms at time t_1 alive at any time t is:

$$f_A = N/N_{t_1} = e^{-\int_{t_1}^{t} k_D(I-I_m)dt} \qquad \text{(Eq. 4)}$$

where all ultimately die if $I > I_m$ and $f_A = 0$ at infinite time. Also $f_A = 1$ for all values of $I \leq I_m$ for all times.

If the net degree of inhibition is maintained constant after $t = t_1$, as by a constant concentration of aminosidine in the biophase of the organism, Eq. 4 reduces to:

$$\log N = -[k_D(I - I_m)/2.303](t - t_1) + \log N_{t_1} \qquad \text{(Eq. 5)}$$

which is consistent with the linear plot of log N against time after a time t_1 observed previously for other bactericidals (7) and for all bactericidal concentrations of aminosidine in Fig. 1 when the data are corrected for the emergence of resistant organisms. Thus, for aminosidine at 37.5°:

$$k_{app} = k_D(I - I_m) = 5.36 \times 10^{-4}/\text{sec} \qquad \text{(Eq. 6)}$$

The degree of inhibition of the necessary biological process should be related to a concentration, C', of the toxic agent in the

biophase. In an occupied receptor site model with a finite number of receptor sites, the degree of inhibition can be expressed in terms of the fraction of receptor sites occupied, which is a function of this concentration (12), so that:

$$I = aC'/(1 + aC') \qquad \text{(Eq. 7)}$$

and if the concentration in the biophase is proportional to the concentration in the nutrient medium, $C = C'/\alpha$:

$$I = a\alpha C/(1 + a\alpha C) = a'C/(1 + a'C) \qquad \text{(Eq. 8)}$$

Thus, at very high concentrations, $I = 1$; at low concentrations, $I = a'C$.

Substitution of forms such as Eq. 8 into Eq. 6 results in:

$$k_{app} = k_D \frac{a'C}{1 + a'C} - k_D \frac{a'C_m}{1 + a'C_m} \qquad \text{(Eq. 9)}$$

where C_m is the concentration in the nutrient medium that gives the steady-state concentration C_m' in the biophase that results in the inhibition, I_m, that does not cause death.

At high concentration, the maximum apparent mortality rate constant is:

$$\lim_{c \to \infty} k_{app} = (k_{app})_\infty = k_D - k_D \frac{a'C_m}{1 + a'C_m} \qquad \text{(Eq. 10)}$$

Thus, on consideration of Eqs. 9 and 10:

$$1/[(k_{app})_\infty - k_{app}] = 1/k_D + (a'/k_D)C \qquad \text{(Eq. 11)}$$

and a plot of the reciprocal of the difference between the maximum mortality rate constant, $(k_{app})_\infty$, and the constant, k_{app}, against the concentration where the latter was observed gives a slope of a'/k_D and an intercept, $1/k_D$, from which the values of k_D and a' can be calculated. These calculated values plus the known $(k_{app})_\infty$ permit the calculation of C_m from a rearrangement of Eq. 10:

$$C_m = [k_D - (k_{app})_\infty]/a'(k_{app})_\infty \qquad \text{(Eq. 12)}$$

Thus, from Eq. 12, when $C_m = 0$, $k_D = (k_{app})_\infty$, and from Eq. 9 or 11:

$$1/k_{app} = [1/a'(k_{app})_\infty](1/C) + 1/(k_{app})_\infty \qquad \text{(Eq. 13)}$$

and a plot of the reciprocal of the constant, k_{app}, against the reciprocal of the concentration gives a slope of $1/a'(k_{app})_\infty$ and an intercept of $1/(k_{app})_\infty$, from which the values of a' and $(k_{app})_\infty$ can be calculated when the latter equals k_D. The apparent linear dependency of kill rate on bactericidal concentrations of penicillin, kanamycin, and rifampin (7) at their studied concentrations implies that $a'C$ and $a'C_m \ll 1$, so Eq. 9 can be modified in these cases to:

$$k_{app} = k_D a'(C - C_m) \qquad \text{(Eq. 14)}$$

Aminosidine (Figs. 1 and 2) and also sulfisoxazole (13) are bacteriostatic below a minimum value, but the organisms demonstrate an invariant ultimate first-order dying rate above a certain minimum bactericidal concentration. These observations imply that the saturation of receptor sites, resulting in complete inhibition of the generation rate, results in a statistical probability of dying with organisms inhibited by these agents. Ribosomal binding of aminosidine that results in the misreading of the messenger-RNA that interferes with proper protein synthesis (4) must be initially reversible or else viable and total counts would not be coincident in the subbactericidal concentration range. An additional irreversible process must occur with aminosidine when generation is completely inhibited so as to account for the bactericidal action.

The fact that the time of achievement of the terminal first-order rate of dying decreases with increasing aminosidine concentrations (Fig. 3) implies a concentration-dependent process of aminosidine transfer from the medium into the biophase to effect antibacterial action. This process is confirmed further by the number of viables achieving a smaller maximum with increasing drug concentrations. At aminosidine sulfate concentrations of 15 μg/ml, the mean organism size did not increase after drug addition, implying a more abrupt halt to metabolic activity. This phenomenon is graphically shown in Fig. 8, where the ratio, N_p/N_o, of total organisms (N_o) produced prior to the emergence of resistants with bactericidal concentrations (see plateau values on plots of total organisms against time in Fig. 1) to the inoculum size at drug addition (N)

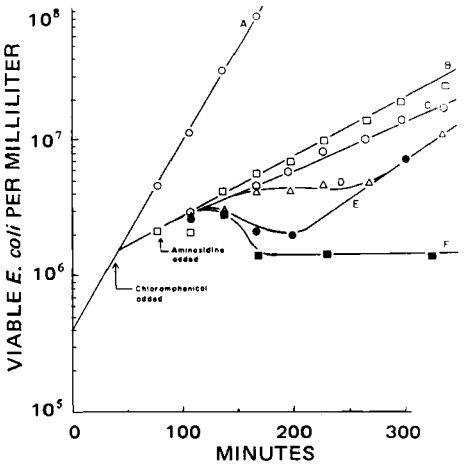

Figure 7—*Generation curves for combinations of aminosidine sulfate and 1.9 μg/ml of chloramphenicol. Curve A is for the control culture, and curve B is for chloramphenicol alone. Curves C, D, E, and F are for chloramphenicol concentrations with 3.0, 3.5, 4.0, and 4.5 μg/ml of aminosidine, respectively. All cultures showed the development of drug-resistant* E. coli *on the following day.*

decreases with aminosidine concentration. This ratio decreases with increasing inoculum size, which may indicate a possible drug binding or drug deactivation dependent on numbers of organisms or of structural mutants present at the time of drug addition. The hypothesis of drug inactivation appears to be negated by the fact that antibiotic-containing medium filtered from drug-affected organisms appeared to maintain its potency against naive organisms. An inoculum size effect of similar small magnitude was shown previously for many organisms (11).

The fact that other bacteriostatic agents, such as tetracycline and novobiocin, decrease the minimum bactericidal concentration of aminosidine implies that generation in their absence produces more receptor sites than necessary to be affected by aminosidine or that the generation process permits repair of the insult engendered by aminosidine.

Aminosidine (4) and tetracycline (3) both bind to the 30S ribosome. The action of novobiocin is not antagonized by tetracycline but is antagonized by chloramphenicol and other 50S binding inhibitors of protein synthesis (7). Thus, by analogous reasoning, it is not unexpected that chloramphenicol lessens the bactericidal activity of aminosidine, and it would be of interest to ascertain if other 50S binding antibiotics, such as erythromycin or lincomycin, act similarly.

The fact that aminosidine acts on organisms affected by such bacteriostatic agents denies a general premise (15) that bactericidals will not be active on organisms whose generation rate is inhib-

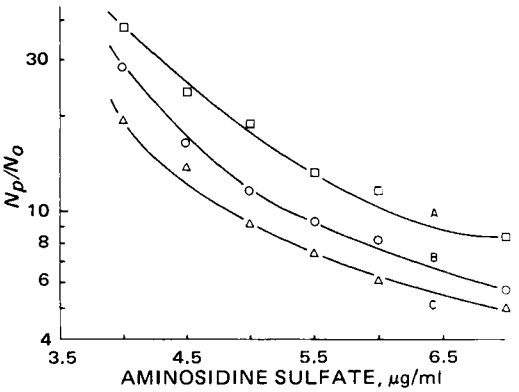

Figure 8—*Effect of inoculum size on aminosidine action. The ratio,* N_p/N_o, *of the plateau value,* N_p, *in total counts to the population,* N_o, *of* E. coli *at the time of drug addition is used as a measure of drug action. The various inoculum sizes were, in* E. coli *per milliliter: A,* 2.8×10^5; *B,* 6.4×10^5; *and C,* 1.29×10^6.

ited by such agents. In fact, the decreased emergence of resistants and lessened minimum concentrations of a drug to affect bactericidal action may indicate the advantages of such combinations.

The emergence of resistant organisms at earlier times with lower bactericidal concentrations of aminosidine (Fig. 1) implies that resistance is acquired in the presence of subbactericidal concentrations of the drug. It is most probably a property exhibited by generating organisms with aminosidine-lessened rates of generation and is consistent with the argument given (4) that altered ribosomes may be produced only by growth in the presence of drug. Aminosidine concentrations of 15 and 25 μg/ml, typical of the plasma levels achieved by the recommended therapeutic regimens (8), caused a rapid initiation of microbial death and did not permit that growth of resistants within 24 hr observed for concentrations below 7 μg/ml. This phenomenon was also observed (7) when penicillin or kanamycin was added to organisms previously treated with bacteriostatic agents, although the final killing rate was also not modified by such prior treatment.

GLC Determination of Carbamazepine Suitable for Pharmacokinetic Studies

ANDRÉ GÉRARDIN [x], FRANÇOISE ABADIE, and JOËLLE LAFFONT

Abstract □ A GLC determination of carbamazepine in plasma and urine is described. It is performed by injecting the cyano derivative, which, in contrast to carbamazepine, has good GLC properties. The method is suitable for pharmacokinetic studies, since it is specific and accurate down to 0.27 μg/ml.

Keyphrases □ GLC—analysis, carbamazepine derivative, plasma and urine □ Anticonvulsants—carbamazepine derivative, GLC analysis, plasma and urine □ Carbamazepine—derivatization, GLC analysis, plasma and urine

Many GLC methods have been described for the determination of anticonvulsants in plasma or serum. Most of them are concerned with the monitoring of the effects of antiepileptic therapy. Some of these methods are suitable for the determination of carbamazepine[1] (I), which is injected either directly or after derivatization (1–12).

Reports on the GLC behavior of I indicate that its thermal stability is weak (6, 8, 9, 13, 14). As a result, some workers have used derivatives such as silylated I (6), dibenz[*b,f*]azepine, which is the thermal decomposition product of I (9), or its methylated derivative, obtained by flash reaction with a quaternary ammonium hydroxide (10). However, flash-reaction techniques sometimes require very precise conditions and may lead to poorly reproducible results. Moreover, these derivatives apparently cannot be obtained in a good state of purity (9). Recently, dimethylformamide dimethylacetal was reported to react with I, giving a derivative suitable for GLC (12).

These techniques generally meet clinical requirements, since the plasma concentrations in patients under continuous therapy (usually 2–10 μg/ml) do not require a high sensitivity. A method for the determination of I in plasma by mass fragmentography has been reported (14). The structure of the selected internal standard is closely related to I to compensate for its loss by thermal decomposition by an equivalent loss of the internal standard.

This paper describes a GLC method for the accurate and sensitive determination of I in plasma and urine, suitable for pharmacokinetic studies and bio-

GLC Determination of Carbamazepine Suitable for Pharmacokinetic Studies

ANDRÉ GÉRARDIN [x], FRANÇOISE ABADIE, and JOËLLE LAFFONT

Abstract □ A GLC determination of carbamazepine in plasma and urine is described. It is performed by injecting the cyano derivative, which, in contrast to carbamazepine, has good GLC properties. The method is suitable for pharmacokinetic studies, since it is specific and accurate down to 0.27 μg/ml.

Keyphrases □ GLC—analysis, carbamazepine derivative, plasma and urine □ Anticonvulsants—carbamazepine derivative, GLC analysis, plasma and urine □ Carbamazepine—derivatization, GLC analysis, plasma and urine

Many GLC methods have been described for the determination of anticonvulsants in plasma or serum. Most of them are concerned with the monitoring of the effects of antiepileptic therapy. Some of these methods are suitable for the determination of carbamazepine[1] (I), which is injected either directly or after derivatization (1–12).

Reports on the GLC behavior of I indicate that its thermal stability is weak (6, 8, 9, 13, 14). As a result, some workers have used derivatives such as silylated I (6), dibenz[*b,f*]azepine, which is the thermal decomposition product of I (9), or its methylated derivative, obtained by flash reaction with a quaternary ammonium hydroxide (10). However, flash-reaction techniques sometimes require very precise conditions and may lead to poorly reproducible results. Moreover, these derivatives apparently cannot be obtained in a good state of purity (9). Recently, dimethylformamide dimethylacetal was reported to react with I, giving a derivative suitable for GLC (12).

These techniques generally meet clinical requirements, since the plasma concentrations in patients under continuous therapy (usually 2–10 μg/ml) do not require a high sensitivity. A method for the determination of I in plasma by mass fragmentography has been reported (14). The structure of the selected internal standard is closely related to I to compensate for its loss by thermal decomposition by an equivalent loss of the internal standard.

This paper describes a GLC method for the accurate and sensitive determination of I in plasma and urine, suitable for pharmacokinetic studies and bio-

availability assays. It involves the formation of 5-cyano-5*H*-dibenz[*b*,*f*]azepine, which is a stable derivative of low polarity, and does not require such expensive equipment as GLC–mass spectrometry.

EXPERIMENTAL

Reagents and Materials—The solvents[2] were analytical grade. Carbon disulfide and methylene chloride were used without further purification. All other solvents were distilled before use. Trifluoroacetic anhydride[3] and triethylamine[3] were used as 10% (v/v) solutions in methylene chloride. Fresh solutions were prepared daily. 10-Methoxycarbamazepine[4] was the internal standard. A 2.5-μg/ml stock solution in methylene chloride was prepared and stored at 4°.

Instrumentation—The GLC determinations were carried out with a gas chromatograph[5] equipped with a flame-ionization detector. The columns were 2-m long glass tubes packed with 5% cyanopropylphenylmethyl silicone[6] on hexamethyldisilazane-treated Chromosorb W (90–115 mesh). The column temperature was 270°. The retention time of the I derivative was about 5 min. Its relative retention volume by comparison with the internal standard was 0.62.

The glassware was cleaned in the usual way and immersed in an ultrasonic bath of chloroform for 15 min. The columns used in the purification step were made up from Pasteur pipets (capillary tips cut off), packed (3 cm high) with silica gel for adsorption column chromatography[7] (activity grade 2). They were immersed in a mixture of ether–pentane (1:1), and the bubbles were drawn off by suction. The prepared columns were stored at a temperature lower than 22°.

Table I—Recovery Experiments[a]

Added, μg/ml	*n*	Mean Recovered, μg/ml	Mean (±*SD*) Recovery, %
0.2	3	0.21	104 (±5.8)
0.5	2	0.48	96
1.2	8	1.22	102 (±4.0)
3.0	2	3.07	102
6.0	2	5.95	99
		Overall	101.3 (±4.7)

[a] The plasma samples were added to known amounts of I.

Procedure—One milliliter of plasma (or urine), 2 ml of ether, 1 ml of internal standard solution in methylene chloride, and 0.25 ml of 30% sodium hydroxide were introduced into a 10-ml ground-glass-stoppered centrifuge tube. The mixture was shaken for 5 min and centrifuged, and the organic phase was removed and evaporated under nitrogen.

The residue was dissolved in 200 μl of ether–pentane (1:1) and transferred to a small column packed with silica gel (described previously). Four milliliters of ether–pentane (1:1) was eluted and discarded, followed by 4 ml of acetone which was collected in a 10-ml glass centrifuge tube and evaporated to dryness under nitrogen.

The residue was dissolved in 100 μl of triethylamine, and 50 μl of trifluoroacetic anhydride was added. The stoppered tube was allowed to stand for 10 min and then 2 ml of hexane and 1 ml of 0.25 *M* sodium hydroxide were added. The mixture was shaken for 3 min and centrifuged. The organic phase was transferred to a conical glass tube and evaporated under nitrogen. The residue was dissolved in 100 μl of carbon disulfide, and 1–5 μl was injected into the gas chromatograph.

The concentrations were read from a calibration curve obtained from methylene chloride solutions containing known amounts of I and the same amount of internal standard as that used for the samples. These solutions were evaporated to dryness under nitrogen, and the residues were derivatized as described.

RESULTS AND DISCUSSION

Derivatization—The I derivative was synthesized (Scheme I) on a preparative scale and identified as Compound II by mass spectrometry.

Anal.—Calc. for $C_{15}H_{10}N_2$: C, 82.54; H, 4.62; N, 12.84. Found: C, 82.32; H, 4.66; N, 12.84.

The internal standard undergoes a similar reaction. A series of samples, containing known amounts of I, was prepared to determine the optimal reaction time. The results (Fig. 1) indicate that the formation of II was completed within a few minutes. The yield,

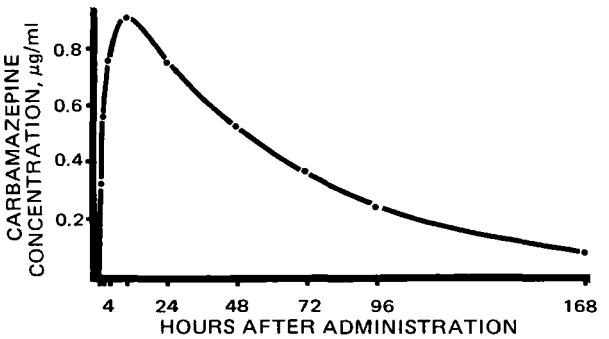

Figure 3—*Plasma concentrations of carbamazepine* versus *time in Subject 6 after the oral administration of a single 100-mg dose.*

Table II—Cross-Check of Methods[a]

Plasma			Urine		
Hours	Isotope Dilution, μg/ml	GLC, μg/ml	Hours	Isotope Dilution, μg/ml	GLC, μg/ml
24	4.28	4.01	0–24	1.28	1.28
48	2.85	3.05	24–48	1.00	1.02
72	2.21	2.25	48–76	0.71	0.72

[a] A volunteer was given a single 400-mg dose of ^{14}C-carbamazepine orally. Samples of blood and urine were collected at the indicated times.

as measured with ^{14}C-carbamazepine, was 85% and did not depend on the amount of carbamazepine. Compound II is stable and can stand as a dry residue for hours before being injected.

GLC—The thermal decomposition of I was thoroughly checked before its derivative was investigated. Various conditions recommended in the literature were carefully reproduced. In addition to the presence of a small peak with the same retention time as dibenzazepine, it was observed that the tailing of the solvent peak was smaller when the pure solvent was injected. This result might imply a partial decomposition of I during GLC. It was confirmed by injecting a larger amount of I (1 μg), which permitted the tailing of the solvent peak to be reduced by increasing the attenuation of the signal. Under these conditions, the chromatogram showed a different baseline level before and after the peak, which is characteristic of this kind of decomposition.

When II was injected, there was no difference in the baseline levels. The peak corresponding to 5 ng was nearly symmetrical, and the response of the flame-ionization detector proved to be linear between 5 ng and 0.5 μg.

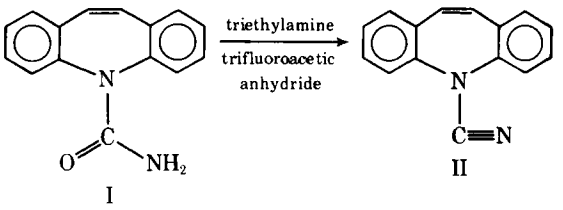
Extraction and Purification—Upon extraction of I, the yield was measured at a plasma concentration of 1 μg/ml and found to be 95%. The crude extracts must be purified to remove cholesterol and other plasma components of low polarity. The absolute yield of the purification step was 87% as measured by adding the internal standard after column chromatography and making the comparison with a pure solution of the two compounds in equal amounts. Experiments showed that the loss was exactly compensated for because the internal standard was lost to the same extent. A series of plasma samples, containing known amounts of I, was prepared to determine a calibration curve; this curve proved to be linear. Therefore, the overall yield of the procedure is not dependent on the concentration of I in the plasma.

Calculations—The calculations were made on the basis of the areas of the peaks. Their ratio remained constant whether I and the internal standard were added to plasma, urine, water, or an organic solution. Furthermore, the ratio remained the same when the internal standard was introduced into the solvent instead of the plasma. Therefore, for convenience, it was decided to use a solution of the internal standard as the extractive solvent and to make the calculations by comparison to a calibration curve obtained from organic solutions containing the same amount of internal standard and known amounts of I.

Recovery Experiments—Plasma samples containing known amounts of I were analyzed according to the described method. Examples of chromatograms are given in Fig. 2. In the blank, the small peak with nearly the same retention time as II corresponds to less than 20 ng/ml of I. The results (Table I) indicated that recovery of I from plasma is quantitative down to 0.2 μg/ml.

Specificity Experiments—A volunteer was given 400 mg of ^{14}C-carbamazepine orally. Samples of blood and urine were collected and analyzed by both inverse isotope dilution and GLC. The results (Table II) indicated a good agreement between the two methods.

The fate of carbamazepine-10,11-epoxide (the main metabolite of I in plasma) during the analytical procedure was investigated. It was shown by elemental analysis and mass spectrometry to undergo a reaction similar to I.



Scheme I—Derivatization of carbamazepine for GLC determination

Anal.—Calc. for $C_{15}H_{10}N_2O$: C, 76.91; H, 4.30; N, 11.96. Found: C, 76.75; H, 4.41; N, 11.87.

However, no peak was obtained with these GLC conditions.

Suitability for Pharmacokinetic Studies—Six healthy volunteers were given I orally in single doses. Blood was collected at different times in heparinized tubes, and plasma samples obtained by centrifugation were kept frozen until analysis. An example of the plasma concentration curves calculated from the results by a digital computer is shown in Fig. 3. The deviation of the experimental points from the calculated curve remains, in all cases, small. Each determination was made in duplicate. The results corresponding to the lowest plasma concentration were 0.084 and 0.078 μg/ml. An extensive study of the pharmacokinetic behavior of I in humans is underway and will be the subject of a future paper.

Antimalarial Amino Alcohols II: Anthraceneaminoethanols and Anthraceneaminopropanols (1- and 9-Substituted)

J. T. TRAXLER ˣ, M. J. MOATS, E. P. LIRA, and C. W. HUFFMAN

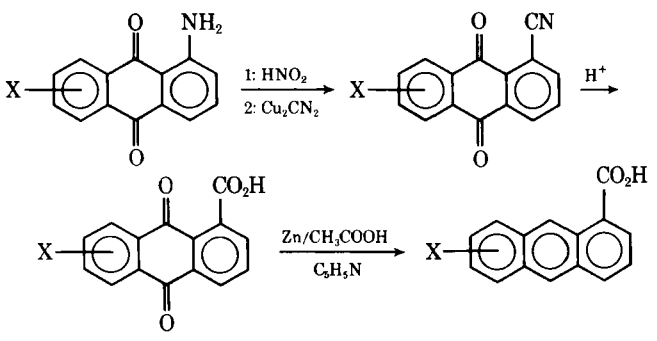
Abstract □ The syntheses of seven anthracene amino alcohols with one, two, or three additional substituents are described. These compounds include three 1-aminoethanols, two 9-aminoethanols, and two 9-aminopropanols, prepared from substituted anthraquinones or from 10-chloro-9-anthraldehydes. The antimalarial activity of these compounds, as well as tentative structure–activity relationships, is discussed in the light of previously published work.

Keyphrases □ Amino alcohols—synthesis of substituted 1- and 9-anthraceneaminoethanols and aminopropanols □ Anthraceneaminoethanols and aminopropanols—synthesis from anthraquinones or anthraldehydes

A previous report (1) summarized earlier investigations into the antimalarial activity of anthracene amino alcohols. Considerably enhanced activity is induced in anthracene-9-aminoethanols if a halogen (preferably chlorine) is substituted for the 10-hydrogen on the anthracene nucleus. Thus, 9-(di-*n*-heptylamino-1-hydroxyethyl)anthracene hydrochloride (2) was curative at 320 mg/kg (two cures out of five[1]) against *Plasmodium berghei* in mice, while the 1-chloro analog (1) was curative (two cures out of five) at 80 mg/kg in the same screen.

Further synthetic work by Stogryn (3), who prepared a series of halogen-substituted anthracene-1-, 2-, and 9-aminoethanols, indicated higher activity (four cures out of five at 80 mg/kg) for 9-(2-di-*n*-heptylamino-1-hydroxyethyl)-4,5-dichloroanthracene. Significant activity (two cures at 320 mg/kg) also was shown (3) by the 1-aminoethanol analog, *i.e.*, 1-(2-di-*n*-heptylamino-1-hydroxyethyl)anthracene, and this activity was increased to three cures out of five at 160 mg/kg by the substitution of chlorine at the 4- and 8-positions. Stogryn's work also showed that anthracenes with the aminoethanol moiety at the 2-position were active but not curative at the highest treatment level used (640 mg/kg).

In an effort to extend these studies and to derive increased antimalarial activity and/or useful structure–activity relationships, the synthesis of additional halogen-substituted anthracene 1- and 9-amino alcohols was undertaken.



Scheme I

RESULTS AND DISCUSSION

The anthracene-1-aminoethanols were prepared from commercially available 1-aminoanthraquinones by a diazonium salt–Sandmeyer combination to give the 1-cyanoanthraquinone derivatives. This preparation was followed by hydrolysis and reduction to the corresponding anthroic acids (Scheme I), which permitted entry into the now classical sequence (4, 5) for the conversion of carboxylic acids to aminoethanols (Scheme II).

Considerable isolation difficulties and poor yields were encountered in the preparation of 6,7-dichloro-1-cyanoanthraquinone until it was realized, on the basis of IR and TLC evidence, that the crude product contained at least one cyanohydrin, formed presumably by reaction of hydrocyanic acid with the anthraquinone carbonyl(s). Oxidation of the crude product with chromium trioxide in acetic acid resulted in a fairly facile isolation procedure for the desired product.

The reduction of 6,7-dichloroanthraquinone-1-carboxylic acid to the corresponding anthroic acid with zinc in ammonium hydroxide resulted in low yields (20–40%) of difficult-to-purify products. It was then found that reduction of the anthraquinone proceeded efficiently if carried out with zinc and acetic acid in pyridine (6).

Because of the finding (3) that several anthracene 1- and 2-amino alcohols could be efficiently prepared by the displacement of the bromine in anthracene 1- and 2-bromomethyl ketones, but not 9-bromomethyl ketones (7), this alternative route to target aminoethanols also was investigated. Reaction of pure (by IR and TLC) 1-bromoacetyl-6,7-dichloroanthracene with di-*n*-butylamine in tetrahydrofuran or dimethylformamide gave the desired amino ketone, but the yield was poor because of the formation of large amounts of di-*n*-butylammonium-6,7-dichloro-1-anthroate[2]. Scarcity of starting material induced the adoption of the sequence given in Scheme II for the preparation of further target anthracene-1-aminoethanols.

This sequence of reactions (Schemes I and II) also was carried out with 1-amino-5-chloroanthraquinone. In this case, however, preparation of the 5-chloro-1-anthroic acid by reduction of the an-

[a] All *n*-alkyl groups. [b] For details of test procedure, see Ref. 19. Test data were supplied by the Walter Reed Army Institute of Research. [c] Increase in mean survival time (IMST) for mice infected with *Plasmodium berghei* after treatment at indicated dosage (in milligrams per kilogram). IMST >6.0 days = active (*); IMST >60 = cure (C). [d] Out of five. [e] Insufficient sample (14.3 mg); not tested. [f] Dosage = 10 mg/kg.

thraquinone with zinc and acetic acid in pyridine gave 5-chloro-1-anthroic acid and 5-chloro-9,10-dihydro-1-anthroic acid in a ratio of about 2:1. Conversion of the anthroic acid to the aminoethanols proceeded *via* Scheme II as expected.

An attempt to prepare other substituted anthracene-1-aminoethanols from benzanthrones (*i.e.*, 7-oxo-7*H*-benz[*d,e*]anthracenes) also was undertaken. The route envisioned involved the preparation of a suitably substituted benzanthrone, followed by oxidation to the anthraquinone-1-carboxylic acid, thus permitting entry into Scheme II after reduction to the corresponding 1-anthroic acid.

The reduction of 6-iodoanthraquinone-1-carboxylic acid [prepared by iodination of benzanthrone (8), followed by oxidation with chromium trioxide in acetic acid] with the classical zinc–ammonium hydroxide procedure resulted, not unexpectedly, in displacement of iodine to give 1-anthroic acid. Use of the much milder basic borane solution (prepared *in situ* from sodium borohydride and boron trifluoride) of Sanchorawala *et al.* (9) gave only a trace of the expected 6-iodo-1-anthroic acid after several experimental modifications. The original plan was to prepare 6-trifluoromethyl-1-anthroic acid by treatment of 6-iodo-1-anthroic acid with trifluoromethyl copper according to McLaughlin and Thrower (10, 11); but in view of the discussed difficulties and of the instability of the trifluoromethyl group to anthraquinone reduction conditions[3], this route was not pursued further.

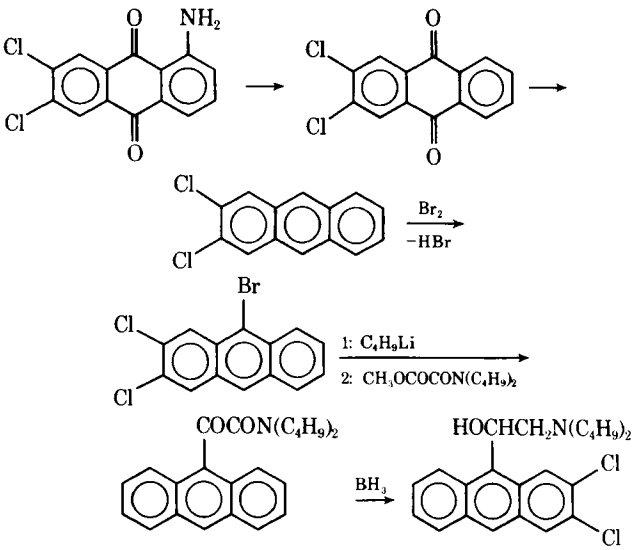
The preparation of anthracene-9-aminoethanols was achieved from 1-amino-6,7-dichloroanthraquinone by diazo deamination, reduction to the anthracene, and bromination–dehydrobromination to give 9-bromo-2,3-dichloroanthracene (Scheme III). The conversion of this material to 9-(2-di-*n*-butylamino-1-hydroxyethyl)-2,3-dichloroanthracene was carried out by the convenient procedure of Temple *et al.* (12). Good recoveries of starting materials resulted from treatment of *N,N*-dibutyl-2,3-dichloro-9-anthrylglyoxylamide and 6,7-dichloro-1-anthroic acid (13, 14) with bromine in acetic acid, as well as from treatment of the glyoxylamide and of 6,7-dichloro-1-anthroyl chloride with bromine in carbon tetrachloride. Reaction of the glyoxylamide with two equivalents of *N*-bromosuccinimide, however, gave a product from which, after reduction with borane, a small amount of 9-(2-di-*n*-butylamino-1-hydroxyethyl)-10-bromo-2,3-dichloroanthracene could be isolated.

The preparation of anthracene-9-aminopropanols was undertaken because of the possibility of increased antimalarial activity, since, with the same substitution pattern and *N*-alkyl groups in the phenanthrenes, the aminopropanols are more active than the aminoethanols[4] (15). The present efforts involved 10-chloro-9-anthraldehydes as starting materials because of their availability (1). Attempts to prepare *N,N*-dibutyl-1-(10-chloro-9-anthryl)-2-hydroxypropionamide *via* a modified Reformatsky procedure (15), as well as the preparation of lithio-*N,N*-dibutylacetamide (for subsequent reaction with 10-chloro-9-anthraldehyde), were unsuccessful.

In view of the higher antimalarial activity of phenanthrene monoalkyl aminoethanols compared to phenanthrene dialkyl aminoethanols (16) and the reactivity of monoalkyl acetamide dianions with phenanthraldehydes (17), attention was turned toward the conversion of the available 10-chloro-9-anthraldehydes to monoalkyl aminopropanols by reaction with dilithio-*N*-butylacetamide, followed by reduction of the amide with borane in tetrahydrofuran. These reactions proceeded generally as expected in the two cases indicated but with poor yields of very crude products. In other instances (*i.e.*, 10-methyl-, 3,10-dichloro-, and 3,6-dibromo-10-chloro-9-anthraldehydes), the presence of the expected crude products was indicated by IR and TLC, but none of the anticipated anthraceneaminopropanols could be isolated after reduction with borane. The complications in the latter three cases may have been caused by the presence of reactive fragments arising from the recently elucidated (18) degradation of tetrahydrofuran by butyl lithium, since excess butyl lithium was used.

The antimalarial activity of these compounds (19) is shown in Table I. The data bear out and extend tentative structure–activity relationships obtained earlier (1, 3) for anthracene amino alcohols. Thus, the *n*-heptyl alkyl groups lend slightly more activity than *n*-butyl (Ia *versus* Ib) (1, 3). With the side chain attached to C_1, monohalogen substitution removed from steric interference with the side chain [*e.g.*, C_5—Cl; Ia and Ib or C_3—Cl (3)] is more active than proximal halogen [*e.g.*, C_8—Cl (3)], and, furthermore, symmetrical [*e.g.*, C_4— and C_8—Cl (3) *versus* Ic] double chlorine substitution is more active than either. Chlorine at C_3, however, is the most active to date in the C_1-side-chain series (3).

The presence of the dialkyl amino alcohol side chain at C_9 on the unsubstituted anthracene nucleus already has been shown[1] to



Scheme III

[3] J. T. Traxler, unpublished observations.

[4] R. E. Strube, Walter Reed Army Institute of Research, personal communication.

be slightly more active than at C_1 (2, 3) and much more active than at C_2 (3). The presence of chlorine and, to a lesser extent, bromine, at C_{10} markedly increases activity (1). Unsymmetrical double halogen substitution (II*a*) is moderately active (curative), but symmetrical double halogen substitution [*e.g.*, 4,5-dichloro (3)] presently is the most active substitution pattern in the anthracene amino alcohols.

The anthracene-9-monoalkyl aminopropanols are much less active than the dialkyl aminoethanols [III*a versus* 9-(2-di-*n*-butylamino-1-hydroxyethyl)-10-chloroanthracene (1)], contrary to the indications cited for the phenanthrenes. As expected, the presence of C_3—CF_3 (III*b*) increases the activity of the 9-monoalkyl aminopropanols but not the level available in the halogen-substituted 9-dialkyl aminoethanols.

EXPERIMENTAL[5]

6,7-Dichloro-1-cyanoanthraquinone—To a stirred solution of 29.2 g (0.10 mole) of 1-amino-6,7-dichloroanthraquinone in 200 ml of sulfuric acid at 5° was added 7.6 g (0.11 mole) of solid sodium nitrite in small portions. The resulting yellow-orange solution was added to about 1.2 liters of ice, stirred well, and filtered. The damp salmon-colored solid was suspended in 200 ml of water and added to a solution of sodium cuprous cyanide [prepared by adding a solution of 38 g (0.77 mole) of sodium cyanide in 100 ml of water to a solution of 46 g (0.184 mole) of cupric sulfate pentahydrate in 200 ml of water and adjustment of the solution pH to 6–7 with sulfuric acid] in a 4-liter beaker at 25° over 2–3 min.

The foamy suspension was warmed to 70° (steam bath) for 2 hr and allowed to stand at 25° overnight. The resulting brown solid was filtered, washed with water, and partially air dried. This material was slurried in 500 ml of acetic acid, and 6.0 g of chromium trioxide in 10 ml of water was slowly added at 25° to oxidize the cyanohydrin. After 0.5 hr under reflux, the acetic acid solution was cooled to 25°, filtered, washed, and air dried to give 24.5 g (81.2%) of red-brown solid, mp 314–318°. A sample of this material was purified by recrystallization from chlorobenzene (two times) followed by sublimation at 200°/0.05 mm to give an analytical sample, mp 326–328°; IR: ν_{max} 2220 (CN) and 1670 (CO) cm^{-1}; TLC (benzene): R_f 0.82.

Anal.—Calc. for $C_{15}H_5Cl_2NO_2$: C, 59.52; H, 1.68; N, 4.64. Found: C, 59.15; H, 1.59; N, 4.35.

6,7-Dichloroanthraquinone-1-carboxylic Acid—To a suspension of 6.0 g (0.02 mole) of 6,7-dichloro-1-cyanoanthraquinone in 20 ml of water was added 75 ml of sulfuric acid in a thin stream with good stirring. Reflux for 0.5 hr gave a dark-brown solution. The reaction mixture was added at about 40° to 600 ml of ice, and the resulting suspension was stirred for 0.5 hr and filtered. Then the precipitate was washed with 50 ml of water and air dried to give 4.5 g of gray solid.

This solid was recrystallized from 50 ml of acetic acid (treated with charcoal[6]) to give 2.65 g of red-brown crystals, mp 275–279° [lit. (20) mp 275–276°]. An additional 0.56 g of product was obtained by concentration of the acetic acid filtrate, giving a total of 3.21 g (50%); IR: ν_{max} 2640 (OH), 1705 (CO), 1675 ($C_{9,10}O$), and 938 (OH) cm^{-1}; TLC (benzene): R_f 0.06.

6,7-Dichloro-1-anthroic Acid—To a solution of 4.1 g (12 mmoles) of 6,7-dichloroanthraquinone-1-carboxylic acid and 15.3 g of zinc dust (0.24 mole) in 150 ml of pyridine, at reflux, was added 65 ml of 80% aqueous acetic acid over 5 hr. The resulting yellow solution was stirred under reflux for an additional 0.5 hr, kept at 25° overnight, and added to a cold (10°) solution of 200 ml of concentrated hydrochloric acid in 1300 ml of water. The mixture was stirred for 15 min and filtered, and the yellow solid was washed with water and dried in a vacuum oven at 80° to give 3.4 g (97.2% crude) of product, mp 302–309°.

Recrystallization from 750 ml of acetic acid gave 1.73 g of product, mp 316–321°. An earlier analytical sample had a melting point of 320–321°. An additional crop of product was obtained by concentration of the acetic acid filtrate, giving a total yield of 2.13 g (61%); IR: ν_{max} 2640 (OH), 1670 (CO), 936 (OH), and 904 ($C_{9,10}H$) cm^{-1}; TLC [benzene–ether (1:2)]: R_f 0.85.

Anal.—Calc. for $C_{15}H_8Cl_2O_2$: C, 61.88; H, 2.78. Found: C, 62.28; H, 2.74.

6,7-Dichloro-1-bromoacetylanthracene—A suspension of 6,7-dichloro-1-anthroyl chloride (1.5 g, 4.8 mmoles, prepared in 65% yield by treatment of 10 mmoles of the acid in benzene with 30 mmoles of oxalyl chloride and recrystallization from methylcyclohexane, mp 193–195°) in 60 ml of tetrahydrofuran was cooled to 0°, and into this magnetically stirred mixture was distilled about 3.0 g of diazomethane (generated from 21.4 g, 0.01 mole, of *p*-tolylsulfonylmethylnitrosamide[7]) in ether over 45 min. Solution was complete after the addition of about one-third of the diazomethane. The reaction solution was allowed to warm to 25° and then was concentrated to 100 ml with a stream of nitrogen at 25°; to the resulting yellow solution at 10° was added 2.0 ml of 48% HBr dropwise.

The stirred solution was allowed to reach 25° and kept at that temperature overnight. The yellow-brown reaction mixture was added to 350 ml of ice water, filtered, washed with water, and air dried to give 1.71 g (96% crude) of yellow solid, mp 150–155°. A sample of this material was recrystallized four times from benzene to give an analytical sample, mp 162–163°; IR: ν_{max} 1675 (CO) and 904 ($C_{9,10}H$) cm^{-1}; TLC (benzene–petroleum ether): R_f 0.91.

Anal.—Calc. for $C_{16}H_9BrCl_2O$: C, 52.21; H, 2.45. Found: C, 52.33; H, 2.81.

5-Chloroanthraquinone-1-carboxylic Acid and Methyl Ester—A solution of 1-amino-5-chloroanthraquinone (39 g, 0.15 mole) in 200 ml of concentrated sulfuric acid was treated portionwise with good magnetic stirring at 5–10° with 12.5 g (0.15 mole) of solid sodium nitrite. The brown solution was stirred at about 5° for 0.25 hr, added to 500 ml of ice, filtered, and dried to a wet cake. The salmon-colored solid was added in portions at 25° to a solution of sodium cuprous cyanide, prepared according to Vogel (21) from 42.0 g of cupric sulfate pentahydrate. The resulting brown foamy mixture was heated for 1 hr on the steam bath and kept at about 60° overnight.

This mixture was filtered, the brown solid was washed with 200 ml of water, and the partially air-dried product was slurried with 600 ml of hot 3% NaOH. The insoluble solid was filtered and washed with 200 ml of hot 3% NaOH, followed by excess water. The partially air-dried 5-chloro-1-cyanoanthraquinone was then added to 800 ml of 65% H_2SO_4 at 25°, and the mixture was heated slowly to reflux, ~125°. After heating for 2 hr at 115–125°, the mixture was cooled to 25° and filtered through a fritted filter. The solid was washed with water and dried to a wet cake on the funnel. Then the filter cake was added to 1200 ml of 20% NH_4OH, and the mixture was heated and stirred at 60° for about 20 min and then filtered to remove 14.55 g of insoluble black solid.

The red filtrate was cooled in an ice bath and acidified with concentrated hydrochloric acid. The resulting yellow-brown solid was filtered, washed, and dried *in vacuo* at 80° to give 9.90 g of a brownish-black solid, mp 304–314° [lit. mp 306° (22) and mp 312° (23)]. An additional 0.60 g of product was obtained by reextracting the brownish-black solid with 750 ml of 20% NH_4OH, giving a total crude yield of 10.5 g (24.7%); IR: ν_{max} 2660 (OH), 1680 (CO), 1670 ($C_{9,10}O$), and 940 (OH) cm^{-1}; TLC (5% ether in benzene): R_f 0.56.

This combined material was very difficult to purify by recrystallization because of its low solubility, so the methyl ester was prepared in 63% yield from methyl iodide by the method of Shaw *et al.* (24) to give a melting point of 177–180° after recrystallization from methanol [lit. (22) mp 181°]; IR: ν_{max} 1725 (CO) and 1275 (OCH_3) cm^{-1}; TLC [benzene–ether (3:1)]: R_f 0.97.

5-Chloro-1-anthroic Acid and 5-Chloro-9,10-dihydro-1-anthroic Acid—Excess zinc dust (12.1 g) was added to a solution of 2.6 g (92 mmoles) of 5-chloroanthraquinone-1-carboxylic acid in 125 ml of pyridine, and the mixture was heated to reflux with mag-

[5] The chemicals were used as obtained from chemical supply houses without purification unless otherwise noted. Melting points were determined with a Thomas-Hoover capillary melting-point apparatus and are not corrected. Most reactions and purification procedures were followed by TLC on Gelman SG (silica gel) sheets. Visualization was accomplished with short- or longwave UV, 0.2% $KMnO_4$ in 1.0% Na_2CO_3, 0.4% bromphenol blue in methanol (for bases; adjust to pH ~8 for acids), iodine vapor, or 0.04% 2,4-dinitrophenylhydrazine in 2 *N* HCl. IR spectra were determined in mineral oil mulls (unless otherwise indicated) with a Beckman IR-5A prism instrument. NMR data were determined at 60 MHz in dimethyl sulfoxide-d_6 with a Varian A-60D instrument by Sadtler Research Laboratories, Philadelphia, Pa. Elemental analyses were carried out with a Hewlett-Packard model 185 carbon, hydrogen, and nitrogen analyzer by the IMC Organic Analysis Group under the direction of Mr. L. Ferrara.

[7] Diazald, Aldrich Chemical Co.

netic stirring. To this refluxing solution was added dropwise, over 5.5 hr, 50 ml of 80% acetic acid. The red solution changed to yellow after about 0.5 hr; after the addition was complete, the clear yellow solution was stirred under reflux for an additional 0.5 hr and kept at 25° overnight. The excess zinc (2.3 g) was removed by filtration, and the filtrate was added to a solution of 150 ml of concentrated hydrochloric acid.

The mixture was stirred and filtered, and the solid was washed and air dried to give 1.4 g of yellow-brown solid, mp 255–285°. The product was recrystallized from 80 ml of acetic acid to give, after treatment with charcoal[6] and standing overnight at 25°, 0.50 g of yellow crystals, mp 285–289°. The filtrate was concentrated on a rotary evaporator to ~70 ml and kept at 10° overnight to give 0.20 g of brown crystals, mp 243–249°. An additional 0.10 g of material was obtained by concentration of this filtrate to 10 ml after standing overnight at 10°.

The higher melting-point product was recrystallized three times more from acetic acid to give an analytical sample, mp 293–294°, of 5-chloro-1-anthroic acid; IR: ν_{max} 2640 (OH), 1660 (CO), 938 (OH), and 901 ($C_{9,10}H$) cm^{-1}; TLC (10% ether in benzene): R_f 0.73; NMR: δ 7.26–7.86 (m, 3H, aromatic), 8.03–8.51 (m, 3H, aromatic), 8.94 (s, 1H, $C_{10}H$), 9.74 (s, 1H, C_9H), and ~13.0 (COOH).

Anal.—Calc. for $C_{15}H_9ClO_2$: C, 70.19; H, 3.53. Found: C, 70.02; H, 3.56.

The lower melting-point solid was recrystallized six times from acetic acid to give an analytical sample of 5-chloro-9,10-dihydro-1-anthroic acid, mp 250–252°; IR: ν_{max} 2640 (OH), 1675 (CO), and 918 (OH) cm^{-1}; TLC (10% ether in benzene): R_f 0.86; NMR: δ 4.08 (broad s, 2H, $C_{10}H_2$), 4.38 (broad s, 2H, C_9H_2), 7.15–7.85 (m, 6H, aromatic), and ~12.7 (b, 1H, COOH).

Anal.—Calc. for $C_{15}H_{11}ClO_2$: C, 69.65; H, 4.28. Found: C, 69.68; H, 4.35.

6-Iodoanthraquinone-1-carboxylic Acid—3,9-Diiodobenzanthrone [1.0 g, 2 mmoles, prepared in 55% yield from benzanthrone by the method of Gotoh and Li (8)] was dissolved in 20 ml of refluxing acetic acid with magnetic stirring. A solution of 2.0 g of chromium trioxide in 25 ml of 25% aqueous acetic acid was added dropwise at reflux over 35 min. The dark-green mixture was stirred under reflux for 2 hr (iodine fumes), 40 ml of warm water was added in a thin stream, and the mixture was allowed to stir while cooling at 25°.

The resulting solid (0.34 g, mp 307–310°) was removed by filtration, and the filtrate was chilled to give a second crop (0.01 g). The chromium salts were neutralized by the addition of 3.7 ml (6.8 g) of concentrated sulfuric acid; and by reducing the volume of the resulting liquid, an additional 0.19 g of product was obtained, giving a total yield of 0.54 g (71%). The combined product was recrystallized from acetic acid to give 0.40 g of light-yellow crystals, mp 309–311°.

A small sample was dissolved in hot ammonium hydroxide and filtered, and the solution was acidified. The resulting solid was recrystallized from acetic acid (three times) to give an analytical sample, mp 314–315°; IR: ν_{max} 2660 (OH), 1700 (shoulder, CO), 1680 ($C_{9,10}O$), and 910 (OH) cm^{-1}; TLC [benzene–ether (1:1)]: R_f 0.44.

Anal.—Calc. for $C_{15}H_7IO_4$: C, 47.64; H, 1.86. Found: C, 47.24; H, 1.96.

9-Bromo-2,3-dichloroanthracene—A suspension of 2.4 g (0.01 mole) of 2,3-dichloroanthracene (prepared in 41% overall yield by diazo deamination of 1-amino-6,7-dichloroanthraquinone followed by zinc–ammonia reduction) in 75 ml of acetic acid at 25° was treated dropwise with 1.6 g (0.01 mole) of bromine in 2 ml of acetic acid. The mixture was stirred at about 30° for 18 hr (hydrogen bromide), heated to boiling, and cooled to 10°. Filtration gave 2.67 g (83.5%) of yellow solid, mp 162–172°, which was recrystallized from toluene (after treatment with charcoal[6]) to give 1.80 g (56.4%) of product, mp 175–182°. An analytical sample was prepared by successive recrystallization of this material from toluene, acetone, and cyclohexane, mp 192–194°; TLC (petroleum ether): R_f 0.96.

Anal.—Calc. for $C_{14}H_7BrCl_2$: C, 51.58; H, 2.17. Found: C, 51.51; H, 2.03.

1-(2-Di-*n*-butylamino-1-hydroxyethyl)-5-chloroanthracene Hydrochloride (Ia)—5-Chloro-1-anthroic acid (3.39 g, 13.4 mmoles) was suspended in 300 ml of benzene, and 3.5 ml (5.06 g, 40 mmoles) of oxalyl chloride was added dropwise with good magnetic stirring. The mixture was stirred at reflux for 2.5 hr (solution after 2 hr) and kept at 25° overnight. A small amount of insoluble brown material was removed by filtration, and the yellow solution was concentrated on a rotary evaporator to give 3.6 g (100%) of yellow crude 5-chloro-1-anthroyl chloride, mp 147–155°; IR: ν_{max} 1750 (CO) and 901 ($C_{9,10}H$) cm^{-1}.

To a solution of 3.6 g (13.4 mmoles) of 5-chloro-1-anthroyl chloride in 100 ml of tetrahydrofuran at 0° was added about 3.0 g (70 mmoles) of diazomethane, generated from 21.4 g of *p*-tolylsulfonylmethylnitrosamide[7]. After stirring at 0° (yellow solid formed) for 0.75 hr, the reaction mixture was concentrated at 25° with a stream of nitrogen to about 100 ml, and 3 ml of 48% HBr was added dropwise with good stirring at 25°. The yellow reaction solution was stirred for 1 hr, added to 600 ml of ice water, and filtered. The yellow solid was washed and air dried to give a golden-yellow solid, 4.07 g, mp 126–132°, 92.7% yield of crude 1-bromoacetyl-5-chloroanthracene; IR: ν_{max} 1665 (CO) and 906 ($C_{9,10}H$) cm^{-1}; TLC (petroleum ether): R_f 0.16.

A solution of crude 1-bromoacetyl-5-chloroanthracene (4.0 g, 12.4 mmoles) in 50 ml of tetrahydrofuran and 30 ml of anhydrous ethanol was treated dropwise at 25° with excess (1.0 g) sodium borohydride in 30 ml of anhydrous ethanol. The solution was stirred at 25° for 0.5 hr and a solution of 3.0 g of sodium hydroxide in 10 ml of water was added dropwise at about 10° with good magnetic stirring, resulting in the separation of a white viscous liquid phase. After the mixture was stirred for 2.5 hr at about 20° (light-yellow solid after 15 min), the reaction mixture was filtered to give, after washing and air drying, 0.36 g of light-yellow product, mp 141–144°; TLC (2% methanol–benzene): R_f 0.94, one major spot; IR: ν_{max} 974 and 842 (epoxide) and 900 ($C_{9,10}H$) cm^{-1}.

The filtrate was added to 1 liter of ice water and stirred well for 0.5 hr; then the solid was washed and air dried to give 2.51 g of light-yellow solid, mp 106–124°. This material was recrystallized from 155 ml of methanol to give an additional 1.34 g of yellow-brown crystalline epoxide, mp 130–134°, shown by TLC and mixed melting point to be slightly less pure than the previous material. The total yield of 5-chloro-1-anthrylethylene oxide was 1.70 g (54.6%).

A mixture of 1.0 g (4.0 mmoles) of 5-chloro-1-anthrylethylene oxide and 7.0 ml of di-*n*-butylamine was stirred at 100° under nitrogen for 18 hr (light-brown solution in about 15 min). The solution was concentrated (rotary evaporator) to give 1.60 g of viscous brown oil, which was dissolved in 300 ml of anhydrous ether and chilled in an ice bath. A saturated solution of hydrogen chloride in ether was added dropwise with good magnetic stirring until a strongly acidic reaction was obtained with moist pH paper. The mixture was kept at 10° for 2 hr, and the light-brown solid was filtered to give 1.10 g, mp 117–130°.

An additional 0.37 g of crude sticky product was obtained by concentration of the ethereal filtrate. The combined product was recrystallized twice from isopropanol to give 1.01 g (58.8%), mp 194–197°. A sample of this material was further recrystallized for analysis from isopropanol (Table II); IR (KBr): ν_{max} 3210 (OH), 2900 and 2855 (CH_2), 2550 (R_3N^+), and 904 ($C_{9,10}H$) cm^{-1}; TLC (free base, 2% methanol–benzene): R_f 0.56.

1-(2-Di-*n*-heptylamino-1-hydroxyethyl)-5-chloroanthracene Hydrochloride (Ib)—A mixture of crude 5-chloro-1-anthrylethylene oxide (0.70 g, 2.67 mmoles, mp 135–145°) and 5.0 ml of di-*n*-butylamine was stirred under nitrogen at 100° for 18 hr (cloudy solution after about 4 hr). The reaction solution was transferred to a 65-mm Hickman still with tetrahydrofuran, and excess amine was removed at 100°/0.02 mm. A small amount of unidentified (nonproduct) yellow sublimate was deposited on the walls of the still. The viscous oily residue in the still was transferred with benzene and concentrated on the rotary evaporator to give 1.0 g of oily product which was dissolved in 250 ml of anhydrous ether. Then a few milliliters of ether was removed by distillation (to dry), the solution was chilled in ice water, and excess hydrogen chloride in ether was added with good magnetic stirring.

The solution (no precipitate formed) was concentrated on a rotary evaporator, and the oily residue was recrystallized from 50 ml of hot methylcyclohexane to give, after standing at 25° and then at 0° overnight, 0.92 g (66.6%) of pink crystals, mp 62–67°. A sample of this material was recrystallized from methylcyclohexane containing a few drops of ethereal hydrogen chloride to give an analytical sample (Table II); IR (KBr): ν_{max} 3210 (OH), 2900 and 2855 (CH_2), 2535 (R_3N^+), and 916 ($C_{9,10}H$) cm^{-1}; TLC (free base) (2% methanol–benzene): R_f 0.84.

1-(Di-*n*-butylamino-1-hydroxyethyl)-6,7-dichloroanthra-

[a] From epoxide and R_2NH. [b] From bromomethyl ketone and R_2NH. [c] From 10-bromo-2,3-dichloroanthracene. [d] From the aldehyde.

cene Hydrochloride (Ic)—To a solution of 6,7-dichloro-1-bromoacetylanthracene (2.15 g, 5.85 mmoles) in 35 ml of tetrahydrofuran was added 1.6 g (11.7 mmoles) of di-*n*-butylamine in 5 ml of tetrahydrofuran, dropwise, with good stirring. The resulting solution was stirred at 25° for 1.5 hr and concentrated on a rotary evaporator, and the resulting brown semisolid was extracted with about 50 ml of petroleum ether (bp 60–110°). After filtration, the solid was washed with about 100 ml of petroleum ether. The air-dried solid, 1.60 g, represented 130% recovery of the calculated amount of di-*n*-butylammonium bromide (see *Results and Discussion*).

The combined petroleum ether solutions were concentrated (rotary evaporator) to give 2.2 g of a yellow-brown viscous oil, which was dissolved in 40 ml of tetrahydrofuran and 20 ml of anhydrous ethanol. To this solution was added a solution of 0.44 g (11.6 mmoles) of sodium borohydride in 10 ml of anhydrous ethanol. The cloudy mixture was stirred at 25° overnight and concentrated on a rotary evaporator. The viscous semisolid residue was dissolved in 110 ml of ether and washed three times with water (100, 50, and 50 ml), and the ether layer was concentrated and dried azeotropically with acetone to give 1.7 g of clear brown viscous oil. This material was dissolved in 250 ml of ether and cooled to 0°, and excess hydrogen chloride in ether was added dropwise with good magnetic stirring.

After stirring at 0° for 0.5 hr, the mixture was filtered to give 0.82 g of light-tan solid, mp 195–205°. Concentration of the ether solution gave 1.0 g of a viscous oil, the IR of which showed carbonyl absorption and no hydroxy or tertiary amine functions. This oil could not be identified by treatment with sodium borohydride, aqueous methanolic sodium hydroxide, or di-*n*-butylamine.

The light-tan solid was recrystallized several times from isopropanol to give a melting point of 232–235°. An analytical sample was recrystallized again from isopropanol (Table II); IR (KBr): ν_{max} 3230 (OH), 2920 and 2852 (CH_2), 2600 (R_3N^+), and 912 ($C_{9,10}H$) cm^{-1}; TLC (free base, 2% methanol–benzene): R_f 0.90.

9-(2-Di-*n*-butylamino-1-hydroxyethyl)-2,3-dichloroanthracene Hydrochloride (IIa)—To a solution of 7.0 g (21.5 mmoles) of crude 9-bromo-2,3-dichloroanthracene in 500 ml of anhydrous ether (nitrogen atmosphere) at 0° was added 10.0 ml of 15% butyl lithium in hexane dropwise over 10 min. The yellow cloudy solution was stirred at 0° for 15 min and cooled to −60° with an isopropanol bath. A solution of 5.1 g (24 mmoles) of methyl-*N,N*-dibutyl oxamate (12) in 75 ml of anhydrous ether was added dropwise at −60°. The resulting reddish solution was stirred for 0.5 hr at −60°, allowed to warm to 25°, and then stirred for 17 hr. The reaction was then quenched by the addition of 250 ml of water in a thin stream with good magnetic stirring.

The layers were separated after filtration of 1.35 g of insoluble material (starting material and 2,3-dichloroanthracene by IR), and the aqueous layer was extracted twice more with 50 ml of ether. The combined ether layers were washed with water (2 × 50 ml), dried with phase separation paper, and concentrated on a rotary evaporator at 65° and then on a vacuum pump at 50°/0.10 mm to give 7.35 g (85.4% crude) of red-brown semisolid, 9-(2,3-dichloroanthryl)-*N,N*-di-*n*-butylglyoxylamide. The crude material could be purified with difficulty by recrystallization from 95% ethanol to give a yellow solid, mp 110–114°; IR: ν_{max} 1670 and 1630 (CO) cm^{-1}; TLC (5% ether–petroleum ether): R_f 0.58.

The crude anthrylglyoxylamide was dissolved in 75 ml of dry (refluxed over and distilled from sodium hydride) tetrahydrofuran and added dropwise to 100 ml of 1 *M* BH_3–tetrahydrofuran, diluted with 75 ml of dry tetrahydrofuran, at 0–5° over 20 min. The yellow solution was stirred for 0.5 hr at 0°, allowed to warm to 25°, stirred under reflux for 1 hr, and allowed to stand at 25° overnight. TLC indicated the absence of starting material, so the solution was cooled to 10° and treated cautiously with 120 ml of 6 *N* HCl.

After no more hydrogen evolution, the tetrahydrofuran was evaporated (steam bath, 1 atm) and the mixture was stirred under reflux for 0.5 hr to hydrolyze the boron complex. To the cooled mixture was added 150 ml of chloroform, the pH was adjusted to 6.5–7.0 with solid sodium bicarbonate, the layers were separated, and the aqueous layer was extracted with chloroform. The combined organic layers were washed (three times) with 75 ml of water and dried with phase separation paper, and the red-brown solution was concentrated on a rotary evaporator to give 6.2 g of red-brown semisolid, to which was added 175 ml of ether. The resulting yellow insoluble solid (0.81 g) was removed by filtration, and the filtrate was diluted with 125 ml of ether and cooled to 10°. An excess of hydrogen chloride in ether was added dropwise with good stirring. After standing (10°) overnight, the yellow sticky solid was filtered and dissolved in 25 ml of isopropanol.

The product was obtained in two crops, mp 213–219° and 212–215°, with a total yield of 1.48 g (15.2%). Recrystallization from isopropanol gave 1.10 g, mp 222–225°. A sample of the product from an earlier exploratory preparation was recrystallized from isopropanol (Table II); IR (KBr): ν_{max} 3190 (OH), 2920 and 2850 (CH_2), ~2540 (R_3N^+), and 900 ($C_{10}H$) cm^{-1}; TLC (free base, 5% ether–petroleum ether): R_f 0.23.

9-(2-Di-*n*-butylamino-1-hydroxyethyl)-10-bromo-2,3-dichloroanthracene Hydrochloride (IIb)—A solution of recrystallized 9-(2,3-dichloroanthryl)-*N,N*-di-*n*-butylglyoxylamide (1.9 g, 4.4 mmoles) in 40 ml of carbon tetrachloride and 0.80 g (4.4 mmoles) of *N*-bromosuccinimide was stirred under reflux for 20 hr, at which time all insoluble material was on top of the solution, but TLC indicated the presence of considerable starting material. An additional 0.80 g (4.4 mmoles) of *N*-bromosuccinimide was added, and the solution was stirred under reflux for an additional 24 hr. Filtration of the cooled solution gave 0.84 g (97.8%) of suc-

cinimide. Concentration of the filtrate on a rotary evaporator gave 2.01 g of crude product, which was recrystallized from anhydrous ethanol to give, after filtration, a yellow-brown insoluble material, mp 140–150°. This material showed one major spot on TLC (5% ether–petroleum ether) at R_f 0.74; IR (film): ν_{max} 2950 and 2850 (CH_2) and 1655 and 1630 (CO) cm^{-1}.

The crude bromodichloroglyoxylamide (2.0 g, about 3.9 mmoles) in 20 ml of dry (refluxed over and distilled from sodium hydride) tetrahydrofuran was added to a solution of 30 ml of 1 *M* BH_3 in tetrahydrofuran in 20 ml of pure tetrahydrofuran at 0–3° over 20 min under nitrogen. The reaction mixture was stirred for 0.5 hr at 0°, allowed to reach 25°, and refluxed for 2.5 hr (monitored for disappearance of starting material by TLC). Then the reaction mixture was cooled to 5°, and 40 ml of 5 *N* HCl was added dropwise with good stirring.

After decomposition of excess borane, the tetrahydrofuran was evaporated on the steam bath and the mixture was stirred under reflux for 0.5 hr. Chloroform (60 ml) was added to the cooled hydrolysis mixture, which was then neutralized with solid sodium bicarbonate to about pH 7 (pH paper). The layers were separated, and the aqueous layer was extracted once with chloroform. The combined organic layers were washed with water, dried with phase separation paper, concentrated on the rotary evaporator, and dried at 60°/0.01 mm to give 1.6 g of brown viscous liquid.

To this material was added 300 ml of ether, 0.25 g of insoluble material (nonproduct) was removed by filtration, and the chilled (0°) solution was treated with excess hydrogen chloride in ether. The resulting mixture was kept at 0° for 2 hr and filtered to give 0.23 g of air-dried brown solid, mp 205–215°. Further concentration of the filtrate gave 0.12 g of a mixture of 2,3-dichloro- and 9-bromo-2,3-dichloroanthracene as well as 0.94 g of an unidentifiable brown viscous oil.

Recrystallization of the product (0.23 g) twice from isopropanol gave light-yellow crystals, mp 241–242°. A sample of this material was recrystallized from isopropanol for analysis (Table II); IR (KBr): ν_{max} 3200 (OH), 2940 and 2860 (CH_2), and ~2550 (R_3N^+) cm^{-1}; TLC (free base) (2% methanol–benzene): R_f 0.84.

9-(3-*N*-*n*-Butylamino-1-hydroxypropyl)-10-chloroanthracene Hydrochloride (IIIa)—A solution of *N*-*n*-butylacetamide (2.76 g, 24 mmoles) in 100 ml of dry tetrahydrofuran was cooled to about −5° under nitrogen. To this vigorously stirred solution was added dropwise a solution of 1.6 *M* butyl lithium in hexane (30 ml, 48 mmoles). The resulting cloudy solution was stirred at from −5 to −10° for 2 hr and then treated dropwise with a solution of 10-chloro-9-anthraldehyde (3.61 g, 15 mmoles) in 150 ml of dry tetrahydrofuran; it was then stirred at −5° for 2 hr.

The reaction mixture was stirred at room temperature overnight and then at reflux for 1.5 hr. The yellowish-red solution was cooled to 2–5° and then treated with acetic acid (3.5 ml) in tetrahydrofuran (20 ml). The solution was stirred for 15 min, water was added, and the solution was stirred for an additional 30 min. Then the mixture was stripped to near dryness and partially taken up with chloroform (500 ml) and water (200 ml). The solid at the interface was isolated by filtration to yield the crude product, 1.8 g (21.5%), mp 208–210° dec. This sample was recrystallized from acetone to yield 1.15 g, mp 208–210° dec., one spot on TLC (50% ether–benzene); IR: ν_{max} 3310 (OH) and 1600 (CO) cm^{-1}.

The chloroform solution was washed with aqueous sodium carbonate and then water, dried, reduced in volume by one-half, and cooled to yield the pure product, 1.4 g (26%), mp 208–210° dec. The combined product was used in the following borane reduction.

To a −5° solution of 1 *M* BH_3 (12 ml, 12 mmoles) in tetrahydrofuran (15 ml) under a nitrogen atmosphere was added dropwise a solution of *N*-*n*-butyl-3-(10-chloro-9-anthryl)-3-hydroxypropionamide (2.3 g, 6.08 mmoles) in 90 ml of tetrahydrofuran. The reaction solution was maintained at −5° for 2 hr, at room temperature overnight, and then at 60° for 23 hr. More borane (10 ml, 10 mmoles) was then added, and the solution was heated for 2.5 hr at 60°.

The solution was cooled and treated cautiously with water and then evaporated to dryness *in vacuo* to give an off-white solid. This solid was taken up in methanol (60 ml) and 10% H_2SO_4 (9 ml) and then heated at reflux for 3 hr. The solution was cooled in ice, and the pH was adjusted to 10.5 with 1 *N* NaOH. The precipitated solid was partitioned between ether and water.

The resulting three-phase system was then filtered to give 0.66 g, mp 151–153° (starting material and unidentified by-products by IR), the layers were separated, and the ether layer was concentrated on a rotary evaporator to give, after azeotropic drying with benzene, 1.5 g of a yellow semisolid. The semisolid was dissolved in about 400 ml of ether, the solution was cooled in an ice bath, and excess hydrogen chloride in ether was added dropwise. The mixture was stirred at 0° for 1 hr, kept at 10° overnight, and filtered to give a light-pink solid, mp 190–213° dec.

Recrystallization of this solid from isopropanol (color change to yellow upon heating) gave 0.82 g of a yellow solid, mp 240–242° dec. Several smaller crops were obtained by concentration and by addition of ether to the filtrates, giving a total yield of 0.98 g. The combined product was suspended in ether–tetrahydrofuran (2:1) and treated with 25 ml of 2 *N* NaOH. The layers were separated and the organic layer was washed with water to pH 7, concentrated on a rotary evaporator, and dried with benzene to give 0.86 g of light-yellow solid. This solid was dissolved in 400 ml of ether and treated with excess hydrogen chloride–ether dropwise in an ice bath. The resulting pink precipitate (0.62 g, mp 211–214°) was recrystallized from 20 ml of isopropanol to give 0.55 g of a yellow solid, mp 234–236° dec. An analytical sample was prepared by recrystallizing this material from isopropanol and then from chloroform–ethanol–cyclohexane (Table II); IR (KBr): ν_{max} 3300 (OH), 2900 and 2840 (CH_2), and 2750 (R_2NH^+) cm^{-1}; TLC (free base) [methanol–benzene (1:1)]: R_f 0.80.

9-(3-*n*-Butylamino-1-hydroxypropyl)-10-chloro-3-trifluoromethylanthracene Hydrochloride (IIIb)—To a solution of *N*-*n*-butylacetamide (1.19 g, 10.3 mmoles) in 43 ml of dry tetrahydrofuran under a nitrogen atmosphere, cooled to about −5°, was added dropwise a solution of 1.6 *M* *n*-butyl lithium in hexane (12.9 ml, 20.7 mmoles). After the resulting cloudy solution was stirred for 3 hr at from −5 to −10°, a solution of 10-chloro-3-trifluoromethyl-9-anthraldehyde (2.00 g, 6.47 mmoles) in 60 ml of dry tetrahydrofuran was added dropwise at −5°. The cooling bath was slowly allowed to rise to 25° while the reaction mixture was stirred overnight.

The reaction mixture was refluxed on a steam bath for 1.5 hr and subsequently found to contain no unreacted starting material *via* TLC, using 10% ether in hexane on silica gel sheets. The dark-brown solution was cooled in ice and hydrolyzed by the dropwise addition of 10% ammonium acetate (130 ml). The pH was adjusted to 7 with acetic acid, and the layers were separated. The aqueous phase was extracted with 4 × 25 ml chloroform, and the combined organic layers were dried over anhydrous sodium sulfate.

Evaporation of the solvent gave a brown oil, which yielded 2.0 g of yellow-brown solid, mp 120–135°, on trituration with hexane. TLC (10% ether–benzene) showed the amide to have R_f 0.33 and to be contaminated with slight impurities at the origin and at R_f 0.8; IR: ν_{max} 3280 (OH), 1600 (CO), and 1168 and 1120 (CF_3) cm^{-1}. The crude *N*-*n*-butyl-3-(10-chloro-3-trifluoromethyl-9-anthryl)-3-hydroxypropionamide was used in the subsequent reduction.

To a stirred solution of 10 ml of 1 *M* BH_3–tetrahydrofuran in 21 ml of dry tetrahydrofuran, cooled to −5° under nitrogen, was added dropwise a solution of *N*-*n*-butyl-3-(10-chloro-3-trifluoromethyl-9-anthryl)-3-hydroxypropionamide (2.0 g, 4.72 mmoles) in 85 ml of dry tetrahydrofuran. The mixture was allowed to stir overnight, then 20 ml of 1 *M* BH_3–tetrahydrofuran was added, and the mixture was refluxed for 24 hr. At the end of the reflux period, no carbonyl absorption could be detected in the IR.

The yellow reaction mixture was cooled in ice and hydrolyzed by the dropwise addition of 5 ml of water–tetrahydrofuran (1:1). The solution was stripped to dryness under vacuum, and the yellow semisolid was refluxed with a solution of 7 ml of 10% H_2SO_4 in 30 ml of methanol for 4 hr. The solution was then cooled in ice, and the pH was adjusted to 10–11 with 1 *N* NaOH. The solution and precipitate were extracted with 3 × 50 ml of ether, and the ether extracts were washed with water and dried over anhydrous sodium sulfate. The ethereal solution was evaporated to a small volume and then diluted to 500 ml with ether. This process was repeated an additional time, and the resulting solution of amine in 500 ml of ether was used to prepare the hydrochloride.

The ethereal solution of amine was cooled in an ice bath, and 50 ml of hydrogen chloride in ether was added dropwise with stirring. The precipitated hydrochloride salt was filtered and washed with ether. The salt was dissolved in 4 ml of isopropanol and chilled to give the yellow hydrochloride, mp 185–190° dec. Concentration of the ethereal filtrate gave an oil, which yielded additional hydrochloride on crystallization from isopropanol–hexane.

A total of 150 mg (7.1%) of the hydrochloride was isolated. Recrystallization from isopropanol gave an analytical sample (Table II); TLC (free base) (5% methanol–benzene): R_f 0.44; IR (KBr): ν_{max} 3300 (OH), 2930 and 2850 (CH_2), 2750 (R_2NH^+), and 1165 and 1120 (CF_3) cm^{-1}. On standing, the melting point of the salt dropped to 120–130°, although TLC showed a single spot with the same R_f. TLC in two additional systems also showed a single component. The decrease in melting point may have been due to crystalline polymorphism.

Synthesis and Biological Evaluation of Potential Hypoglycemic Agents I: Carnitine Analogs

SHARON G. BOOTS and MARVIN R. BOOTS [x]

Abstract □ A series of 4-dialkylamino-3-hydroxybutyric acid hydrochlorides and methochlorides, analogs of carnitine, was synthesized by treatment of *tert*-butyl 3,4-epoxybutyrate with the appropriate amine or amine hydrochloride in methanol followed by mild acid hydrolysis. The compounds had no effect on blood glucose or serum fatty acid levels in rats.

Keyphrases □ Carnitine analogs—potential hypoglycemic agents, synthesis, biological evaluation, IR and NMR spectra □ Hypoglycemic agents, potential—carnitine analogs, synthesis, biological evaluation, IR and NMR spectra

For years, diabetes mellitus has been described as a disorder of carbohydrate metabolism and the changes observed in lipid metabolism were thought to be secondary. Recently, however, Randle (1) suggested that the primary event in the development of diabetes mellitus might be an abnormality of glyceride metabolism.

Randle suggested a possible mechanism involving an increased release of free fatty acids. This release, in turn, produces a resistance to the hypoglycemic action of insulin, thereby causing a rise in fasting glucose levels and eventual exhaustion of the pancreatic β-cells. As a result of the increased serum free fatty acid levels, a corresponding increase in the rate of fatty acid oxidation is noted. This increase causes the tissue concentration of acetyl coenzyme A to rise, which results in a disruption of carbohydrate metabolism (2) through inhibition of several enzymes (pyruvate dehydrogenase, phosphofructokinase, and hexokinase).

If this hypothesis is correct, a possible approach to the treatment of diabetes mellitus would involve the design of agents that would decrease the high rate of fatty acid oxidation and increase glucose oxidation. Evidence in support of this approach is provided by the hypoglycemic activity of α-bromopalmitic acid (3), a known inhibitor of fatty acid oxidation (4).

Using the Randle hypothesis as a basis, Stewart

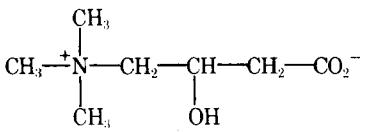
[a] Attempted distillation of III*a*–III*d* led to extensive decomposition; therefore, no boiling-point or analytical data are reported. The spectral data are reported because this method was used for identification of these products. [b] IR spectra for III*a*–III*d* were run as liquid films. NMR spectra for III*a*–III*d* were run in deuterochloroform. [c] IV*a*–IV*d* were recrystallized from absolute ethanol–acetone to yield white prisms. [d] IR spectra for IV*a*–IV*d* were run as mineral oil mulls. NMR spectra for IV*a*–IV*d* were run in deuterium oxide.

and Hanley (5) suggested several sites where control of fatty acid metabolism is feasible. One possible point of pharmacological control would involve the inhibition of entry of long chain (>10 carbons) fatty acid coenzyme A derivatives into the mitochondria where oxidation occurs. Since long chain fatty acid coenzyme A derivatives cannot diffuse through the mitochondrial membrane, a transport system is required if they are to reach the enzymes involved in β-oxidation. This mechanism is called carnitine transport, and it is dependent on the presence of (−)-carnitine (I) and carnitine acyl transferases to transport long chain fatty acids into the mitochondria. The activity of this system has been shown to increase in livers of diabetic rats (6) and appears to be rate limiting for fatty acid oxidation.

Thus, the goals of this study were the design and synthesis of analogs of carnitine that would act as inhibitors of this transport system. Relatively few compounds have been studied as inhibitors of carnitine acyl transferases (7). Norcarnitine acts as a substrate in the absence of carnitine and as a competitive inhibitor in the presence of carnitine. Other related compounds, (*RS*)-β-hydroxy-γ-aminobutyric acid, *tert*-butylacetic acid, (*RS*)-β-hydroxy-γ-dimethylaminobutyramide, and choline, failed to act as inhibitors or substrates in this system.

A weak competitive inhibitor (3-deoxycarnitine) resulted when the β-hydroxyl group of carnitine is removed (7). The observed reduction of the affinity of



I

3-deoxycarnitine for the enzyme may result from a loss of the hydroxyl group as a binding site. Alternatively, the loss of the hydroxyl group may produce a change in the conformation of the inhibitor molecule, which alters its ability to bind to the enzyme.

These preliminary data indicate that the distance between the carboxyl group and the cationic function may be important. Therefore, initial synthetic efforts were directed toward compounds having the same chain length found in carnitine.

Thus, a series of dialkylaminohydroxybutyric acid hydrochlorides (IV*a*–IV*d*) and methochlorides (VI*a*–VI*c*), analogs of carnitine, was synthesized and evaluated with regard to their effects on blood glucose and serum free fatty acid levels.

DISCUSSION

tert-Butyl 3,4-epoxybutyrate (II) (8) was used as the starting material for the synthesis of the carnitine analogs IV*a*–IV*d* and VI*a*–VI*c* (Scheme I). The epoxy ester II readily reacted with the four secondary amines shown in Table I in methanol to provide the desired dialkylaminohydroxy esters (III*a*–III*d*). The yields were variable, and the major side reaction that occurred will be discussed in a future publication. The NMR spectral data afforded evidence that nucleophilic attack by the amine occurred at the desired 4-position and not at the 3-position. Hydrolysis of III*a*–III*d* with a dilute hydrochloric acid solution yielded the desired dialkylaminohydroxybutyric acid hydrochlorides (IV*a*–IV*d*) (Table I).

The synthesis of VI*a*–VI*c* was patterned after the synthesis of (*RS*)-carnitine chloride (8). It was found that II could be converted directly into the *tert*-butyl dialkylamino-3-hydroxybutyrate methochlorides (V*a*–V*c*) by treatment with the appropriate tertiary amine hydrochloride in methanol (Table II).

Hydrolysis of the esters V*a*–V*c* to the desired free acids VI*a*–VI*c* was again carried out by treatment with dilute hydrochloric acid. Although VI*a*–VI*c* (Table II) were all extremely hygroscopic (as were V*a*–V*c*), satisfactory NMR spectral data were obtained for all compounds. Since VI*c* could not be obtained in crystalline form, analytical data were obtained for the tetraphenylboronate salt (9).

Table II—Properties of Compounds Va–Vc and VIa–VIc

Compound	R_1	R_2	R_3	Yield, %	Physical Description (Melting Point when Crystalline)	NMR Data, ppm	Formula	Analysis, % Calc.	Found

[a] Attempted purification of Va–Vc by crystallization was unsuccessful; therefore, no analytical data are reported. [b] IR spectra for Va–Vc and VIa–VIc could not be run because these compounds were extremely hygroscopic. [c] NMR spectra for Va–Vc and VIa–VIc were run in deuterium oxide. [d] Although satisfactory analytical data were obtained for this compound, it was too hygroscopic to obtain a melting point. [e] VIb was recrystallized from absolute ethanol–acetone. [f] VIc was analyzed as the tetraphenylboronate salt (Ref. 9) because the chloride could not be obtained in crystalline form.

RESULTS

Hypoglycemic Activity in Rats—Three control and three treated male rats, 140–160 g, from the local Harlan colony were fasted for 18 hr. All rats were given 100 mg of glucose in water subcutaneously, followed immediately by a single oral administration of the test compound in 5% aqueous acacia. Control rats received an equal volume of the vehicle. Blood samples were taken from the tail vein of all animals at 2 and 5 hr after administration of the test compound and were assayed for glucose with an automatic analyzer[1] using a modification of the method of Hoffman (10). Results for blood glucose are reported as the percent difference of the mean value for the treated animals from the mean value for the control animals.

No significant differences in the blood glucose levels relative to controls were observed for IVa–IVd and VIa–VIc when administered orally at a dose of 100 mg/kg.

Serum Free Fatty Acids—Three control and three treated male rats, 140–160 g, from the local Harlan colony were fasted for 18 hr. A single oral administration of the test compound in 5% aqueous acacia was given to the treated rats. Control rats received an equal volume of the vehicle. Blood samples were taken from the orbital sinus of all animals 1 hr after administration of the test compound for determination of serum free fatty acids. Serum free fatty acids were extracted using the method of Dole and Meinertz (11) and were assayed with an automatic analyzer[1] using the method of Baird *et al.* (12). Results for serum free fatty acids are reported as the percent difference of the mean value for the treated animals from the mean value for the control animals.

No significant differences in the serum free fatty acid levels relative to control levels were observed after IVa–IVd and VIa–VIc were administered orally at a dose of 100 mg/kg.

EXPERIMENTAL[2]

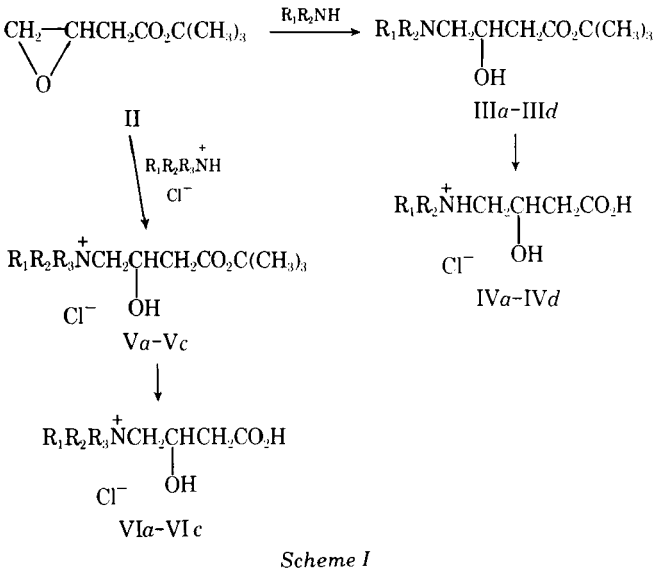
***tert*-Butyl 4-Diethylamino-3-hydroxybutyrate (IIIa)**—This example typifies the method used to prepare IIIa–IIId (Table I). To a solution of 1.58 g (0.010 mole) of *tert*-butyl 3,4-epoxybutyrate (II) (8) in 6 ml of methanol was added 1.3 ml (0.013 mole) of distilled diethylamine. The pale-yellow solution was stirred at 26° for 21 hr under a dry nitrogen atmosphere. The solvent was removed under reduced pressure to afford 1.91 g of a yellow liquid. This liquid was added to ether and an ice-cold 5% hydrochloric acid solution.

The acidic, aqueous extract was adjusted to pH 12 with 5% sodium hydroxide and then was extracted with ethyl acetate. The organic phase was washed with water and then a saturated sodium chloride solution. The organic phase was dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure to afford 0.943 g (41%) of IIIa as a pale-yellow liquid.

Attempted distillation of IIIa, as well as IIIb–IIId, resulted in extensive decomposition, so these products were identified by spectral methods only; IR (liquid film): 3420 (OH) and 1730 (ester C=O) cm^{-1}; NMR (deuterochloroform): δ 1.04 (t, J = 7 Hz, 6H, CH_3 in ethyl groups), 1.48 [s, 9H, $-C(CH_3)_3$], 2.32–2.83 [m, 8H, $(-CH_2)_2NCH_2-$, $-CH_2CO_2-$], 3.82 (s, 1H, —OH), and 3.75–4.73 (m, 1H, >CH—) ppm.

4-Diethylamino-3-hydroxybutyric Acid Hydrochloride (IVa)—This example typifies the method used to prepare IVa–IVd (Table I). A solution of 0.943 g (0.004 mole) of IIIa in 20 ml of 7% hydrochloric acid was stirred at 25° for 20 hr under a nitrogen atmosphere. The water was removed under high vacuum at 50° to afford 0.863 g of a pale-yellow oil, which crystallized upon trituration with acetone followed by storage at 5° for 3 days.

The acetone was removed from the resulting white crystalline solid and the solid was dried, affording 0.723 g (83%) of IVa, mp



Scheme I

[1] Technicon Autoanalyzer.

[2] Melting points were determined with a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Elemental analyses were obtained from Galbraith Laboratories, Knoxville, Tenn. IR spectra were determined using a Perkin-Elmer model 237 spectrophotometer. NMR spectra were determined on a Perkin-Elmer model R-24 spectrometer in deuterochloroform, using tetramethylsilane as the internal reference, or in deuterium oxide, using sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal reference.

104–106°. An analytical specimen of IV*a*, mp 109–111°, was prepared by recrystallization from absolute ethanol–acetone; IR (mineral oil): 1718 (CO_2H) cm^{-1}; NMR (deuterium oxide): δ 1.28 (t, J = 7 Hz, 6H, CH_3 in ethyl groups), 2.65 (d, J = 6 Hz, 2H, $—CH_2CO_2—$), 3.05–3.50 [m, 6H, $(—CH_2)_2NCH_2—$], and 4.20–4.80 (m, 1H, >CH—) ppm.

***tert*-Butyl 4-Ethylmethylamino-3-hydroxybutyrate Methochloride (V*a*)**—This example typifies the method used to prepare V*a*–V*c* (Table II). A mixture of 0.656 g (4.2 mmoles) of *tert*-butyl 3,4-epoxybutyrate (II) (8), 0.361 g (3.30 mmoles) of dimethylethylamine hydrochloride, and 2.0 ml of anhydrous methanol was allowed to stand at 25° for 6 days in a glass-stoppered flask. The methanol was removed under reduced pressure, and the residue was added to ether and water. The organic phase was washed an additional time with water, and the aqueous extracts were combined. The water was removed under high vacuum at approximately 30–40°, and then the traces of water remaining were removed by azeotropic distillation with four 10-ml portions of *tert*-butyl alcohol under reduced pressure.

The resulting oil was dried for 19 hr at 25° under high vacuum (a pale-cream semisolid resulted after drying). All attempts at further purification by recrystallization failed, since all compounds listed in Table II were extremely hygroscopic; NMR (deuterium oxide): δ 4.30–4.60 (m, >CH—, no integration on this proton could be obtained because it was located underneath the HOD peak), 3.32–3.75 (m, 4H, $—CH_2NCH_2—$), 3.12 [s, 6H, $(CH_3)_2N—$], 2.57 (d, J = 6 Hz, 2H, $—CH_2CO_2—$), 1.45 [s, 9H, $—C(CH_3)_3$], and 1.35 (t, J = 6 Hz, 3H, CH_3— in ethyl group) ppm.

4-Ethylmethylamino-3-hydroxybutyric Acid Methochloride (VI*a*)—This example typifies the method used to prepare VI*a*–VI*c* (Table II). A solution of 0.760 g (2.86 mmoles) of V*a*, 50 ml of water, and 2.4 ml of concentrated hydrochloric acid was stirred at 25° for 17 hr. The water was removed at 30–40° under high vacuum, and then four 30-ml portions of *tert*-butyl alcohol were added as described for V*a* to remove azeotropically the remaining water. The resulting pale-yellow viscous oil (0.550 g, 91%) was triturated with acetone and a few drops of absolute ethanol. The white gummy oil crystallized slowly after standing at 5° for 5 days.

The resulting white prisms were dried under high vacuum at 25° for 1 day. The yield was 0.266 g (44%) of VI*a*, which was too hygroscopic to obtain melting-point or IR data; NMR (deuterium oxide): δ 4.55–4.82 (m, >CH—, no integration on this proton could be obtained because it was located underneath the HOD peak), 3.30–3.70 (m, 4H, $—CH_2NCH_2—$), 3.12 [s, 6H, $(CH_3)_2N—$], 2.67 (d, J = 6 Hz, 2H, $—CH_2CO_2—$), and 1.35 (t, J = 6 Hz, 3H, CH_3— in ethyl group) ppm.

Anal.—Calc. for $C_8H_{18}ClNO_3$: C, 45.4; H, 8.5; N, 6.6. Found: C, 45.2; H, 8.4; N, 6.4.

Alkaloids of *Vinca rosea* L. (*Catharanthus roseus* G. Don) XXXVI: Isolation and Characterization of New Dimeric Alkaloids

S. TAFUR ˣ, W. E. JONES, D. E. DORMAN, E. E. LOGSDON, and G. H. SVOBODA

Abstract □ In a continuing effort to study thoroughly the alkaloids of *Catharanthus roseus*, new dimeric alkaloids were isolated and characterized. Structures are proposed for leurocolombine and vinamidine based on UV, IR, PMR, high-resolution mass spectrometry, and CMR. Pseudovincaleukoblastine diol was identified by PMR and mass spectrometry. Leurocolombine exhibited antimitotic activity and marginal antitumor activity against the Ridgeway osteogenic sarcoma.

Keyphrases □ Alkaloids—isolation of three from *Catharanthus roseus*, characterization by UV, IR, NMR, and mass spectra □ *Vinca rosea*—isolation of three dimeric alkaloids, characterization by UV, IR, NMR, and mass spectra □ *Catharanthus roseus*—isolation of three dimeric alkaloids, characterization by UV, IR, NMR, and mass spectra □ Leurocolombine—isolation from *Catharanthus roseus*, UV, IR, NMR, and mass spectral structure identification □ Vinamidine—isolation from *Catharanthus roseus*, UV, IR, NMR, and mass spectral structure identification □ Pseudovincaleukoblastine diol—isolation from *Catharanthus roseus*, UV, IR, NMR, and mass spectral structure identification

In continuing efforts to study thoroughly the alkaloids of *Catharanthus roseus* G. Don[1], three new dimeric alkaloids were isolated: leurocolombine (I), vinamidine (II), and pseudovincaleukoblastine[2] diol (III). Postvincaleukoblastine–preleurocristine (1) production-scale chromatographic column cuts were subjected to preparative high-pressure liquid chromatography (HPLC), gradient pH purification (2), or gradient pH followed by preparative HPLC or preparative TLC. Structure elucidation studies of the three new dimeric alkaloids are reported in this paper.

Leurocolombine demonstrated antimitotic activity[3] at 2×10^{-2} μg/ml and produced 27% inhibition against the Ridgeway osteogenic sarcoma at 15 mg/kg. Vinamidine was not toxic to Swiss white mice at 30 mg/kg and showed no antimitotic activity, so *in vivo* testing was not attempted. Pseudovincaleukoblastine diol did not show antimitotic activity, and insufficient material was available for further testing.

EXPERIMENTAL

Isolation of Leurocolombine (I)—Twenty grams of a production-scale postvincaleukoblastine–preleurocristine chromatographic column cut was subjected to gradient pH purification. Leurocolombine cocrystallized from methanol with vincaleukoblastine, leurosine, and other trace impurities from pH 3.90 and 4.40 as the free base. Each pH fraction was subjected to sulfate formation in the usual manner[4]. Sulfates from pH 3.90, 4.40, and 4.90 were shown by TLC on silica gel[5] in ethyl acetate–ethanol (3:1) to contain vincaleukoblastine, leurosine, desacetylvincaleukoblastine, leurocolombine, and trace quantities of unidentified compounds.

The mixed sulfates were combined and dissolved in 2 liters of hot ethanol for recrystallization. Upon cooling to room temperature, a white amorphous precipitate deposited and was harvested to give 2.2184 g of first crop material. Three subsequent crops of amorphous sulfates, totaling 0.7023 g, were harvested from the chilled concentrated mother liquor. All crops in the attempted recrystallization of the mixed sulfates were amorphous mixtures, and none was appreciably enriched in I. Consequently, the second, third, and fourth crops of mixed sulfates were converted to their free bases for preparative TLC.

Between 80 and 100 mg of bases was applied to 20 × 20-cm silica gel preparative plates[6], which were developed in ether–diethylamine–toluene–methanol (100:5:5:5). Bands were distinguished by their UV-quenching effect and removed and eluted with chloroform and methanol. This method yielded 105 mg of I. The first crop sulfate (2.2184 g) was converted to its free base (1.98 g) and subjected to gradient pH purification to enrich fractions prior to preparative TLC. Leurocolombine was again found in pH 3.90, 4.40, and 4.90 (total weight 1.07 g) and cocrystallized with vincaleukoblastine and other trace impurities as both the free base and sulfate. Preparative TLC of all mixtures yielded an additional 150.6 mg of I.

Leurocolombine had a typical indole–dihydroindole UV spectrum[7]: λ_{max} 217 (a_m = 51,091) and 265 (a_m = 15,666) nm with shoulders at 290 and 298 nm. The IR spectrum[8] had a strong band at 3570 cm^{-1} (OH) in addition to the other typical bands found in vincaleukoblastine and leurosine (3). Leurocolombine has pKa values of 5.05 and 6.3. The mass spectrum[9] indicated a molecular ion at *m/e* 826.

Acetylation of Leurocolombine (I)—To a solution of 21.9 mg of I in 0.5 ml of dry pyridine, excess acetic anhydride was added. The reaction mixture was allowed to stand at room temperature overnight. After evaporating to dryness *in vacuo*, the mixture was shown by TLC on silica gel in ethyl acetate–ethanol (3:1) to contain unreacted I and one reaction product. Preparative separation afforded leurocolombine acetate (M^+ 868).

Isolation of Vinamidine (II)—Ten grams of a production-scale chromatographic preleurocristine fraction was fractionated in a series of preparative HPLC runs. Chromatography was carried out in stainless steel columns, using neutral alumina packing[10] and ethyl acetate–methylene chloride (25:75). The initial run was made on a 2.5-cm × 7-m column at 900 psi with a consequent flow rate of 66 ml/min. Eluent was subdivided based on the profile generated by a 280-nm UV flow monitor.

TLC of fractions on silica gel in ether–diethylamine–toluene–methanol (100:5:5:5) revealed a fraction containing a new alkaloid. This fraction was further purified by three sequential runs on an 8-mm × 7-m column at 320 psi with a 7-ml/min flow rate. Final purification was completed in an 8-mm × 2-m column using meth-

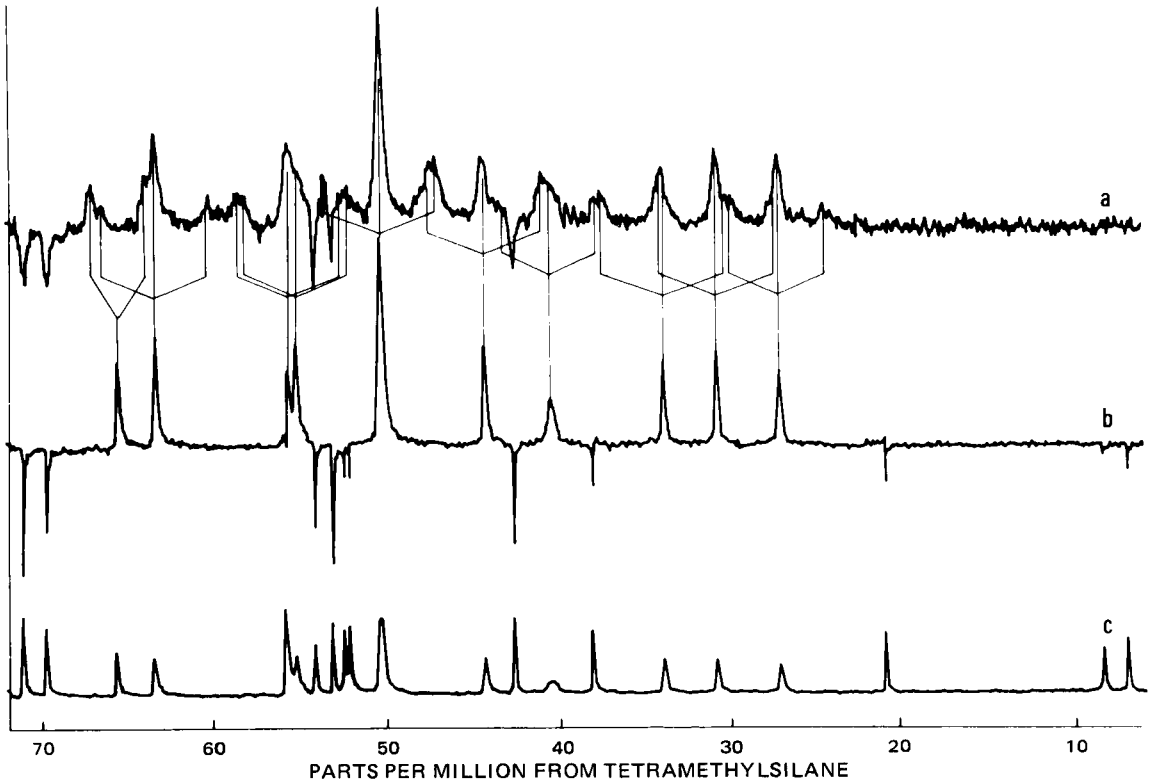

Figure 1—*Upfield portion of ^{13}C spectrum of leurocolombine. Key:* a, *off-resonance decoupled spectrum at τ = 0.4 sec;* b, *proton decoupled spectrum at τ = 0.4 sec; and* c, *proton decoupled spectrum.*

yl acetate–methylene chloride (60:39) at 1 atm of pressure and a flow rate of 1.5 ml/min. A total of 152 mg of II was isolated, being equivalent to 19 ppb of *C. roseus* leaf.

Vinamidine exhibited λ_{max} 216 (a_m = 57,278) and 268 (a_m = 16,815) nm with shoulders at 285, 295, and 311 nm. The IR spectrum exhibited an intense band at 1660 cm^{-1}, which is typical of an amide. The mass spectrum indicated a molecular ion at *m/e* 824.

Acetylation of Vinamidine (II)—Vinamidine acetate (M^+ 866) was prepared in the manner described for I.

Sodium Borohydride Reduction of Vinamidine (II)—Thirty milligrams of vinamidine base was dissolved in anhydrous methanol. An excess of sodium borohydride was added slowly with stirring. After stirring at room temperature for 0.5 hr, 10 ml of water was added and the methanol was removed *in vacuo*. The aqueous suspension was then extracted with chloroform; the chloroform extract was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness *in vacuo* to yield a one spot reaction product (M^+ 826).

Acetylation of Vinamidine Reduction Product—The vinamidine reduction product was acetylated in the manner described for I to yield two reaction products, subsequently identified as a monoacetate (M^+ 868) and a diacetate (M^+ 910) of the vinamidine reduction product.

Isolation of Pseudovincaleukoblastine Diol (III)—To isolate III, 11.75 g of a postvincaleukoblastine–preleurocristine production-scale chromatographic column cut was subjected to gradient pH purification. After sulfates were made in the usual manner, mixed sulfates containing vincaleukoblastine, leurocristine, and a third component were obtained from pH 5.40 and 5.90. A 100-mg sample of sulfate from pH 5.40 was fractionated in a preparative HPLC run on a stainless steel 0.793-cm × 6-m column packed with neutral alumina[11] using a linear gradient of 0–5% ethanol in methylene chloride.

The weighed sample was dissolved in 5 ml of water, and ammonium acetate was added to pH 9.0. The precipitate was centrifuged, the supernate was decanted, and the precipitate was dissolved in 3 ml of methylene chloride for application to the column. The run was made at 1100 psi (uncorrected) with a consequent flow rate of 180 ml/hr[12]. Fractions were collected every 3 min once peaks were observed on a UV profile. Compound III (M^+ 768) was located in fractions 30–32 by TLC on silica gel in ether–diethylamine–toluene–methanol (100:5:5:5). The remainder of the mixed sulfates containing the compound was subjected to preparative TLC in the same system since better yields were obtained than with the preparative HPLC run. After two additional preparative TLC runs, a total of 25.2 mg of III was isolated.

Acetylation of Pseudovincaleukoblastine Diol (III)—Compound III was acetylated in the manner described previously to yield its diacetate (M^+ 852) as the major reaction product with traces of a monoacetate (M^+ 810).

DISCUSSION

In the structure analyses of the new dimeric alkaloids, it is helpful to relate the unknown structures to the known structure of vincaleukoblastine (4). The vindoline portion of the dimers can readily be identified by characteristic chemical shifts in the PMR spectrum (5), by characteristic fragments in the mass spectrum (6), and by characteristic carbon resonances in the CMR spectrum (7).

Leurocolombine (I)—The mass spectrum of I indicated a molecular weight of 826, and high-resolution measurements verified a molecular formula of $C_{46}H_{58}N_4O_{10}$ (Table I). Deuterium exchange in combination with mass spectrometry disclosed that I had one more exchangeable proton than vincaleukoblastine, indicating that the additional oxygen was most likely a hydroxy group. The vindoline half of the dimer appeared intact, as evidenced by peaks at *m/e* 121, 122, 135, 282, 469, and $M^+ - C_6H_7O_5$ (6). Since typical indole fragments at *m/e* 143 and 144 were present, the extra hydroxy was assumed to be in the alicyclic portion of the indole half of the molecule.

In vincaleukoblastine, *m/e* 154 is characteristic for the alicyclic portion of the velbanamine portion of the molecule (8). If the extra hydroxy was in this portion, a peak at *m/e* 170 would be expected; indeed, a weakly intense peak did appear, but high resolution indicated it was a mass triplet. One component did correspond to the

$C_{10}H_9N$	143.07408	143.07350

desired molecular formula for the additional hydroxy while the other components were determined to be the indole portion of the molecule together with attached carbon and nitrogen atoms.

A peak at *m/e* 152 had an empirical formula corresponding to loss of water from the $C_9H_{16}NO_2$ component at *m/e* 170. This region of the mass spectrum was further complicated by a mass doublet at *m/e* 156, the more intense component together with its associated ^{13}C isotope peak corresponding to the alicyclic portion of the molecule and containing two oxygens. Deuterium exchange in this region showed an increase in intensity at *m/e* 157 with no other discernible significant changes.

Inspection of the PMR spectrum of I showed few differences from that of vincaleukoblastine. The resonances that are usually identified as vindoline protons were present with few changes. The aromatic resonances, H-9 and OCH_3-11 closest to the bond linking the two monomers, were broadened, suggesting possible restriction of rotation around that bond. In addition, a doublet at δ 4.16 was resolved, with a coupling constant of 15 Hz characteristic of geminal coupling of a methylene proton attached to a heteroatom.

The key to placement of the extra hydroxy in I came from CMR studies[13]. The initial experiment involved running the proton-decoupled CMR spectrum to get chemical shift values for as many of the carbons as possible. Overlap made it difficult to distinguish all 46 carbon resonances, and additional experiments were performed to resolve the resonances and to gain data useful for making assignments.

From relaxation time (T_1) measurements on vincaleukoblastine and other dimeric alkaloids, the nonprotonated carbons with long T_1 values were easily distinguished from protonated carbons that have shorter T_1 values (9). Average T_1 values were 1–3 sec for nonprotonated carbons; 0.5 sec for methyl carbons attached to carbon, oxygen, or nitrogen; 0.1 sec for methine carbons; and 0.05 sec for methylene carbons. The T_1 values of methines and methylenes were not always clearly differentiated, so a procedure using the inversion-recovery (180–τ–90) method (10) in conjunction with off-resonance decoupling (11) was used to distinguish these two types of carbons.

In the inversion-recovery method, resonances are inverted by a 180 R_f pulse and allowed to relax only partially before being measured by a 90 pulse. A resonance having a relaxation time, T_1, is nulled if an interval (τ) of ln $2T_1$ (0.69 T_1) is used. By using an interval of 0.35 sec (0.69 × 0.5), the methyl resonances were nulled in vincaleukoblastine. Leurocolombine required a τ value of 0.4 sec. The resulting spectrum showed nonprotonated carbon resonances as inverted peaks and the methines and methylenes as upright peaks (Fig. 1*b*). At this point, nonprotonated carbons and methyl carbons were clearly identified, but methine and methylene carbon resonances were not yet differentiated. The inversion-recovery spectrum was subsequently recorded with off-resonance decoupling to produce methines as "doublets" and methylenes as "triplets" (Fig. 1*a*).

The ^{13}C resonances of the vindoline half of vincaleukoblastine have been reported (7). These resonances were subjected to the inversion-recovery/off-resonance decoupling procedure to test both the assignments and the procedure. Excellent agreement was obtained. Resonances in I with chemical shifts similar to the assigned vindoline resonances in vincaleukoblastine were checked by the procedure to confirm their assignments in I (Table II).

[13] Recorded on a JEOL PS-100 spectrometer in Fourier transform mode operating at 25 MHz with repetition times of 2–3 sec. Chemical shifts are reported relative to internal tetramethylsilane, using concentrations of 50–200 mg/2 ml deuterated chloroform, depending on availability of sample.

By schematically representing the I spectrum (Fig. 2*a*) and subtracting the vindoline resonances (Fig. 2*b*), only those resonances corresponding to the velbanamine-like half of the dimer remained (Fig. 2*c*). This procedure reduced the complexity of the total spectrum.

The aromatic carbons of the indole half and the ester carbonyl and methoxy were readily assigned by comparison of chemical shifts to vincaleukoblastine (7), and these assignments were confirmed by the inversion-recovery/off-resonance decoupling procedure (Table III). This procedure confirmed the deduction based on mass and PMR spectra that the indole portion of the molecule was unsubstituted. From the remaining resonances, it was observed that I contained three "singlets," *i.e.*, nonprotonated carbons, rather than two as in vincaleukoblastine. One singlet corresponded well to C-20′ of vincaleukoblastine, and one was in the range of C-16′. The third singlet resonated at 71.2 ppm in the range of carbons singly bonded to oxygen (12) and thus had the extra hydroxy. Since the methine doublet corresponding to C-14′ in vincaleukoblastine is absent in I, the hydroxy must be placed at C-14′. These data are accommodated by Structure I.

Since vincaleukoblastine and I have identical C-18′ chemical shifts, it may be concluded that the configuration at C-20′ is the same in I as in vincaleukoblastine. At present, no configuration has been determined for C-14′.

A hydroxy at C-14′ could possibly sterically hinder rotation around the bond linking the two monomers, and this would ex-

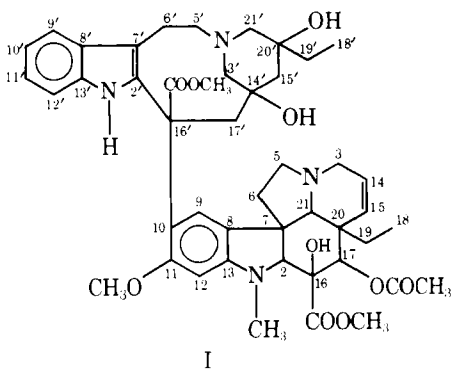
plain the broadened signals observed in the PMR spectrum. Both C-16′ and C-10 showed 1-ppm shifts in the CMR spectrum, which could reflect an effect on that bond.

Vinamidine (II)—The mass spectrum of II indicated a molecular weight of 824, and high resolution established a molecular formula of $C_{46}H_{56}N_4O_{10}$, which is isomeric with leurocristine (13). The IR spectrum had an intense band at 1660 cm^{-1}, characteristic of an amide.

In the PMR spectrum, the characteristic chemical shifts for the vindoline half of the molecule were observed. Likewise, the carbon resonances for the vindoline half of vinamidine agreed well with the assigned chemical shift values for the vindoline carbons in vincaleukoblastine and were checked by the inversion-recovery/off-resonance decoupling procedure. Consequently, an *N*-formyl group in the vindoline half was eliminated as the source of the intense amide band in the IR spectrum.

The CMR studies indicated the presence of a ketone at 210.4 ppm (12) in the indole half of the molecule. Sodium borohydride reduction resulted in the disappearance of the ketone resonance, with a new signal appearing at 68.4 ppm, indicative of an alcohol (12). The vinamidine reduction product formed a diacetate, while the parent compound formed a monoacetate. The CMR spectrum also had a resonance at 163.4 ppm, which appeared as an upright doublet in the inversion-recovery/off-resonance decoupling procedure. This downfield chemical shift, coupled with the fact that the carbon bears one proton, suggested a formamide. An N_b-formyl group would be consistent with the observed CMR resonance as well as the IR band. The reduction reaction affected neither this carbon resonance nor the IR band.



I

The ketone was placed at C-15′, although C-14′ is the biogenetically preferred position. Despite C-20′ being nonoxygenated, the chemical shift of C-18′ in II is quite similar to C-18′ in vincaleukoblastine. A ketone at C-15′ rather than C-14′ would exert a shielding effect (14) on C-18′ to cause a slight upfield shift and effectively compensate for any downfield shift due to no oxygenation at C-20′. From these data, Structure II is proposed for vinamidine.

The structure of catharine, another *Catharanthus* indole–dihydroindole alkaloid, was reported recently[14]. It differs from II by having a double bond between C-20′ and C-21′ and a ketone at C-14′ rather than C-15′. The hydrogenation products of the two compounds were not identical, thus indicating that II was not merely dihydrocatharine. Sodium borohydride reduction of catharine produced a lactone between the carbomethoxy carbonyl and the reduced ketone, but II formed only the alcohol to substantiate again different placement of the ketone.

Pseudovincaleukoblastine Diol (III)—The mass spectrum of III indicated a molecular ion of M^+ 768, which corresponds to the molecular weight of desacetylvincaleukoblastine; however, the remainder of the spectrum showed that the compounds differed. The characteristic vindoline fragments of *m/e* 469 and 282 were shifted

III

58 mass units to *m/e* 411 and 224, respectively. Similarly, the usual $M^+ - 160$ (5) was shifted to $M^+ - 102$, which indicated a desacetoxy rather than desacetyl compound. Comparison to the mass spectrum of pseudovincaleukoblastine[2] showed identical fragments of *m/e* 411, 224, and $M^+ - 102$. The peaks at *m/e* 154 and 355, which are characteristic of the velbanamine half of vincaleukoblastine (8), were shifted to *m/e* 170 and 371 in III to indicate an extra hydroxy group in the alicyclic portion of the indole half of the dimer. These two peaks are also seen in the mass spectrum of vincadioline[15].

Inspection of the PMR spectrum of III showed the compound lacked an acetate peak. In the PMR of desacetyl compounds of the vindoline-containing dimeric alkaloids, H-17 is shifted to δ 4.075 (5) and the vinyl protons coincide in a multiplet around δ 5.85 (15). Compound III had no signal near δ 4.0 assignable to H-17 and had a broad multiplet at δ 5.46–5.78, which was clearly different from the multiplet observed in a simple desacetyl derivative.

Compound III formed a diacetate with one acetate group in the vindoline half and the other acetate in the indole half as evinced by the peak at *m/e* 371 shifting to *m/e* 413. More specifically, the peak at *m/e* 170 is shifted to *m/e* 212 to locate the acetate group in the alicyclic portion. The two acetates were observed in the PMR spectrum at δ 1.88 and 1.90. The peak at δ 1.90 was assigned to the acetate at C-16 in the vindoline half, which is identical to the chemical shift of the C-16 acetate in desacetoxyvincaleukoblastine acetate[2]. The acetate peak at δ 1.88 is quite similar to the one observed C-15′ acetate in vincadioline diacetate at δ 1.85[15]. The acetate derivatives of both III and vincadioline exhibited a new one-proton singlet at δ 4.47–4.48, assigned to the proton at the C-15′ acetate. In the parent compounds, this proton is hidden but, upon acetylation, shifts downfield to be clearly identified.

From these data, Structure III, where R_1 is OH, is proposed for pseudovincaleukoblastine diol. There is a possibility that the hydroxy could be placed at C-3′ or C-21′ since a carbinolamine could form an acetate under the conditions used. The most likely placement, however, of the hydroxy is at C-15′, based on comparison to vincadioline. The small amount of compound precluded further evidence of the structure.

[15] Vincadioline is 15′-hydroxyvincaleukoblastine, a minor alkaloid from *C. roseus;* unpublished results from Lilly Research Laboratories.

Absorption of ^{3}H-Benzocaine from Ointments following Rectal Administration in Rats

JAMES W. AYRES ˣ, DUANGCHIT LORSKULSINT, and ALBERT LOCK

Abstract □ Total radioactivity in the blood of rats for 5 hr following rectal administration of ^{3}H-benzocaine in oleaginous, absorption, emulsion (water-in-oil and oil-in-water), and water-soluble ointment vehicles was measured. The release was greatest from the water-soluble vehicle and followed the same relative order as seen in an earlier *in vitro* experiment. No intact benzocaine was found in the blood using radiochromatography. *In vitro* hydrolysis of benzocaine by rat blood did not occur as determined with the techniques of this experiment.

Keyphrases □ Benzocaine—absorption from ointments, rectal administration, rats □ Anesthetics, local—benzocaine, absorption from ointments, rectal administration, rats □ Ointments—benzocaine absorption, rectal administration, rats

Benzocaine (ethyl *p*-aminobenzoate) is an extensively used local anesthetic, commercially available in semisolid dosage forms in concentrations varying from 0.5 to 20%. Different vehicles are used in the multitude of products listing benzocaine as an active ingredient. The *in vitro* release of benzocaine from oleaginous, absorption, emulsion (water-in-oil and oil-in-water), and water-soluble ointment vehicles through a cellulose membrane to an aqueous sink was recently studied (1). It was shown that vehicle composition markedly affected the rate of release of the active ingredient.

Benzocaine is often included in hemorrhoidal products for the treatment of pain and pruritis. The drug must leave the vehicle and pass into the mucous membranes in order to act as a local anesthetic by blocking nerve conduction. After penetration, the drug is removed from the rectal tissues *via* the hemorrhoidal veins. The lower hemorrhoidal veins bypass the liver and carry absorbed drug directly into the general circulation; the upper hemorrhoidal vein connects with the portal vein leading to the liver (2).

The rate of appearance and amount of drug in the blood after rectal application should be a useful measure of the rate and amount of drug transfer from a dosage form to the sensory nerve endings in the rectal mucosa. Absorption of some local anesthetics has been reported to be dependent on the mucous surface involved (3). The rate of absorption largely depends upon the blood supply to the tissue (4).

The absorption of detectable amounts of benzocaine after application to abraded abdominal skin in dogs (3) and the ability of various benzocaine-containing preparations to obtund the itch and burning of electrical stimulation in humans (5) were reported. No comparisons of absorption of benzocaine from various formulations of semisolids through mucous membranes have been published.

The metabolic fate of local anesthetics has important clinical significance (4), but no metabolic studies of benzocaine have been reported. It may, however, follow the metabolic pathways of procaine (6, 7), which is also a local anesthetic ester. Although detoxification of most local anesthetics is accomplished almost entirely by the liver (4), procaine is rapidly hydrolyzed in human plasma. The enzymes involved are nonspecific (4) and hydrolyze different local anesthetics at various rates. For example, piperocaine was hydrolyzed 6.1 times faster than procaine, and tetracaine was hydrolyzed only 0.22 times as fast as procaine (7).

Hydrolysis of the local anesthetics in the plasma of laboratory animals was shown to be very slow (8) and dependent on the animal plasma used. In another experiment using isolated, perfused rat liver, procaine was not hydrolyzed in the rat blood but was hydrolyzed by the liver (9). Hydrolysis studies of benzocaine by the enzymes in rat blood have not been reported.

The purposes of the present investigation were to: (*a*) compare the effects of various ointment bases, with markedly different physical–chemical properties, on the rate of release of benzocaine after rectal administration in rats; (*b*) relate these results to a previously reported *in vitro* study (1); and (*c*) investigate the stability of benzocaine in whole rat blood *in vitro*.

EXPERIMENTAL

Reagents and Equipment—^{3}H-Benzocaine[1] (general label) was used as obtained. An internal standardization method was used to determine the activity of the drug as 0.067 mCi/mmole. A liquid scintillation spectrophotometer[2] was used to count all samples.

Other reagents and equipment used were: dioxane[3] (scintilAR), naphthalene[3] (purified), 70% perchloric acid[3], 30% hydrogen peroxide[3], benzene[3], dioxane[3], 2,5-diphenyloxazole (scintillation grade)[4], 1,4-bis[2-(4-methyl-5-phenyloxazolyl)]benzene (scintillation grade)[4], polyethylene glycol 1000[5], polyethylene glycol 4000[5], white petrolatum[6], pentobarbital sodium[7], heparin sodium injection[8] (1000 USP units/ml), polyethylene tubing[9], commercial fluor[10], acetic acid[11], chromatographic plates[12], absorption vehicle[13], water-in-oil emulsion[14], and oil-in-water emulsion[15].

Pharmacology—Female Sprague–Dawley rats, 100–280 g, were

used. Pentobarbital sodium (55 mg/kg ip) was used for induction and maintenance of general anesthesia. The trachea was intubated [polyethylene tubing, 0.139 cm (0.055 in.) i.d., 0.191 cm (0.075 in.) o.d.] to facilitate respiration. A midventral incision was made into the abdominal cavity extending from the xyphoid process to the midabdominal region. The inferior vena cava was cannulated [polyethylene tubing, 0.076 cm (0.030 in.) i.d., 0.122 cm (0.048 in.) o.d.], and the abdominal incision was closed with wound clips.

The ointments were inserted rectally from a U-80 insulin syringe with the barrel cut off at the 10-U mark. The dosage form was followed by a short, blunt, glass rod, which served as a plug to prevent leakage. A 0.1-ml blood sample was withdrawn *via* the inferior vena cava cannula before the drug was inserted and at 5, 10, 20, 40, 60, 90, 120, 240, and 300 min after insertion.

A 0.1-ml heparinized normal saline solution (7.5 units of heparin/ml) was injected through the cannula immediately after each blood sample was obtained. All blood samples were placed directly into the counting vials. When necessary, additional pentobarbital sodium (2.75 mg/kg ip) was injected to maintain anesthesia.

Sample Analysis—Total radioactivity in each blood sample was determined using a wet oxidation method (10) as follows. First, 0.1 ml of blood was placed in each counting vial. Then 0.2 ml of 70% perchloric acid was added to each sample vial for digestion, and the contents were agitated until the acid was well mixed with the sample. Then 0.4 ml of 30% hydrogen peroxide was added, and the contents were mixed again.

The vial was tightly capped to minimize evaporation of fluid during digestion and then placed in a water bath at about 70° for 60 min or until the contents of the vial became clear and colorless. After the samples were cooled, 8 ml of 2-methoxyethanol and 10 ml of toluene scintillation solution were added. The vial was capped and shaken, and a clear solution was formed.

The toluene scintillation solution consists of 4 g of a commercial fluor[10] in enough toluene to make 1 liter. All samples were counted on a liquid scintillation spectrometer[2] using the ^3H quick set and a preset time of 10 min. The counting efficiency was determined by use of external standardization (AES ratio).

Metabolism—TLC was used to separate radioactive benzocaine from its metabolites after rectal administration of 20% ^3H-benzocaine in polyethylene glycol. At 30, 60, 120, 180, 240, and 300 min, 0.1 ml of blood was withdrawn through the cannula, immediately placed in a small test tube containing 1 drop of 50% sodium arsenite solution and 1 drop of 10% saponin solution, and mixed well. The sample was then spotted on commercially available plates[12] and developed (11) in benzene–dioxane–acetic acid (90:75:8).

After solvent evaporation, the plate was examined under UV light for spot separation. Then the entire chromatographic band, from the origin to the solvent front, was divided into 1-cm successive zones, and the adsorbent of each zone was removed with a razor blade and placed in counting vials. 2-Methoxyethanol (8 ml) and commercial fluor[10] (10 ml) in toluene scintillation fluid were added and mixed. After the adsorbent completely settled in the bottom of the vials, each vial was counted for 10 min.

For the *in vitro* study of benzocaine hydrolysis, 2 ml of blood was freshly withdrawn from the inferior vena cava of the rat and placed in a 10-ml beaker containing 1 drop of heparin solution (1000 units/ml). Two drops of ^3H-benzocaine solution (50 mg/ml in alcohol) were added. At 0, 5, 30, and 60 min, 0.1 ml of blood was taken from the beaker and immediately placed in a test tube. The tube contained 1 drop of 50% sodium arsenite solution to inhibit enzyme activity (6) and 1 drop of 10% saponin solution to lyse the red blood cells, and the solution was mixed well.

The sample was then spotted as a row of small spots on a 10 × 20-cm precoated thin-layer plate[12] and developed with the three-component solvent system. The chromatoplates were examined under UV light to locate the benzocaine and its metabolites. The plates were divided and counted as already described. The same procedure was repeated with a saturated solution of ^3H-benzocaine in water and 50 mg of ^3H-benzocaine/ml in polyethylene glycol 4000. The blood was analyzed after 60 min only in the latter study, and the blood was maintained at 37° in a water bath.

Dosage Form Preparation—^3H-Benzocaine was incorporated in the vehicle with the use of a spatula and an ointment slab by geometric dilution. The ointment was loaded into a plastic disposable U-80 insulin syringe and stored for no more than 1 week in the refrigerator. The end of the syringe was cut off at the 10-U mark, and the contents were inserted directly from the modified syringe into the rectal cavity.

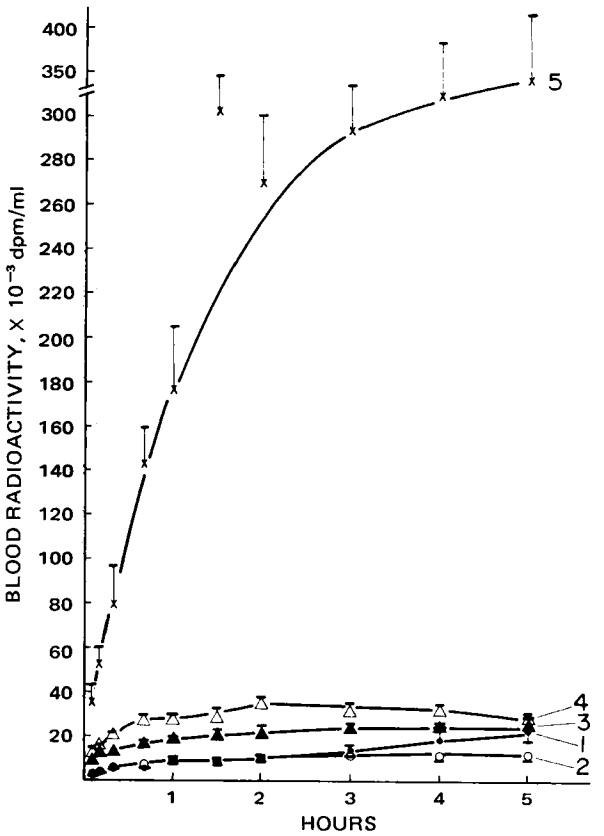

Figure 1—*Blood radioactivity after the application of 20% ^3H-benzocaine in different ointment vehicles. Key: 1, white petrolatum; 2, absorption vehicle; 3, water-in-oil emulsion; 4, oil-in-water emulsion; and 5, polyethylene glycol. The standard error of the mean is shown on one side of each point.*

RESULTS AND DISCUSSION

The rectal absorption in rats of radioactivity from 20% ^3H-benzocaine in five different ointment bases (white petrolatum, absorption vehicle, oil-in-water emulsion, water-in-oil emulsion, and water-soluble vehicle) was compared. The means of at least five animals for each formulation are shown in Fig. 1. The results of a point-by-point comparison of the means obtained at each sample time was made using the Student *t* test.

The experimental values obtained were significantly different (95% confidence level) for almost every sample time when comparing all products except Formulation 1 *versus* 2. Statistical analysis using an unequal variance technique showed that less than 5% of the variation in blood level radioactivity among different rats receiving different formulations was due to rat weight variation. No pharmacokinetic analysis was attempted since total radioactivity was measured and the method is not specific for benzocaine.

In fact, as will be seen later, no intact benzocaine was detected *in vivo*, and the radioactivity represents metabolized drug. However, total radioactivity can be used to indicate the relative rate of absorption of the drug from the various formulations, since all radioactivity in the blood originated as intact radioactive drug in the dosage forms.

For a drug to be absorbed from the rectum, it must be released from the vehicle and be distributed through the surrounding fluids where it is absorbed through the rectal mucosa. The rectum contains fluids in which water-soluble vehicles can dissolve. However, the quantity of this fluid is not sufficient to effect rapid dissolution of a suppository (12).

The release of drug from the suppository vehicle depends on the relative affinities of drug for the vehicle and the rectal fluid. Low affinity of the drug for the vehicle or ready solubility of drug in the

aqueous rectal fluid favors rapid release of drug. Conversely, high affinity of drug for the vehicle and poor drug solubility in aqueous rectal fluid decrease the rate of released drug (13). Benzocaine is known to have a low affinity for, or a low solubility in, aqueous fluids.

The five types of vehicles chosen for this experiment represent a wide range of physical–chemical properties and relative affinities for benzocaine. The relative release profiles in Fig. 1 show that the semisolid polyethylene glycol solution released the drug much more rapidly than the semisolid suspensions, even though the polyethylene glycol vehicle has a much greater affinity for the drug than the other vehicles. These results support the contention that one primary rate-limiting step in drug absorption from suppositories is the partitioning of the dissolved drug from the vehicle rather than the dissolution of the drug in the body fluids (2).

Although it is desirable that the partition coefficient of the drug favor solubility in the rectal fluids rather than in the vehicle, a drug that is very insoluble and suspended in the vehicle will be absorbed slowly due to the small concentration of dissolved drug available to partition into the rectal fluid. It follows that the onset of the local anesthetic action of benzocaine applied rectally as a suspension is likely to be slower and perhaps less intense than when applied as a solution, even though the solubilizing vehicle may have a relatively high affinity for the drug. Theoretically, the suspensions will continue to release the drug over a longer time period than the polyethylene glycol solution, but this has no significance during the first 5 hr and the significance beyond that time is unknown (Fig. 1). The relative release rates *in vivo* are in agreement with an earlier *in vitro* study (1) which measured the relative release rates of benzocaine from these vehicles.

When the radioactivity of a sample is counted, the total radioactivity is the sum of the total number of radioactive molecules of any chemical form in the sample. Generally, each metabolite formed from the drug has its own rate of formation, rate of elimination, and volume of distribution and their pharmacokinetic parameters are different from each other and from the original drug. Therefore, a thin-layer radiochromatographic method of separating benzocaine from its metabolites was investigated to determine if the total radioactivity was due to intact ^{3}H-benzocaine.

Procaine, which is structurally similar to benzocaine, has been reported (6) to be rapidly hydrolyzed by human serum cholinesterase and rat liver (9) to *p*-aminobenzoic acid. Since hydrolysis of benzocaine would also lead to *p*-aminobenzoic acid, a TLC system (11) that separated benzocaine (R_f 0.85) from *p*-aminobenzoic acid (R_f 0.70) was chosen. The R_f values of both substances were high enough to leave room to detect more polar metabolites, since *p*-aminobenzoic acid is reported to be converted to various polar conjugates (6, 11).

Periodic blood samples were collected to measure the *in vivo* degradation of benzocaine. The 30-min blood sample did not show any radioactivity above background in the zone where benzocaine should be located. The counts were high in the zone where the R_f value was approximately 0.70, the R_f value of *p*-aminobenzoic acid. For the 60-, 120-, 180-, 240-, and 300-min samples, the R_f value of the zone where the highest count was located was approximately 0.60–0.66. Another radioactive zone with an R_f value of 0.40–0.50 was present. The R_f values obtained in this study can only be approximations, because the exact positions of the spots could not be determined using scintillation. Oxidation of the silica gel to release absorbed radioactive molecules increased the counts but did not provide any further information concerning the hydrolysis of benzocaine.

The possibility that the prolonged blood level of radioactivity (Fig. 1) was due to formation of tritiated body water due to exchange of ^{3}H from the drug or its metabolites was ruled out in the following manner. Whole blood (1.0 ml) collected at different times from five rats was treated with 1 drop of 10% saponin solution to lyse the red blood cells and microdistilled at atmospheric pressure to collect 0.1 ml of aqueous material. The distillate contained less than 8% of the radioactivity of an equal volume of whole blood, indicating that little or none of the radioactivity in whole blood was due to tritiated water formed by exchange with the tritiated drug or its metabolites. From these results, it is probable that benzocaine is hydrolyzed *in vivo* in rats to *p*-aminobenzoic acid, which is then further metabolized.

An attempt was made to determine if benzocaine was being hydrolyzed by blood enzymes in the rat. Various amounts of ^{3}H-benzocaine in different solvents (see *Experimental*) were introduced into heparinized blood. At specified time intervals, the blood enzymes were inactivated, the cells were lysed, and the samples were chromatographed. The chromatoplates were scraped off and counted in a liquid scintillation spectrometer, but the distribution of the total radioactivity was not well delineated. Some zones on the plate, below the benzocaine zone, did show slightly higher counts than background but represented an extremely small amount of, if any, metabolites. Scintillation counting showed much higher counts than background only in the zone for benzocaine as detected with UV light.

Therefore, no *in vitro* hydrolysis of benzocaine was found with the method used in this study. The reason could be that (*a*) benzocaine is not hydrolyzed in rat blood, (*b*) the enzyme was inactive under the *in vitro* conditions utilized, or (*c*) the method used was not sensitive enough to detect the amount that was hydrolyzed. The first reason for the results is the most probable (7, 8). Benzocaine is clearly degraded *in vivo*, however, and the degradation probably occurs in the liver (9).

CONCLUSIONS

1. The rectal absorption and blood concentration of total radioactivity in rats following insertion of ^{3}H-benzocaine in various ointment vehicles were determined.

2. The total radioactivity absorbed rectally from the vehicles was in the following decreasing order: polyethylene glycol > oil-in-water emulsion > water-in-oil emulsion > absorption base and white petrolatum. The absorption base and white petroleum did not give significant differences in the blood level curves.

3. Relative *in vivo* results for the formulations studied here correlated well with results of an *in vitro* method reported earlier.

4. No intact benzocaine was found in the blood at the time periods studied following rectal administration of the drug.

5. *In vitro* hydrolysis of benzocaine by whole rat blood was not found. More research is needed to determine the mechanism of benzocaine degradation.

Synthesis of 2-Pyridyl-α-toluenesulfonates as Antimalarials

M. HAMER [x], O. F. BATZER, M. J. MOATS, C. C. WU, and E. P. LIRA

Abstract □ A series of substituted 2-pyridyl-α-toluenesulfonates was synthesized for antimalarial testing. They were prepared by treating various 2-pyridinols with α-toluenesulfonyl chlorides in the presence of an alkali. In tests against *Plasmodium berghei* in mice at 640 mg/kg, only 3,5-dichloro-2-pyridyl-α-toluenesulfonate was considered active, *i.e.*, doubled the mean survival time.

Keyphrases □ 2-Pyridyl-α-toluenesulfonates—synthesis, screened for antimalarial activity □ Antimalarials, potential—synthesis and screening of 2-pyridyl-α-toluenesulfonates

Some time ago, a series of alkanesulfonate esters of variously substituted 2-pyridinols was prepared in these laboratories (1). In connection with this earlier study, some α-toluenesulfonates also were prepared. One of these, 3,5-dichloro-2-pyridyl-α-toluenesulfonate (I), was found to be active against *Plasmodium berghei* in mice. The mean survival time (MST) for mice treated with I at 640 mg/kg was 15.8 days; for controls, it was 6.1 days. Consequently, a series of substituted 2-pyridyl-α-toluenesulfonates was prepared for antimalarial testing[1].

DISCUSSION

These compounds were prepared mainly by treatment of a 2-pyridinol[2] with an α-toluenesulfonyl chloride in toluene at 25° in the presence of a small excess of triethylamine (Scheme I). The yields were generally in the range of 30–90%. In two instances, the insolubility of the pyridinol in the toluene and triethylamine mixture necessitated the use of 1% KOH or 1% NaOH in the Schotten–Baumann procedure (Table I, XXV and XXIX).

Sulfonylation of the 2-pyridinols occurred at the oxygen in all but one case. The single exception was the product from the reaction of 5-carbethoxy-3-chloro-2-pyridinol with α-toluenesulfonyl chloride. The insolubility of this pyridinol also required the use of 1% KOH. In this case, only the *N*-substituted product was isolated, as evidenced by its IR and UV spectra (see *Experimental*).

Previous work from these laboratories showed that the products from the reaction of various 2-pyridinols with alkanesulfonyl chlorides gave exclusively sulfonate esters (1). When various arenesulfonyl chlorides were used with a specific 2-pyridinol, 3,5-dichloro-2-pyridinol, both *O*- and *N*-sulfonated products resulted (2) in each case.

Four of the 2-pyridinols employed have not previously been reported (Table II). The product resulting from the chlorination of 3-methoxy-2-pyridinol at 25° in 10% hydrochloric acid (Table II, XXXII) proved to be the 6-chloro isomer, as evidenced by its NMR spectrum. Chlorination of 4-methyl-2-pyridinol [from diazotization and hydrolysis (3) of 2-amino-4-picoline] gave the previously unreported 3,5-dichloro-4-methyl-2-pyridinol (Table II, XXXIII). The intermediate 5-carbethoxy-3-chloro-2-pyridinol (Table II, XXXIV) was synthesized *via* chlorination of the reported (4) 5-carbethoxy-2-pyridinol. Attempts at chlorinating the acid (6-hydroxynicotinic acid) prior to esterification were unsuccessful.

The reported 5-chloro-3-methyl-2-pyridinol (5) was obtained by chlorination of 3-methyl-2-pyridinol. However, when 5-methyl-2-pyridinol was chlorinated under the same conditions in an attempt to prepare the 3-chloro derivative, a semisolid was obtained which could not be purified by distillation or recrystallization without decomposition. This material gave a positive test for an active halogen with alcoholic silver nitrate, and treatment with dilute sodium hydroxide at 25° gave an intensely dark-violet solution within 5 min.

The known 3,5-dichloro-6-methyl-2-pyridinol (5) was prepared from 3-methyl-2-pyridinol. Chlorination (5) or bromination (6) of 2-pyridinol at room temperature in dilute mineral acid gave the 3,5-dihalo product in good yield; the 3,5-dinitro intermediate was obtained on treatment of 2-pyridinol with fuming nitric and sulfuric acids at 80° (7). Similarly prepared were the 3,5- and 5,3-chloronitro-2-pyridinols (8).

The α-toluenesulfonyl chlorides were prepared by treatment of the appropriate chloromethylbenzene with sodium sulfite in refluxing 50% aqueous ethanol, and the sodium α-toluenesulfonates thus obtained were treated with refluxing phosphorus oxychloride (Table III). This method worked fairly well with those chloromethylbenzenes that contained electronegative halogen groups. However, in the two cases where electron-donating methyl groups were present (Table III, XLI and XLII), the sodium salts were converted back to the original benzyl chlorides, instead of the expected sulfonyl chlorides, on treatment with refluxing phosphorus oxychloride. Presumably the sulfonyl chlorides formed and, activated by the 3- or 4-methyl, were displaced by a chloride ion. When the reactions were carried out with phosphorus oxychloride at a reduced temperature (60°), the desired 3- and 4-methyl-α-toluenesulfonyl chlorides were obtained. The unreported α-toluenesulfonyl chlorides prepared are listed in Table III. The known α-toluenesulfonyl chlorides utilized include: 2- and 4-chloro (9); 2,4- and 3,4-dichloro (9); 2-bromo, 3-chloro, and 2- and 3-fluoro (10); and 2,4,5-trichloro (11).

EXPERIMENTAL

Activity—This series of compounds was tested[3] for blood schizonticidal antimalarial activity according to a literature method (12).

Only one compound, 3,5-dichloro-2-pyridyl-α-toluenesulfonate (I), was considered active, *i.e.*, gave an increase in mean survival time of at least 100% (+6.1 days) in mice infected with *P. berghei*. It gave an increase in mean survival time of 9.7 days at 640 mg/kg. Two other compounds, 3,5-dichloro-2-pyridyl-4-chloro-α-toluenesulfonate (Table I, IV) and 3,5-dichloro-4-methyl-2-pyridyl-α-toluenesulfonate (Table I, XXVIII), caused significant prolongation of life with infected mice, but the increases were not sufficient for them to be considered active. They increased the mean survival time by 5.6 (92%) and 4.9 (80%) days, respectively, at 640 mg/kg.

Chemistry—A single detailed example is given for the preparation of each of the two types of intermediates and also of an α-toluenesulfonate ester and an *N*-sulfonated product. In cases where the experimental procedure differed markedly from the examples given, the details are given in the table footnotes.

3-Bromo-α-toluenesulfonyl Chloride—To a boiling solution of 3-bromobenzyl bromide[4] (20.0 g, 0.08 mole) in 50 ml of 95% ethanol was added a solution of sodium sulfite, 10.1 g (0.08 mole), in 50 ml of water, dropwise with stirring over about 0.5 hr. The mixture was heated at reflux for 64 hr and cooled. The crystals were removed by filtration, washed with benzene, and dried under vacuum over phosphorus pentoxide, giving 13.7 g (63%) of dried sodium salt. All of this material (0.05 mole) was treated with 40 ml of

[3] Rane Laboratory, University of Miami.

[4] In most of the cases, the benzyl chloride was used.

[a] A = isopropanol, and B = cyclohexane. [b] Distilled at 120° (2.5 mm). [c] Treatment of the sodium α-toluene sulfonate with phosphorus oxychloride was carried out at 60° instead of the usual 105°. [d] Boiling point (mm).

phosphorus oxychloride by heating at reflux for 18 hr.

The excess phosphorus oxychloride was removed under vacuum, and the residue was treated with ice and then extracted with ether. The ether extract was washed with water and then with sodium bicarbonate solution and dried over magnesium sulfate. The ether was removed by evaporation, and the residue was recrystallized from 2-propanol, giving 8.5 g (62%) of white solids, mp 88.5–89.5°.

5-Bromo-3-chloro-2-pyridinol—Into a solution of 5-bromo-2-pyridinol (20.8 g, 0.12 mole) in 70 ml of 12% hydrochloric acid was bubbled chlorine (8.5 g, 0.12 mole) over 30 min. Water was added to keep the mixture stirrable as solids precipitated. After the addition, the mixture was stirred another hour, and the solids were filtered, washed with water, and dried *in vacuo* to give 18.2 g (73%) of white solids, mp 195–200°.

Two recrystallizations from isopropanol raised the melting point to 199–201.5°.

3,5-Dichloro-2-pyridyl-α-toluenesulfonate—α-Toluenesulfonyl chloride (31.5 g, 0.165 mole) in 200 ml of toluene was added to a solution of 3,5-dichloro-2-pyridinol (27.0 g, 0.165 mole) in 100 ml of toluene and triethylamine (20.0 g, 0.20 mole) at 25° with cooling in 15 min. The mixture was stirred at 25° for 1 hr and filtered to remove triethylamine hydrochloride, which was washed with fresh toluene (150 ml). The washings were collected with the filtrate.

Excess triethylamine was removed by distilling about 375 ml, and this volume of fresh toluene was added back before washing, first with 4% sodium hydroxide and then with 1% acetic acid. The toluene was removed under vacuum, and the residue was stirred with 100 ml of cyclohexane after crystallization commenced. The mixture was filtered, and the solids were dried and purified by recrystallization from ethanol, giving 32.2 g (61%) of white crystals, mp 117–118°. The analytical sample was purified by another recrystallization from ethanol, mp 118–118.5°.

5-Carbethoxy-3-chloro-1-(α-toluenesulfono)-2-pyridone—α-Toluenesulfonyl chloride (3.4 g, 0.02 mole) in 80 ml of toluene was added to a solution of 5-carbethoxy-3-chloro-2-pyridinol (3.6 g, 0.02 mole) in 1% potassium hydroxide solution over 10 min at 22°. The mixture was then stirred for an additional 0.5 hr, while sufficient 5% potassium hydroxide solution was added to maintain the pH at 9–10. The reaction mixture was then filtered to remove unreacted 2-pyridinol (0.5 g, 14%). The aqueous layer was separated and acidified, yielding an additional 1.0 g (28%) of starting material.

The toluene layer was washed once with dilute sodium hydroxide and then with cold water until neutral and evaporated under vacuum. The crude solids left on evaporation were purified on a silica gel column by eluting first with hexane–benzene (3:1) to remove unreacted α-toluenesulfonyl chloride, then with mixtures of these solvents progressively richer in benzene, and finally with benzene alone to yield 0.7 g (11%) of white solids, mp 130–131°; NMR (deuterochloroform): δ 1.32 (t, 3H, CH_3), 4.29 (q, 2H, CH_2), 5.13 (s, 2H, CH_2), 7.35 (s, 5H, phenyl), 8.04 (d, 1H, pyridone, J_{AB} = 2.5 Hz), and 8.27 (d, 1H, pyridone, J_{AB} = 2.5 Hz, J_{AX} = 14 Hz) ppm; IR (potassium bromide): λ_{max} 5.8, 5.9, 7.1, 7.35, 7.85, 8.6, 11.2, and 13.2 μm; UV (methanol): λ 265 (ε 12.3 × 10^3) and 300 (ε 5.9 × 10^3) nm.

Anal.—Calc. for $C_{15}H_{14}ClNO_5S$: C, 50.64; H, 3.97; N, 3.94. Found: C, 51.07; H, 4.09; N, 3.88.

Determination of Tolmetin in Human Plasma by GLC and Spectrophotometric Procedures

WILLIAM A. CRESSMAN ˣ, BARBARA LOPEZ, and DARRELL SUMNER *

Abstract □ GLC and spectrophotometric methods for the determination of tolmetin in plasma were developed. The methods can detect tolmetin in concentrations above 0.5 μg/ml. The plasma levels obtained with a 600-mg dose of tolmetin to a human subject are reported.

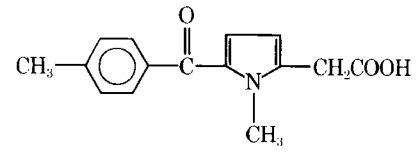
Keyphrases □ Tolmetin—GLC and spectrophotometric analyses, plasma □ GLC—analysis, tolmetin in plasma □ Spectrophotometry—analysis, tolmetin in plasma

The pyrrole derivative 1-methyl-5-*p*-toluoylpyrrole-2-acetic acid, tolmetin[1] (I), is a new anti-inflammatory agent currently undergoing clinical trials in rheumatoid arthritis (1, 2). GLC and spectrophotometric assays were developed to evaluate the absorption, distribution, and excretion of tolmetin in human subjects. These procedures were used to evaluate dose–response relationships, bioavailability, and the potential drug interaction between tolmetin and aspirin. The spectrophotometric assay has primary utility in bioavailability and other studies conducted under controlled conditions. The GLC assay has broader utility for monitoring blood levels of tolmetin in clinical therapy.

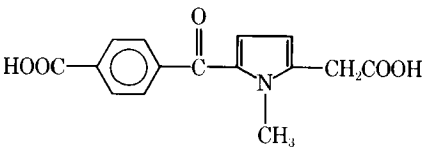
The major tolmetin metabolite in humans (3) is 5-(*p*-carboxybenzoyl)-1-methylpyrrole-2-acetic acid (II).

EXPERIMENTAL

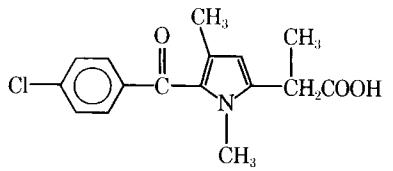
Reagents—Citric acid buffer was prepared by dissolving 210 g of citric acid in 1000 ml of water and adjusting the pH to 2.5 with 5 *N* NaOH. Phosphate buffer was prepared by dissolving 69 g of monobasic sodium phosphate in 1000 ml of water and adjusting to pH 7.0 with 5 *N* NaOH.



I



II



III

[1] Tolectin, McNeil Laboratories.

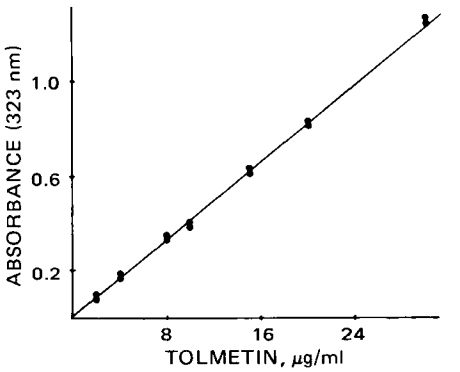


Figure 1—*Standard curve for the spectrophotometric determination of tolmetin in plasma (blank absorbance = 0.03 absorbance unit).*

The GLC internal standard (III) was dissolved in ether to give a concentration of 0.5 μg/ml. Diazomethane was prepared by adding 50 mg of *N*-nitrosomethylurea to 5 ml of ether and 3 ml of 40% KOH. The resulting diazomethane–ether solution was dried over potassium hydroxide pellets prior to use.

Spectrophotometric Assay—*Step 1*—To a 3-ml plasma sample in a 30-ml (1-oz) disposable glass screw-capped bottle with a polyethylene-lined cap were added 1 ml of water, 3 ml of pH 2.5 citric acid buffer, and 20 ml of 1% isopentyl alcohol in methylcyclohexane. The bottle was shaken for 20 min on a wrist-action shaker.

Step 2—Eighteen milliliters of the 1% isopentyl alcohol–methylcyclohexane layer was transferred to a clean 30-ml (1-oz) bottle, 2.5 ml of pH 7.0 phosphate buffer was added, and the mixture was shaken for 20 min.

Step 3—The 1% isopentyl alcohol–methylcyclohexane layer was removed and discarded, 2 ml of ether was added to the phosphate buffer layer, and the mixture was shaken for 15 min.

Step 4—The ether layer was then removed and discarded. An additional 2 ml of ether was added, the mixture was shaken for 15 min, and the new ether layer was removed and discarded.

Step 5—The absorbance of the pH 7.0 phosphate buffer layer was read at 323 nm against a pH 7.0 phosphate buffer blank. A plasma blank was also run, and each sample absorbance reading

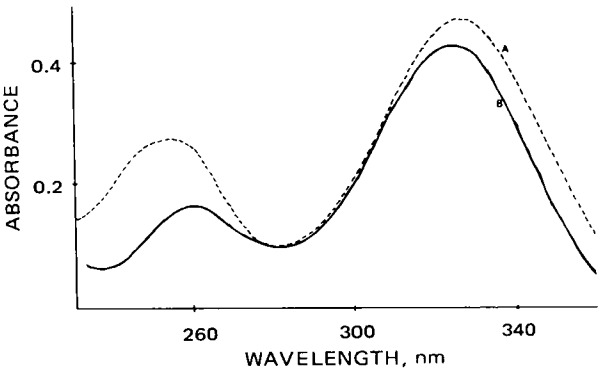

Figure 2—*Spectrum of 10-μg/ml solutions of tolmetin (B) and the tolmetin metabolite (A) in pH 7.0 buffer.*

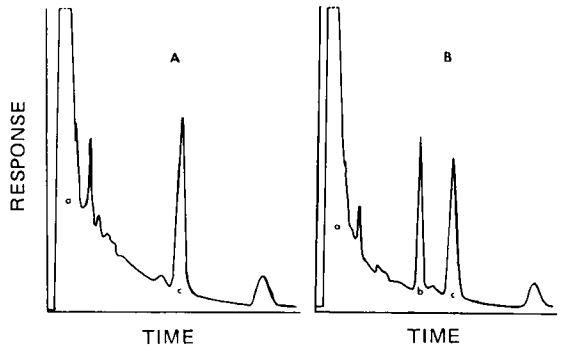

Figure 3—*Chromatograms of a blank human plasma sample (A) and a plasma sample containing 16 μg/ml of tolmetin (B). Key: a, solvent front; b, tolmetin methyl esther peak; and c, internal standard (III) methyl ester peak.*

was corrected for the blank (absorbance observed was usually 0.01–0.02 absorbance unit).

GLC Assay—*Instrumental Conditions*—A gas chromatograph[2] equipped with a flame-ionization detector was used. The column was a 1.8-m (6-ft) × 7-mm o.d. (4-mm i.d.) glass coil packed with 3% OV-1 on 60 – 80 - mesh Gas Chrom Q[3]. The injection port was maintained at 265°, the column was maintained at 200°, and the detector was maintained at 310°. Nitrogen carrier gas was used at a flow rate of 60 ml/min. The column was silylated[4] regularly each morning prior to use.

Under these conditions, the following retention times were observed: tolmetin (I) (methyl ester), 6 min; internal standard (III) (methyl ester), 8.5 min; and tolmetin metabolite (II) (dimethyl ester), > 13 min.

Sample Preparation—The first four steps of sample preparation are similar to those noted for the spectrophotometric assay with the following minor changes. In Step 1, only 1 ml of plasma was required; in Step 2, 5 ml of buffer was used; and in Steps 3 and 4, 3 ml of ether was used. The assay was then continued as follows.

The ether layer was removed and discarded; 4.5 ml of the aqueous layer (pH 7 phosphate buffer) was transferred to a clean 30-ml (1-oz) bottle, and the pH was adjusted to ~1 with 3.0 ml of 1 *N* HCl. Then 20 ml of the ethereal internal standard solution was added and shaken for 20 min.

Eighteen milliliters of the ether layer was removed and evaporated to about 2 ml. The sample was placed in a hood, and 2–3 ml of the anhydrous, ethereal diazomethane solution was added (sample should retain a yellow color). Additional reagent was added if the yellow color was dissipated, and the mixture was allowed to stand for 10 min or until the bubbling stopped. The excess diazomethane was evaporated with nitrogen in a hood until the sample turned colorless. The sample was evaporated to dryness using nitrogen and a warm water bath (30–50°). At this point, the sample was stored in a refrigerator.

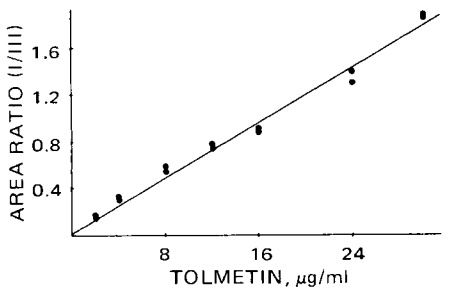

Figure 4—*Standard curve for the GLC determination of tolmetin in plasma.*

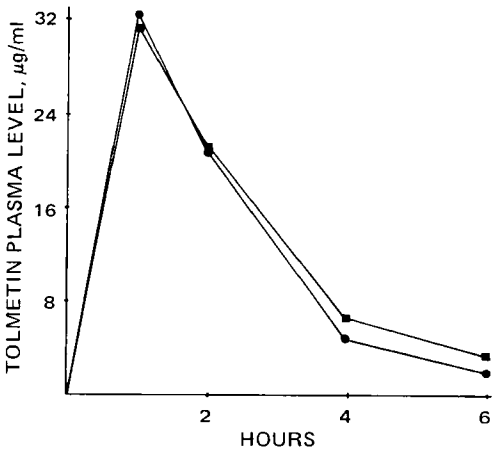

Figure 5—*Plasma and urine levels of tolmetin in a human subject administered 600 mg of tolmetin as an oral solution. Key: ●, GLC assay; and ■, spectrophotometric assay. One hundred percent of the radioactivity from an oral dose of ^{14}C-tolmetin is excreted in the urine within 24 hr.*

The dried residue was dissolved in 30 μl of methanol, and the sides of the tube were washed down with methanol. One-tenth of the sample (3 μl) was injected into the gas chromatograph using a 1-μl methanol plug in the syringe behind the sample. The appropriate attenuation setting for a 30-μg/ml plasma sample is 1×10^{-10} amp full-scale deflection.

In these studies, with this and other GLC plasma assays, the results were always more reproducible when the internal standard was added in the last step prior to evaporation or derivatization, *i.e.*, to monitor derivative formation and/or injection variables. In most cases, addition of the internal standard in earlier steps resulted in increased variability, which appears to increase with the number of extraction steps involved in the assay.

Standard Curves—Standard samples were prepared by dissolving tolmetin sodium dihydrate in water at appropriate concentrations so that 1 ml of the seeded solution could be used in place of the 1 ml of water that is added to each sample in Step 1 of the assay. The standard samples were prepared using heparinized human plasma from an untreated subject.

RESULTS AND DISCUSSION

Spectrophotometric Assay—A typical standard curve for the spectrophotometric assay, using duplicate seeded samples, is shown in Fig. 1. The lower limit of detection of the assay is 0.5 μg/ml. Samples of urine carried through the procedure gave low blank absorbance values (0.02 absorbance unit at 323 nm). Since II (the major metabolite of tolmetin in human subjects) also shows an absorption maximum at 323 nm with approximately the same absorptivity (Fig. 2), the potential interference of this compound was evaluated.

Less than 2% of the initial amount of II was recovered in the final assay layer. Studies with ^{14}C-tolmetin have shown that plasma levels of II are always less than 50% of the levels of tolmetin and that the plasma half-life of II is similar to that of tolmetin[5]. Therefore, no significant interference from II is expected.

GLC Assay—Using the chromatographic conditions described, tolmetin has a retention time of 6 min. A typical gas chromatogram of plasma extracted with and without the addition of tolmetin is shown in Fig. 3. The use of larger volumes of plasma to increase the sensitivity of the procedure was explored, but this procedure was accompanied by an equivalent increase in background "noise" and/or minor interfering peaks and was not pursued further. The dimethyl ester of II has a retention time greater than 13 min and, therefore, should not interfere in the assay. In addition, only 2% of the II seeded into plasma was carried through the assay.

A typical standard curve for the GLC assay, using duplicate seeded samples, is shown in Fig. 4. The lower limit of detection

[5] Data on file at McNeil Laboratories, Inc.

Table I—Urine Levels (Percent of Dose)

Method	0–12 hr	12–25 hr
GLC	2.9	0.31
UV	2.4	0.25

used in this procedure is 0.5 μg/ml. A similar GLC assay designed to measure both I and II was reported recently (4).

Interference of Aspirin and Salicylic Acid—Since tolmetin often could be used with large doses of aspirin, the interference of aspirin or salicylic acid in the spectrophotometric and GLC assay for tolmetin was evaluated. Plasma was seeded with 500 μg/ml[6] of aspirin or 500 μg/ml of salicylic acid and assayed by both procedures.

No interference was observed from either aspirin or salicylic acid with the GLC assay, but significant interference was observed in the spectrophotometric assay. For 500 μg/ml of aspirin, the spectrophotometric assay gave an absorption equivalent to ~10 μg/ml of tolmetin. For 500 μg/ml of salicylic acid, the assay gave absorption equivalent to 50 μg/ml of tolmetin. Since the levels of tolmetin at therapeutic doses (400–600 mg) are between 10 and 30 μg/ml, the spectrophotometric assay would not be suitable for the determination of plasma levels of tolmetin in patients who are simultaneously receiving aspirin products.

With the spectrophotometric assay, one can easily assay 36 samples/day. With the GLC assay, using a dual-column gas chromatograph and manual injection, analytical productivity is reduced by approximately half. Therefore, the spectrophotometric assay offers significant economic advantages over the GLC assay in controlled situations, *e.g.*, bioavailability studies (6). Because of the greater specificity of the GLC procedure, it offers greater utility in the assay of plasma levels of tolmetin in clinical practice (6).

[6] The 500-μg/ml level of aspirin or salicylic acid is at least two to three times the level expected from a 4.5-g dose of aspirin per day (5).

Comparison of the Two Analytical Procedures—To evaluate the applicability of the assay procedures, plasma and urine samples from a fasted subject dosed with 600 mg of tolmetin as an oral solution were assayed using both methods. The results are shown in Fig. 5. Studies with ^{14}C-tolmetin (3) showed that 100% of the administered dose of radioactivity is excreted in the urine within 24 hr. These radioactive studies also demonstrated that only 2–3% of the administered dose is excreted in the urine as intact drug. Therefore, the urine assay (Table I) provides a severe test of both assay procedures. The agreement of the urine and plasma assays by both methods, as well as the agreement of the results with data from other studies using radioactive and nonradioactive tolmetin (3, 4), validates the utility of both assay procedures.

GLC Determination of Procainamide in Biological Fluids

K. J. SIMONS and R. H. LEVY [x]

Abstract □ A GLC method for the determination of procainamide in biological fluids is presented. By using a dipropyl analog of procainamide as an internal standard, both compounds can be chromatographed directly, yielding linear calibration curves and a sensitivity that allows quantitative determination of concentrations as low as 0.1 μg/ml. The extraction procedure was carefully modified to avoid hydrolysis of *N*-acetylprocainamide, a major metabolite of procainamide. The usefulness of the procedure is demonstrated by following the disappearance of procainamide from the plasma and urine of human subjects treated with the drug.

Keyphrases □ Procainamide—GLC analysis, biological fluids, therapeutic range □ GLC—analysis, procainamide in biological fluids

The effectiveness of procainamide[1] (I) in the prevention or treatment of cardiac arrhythmias has been firmly established (1, 2). Careful clinical studies demonstrated that plasma levels of procainamide may be correlated with pharmacological responses. The range of therapeutic plasma concentrations is 4–8 μg/ml (2–4).

Due to individual differences in absorption and elimination of procainamide, dosages necessary for therapeutic effects may vary widely (2). Several methods are presently available for the determination of procainamide plasma concentrations within the therapeutic range.

The most commonly used method of determining procainamide in biological fluids is a colorimetric method (1) where, following complexation with *N*-(1-naphthyl)ethylenediamine, absorbance is read at 550 nm. This method has been used by many investigators (2, 4–11) and has been shown to have satisfactory precision above 2–3 μg. However, its specificity recently has been questioned. Gibson *et al.* (12) reported that *N*-acetylprocainamide, the major metabolite in humans (5), is hydrolyzed to procainamide under the conditions of the procedure of Mark *et al.* (1).

Spectrophotofluorometric detection is also possible

[1] Pronestyl, E. R. Squibb & Sons. The chemical name is *p*-amino-*N*-[2-(diethylamino)ethyl]benzamide hydrochloride.

Table I—Urine Levels (Percent of Dose)

Method	0–12 hr	12–25 hr
GLC	2.9	0.31
UV	2.4	0.25

used in this procedure is 0.5 μg/ml. A similar GLC assay designed to measure both I and II was reported recently (4).

Interference of Aspirin and Salicylic Acid—Since tolmetin often could be used with large doses of aspirin, the interference of aspirin or salicylic acid in the spectrophotometric and GLC assay for tolmetin was evaluated. Plasma was seeded with 500 μg/ml[6] of aspirin or 500 μg/ml of salicylic acid and assayed by both procedures.

No interference was observed from either aspirin or salicylic acid with the GLC assay, but significant interference was observed in the spectrophotometric assay. For 500 μg/ml of aspirin, the spectrophotometric assay gave an absorption equivalent to ~10 μg/ml of tolmetin. For 500 μg/ml of salicylic acid, the assay gave absorption equivalent to 50 μg/ml of tolmetin. Since the levels of tolmetin at therapeutic doses (400–600 mg) are between 10 and 30 μg/ml, the spectrophotometric assay would not be suitable for the determination of plasma levels of tolmetin in patients who are simultaneously receiving aspirin products.

With the spectrophotometric assay, one can easily assay 36 samples/day. With the GLC assay, using a dual-column gas chromatograph and manual injection, analytical productivity is reduced by approximately half. Therefore, the spectrophotometric assay offers significant economic advantages over the GLC assay in controlled situations, *e.g.*, bioavailability studies (6). Because of the greater specificity of the GLC procedure, it offers greater utility in the assay of plasma levels of tolmetin in clinical practice (6).

[6] The 500-μg/ml level of aspirin or salicylic acid is at least two to three times the level expected from a 4.5-g dose of aspirin per day (5).

Comparison of the Two Analytical Procedures—To evaluate the applicability of the assay procedures, plasma and urine samples from a fasted subject dosed with 600 mg of tolmetin as an oral solution were assayed using both methods. The results are shown in Fig. 5. Studies with ^{14}C-tolmetin (3) showed that 100% of the administered dose of radioactivity is excreted in the urine within 24 hr. These radioactive studies also demonstrated that only 2–3% of the administered dose is excreted in the urine as intact drug. Therefore, the urine assay (Table I) provides a severe test of both assay procedures. The agreement of the urine and plasma assays by both methods, as well as the agreement of the results with data from other studies using radioactive and nonradioactive tolmetin (3, 4), validates the utility of both assay procedures.

GLC Determination of Procainamide in Biological Fluids

K. J. SIMONS and R. H. LEVY [x]

Abstract □ A GLC method for the determination of procainamide in biological fluids is presented. By using a dipropyl analog of procainamide as an internal standard, both compounds can be chromatographed directly, yielding linear calibration curves and a sensitivity that allows quantitative determination of concentrations as low as 0.1 μg/ml. The extraction procedure was carefully modified to avoid hydrolysis of *N*-acetylprocainamide, a major metabolite of procainamide. The usefulness of the procedure is demonstrated by following the disappearance of procainamide from the plasma and urine of human subjects treated with the drug.

Keyphrases □ Procainamide—GLC analysis, biological fluids, therapeutic range □ GLC—analysis, procainamide in biological fluids

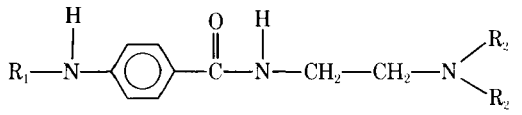
The effectiveness of procainamide[1] (I) in the prevention or treatment of cardiac arrhythmias has been firmly established (1, 2). Careful clinical studies demonstrated that plasma levels of procainamide may be correlated with pharmacological responses. The range of therapeutic plasma concentrations is 4–8 μg/ml (2–4).

Due to individual differences in absorption and elimination of procainamide, dosages necessary for therapeutic effects may vary widely (2). Several methods are presently available for the determination of procainamide plasma concentrations within the therapeutic range.

The most commonly used method of determining procainamide in biological fluids is a colorimetric method (1) where, following complexation with *N*-(1-naphthyl)ethylenediamine, absorbance is read at 550 nm. This method has been used by many investigators (2, 4–11) and has been shown to have satisfactory precision above 2–3 μg. However, its specificity recently has been questioned. Gibson *et al.* (12) reported that *N*-acetylprocainamide, the major metabolite in humans (5), is hydrolyzed to procainamide under the conditions of the procedure of Mark *et al.* (1).

Spectrophotofluorometric detection is also possible

[1] Pronestyl, E. R. Squibb & Sons. The chemical name is *p*-amino-*N*-[2-(diethylamino)ethyl]benzamide hydrochloride.



I: procainamide, $R_1 = H$, $R_2 = -CH_2CH_3$
II: internal standard, $R_1 = H$, $R_2 = -CH_2CH_2CH_3$
III: *N*-acetylprocainamide, $R_1 = CH_3C(=O)-$, $R_2 = -CH_2CH_3$

since procainamide fluoresces at 385 nm following excitation at 295 nm at pH 11 (13). This method has been useful (14–17) and successfully compared to the colorimetric method (2), but it retains the limitations of sensitivity and specificity.

A GC method for procainamide determinations was developed (18) but shows nonlinearity in the calibration curve at low concentrations as a result of adsorption to active sites on the column and/or packing material. Karlsson (14) used GC for the determination of procainamide in urine, but the method has not been published.

Sterling *et al.* (19) developed a GC method using polyamide incorporated onto the packing to reduce adsorption. They also developed a fluorometric method which involves coupling with fluorescamine to enhance the fluorescence of procainamide. Both methods were tested with pooled human plasma spiked with procainamide to concentrations as low as 2 μg/ml and with plasma from patients chronically maintained on procainamide.

However, to conduct safe, low-dose pharmacokinetic studies with procainamide in normal subjects (where many blood samples have to be drawn), it is necessary to have an assay that requires 1 or at most 2 ml of plasma and is sensitive at levels below 1 μg/ml. A GLC method was developed in this laboratory in which adsorption is minimized to yield linearity and sensitivity to levels as low as 0.1 μg/ml. Furthermore, the extraction procedure is modified to eliminate the hydrolysis of *N*-acetylprocainamide.

EXPERIMENTAL

Reagents—Procainamide and the internal standard, a dipropyl analog of procainamide, *p*-amino-*N*-[2-(dipropylamino)ethyl]-benzamide hydrochloride (II), mp 188–190°, were used[2]. Stock solutions of procainamide contained 2, 5, 10, 15, and 20 μg/ml for plasma and 10, 25, 50, 75, and 100 μg/ml for urine in water. Stock solutions of the internal standard contained 5, 10, 25, and 50 μg/ml in water. Solutions of phthalate buffer (pH 3) (20) and 2 *N* Na_2CO_3 buffer (pH 10.8) also were used.

All solvents were reagent grade, except for chloroform which was spectral grade. *N*-Acetylprocainamide (III), mp 189–190°, was synthesized according to the method of Dreyfuss *et al.* (6). GC and colorimetric analysis showed it to be 95% pure with 5% unchanged procainamide.

Extraction of Plasma Standards and Specimens from Dosed Subjects—*Control Plasma Standards*—The extraction procedure is a modification of the approach proposed by Mather and Tucker (21) for basic amine drugs. To 1 ml of pooled control plasma samples in 15-ml Pyrex culture tubes, fitted with Teflon-lined screw caps, were added 0.5 ml of aqueous procainamide solution, 0.5 ml of the appropriate internal standard solution, and 0.5 ml of carbonate buffer (pH 10.8).

The samples were extracted with 8 ml of ether by shaking at high speed on a reciprocating shaker for 5 min. Then sufficient sodium chloride was added to saturate the aqueous layer completely. The samples were shaken again at a low speed for 30 sec and at high speed for 5 min, followed by centrifugation at 2000 rpm for 20 min. This shaking procedure minimizes emulsion formation from the plasma protein–ether mixture.

The samples were then frozen in an acetone–carbon dioxide bath, the ether layers were poured into 15-ml test tubes, and the aqueous layer was discarded. After the addition of 0.2 ml of phthalate buffer (pH 3), each sample was mixed[3] for 60 sec and centrifuged as before for 5 min. The samples were frozen again, and the ether layers were discarded. Then the samples were heated in a water bath at 50° for 10 min to thaw the aqueous layer and evaporate remaining traces of ether.

The aqueous layers were poured from the test tubes into 1-ml conical centrifuge vials[4]. To each vial were added 0.1 ml of carbonate buffer (pH 10.8) and sufficient sodium chloride to saturate the aqueous layer; then the vials were mixed[3] for 30 sec. Samples were extracted with 10 μl of water-saturated chloroform by high speed shaking for 20 min, followed by centrifugation at 2000 rpm for 20 min. From the chloroform bead formed in the conical tip of the vial, 1–3 μl was injected directly into the gas chromatograph.

Plasma Samples from Dosed Subjects—Appropriate aliquots (0.5–2 ml) of plasma were pipetted into 15-ml tubes. Following addition of the internal standard, the samples were extracted by the same procedure as was used for the plasma standards.

Extraction of Urine Standards and Specimens from Dosed Subjects—*Control Urine Samples*—Procainamide concentrations in urine are about 10 times that found in plasma, and significant protein is not usually present. Therefore, the plasma assay was simplified for urine samples by omitting the ether extraction. Calibration curves were prepared by adding 0.1-ml samples of both procainamide and internal standard stock solutions and 0.1 ml of carbonate buffer (pH 10.8) directly into the 1-ml vials[4]. Sufficient sodium chloride was added to saturate the aqueous layer, followed by mixing[3] for 30 sec. Samples were then extracted with 10 μl of water-saturated chloroform by high speed shaking for 20 min, followed by centrifugation at 2000 rpm for 20 min. From the chloroform bead formed in the conical tip of the vial, 1–3 μl was injected directly into the gas chromatograph.

Urine Samples from Dosed Subjects—A 0.1-ml sample of urine, suitably diluted to contain between 1 and 10 μg of procainamide, was pipetted directly into the 1-ml vials[4]. To each sample was added 0.1 ml of internal standard solution and then the same extraction procedure was used as for the urine standards.

GLC—GLC was carried out on a gas chromatograph[5] equipped with a flame-ionization detector. Glass columns (coiled 0.91 m × 0.63 cm, 2 mm i.d.), packed with 10% OV-7-coated Gas Chrom Q[6] (60–80 mesh), were maintained for isothermal chromatography at 245° with the injector at 280° and the detector at 300°. Helium, the carrier gas, was maintained at 40 ml/min, with hydrogen and air at 30 and 450 ml/min, respectively. Under these conditions, procainamide, the internal standard, and *N*-acetylprocainamide have retention times of ~3, ~4, and ~9 min, respectively (Fig. 1).

To prolong column life, temperatures were reduced at night. Prior to raising temperatures at the beginning of a run and before igniting, the columns were conditioned with 30 μl of a trimethylsilyl mixture[7]. With these precautions, columns were used for up to 8 months.

The first sample each day was injected two or three times to ensure reproducibility and column stability. Where possible, samples were usually injected in order of decreasing drug concentration, and larger volumes were injected into the gas chromatograph as drug concentrations decreased.

Calculations—Peak height ratios were calculated by dividing the height of the procainamide peak by the height of the internal standard peak. Calibration curves were constructed daily from the

results of spiked pooled control plasma samples by plotting peak height ratios against concentration of procainamide (micrograms per milliliter).

GLC–Mass Spectrometry—A gas chromatograph–mass spectrometer[8], fitted with a Gohlke separator, was used to check the identity and purity of the procainamide, internal standard, and *N*-acetylprocainamide peaks in a control aqueous solution and in plasma and urine samples. The ionizing energy was 70 ev.

RESULTS AND DISCUSSION

GLC—Figure 1 shows typical chromatograms obtained after addition of 1 and 10 μg of procainamide to pooled plasma samples and a chromatogram of a patient urine sample showing procainamide, internal standard, and *N*-acetylprocainamide peaks. Procainamide and the internal standard gave well-resolved, symmetrical peaks with no tailing. The *N*-acetylprocainamide peak, although well resolved, was broad and tailing, which makes quantification more difficult under these chromatographic conditions.

The identity and purity of the peaks were confirmed by mass spectrometry. The spectra and fragmentation patterns were comparable to those reported previously (17, 18).

The linearity of the system was established by analyzing the results of six calibration curves assayed simultaneously (Table I). The calibration curve constructed from the mean values had the linear regression equation $y = 0.229x - 0.002$ ($r = 1.000$). The precision of this method was determined from these data; for amounts ranging from 1 to 10 μg, coefficients of variation ranged from 3.6 to 9.5%. The standard deviation of the slope of nine routine calibration curves over 8 months was 4.0%.

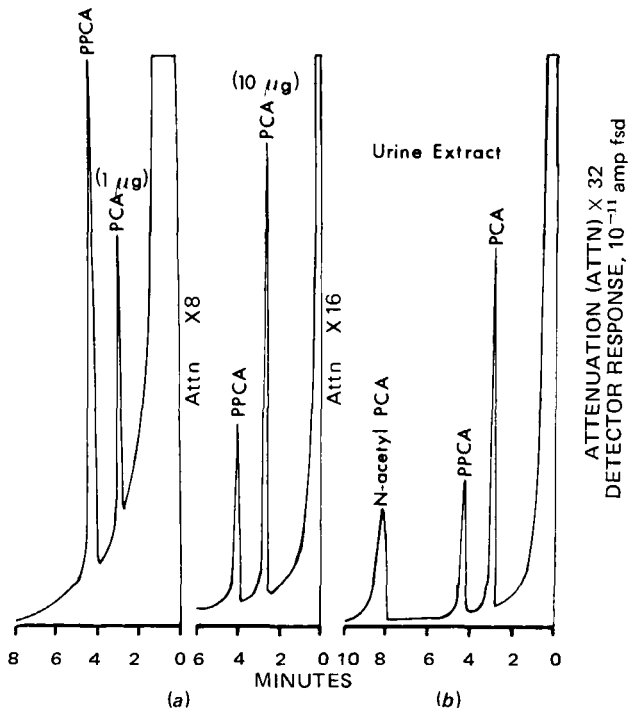

Figure 1—(a) *Gas chromatograms of procainamide (PCA) and internal standard (PPCA), showing 1 and 10 μg of drug extracted from spiked human plasma samples.* (b) *Chromatogram of a urine sample from a patient given 3.5 mg/kg iv showing procainamide (PCA), internal standard (PPCA), and* N*-acetylprocainamide* (N*-acetyl PCA*).

		37.29 ± 1.90		82.89 ± 7.65

[a] $n = 2$.

The standard deviation of the peak height ratio of the 1-μg sample of the same nine calibration curves over 8 months was 7.2%. The absolute peak height of a 1-μg sample from 1 ml of plasma was as high as 90 mm. Levels as low as 0.1 μg/ml, using 2-ml aliquots, could be measured. This sensitivity was made possible by using a small volume (10 μl) of chloroform in the final extraction. Although amounts of 0.2–0.5 μg were not included in the daily calibration curve, experience with duplicate determinations showed a variability of less than 10%. Duplicate calibration curves using 1 and 2 ml of plasma had the same slope, demonstrating that the extraction efficiency was not affected by increasing the plasma volume to 2 ml.

The recovery of procainamide from spiked plasma samples was determined to be 37.3%, and the recovery from urine samples was 82.8% (Table II). The low recovery in the double-extraction procedure is due to several factors: (*a*) the unfavorable solvent ratio of 8 ml of ether to 0.2 ml of phthalate buffer (pH 3), (*b*) the transfer of this small volume from test tubes to the vials, and (*c*) the necessity of two extractions at pH 10.8 [procainamide pKa 9.23 (2)] to prevent hydrolysis of *N*-acetylprocainamide.

However, in spite of the low absolute recovery, the overall precision of the method was satisfactory and comparable to that obtained by other GLC methods (18, 19). The variability of recovery shown in Table II is larger than that suggested by Table I, because in this instance the internal standard was not added until the final extraction step was completed and the extraction steps were not made quantitative.

Chromatographic Adsorption—The problem of procainamide adsorption onto the column and/or support during GLC is adequately documented (18, 19). Two approaches generally are used to prevent drug adsorption: (*a*) formation of a derivative of the drug, by which means the active sites on the drug are protected; and (*b*) use, if possible, of a combination of column supports and stationary phases that eliminates active sites for adsorption.

In the present work, it was possible to form derivatives of both procainamide and the internal standard with dimethylformamide dimethyl acetal[9], but the resulting derivatives still showed adsorption characteristics. Benzoyl derivatives, synthesized and chromatographed, also revealed that the adsorption problem was not resolved. Attempts were made to use base-washed column supports and amine packings, including 10% Apiezon L plus 2% KOH[10] and 28% Penwalt 223 plus 4% KOH[6]. When using these stationary phases, it was not possible to develop narrow peaks even at maximum stationary phase temperatures.

The approach of Meijer (22) was then used in which the percent of the stationary phase (of optimum polarity) is increased, the par-

[a] Determined by measuring the appearance of procainamide using this GLC method for samples at 50° and the colorimetric method (4) for samples at 25°.

ticle size of the support is also increased, thereby decreasing the surface area, and the column length is shortened. The percent of OV-17[6] was increased from 3 to 10% on 80–100-mesh support, yielding improved peaks and a reduced solvent front but little effect on adsorption. Ten percent OV-17[6] on 60–80 mesh also gave little improvement. Increasing the percent of this phase to 20% on 60–80-mesh[6] support yielded no improvement over the 10%, and the column temperature had to be raised to obtain usable peaks.

A switch to an OV-1[6] phase allowed the use of lower temperatures, and adsorption was decreased when column length was reduced to 0.91 m. A 10% OV-7[6] phase showed optimum polarity and reduced adsorption to the extent that the calibration curves became linear with negligible intercepts (less than 0.1 μg) (Table I).

Specificity—Elson *et al.* (23) found that patients maintained on procainamide therapy often have plasma levels of *N*-acetylprocainamide several times higher than those of procainamide. In addition, Gibson *et al.* (12) reported on the potential of hydrolysis of *N*-acetylprocainamide during the colorimetric analysis of procainamide using the method of Mark *et al.* (1). Therefore, an assessment of the specificity of any procedure is dependent on an understanding of the conditions of hydrolysis of *N*-acetylprocainamide.

A study of the hydrolysis of *N*-acetylprocainamide in 1 *N* HCl revealed 77.5% hydrolysis in 8 hr at 50° and 26.3% hydrolysis in 18 hr at 25°. In 1 *N* NaOH, 83.0% hydrolysis of *N*-acetylprocainamide was found in 8 hr at 50°. Control studies on procainamide showed no hydrolysis in either 1 *N* HCl or 1 *N* NaOH in 8 hr at 50°. There was, however, no hydrolysis of *N*-acetylprocainamide between pH 3 and 10 for up to 40 hr at 50° (Table III). Therefore, buffers at pH 3 (phthalate buffer) and pH 10.8 (2 *N* Na_2CO_3) were substituted for the 2 *N* HCl and 2 *N* NaOH solutions, respectively, used in the procedure of Mather and Tucker (21). Analysis of solutions of *N*-acetylprocainamide by the proposed method showed no more procainamide present than control solutions of *N*-acetylprocainamide injected directly into the gas chromatograph without extraction.

Application—This method was used to follow the disappearance of procainamide from the plasma and urine of seven normal human subjects given 4 mg/kg iv. The plasma concentration *versus* time curves showed that all plasma procainamide concentrations following the first 0.5 hr postadministration were less than 1 μg/ml and that values fell to below 0.1 μg/ml in less than 6 hr after the dose.

CONCLUSIONS

This GLC method for the determination of procainamide in biological fluids minimizes the adsorption problem so that concentrations as low as 0.1 μg/ml can be quantitatively determined. Also, it has the added advantage of specificity, thus eliminating the interference of *N*-acetylprocainamide. With respect to monitoring procainamide concentrations in the therapeutic range, this procedure is slightly more tedious than other currently available GLC methods. However, with its added sensitivity, it is useful when only small volumes of plasma are available.

Molecular Connectivity I: Relationship to Nonspecific Local Anesthesia

LEMONT B. KIER *x, LOWELL H. HALL *§, WALLACE J. MURRAY *, and MILAN RANDIĆ ‡

Abstract □ A very significant linear correlation was found between a recently proposed connectivity index and molecular polarizability, cavity surface areas calculated for water solubility of alcohols and hydrocarbons, and biological potencies of nonspecific local anesthetics. The simplicity of calculation of the index from the connectivity in the molecular skeleton, together with the very significant correlation, indicates its practical value.

Keyphrases □ Molecular connectivity—correlation with polarizability, cavity surface areas, and biological potencies, hydrocarbons, alcohols, nonspecific local anesthetics □ Polarizability—correlation with molecular connectivity, hydrocarbons, alcohols, nonspecific local anesthetics □ Cavity surface area—correlation with molecular connectivity, hydrocarbons, alcohols, nonspecific local anesthetics □ Anesthetics, nonspecific local—correlation between molecular connectivity and polarization, cavity surface areas, and biological potencies

Recent studies in these laboratories on fundamental aspects of drug–receptor interactions have considered, as part of the total energy, the long-range forces of dispersion and polarization (1–4). These forces are predicted to be dominant in interaction phenomena involving molecules with nonpolar to moderately dipolar structures. The predicted energies of interaction involving these forces between model compounds, simulating all or parts of the drug and receptor molecules, were shown to relate to the quantitative biological response of several series of compounds (1–4).

A fundamental property governing the dispersion and polarization energies of interaction is the polarizability of atoms in a molecule (5). The polarizability of bonds between these atoms is derived from this property (6). Close relationships have indeed been found directly between calculated bond and molecular polarizabilities and the extent of a biological response (1, 7).

The atomic polarizability relates to the volume of the atom; hence, the total molecular polarizability should bear a relationship to some topological property of a molecule (8). In a recent study, Randić (9) devised an index relating to a topological property of a hydrocarbon: the degree of branching or connectivity in the molecule. He showed that this index has a linear relationship to certain physical properties in a series of molecules, including boiling points, the Kovats constant, and empirical parameters dealing with vapor pressure in the Antoine equation.

It is possible that this simply derived index may be fundamental to a topological property governing physical and, in turn, biological properties, which in some areas may be influenced by molecular volume or surface. The purpose of this study was to test the relationship between this index and a biological property relating to polarizability; a very significant correlation was found. Subsequent papers in this series will show that a very close relationship exists with other molecular properties such as water solubility of organic compounds, partition coefficients, molar refractivity, parachor, and physicochemical and thermodynamic properties of the linear free energy type.

EXPERIMENTAL

Calculation of Connectivity Index—The index is derived from the numerical extent of branching or connectivity in the molecular skeleton. The first row atoms of a molecule are dealt with in an identical manner. The hydrogen atoms are suppressed. The degree of bond saturation is ignored in this study but will be considered later.

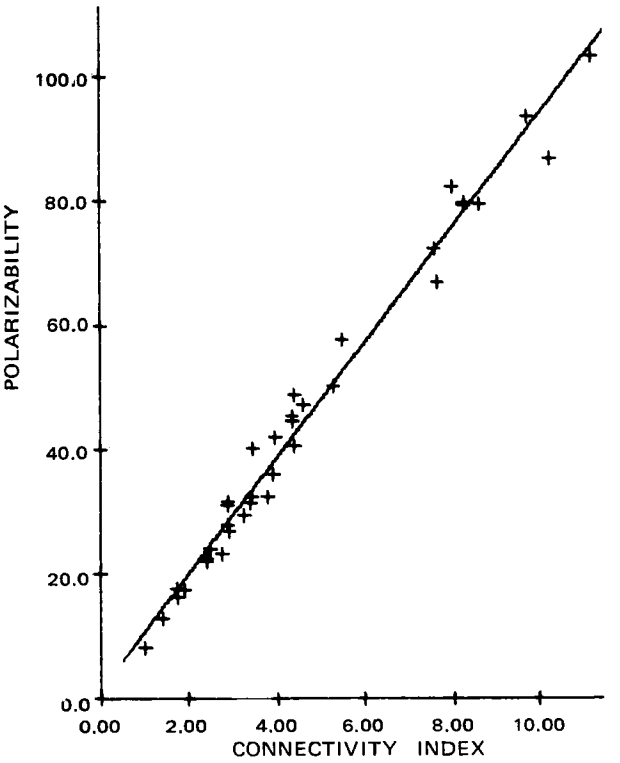

Figure 2—*Computer-drawn plot of the molecular polarizability* versus *the connectivity index for 36 compounds used in a nonspecific anesthesia study.*

The structure is drawn out in skeletal form. Each atom is assigned a number corresponding to the number of atoms attached, *i.e.*, 1, 2, 3, or 4 in the case of a carbon atom. Hydrogen atoms are not included in the count. A number is derived for each bond by calculating the product of the numbers associated with the two

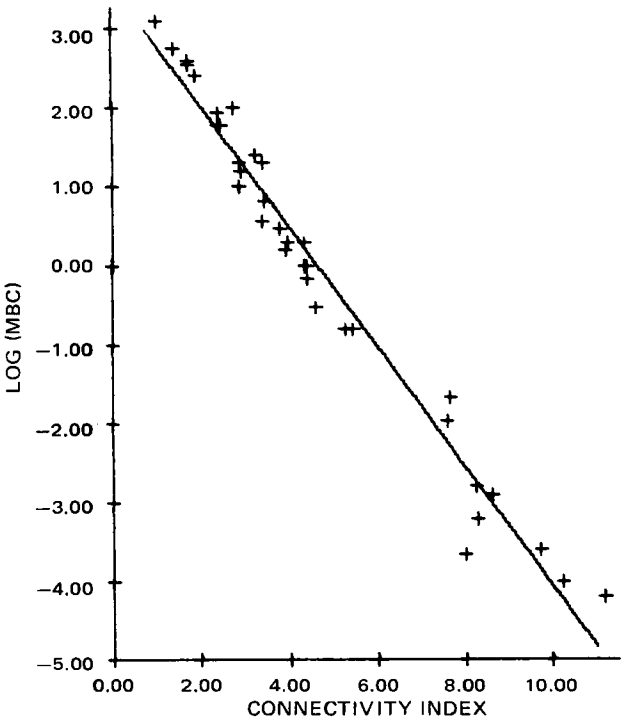

Figure 3—*Computer-drawn plot of the log of the minimum blocking concentration* versus *the connectivity index for 36 compounds used in a nonspecific anesthesia study.*

Table II—Polarizability (α), Minimum Blocking Concentration (MBC), and Connectivity Index (χ) of Local Anesthetics

Anesthetic	χ	α	Predicted α	Log MBC, mM	Predicted Log MBC
Methanol	1.000	8.2	10.9	3.09	2.79
Ethanol	1.414	12.9	14.7	2.75	2.47
Acetone	1.732	16.2	17.7	2.6	2.23

Physostigmine	7.969	82.4	75.4	−3.66	−2.52
Caramiphen	10.224	87.0	96.3	−4.0	−4.24
Dibucaine	11.182	103.6	105.2	−4.2	−4.97

atoms of the bond. The reciprocal of the square root of this number is then computed and becomes the bond value. Finally, the bond values are summed to give a number, called the connectivity index (χ) for the molecule. Two examples of this process are illustrated in Scheme I.

The two molecules, isomers differing only in their branching, yield different connectivity indexes, which are also different from the index for 1-heptanol, 3.914. It appears, then, that the degree of branching is also related to the connectivity index.

Cyclic structures possess one additional bond for each ring relative to the chain isomer. The value of one bond must be subtracted for each ring. For cyclohexane, the summation yields 3.000, from which $1/\sqrt{2 \times 2}$ must be subtracted to yield $\chi = 2.500$. Aromatic molecules are treated in the same way in this study. Thus, benzene has $\chi = 2.500$ while acetanilide has $\chi = 4.287$. Molecules that can ionize are considered in their neutral state.

Correlation of Solvent Cavity Surface Area with Connectivity Index—In studies of hydrocarbon solubility in water, Hermann (10) developed a method for calculating the surface area inside the idealized solvent cavity required to accommodate the hydrocarbon solute. The calculated cavity surface contains the centers of the water molecules in the first layer around the solute. Since this cavity area has the properties of an envelope of enclosure, and hence depends upon the connectivity of the molecular skeleton, it was felt that it may be related to the connectivity index.

These studies found a highly significant correlation between the calculated cavity surface area (CSA) and the connectivity index for 18 hydrocarbons (branched or straight chain). Cyclohexanol is the only cyclic alcohol included. In computing the connectivity index, the quantity 0.5 is subtracted for each ring in the cyclic compounds; *e.g.*, for methylcyclohexane, $\chi = 3.393 - 0.500$.

The regression equation, correlation coefficient, and standard deviation are:

$$\text{CSA} = 133.4 + 58.24\chi \qquad \text{(Eq. 1)}$$
$$r = 0.978 \quad s = 11.2 \quad n = 69$$

The plot of the cavity surface area *versus* the connectivity index is shown in Fig. 1, and the supporting data are presented in Table I.

The second paper in this series discusses the relationship between the connectivity index and the water solubility of hydrocarbons and aliphatic alcohols (11), a property whose fundamental relationship to the cavity surface area was explored by Hermann (10).

Correlation of Molecular Polarizability with Connectivity Index—The polarizability (α) of a molecule may be derived as a sum of atomic refraction constants (7). To explore further how the connectivity index may be related to physical properties of biological importance, the dependence of polarizability on the connectivity index was considered, and a high degree of correlation between these quantities was found.

In Fig. 2 the polarizability is plotted against the connectivity index, and the supporting data are displayed in Table II. The regression equation, correlation coefficient, and standard deviation are:

$$\alpha = 1.60 + 9.26\chi \qquad \text{(Eq. 2)}$$
$$r = 0.990 \quad s = 3.59 \quad n = 36$$

Because of the high degree of correlation found between the connectivity index and polarizability, the relationship of the connectivity index to nonspecific anesthesia, a property thought to be related to molecular polarizability (7), was examined.

Correlation between Local Anesthetic Potency and Connectivity Index—Agin *et al.* (7) compiled and obtained experimentally the minimum blocking concentrations (MBC) of almost 40 molecules on isolated nerve or muscle fiber. They measured the minimum concentration required to excite cells in a standardized set of conditions (Table II). The relationship between the log MBC and the connectivity index is shown in Fig. 3. The regression equation, correlation coefficient, and standard deviation are:

$$\log \text{MBC} = 3.55 - 0.762\chi \qquad \text{(Eq. 3)}$$
$$r = 0.983 \quad s = 0.390 \quad n = 36$$

Acetanilide and aminopyrine were not included from the Agin *et al.* data, because they made an unexplained correction in the activ-

ity for these molecules. Chloroform was not included because of some uncertainties about the chlorine parameter.

DISCUSSION

Two observations come boldly into view: the correlations of the connectivity index with cavity surface area, polarizability, and biological activity are very good, suggesting a fundamental significance for the connectivity index; and the connectivity index value for each molecule is very simply derived, almost by inspection, from no more than four numbers (1, 2, 3, and 4) describing connections.

The mathematical derivation of the connectivity index is extremely simple and is based on discrimination of bond types in a molecule according to the number of its nearest neighbors. The physical significance of the connectivity index is more fundamental than may appear. The individual connectivity index values reflect molecular connectivity and present ultimate fragmentation of the molecular skeleton. Any function of a molecule can be represented as a power expansion of bond contributions. At this initial stage, attention was confined to the linear term of such bond additive schemes.

One may look at connectivity index values as distinctive weighting of bond contributions. It is very significant that the weighting is based solely on the valency of vertexes of molecular graphs and, hence, is nonempirical.

It is plausible to expect that the connectivity index relates to such molecular properties as enclosure volume and surface area. The predictive value of this simply computed index is demonstrated to the biological scientist. In subsequent papers, additional correlations will be described.

Molecular Connectivity II: Relationship to Water Solubility and Boiling Point

LOWELL H. HALL *, LEMONT B. KIER ˣ, and WALLACE J. MURRAY

Abstract □ The connectivity index, easily computed by arithmetic and based upon the degree of connectedness at each vertex in the molecular skeleton, is shown to give highly significant correlations with water solubility of branched, cyclic, and straight-chain alcohols and hydrocarbons as well as with boiling points of alcohols. These correlations are superior to those based on well-founded theory relating to solvent cavity surface area. An empirical modification to the connectivity index gave an improved correlation for both solubilities and boiling points.

Keyphrases □ Molecular connectivity—correlation with water solubility and boiling point, hydrocarbons, alcohols □ Solubility—correlation with molecular connectivity, hydrocarbons, alcohols □ Boiling point—correlation with molecular connectivity, hydrocarbons, alcohols

It has long been known that branched- and straight-chain organic molecules differ in their properties. For example, branched-chain alcohols and hydrocarbons generally have lower boiling points and higher solubilities than the corresponding straight-chain isomers. However, until the recent suggestion by Randić (1), there was no simply computed quantitative scheme for correlating physicochemical data with such topological characteristics as branching. The earlier ideas of Hosoyea (2) and Smolenski (3) have not received acceptance as means for correlating properties. The Hosoyea index shows only a qualitative correlation, and the Smolenski additivity function becomes complex to apply.

Since the manner in which organic groups are connected to form a molecule appears to influence molecular properties, the relationship between a connectivity index and various physicochemical and biological properties was studied. Success in correlating the connectivity index (χ) with polarizability and biological activity of certain nonspecific local anesthetics was reported in Part I (4).

The great utility of a simply computed index that could be used to predict physicochemical properties led to the study of the water solubilities of aliphatic alcohols and hydrocarbons. By applying the significant structure theory to the solubilities of these compounds, several studies showed that the log of the solubilities correlates well with the calculated surface area of the cavity required to accommodate the solute in the solvent water (5, 6).

In Part I, a highly significant correlation of the cavity surface area to the connectivity index was shown (4). This paper explores the correlation of the

ity for these molecules. Chloroform was not included because of some uncertainties about the chlorine parameter.

1-Propanol	1.914	97.4°	97.5°	—	—

[a] Solubility (S), expressed as molality, and boiling points (Tb), expressed in degrees centigrade, were taken from Refs. 5 and 6 and "Handbook of Chemistry and Physics," 51st ed., Chemical Rubber Co., Cleveland, Ohio, 1971, and the references cited therein. [b] Calculated boiling points are based on Eq. A3. [c] Calculated solubilities are based on Eq. A2. [d] For these cyclic compounds, the connectivity index is modified as described in Part I (4): a value of 0.500 is subtracted from the computed connectivity index for the solubility study only.

connectivity index with the water solubility of aliphatic alcohols and hydrocarbons. Furthermore, since boiling points tend to show a variation with structure similar to that of solubilities, the relationship between the connectivity index and the boiling point was also developed.

EXPERIMENTAL

Formulation of Connectivity Index—The connectivity index (χ) (4) is obtained from the molecular skeleton, which is also called the skeletal graph or, more simply, the graph. Hydrogen atoms are suppressed. The degree of connectivity, δ_i, is assigned to each vertex of the skeletal graph. The value of $\delta_i = 1, 2, 3$, or 4, the number of connections at the ith vertex. Then the connectivity index is the sum of connectivities, C_k, of each connection (or edge) of the graph between vertexes i and j:

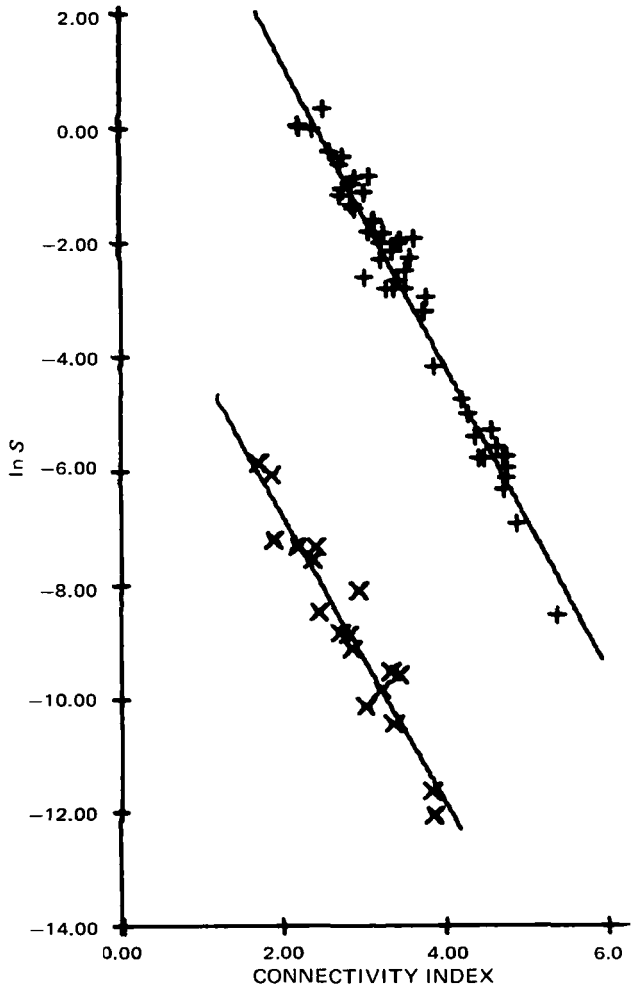

Figure 1—*Computer-drawn plot of the natural logarithm of solubility* versus *the connectivity index for 51 alcohols* (+) *and 18 hydrocarbons* (×) *with the corresponding regression lines.*

$$\chi = \sum_{k=1}^{N} C_k = \sum_{k} \frac{1}{(\sqrt{\delta_i \delta_j})_k} \qquad \text{(Eq. 1)}$$

where N is the number of edges and χ is then simply a sum of terms, each of which is a connectivity contribution for each bond in the molecular skeleton. Illustrations of the calculation of the connectivity index were given in Part I (4). Only simple arithmetic is required: the summation of reciprocal square roots.

Correlation of Water Solubility with Connectivity Index—The correlation of the connectivity index with the water solubility of the hydrocarbons (5, 6) and alcohols (6) was determined. The regression equations, correlation coefficients, and standard errors are as follows (Table I).

For alcohols:

$$\ln S = 6.702 - 2.666\chi \qquad \text{(Eq. 2)}$$

$$r = 0.978 \quad s = 0.455 \quad n = 51$$

For hydrocarbons:

$$\ln S = -1.505 - 2.533\chi \qquad \text{(Eq. 3)}$$

$$r = 0.958 \quad s = 0.511 \quad n = 18$$

where S is solubility expressed as molality (see *Appendix*).

The correlations are of a general high quality (Fig. 1). It is useful to consider the predictive power of this relationship based on connectivity. Table II presents measured and predicted solubilities for three solid alcohols. The solubilities are for the supercooled liquid (6).

The obvious utility of the connectivity index in correlating and predicting solubility is the extraordinary simplicity of its calculation by simple arithmetic from the integers 1, 2, 3, and 4, representing the degrees of connectedness in the molecular skeleton.

Correlation of Boiling Point with Connectivity Index—The correlation between the connectivity index and the boiling points of two sets of alcohols was determined. The regression equations, correlation coefficients, and standard errors are as follows.

For 51 alcohols (from Ref. 6):

$$bp = 10.25 - 39.22\chi \qquad \text{(Eq. 4)}$$

$$r = 0.964 \quad s = 8.68 \quad n = 51$$

For 63 alcohols (from Ref. 6 plus the last 12 compounds in Table I):

$$bp = 11.60 - 39.13\chi \qquad \text{(Eq. 5)}$$

$$r = 0.970 \quad s = 9.35 \quad n = 63$$

It can be clearly seen from Fig. 2 that the use of the connectivity index is excellent both by virtue of its great simplicity and its superior correlation in the case of boiling points. Furthermore, this study included 10 cyclic alcohols in addition to straight-chain and variously branched alcohols.

An empirical improvement to the correlation may be obtained if the degree of connectivity of the hydroxyl group is allowed to vary and its value is determined by multiple regression analysis of alcohol solubility (see *Appendix*).

CONCLUSIONS

A simple connectivity index, easily calculated by arithmetic, based on the degree of connectedness at each vertex in a molecular graph which depicts the molecular skeleton, gives highly significant correlations with the water solubility of hydrocarbons and alcohols as well as with boiling points of alcohols. These correlations

Table II—Observed and Predicted Solubilities for Three Solid Alcohols

Compound	S_{obs}, molal	S_{calc}, molal	S_{calc}[a], molal	χ	c_{OH}
1-Tetradecanol	2.84×10^{-6}	2.12×10^{-6}	2.43×10^{-6}	7.414	0.707

1-Hexadecanol	4.55×10^{-7}	1.47×10^{-7}	1.94×10^{-7}	8.414	0.707

[a] Based on Eq. A2.

are superior to those based on well-founded theory which relates these properties to the surface area of the cavity required to accommodate the solute in water.

The great appeal of the connectivity index lies both in the utter simplicity of its computation and in its fundamental relationship to molecular connectivity. At the heart of chemistry is the concept that an important characteristic of a molecule is the manner in which its substituent parts are connected. The evidence of the first two papers in this series strongly suggests that the connectivity index expresses the fundamental connectedness of organic molecules.

The ability to correlate water solubility with the connectivity index strongly suggests a possible correlation of the connectivity index with the partition coefficients studied by Hansch *et al.* (7). These correlations, as well as those with related biological activity, are presented in Part III.

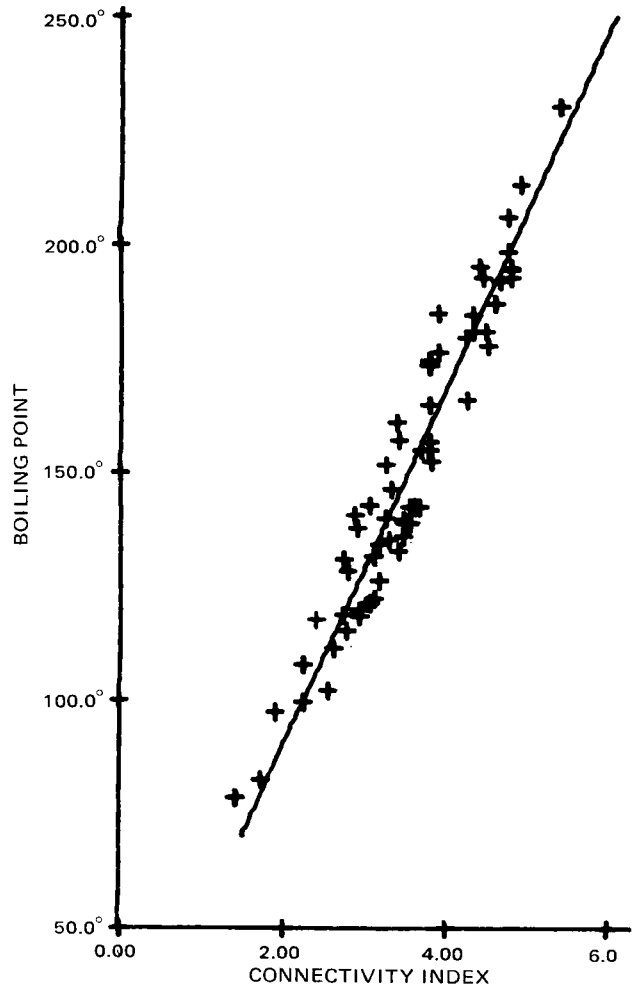

Figure 2—*Computer-drawn plot of the boiling point* versus *the connectivity index for 63 alcohols with the corresponding regression line.*

APPENDIX

The multiple regression equation in this additional study is:

$$\ln S = b_0 - b_1\chi - b_2 c_{OH} - b_3 Q \qquad \text{(Eq. A1)}$$

where b_i terms are regression coefficients, c_{OH} is the contribution of the C—OH bond graph edge to the connectivity index calculated with the OH degree of connectivity equal to 1, and Q has a value of 1 for an alcohol and of 0 for a hydrocarbon. Hence, solubility data for 51 alcohols and 18 hydrocarbons were merged for this multiple regression analysis.

The results of the analysis are:

$$\ln S = -1.516 - 2.528\chi - 3.961 c_{OH} - 10.13Q \qquad \text{(Eq. A2)}$$

$$r = 0.994 \qquad s = 0.383 \qquad n = 69$$

As can be seen, this modification provides a significant improvement in correlation, with a 16% decrease in the standard error of the log of alcohol solubility from 0.455 to 0.383. The calculated solubilities (Table I) are based on the multiple regression equation (Eq. A2).

Based on this improved equation (Eq. A2), the predicted solubilities for the three solid alcohols mentioned earlier are given in Table II.

A similar approach to modification of the connectivity index was applied to the boiling points of the studied alcohols, and significant improvement was also achieved. The regression equation and associated parameters are:

$$\text{bp} = -36.23 - 38.41\chi - 2.216 c_{OH} \qquad \text{(Eq. A3)}$$

$$r = 0.982 \qquad s = 6.47 \qquad n = 63$$

The calculated boiling points in Table I are based on Eq. A3. This and related modifications are currently under study and will be reported later.

Molecular Connectivity III: Relationship to Partition Coefficients

WALLACE J. MURRAY, LOWELL H. HALL *, and LEMONT B. KIER ×

Abstract □ The molecular connectivity index is shown to be linearly related to the octanol–water partition coefficients of a variety of monofunctional chemical classes including esters, alcohols, ketones, ethers, carboxylic acids, amines, and hydrocarbons. A modification of the connectivity index, taking into account the valency or degree of unsaturation of an atom, merges the data for all compounds except hydrocarbons. The connectivity index is also shown to be useful for correlating biological activity. These studies indicate that partition coefficients represent empirical quantities having intermediate significance between biological data and the more fundamental property of molecular connectivity.

Keyphrases □ Molecular connectivity—relationship to octanol–water partition coefficients of various chemical classes □ Partition coefficients—octanol–water, relationship to molecular connectivity of various chemical classes

Parts I and II showed the relationship of molecular connectivity, given by χ, to polarizability, cavity surface area, local anesthetic action (1), water solubilities, and boiling points (2). The connectivity index appears to be a topological index in that the calculation is fundamentally dependent on the way constituent atoms of a molecule are attached to one another. Seemingly encoded in the connectivity index, which results from a simple mathematical operation (1), is the molecular structure of a chemical species. It might be expected that any physicochemical or biological property that is a function of the topological structure of a molecule, in this case its connectedness, is going to be related in some fashion to the connectivity index. Having shown the high correlation of a linear relationship between water solubilities and the connectivity index (2), it seems logical to examine the relationship of the connectivity index to partition coefficients.

The work of Hansch *et al.* (3, 4) and Nys and Rekker (5) on the partition coefficients of various compounds in an octanol–water system provided partition data (log P) for comparison. From their work were selected log P values for 45 hydrocarbons, 24 esters, nine carboxylic acids, 49 alcohols, 28 amines, 16

[a] The connectivity index was calculated using valency modification described in text. [b] Partition coefficients in a 1-octanol–water system were taken from Refs. 3, 5, and 7 and references cited therein. [c] Calculated log P values were derived from the equations developed for each functional group series compiled in Table II.

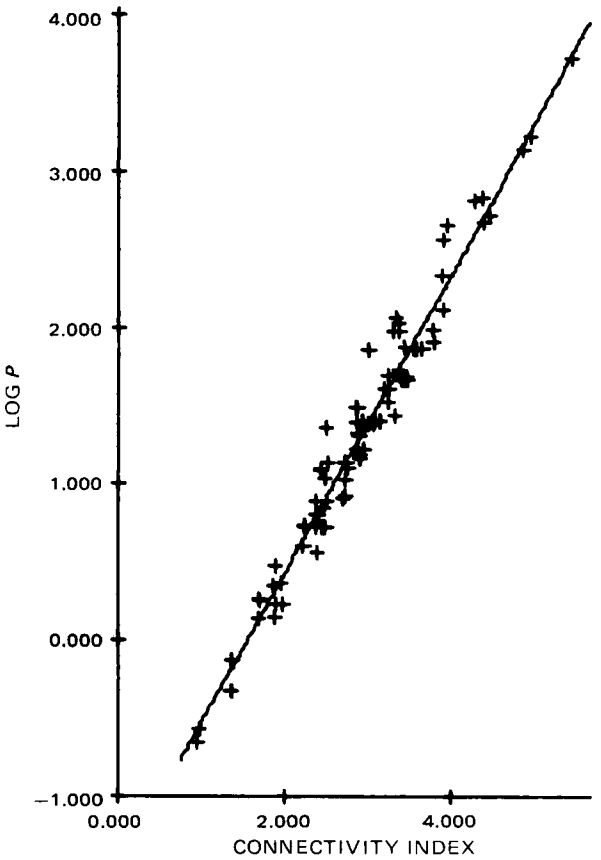

Figure 1—*Computer-drawn plot of the logarithm of the partition coefficient* versus *the molecular connectivity index for 24 esters, nine carboxylic acids, 49 alcohols, 28 amines, 16 ketones, and 12 ethers with the corresponding regression line.*

Table II—Summary of Regression Equations, Correlation Coefficients, and Standard Deviations

Class of Compounds	n	Slope	Intercept	r	s
Carboxylic acids	9	0.927 ± 0.03	−1.41 ± 0.11	0.996	0.122
Esters	24	0.996 ± 0.01	−1.71 ± 0.04	0.999	0.060
Ethers	12	0.964 ± 0.07	−1.30 ± 0.19	0.976	0.080
Alcohols	49	0.966 ± 0.03	−1.53 ± 0.09	0.997	0.151
Amines	28	0.977 ± 0.04	−1.51 ± 0.12	0.979	0.179
Ketones	16	0.982 ± 0.03	−1.16 ± 0.09	0.993	0.094
Hydrocarbons	45	0.884 ± 0.03	0.406 ± 0.09	0.975	0.160
All compounds except hydrocarbons	138	0.950 ± 0.01	−1.48 ± 0.04	0.986	0.152

ketones, and 12 ethers (Table I). In addition to the functional group differences, each series provides compounds with structural diversity, *i.e.*, branched, straight-chain, cyclic, unsaturated, and aromatic hydrocarbon skeletons. This selection provides sufficient breadth of structure to demonstrate that a linear relationship between log P and the connectivity index is more than simply fortuitous.

EXPERIMENTAL

The molecular connectivity (χ) was calculated in the usual manner (1, 2). The molecular skeleton was drawn and each carbon atom in the skeleton was assigned a number, 1, 2, 3, or 4, corresponding to the number of nonhydrogen atoms connected to the carbon atom. The isosteric relationship of $-CH_3$, $-OH$, and $-NH_2$ was utilized so hydroxyl and amino functionalities were assigned the number 1, an ether oxygen was assigned the number 2, and the nitrogen atom of substituted amines, RNH— and R_2N—, were assigned connectivities of 2 and 3, respectively. Initially, the valency of atoms was ignored so that, for example, a carbonyl oxygen was assigned a connectivity of 1 and unsaturated carbon atoms, RHC=, were given connectivity numbers based solely on the number of nonhydrogen attachments.

Plots of log P *versus* the connectivity index were computed, and families of parallel lines were obtained, each having approximately the same slope but different intercepts. These families of curves appear to be related to the degree of unsaturation inherent in each functional group or in the hydrocarbon skeleton.

Table III—Molecular Connectivity Index (χ) *versus* Selected Biological Activities[a]

Compound	χ[b]	V-17[c], pC obs.	V-18[d], pC obs.	V-19[d], pC obs.

[a] Biological activities (pC, obs.) were obtained from Ref. 9. [b] The connectivity index was calculated using valency modification described in text. [c] Biological activity is barnacle larvae narcosis (10). [d] Biological activity is I_{100}, movement of 2.5-day-old and 12-day-old tadpoles at 18° (11). [e] Not included in the derivation of regression equation.

It is assumed that a π-bond increases the connectivity of a carbon or oxygen atom by one unit, *e.g.*, CH_2= has connectivity 2, RHC= has connectivity 3, R_2C= connectivity 4, O= connectivity 2, and HC≡ connectivity 3. The valency modification merges the data for all classes of compounds (except the hydrocarbons) onto one line (Fig. 1). Table II summarizes the regression equations, correlation coefficients, and standard deviations for each class of compounds.

This refinement, *i.e.*, the use of valency, is not always necessary. In the linear relationship between the connectivity index and polarizability (1), a correlation coefficient of 0.990 was obtained, taking into account only attachments. The modification does, however, appear to be necessary in correlating the connectivity index to log P and solubility (2).

DISCUSSION

The molecular connectivity index, suggested by Randić (6), correlates significantly with a number of physicochemical properties (1, 2). It is now shown to have a high degree of correlation with the partition coefficients (log P) of a variety of compounds, encompassing several monofunctional groups and having structural diversity.

The importance of log P as a measure of lipophilicity and its use in structure–activity relationships are well known (7–9). It seems obvious that since the connectivity index is linearly related to log P, it should correlate in the same fashion as log P to biological activity. This hypothesis was tested on several systems where log P had been correlated with biological activity (9). Table III summarizes the data. These systems were all linearly related to log P and the connectivity index. For these systems, the following relationship and statistics were obtained.

For Study V-17 [narcosis, larvae, barnacle (10)]:

$$pC = -1.167(\pm 0.011) + 1.073(\pm 0.041)\chi \qquad \text{(Eq. 1)}$$

$$r = 0.991 \quad s = 0.141 \quad n = 15$$

For Study V-18 [I_{100}, movement 2.5-day-old tadpoles, 18° (11)]:

$$pC = -1.541(\pm 0.115) + 1.328(\pm 0.040)\chi \qquad \text{(Eq. 2)}$$

$$r = 0.997 \quad s = 0.127 \quad n = 8$$

For Study V-19 [I_{100}, movement 12-day-old tadpoles, 18° (11)]:

$$pC = -1.41(\pm 0.088) + 1.294(\pm 0.030)\chi \qquad \text{(Eq. 3)}$$

$$r = 0.998 \quad s = 0.097 \quad n = 8$$

These results compare very favorably with relationships to log P (9). Current studies are extending this exploration of the direct correlation of molecular connectivity to biological activity. The relationship of the connectivity index to other parameters such as Taft's steric parameter, E_s (12), used in structure–activity relationships is also being investigated.

Apparently, the partition coefficient represents an experimental quantity of intermediate significance between biological data and the more fundamental property of molecular connectivity, expressed as χ.

The tremendous utility of the connectivity index lies in the simplicity of its computation; no tables are needed for the calculations. Simply by assigning the degree of connectedness and the valency of an atom in a molecule and by performing a simple arithmetic computation, the connectivity index may be calculated. Simultaneously, the connectivity index appears to be related to the

fundamental notion that molecular structure, or connectedness, plays an important role in physicochemical and, hence, biological properties. The relation of the connectivity index to other constitutive, additive properties is being pursued.

Size Distribution Effects in Multiparticulate Dissolution

PETER VENG PEDERSEN [x] and K. F. BROWN

Abstract □ The evaluation of models for single-particle dissolution, based on multiparticulate dissolution data, is complicated by the distribution effect present when the particles are not truly monodispersed. By using simulated data, it is shown that remarkably good linearity can be obtained with log-normal powders using an incorrect model. It is suggested that particle-size analysis is necessary to enable calculation of the distribution effect and to prevent this type of misinterpretation. The change in particle-size distribution during dissolution is calculated and shows potential for distinguishing between two, but not all three, of the models investigated. Four theoretical rules for multiparticulate dissolution are stated and discussed. The concept of "time scaling" is presented. By using this procedure, it should be possible to reduce considerably computational errors arising from nonlinear dissolution data. It is demonstrated that dissolution profiles can be transformed to a standard form, enabling the distribution effect to be evaluated without interference from rate or particle-size parameters.

Keyphrases □ Dissolution, multiparticulate—size distribution effects, log-normal powders, three single-particle models investigated □ Powders, dissolution—size distribution effects, log-normal distribution profile, three single-particle models investigated □ Particle dissolution—size distribution effects, log-normal powders, three single-particle models investigated

The dissolution profile of a powder is determined by its particle-size distribution and the way the single particles dissolve. Several mathematical models have been presented to describe single-particle dissolution (1–4), but none of these has yet received complete acceptance. Experimental evaluation of the models on the basis of multiparticulate dissolution data is complicated by the distribution effect present when the powder is not truly monodispersed. Such powders are impossible to obtain in most cases (5). Processes such as sieving, precipitation, and grinding do not yield completely uniform particles. This situation is particularly true for fine powders which are of greatest pharmaceutical importance.

In recent years, there has been increasing interest in evaluating the distribution effect in multiparticulate dissolution (6–9). A previous paper (9) discussed the theory and mathematics of multiparticulate systems in relation to single-particle dissolution and the initial size distribution. The present paper evaluates distribution effects for log-normal powder systems; three single-particle dissolution models from the literature are considered. By using simulated dissolution data and particle-size distributions, the possibility of distinguishing between the models is investigated.

THEORY

Let:

$$w = g(w_0,t) \qquad \text{(Eq. 1)}$$

and:

$$w_0 = g^{-1}(w,t) \qquad \text{(Eq. 2)}$$

describe the dissolution equation and inverse dissolution equation, respectively, for a single particle, where w and w_0 are the particle weights at time t and 0, respectively. Further, let $l_0(a_0)$ denote the initial ($t = 0$) particle-size density ("probability") distribution. By assuming that particles are spherical and remain so during dissolution, the particle weight, w, is related to the diameter, a, at any time by $w = \rho\pi a^3/6$, where ρ is the particle density.

By using a technique similar to the one used in a previous paper (9), the following equation can be derived which rigorously describes the particle-size distribution, $l(a)$, at any time if the initial distribution, $l_0(a_0)$, is known together with the particle dissolution function, g:

fundamental notion that molecular structure, or connectedness, plays an important role in physicochemical and, hence, biological properties. The relation of the connectivity index to other constitutive, additive properties is being pursued.

Size Distribution Effects in Multiparticulate Dissolution

PETER VENG PEDERSEN [x] and K. F. BROWN

Abstract □ The evaluation of models for single-particle dissolution, based on multiparticulate dissolution data, is complicated by the distribution effect present when the particles are not truly monodispersed. By using simulated data, it is shown that remarkably good linearity can be obtained with log-normal powders using an incorrect model. It is suggested that particle-size analysis is necessary to enable calculation of the distribution effect and to prevent this type of misinterpretation. The change in particle-size distribution during dissolution is calculated and shows potential for distinguishing between two, but not all three, of the models investigated. Four theoretical rules for multiparticulate dissolution are stated and discussed. The concept of "time scaling" is presented. By using this procedure, it should be possible to reduce considerably computational errors arising from nonlinear dissolution data. It is demonstrated that dissolution profiles can be transformed to a standard form, enabling the distribution effect to be evaluated without interference from rate or particle-size parameters.

Keyphrases □ Dissolution, multiparticulate—size distribution effects, log-normal powders, three single-particle models investigated □ Powders, dissolution—size distribution effects, log-normal distribution profile, three single-particle models investigated □ Particle dissolution—size distribution effects, log-normal powders, three single-particle models investigated

The dissolution profile of a powder is determined by its particle-size distribution and the way the single particles dissolve. Several mathematical models have been presented to describe single-particle dissolution (1–4), but none of these has yet received complete acceptance. Experimental evaluation of the models on the basis of multiparticulate dissolution data is complicated by the distribution effect present when the powder is not truly monodispersed. Such powders are impossible to obtain in most cases (5). Processes such as sieving, precipitation, and grinding do not yield completely uniform particles. This situation is particularly true for fine powders which are of greatest pharmaceutical importance.

In recent years, there has been increasing interest in evaluating the distribution effect in multiparticulate dissolution (6–9). A previous paper (9) discussed the theory and mathematics of multiparticulate systems in relation to single-particle dissolution and the initial size distribution. The present paper evaluates distribution effects for log-normal powder systems; three single-particle dissolution models from the literature are considered. By using simulated dissolution data and particle-size distributions, the possibility of distinguishing between the models is investigated.

THEORY

Let:

$$w = g(w_0,t) \qquad \text{(Eq. 1)}$$

and:

$$w_0 = g^{-1}(w,t) \qquad \text{(Eq. 2)}$$

describe the dissolution equation and inverse dissolution equation, respectively, for a single particle, where w and w_0 are the particle weights at time t and 0, respectively. Further, let $l_0(a_0)$ denote the initial ($t = 0$) particle-size density ("probability") distribution. By assuming that particles are spherical and remain so during dissolution, the particle weight, w, is related to the diameter, a, at any time by $w = \rho\pi a^3/6$, where ρ is the particle density.

By using a technique similar to the one used in a previous paper (9), the following equation can be derived which rigorously describes the particle-size distribution, $l(a)$, at any time if the initial distribution, $l_0(a_0)$, is known together with the particle dissolution function, g:

$$l(a) = \frac{l_0\left(\left[\frac{6}{\pi\rho}g^{-1}\left(\frac{\pi\rho}{6}a^3,t\right)\right]^{1/3}\right)\frac{d}{da}\left[\frac{6}{\pi\rho}g^{-1}\left(\frac{\pi\rho}{6}a^3,t\right)\right]^{1/3}}{\int_{L_1}^{L_2} l_0(a)\,da} \quad \text{(Eq. 3)}$$

for:

$$P\left[\frac{6}{\pi\rho}g\left(\frac{\pi\rho}{6}d_0^3,t\right)\right]^{1/3} \leq a \leq P\left[\frac{6}{\pi\rho}g\left(\frac{\pi\rho}{6}D_0^3,t\right)\right]^{1/3}$$

and $l(a) = 0$ elsewhere.

The integration limits L_1 and L_2 depend on time as follows:

$$L_1 = d_0 \quad \text{for } t \text{ such that } Pg\left(\frac{\pi\rho}{6}d_0^3,t\right) > 0 \quad \text{(Eq. 4a)}$$

$$L_1 = \left[\frac{6}{\pi\rho}g^{-1}(0,t)\right]^{1/3} \quad \text{for } t \text{ such that } Pg\left(\frac{\pi\rho}{6}d_0^3,t\right) = 0 \quad \text{(Eq. 4b)}$$

$$L_2 = D_0 \quad \text{for } t \text{ such that } Pg\left(\frac{\pi\rho}{6}D_0^3,t\right) > 0 \quad \text{(Eq. 4c)}$$

$$L_2 = \left[\frac{6}{\pi\rho}g^{-1}(0,t)\right]^{1/3} \quad \text{for } t \text{ such that } Pg\left(\frac{\pi\rho}{6}D_0^3,t\right) = 0 \quad \text{(Eq. 4d)}$$

where d_0 and D_0 denote the initial diameters of the smallest and largest particles, respectively. The operator P has been introduced to make the expression generally applicable (9). It is defined to be equal to one in the time period before the operand becomes zero and is equal to zero beyond that time. The lower integration limit, L_1, changes value at $g[(\rho\pi/6)d_0^3,t] = 0$, that is the critical time, when the particles start to disappear. The time at which $g[(\rho\pi/6)D_0^3,t] = 0$ corresponds to the disappearance of the last particle and marks the completion of the dissolution process.

Many powders have size distributions that are approximately log-normal (5). Consider such a powder distributed such that $\ln a_0$ approximates a normal distribution with mean μ and standard deviation σ truncated at $\ln d_0 = \mu - i\sigma$ and $\ln D_0 = \mu + j\sigma$, where i and j are truncation parameters. The initial particle-size distribution, $l_0(a_0)$, is then given by (9):

$$l_0(a_0) = \frac{a_0^{-1}N(\ln a_0,\mu,\sigma)}{\int_{d_0}^{D_0} a_0^{-1}N(\ln a_0,\mu,\sigma)da_0} \qquad d_0 \leq a_0 \leq D_0 \quad \text{(Eq. 5)}$$

where $N(\,)$ is the normal distribution with $\ln a_0$ as the variable.

The change in the particle-size distribution during dissolution depends on the way the individual particles dissolve. Three widely known models for single-particle dissolution are considered. When written in the same form as Eq. 1, the Hixson–Crowell "cube root law" (3) can be expressed as:

$$w = (w_0^{1/3} - k_3t)^3 \quad \text{(Eq. 6)}$$

In a similar way, the equation presented by Niebergall *et al.* (2) can be written simply:

$$w = (w_0^{1/2} - k_2t)^2 \quad \text{(Eq. 7)}$$

and the model proposed by Higuchi and Hiestand (1) can be written:

$$w = (w_0^{2/3} - k_1t)^{3/2} \quad \text{(Eq. 8)}$$

For simplicity and because their evaluation is not important to the theoretical discussion, the constants k_1, k_2, and k_3 are used in place of the original time coefficients which included parameters such as the shape factor, particle density, and diffusion coefficient. In the following discussion, Eqs. 8, 7, and 6 will be referred to as Models 1, 2, and 3, respectively.

By having defined the initial size distribution, $l_0(a_0)$ (Eq. 5), and the dissolution function (Eqs. 6–8), the size distribution at time t, $l(a)$, can be expressed applying Eq. 3:

$$l(a) = \frac{a^{\left(\frac{3}{m}-1\right)}(a^{\frac{3}{m}} + Kt)^{-1}N[\ln(a^{\frac{3}{m}} + Kt)^{\frac{m}{3}},\mu,\sigma]}{F\left(\frac{T_2-\mu}{\sigma}\right) - F\left(\frac{T_1-\mu}{\sigma}\right)} \quad \text{(Eq. 9)}$$

for:

$$P(e^{\frac{3}{m}(\mu-i\sigma)} - Kt)^{\frac{m}{3}} \leq a \leq P(e^{\frac{3}{m}(\mu+j\sigma)} - Kt)^{\frac{m}{3}}$$

and $l(a) = 0$ elsewhere. Also:

$$T_1 = \mu - i\sigma \quad \text{for } \frac{m}{3}\ln(Kt) < \mu - i\sigma \quad \text{(Eq. 10a)}$$

$$T_1 = \frac{m}{3}\ln(Kt) \quad \text{for } \frac{m}{3}\ln(Kt) \geq \mu - i\sigma \quad \text{(Eq. 10b)}$$

$$T_2 = \mu + j\sigma \quad \text{for } \frac{m}{3}\ln(Kt) < \mu + j\sigma \quad \text{(Eq. 10c)}$$

$$T_2 = \frac{m}{3}\ln(Kt) \quad \text{for } \frac{m}{3}\ln(Kt) \geq \mu + j\sigma \quad \text{(Eq. 10d)}$$

and:

$$K = (6/\rho\pi)^{\frac{1}{m}}k \quad \text{(Eq. 11)}$$

Equation 9 describes the size distribution for all three models. For Model 1, $m = 3/2$; for Model 2, $m = 2$; and for Model 3, $m = 3$. The constants k and K for each model should be k_1, k_2, and k_3 and K_1, K_2, and K_3, respectively. The function $F(\,)$, the commonly tabulated area under the standard normal curve function, is defined as:

$$F(x) = \int_{-\infty}^{x}(1/\sqrt{2\pi})e^{-\frac{x^2}{2}}\,dx \quad \text{(Eq. 12)}$$

The mean particle size (diameter), $\bar{a}$, can be obtained by applying the usual integration approach used in mathematical expectation:

$$\bar{a} = \frac{\int_R a^{\frac{3}{m}}(a^{\frac{3}{m}} + Kt)^{-1}N[\ln(a^{\frac{3}{m}} + Kt)^{\frac{m}{3}},\mu,\sigma]da}{F\left(\frac{T_2-\mu}{\sigma}\right) - F\left(\frac{T_1-\mu}{\sigma}\right)} \quad \text{(Eq. 13)}$$

The integration interval R in Eq. 13 is the same as the interval for a defined in Eq. 9. Equation 13 considers Models 1 and 2 ($m = 3/2$ and $m = 2$, respectively). The mean particle size for the third model ($m = 3$) simplifies further to:

$$\bar{a} = \frac{F\left(\frac{T_2-\mu}{\sigma} - \sigma\right) - F\left(\frac{T_1-\mu}{\sigma} - \sigma\right)}{F\left(\frac{T_2-\mu}{\sigma}\right) - F\left(\frac{T_1-\mu}{\sigma}\right)}e^{\mu+\sigma^2/2} - K_3t \quad \text{(Eq. 14)}$$

where T_1 and T_2 are still defined as in Eqs. 10a–10d. The exact dissolution profile of a log-normal powder with single particles dissolving according to each of the three models can be derived using Eq. 13 presented in the previous paper (9):

$$\frac{W}{W_0} = \sum_{n=0}^{m}\binom{m}{n}(-Kt)^{(m-n)} \times \frac{F\left(\frac{T_2-\mu}{\sigma} - \frac{3n\sigma}{m}\right) - F\left(\frac{T_1-\mu}{\sigma} - \frac{3n\sigma}{m}\right)}{F(j-3\sigma) - F(-i-3\sigma)} \times e^{\frac{3}{m}(n-m)[\mu+\frac{3}{m}(n+m)\sigma^2/2]} \quad \text{(Eq. 15)}$$

where W_t and W_0 are the amounts of undissolved powder at time t and 0, respectively. Equation 15 with $m = 3$, although presented in more compact form, is identical to Eq. 18 in the previous paper (9). Equation 15 is not defined for Model 1 ($m = 3/2$), which must be considered separately:

$$\frac{W}{W_0} = \frac{\int_{R_1}^{R_2}(w^2 - K_1t)^{3/2}w^{-1}N(\ln w,\mu,\sigma)\,dw}{F(j-3\sigma) - F(-i-3\sigma)}e^{-3\mu-9\sigma^2/2} \quad \text{(Eq. 16)}$$

where:

$$R_1 = e^{\mu-i\sigma} \quad \text{for } (K_1t)^{1/2} < e^{\mu-i\sigma} \quad \text{(Eq. 17a)}$$

$$R_1 = (K_1t)^{1/2} \quad \text{for } (K_1t)^{1/2} \geq e^{\mu-i\sigma} \quad \text{(Eq. 17b)}$$

$$R_2 = e^{\mu+j\sigma} \quad \text{for } (K_1t)^{1/2} < e^{\mu+j\sigma} \quad \text{(Eq. 17c)}$$

$$R_2 = (K_1t)^{1/2} \quad \text{for } (K_1t)^{1/2} \geq e^{\mu+j\sigma} \quad \text{(Eq. 17d)}$$

The derivations of these equations are based on two assumptions: (*a*) that the particles in the multiparticulate system dissolve

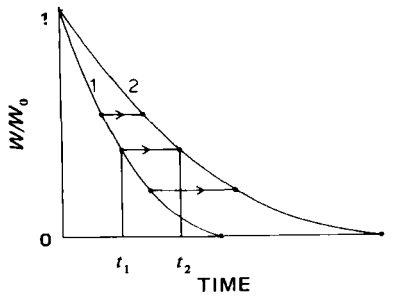

Figure 1—*Two dissolution curves having the same intrinsic dissolution profile. Curve 1 can be brought into curve 2 by a time-scaling factor,* t_2/t_1. *Rule 2 states that* $k_{(1)} = (t_2/t_1)k_{(2)}$, *where* $k_{(1)}$ *and* $k_{(2)}$ *are the rate parameters in the single-particle dissolution equation for Systems 1 and 2 having the same particle-size distribution. These statements also include plots where* W/W_0 *is raised to any other exponent.*

independently of each other, which will be approximated well under sink conditions; and (*b*) that they dissolve according to the same single-particle dissolution model having fixed parameters (for these cases, k_1, k_2, and k_3 are the same for all particles and do not vary during the dissolution). If these conditions exist, then it is possible to make some general rules concerning the dissolution process. These rules are explained in relation to what will be termed "the intrinsic dissolution profile," which can be defined in the following way. Dissolution curves have the same intrinsic dissolution profile if, by a suitable scaling of time, they can be brought into each other in a W/W_0 *versus* time plot (Fig. 1).

It should be clear from observation of Eqs. 12 and 13 in the previous paper (9) that the coefficient of time in an expression correctly defining the multiparticulate dissolution profile originates directly from the coefficient of time in the single-particle dissolution equation. Thus, a different value of the rate parameter, that is, a different coefficient of time in the single-particle dissolution equation, has the same effect as a different scaling of time. Therefore, the intrinsic dissolution profile will still be the same. The following rule can thus be stated:

1. *The intrinsic dissolution profile is independent of the value of the rate parameter, that is, the coefficient of time in the single-particle dissolution equation.*

According to this rule, the rate parameters k_1, k_2, and k_3 (Eqs. 6–8) have no influence on the intrinsic dissolution profile. Furthermore, there will always be a proportional relationship between the coefficient of time in the multiparticulate dissolution equation and the rate parameter [note, for example, that K in Eqs. 15 and 16 is related to k by $K = (6/\rho\pi)^{1/m}k$ as seen in Eq. 11]. The following rule can therefore be stated:

2. *In two systems having identical particle-size distributions, the time-scaling factor that brings one dissolution curve into another is equal to the factor with which the rate parameters are proportionally related in the two systems* (Fig. 1).

Consider two particle-size distributions that on a logarithmic scale are distributed $l_1(\log a)$ and $l_2(\log a)$, having the same shape. Then, for any diameter, a (Fig. 2) $l_1(\log a) = l_2(\log a + \log K_a)$;

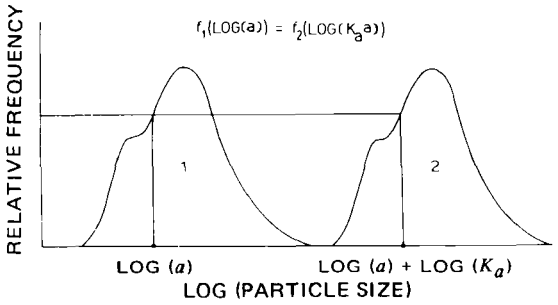

Figure 2—*Two particle-size distributions having the same shape on a logarithmic scale. According to Rule 3, these distributions result in dissolution curves with the same intrinsic dissolution profile (for example, curves 1 and 2 of Fig. 1).*

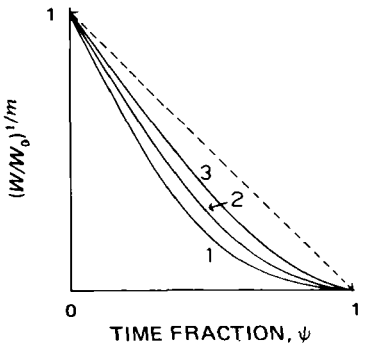

Figure 3—*Normalized dissolution profiles of powders initially log-normal* ($\sigma = 0.2$, i = j = 2), *calculated (Eqs. 16 and 19) to dissolve and plotted according to Models 1, 2, and 3: Model 1,* m = 3/2; *Model 2,* m = 2; *and Model 3,* m = 3. *The stippled line represents monodispersed powders* ($\sigma = 0$).

i.e., $l_1(\log a) = l_2(\log K_a a)$, where $\log K_a$ is a measure of the distance between the logarithmic distributions. Therefore, if the particles in System 2 are scaled (measured) in units of K_a, the resulting distribution is the same as that for System 1. Such a scaling of the particle sizes has an effect on the calculated dissolution profile.

However, if the coefficient of time in the single-particle dissolution equation is dimensionally dependent on length, as in a model that is not first order, then a scaling in length, as in the above transformation of the particle-size distribution, has the same effect as a scaling in time. If the single-particle dissolution is a first-order process, then the dissolution profile is completely independent of the particle-size distribution, because the fraction of each particle that dissolves in a given time is the same, independent of its size. Therefore, it can be concluded that Systems 1 and 2 have the same intrinsic dissolution profile, and the following rule can be given:

3. *Two powders dissolving according to the same single-particle dissolution model have the same intrinsic dissolution profile if their particle-size distributions are of the same shape on a logarithmic scale* (Fig. 2).

It follows from this rule that it is not the "position" of the distribution, that is, not the actual size of the particles, but the shape of the distribution that affects the intrinsic dissolution profile. Thus it can be stated that:

4. *The intrinsic dissolution profile does not depend on the actual sizes of the particles but on the shape of their distribution.*

RESULTS AND DISCUSSION

According to Rule 2, the concept of time scaling in dissolution studies should have some practical application. It already has been stated that it is impossible to prepare completely monodispersed powders; therefore, some nonlinearity always is present in the dissolution profile due to the distribution effect (9). This nonlinearity

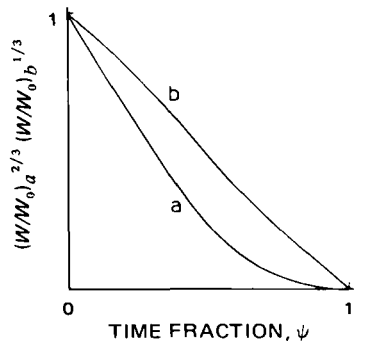

Figure 4—*Normalized dissolution profiles of powders initially log-normal* ($\sigma = 0.14$, i = j = 2), *calculated (Eq. 16) to dissolve and plotted according to Model 1 (curve a). Curve b is the same data plotted according to Model 3, resulting in almost complete cancellation of the size distribution effect observed in curve a.*

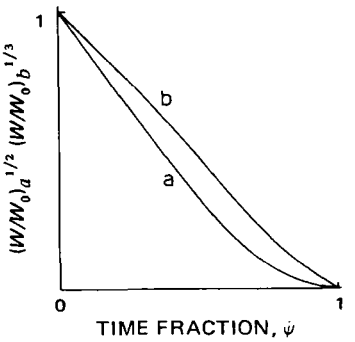

Figure 5—*Normalized dissolution profiles of powders initially log-normal (σ = 0.12, i = j = 2), calculated (Eq. 19, m = 2) to dissolve and plotted according to Model 2 (curve a). Curve b is the same data plotted according to Model 3, resulting in almost complete cancellation of the size distribution effect observed in curve a.*

introduces errors into determination of the influence of factors such as the stirring rate, temperature, and vehicle composition on the rate parameter (k_1, k_2, or k_3) using conventional "initial slope" or "line of best fit" computational techniques.

However, Rule 2 provides an alternative approach where this type of error is negligible. The new technique simply involves finding a time-scaling factor that brings one curve into the other or, more correctly, minimizes the separation of the curves. This factor is then equal to the factor by which the two rate parameters are proportionally related. Possibly the best criterion is to minimize the squared horizontal differences between the curves.

According to Rules 1 and 3, it should be possible to normalize the calculated dissolution profiles for log-normal powders by appropriate scaling of time to a form that does not depend on either the rate parameter (k_1, k_2, or k_3) or the actual sizes of the particles. One approach is to scale the time in the W/W_0 *versus* time plots as the time fraction, ψ, defined as the fraction of the time necessary for complete dissolution. The expression defining the resulting normalized dissolution profile can be obtained in the following way, using Models 2 and 3 as examples. The time for complete dissolution, t_0, is given by $(m/3)\ \ln\ (Kt_0) = \mu + j\sigma$ (Eqs. 9 and 15); then since $\psi = t/t_0$, it follows that:

$$\psi = Ke^{-\frac{3}{m}(\mu + j\sigma)}t \qquad \text{(Eq. 18)}$$

Accordingly, the Kt terms in Eq. 15 can be substituted by

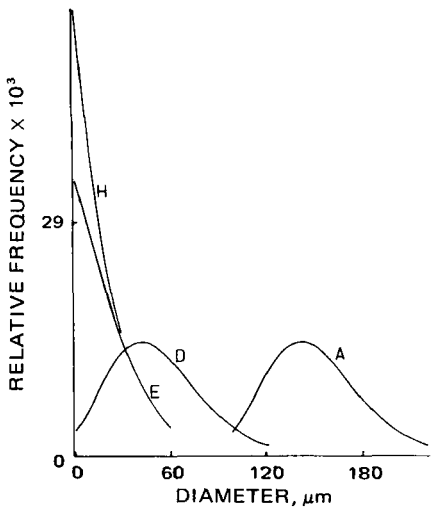

Figure 6—*Size distribution change with time for a powder initially log-normal (μ = 5, σ = 0.2, i = j = 2), calculated (Eq. 9, m = 3) to dissolve according to Model 3. Distributions are labeled in chronological order. Key: A, initial distribution; and D, distribution at critical time.*

$\psi^{3(\mu+j\sigma)/m}$, which causes the μ terms to cancel out. After rearrangement, Eq. 15 can be written:

$$\frac{W}{W_0} = \sum_{n=0}^{m}\binom{m}{n}(-\psi)^{(m-n)}\frac{F\left(j - \frac{3n\sigma}{m}\right) - F(A)}{F(j - 3\sigma) - F(-i - 3\sigma)} \times e^{\frac{3}{m}(n-m)(-j\sigma + \frac{3}{m}(n+m)\sigma^2/2)} \qquad \text{(Eq. 19)}$$

where:

$$A = i - \frac{3n\sigma}{m} \qquad \text{for } 0 \le \psi < e^{-\frac{3}{m}(i+j)m} \qquad \text{(Eq. 20)}$$

and:

$$A = j + \frac{m \ln \psi}{3\sigma} - \frac{3n\sigma}{m} \qquad \text{for } e^{-\frac{3}{m}(i+j)m} \le \psi \le 1 \qquad \text{(Eq. 21)}$$

It is seen that the normalized dissolution profile (Eq. 19, m = 2 or m = 3) does not contain any rate terms (k_3 or k_2 from Eq. 6 or 7) or any term (μ) representing the sizes of the particles[1]. Scaling of time according to Eq. 18 has brought all dissolution curves originating from distributions with the same "logarithmic shape" (which is completely defined by parameters σ, i, and j) into one single curve (Eq. 19) which does not depend on the sizes of the particles or the rate parameter from the single-particle equation. This finding confirms Rules 1 and 3.

The transformation has essentially normalized all possible systems having the same intrinsic dissolution profile into one single curve. This curve is unique in that it makes it possible to evaluate the isolated distribution effect. This evaluation is best done by plotting in a way that linearizes the underlying single-particle dissolution equation (Eqs. 6–8), by using $(W/W_0)^{1/m}$ instead of W/W_0 in the plot. Such a plot will be linear with slope = −1 for a true monodispersed system. Any deviation from this linearity and slope will be due solely to the distribution effect.

Figure 3 shows such normalized dissolution profiles, calculated according to Eqs. 16 and 19, for powders initially log-normal, having distribution (shape) parameters σ = 0.2 and $i = j = 2$, for particles dissolving according to each of the three models[2] (Eqs. 6–8). The fraction of undissolved powder, W/W_0, is raised to the powers of 1/3, 1/2, and 2/3 for the reason just given. The distribution effect is smallest for Model 3 and greatest for Model 1. Remarkably good linearity is observed for the first part of the dissolution process for all three models. This result does not mean, however, that the distribution effect is negligible in the beginning, as is seen from the fact that the slopes differ considerably from −1.

It is obvious that good linearity in such plots is no necessary guarantee that the powder is monodispersed or that there is no distribution effect. This error has been made frequently in investigations where the dissolution process is not followed to the end or very near the end. Furthermore, the validity of a particular dissolution model cannot always be assessed solely from the linearity of a plot of data according to that model *even when the dissolution is followed to the very end.* This fact is clearly demonstrated in Figs. 4 and 5.

Curve a in Fig. 4 shows a normalized dissolution profile of log-normal powders (σ = 0.14, $i = j = 2$) calculated (Eq. 16) to dissolve and plotted (W/W_0 to power of 2/3) according to Model 1. The size distribution effect is clearly reflected in the nonlinearity of the curve. By plotting the same data according to an incorrect model, Model 3 (W/W_0 to power of 1/3), the size distribution effect is almost entirely canceled and surprisingly good linearity is obtained *that extends to the very end of the dissolution process* (curve b). Figure 5 shows the same phenomenon for powders (σ = 0.12, $i = j$ = 2) where the particles are calculated to dissolve according to Model 2 (Eq. 19, m = 2).

A judgment based solely on the linearity of such plots will often

[1] The normalized dissolution profile can also be obtained directly from Eq. 15 or 16 by choosing an arbitrary value for μ and calculating W/W_0 for different Kt values, ranging from 0 to $e^{3(\mu+j\sigma)/m}$, corresponding to a set of ψ values (Eq. 18). This technique was applied for Model 1 using Eq. 16. The computations were done for a wide range of μ values and showed independence of this parameter, in agreement with theory.

[2] A CDC Cyber 76 digital computer, equipped with calcomp plotter, was used for calculations and plots. Numerical evaluations were tested to six digits.

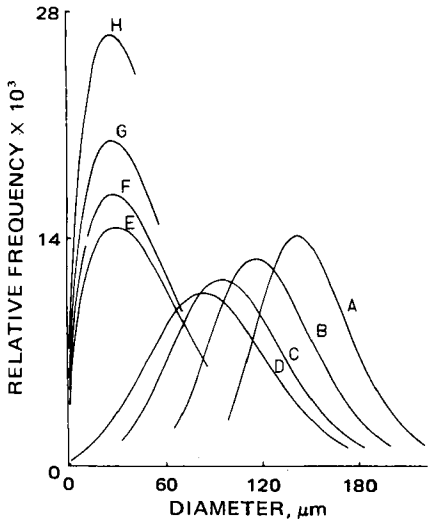

Figure 7—*Size distribution change with time for a powder initially log-normal ($\mu = 5$, $\sigma = 0.2$, i = j = 2), calculated (Eq. 9, m = 2) to dissolve according to Model 2. Distributions are labeled in chronological order. Key: A, initial distribution; and D, distribution at critical time.*

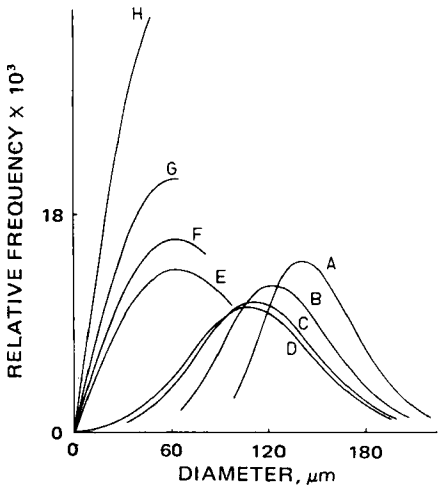

Figure 8—*Size distribution change with time for a powder initially log-normal ($\mu = 5$, $\sigma = 0.2$, i = j = 2), calculated (Eq. 9, m = 3/2) to dissolve according to Model 1. Distributions are labeled in chronological order. Key: A, initial distribution; and D, distribution at critical time.*

lead to false conclusions about the validity of the model, even where dissolution is followed to completion, unless an analysis of particle size is made. The phenomena demonstrated in Figs. 4 and 5 are not special cases for the particular values of σ chosen but were observed to apply for a wide range of σ values.

These findings clearly emphasize the importance of particle-size analysis in investigations of dissolution kinetics. It is of interest to see how the particle-size distribution changes during dissolution. The distribution of a powder that is initially log-normal ($\mu = 5$, $\sigma = 0.2$, $i = j = 2$) was calculated at various times according to Eq. 9 and plotted in Figs. 6, 7, and 8, illustrating dissolution according to Models 3, 2, and 1, respectively. The distributions are labeled in chronological order from A to H. Curves A and D represent the distributions initially and at critical time, respectively.

When particles dissolve according to Model 3 (Fig. 6), then the shape of the size distribution remains constant before critical time, consistent with isotropic dissolution ($da/dt = -K_3$). This is not the case for dissolution according to Models 1 and 2 where the absolute rate of change in size of the particles, da/dt, increases with time. For Model 1:

$$da/dt = -\frac{K_1}{2}(a_0^2 - K_1 t)^{-1/2} \qquad \text{(Eq. 22)}$$

and for Model 2:

$$da/dt = -\frac{2}{3}K_2(a^{3/2} - K_2 t)^{-1/3} \qquad \text{(Eq. 23)}$$

As a result, the distribution broadens before critical time (Figs. 7 and 8) and is particularly affected at the small particle end as zero is approached where da/dt takes extreme values. Because of the latter effect, near the end of the dissolution process the relative frequency of the very small particles increases with increasing size for Models 1 and 2 (Figs. 8 and 7) while it decreases for Model 3 (Fig. 6). This information should be of value for distinguishing Model 3 from the two others. However, from the distribution change alone, it is difficult to distinguish between Models 2 and 3.

It appears from this discussion that it is not possible to distinguish clearly between all three models from dissolution data or from particle-size measurements alone. It would be of interest to determine whether this could be done if both types of information are combined quantitatively. One convenient combination seems to have potential for discriminating between the models. It will be called the dispersion product, s, and is defined as:

$$s = \left(\frac{\bar{a}}{\bar{a}_0}\right)^3 \times \frac{W_0}{W} \qquad \text{(Eq. 24)}$$

where $\bar{a}$ and $\bar{a}_0$ are the mean particle diameters at times t and 0, respectively. The dispersion product is readily obtained, requiring only information for the fraction dissolved and simple averages from particle-size measurements. Time-consuming evaluations of distribution parameters are not required. It is a dimensionless variable that depends only on the initial distribution parameter, σ (for fixed i and j), and the single-particle dissolution equation[3]. The variation of s during the dissolution period should for this reason reflect the basic equation.

Figure 9 shows this variation for powders initially log-normally distributed ($\sigma = 0.2$, $i = j = 2$). The curves representing the three dissolution models are significantly different. The basic shape of the curves remains the same for varying values of σ, although the minima shift to the right and to higher values for very narrow distributions. All three curves approach $s = 1$ (stippled line) when σ approaches zero as expected for a completely monodispersed powder. The values of the three minima remain approximately con-

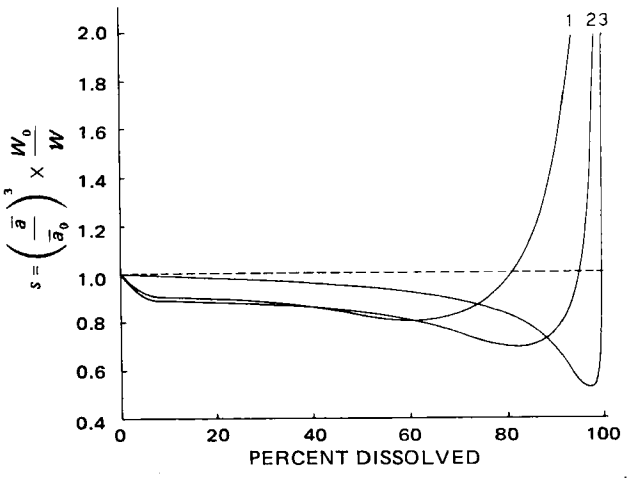

Figure 9—*Variation of the dispersion product (Eq. 24), with progress of dissolution of powders initially log-normal ($\sigma = 0.2$, i = j = 2), calculated (Eqs. 13, 14, 16, and 19) to dissolve according to Models 1, 2, and 3. The stippled line represents a monodispersed powder ($\sigma = 0$).*

[3] The numerical evaluation of the dispersion product was made using several widely different arbitrarily chosen values for μ and confirmed that this parameter cancels out in the calculations as expected. It is clear from previous discussions that s does not depend on the value of the rate parameter (k_1, k_2, or k_3 in Eqs. 6–8).

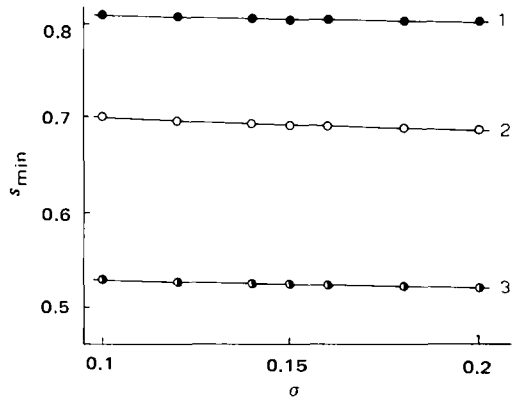

Figure 10—*Variation of dispersion product minima, s_{min}, with the initial distribution parameter, σ, for dissolution according to Models 1, 2, and 3* (i = j = 2).

stant when σ ranges from somewhat less than 0.1 to at least 0.2 (Fig. 10), which should encompass most fine powder distributions encountered in practice. Theoretically, the considerable difference between the s_{min} values should make it possible to distinguish clearly between the three models.

The dispersion product profile (s *versus* W/W_0 or percent dissolved) has some powerful properties, since it is a dimensionless quantity dependent only on the *shape* of the distribution and the *form* of the single-particle dissolution equation. Any change in the coefficient of time k_1, k_2, or k_3 (Eqs. 6–8) during the dissolution will have no effect on the s profile, because s is essentially parametrically represented by the time, provided the change is the same for all particles irrespective of their size. Thus, if changes in such conditions as temperature, agitation, or vehicle composition during dissolution have identical influence on all particles, these changes will have no effect on the s profile. Alternatively, if the external conditions are maintained constant, then s should indicate whether the coefficients are independent of particle size and, hence, whether such parameters as the interfacial concentration gradient, shape factor, and interfacial reaction rate are independent of particle size. The dispersion product should, therefore, be a valuable tool in dissolution kinetic studies.

The extent to which these mathematical models can be applied to describe the dissolution of a "real" powder depends on three assumptions.

1. As mentioned earlier, it was assumed that the particles dissolve independently of each other. This should be approximated well under sink conditions.

2. It was assumed that the dissolution of each particle in the powder can be described by an equation having the same parameter value (k) for all of the particles. In practice, this assumption is rarely valid because of differences in individual particle shapes, crystal structure, and interaction with the vehicle. However, these types of effects probably can be averaged to produce a parameter value for the single-particle dissolution model which, when used in the multiparticulate dissolution equation, results in a good approximation of the actual multiparticulate dissolution behavior.

3. It was assumed that the initial particle-size distribution can be approximated by a truncated log-normal distribution. Although it is generally accepted that most powders are approximately "log-normal," it is likely that the log-normal distribution function only provides a coarse approximation of the actual particle-size distribution, which usually contains a number of irregularities.

This paper has dealt only with log-normal powders and three dissolution models. However, Eq. 3, together with Eq. 13 from the previous paper (9), makes it possible to calculate dissolution characteristics for a powder of any initial size distribution, or a sieve fraction of such a powder, considering any single-particle dissolution equation of explicit form.

SYMBOLS

w = weight of dissolving particle at time t
w_0 = initial weight of particle
$W = \sum w$ = weight of undissolved powder at time t
$W_0 = \sum w_0$ = initial weight of powder
a = diameter of dissolving particle at time t
a_0 = initial diameter of particle
$\bar{a}$ = mean particle diameter at time t
$\bar{a}_0$ = initial mean particle diameter
t = time
$N(x,\mu,\sigma) = (1/\sigma\sqrt{2\pi})e^{(x-\mu)^2/2\sigma^2}$ = normal distribution function
μ = mean of normal distribution
σ = standard deviation of normal distribution
i, j = lower and upper truncation parameters for the initial size distribution that is log-normal and truncated at $\ln a_0 = \mu - i\sigma$ and $\ln a_0 = \mu + j\sigma$
d_0 = min a_0 ($\ln d_0 = \mu - i\sigma$)
D_0 = max a_0 ($\ln D_0 = \mu + j\sigma$)
$F(x) = \int_{-\infty}^{x} (1/\sqrt{2\pi})e^{-x^2/2}\,dx$ = area under standard normal distribution function
$w = g(w_0,t)$ = particle dissolution function (for example, Eqs. 6–8)
$w_0 = g^{-1}(w,t)$ = inverse particle dissolution function
$l(a)$ = particle-size density distribution at time t
$l_0(a_0)$ = initial particle-size density distribution
Model 1 = $w = (w_0^{2/3} - k_1 t)^{3/2}$
Model 2 = $w = (w_0^{1/2} - k_2 t)^2$
Model 3 = $w = (w_0^{1/3} - k_3 t)^3$
ψ = time fraction = fraction of time necessary for complete dissolution
m = 3/2, 2, and 3 for Models 1, 2, and 3, respectively
k_i = parameter in model, i = 1–3
$K_i = (6/\rho\pi)^{1/m} k_i$
$s = (\bar{a}/\bar{a}_0)^3 \times W_0/W$, dispersion product
$\binom{m}{n} = m!/[n!\,(m-n)!]$, binomial coefficient
P = operator that is equal to 1 in the time period before the operand becomes equal to zero and is equal to zero after that time

Elementary Osmotic Pump

FELIX THEEUWES

Abstract □ The elementary osmotic pump is a new delivery system for drugs or other active agents; it delivers the agent by an osmotic process at a controlled rate. Control resides in the: (*a*) water permeation characteristics of a semipermeable membrane surrounding the formulated agent, and (*b*) osmotic properties of the formulation. In its simplest embodiment, the system is constructed by coating an osmotically active solid agent with the rate-controlling, semipermeable membrane. This membrane contains an orifice of critical size through which solubilized agent is dispensed. The system can contain the agent in solid form at loadings higher than 90% of the total volume, and the agent can be delivered at rates several orders of magnitude higher than can be achieved by solution diffusion through polymeric membranes. The delivery rate, the fraction of total content delivered at zero order, and the system's delivery portal size have been calculated for delivery of a single compound. Experimental work verified the theory. The release rate from the system was found to be independent of outside agitation when the system is not deformed by shaking action, the pH of the environment, and delivery portal size for sizes within a specified range. The delivery rate from this system *in vitro* and in the GI tract of dogs was found to be equal.

Keyphrases □ Delivery systems, drug—elementary osmotic pump, controlled delivery rate, release characteristics, equations □ Drug delivery systems—elementary osmotic pump, controlled delivery, release rates, equations □ Osmotic pump—osmotic process, controlled rate drug delivery system, release rates, equations □ Membrane permeation—osmotic process, controlled rate drug delivery system

To achieve controlled administration of active agents, delivery mechanisms that can provide desired temporal patterns of the delivery rate have attracted great interest. The mechanism of delivering the active species by solution diffusion through a rate-controlling barrier has been found to be flexible and dependable (1) but limited in magnitude [maximum on the order of 0.2 μg/(cm hr)] unless microporous barriers are used. To overcome these low rates and to permit the delivery of water-soluble species, an osmotic system was developed which delivers at membrane-controlled rates that can be several orders of magnitude higher than the drug diffusional rates. This new system is called the elementary osmotic pump (2). This paper describes such systems and gives examples of their characteristics for single-compound delivery.

The principles discussed here are applicable to systems using water or other solvents, but the reported work involved only water.

The elementary osmotic pump consists of an osmotic core containing the drug, surrounded by a semipermeable membrane with a delivery orifice. A cross section of the system is shown in Fig. 1.

When exposed to water, the core imbibes water osmotically at a controlled rate, determined by the membrane permeability to water and by the osmotic pressure of the core formulation. For a system at a constant internal volume, the device delivers, in any time interval, a volume of saturated solution equal to the volume of solvent uptake. The rate of solute delivery by the system is constant as long as excess solid is present inside the device, but the rate declines parabolically toward zero once the concentration falls below saturation. The solution volume and mass solute delivery rate from the elementary osmotic pump can be predicted from the physicochemical parameters defining the system, as will be discussed. A typical release rate obtained from this system is illustrated in Fig. 2.

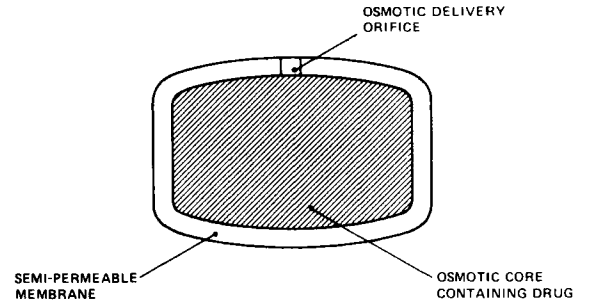

Figure 1—*Elementary osmotic pump cross section.*

THEORETICAL

Delivery Rate—The delivery of agent from the system is controlled by the solvent influx across the semipermeable membrane, which in turn carries the agent to the outside (Fig. 1). Liquid transport by osmosis was qualitatively discussed by Starling (3), who identified the osmotic and hydrostatic pressure differences across capillary membranes as important factors governing transcapillary fluid transport. The process was rigorously treated in the field of nonequilibrium thermodynamics; Eq. 1, which describes the volume flux, dV/dt, across semipermeable membranes has been basic to the field of reverse osmosis (4):

$$\frac{dV}{dt} = \frac{A}{h} L_p(\sigma \Delta\pi - \Delta P) \qquad \text{(Eq. 1)}$$

where $\Delta\pi$ and ΔP are the osmotic and hydrostatic pressure differences, respectively, between the inside and outside of the system; L_p is the mechanical permeability; σ is the reflection coefficient; A is the membrane area; and h is the membrane thickness.

Equation 1 also describes the water flux into the elementary os-

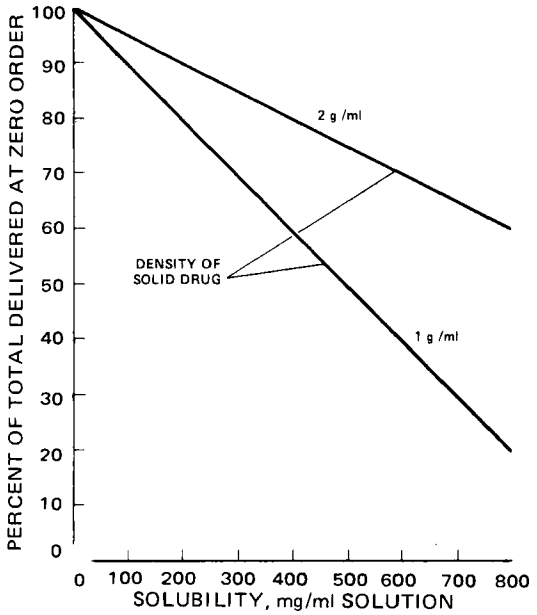

Figure 3—*Fraction of drug content delivered from the elementary osmotic pump at constant rate.*

motic pump (Fig. 1). The general expression for the solute delivery rate, dm/dt, obtained by pumping through the orifice is described by:

$$\frac{dm}{dt} = \frac{dV}{dt} C \qquad \text{(Eq. 2)}$$

where C is the concentration of compound in the dispensed fluid expressed per unit volume of solution.

Substituting Eq. 1 into Eq. 2 results in Eq. 3, which most broadly describes the solute delivery rate:

$$\frac{dm}{dt} = \frac{A}{h} L_p(\sigma \Delta\pi - \Delta P)C \qquad \text{(Eq. 3)}$$

As the delivery orifice increases, hydrostatic pressure inside the system is minimized as expressed by the condition $\Delta\pi \gg \Delta P$.

When the osmotic pressure of the formulation (π) is large compared to the osmotic pressure of the environment, π can be substituted for $\Delta\pi$. Equation 3 then reduces to a much simpler expression in which the constant k replaces the product $L_p\sigma$:

$$\frac{dm}{dt} = \frac{A}{h} k\pi C \qquad \text{(Eq. 4)}$$

Zero-Order Delivery Rate—The release rate from the elementary osmotic pump is zero order from $t = 0$ until a time t_z, at which time all of the solid in the core has dissolved and is described by:

$$\left(\frac{dm}{dt}\right)_z = \frac{A}{h} k\pi_s S \qquad \text{(Eq. 5)}$$

where S is the solubility, and π_s is the osmotic pressure at saturation.

The rate of dissolution of a single compound within the system is much larger than the rate of pumping as given by Eq. 5. For this reason, the concentration, C, can be replaced by the component solubility, S, from time $t = 0$ to $t = t_z$.

Nonzero-Order Release Rate—The nonzero-order release rate from the system (Eq. 4) is obtained by describing the concentration, C, as a function of time. For simplicity, the volume flux into the system is replaced by the symbol F:

$$F = \frac{A}{h} k\pi \qquad \text{(Eq. 6)}$$

and F_s represents the flux during the zero-order time and is related to F by:

$$\frac{F_s}{F} = \frac{\pi_s}{\pi} = \frac{S}{C} \qquad \text{(Eq. 7)}$$

By substituting Eq. 7 into Eq. 4, the nonzero-order release rate as a function of concentration is given by:

$$\frac{dm}{dt} = \frac{F_s}{S} C^2 \qquad \text{(Eq. 8)}$$

Beyond t_z, the mass, m, of component dissolved into the elementary pump volume, V, is given by:

$$m = CV \qquad \text{(Eq. 9)}$$

The change in mass at constant volume, V, causes a concentration change, dC/dt, given by:

$$\frac{dm}{dt} = -V\frac{dC}{dt} \qquad \text{(Eq. 10)}$$

The delivery rate, dm/dt, can be eliminated between Eqs. 8 and 10 as shown by:

$$-\frac{dC}{dt} = \frac{F_s}{VS} C^2 \qquad \text{(Eq. 11)}$$

The concentration, C, inside the system is obtained by integrating Eq. 11 from time t_z to t, when the concentration changes from S to C:

$$-\int_S^C \frac{dC}{C^2} = \frac{F_s}{VS}\int_{t_z}^t dt \qquad \text{(Eq. 12)}$$

Solving Eq. 12 and rearranging terms result in an expression for the concentration as a function of time:

$$C = \frac{VS}{V + F_s(t - t_z)} \qquad \text{(Eq. 13)}$$

Substituting Eq. 13 into Eq. 8 gives the release rate as a function of time, indicating the parabolic decline:

$$\frac{dm}{dt} = \frac{F_s S}{\left[1 + \frac{F_s}{V}(t - t_z)\right]^2} \qquad \text{(Eq. 14)}$$

The nonzero-order release rate can also be expressed as a fraction of the zero-order rate:

$$\frac{dm}{dt} = \frac{(dm/dt)_z}{\left[1 + \frac{1}{SV}\left(\frac{dm}{dt}\right)_z (t - t_z)\right]^2} \qquad \text{(Eq. 15)}$$

The delivery rate discussed in this section is the rate from the elementary osmotic pump when most of the contents are delivered by pumping. When the membrane is not ideally semipermeable, a fraction of the agent is delivered by diffusion through the membrane. The case involving both pumping and diffusion is treated in the *Appendix*.

Mass Delivered at Zero Order, m_z, and Zero-Order Delivery Time, t_z—For a total mass, m_t, contained in the core of the elementary osmotic pump, only an amount m_z is delivered at zero order, and an amount m_{NZ} is delivered at a parabolically declining rate given by Eq. 14. The amount m_{NZ} is the mass that just fills the internal volume of the system with a saturated solution, as shown by:

$$m_{NZ} = SV \qquad \text{(Eq. 16)}$$

The internal volume, V, of the system containing a pure component is related to the total mass, m_t, by the density, ρ, of the core by:

$$m_t = \rho V \qquad \text{(Eq. 17)}$$

The fraction not delivered at zero order is obtained from Eqs. 16 and 17 and given by:

$$\frac{m_{NZ}}{m_t} = \frac{S}{\rho} \qquad \text{(Eq. 18)}$$

Since the sum of m_{NZ} and m_z is equal to m_t, the fraction of the total mass delivered at zero order is given by:

$$\frac{m_z}{m_t} = 1 - \frac{S}{\rho} \qquad \text{(Eq. 19)}$$

The fraction of total device content expressed in percent calculated from Eq. 19 is shown in Fig. 3 for two different compound densities as a function of compound solubility.

The time t_z at which the mass m_z is delivered for an ideal system, with zero startup time, is obtained from:

$$\frac{m_z}{t_z} = \left(\frac{dm}{dt}\right)_z \qquad \text{(Eq. 20)}$$

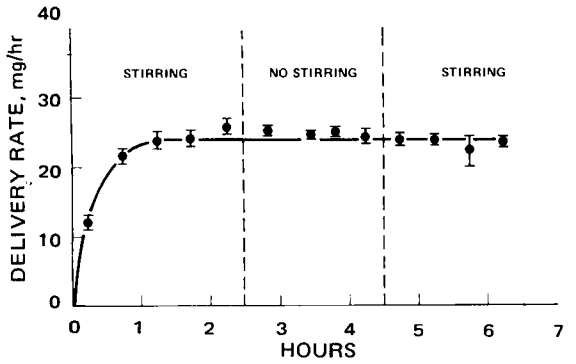

Figure 4—In vitro *release rate of potassium chloride from elementary osmotic pumps in water at 37°. The vertical dashed lines indicate the time at which the systems were transferred from a stirred to a stagnant medium and back to a stirred medium.* ⧳ *represents the range of experimental data obtained from five systems.*

Combining Eqs. 19 and 20 gives:

$$t_z = m_t \left(1 - \frac{S}{\rho}\right) \frac{1}{(dm/dt)_z} \qquad \text{(Eq. 21)}$$

Size of Delivery Orifice—The size of the delivery orifice must satisfy two conditions:

1. It must be smaller than a maximum size, A_{max}, to minimize the contribution to the delivery rate made by solute diffusion through the orifice.

2. It must be sufficiently large, above a minimum size, A_{min}, to minimize hydrostatic pressure inside the system that would affect the zero-order release rate in the following ways. Hydrostatic pressure within the system not only decreases the osmotic influx as seen from Eq. 1, but also it can increase the volume of the system. During the time that the system volume is increasing, the outflow would be smaller than the inflow, resulting in a depressed delivery rate.

Mathematically, these two conditions can be expressed by $A_{min} \leq A_0 \leq A_{max}$, where the cross-sectional area of the orifice, A_0, is larger than or equal to a minimum value and smaller than or equal to a maximum value.

The minimum cross-sectional area can be estimated from Poiseuille's law (4):

$$A_{min} = 5 \left(l \frac{dV}{dt} \frac{\eta}{\Delta P_{max}}\right)^{1/2} \qquad \text{(Eq. 22)}$$

where dV/dt is the volume flux through the orifice, l is the length of the orifice, η is the viscosity of the dispensed solution, and ΔP_{max} is the maximum hydrostatic tolerated pressure difference between the inside and outside of the device. The ΔP_{max} is the pressure at which deformation of the membrane housing occurs or that is significant with respect to the osmotic driving pressure, whichever is smallest.

The maximum cross-sectional area allowed, A_{max}, is obtained by imposing the condition that the diffusional contribution to the release rate must be a factor, F, smaller than the zero-order pumping rate as defined by Eq. 5. This condition is expressed by:

$$A_{max} = \frac{l}{F} \left(\frac{dm}{dt}\right)_z \frac{1}{DS} \qquad \text{(Eq. 23)}$$

in which D is the diffusion coefficient of the compound being delivered in the solvent within the orifice.

In practice, perfect membrane-controlled osmotic delivery has been obtained when $F \geq 40$, as will be discussed.

EXPERIMENTAL

Potassium Chloride Elementary Osmotic Pump Fabrication—Systems were prepared containing 500 mg of potassium chloride each, described by the following parameters: $V = 0.25$ cm^3, $h = 0.025$ cm, $A = 2.2$ cm^2, $k\pi_s = 0.686 \times 10^{-3}$ cm^2/hr, $P = 0.122 \times 10^{-3}$ cm^2/hr, $S = 330$ mg/ml, and $\rho = 2$ g/ml.

The total mass was compressed in a hard tablet and the volume, V, was calculated assuming the density, ρ (5). The area, A, was calculated from the tablet geometry, and the membrane thickness

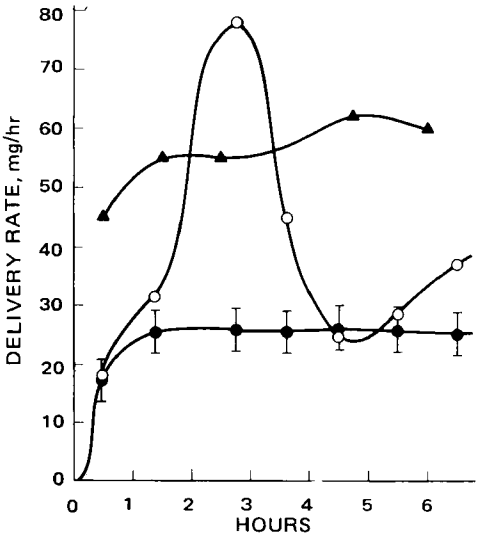

Figure 5—In vitro *release rate of potassium chloride from elementary osmotic pump systems in water at 37°. Key:* ⧳, *range of experimental data obtained from systems with cylindrical orifices of diameters 75, 128, 190, and 274 μm;* ○, *system with 435-μm orifice diameter; and* ▲, *system with 368-μm orifice diameter.*

was measured using a standard thickness gauge. The solubility, S, at 37° was determined by electrical conductance measurements after dilution of the filtered saturated solution into the concentration range where a calibration curve was constructed.

The permeability coefficient, P, and the product, $k\pi_s$, were determined in a permeation experiment (4) where the membrane was placed in a diffusion cell separating water from the stirred saturated solution of potassium chloride. The permeability coefficient, P, was calculated, by measuring the salt transported across the membrane by electrical conductance, from an equation of the form of the second term of Eq. A3. The product, $k\pi_s$, was calculated from Eq. 6, where the volume flow was determined by the displacement of the meniscus of the saturated solution in a graduated cylinder mounted on the cell half containing the saturated solution during a time interval, Δt, measured with a stopwatch.

***In Vitro* Delivery Rate Measurements**—The release rate from the systems was obtained by transferring each at regular, usually hourly, intervals from one test tube to the following and measuring the amount released in each test tube. All experiments were carried out at 37° in the fluids indicated on the figures. The potassium chloride systems were agitated with a stroke of 2.5 cm at a frequency of 0.5 stroke/sec for the experiments shown in Figs. 2, 4, 5, and 6. The larger phenobarbital sodium elementary osmotic pumps referred to in Fig. 7 were manually transferred to sequential flasks in which the liquid was stirred constantly.

Potassium chloride concentrations were measured by electrical conductance. Phenobarbital sodium concentrations were measured spectrophotometrically.

***In Vivo* Delivery Rate Measurements**—Color-coded 500-mg

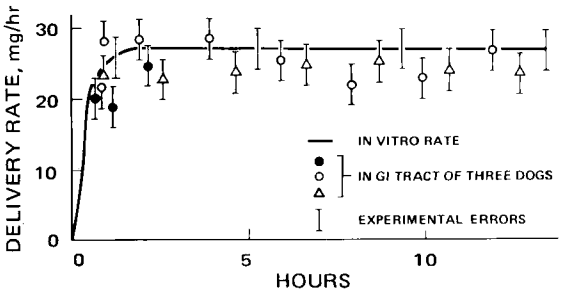

Figure 6—In vitro *and* in vivo *release rate of potassium chloride from elementary osmotic pumps. Key:* —, *average* in vitro *rate from systems of the same batch; and* △, ○, ●, *average release rate of one system in the GI tract of Dogs 1, 2, and 3, plotted at the total time period each system resided in the dog.*

The vertical dashed line indicates the time at which the systems were transferred from gastric to intestinal fluid.* ⧳ *represents the range of experimental data obtained from three systems.*

potassium chloride elementary osmotic pump systems were administered to three dogs at recorded time intervals. The dogs were sacrificed, the devices were retrieved, and the *in vivo* rates were determined gravimetrically from the initial and final dry weights of each individual system.

RESULTS AND DISCUSSION

Predictability of Delivery Rate—For elementary osmotic pump systems containing 500 mg of potassium chloride and prepared as already described, the predicted pumping rate, as calculated from Eq. 5, was 20 mg/hr. By correcting for the 20% diffusional contribution, as shown by Eq. A4 (*Appendix*), the release rate was found to be 24 mg/hr.

When assuming one adjustable parameter, $(dm/dt)_z$ = 22 mg/hr, as the observed experimental rate, the zero-order time, t_z = 19 hr, was calculated from Eq. 21. When using the experimental zero-order rate, the nonzero-order tail was calculated from Eq. 15 (solid line in Fig. 2). An identical curve was obtained by accounting for the diffusional contribution (treated in *Appendix*) by calculating the nonzero-order rate from Eqs. A5 and A13. The data are represented within the limits of experimental error by these equations. For simplicity, the system is well described by the equations applying to pumping when the diffusional contribution is not more than 20%.

Because of its osmotic action, the system exhibits two important characteristics which are described in the next two subsections.

Delivery Rate Is Independent of Outside Agitation—The release rates of five similar potassium chloride systems were measured sequentially in (*a*) stirred, (*b*) stagnant (no stirring), and (*c*) stirred media. The release rate was measured by the mass delivered during about 30-min intervals (Fig. 4). During stirring, the systems were moved up and down with a stroke of 2.5 cm and a frequency of 0.5 stroke/sec in water at 37°. The devices were kept immobile during the stagnant period. As can be seen in Fig. 4, the release rate under both conditions was identical.

Delivery Rate Is Independent of pH—Because of the semipermeable characteristics of the membrane, ions are not readily exchanged across it and the formulation contained within the device can be programmed at a pH independent from its environment. A compound with a solubility that is highly pH dependent can be incorporated in the water-soluble salt form. During operation, the internal core of the elementary pump keeps the pH created by this salt form as its *in situ* created formulation. The delivery rate from the system, as explained previously, is governed by the osmotic pressure of the formulation and the water permeability of the membrane and is therefore independent of the pH of the environment.

As an example, the average release rate from three elementary osmotic pump systems delivering phenobarbital sodium in artificial gastric (pH 2) and intestinal fluid (pH 7.5) (without enzymes) is shown in Fig. 7. The release rate was independent of the pH of the delivery medium.

Delivery Rate Is Independent of Delivery Port Sizes within Predictable Limits—According to $A_{min} \leq A_0 \leq A_{max}$, the delivery rate should be independent of the delivery orifice size for sizes within the range expressed by Eqs. 22 and 23. For pharmaceutical dosage forms where the orifice length is on the order of the membrane thickness, $l = h \simeq 25 \times 10^{-4}$ cm, η = 1 cps, $(dV/dt) \simeq 0.1$ ml/hr, and $\Delta P \simeq 1$ atm, the minimum orifice area calculated from Eq. 22 is on the order of $A_{min} \simeq 13 \times 10^{-8}$ cm^2. For a cylindrical hole, the diameter is then 4×10^{-4} cm—difficult or impossible to be drilled.

To find an operational delivery orifice, it is of practical importance to calculate only the upper size, A_{max}, as defined by Eq. 23. The sizing factor, F, has been experimentally determined by measuring the release rate as a function of the hole size. In Fig. 5, the release rate from 500-mg potassium chloride elementary osmotic pumps is plotted for various hole sizes. Complete membrane-controlled delivery was observed for all hole diameters, 75, 128, 190, and 274×10^{-4} cm. At 368×10^{-4} cm and above, control over the delivery rate was lost. The transition from membrane control to the occurrence of diffusion and probably convection within the orifice was dramatic. No systematic trend in delivery was observed within the hole size range from 75 to 274 μm.

The sizing factor, F, was calculated from Eq. 23 assuming A_{max} as the orifice area corresponding to the 274-μm diameter hole. The length of the passageway through the membrane was $l = 25 \times 10^{-4}$ cm; $(dm/dt)_z$ = 25 mg/hr, as seen from Fig. 5; S = 330 mg/ml; and diffusion coefficient $D = 2 \times 10^{-5}$ cm^2/sec (5). The sizing factor was found to be F = 40.

Delivery Rate in GI Tract Is Equal to *In Vitro* Rate—The elementary pump system can be broadly applied to controlled delivery. A number of pharmaceutical applications such as implants, inserts in body cavities, or oral delivery come to mind, since all of these applications provide an environment of constant water activity.

The system is of special interest in oral application because high, predictable delivery rates can be obtained independent of GI motility and the pH of luminal fluids. An additional benefit is the system's delivery of the drug in solution ready for absorption. Thus, the elementary osmotic pump is an *in situ* prepared liquid dosage form.

In the example shown in Fig. 6, the *in vivo* functionality of the system is demonstrated in the GI tract of dogs. Each experimental point represents the average *in vivo* release rate from each system during its total residence time in the GI tract. The data points are plotted at the total residence time observed for the device. The solid line is the *in vitro* release rate.

The *in vitro* delivery profile was measured for systems of the same batch in water at 37°. The average *in vivo* delivery rate was found to be systematically lower by about 10%. The *in vivo* data agree with the *in vitro* data within the combined experimental error of 20% (6).

CONCLUSIONS

1. The mode of operation of the elementary pump is well understood, and the *in vitro* delivery rate from the system can be accurately predicted.
2. The fraction of drug delivered at zero order can be predicted from the compound solubility and core density.
3. The delivery rate is independent of: (*a*) the pH of the environment, (*b*) the agitation of the environment, and (*c*) the size of the orifice for orifices within the predictable range.
4. The *in vivo* delivery rate from the system is essentially equal to the predictable *in vitro* delivery rate.

APPENDIX

The release rate from the elementary osmotic pump is the total mass delivered per unit time from this system. In practice, three mechanisms contribute to the delivery: (*a*) delivery by pumping, $(dm/dt)_P$, which was described previously; (*b*) delivery by diffusion through the orifice, $(dm/dt)_{DO}$; and (*c*) delivery by diffusion through the membrane, $(dm/dt)_{DM}$. The total delivery rate is then given by:

$$\left(\frac{dm}{dt}\right)_t = \left(\frac{dm}{dt}\right)_P + \left(\frac{dm}{dt}\right)_{DO} + \left(\frac{dm}{dt}\right)_{DM} \qquad \text{(Eq. A1)}$$

By design of the system, the diffusion through the orifice was selected to be negligible, as expressed by $A_{min} \leq A_0 \leq A_{max}$, and Eq. A1 reduces to:

$$\left(\frac{dm}{dt}\right)_t = \left(\frac{dm}{dt}\right)_P + \left(\frac{dm}{dt}\right)_{DM} \quad \text{(Eq. A2)}$$

For most agents that have a high molecular weight and/or are ionic, the membrane will appear as ideally semipermeable and a negligible amount of agent will be delivered by diffusion through it.

When delivering low molecular weight substances and when the membrane is sufficiently solvated, the second term in Eq. A2 can become important. The total release rate (Eq. A2) is controlled by the same membrane and, as before, a zero-order and nonzero-order pattern will be observed.

Zero-Order Delivery by Pumping and Diffusion—The total zero-order rate is given by the sum of two terms: the pumping rate expressed by Eq. 5 and the diffusional term expressed by Fick's law:

$$\left(\frac{dm}{dt}\right)_{t,z} = \frac{A}{h} k\pi_s S + \frac{A}{h} PS \quad \text{(Eq. A3)}$$

where P is the permeability coefficient. Equation A3 reduces to:

$$\left(\frac{dm}{dt}\right)_{t,z} = \frac{A}{h} S(k\pi_s + P) \quad \text{(Eq. A4)}$$

which is of the same form as Eq. 5 for the ideal case.

In practice, the zero-order rate can be calculated from Eq. A4 or 5 after defining an effective $k\pi_s$ or solubility number.

Nonzero-Order Delivery by Pumping and Diffusion—The nonzero-order delivery rate is given by the sum of the pumping rate, Eq. 8, and the diffusional term:

$$\frac{dm}{dt} = \frac{F_s}{S} C^2 + \frac{A}{h} PC \quad \text{(Eq. A5)}$$

To express dm/dt as a function of time, the concentration, C, inside the system must be expressed as a function of time. This can be done by solving the differential Eq. A6 derived from Eq. A5 by substituting again Eq. 10 for dm/dt:

$$-\frac{dC}{dt} = \frac{F_s}{VS} C^2 + \frac{AP}{Vh} C \quad \text{(Eq. A6)}$$

Then substituting:

$$R = \frac{F_s}{VS} \quad \text{(Eq. A7}a\text{)}$$

$$Q = \frac{AP}{Vh} \quad \text{(Eq. A7}b\text{)}$$

into Eq. A6 results in:

$$\frac{dC}{C(RC + Q)} = -dt \quad \text{(Eq. A8)}$$

Equation A8 can be integrated by fractions after identifying the coefficients α and β as shown in:

$$\frac{1}{C(RC + Q)} = \frac{\alpha}{C} + \frac{\beta}{RC + Q} \quad \text{(Eq. A9)}$$

Equalizing the coefficients of equal powers of C results in:

$$\alpha = \frac{1}{Q} \quad \text{(Eq. A10)}$$

$$\beta = -\frac{R}{Q} \quad \text{(Eq. A11)}$$

Substituting Eqs. A10 and A11 into Eq. A9 and substituting Eq. A9 into Eq. A8 result in:

$$\frac{dC}{QC} - \frac{R}{Q}\frac{dC}{(RC + Q)} = -dt \quad \text{(Eq. A12)}$$

Equation A12 can be integrated from time t_z to t when the concentration changes from S to C. Also, replacing R and Q by their values given in Eq. A7 results in:

$$t - t_z = \frac{Vh}{AP} \ln \frac{\left(F_s \frac{C}{S} + \frac{AP}{h}\right)}{\left(F_s + \frac{AP}{h}\right)\frac{C}{S}} \quad \text{(Eq. A13)}$$

Equation A13 does not give the concentration, C, as an explicit function of time for substitution into Eq. A5. From Eq. A13, C and C^2 can be tabulated as a function of time, and from these values the rate can be calculated using Eq. A5.

New and Expedient Determination of Atenolol in Biological Samples

J. O. MALBICA ˣ and K. R. MONSON

Abstract □ A method is described for the GLC determination of atenolol BP in plasma and urine. Extraction is accomplished under dehydrating conditions, and interfering impurities are removed by using an acidified cyclohexane–isopropanol mixture (2:1) and charcoal-treated paper disks. The drug thus isolated appears to react more efficiently with heptafluorobutyric anhydride, increasing the sensitivity of GLC electron-capture analysis. Concentrations as low as 0.02 μg/ml were measured using 0.5-ml aliquots of plasma or 0.1 ml of urine. Amino alcohols such as atenolol may form hydrates or alcoholates, precluding complete derivatization with heptafluorobutyric anhydride.

Keyphrases □ Atenolol—GLC analysis, biological samples □ GLC—analysis, atenolol, biological samples □ Adrenergic agents—atenolol, GLC analysis, biological samples

Atenolol[1] [4-(2-hydroxy-3-isopropylaminopropoxy)phenylacetamide] (I) is a new β-adrenergic blocking agent. The results of animal studies indicate that atenolol differs from other β-blocking drugs currently available for study in humans because of its cardioselectivity, absence of intrinsic sympathomimetic activity, and membrane-stabilizing activity (1–4). The compound may be valuable as an antihypertensive agent in humans (5, 6).

A GC method for the determination of atenolol in whole blood, serum, tissue, and urine was recently reported (7). The method required an initial aqueous–solvent extraction followed by purification steps involving back-extraction techniques. This extraction procedure was tedious, and a great chance for error resulted from the number of transfer steps involved. As a result, a simplified extraction procedure was developed.

The extraction procedure for both plasma and urine, as developed in this laboratory, is performed under dehydrating conditions. It is both expedient and efficient, requiring only 0.5 ml of plasma or blood and 0.1 ml or less of urine. The method is of sufficient sensitivity (0.02 μg/ml) to determine plasma levels of atenolol in humans after a single 25-mg oral dose.

EXPERIMENTAL

Reagents—Ethyl acetate[2], cyclohexane[2], isopropyl alcohol[2], and acetone[2] were glass-distilled, reagent grade solvents. Acetic acid[3], ammonium hydroxide[3] (14.8 *N*), anhydrous sodium sulfate[3], and anhydrous ether[3] were all reagent grade, ACS certified.

Heptafluorobutyric anhydride was freshly prepared from heptafluorobutyric acid[4] (sequenation grade) by refluxing over excess phosphorus pentoxide[5] for 3 hr. The mixture was then fractionally distilled through a 25.4-cm (10-in.) Vigreux column, and the anhydride was collected at 107–108°. The acidic wash solvent was prepared by adding 128 ml of isopropyl alcohol to a mixture of 250 ml of cyclohexane and 5 ml of acetic acid.

Table I—Effect of Acetone in Removing Solvate from Atenolol Residue prior to Reaction with Heptafluorobutyric Anhydride[a]

Original Solution	Relative GLC Peak Area	
	Control	Acetone
Water	0.589	0.955
Absolute ethanol	0.603	0.955

[a] Concentration of atenolol was 0.4 μg/ml. Conditions were as described in the text.

Plasma Level Study—Atenolol was administered to two healthy male volunteers[6]. Subject 1 (24 years, 75.5 kg) received a 25-mg tablet[7], and Subject 2 (31 years, 71.9 kg) received a 100-mg tablet[7]. Blood was withdrawn at various time intervals from an indwelling needle attached to a plastic catheter[8] in a superficial vein of the forearm. The blood was collected in oxalated containers and centrifuged, and the plasma was transferred and stored in plastic vials at −10°. Urine samples were also collected during 24-hr intervals within a 72-hr period and pooled.

Extraction of Atenolol—A premeasured volume of anhydrous sodium sulfate (1.0 ml) was added to a 15.0-ml graduated conical centrifuge tube containing 0.5 ml of plasma. The tube was mixed[9], and 2.5 ml of the acidic wash solvent was added to the resulting paste. The tube was again mixed until the solid sodium sulfate was dispersed and then was centrifuged at 2000 rpm in an angular head, clinical centrifuge for 3 min.

The organic phase was removed and discarded using a disposable Pasteur pipet. One drop (0.05 ml) of 14.8 *N* NH_4OH was added to the residue, followed by 4.0 ml of freshly distilled ethyl acetate. The tube was mixed, and two 6.5-mm diameter charcoal-treated paper disks[10] were added. After mixing for 30 sec, the tube was centrifuged as before.

The ethyl acetate layer was carefully transferred, using a Pasteur pipet, into a tube and flash evaporated *in vacuo*[11] to dryness. To the residue was added 0.4 ml of heptafluorobutyric anhydride–ether (1:4). After reacting at ambient temperature for 5 min, the contents of the tube were dried under a nitrogen stream (using an in-line activated silica gel desiccant filter) for 15 min. The residue was dissolved in 1.0 ml, or some other suitable volume, of freshly distilled ethyl acetate. Atenolol extracts from plasma or urine that

[a] Each value represents a separate plasma extraction and is the average of a duplicate run on GLC. The maximum volume of atenolol used to spike plasma was 25 μl.

were not reacted immediately after extraction were stored in a desiccator over phosphorus pentoxide.

Urine—A fresh solution of urease[12] was prepared just before use (25 mg/ml, approximately 3500 units/g in 1 *M* KH_2PO_4 buffer, pH 7.4). To 0.5 ml of diluted urine (1:5 dilution with distilled water) in a 15-ml conical centrifuge tube was added 0.2 ml of the urease solution. The mixture was then incubated at 30° for 10 min. After incubation, the mixture was analyzed as previously described for plasma except that 1.2 ml of premeasured anhydrous sodium sulfate was used instead of 1.0 ml.

Electron-Capture GLC—The derivatized samples were analyzed using a gas chromatograph[13] equipped with a ^{63}Ni-electron-capture detector. A glass column (1.2 m × 6 mm o.d.) was packed with a 3.8% UCW 98 on Gas Chrom Q, 80–100 mesh. The injection port and oven temperatures were maintained at 225 and 208°, respectively. The detector temperature was set at 320° and operated with a pulse interval of 150 μsec. The carrier gas was argon with 5% methane at a flow rate of 60 ml/min. Under these conditions, the retention time of the atenolol derivative was approximately 3 min. The injection volume was 2 μl.

Calculations—A stock solution of atenolol in absolute ethanol (1.0 mg/ml) was used to prepare daily working standards (0.02–1.0 μg/ml) by spiking plasma or urine obtained from undosed controls. From these standards, a calibration curve of concentration *versus* peak area was determined. The overall recovery of atenolol from plasma or urine was determined by comparing standards extracted from plasma or urine by the described procedure with nonextracted acetone-stripped standards. The latter procedure involved flash evaporating a standard solution *in vacuo*[11], then adding 5.0 ml of acetone, and flash evaporating once again. This procedure with acetone was repeated one more time. The stock solution of atenolol was stored at 5°, protected from light, and was stable for several months.

RESULTS AND DISCUSSION

The GLC peak of the heptafluorobutyrate derivative of atenolol isolated from human plasma and urine is shown in Fig. 1. The GLC recorder trace for the blank plasma and urine is shown in Fig. 2. The electron-capture detector response was very high for this derivatized amino alcohol. The structure of the atenolol heptafluorobutyrate derivative was confirmed by mass spectrometry (7), which showed that the secondary alcohol was esterified and the amino group was acylated. The amide group on the phenyl ring was dehydrated on reaction with heptafluorobutyric anhydride to form the nitrile.

The relative GLC peak area was diminished significantly if an aqueous or ethanol solution of atenolol was reacted with heptafluorobutyric anhydride without prior removal of solvate from residue with acetone, as described under *Experimental*. Typical data are shown in Table I; the GLC peak area was enhanced as much as

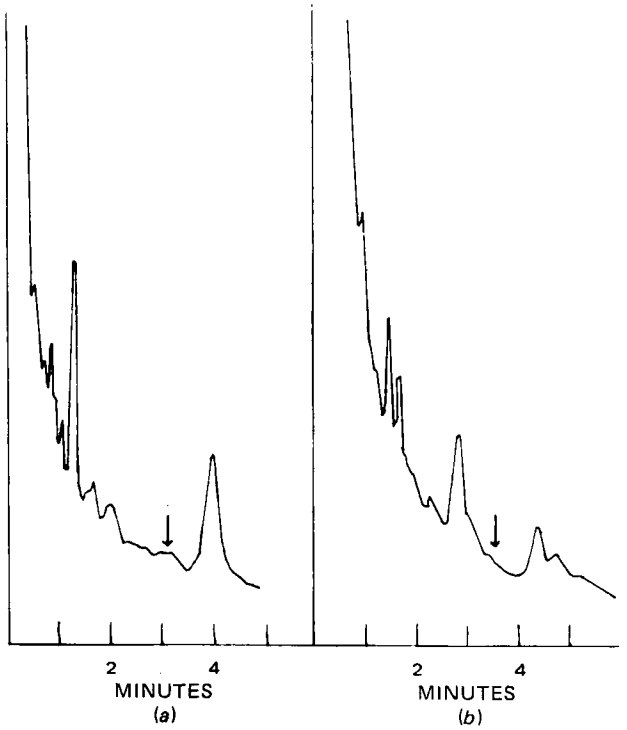

Figure 2—*(a) GLC trace of extract from plasma blank. (b) GLC trace of extract from urine blank. (Position of atenolol is designated by the arrow.)*

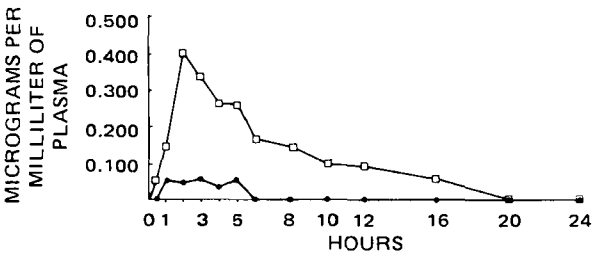

Figure 3—*Plasma concentrations of atenolol in two subjects administered a single oral dose. Key:* ●, *Subject 1, 25 mg; and* □, *Subject 2, 100 mg.*

38% by using acetone to remove solvate.

The overall recovery of atenolol extracted from plasma or urine was 60 ± 4% over the concentration range of 0.05–1.0 μg/ml[14]. This range is comparable to what was previously reported (7). A consistent 27–30% of the drug, independent of the concentration, was lost in the initial wash step. Attempts to minimize this loss by using solvents of different polarities resulted in an increase in interfering impurities on GLC. Preextraction with the acidic wash solvent resulted in the removal of some plasma components which, if carried to the derivatization step, would elute from the GLC column approximately 50 min after an initial sample injection. Other interfering plasma impurities were found to absorb preferentially onto charcoal-coated paper disks.

The somewhat lower recoveries (approximately 40–50%) obtained using the aqueous–solvent extraction procedure previously reported (7) may be attributed to an apparent hydrated form of the amino alcohol and also possibly to a less efficient extraction procedure.

Plasma and urine samples containing atenolol (0.05 and 0.2 μg/ml) and stored at −10° were stable for at least 1 month, with no significant change in concentration noted.

The high and variable concentration of urea in urine interfered with the heptafluorobutyric anhydride derivatization step. Pretreating a urine aliquot with urease and incubating for the prescribed period eliminated this interference.

Within-day and day-to-day variation and reproducibility of the extraction procedure were evaluated at four different concentrations of atenolol in plasma (Table II). From these data, the slope and intercept variations within the day and from day to day were obtained (Table III). As described, the am and pm slopes within the day were not significantly different. However, the day-to-day slope and intercept variation were significantly different ($p < 0.01$). For this reason, a fresh control plasma standard calibration curve was prepared daily. Calibration plots were strictly linear over the range of 0.0–1.0 ng injected onto the column.

[14] Based on aqueous standard, dried *in vacuo*, and stripped with acetone as described in the text prior to reacting with heptafluorobutyric anhydride.

Table IV—Atenolol Excreted in Urine after a Single Oral Dose

Subject	Dose, mg	Atenolol Excreted, mg			Percent of Dose
		0–24 hr	24–48 hr	48–72 hr	
1	25	7.15	0.39	0.06	30.4
2	100	25.15	0.92	0.13	26.2

Plasma levels of atenolol (preliminary experimental formulation) administered to two human volunteers following a single oral dose are shown in Fig. 3. The amount of atenolol excreted in urine over 72 hr is shown in Table IV. A 25-mg oral dose resulted in plasma levels close to the limit of detection (0.02 μg/ml).

The method described is sensitive for the determination of atenolol concentrations as low as 0.02 μg/ml in plasma or urine. It offers several advantages over aqueous–solvent extractions, employing back-extraction techniques. First, the number of transfer steps is kept to a minimum by extracting under dehydrating conditions. Second, under these same conditions, an apparent hydrate of atenolol is prevented from forming, thus favoring a more complete reaction with heptafluorobutyric anhydride.

Acetone was effective in removing apparent bound water or alcohol to drug molecules when prepared for standard use. Preliminary data indicate that this phenomenon may be peculiar only to amino alcohols when used for derivatization by heptafluorobutyric anhydride.

Comparative Pharmacokinetics of Coumarin Anticoagulants XV: Relationship between Pharmacokinetics of Dicumarol and Warfarin in Rats

AVRAHAM YACOBI, CHII-MING LAI, and GERHARD LEVY ˣ

Abstract □ The distribution, elimination, and anticoagulant effect of dicumarol and warfarin were determined in adult male rats following intravenous injection of single doses of these drugs in crossover experiments. The biological half-life of dicumarol ranged from 5 to 28 hr; that of warfarin ranged from 9 to 30 hr. There was a statistically significant correlation between the following pharmacokinetic characteristics of dicumarol and warfarin in individual animals: biological half-life, apparent volume of distribution, total plasma clearance, and concentration in plasma eliciting one-half the maximum anticoagulant effect (effective concentration). The mean ratio of the respective biological half-lives (warfarin/dicumarol) was 1.42, and that of the apparent volumes of distribution was 1.50. The ratio of the effective plasma concentrations (dicumarol/warfarin) was correlated negatively with the half-life of dicumarol and positively with the ratio of the half-life values (warfarin/dicumarol) in individual animals. Additional studies with serum samples from other rats showed pronounced interindividual differences in the serum protein binding of both dicumarol and warfarin and a strong correlation between the protein binding of these two drugs in serum of individual animals. The results of this study, together with the results of previous studies in this series, indicate that serum protein binding is the major determinant of interindividual differences in the pharmacokinetics of dicumarol and warfarin in rats under these experimental conditions.

Keyphrases □ Dicumarol—distribution, half-life, elimination, anticoagulant effect determined, compared to warfarin, rats □ Warfarin—distribution, half-life, elimination, anticoagulant effect determined, compared to dicumarol, rats □ Coumarin anticoagulants—comparative pharmacokinetics of dicumarol and warfarin, rats □ Anticoagulants—comparative pharmacokinetics of dicumarol and warfarin, rats

The relationship between the elimination kinetics of different drugs in the same subjects has been the subject of a number of recent studies (1–4). The purposes of these studies were to explore the possible existence of common biotransformation pathways and genetic influences and to assess the feasibility of determining the elimination kinetics of one drug and using the results to predict the elimination kinetics of one or more other drugs in the same individual. The cited studies were limited generally to determinations of the biological half-life of the drugs. The study reported here was designed to obtain more comprehensive information about the relationship between the pharmacokinetic characteristics of two major anticoagulants, dicumarol and warfarin, in the same animals. Crossover studies were carried out in rats to determine the apparent volume of distribution, biological half-life, serum protein binding, and anticoagulant effect of these two drugs.

[a] These animals received dicumarol first.

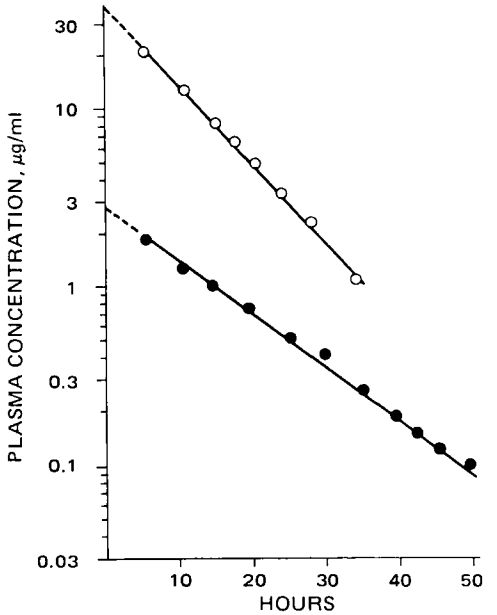

Figure 1—*Concentrations of dicumarol (○) and warfarin (●) in the plasma of a rat (Rat 3) as a function of time after administration of dicumarol, 6 mg/kg iv, and warfarin, 0.6 mg/kg iv, in separate experiments 3 weeks apart.*

EXPERIMENTAL

Thirty male Sprague–Dawley rats[1], 270–390 g, with unrestricted access to food[2] and water at all times, received ^{14}C-dicumarol, 6 mg/kg iv, in an initial screening experiment. The biological half-life of dicumarol was determined from the time course of drug concentrations in plasma (5). Eight animals, with dicumarol half-lives of 4.8–23.8 hr, were selected for further study 3 weeks later. The purpose of this selection process was to obtain a group of animals with a wide and relatively even distribution of dicumarol half-lives.

A crossover experiment was carried out in which four rats received dicumarol, 6 mg/kg iv, including about 30 μCi/kg of ^{14}C-dicumarol (10.9 μCi/mg). The other four rats received warfarin, 0.6 mg/kg iv, including about 26 μCi/kg of ^{14}C-warfarin (71 μCi/mg).

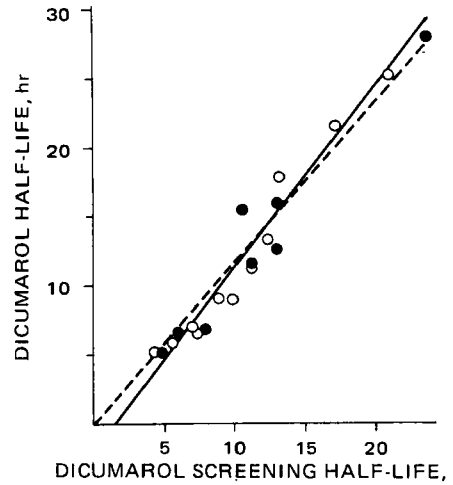

Figure 2—*Relationship between the biological half-life of dicumarol in the initial screening experiment and in the subsequent crossover study on the same animals (●). The open circles represent data for control animals from another study under the same conditions (to be published) (r = 0.967, p < 0.001). The continuous regression line was obtained by double regression analysis (11), and the stippled line was forced through the origin in this figure and in Figs. 3, 4, and 7.*

Three weeks later, the first group of animals received warfarin and the second received dicumarol. Serial blood samples (0.45 ml) were obtained after injection until the prothrombin complex activity returned to 65–100% of normal. Determinations of prothrombin complex activity, dicumarol and warfarin concentrations, and pharmacokinetic calculations were carried out as previously described (5–7).

Serum protein binding of dicumarol and warfarin was determined by equilibrium dialysis at 37° (8). Portions of serum from unmedicated individual rats were spiked with ^{14}C-warfarin (about 1 μg/ml) or ^{14}C-dicumarol[3] (about 20 μg/ml). A total of 21 rats was used. Warfarin concentrations were determined by scintillation counting after extraction and TLC (6, 7). Dicumarol concentrations were determined by scintillation counting after selective extraction (5) of samples from 10 rats and by scintillation counting after TLC of samples from the other 11 animals.

^{14}C-Dicumarol determinations by TLC were carried out by adding 0.1 ml of the serum or 1 ml of the dialysate sample to 0.1 ml of an aqueous solution of unlabeled dicumarol (400 μg/ml) in 0.15 *M* isotonic phosphate buffer, pH 7.4. This solution was acidified with 1 ml of 0.5 *N* hydrochloric acid and extracted into 2.5 ml of ethylene dichloride. After shaking for 45 min, the phases were separated by centrifugation at 1000×*g* for 3 min and the aqueous phase was removed by aspiration.

A 2-ml portion of the organic phase was placed in a vial[4] and evaporated at room temperature to dryness under a flow of nitrogen. The sides of the vial were washed down three times with chloroform, which was also evaporated. The residue was dissolved in 25 μl of chloroform and spotted on a silica gel TLC sheet[5] which had been activated (30 min at 100°) immediately before use. The vial was rinsed three times with 25-μl portions of chloroform, which were also applied to the TLC sheet. The sheet was developed immediately with toluene–ether–acetic acid (20:5:1) in a chamber which had been equilibrated with the solvent system. The development was stopped when the solvent front had advanced about 10 cm.

The dicumarol spot on the dried plate was visualized under UV light and identified as such by its R_f value (0.65). It was scraped off the TLC sheet and placed in a vial with 10 ml of scintillation fluid, and the radioactivity was determined[6] at 15° using an external standard. The recovery of dicumarol from serum samples con-

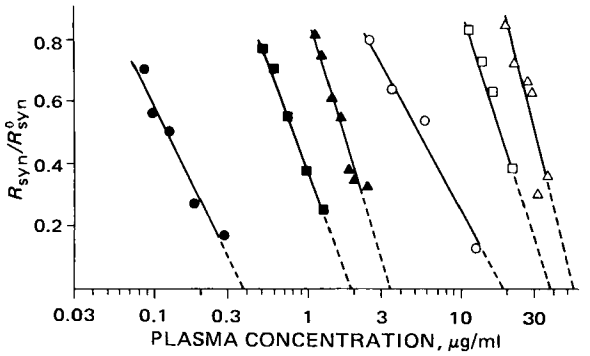

Figure 5—*Relationship between the anticoagulant effect (relative synthesis rate of prothrombin complex activity, expressed as R_{syn}/R^0_{syn}) and the concentrations of dicumarol (open symbols) and warfarin (solid symbols) in Rat 1 (circles), Rat 4 (squares), and Rat 8 (triangles).*

taining 0.01–48 μg/ml was independent of drug concentration and averaged 90.8 ± 2.4% (mean ± *SD*, n = 14). In preliminary experiments, excellent agreement was found between results when dicumarol-spiked serum samples were analyzed by both the selective extraction and TLC methods.

RESULTS

Figure 1 shows the time course of dicumarol and warfarin concentrations observed in one animal in separate experiments, 3 weeks apart. The biological half-life ($t_{1/2}$) of dicumarol in the individual rats ranged from 4.75 to 23.8 hr in the initial screening experiment and from 5.12 to 27.9 hr in the crossover study, while the $t_{1/2}$ of warfarin ranged from 8.89 to 30.5 hr (Table I). The apparent volume of distribution (V_d) of dicumarol in the crossover study ranged from 106 to 182 ml/kg, and the V_d of warfarin ranged from 172 to 323 ml/kg (Table II). There was a statistically significant positive correlation between the apparent first-order elimination rate constant (k_{el}) and V_d for dicumarol (r = 0.721, $p < 0.05$) and warfarin (r = 0.878, $p < 0.005$).

Figure 2 shows the relationship between the $t_{1/2}$ of dicumarol in the screening experiment and in the subsequent crossover study on the same animals. Included in the figure are 11 data points from control rats of another study. The correlation was very strong, and the average ratio of the individual $t_{1/2}$ values (crossover experiment/screening experiment) was 1.09. There was a strong and statistically highly significant correlation between the $t_{1/2}$ for dicumarol and warfarin in the crossover study (Fig. 3) and between the $t_{1/2}$ for dicumarol in the screening study and the $t_{1/2}$ for warfarin in the subsequent crossover study on the same animals (Fig. 4). The ratio of the warfarin $t_{1/2}$ to the dicumarol $t_{1/2}$ in the individual rats ranged from 1.00 to 1.90, with a mean of 1.42 (Table I).

The V_d of warfarin was 50% larger than that of dicumarol on the average (Table II), and the difference was highly statistically significant ($p < 0.005$ by paired t test). The correlation coefficient between the individual V_d values for dicumarol and warfarin was 0.696, but the correlation was not statistically significant in the eight animals. There was a strong correlation between the total plasma clearances of dicumarol and warfarin (r = 0.930, $p <$ 0.001); the mean ratio of the clearance values (warfarin/dicumarol) was 1.12 (Table II).

Figure 5 shows the relationship between the anticoagulant effect and the plasma concentrations of dicumarol and warfarin for three animals in this study. The regression lines were characterized by a slope (m) and by the plasma concentration at which the synthesis rate of prothrombin complex activity (R_{syn}) was one-half of its normal value (R^0_{syn}). That concentration is designated as $C_{50\%}$. The $-m$ and $C_{50\%}$ values for dicumarol and warfarin in all eight animals are listed in Table III.

There was a statistically significant correlation between $-m$ and $t_{1/2}$ for dicumarol (r = 0.920, $p < 0.001$) but not for warfarin (r = 0.470, $p > 0.2$). There also was a statistically significant correlation between $C_{50\%}$ and $t_{1/2}$ for dicumarol (r = 0.809, $p < 0.02$) and warfarin (r = 0.950, $p < 0.001$). Furthermore, there was a statistically significant negative correlation between $C_{50\%}$ and V_d with dicumarol (r = −0.789, $p < 0.02$) as well as warfarin (r = −0.707, $p <$ 0.05).

Table III—Relationship between Anticoagulant Effect (Inhibition of Prothrombin Complex Activity Synthesis Rate) and Plasma Concentration of Dicumarol (D) and Warfarin (W) in Individual Rats

Rat	—Slope[a] ($-m$), %/Day		Ratio of m Values (D/W)	Plasma Concentration when R_{syn}/R^0_{syn} = 0.5 μg/ml		Ratio of Concentrations (D/W)
	Dicumarol	Warfarin		Dicumarol	Warfarin	
1	0.932	1.02	0.91	5.41	0.123	44.0
2	0.899	1.11	0.81	5.62	0.177	31.8
3	0.854	1.52	0.56	8.19	0.217	37.7
4	1.63	1.38	1.18	18.8	0.813	23.1
5	1.46	1.42	1.03	28.5	0.830	34.3
6	1.41	1.69	0.83	14.0	0.599	23.4
7	1.66	1.13	1.47	13.9	0.725	19.2
8	2.06	1.63	1.26	30.5	1.63	17.6

[a] Slope of a plot of R_{syn}/R^0_{syn} *versus* log plasma concentration (m).

The average ratio of the individual m values (dicumarol/warfarin) was 1.01 ± 0.29, and there was no apparent correlation with the $t_{1/2}$ of either drug. This finding permits a determination of the relative potency of the two drugs on the basis of the ratio of their equieffective plasma concentrations ($C_{50\%}$). The ratio of the $C_{50\%}$ values (dicumarol/warfarin) ranged from 17.6 to 44.0 (Table III) and varied systematically with the $t_{1/2}$ of dicumarol (Fig. 6). This ratio also correlated with the ratio (warfarin/dicumarol) of the $t_{1/2}$ for the two drugs (r = 0.828, $p < 0.01$). There was a strong positive correlation between the $C_{50\%}$ values of dicumarol and warfarin in individual rats (r = 0.911, $p < 0.005$).

For technical reasons, serum protein binding of the two anticoagulants was determined in another group of 21 animals. These animals did not receive either dicumarol or warfarin; the drugs were added directly to the individual serum samples. There were pronounced interindividual differences in the serum protein binding of dicumarol and warfarin, but there was a strong correlation (r = 0.978, $p < 0.001$) between the free fraction (100 × free fraction = percent free) of the two drugs in the serum of the individual animals (Fig. 7). At the concentrations used, the ratio of free fraction values (warfarin/dicumarol) was 53.3 ± 7.0 (mean ± *SD*).

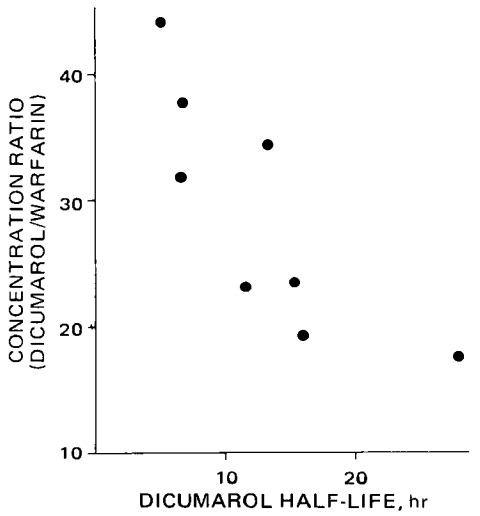

Figure 6—*Relationship between anticoagulant potency ratio (warfarin/dicumarol) [expressed as the ratio (dicumarol/warfarin) of plasma concentrations at which the rate of synthesis of prothrombin complex activity is 50% of normal] and biological half-life of dicumarol in individual rats (r = −0.800, $p < 0.02$).*

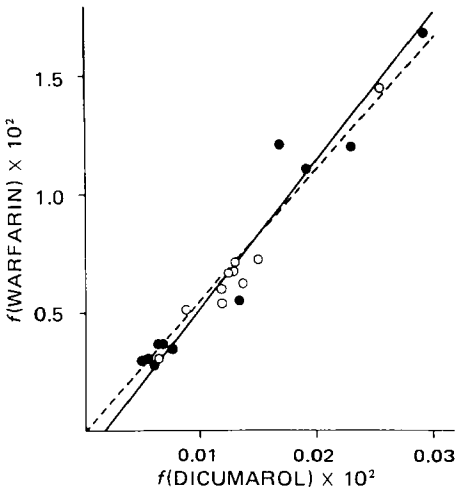

Figure 7—*Relationship between protein binding of dicumarol and warfarin in the serum of individual rats. Plotted are the free fractions (f) determined by equilibrium dialysis at 37°. Key: ●, data from 11 animals with dicumarol assayed by TLC; and ○, data from 10 other animals with dicumarol assayed by selective extraction method (5) (r = 0.978, p < 0.001). Dicumarol was 99.97–99.995% bound and warfarin was 98.3–99.7% bound to serum protein.*

DISCUSSION

The results of this investigation reveal a very strong correlation between dicumarol and warfarin with respect to their $t_{1/2}$, V_d, total plasma clearance, and serum protein binding characteristics in individual rats. The $t_{1/2}$ of warfarin was 42% longer than that of dicumarol, and the V_d of warfarin was 50% larger than that of dicumarol on the average. Consequently, the total plasma clearance of the two drugs was almost identical (Table II). The excellent reproducibility of the dicumarol $t_{1/2}$ values found in this investigation also was observed in a previous study (9); the $t_{1/2}$ of warfarin also showed excellent reproducibility in individual animals (7).

We have found that the interindividual differences in the elimination kinetics of warfarin are related to (and presumably caused by) differences in serum protein binding of the drug (8, 10). The higher the free fraction of warfarin, the shorter is the $t_{1/2}$ and the larger is the V_d of the drug (8). The results of this study suggest that the same relationship holds true for dicumarol (although the evidence is only indirect) and that the correlation of pharmacokinetic characteristics of the two drugs in individual animals is a consequence of the strong correlation of their serum protein binding characteristics.

Because of the relative constancy of the individual $t_{1/2}$ and V_d ratios, it is possible to compare the two drugs with respect to $t_{1/2}$ and V_d, despite pronounced interindividual variations in the value of these constants. It is much more difficult to compare the relative potency of dicumarol and warfarin. The ratio of equieffective plasma concentrations (dicumarol/warfarin) is higher in rapid metabolizers than in slow metabolizers of these drugs (Table III). The reasons for this systematic variation are complex and relate in part to the nonlinear serum protein binding characteristics of dicumarol[7], the different potency of the two enantiomers of warfarin (7), and the time-dependent change in the enantiomer concentration ratio following administration of racemic warfarin (7).

It is interesting, however, that in this group of rats warfarin was *approximately* 30 times as potent as dicumarol on the basis of the mean ratio of their equieffective concentrations[8], while the non-protein-bound fraction of warfarin was *approximately* 50 times larger than that of dicumarol. Thus, the two anticoagulants were almost equipotent in the rat if compared on the basis of their free (non-protein-bound) concentrations.

[7] To be published.

[8] This refers to the concentrations at which R_{syn} is one-half of normal (*i.e.*, $C_{50\%}$). Moreover, the equieffective concentration ratio of dicumarol and warfarin differs in rapid and slow metabolizers of these drugs, and it is generally advisable to focus on individual values rather than on the average value of this ratio.

Selective Assay of Benzoyl Peroxide in Lotions and Creams

ROBERT E. DALY ˣ, JOSEPH J. LOMNER, and LESTER CHAFETZ

Abstract □ A selective titrimetric method for the determination of benzoyl peroxide in lotions and creams was developed. It is based on the work of Horner and Jürgens, in which diacylperoxides, dialkylperoxides, peracids, and alkylhydroperoxides can be determined selectively by iodometry and acidimetry. The proposed assay is stability indicating with respect to peracids. Good recovery data were obtained.

Keyphrases □ Benzoyl peroxide—titrimetric, TLC, and spectrophotometric analyses compared, lotions and creams □ Titrimetric analysis—benzoyl peroxide in lotions and creams, compared to TLC and spectrophotometric analyses □ TLC—analysis, benzoyl peroxide in lotions and creams, compared to titrimetric and spectrophotometric analyses □ Spectrophotometric analysis—benzoyl peroxide in lotions and creams, compared to titrimetric and TLC analyses

Gruber and Klein (1) reported that the iodometric titration generally used for the assay of benzoyl peroxide and its pharmaceutical preparations is nonspecific. They proposed a spectrophotometric method based on the measurement of iodine liberated by the oxidation of iodide ion by benzoyl peroxide, and they compared the spectrophotometric and titrimetric procedures with a polarographic assay for benzoyl peroxide. In this laboratory, the Gruber and Klein (1) spectrophotometric assay provides essentially the same results as the titrimetric method, a finding that is not surprising in view of the identity of the chemistry of both methods. Moreover, the polarographic method used by Gruber and Klein (1) could not be reproduced in this laboratory.

Horner and Jürgens (2) described an assay scheme wherein diacylperoxides, dialkylperoxides, peracids, and alkylhydroperoxides can be determined by iodometry and acidimetry with the aid of phenyl sulfide and triethylarsine. Because the simple formulations investigated would not be expected to contain any alkylhydroperoxides or dialkylperoxides, a procedure was developed, based on the Horner and Jürgens work (2), which is selective for benzoyl peroxide in the presence of perbenzoic acid. The procedure is a simple modification of the presently used iodometric titration, requiring only the addition of phenyl sulfide before titration to destroy any perbenzoic acid present.

Table I—Rate of Destruction of Perbenzoic Acid by Phenyl Sulfide

Minutes after Addition	Milligrams Found as Benzoyl Peroxide
0	11.2
2	0
4	0
6	0
8	0
10	0

Table II—Effect of Phenyl Sulfide on Benzoyl Peroxide

Minutes after Addition	Milligrams Taken	Milligrams Found	Percent Recovery
0	24.0	23.4	97.5
3	24.0	22.9	95.5
5	24.0	22.9	95.5
10	24.0	22.9	95.5

The proposed assay was compared with the titrimetric method, the Gruber and Klein spectrophotometric assay (1), and a quantitative thin-layer method. The proposed selective titrimetric method gave results comparable to quantitative TLC values. The modified procedure is presented and the results obtained in the assay of benzoyl peroxide formulations are described in this report.

EXPERIMENTAL[1]

Equipment and Supplies—Phenyl sulfide[2], acetone, sodium thiosulfate, potassium iodide, benzene (all ACS grade or equivalent), and silica gel GF plates[3] (20 × 20 cm, 250 μm) were used.

Quantitative TLC—*Standard Preparation*—Dissolve 250 mg of recrystallized benzoyl peroxide, accurately weighed, in exactly 50 ml of acetone.

Assay Preparation—Transfer a quantity of lotion or cream equivalent to about 250 mg of benzoyl peroxide, accurately weighed, to a 50-ml volumetric flask. Dissolve in, or uniformly disperse in, 30 ml of acetone and dilute to volume with acetone.

Procedure—Streak 0.5 ml (5 × 100 μl followed by a 100-μl rinse of the micropipet with acetone) of the assay preparation and the standard preparation on separate silica gel GF_{254} plates (20 × 20 cm, 250 μm), which had been previously activated for 15–30 min at 105° and which had been prechromatographed in the developing solvent. Develop the plates in a standard unequilibrated chromatography tank (27 × 7 × 28 cm) to within 2–3 cm of the top, employing benzene as the developing solvent.

Locate the benzoyl peroxide streak under shortwave UV light, scrape the streak off, and transfer it into a 125-ml conical flask through a powder funnel. Quantitatively rinse the funnel with 30 ml of acetone. Stir the mixture for about 5 min with a magnetic stirrer and filter quantitatively[4] into a 100-ml beaker, rinsing the flask and funnel with 4 × 5 ml of acetone.

Add 5 ml of a 20% solution of potassium iodide to the filtrate, cover with a watch glass, and place in the dark for about 5 min. Then titrate the liberated iodine against a white background with

Table III—Assay for Benzoyl Peroxide in Commercial[a] Products by Four Methods

Sample	Lot	Benzoyl Peroxide, %				
		Claimed	Titrimetric	Spectrophotometric	Proposed	Quantitative TLC
Acne lotion	A	5.0	5.03, 5.16, 4.87	5.02, 5.06	4.34, 4.24, 4.26	4.3
Cream	A	5.0	5.10, 5.09, 5.20	5.40, 5.38	4.91, 4.95, 4.90	3.6
Sulfur cream	A	10.0	10.5, 10.4, 10.5	11.2, 11.2	9.81, 9.67, 9.67	10.5
Cream	B	5.0	4.23, 4.12, 4.15	4.28, 4.25	3.97, 3.99, 3.97	4.4
Cream	C	5.0	5.24, 5.27, 5.26	5.51, 5.53	4.92, 4.85, 4.84	4.9
Lotion	B	5.0	5.30, 5.42, 5.20	5.61, 5.52	4.72, 4.72, 4.70	4.7
Lotion	C	5.0	5.60, 5.60, 5.60	5.69, 5.73	4.52, 4.52, 4.52	4.5

[a] Persadox lotion or cream, Texas Pharmacal Co.

0.01 *N* sodium thiosulfate from a 5-ml buret to the disappearance of the yellow iodine color. Calculate the percent benzoyl peroxide with:

$$\% \text{ benzoyl peroxide} = \frac{\text{ml thiosulfate (assay preparation)}}{\text{ml thiosulfate (standard preparation)}} \times \frac{\text{concentration of standard (g/50 ml)}}{\text{sample weight (g)}} \times 100 \quad \text{(Eq. 1)}$$

Selective Titrimetric Method—*Assay Preparation*—Accurately weigh a sample of cream or lotion equivalent to about 250 mg of benzoyl peroxide into a 100-ml beaker. Add 30 ml of acetone and stir the mixture until a solution or uniform dispersion results. Quantitatively transfer the mixture to a 100-ml volumetric flask with the aid of at least 4 × 10 ml of acetone. Then dilute the mixture to volume with acetone.

Procedure—Transfer 10.0 ml of the assay preparation to a 125-ml glass-stoppered conical flask, add 0.2 ml of phenyl sulfide, and let stand for 4 min. Add 2 ml of a 20% potassium iodide solution and let stand, protected from light, for 15 min. Add 25 ml of acetone and titrate the liberated iodine against a white background with standard 0.01 *N* sodium thiosulfate to the disappearance of the yellow color. Each milliliter of 0.01 *N* sodium thiosulfate is equivalent to 1.211 mg of benzoyl peroxide.

RESULTS AND DISCUSSION

To validate the method, perbenzoic acid was synthesized according to a literature method (3). A solution of perbenzoic acid in chloroform thus obtained, containing 610 mg/ml, was diluted to represent a concentration equivalent in iodide-oxidizing capacity to about 10 mg of benzoyl peroxide/sample aliquot. Samples were assayed at various time intervals after the addition of 0.2 ml of phenyl sulfide (Table I).

The effect of phenyl sulfide on benzoyl peroxide was found to be minimal (Table II). The reduction in assay value after addition of phenyl sulfide may be attributable to the presence of some perbenzoic acid in the sample employed.

Mixtures of benzoyl peroxide with perbenzoic acid were prepared to contain 90.0 and 50.0% of the labeled amount of benzoyl peroxide. Assays of these samples by the proposed method provided results of 90.1 and 50.2%, respectively, as the average of triplicate determinations.

Results of assays of commercial products by the proposed method, a quantitative TLC method, the titrimetric method (same as proposed method without phenyl sulfide), and the Gruber and Klein spectrophotometric method (1) are presented in Table III. A standard of recrystallized benzoyl peroxide, mp 104.8–105.5°, was used in the quantitative TLC method.

Results obtained by the proposed procedure on commercial products were in fair agreement with those obtained by TLC and, in every case, were lower than those obtained by the titrimetric or spectrophotometric method (1). Results obtained by the spectrophotometric method (1) are in good agreement with those obtained by the titrimetric method.

The proposed method is also applicable to the determination of purity of benzoyl peroxide raw materials.

Colorimetric Determinations of Chlorpheniramine Maleate, Ephedrine Hydrochloride, and Guaiacolsulfonate Potassium in a Cough Syrup

V. DAS GUPTA ˣ and ANA J. L. de LARA *

Abstract □ Colorimetric methods for the quantitative determinations of chlorpheniramine maleate, ephedrine hydrochloride, and guaiacolsulfonate potassium in a cough syrup containing color (amaranth) are reported. Chlorpheniramine maleate can be assayed using the cyanogen bromide method as reported in the literature. Ephedrine hydrochloride can be assayed using a dye method in which interference from chlorpheniramine maleate is taken into consideration. Guaiacolsulfonate potassium can be assayed by coupling it with 4-aminoantipyrine (the method is similar to the one for phenylephrine hydrochloride). All of the methods are simple, accurate, and precise. The application of the guaiacolsulfonate potassium assay method to commercial dosage forms is reported.

Keyphrases □ Chlorpheniramine maleate—colorimetric determination in cough syrups □ Ephedrine hydrochloride—colorimetric determination in cough syrups □ Guaiacolsulfonate potassium—colorimetric determination in cough syrups

Many cough syrups contain an antihistamine such as chlorpheniramine maleate, a bronchodilator such as ephedrine hydrochloride, and an expectorant such as guaiacolsulfonate potassium. The USP method (1) for the analysis of chlorpheniramine maleate in elixir and the NF methods for the analysis of ephedrine hydrochloride (2) and guaiacolsulfonate potassium (3) are not applicable for quantitative determinations due to interference of one active ingredient with the other. The purposes of these investigations were to develop a colorimetric method for the quantitative determination of guaiacolsulfonate potassium (I) and to modify calculations in the previously reported dye method (4) for the analysis of ephedrine hydrochloride (II). These modifications were necessary due to the interference from chlorpheniramine maleate (III), since it could be accurately determined by the cyanogen bromide method (5).

A colorimetric method for the determination of guaiacolsulfonate potassium (6) was not used because of a lack of reproducibility. Another colorimetric method (7) was not preferred due to a lack of sensitivity, since it is important to dilute the syrup as much as possible before the analysis to prevent interference from the coloring agent. The method developed in these investigations is based on oxidizing I with potassium ferricyanide in an alkaline borate buffer solution and then coupling it with 4-aminoantipyrine; the method is similar to that reported for the determination of phenylephrine hydrochloride (8).

Table I—Assay Results on Cough Syrup

Average	100.40	99.08	99.59
Average deviation	±0.44	±0.42	±0.30

Table II—Assay Results on Guaiacolsulfonate Potassium in Commercial Dosage Forms

Product	Percent of Label Claim Found[a]
Expectorant I	101.38
Expectorant II	99.23
Expectorant III	122.35[b]
Expectorant IV	101.77

[a] Average of three results. [b] Results are high due to interference from phenylephrine hydrochloride.

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were USP, NF, or ACS grade. Chlorpheniramine maleate[1], ephedrine hydrochloride[2], guaiacolsulfonate potassium[2], cherry flavor[3], and coloring agent (amaranth[4]) were purchased and used without further purification.

Preparation of Cough Syrup—The cough syrup was prepared from two stock solutions. The aqueous stock solution contained 4.0 g of guaiacolsulfonate potassium, 200 mg of chlorpheniramine maleate, 500 mg of ephedrine hydrochloride, 50 ml of distilled water, and 190 ml of syrup USP. The alcoholic stock solution contained 12.5 mg of methylparaben, 5 mg of propylparaben, 25 mg of amaranth, 1.0 ml of chloroform, 0.6 ml of cherry flavor, and 2.5 ml of alcohol. The aqueous and alcoholic stock solutions were mixed together and brought to a volume of 250 ml with distilled water.

Preparation of Solutions—The following standard solutions were prepared: 40.0 μg/ml of III in approximately 0.25 *N* HCl; 4.0 μg/ml of III in distilled water; 10.0 μg/ml of II in distilled water; 10.0 μg/ml of II plus 4.0 μg/ml of III in distilled water; and 150.0, 200.0, 250.0, and 300.0 μg/ml of I in distilled water.

The cyanogen bromide solution was prepared by decolorizing bromine TS with 10% potassium cyanide solution.

A buffer solution containing sulfanilic acid and sodium acetate for the analysis of III was prepared according to a reported procedure (5), as was a 1×10^{-4} *M* solution of bromothymol blue in phosphate buffer solution (pH 6.2) (4).

The following aqueous solutions were prepared fresh daily: a 2% solution of sodium borate (buffer for the analysis of I), a 3% solution of 4-aminoantipyrine, and a 4% solution of potassium ferricyanide. Assay solutions for the analysis of I and II were prepared by diluting 10.0 ml of the cough syrup to 100.0 ml with water and then diluting 5.0 ml of the 1:10 dilution to 100.0 ml with water. For III, 5.0 ml of cough syrup was diluted to 100.0 ml with approximately 0.25 *N* HCl.

Preparation of Calibration Curve for Guaiacolsulfonate Potassium—A 2.0-ml quantity of each standard solution was mixed with 1 ml of potassium ferricyanide solution in a 50-ml volumetric flask. The volume was brought to approximately 48 ml

[1] Schering Corp., Bloomfield, N.J.
[2] Merck & Co., Rahway, N.J.
[3] Dolco cherry No. 5225 imitation, Dodge & Olcott, Inc., New York, N.Y.
[4] Hartman Leddon Co., Philadelphia, Pa.

with sodium borate buffer solution, and the solution was mixed. A 1-ml aliquot of 4-aminoantipyrine solution was then added, and the mixture was brought to volume with borate buffer and mixed. The absorbance of each clear solution was determined[5] at 500 nm against a reagent blank prepared by substituting water for the standard solution. Beer's law was followed.

Assay Procedure for Guaiacolsulfonate Potassium—The same procedure was followed except that 5.0 ml of the assay preparation was used for the analysis instead of 2.0 ml of the standard solution. Since Beer's law was followed, the results (Table I) were calculated using the following equation:

$$\frac{A_a}{A_s} \times 10 = \mu g/ml \text{ of I} \qquad \text{(Eq. 1)}$$

where A_a = absorbance of the assay solution, and A_s = absorbance (0.426) of a standard solution that provides 10 μg/ml of I in a 50-ml volumetric flask.

Assay Procedure for Chlorpheniramine Maleate—A 1.0-ml quantity of the standard solution (in 0.25 *N* HCl) and 1.0 ml of the assay preparation were mixed (separately) with 7.0 ml of the buffer solution and 3.0 ml of cyanogen bromide solution and then allowed to stand for 30 min. The absorbance of each solution was measured at 480 nm against a reagent blank prepared by substituting 1.0 ml of 0.25 *N* HCl for the standard solution. Since Beer's law was followed, the results (Table I) were calculated as follows:

$$\frac{A_a}{A_s} \times 100 = \% \text{ of label claim} \qquad \text{(Eq. 2)}$$

where A_a = absorbance of the assay solution, and A_s = absorbance of the standard solution.

Assay Procedure for Ephedrine Hydrochloride—To five different separators, each containing 5.0 ml of bromothymol blue solution and 10.0 ml of chloroform, the following solutions were added: 5.0 ml of distilled water (reagent blank), 5.0 ml of standard aqueous solution of II (A_s), 5.0 ml of standard aqueous solution of II plus III (A_{sc}), 5.0 ml of standard aqueous solution of III (A_c), and 5.0 ml of assay preparation (A_a). Each separator was shaken for 60 sec, layers were allowed to separate, and the absorbance of each clear chloroform layer was measured at 420 nm against the reagent blank.

The absorbance of A_{sc} was equal to $A_s + A_c$. The corrected absorbance value (A_{cc}) due to chlorpheniramine maleate in the assay preparation was determined as follows:

$$A_{cc} = A_c \times \frac{\% \text{ of III present (from Table I)}}{100} \qquad \text{(Eq. 3)}$$

The A_{cc} was subtracted from the A_a value to get the corrected absorbance value (A_{ac}) due to ephedrine hydrochloride in the assay preparation. Since Beer's law was followed (5), the results (Table I) on II were calculated as follows:

$$\frac{A_{ac}}{A_s} \times 100 = \% \text{ of label claim} \qquad \text{(Eq. 4)}$$

Application of Assay Procedure for Guaiacolsulfonate Potassium to Commercial Dosage Forms—The assay procedure for guaiacolsulfonate potassium was tested on four commercial products.

Expectorant I[6] contained, per 5 ml: 10 mg of codeine sulfate, 0.5 mg of menthol, 3.75 mg of bromodiphenhydramine hydrochloride, 8.75 mg of diphenhydramine hydrochloride, 80 mg of guaiacolsulfonate potassium, 80 mg of ammonium chloride, and 5% alcohol.

Expectorant II[7] contained, per 5 ml: 10 mg of codeine phosphate, 5 mg of promethazine hydrochloride, 0.01 ml (0.17 minims) of ipecac fluidextract, 0.015 ml (0.25 minims) of chloroform, 44 mg of guaiacolsulfonate potassium, 66 mg of citric acid, 197 mg of sodium citrate, and 7% alcohol.

Expectorant III[8] contained 5 mg/5 ml of phenylephrine hydrochloride in addition to the ingredients contained in Expectorant II. Expectorant IV[8] (a pediatric product) contained 7.5 mg/5 ml of dextromethorphan hydrobromide instead of 10 mg of codeine phosphate as in Expectorant II.

For the analysis of guaiacolsulfonate potassium, 4.0 ml of Expectorant I was diluted to 250 ml while 7.0 ml each of the other expectorants was diluted to 250 ml with water. A 2.0-ml quantity of the diluted expectorant was mixed with 1 ml of potassium ferricyanide solution in a 50-ml volumetric flask. The rest of the procedure was the same as reported under *Preparation of Calibration Curve for Guaiacolsulfonate Potassium*. In separate experiments, it was determined that there was no interference from other ingredients except phenylephrine hydrochloride, which was present in Expectorant III with codeine. The results, calculated using Eq. 1, are presented in Table II.

DISCUSSION

The results indicate that all three active ingredients of a cough syrup, guaiacolsulfonate potassium, ephedrine hydrochloride, and chlorpheniramine maleate, can be assayed accurately (Table I) using colorimetric methods. All three methods are simple, accurate, and precise. There is no interference from the other active or inactive ingredients, except from chlorpheniramine maleate in the assay procedure for ephedrine hydrochloride. This interference can be taken into consideration easily as explained under *Experimental*.

The new technique for the analysis of guaiacolsulfonate potassium (coupling with 4-aminoantipyrine) follows Beer's law and is rapid (10 min/assay after the standard curve is prepared). The assay method for the analysis of guaiacolsulfonate potassium can be applied to a number of commercial dosage forms (Table II) containing other ingredients such as codeine, menthol, dextromethorphan, promethazine, bromodiphenhydramine, diphenhydramine, and ammonium chloride. Phenylephrine hydrochloride does interfere, which was expected (8).

Time Course and Dose Dependence of Antacid Effect on Urine pH

MILO GIBALDI ˣ, BARBARA GRUNDHOFER, and GERHARD LEVY

Abstract □ Daily administration of a proprietary magnesium and aluminum hydroxides suspension, 15 ml four times a day, to normal adult volunteers resulted in a statistically significant increase in urine pH on the 1st day of treatment. The urine pH's on the 2nd and subsequent days of treatment were statistically significantly higher than on the 1st day. A 7.5-ml dose of the antacid suspension, taken four times a day, had only a small and not statistically significant effect on urine pH, while 30 ml four times a day increased urine pH by approximately the same magnitude as the 15-ml doses. The effect of the antacid on urine pH persisted for at least 1 day after discontinuation of dosing.

Keyphrases □ Antacid—magnesium and aluminum hydroxides suspension, effect on urine pH □ Magnesium and aluminum hydroxides suspension—effect on urine pH □ Aluminum and magnesium hydroxides suspension—effect on urine pH □ pH, urine—effect of magnesium and aluminum hydroxides suspension

Regular administration of certain antacids can increase urine pH sufficiently to have pronounced effects on the kinetics of elimination of some acidic and alkaline drugs (1). A widely used proprietary antacid product containing magnesium and aluminum hydroxides[1] was the most effective of the products tested in increasing urine pH. To extend the information obtained in the initial study (1), an investigation was undertaken to determine the time course and dose dependence of the effect of this antacid on urine pH.

EXPERIMENTAL

The study panel consisted of eight healthy males, 23–38 years of age, who by education and experience (graduate students in pharmaceutics) were capable of giving their informed consent to participate in this investigation. The subjects were under no dietary restrictions but took no drugs during the study. They were instructed to empty their bladders and to collect the urine from 8:00 am to 10:00 am, 10:00 am to 2:00 pm, and 2:00 pm to 4:00 pm. The urine pH was determined immediately after voiding. All measurements were carried out by the same individual on a pH meter[2], which was routinely standardized with buffer solutions of pH 4.0, 7.0, and 9.0.

To determine the time course of the antacid effect on urine pH, seven subjects collected urines on the 1st and 2nd days and took 15 ml of the antacid suspension at 8:00 am, 1:00 pm, 6:00 pm, and 11:00 pm from the 3rd to 8th day. Urine samples were collected until the 10th day, except on Days 6 and 7.

To determine the effect of antacid dose on urine pH, eight subjects took 0, 7.5, 15, or 30 ml of the antacid suspension at 8:00 am, 1:00 pm, 6:00 pm, and 11:00 pm on a Sunday and Monday according to a Latin-square experimental design. Urine samples were obtained on Mondays and Tuesdays, *i.e.*, the 2nd day of antacid administration and the day after antacid was discontinued.

The daily mean pH values reported in the tables were obtained by averaging as such the pH of the three urine samples obtained from every subject.

9	—	6.07 ± 0.41[f]	N.S.
10	—	5.80 ± 0.66[e]	N.S.

[a] Fifteen milliliters of Maalox Suspension at 8:00 am, 1:00 pm, 6:00 pm, and 11:00 pm. [b] Mean of seven subjects except where indicated. [c] Paired *t* test, compared to average pH on Days 1 and 2. [d] Not determined (Saturday and Sunday). [e] Mean of six subjects (one subject discontinued antacid on Day 6 due to a respiratory infection). [f] Mean of five subjects (a second subject was unable to collect urine samples on that day).

RESULTS AND DISCUSSION

The time course of urine pH change caused by administration of 15 ml of the antacid four times a day for 6 days is summarized in Table I. A small but statistically significant increase in urine pH was noted on the 1st day of antacid administration. There was no increase in urine pH with time on that day (mean pH 6.28 ± 0.62, 6.09 ± 0.54, 6.14 ± 0.64 for the first, second, and third collection periods, respectively). The previous study had shown that there are no significant differences in control urine pH for the three urine collection periods (1).

The mean urine pH on the 2nd, 3rd, and 6th days of antacid administration was almost 1 unit higher than during the control period and was also statistically significantly higher than during the 1st day of antacid administration. There was no systematic change

Table II—Relationship between Dose of Magnesium and Aluminum Hydroxides Suspension and Urine pH in Healthy Adults

Dose[a], ml	Day[b]	Mean Urine pH ± *SD*[c]	Significance of Difference from Control pH (*p* Values)[d]
0	2	5.73 ± 0.42	—
0	3	5.74 ± 0.38	—
7.5	2	6.08 ± 0.54	N.S.
0	3	6.14 ± 0.61	N.S.
15	2	6.56 ± 0.40	<0.0025
0	3	6.17 ± 0.45	<0.025
30	2	6.44 ± 0.57	<0.01
0	3	6.45 ± 0.34	<0.0025

[a] Volume of Maalox Suspension taken at 8:00 am, 1:00 pm, 6:00 pm, and 11:00 pm. [b] Antacid was taken on Days 1 and 2 except in the control experiment. [c] Mean of eight subjects. [d] Paired *t* test, compared to average pH of Days 2 and 3 of the control period.

in mean urine pH with time from the 2nd to the 6th day of antacid administration. The mean pH on the 1st day after discontinuation of the antacid was somewhat above the control value but not statistically significantly so. Urine pH was in the normal control range on the following day.

The results of the experiments to determine the relationship between the dose of the antacid and urine pH are summarized in Table II. Urine pH was determined on the 2nd day of treatment in view of the results obtained in the first part of this investigation. A dose of 7.5 ml four times a day had only a small and not statistically significant effect on urine pH *on the average*.

However, it was noted previously that the magnitude of the antacid effect on urine pH is inversely proportional to the urine pH during the control period (1). The same tendency was apparent in this study; some individuals with low control pH values showed an increase of more than 0.5 pH unit with the 7.5-ml dosing regimen. The 15-ml dosing regimen increased urine pH by more than 0.8 unit on the average, a highly statistically significant difference from the control value. No further increase was observed when the dose of the antacid was raised to 30 ml. Urine pH on the 1st day after discontinuation of the 15- and 30-ml doses was significantly above the control value; this residual effect was particularly pronounced after the 30-ml dose.

The results of this study show that a pharmacokinetically significant increase in urine pH is produced within 24 hr of administration of regular therapeutic doses of a widely used antacid and that this effect persists for about 24 hr after the antacid has been discontinued. The residual effect on urine pH is probably due to the retention of antacid in the GI tract for some time. It is not known if the lack of difference between the effect of the 15- and 30-ml dosage regimens on urine pH is paralleled by a similar lack of dose–response relationship with respect to antacid efficacy.

GLC Determination of Underivatized Carbamazepine in Whole Blood

MICHAEL SHEEHAN [x] and RAYMOND E. BEAM [*]

Abstract □ This report describes a rapid GLC assay for carbamazepine in blood. Carbamazepine is chromatographed directly using phenyl methyl silicone gum as the stationary phase. The calibration curve is linear up to 50 μg/ml, with a lower limit of sensitivity of 1 μg/ml. Other anticonvulsants may be measured simultaneously, and the procedure works equally well with plasma or blood.

Keyphrases □ Carbamazepine—GLC analysis, whole blood □ Anticonvulsants—GLC analysis of carbamazepine in whole blood □ GLC—analysis, carbamazepine in whole blood

Carbamazepine is used for the relief of pain from trigeminal neuralgia (1) and in the treatment of epilepsy (2–4). Frequently, patients with complicated seizure disorders are given several other anticonvulsants (*e.g.*, phenytoin, primidone, and phenobarbital) as well as carbamazepine (the usual case in this hospital).

Methods of analysis for carbamazepine that rely on spectrophotometry (5) are complicated by interfering absorbances when mixtures of drugs are analyzed. For such mixtures, GLC is usually the preferred method, and several GLC methods for measuring carbamazepine in serum or plasma recently were reported (6–13). Because of various drawbacks (*e.g.*, tedious extraction requirements, necessity of derivative formation, and inability to use whole blood), none of these methods is considered suitable.

This paper describes a GLC method for the assay for carbamazepine levels in whole blood. This method is simple and rapid and does not require derivative formation. Furthermore, other anticonvulsants can be measured simultaneously.

EXPERIMENTAL

Reagents—Reagent grade chloroform, methanol, and acetic acid were used without further purification. Authentic iminostilbene was obtained commercially[1].

Standards—A stock solution equivalent to 1.0 mg/ml of heptabarbituric acid was prepared by dissolving exactly 108.4 g of dry heptabarbital sodium[2] in 0.9% saline, which had been made alkaline with 5.0 ml of 0.45 *N* sodium hydroxide. The final volume of the solution was adjusted to 100 ml with 0.9% saline. A 20.0-μg/ml working internal standard was prepared by diluting 10.0 ml of the stock solution to 500 ml with 0.9% saline. The 16.3-μg/ml carbamazepine blood standard was prepared by dissolving 4.80 mg of carbamazepine[2] in 10.0 ml of anhydrous methanol and then diluting a 0.34-ml aliquot of this solution with 100 ml of expired blood bank blood. Blood standards of other concentrations were prepared from the carbamazepine stock solution as needed.

Apparatus—The GLC analyses were performed on a gas chromatograph[3] equipped with dual flame-ionization detectors. The chromatograph was fitted with 1.83-m (6-ft) long, U-shaped, glass columns (4.0 mm i.d.) packed with 1.5% phenyl methyl silicone gum (OV-17) on Gas Chrom G HP[4] (80–100 mesh). For the combined analysis of primidone and carbamazepine, a column packed with 1.5% OV-225 on Gas Chrom G HP[4] (80–100 mesh) also was used. The columns were conditioned before use by heating at 290° (260° for OV-225) for 24 hr with 5-ml/min carrier gas flow.

[a] Column temperature was programmed to 266° at 6°/min. [b] Measurements were made from chromatograms of extracts of a 10.0-μg/ml carbamazepine standard.

The chromatography settings for the OV-17 column were as follows: nitrogen as carrier gas, 30 ml/min; air, 300 ml/min; hydrogen, 30 ml/min; injection port and detector temperatures, 270°; initial column temperatures, 180°; and program rate, 6°/min up to 266° followed by isothermal heating at 266° for 10 min. For the OV-225 column, the initial column temperature was 230° and the program rate was 10°/min up to 270°.

The mass spectral analysis was performed on a gas chromatograph–mass spectrometer[5] under the following conditions: electron energy, 60 ev; emission current, 450 μamp; electron multiplier[6], 2.2 kv; preamplifier range, 10^{-7} amp-v^{-1}; and GLC conditions, same as for OV-17 column.

Extraction Procedure—To a 25-ml glass vial were added 2.0 ml of whole blood (ethylenediaminetetraacetic acid as anticoagulant), 1.0 ml of the 20.0-μg/ml heptabarbital working standard, and 10 drops of acetic acid. The vial was swirled gently for a few seconds, and 10 ml of chloroform was added. After being capped tightly, the vial was shaken vigorously for 5 min mechanically.

The solution was allowed to settle for 30 sec, and the chloroform layer was separated (the congealed blood cells usually adhered to the sides of the vial) and evaporated to dryness under a gentle stream of air in a 60° water bath. (For plasma, the solution was first filtered through 1 g of anhydrous sodium sulfate.) The residue was reconstituted with 50 μl of chloroform, and 5 μl of this solution was injected into the chromatograph.

RESULTS AND DISCUSSION

Figure 1 shows a chromatogram of an extract from 2 ml of blood containing 16.3 μg/ml of carbamazepine to which 20 μg of heptabarbital had been added. As previously reported (10–13), a substantial percentage of the carbamazepine had decomposed to a second compound with a relative retention time of 0.85. This peak also was found when a pure sample of carbamazepine was chromatographed directly.

It has been reported (11, 13) that carbamazepine undergoes on-column decomposition to give iminostilbene; under the given GLC conditions, an authentic sample of iminostilbene had the same relative retention time as this peak (0.85 relative to heptabarbital). Likewise, the mass spectra of authentic iminostilbene and the decomposition product were identical (base peak and M^+ both at *m/e* 193). From these findings it was concluded that the decomposition product was iminostilbene.

Table I shows that this transformation was not strictly a function of temperature. That is, the ratio of carbamazepine to iminostilbene was variable at all temperatures studied. Even with derivatization (10, 13), the problem of iminostilbene formation still exists, although the authors claim that accurate quantitation of carbamazepine can still be achieved. In view of these results, it was felt that any GLC assay for carbamazepine should also account for the formation of iminostilbene.

Primidone	1.58	—
Carbamazepine	1.63	1.83
Phenytoin	1.68	2.41

[a] See *Experimental* for GLC conditions.

It seemed likely that whereas the ratio of carbamazepine to iminostilbene might vary from one run to the next for any given concentration of carbamazepine, the sum of the relative responses of these two drugs might not vary; and if the sum of the relative responses did not vary, then carbamazepine could be quantitated by simply comparing the sum of the areas (peak heights) of the two peaks to that of an internal standard. This assumption proved to be correct: the ratio of carbamazepine to iminostilbene varied from 2.5 to 0.9 for 20 consecutive runs of a 16.3-μg/ml blood standard whereas the sum of the relative responses for this standard did not vary by more than 2.5% from the mean (Table II). Thus, the carbamazepine concentration was linearly related to the sum of the relative responses of carbamazepine and iminostilbene over the range investigated (up to 50 μg/ml). Recovery of carbamazepine from whole blood ranged from 90 to 114% (Table III), and the between-run standard deviation was only 0.4 μg/ml, with a lower limit of sensitivity of approximately 1 μg/ml.

The other anticonvulsants that can be determined simultaneously with this method are listed in Table IV. For the combination of primidone and carbamazepine, the phenylethylmalonamide metabolite is not completely resolved from iminostilbene on the OV-17 column. For a patient on these drugs, it is necessary to estimate and subtract the amount of phenylethylmalonamide in the combined peak by taking advantage of the fact that phenylethylmalonamide and iminostilbene are completely resolved on an OV-225 column (see *Experimental* for GLC conditions). The blood extract is chromatographed on both OV-17 and OV-225 columns, and the amount of phenylethylmalonamide (relative to the standard) is estimated from the latter chromatogram (the ratio of phenylethylmalonamide to internal standard did not vary from one run to another).

Various therapeutic ranges for carbamazepine in serum or plasma have been reported (3–8), with consensus being a range of 4–13 μg/ml. Since this assay used whole blood, it was necessary to compare blood with plasma or serum levels of carbamazepine to determine whether therapeutic ranges could be correlated. This precaution was felt to be necsssary due to the well-known (14) dilutional effect of red cells on the concentration of some drugs. Accordingly, whole blood specimens from several patients were obtained, and one portion of each was analyzed as blood and the other portion was spun down and analyzed as plasma. *No* significant differences for carbamazepine levels were observed between the two different specimens for these patients.

To determine the linearity of this comparison, whole blood standards of carbamazepine were prepared and analyzed in the same manner, and again no appreciable differences were found up to the highest concentrations studied (50 μg/ml). In addition, this comparison shows that either plasma or whole blood can be used in this assay. From the limited analyses carried out to date (less than 10 patients), a therapeutic range has not been determined. Levels between 2 and 8 μg/ml have been found, but other anticonvulsants as well as carbamazepine were being administered to these patients. Further clinical studies are necessary to determine the therapeutic range or ranges of carbamazepine in combination with various other anticonvulsants.

Quantitative Analysis of Tribromsalan in Blood and Urine

H. S. CHUN HONG ˣ, R. J. STELTENKAMP, and N. L. SMITH

Abstract □ Tribromsalan can be quantitatively measured in whole blood and urine by a technique involving extraction with ethyl acetate, treatment with silica gel, separation by TLC, and quantitative measurement by fluorescent spectrophotometry. This method has a sensitivity down to 125 ng (25 ppb in 5.0 ml of sample) of free tribromsalan and shows an average 90% recovery of tribromsalan in blood and urine with standard deviations of 9.7 and 7.4%, respectively.

Keyphrases □ Tribromsalan—analysis, blood and urine, TLC, fluorometry □ TLC—analysis, tribromsalan, blood and urine □ Fluorometry—analysis, tribromsalan, blood and urine □ Bacteriostatic agents—tribromsalan, analysis, blood and urine, TLC, fluorometry

Tribromsalan[1] is a bacteriostat which was widely used in soap and detergent products. It is effective against common Gram-positive bacteria (*e.g., Staphylococcus* type) (1–3).

Since recent studies demonstrated the absorption of hexachlorophene through human skin into the blood (4–6), other bacteriostats used in skin products must also be examined for skin absorption. Such study requires detection methods sensitive to parts per billion in blood. Tribromsalan was analyzed in toilet soaps by rapid liquid chromatography (7) with a detection limit of 100 ng. This method was not applicable to tribromsalan in blood or urine because of extracted interference.

A method is now presented for quantitatively determining tribromsalan in blood. It involves extraction of tribromsalan with ethyl acetate, isolation by TLC, and measurement through fluorescence spectrophotometry.

EXPERIMENTAL

Reagents—Tribromsalan was 99% pure as analyzed by the manufacturer. The solvents used were ethyl acetate, acetic acid, and absolute methanol, all reagent grade. Silica gel G-325[2] was used.

Procedure—The standards (25–1000 ppb) were prepared by adding known amounts of tribromsalan stock solution (1 μg/10 μl of ethanol) to each 5.0-ml blood sample; they were treated the same way as other samples to be described.

A 5.0-ml blood sample (5 mg of sodium citrate or 0.2 mg of heparin/ml of blood was added as anticoagulant) was frozen in an ethylene glycol–ether–dry ice bath (−20°) for 10 min for complete hemolysis and then thawed. Extraction was made with 15 ml of ethyl acetate on a mixer[3] for 2 min followed by centrifuging at 3500 rpm for 5 min.

Ten milliliters of the supernate was transferred to a 15-ml graduated centrifuge tube and evaporated to 3.0 ml on a water bath[4] at 60°. Approximately 100 mg of silica gel G was added, mixed well, and centrifuged. The supernate, 2.5 ml, was then transferred to a 2.5-ml centrifuge tube and evaporated to exactly 0.2 ml. If the final volume became less than 0.2 ml, it was adjusted with additional ethyl acetate.

Sixty microliters of this aliquot was spotted on a diethylaminoethylcellulose-coated glass plate[5]. At least three standards of tribromsalan were spotted on each plate along with unknown samples. The plate was developed to the top three times with absolute methanol to remove the interfering background from the original tribromsalan spot. Finally, the plate was developed with 7.5% acetic acid in methanol to approximately one-third of the plate (7–8 cm, R_f value for tribromsalan = 0.43). The plate was air dried thoroughly (see *Results and Discussion*).

The tribromsalan spot was located visually under UV light (350 nm). The plate was run on a fluorescent spectrophotometer[6] with a TLC scanner for quantitative measurements. A No. 390-nm cutoff filter was used before the emission monochromator with a 0.5 × 0.5-cm scanning slit. Spectra for tribromsalan were obtained at an excitation wavelength of 362 nm and an emission wavelength of 422 nm.

Spectra were photocopied, cut out, and weighed for quantitative measurement. Since the instrument setting for the TLC scanner can be varied from one reading to another, peak height measurement alone was not satisfactory. For area measurement, a photocopying and weighing method was convenient and as accurate as measuring height times width at half-height.

For the analysis of urine samples, the procedure was followed as described for blood samples with these exceptions:

1. The pH of urine samples was adjusted to 6.8 with monobasic or dibasic potassium phosphate before extraction with ethyl acetate, since the natural pH of urine samples varies a great deal.
2. The samples were not frozen in dry ice, since they did not need hemolysis.
3. The silica gel treatment was omitted, and the 10-ml aliquot of the ethyl acetate extract was evaporated to a final volume of 0.3 ml before spotting.

RESULTS AND DISCUSSION

The average recovery of tribromsalan from human blood was 90.6 ± 9.7% (14 samples). This value was established by extracting blood samples containing known amounts of tribromsalan (100–2500 ppb) and comparing with ethyl acetate solutions of known amounts of tribromsalan.

The linearity of the method was confirmed with human blood, rabbit blood, and human urine samples through standard curves. Correlation coefficients (r) for linearity were calculated (8) for eight different sets of experiments with three to five points for each set. They were found to be 0.976, 0.983, 1.000, 0.996, 0.992, and 1.000 for blood samples (25–1000 ppb) and 0.982 and 0.960 for urine samples (100–1000 ppb). Greater background interferences were noticed for urine samples than for blood samples. With urine, the lower limit of sensitivity was 100 ppb.

The precision of the method was determined by 10 replicate analyses of a human blood sample containing 500 ppb of tribromsalan. These blood samples were prepared by adding 50 μl of an ethanolic tribromsalan solution (1 μg of tribromsalan/μl of alcohol) to 100 ml of human blood. After thorough mixing, 10 5-ml samples of this blood were analyzed on the same TLC plate. The relative standard deviation was 7.4%.

Lowering the pH of blood to 5.9 using 10% acetic acid did not affect the recoveries. Since the minor variations (pH 7.0–7.4) that

occur with human or animal blood would not be expected to have any effect, no buffering was used. Urine samples, however, vary significantly in pH and need pH adjustment to 6.8.

The character of the fluorescent spectrum changed as the plate dried. The peak became larger and more defined at the given excitation and emission wavelengths (362 and 422 nm, respectively). There was also a significant shift of both the excitation and emission maximum wavelengths to 330 and 480 nm, respectively, when tribromsalan was in 7.5% acetic acid in methanol. Spectra obtained with wet plates resembled those in 7.5% acetic acid in methanol. The change of fluorescence in the presence of acid was also observed by other investigators with aspirin (9). Drying the plate for more than 24 hr in the air provided peaks with consistent intensities without a shift of maximum wavelengths on the fluorescent spectrophotometer.

pH-Dependent Secretion of Procainamide into Saliva

JEFFREY R. KOUP, WILLIAM J. JUSKO [x], and ALLEN L. GOLDFARB

Abstract □ The relationship between serum and stimulated, mixed saliva concentrations of procainamide was determined in 12 chronically medicated patients. Samples were obtained at times chosen to approximate the maximum and minimum serum concentrations of the drug during a dosing interval. Marked intersubject variability was found in the ratio of saliva to serum concentration of the drug (0.27–8.93). There was no correlation between the dose (milligrams per kilogram per day) and the minimum serum or saliva concentration of procainamide. Saliva pH ranged from 6.3 to 8.0 in eight subjects. The ratio of saliva to serum concentration of procainamide increased with decreasing pH. This result can be largely explained by the pH-dependent ionization and distribution of procainamide, a weak base.

Keyphrases □ Procainamide—pH-dependent secretion into saliva, ratio of saliva to serum concentration, humans □ Saliva—concentration of secreted procainamide, pH dependent, compared to serum concentration, humans

Procainamide, an antiarrhythmic compound, demonstrates marked intersubject variability in absorption and elimination (1). The range of therapeutic serum concentrations, however, has been defined (1). Mean plasma concentrations ranging from 4 to 8 μg/ml are generally effective in controlling arrhythmias, while toxicity is likely to occur at concentrations above 12 μg/ml. Thus, serum concentration measurements are useful in monitoring therapy in individual patients. However, procainamide has a short half-life, approximately 3–6 hr, which necessitates multiple venipunctures to characterize the peak and minimum serum concentrations during a dosing interval and during continued therapy. These requirements may be excessively traumatic for routine clinical application. The purpose of this study was to assess whether saliva concentrations of procainamide can be used to monitor drug concentrations in the plasma of patients receiving the drug.

The salivary secretion of other drugs has been the subject of several investigations. Good correlation between either total or unbound serum and mixed saliva concentrations was demonstrated in humans for theophylline (2), lithium (3), digoxin (4), acetaminophen (5), salicylate (at low concentrations) (6), phenytoin (7), and several sulfonamides (8).

EXPERIMENTAL

Twelve patients in an acute coronary care unit[1], who had been receiving a fixed dose of procainamide hydrochloride[2] for at least 2 days, were studied. Daily doses, dosage intervals, and times of sample collection in relation to dose are listed in Table I for the individual patients. The clinical records indicated that renal and liver functions were essentially normal in all subjects.

Blood and mixed, stimulated saliva were collected simultaneously before and after a regularly scheduled dose of procainamide. Saliva flow was stimulated by having the patients chew on waxed film[3]. For Patients K and L, only one sample set was obtained. A third sample set was obtained at approximately 1 week after the initial samples for Patients A and E. All samples were obtained between 10 and 11 am and between 1 and 3 pm to avoid mealtimes and to minimize the possible effects of diurnal variation in saliva composition (9).

Saliva pH was determined immediately after sample collection for Patients E–L. The serum and saliva samples were refrigerated at 4° and analyzed within 2 days. Serum and saliva concentrations of procainamide were assayed by a double-extraction, spectrophotofluorometric method (1, 10).

[a] Third samples were also collected for these patients. [b] Saliva pH was not measured.

RESULTS

The serum and saliva procainamide concentrations measured in the 12 subjects are listed in Table I. There was no correlation between the dose (milligrams per kilogram per day) and either the minimum serum or saliva concentration of procainamide. No attempt was made to correlate the drug dose with the maximum concentrations since a single sample taken 1–2 hr after the dose would not be expected to identify accurately the actual peak concentration. These observations are in agreement with the findings of Koch-Weser and Klein (1), who noted a substantial degree of intersubject variability in serum concentrations of procainamide among patients receiving similar doses.

The saliva–serum concentration ratio of procainamide is plotted *versus* the serum concentration of the drug in Fig. 1. Pronounced intersubject variation was observed in this ratio, with values ranging from 0.27 to 8.93. Substantial intrasubject variation was also observed. A notable example is Patient E, in whom the ratio varied from 2.75 to 7.16 to 3.28 on three different occasions.

One possible reason for this variation was thought to be the differences among patients with respect to saliva pH. Procainamide is a weak base with a pKa of 9.4. The unionized form of the drug is more lipophilic than the cation and would be expected to diffuse more freely across mucosal membranes and the epithelial cells lining the salivary ducts. The relationship between the saliva–serum concentration ratio of procainamide and saliva pH is shown in Fig. 2.

The theoretical distribution ratio expected for the total concentration of an ionizable species found on two sides of a lipoid membrane where differences in pH exist is also shown in Fig. 2. This ratio is described by the following relationship derived from the Henderson–Hasselbach equation:

$$\frac{C_{sal}}{C_{ser}} = \frac{1 + 10^{(pKa - pH_{sal})}}{1 + 10^{(pKa - pH_{ser})}} \qquad \text{(Eq. 1)}$$

where the subscripts sal and ser refer to the respective concentration (C) or pH values for saliva and serum. Serum pH values of 7.2–7.6 were used, reflecting the lower and upper limits of the theoretical range. There was a significant correlation ($r = 0.57$, $p < 0.05$) between the actual and theoretical ratios (at a serum pH of 7.4).

Besides accounting for much of the intersubject variability in salivary distribution of procainamide, the differences in saliva pH also accounted for intrasubject changes in the distribution ratio. For each patient who exhibited differences in saliva pH between the two collection periods, the change in ratio was in the direction predicted by Eq. 1.

DISCUSSION

The measurement of procainamide concentrations in saliva is not a useful method for monitoring the plasma concentration of procainamide in patients. The variability in the saliva–serum concentration ratio is large and unpredictable. Even if saliva pH measurements were made for the purpose of applying a correction factor based on Eq. 1, the range of saliva concentrations found at any given pH is appreciable. For example, three patients had saliva pH values near 7.0 and the saliva–serum concentration ratio varied more than fourfold (Fig. 2).

The variability in salivary distribution of procainamide may be partly due to several other factors. Since the drug is only 15% bound to serum proteins (10), protein binding is not a likely factor. The contact time of procainamide with the buccal mucosa may be of slight importance. Meyers *et al.* (11) instilled buffered (pH 5–11) solutions of procainamide into the mouth and measured the loss of drug after 5 min. The absorption rate of procainamide was slow; only 4.5 and 14.3% absorption occurred at pH 5 and 11, respectively. The magnitude of these differences in absorption rate is much less than anticipated based on the degree of ionization of procainamide. However, these investigators did not measure the pH of the solution after equilibrium in the mouth. Saliva contains sufficient bicarbonate (40–50 mEq/liter) (12) to alter the pH of weakly buffered acidic solutions and possibly mute the pH differences.

A major factor which may affect the distribution ratio is the intrinsic and effective pH values at the site of saliva secretion. Serum pH may not adequately reflect the pH of the interstitial fluid on one side of the salivary glands while saliva pH, after mixing with the contents of the mouth, may differ from that which was formed by the gland and which contacts the epithelial cells within the gland. Thus, the theoretical curves shown in Fig. 2 may only approximate the effects of real pH differences across the salivary gland on a microscopic level. Finally, the rate of secretion of saliva affects the saliva concentration of some small molecules. For example, the concentration of urea in saliva decreases with the rate of salivary flow (13).

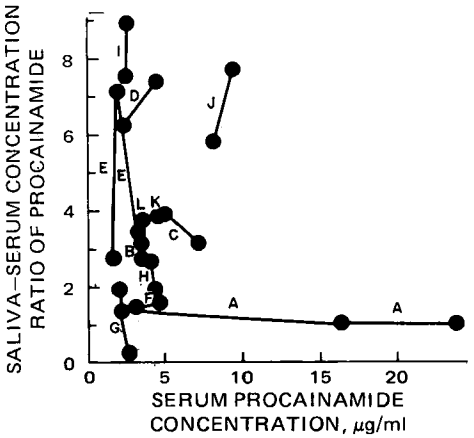

Figure 1—*Range of saliva–serum concentration ratios of procainamide as a function of serum concentration of procainamide in 12 patients during therapy with the drug. Lines connect data obtained repeatedly in individual patients. Letters identify data points for each patient in Table I.*

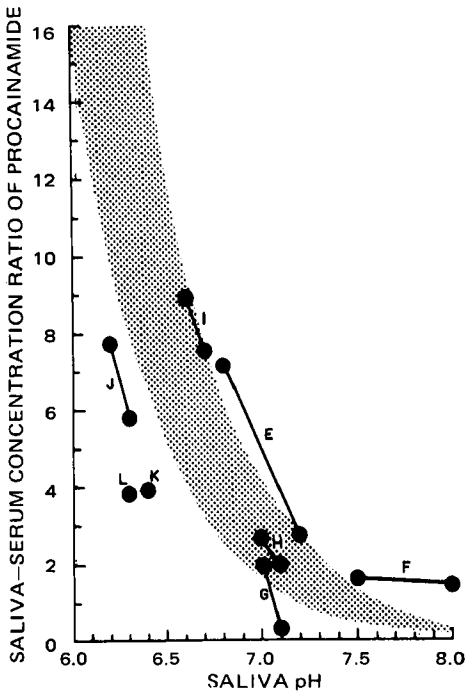

Figure 2—*Relationship between saliva–serum concentration ratios of procainamide and salivary pH in individual patients. The shaded area shows the theoretical concentration ratios calculated from Eq. 1, using a serum pH range of from 7.2 (lower edge) to 7.6 (upper edge).*

Examination of the effects of modifying pH on procainamide secretion into saliva in individual volunteer subjects does not appear feasible. Levy and Lampman (14) found that administration of large doses (5 g) of sodium bicarbonate did not significantly increase the pH of saliva of healthy subjects while urine pH changed appreciably. Doses of ascorbic acid or ammonium chloride were similarly without effect on saliva pH in single preliminary tests in this laboratory. Thus, the only reasonable approach to study the effect of pH on drug secretion into saliva is the present one, namely, a panel of subjects or patients with naturally different salivary pH values.

Other drugs have exhibited salivary secretion rates that were dependent on pH and protein binding. Gruneison and Witzgall (8) found a linear relationship between the saliva concentrations of several sulfonamides and the unbound drug in plasma of humans. Differences in ratios among the sulfonamides were consistent with the degree of ionization of these drugs. Sulfanilamide (pKa 10.4) produced the highest saliva–serum water concentration ratio (1.08), while sulfadiazine (pKa 6.28) yielded a ratio of 0.338. These studies were performed at only one salivary pH value (slightly lower than 7.4). However, the data of Rasmussen (15) on the same two drugs in cows and goats are of interest. These animals had a saliva pH of 8.2. Sulfanilamide, which would be essentially 100% unionized at pH 7.4 and 8.2, had a saliva–serum ultrafiltrate ratio of 1.0. Sulfadiazine, which would be 2% unionized at pH 8.2 and 11% unionized at pH 7.4, had a saliva–serum ultrafiltrate ratio of 1.3 in the animals.

Another weak base, trimethoprim (pKa 7.3), appears to behave like procainamide with respect to pH-dependent salivary secretion. Hansen *et al.* (16) reported a range in saliva-to-plasma concentration ratios of 1–8.3 in 14 patients. With the use of Eq. 1, the theoretical concentration ratios over a saliva pH range of 6.3–8.0 is 7.6 to 0.7, in close agreement with observed data.

Fluorometric Determination of 2,3-Bis(*p*-methoxyphenyl)imidazo[1,2-*a*]pyrimidine in Biological Materials

DAVID G. KAISER ˣ and ARLINGTON A. FORIST

Abstract □ Interest in 2,3-bis(*p*-methoxyphenyl)imidazo[1,2-*a*]-pyrimidine as a potent, orally active, anti-inflammatory agent required a method for its determination in serum, urine, and feces to permit studies of its absorption, metabolism, and excretion. A simple, rapid, sensitive, and specific procedure was developed based on an ethyl acetate extraction of alkaline specimens and subsequent fluorometric analysis of ethanolic solutions of the extract residues. The method is sensitive to 0.2 μg/ml, 0.3 μg/ml, and 1.2 μg/100 mg of drug in serum, urine, and feces, respectively. The overall mean recovery and the standard deviation from biological samples are 99.8 ± 5.1%. The procedure has been successfully applied to absorption studies in the dog.

Keyphrases □ 2,3-Bis(*p*-methoxyphenyl)imidazo[1,2-*a*]pyrimidine—fluorometric analysis, biological materials, anti-inflammatory agent □ Anti-inflammatory agents—2,3-bis(*p*-methoxyphenyl)-imidazo[1,2-*a*]pyrimidine, fluorometric analysis, biological materials □ Fluorometry—analysis, 2,3-bis(*p*-methoxyphenyl)imidazo-[1,2-*a*]pyrimidine, anti-inflammatory agent, biological materials

In a continuing search for nonsteroidal anti-inflammatory drugs, 2,3-bis(*p*-methoxyphenyl)imidazo[1,2-*a*]pyrimidine (I), together with some structurally related compounds, was found to be a highly potent agent (1). Studies of the absorption, metabolism, and excretion of I required a method for its determination in serum, urine, and feces.

Previous reports described fluorometric procedures for the determination of indoxole [2,3-bis(*p*-methoxyphenyl)indole] (2) and 4,5-bis(*p*-methoxyphenyl)-2-phenylpyrrole-3-acetonitrile (3) in biological materials. These methods were successfully used in investigations in animals and humans (3–6).

Exploratory studies showed that I possessed useful fluorescence characteristics. Therefore, a simple, rapid, sensitive, and specific fluorometric procedure was developed for the determination of I in biological materials.

EXPERIMENTAL

Reagents and Materials—Aqueous sodium hydroxide (1 *N*) was stored in glass containers. Ethyl acetate was equilibrated with an equal volume of water prior to use in the extraction step. A solution of quinine sulfate[1] (2.25 μg/ml in 0.1 *N* aqueous sulfuric acid) was utilized as a spectrophotofluorometric standard. All pipets and centrifuge tubes were thoroughly rinsed with alcohol or acetone and air dried prior to use.

Instrumentation—A blender[2] and/or homogenizer[3] were used in the preparation of fecal specimens for extraction. A two-speed reciprocating shaker[4] was utilized for sample extractions in the horizontal position. Fluorometric measurements were made with a spectrophotofluorometer[5] equipped with a xenon lamp dc power supply[6], a compact xenon arc lamp (150 w)[7], a potted photomultiplier tube (1P28)[5], and a two-axis recorder[8].

Table I—Lower Limits of Detection for I in Rat and Dog Serum, Urine, and Feces

Specimen	Detection Limit[a]
Rat serum	0.06 μg/ml
Dog serum	0.18 μg/ml
Rat urine	0.30 μg/ml
Dog urine	0.24 μg/ml
Rat feces	1.20 μg/100 mg
Dog feces	0.88 μg/100 mg

[a] Based on a sample response twice that of the appropriate specimen blank.

Standards—A stock solution of I was prepared by dissolving 5–10 mg in 100 ml of 95% ethanol with shaking. Working standards were prepared by dilution of the stock solution with 95% ethanol to give final concentrations of approximately 0.05, 0.1, 0.2, 0.4, 0.6, and 0.8 μg/ml. No special storage conditions were required since I is photochemically stable in acidic, neutral, or basic ethanolic solutions for at least 24 hr.

Collection and Storage of Specimens—Blood samples were allowed to clot at room temperature (27°) for 1 hr and then were centrifuged at 2000 rpm for 10 min, and the serum was harvested. Urine specimens were collected with 1 ml of 37% formaldehyde added for each 50 ml. All serum, urine, and fecal specimens were stored at −18° until analyzed.

Extractions—In a 15-ml glass-stoppered centrifuge tube were placed 1 ml of serum or urine, 0.05 ml of 1 *N* aqueous sodium hydroxide, and 3 ml of ethyl acetate. The mixture was shaken in a horizontal position for 10 min and then centrifuged for 10 min at 2000 rpm. A 1-ml aliquot of the ethyl acetate layer was transferred to a separate glass-stoppered centrifuge tube and evaporated to dryness in a stream of nitrogen. The residue was reconstituted in 5 ml of 95% ethanol for fluorometric analysis.

For rat feces, the frozen specimen was weighed and placed in the homogenizer[3]. A volume of water equivalent to twice the sample weight was added, and the mixture was homogenized at high speed for 1 min. A 100-mg aliquot of the slurry was weighed into a 15-ml glass-stoppered centrifuge tube, and 1 ml of water, 0.05 ml of 1 *N* aqueous sodium hydroxide, and 3 ml of ethyl acetate were added. The extraction was completed as described for serum and urine.

For dog feces, the total specimen was weighed and placed in the blender[2]. A volume of water equivalent to twice the sample weight was added, and the mixture was homogenized at high speed for 1 min. An aliquot (about 20 ml) was removed and homogenized[3] at high speed until a fine slurry was produced. A 100-mg aliquot was weighed into a 15-ml glass-stoppered centrifuge tube, and 1 ml of water, 0.05 ml of 1 *N* aqueous sodium hydroxide, and 3 ml of ethyl

	19.9	20.7	104.0
		Mean ± *SD*	96.0 ± 9.2
Dog feces	5.0	4.7	94.0
	10.0	10.0	100.0
	19.9	20.6	103.5
		Mean ± *SD*	99.1 ± 1.8

[a] Values for water, serum, and urine are expressed as micrograms per milliliter; values for feces are expressed as micrograms per 100 mg. [b] Corrected for appropriate specimen blank.

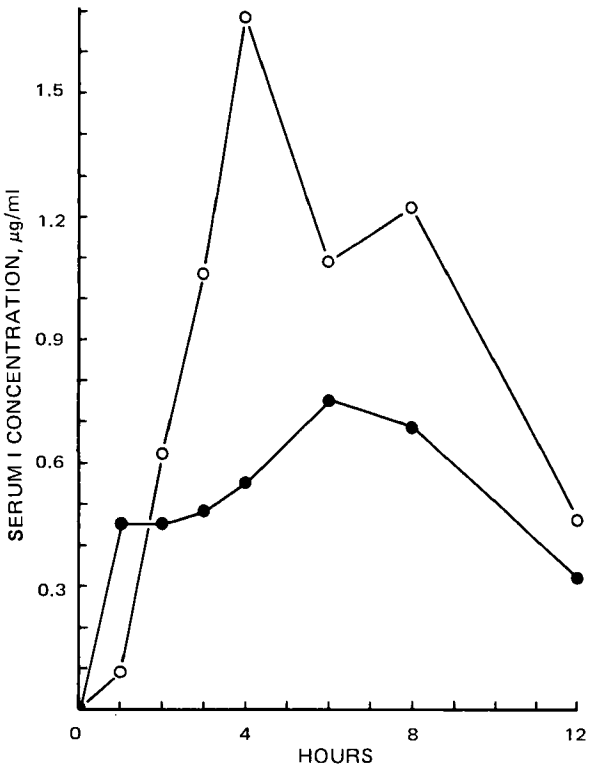

Figure 1—*Serum concentrations of I in dogs after single-dose oral drug administration in polysorbate 80. Key:* ○, *Dog BL-73 (male), 43.3 mg/kg; and* ●, *Dog 366 (male), 37.3 mg/kg.*

acetate were added. The extraction was completed as described for serum and urine.

Fluorometric Analysis—The spectrophotofluorometer was standardized with the quinine sulfate solution (60% transmission at 0.3 meter multiplier setting)[5], using the excitation (370 nm) and emission (470 nm) maxima for I. Fluorescence intensities of the extract residue solutions were measured at these wavelength settings. Compound I concentrations were calculated from a standard curve (working standards) with appropriate corrections for serum, urine, or feces blanks.

Preparation of Animals—In studies designed to determine the utility of the analytical methodology, three male beagle dogs, 10.5 ± 1.4 kg, were fasted for 16 hr prior to single-dose oral drug administration. Two dogs received ~40 mg of I/kg in polysorbate 80, and the remaining animal served as a vehicle-treated control. All animals were fasted for an additional 4 hr after drug administration and were then allowed free access to food and water.

Blood specimens were withdrawn from the jugular veins at 0, 1, 2, 3, 4, 6, 8, and 12 hr after drug administration. Urine specimens were collected at predetermined time intervals during the first 24 hr after drug administration. All specimens were stored at −18°.

TLC—All chromatography was conducted on thin layers (250 μm) of silica gel F_{254}[9], ascendingly developed in a solvent system of acetone–*n*-heptane–concentrated ammonium hydroxide (200:200:1 v/v). The separated materials were visualized by (*a*) irradiation of the plates with short wavelength (254 nm) and long wavelength (366 nm) UV lamps, or (*b*) spraying with 50% (v/v) aqueous sulfuric acid and heating at 110° for 20 min. Under these conditions, intact I had an R_f value of 0.18.

RESULTS AND DISCUSSION

Earlier studies with indoxole (2) and 4,5-bis(*p*-methoxyphenyl)-2-phenylpyrrole-3-acetonitrile (3) showed those compounds to be susceptible to photochemical degradation. By contrast, I is stable in acidic, neutral, or basic ethanolic solutions in the presence of light for at least 24 hr. Therefore, no special precautions are necessary in the storage of specimen extracts.

The maximum fluorometric sensitivity for I in 95% ethanol is 0.005 μg/ml (meter multiplier setting of 0.003)[5]. However, the practical lower limits of detection in biological matrixes are controlled by the magnitude of the specimen blanks in addition to the inherent fluorescence emission of I. Calculated lower detection limits for I, based on sample responses twice those of the appropriate blanks, are shown in Table I. In serum, urine, and feces, I may be detected at levels of ≥0.2 μg/ml, ≥0.3 μg/ml, and ≥1.2 μg/100 mg, respectively.

Under the described conditions, a linear relationship between fluorescence response and concentration of I is obtained over the 0–0.8-μg/ml range in 95% ethanol. Direct quantification from a standard curve has been adequate.

To determine recoveries from biological samples, known amounts of I in 95% ethanol were evaporated to dryness in centrifuge tubes, and water or specimens of rat or dog serum, urine, or feces were added. The samples were thoroughly mixed and analyzed by the standard procedure. Recoveries were quantitative (overall mean and standard deviation of 99.8 ± 5.1%), justifying the use of a simple standard curve in routine analysis as described previously (Table II).

Utility of the method was established by a limited study in dogs. Following oral administration of approximately 40 mg of I/kg, peak serum I levels of 0.75–1.7 μg/ml were observed between 4 and 6 hr (Fig. 1). Measurable concentrations were present throughout the 12-hr sampling interval. These results are similar to those reported for indoxole (2, 5) and 4,5-bis(*p*-methoxyphenyl)-2-phenylpyrrole-3-acetonitrile (3) in dogs.

The present method detects materials that are extractable from an alkaline solution with ethyl acetate and that possess excitation and fluorescence emission characteristics in 95% ethanol similar to I. Interference by endogenous materials in most specimens is very low, as indicated by the lower limits of detection (Table I). However, metabolic transformations could give rise to compounds responding in the assay. Accordingly, excitation spectra were routinely obtained on serum extracts as a check on specificity meta-

[9] Brinkmann Instruments, Westbury, N.Y.

bolic changes would be expected to result in altered UV spectra and, therefore, fluorescence excitation spectra. No such changes were observed in the dog. Moreover, TLC of serum extracts showed that the major component (>85%) was similar to I, confirming the measurement of intact drug. Thus, the method possesses adequate sensitivity and specificity for drug absorption studies in animals.

Based on fluorometric and TLC analyses, less than 1% of the dose was excreted in urine as intact I by the dog during the 24-hr collection interval. Extensive metabolism and/or biliary secretion are indicated.

Conformationally Constrained Analogs of Mescaline II

ROBERT J. WOLTERS [x], A. J. BEJ, and N. S. TANNER

Abstract □ The synthesis of methyl-2-(3,4,5-trimethoxyphenyl)-2-(2-piperidyl) acetate is described. In addition, preliminary pharmacological data comparing the compound with mescaline are given.

Keyphrases □ Mescaline—synthesis of conformationally constrained analog, methyl-2-(3,4,5-trimethoxyphenyl)-2-(2-piperidyl) acetate, IR and NMR spectra □ Methyl-2-(3,4,5-trimethoxyphenyl)-2-(2-piperidyl) acetate—analog of mescaline, synthesis, IR and NMR spectra

In an earlier publication (1), the synthesis of several conformationally constrained analogs of mescaline (I) was reported. This article reports the synthesis of methyl -2-(3,4,5-trimethoxyphenyl) -2- (2-piperidyl) acetate (II) as a modified mescaline analog. Compound II possesses the trimethoxyphenyl ring and the two-carbon chain of mescaline. The nonmethoxy analog of II, methylphenidate[1] (III), is a known central nervous system stimulant (2). It was anticipated that II would possess stimulant properties like mescaline and methylphenidate.

DISCUSSION

The synthetic route utilized for II was basically the same as that employed by Hartmann and Panizzon (3) for the synthesis of methylphenidate (Scheme I). The starting material, 3,4,5-trimethoxyphenylacetonitrile (IV), was synthesized according to the procedure of Telang and Smith (4).

Compound IV was reacted with 2-chloropyridine, using sodium hydride as the base, to form 2-(3,4,5-trimethoxyphenyl)-2-(2-pyridyl)acetonitrile (V). Compound V was hydrolyzed with sulfuric acid to form the amide VI. Methanolysis of VI gave the methyl ester VII. Catalytic hydrogenation of VII afforded the desired product II.

II: R = —OCH_3

III: R = —H

EXPERIMENTAL[2]

Pharmacology—The spontaneous activity of the test compound was compared to amphetamine, methylphenidate, and mescaline by means of activity chambers according to the procedure of Wolters *et al.* (1). The response of amphetamine, methylphenidate, and mescaline was reported previously (1).

The test compound at the 50-mg/kg dosage induced locomotor activity corresponding to that of saline in the first 40 min. Beyond 40 min, the rate of activity was comparable to mescaline, although the stereotyped behavior of mescaline scratching was not observed with the test compound at this dose.

Chemistry *2- (3,4,5-Trimethoxyphenyl) -2- (2-pyridyl)acetonitrile Hydrochloride (V-HCl)*—A solution of 75 ml of anhydrous dimethylformamide and 11.0 g (0.0531 mole) of IV was cooled to 0°. Then 3.0 g (0.060 mole) of sodium hydride was added. After the cessation of hydrogen evolution, a solution of 6.07 g (0.053 mole) of 2-chloropyridine in 50 ml of dimethylformamide was added drop-

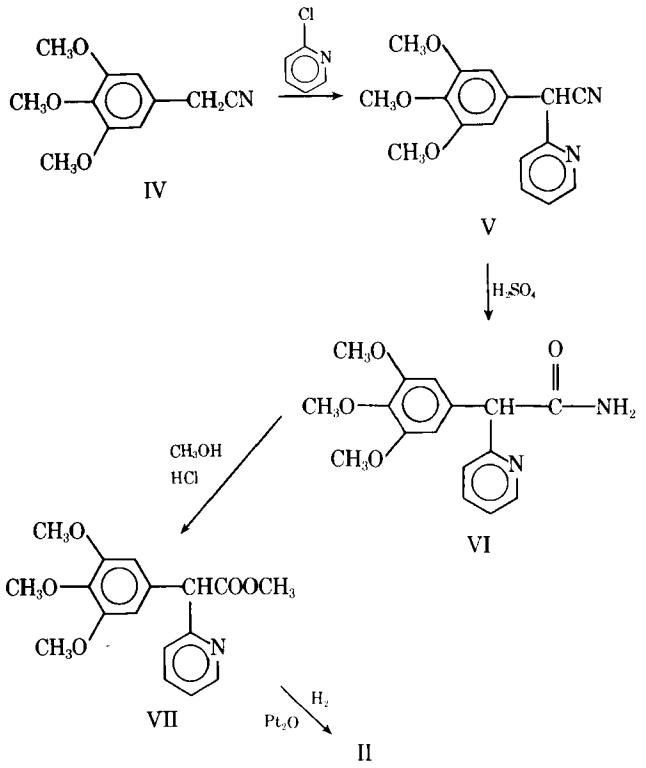

Scheme I

wise and the reaction mixture was stirred for an additional hour. The mixture was allowed to equilibrate to room temperature and was stirred for an additional 12 hr.

Approximately 1.5 liters of water was added to the mixture, and the organic phase was separated and extracted with ether. Then the ether phase was extracted with several 25-ml portions of 10% hydrochloric acid. The combined acid extract was neutralized with 10% sodium hydroxide and extracted exhaustively with ether. The ether extract was evaporated on a steam bath to yield 8.9 g (61%) of viscous oil, and the oil was dissolved in anhydrous ether. Dry hydrogen chloride was bubbled into the ether solution to yield 10 g (59%) of crude product.

After recrystallization from a mixture of ethanol and anhydrous ether, the product melted at 162–180°. Additional recrystallizations did not appreciably reduce the melting-point range. The IR spectrum showed a peak at 2250 cm^{-1}, indicative of a nitrile group. The NMR spectrum of the free base gave the following: δ 3.9 (2s, 9H, methoxys), 6.5 (s, 1H, —CH), 7.1 (2s, 2H, aromatic), 7.5 (b, 3H, pyridine ring), and 8.2 (b, 1H, pyridine ring).

Anal.—Calc. for $C_{16}H_{16}N_2O_3 \cdot HCl$: C, 59.91; H, 5.34; N, 8.73. Found: C, 59.76; H, 5.50; N, 8.54.

2-(3,4,5-Trimethoxyphenyl)-2-(2-pyridyl)acetamide (VI)—To 35 ml of concentrated sulfuric acid was added 6.59 g (0.0232 mole) of V. The resulting solution was allowed to stand for 12 hr at room temperature. The reaction mixture was poured into crushed ice and neutralized with sodium carbonate, and the product was extracted with chloroform. The chloroform was removed on a steam bath, and the residue was recrystallized from ethyl acetate to yield 5.01 g (72%) of product, mp 144–146°.

The IR spectrum showed a peak at 1700 cm^{-1}, indicative of amide carbonyl. The NMR spectrum gave the following: δ 3.8 (s, 9H, methoxys), 5.0 (s, 1H, —CH), 6.8 (s, 2H, aromatic), 7.6 (b, 3H, pyridine ring, and 2H, amide), and 8.6 (b, 1H, pyridine ring).

Anal.—Calc. for $C_{16}H_{18}N_2O_4$: C, 63.56; H, 6.00; N, 9.27. Found: C, 63.59; H, 6.11; N, 9.08.

Methyl-2-(3,4,5-trimethoxyphenyl)-2-(2-pyridyl) Acetate (VII)—Hydrogen chloride gas was bubbled into a solution of 5.01 g (0.0166 mole) of VI and 150 ml of anhydrous methanol for 6 hr. After most of the methanol was removed, sodium carbonate was added to form the free base. The precipitate was filtered and recrystallized from 50% ethanol and then from ether, yielding 2.79 g (53%) of product, mp 101–104°.

The IR spectrum showed a carbonyl peak at 1740 cm^{-1}. The NMR spectrum gave the following: δ 3.8 (s, 3H, methoxys), 3.9 (s, 9H, methoxys), 5.2 (s, 1H, —CH), 6.8 (s, 2H, aromatic), 7.5 (b, 3H, pyridine ring), and 8.6 (b, 1H, pyridine ring).

Anal.—Calc. for $C_{17}H_{19}NO_5$: C, 64.34; H, 6.03; N, 4.41. Found: C, 64.26; H, 6.21; N, 4.25.

Methyl-2-(3,4,5-trimethoxyphenyl)-2-(2-piperidyl) Acetate Hydrochloride (II-HCl)—A mixture of 1.34 g (0.00423 mole) of VII, 10 ml of acetic acid, and 5 mg of platinum oxide was shaken with hydrogen (initial pressure of 55 psi) in a Parr hydrogenator for 20 hr. The platinum oxide was removed by filtration. The filtrate was diluted with three times its volume of water, and sodium carbonate was added to precipitate the free base, which was extracted with ether. The ether solution was dried over anhydrous magnesium sulfate, and the hydrochloride salt was made from the dried ether solution in the usual manner.

The crude product was recrystallized from methyl ethyl ketone, yielding 0.69 g (45%) of product, mp 202–203°. The NMR spectrum of the free base gave the following: δ 1.8 (b, 9H, piperidine ring), 3.6 (b, 1H, —NH), 3.8 (s, 3H, methoxys), 3.9 (2s, 9H, methoxys), 4.0 (b, 1H, —CH), and 6.6 (2s, 2H, aromatic).

Anal.—Calc. for $C_{17}H_{25}NO_5 \cdot HCl$: C, 56.76; H, 7.28; N, 3.89. Found: C, 56.84; H, 7.16; N, 4.00.

Bioequivalency of Doxycycline Products

EDWARD J. ANTAL, JAMES M. JAFFE, ROLLAND I. POUST, and JOHN L. COLAIZZI ˣ

Abstract □ The bioavailability of three different brands and three different dosage forms of doxycycline was studied in normal subjects. Single doses, equivalent to 200 mg of doxycycline, were administered to six subjects in a crossover design as the innovator's intravenous solution given orally (Treatment A), the innovator's capsule product (Treatment B), a noninnovator's capsule product (Treatment C), the innovator's oral suspension product (Treatment D), and a second noninnovator's capsule product (Treatment E). All dosage forms contained doxycycline as the hyclate, except the suspension which contained the nonhyclate form. Serum levels were determined periodically over 48 hr, and cumulative urinary excretion was measured concurrently over a 120-hr collection period. No statistically significant differences were observed in any *in vivo* indicator of bioequivalence when the three capsule products were compared. Consequently, they were judged to be bioequivalent. When these capsule products were compared to the oral solution, no statistically significant differences were observed. However, when the capsules and the suspension were compared, statistically significant differences were found in the rate of absorption. *In vitro* dissolution tests were also conducted on the three brands of capsules, and times required to achieve 50% dissolution showed rank-order correlation with corresponding absorption rate constants.

Keyphrases □ Doxycycline products—bioavailability, three different brands and three different dosage forms □ Bioavailability—doxycycline products, three different brands and three different dosage forms

In recent years, numerous products introduced by pharmaceutical manufacturers have been chemical equivalents rather than innovator products. Consequently, the biological equivalency of the available solid, oral, multiple-source dosage forms of a given drug entity has become important and comparative bioequivalency studies have become a means of evaluating the quality and acceptability of such noninnovator products. The tetracycline analog, doxycycline, recently became available on a multiple-source basis. Since cases of bioinequivalence for some chemically equivalent products of the tetracycline antibiotics have been documented (1–4), bioequivalence of different sources of doxycycline cannot be merely assumed.

Two tetracycline antibiotics for which a substantial bioequivalency literature exists, tetracycline and oxytetracycline, were recently classified as "drugs whose solid oral dosage forms it is not possible at this time to state categorically there is, or is not, a potential for bioequivalence . . . problems" in a report of the APhA Academy of Pharmaceutical Sciences (5). In a recent study (6), the 50- and 100-mg capsules of one of the two noninnovator's brands of doxycycline capsule dosage forms were compared and determined to be bioequivalent to the innovator product.

The objectives of the present study were: (*a*) to evaluate the bioequivalency of the two currently commercially available, chemically equivalent, noninnovator brands of doxycycline capsules, using the innovator's capsule product as the standard; (*b*) to study the bioavailability of all three brands of capsules in comparison to equivalent doses of an oral solution and an oral suspension of the drug; and (*c*) to determine the correlation, if any, between the dissolution profiles of the capsule dosage forms and their relative bioavailability.

EXPERIMENTAL

***In Vivo* Bioavailability Study Protocol**—Six healthy, normal, adult male volunteers, 21–30 years old, with normal creatinine clearance values were employed as subjects. Five different dosage forms or brands of doxycycline were administered with approximately 240 ml of water. Each of the five treatments provided a dose of 200 mg of doxycycline, calculated as the base.

In Treatment A, reconstituted doxycycline hyclate for injection[1] was administered as an oral solution; Treatments B[2], C[3], and E[4] consisted of different brands of capsules, each containing doxycycline hyclate equivalent to 100 mg of doxycycline base. Treatment D consisted of an oral suspension[5], which contained 25 mg of doxycycline base, present as the monohydrate, per 5 ml after reconstitution.

Each treatment was administered using a complete crossover design, which was randomized to minimize any possible sequential effects. A time interval of at least 1 week elapsed between treatments, allowing adequate time for essentially complete doxycycline elimination. The subjects fasted at least 3 hr prior to dosing and continued to fast until 3 hr after drug administration.

Blood samples (4 ml) were collected in evacuated glass containers[6] just prior to dosing and at 1, 2, 3, 4, 7, 12, 24, 28, 34, and 48 hr after drug administration. Urine voids were collected at specific intervals and pooled for 120 hr postadministration.

***In Vitro* Dissolution Studies**—*In vitro* dissolution determinations were conducted on the three brands of capsules. Although doxycycline has no compendial monograph dissolution requirement, the general Method I of NF XIV (7) was used to establish and compare dissolution profiles. The mesh screen basket[7] was rotated at 25 rpm in a dissolution fluid of 0.1 *N* HCl. Samples were taken at 3-min intervals, filtered through a 0.22-μm membrane filter[8], and analyzed spectrophotometrically[9] at a wavelength of 268 nm. Doxycycline concentrations in solution were determined from a standard calibration plot prepared using doxycycline base[10] as a standard.

Potency Determinations of Test Products—Maximum concentrations of doxycycline achieved in the dissolution medium were employed as an indicator of the actual potency for each brand of capsule, thus providing information concerning content uniformity. Six oral suspension and intravenous solution products of identical lot number were analyzed by the method used in serum

Table I—Derived Pharmacokinetic Parameters from Both Serum Level and Urinary Excretion Data

Parameter	Treatment					Statistics[a]
	A	B	C	D	E	
Peak value of mean serum concentration–time curve, μg/ml	3.65	3.57	3.53	4.12	3.51	N.S.[b]
Mean value of peaks of individual serum concentration–time curves, μg/ml	3.86	3.68	3.55	4.29	3.69	$p < 0.05$
Mean time of peak values of individual serum concentration–time curves, hr	2.50	2.83	2.83	2.67	3.00	N.S.
Mean of area under individual serum concentration–time curves, μg/ml × hr	80.89	79.08	93.39	94.96	77.97	N.S.
Mean of individual total urinary excretion of unchanged drug, mg	97.69	92.93	85.20	100.16	90.21	N.S.

[a] Analysis of variance for repeated measures design. [b] N.S. = not statistically significant at 0.05 level of significance ($p > 0.05$).

and urine concentration determinations because of excipient interference in the UV spectral analysis.

Fluorometric Determination of Doxycycline in Biological Samples—The analytical technique employed for the determination of doxycycline in urine and serum was based on the fluorometric[11] method of Kohn (8). This method yields results comparable in accuracy and reproducibility to microbiological methods (9).

Statistical Evaluation of Results—Serum concentrations at each time period, peak serum concentrations, areas under the serum level–time curves, and total urinary excretion of doxycycline were analyzed by analysis of variance for a crossover design, using a computerized statistical program (10). This program utilizes a repeated measures design to allow for treatment interactions in the same subject, which would not be seen if each treatment was given separately to different subjects (11).

Any statistical differences found among treatments were further compared to determine differences between treatments by Tukey's Allowable Difference Test (12). Differences in calculated absorption rate constants for each treatment were tested for statistical significance using the Student t test for each possible combination of treatment pairs.

RESULTS

A summary of the average serum concentrations of the six subjects for each treatment at each of the 10 sampling times after drug administration is shown in Fig. 1. The insert in the figure depicts these same values but on an expanded time scale from 0 to 12 hr postadministration. Derived pharmacokinetic parameters from both serum levels and urinary excretion data appear in Table I. The results of the analysis of variance among treatments are recorded in the final column of this table. A significant difference was found among treatments for the average peak values of the individual serum concentration–time curves (Table I) and also at the 2-hr postadministration time (Fig. 1) when the mean serum concentrations were evaluated.

These differences among treatments were further compared by means of a multiple-range test, Tukey's Allowable Difference Test, to determine significant differences between treatments at the 0.05 level of significance (12). At 2 hr postadministration, a statistical difference was noted between the serum levels produced by Treatment D, the oral suspension, and Treatment E, a noninnovator capsule product. A borderline difference was also observed between the suspension serum levels and Treatment C, the other noninnovator capsule product. All other paired comparisons did not produce statistically different results.

When comparing the mean peak values of the individual serum concentration–time curves, a statistically significant difference was observed between Treatments D and C. Borderline differences were noted between the suspension and both Treatment B, the innovator's capsule, and Treatment E. No statistically significant differences were observed in other paired comparisons.

Absorption rate constants, k_a, were calculated for each treatment by fitting the mean serum level data for six subjects to the classical one-compartment pharmacokinetic model (13), using a nonlinear least-squares regression computer program (14, 15) adapted for use on the PDP-10 system[12]. The k_a values determined were as follows: Treatment A, 1.38 hr^{-1}; Treatment B, 0.91 hr^{-1}; Treatment C, 0.87 hr^{-1}; Treatment D, 1.32 hr^{-1}; and Treatment E, 0.88 hr^{-1}. No statistical significance was observed when these values were compared using a two-tailed Student t test at the 0.05 level of significance.

A summary of the *in vitro* test results is provided in Table II. Six capsules of each manufacturer's product were studied, and the dissolution profiles of the three capsule products are presented in Table II. The mean cumulative amounts of doxycycline dissolved are reported for each time up to one interval past the maximum amount dissolved. The time to achieve 50% dissolution was calculated after the dissolution data were fitted to a model describing the dissolution profiles of conventional capsule dosage forms (16).

Table II also shows the actual amount of active drug present in each capsule dosage form. These values were derived from the dissolution profiles. The maximum amounts of drug in solution were averaged for each of the six capsules used to study a certain manufacturer's product. For the oral solution and suspension, six containers with identical lot numbers were assayed by the method previously described, and the average amounts of active drug present in the solution and suspension dosage forms were 107.2 ± 3.4 and 112.9 ● 3.2 mg, respectively.

DISCUSSION

Bioavailability involves both the rate and extent of drug absorption. In this study, the bioavailability of two chemically equivalent capsule formulations was compared to a recognized standard, the formulation of the innovator whose efficacy has been documented by clinical experience. Chemically equivalent products that achieve the same bioavailability profile as measured by appropriate *in vivo* parameters are generally assumed to produce the same therapeutic effects (17).

Parameters used to compare the extent of bioavailability or the amount of drug absorbed from the formulations are the area under the serum concentration–time curve and the amount of unchanged drug excreted in the urine. According to an evaluation of these two parameters, the three different brands of doxycycline capsules did not produce any statistically significant differences. Therefore, the amount of drug absorbed from each was essentially equal for the subjects tested.

To be effective, doxycycline must be present in the blood and tissues at certain concentrations for certain durations of time. In comparing the three brands of capsules, no statistically significant differences were observed in serum concentrations, including the peak serum concentrations, at any sampling time period studied. The peak serum concentrations were compared both for the means of the six subjects and also on an individual subject basis, with no observed statistical difference.

Differences in rate of absorption can be compared by evaluating differences in peak times. The insert in Fig. 1 shows that mean serum concentration plots for the six subjects result in peak times of 3 hr for the three brands of capsules. Analysis of mean peak times of the individual serum concentration–time curves for the three capsule formulations tested revealed no statistically significant differences for this parameter. Therefore, on the basis of bioavailability profiles, these three capsule brands were judged to be similar in both rate and extent of absorption and may be termed bioequivalents.

A conclusion of bioequivalency for doxycycline products was also determined in another recent study (6) involving the 50- and 100-mg capsules of the innovator and one noninnovator[13]. Plasma levels were determined by a microbiological assay in 12 volunteers from 0 to 12 hr postadministration of a 100-mg dose of the drug. Each capsule was administered after a 1-hr fast in a randomized crossover design. No statistically significant differences were observed in mean plasma levels, areas under the plasma level curves, and the times for attaining the peak plasma levels (6). Although there were differences in the protocols and the observed peak times, both studies show bioequivalence for the brands of doxycycline capsule products studied. Differences in the protocols of the two studies included the number of subjects tested, assay methodology, biological samples tested, sampling times and duration, fasting period, dose of drug given, and number of different brands and dosage forms tested.

In comparing the bioavailabilities of the capsule dosage forms to those of the oral solution (Treatment A) and oral suspension (Treatment D), the parameters evaluated were the same as those used in determining the bioequivalence between capsule products. Statistically significant differences ($p < 0.05$) were observed for two of these parameters. The first parameter occurred at the 2-hr postadministration sampling time, with a statistically higher mean serum concentration produced by the oral suspension (Treatment D) as compared to one generic capsule (Treatment E). Differences at this early sampling time, which is prior to achieving the peak concentration, reflect differences in the rates of drug absorption. Since a drug must undergo dissolution before it can be absorbed, the suspension may present the drug in a form that permits it to undergo more rapid dissolution, leading to a higher serum concentration in the prepeak time periods. Another possible explanation for this result may be related to the fact that the suspension dosage form contained the nonhyclate (nonsalt) form of doxycycline, whereas all of the other dosage forms in this study contained the hyclate (hydrochloride salt) form.

The second statistically different parameter resulted from the peak serum concentrations produced in the individual subjects. Statistically higher ($p < 0.05$) concentrations were produced by the suspension (Treatment D) than by one noninnovator capsule (Treatment C). Although the peak serum levels of Treatment D showed a trend toward higher levels as compared to the other two capsule products (Treatments B and E), these differences were just short of statistical significance. These differences could be related to the different forms (salt *versus* nonsalt) of doxycycline involved or to other formulation differences between the capsules and the suspension. Since there were no differences in the compared areas under the serum concentration–time curves between capsules and suspension, a faster rate of absorption might have been responsible for producing the higher peaks, rather than differences in the active amounts of doxycycline present in the different dosage forms.

When the dissolution rates, as measured by the time required to achieve 50% dissolution, and the corresponding absorption rate constants of each capsule formulation were compared, rank-order correlation was observed. The innovator's capsule formulation (Treatment B) corresponded to the shortest time to reach 50% dissolution and the greatest absorption rate, as indicated by the k_a. The noninnovator's formulations followed in numerical ranking, with Treatment C corresponding to the longest time to reach 50% dissolution and the smallest absorption rate constant. However, since there were no statistically significant differences among any of the *in vivo* parameters studied, including the calculated rate constants of absorption, for the three capsule products, dissolution data could presumably represent a range of acceptable values.

This study was undertaken to ascertain the bioequivalency of

Table II—*In Vitro* Dissolution Data for Three Manufacturers' Capsule Dosage Forms of Doxycycline

Minutes	Mean Cumulative Amount Dissolved for Six Capsules (mg ± *SD*)

the three currently commercially available capsule dosage forms of doxycycline hyclate and to compare their bioavailability profiles with those obtained from oral administration of an equivalent amount of doxycycline hyclate in solution form or an equivalent dose of doxycycline base in suspension form. Through the use of serial serum determinations and cumulative urinary excretion data collected in a single-dose study of crossover design, *in vivo* parameters were compared.

No statistically significant differences among the three capsule products were found, and the products were judged to be bioequivalent. This finding corroborates one other study (6) which concluded bioequivalency between two of the three brands employed in this study. When these same capsules were compared to the oral solution and suspension, differences were found in one prepeak mean serum level. *In vitro* dissolution tests were conducted on the three capsule products; time for 50% dissolution showed rank-order correlation with corresponding absorption rate constants.

Stability of Aspirin in Liquid and Semisolid Bases V: Polyglycerol Esters

C. W. WHITWORTH [x] and A. F. ASKER

Abstract □ The stability of aspirin in decaglycerol tetraoleate, decaglycerol octaoleate, and decaglycerol decaoleate was studied at 4, 26, and 45°. Degradation of aspirin in these polyglycerol esters was temperature dependent. Aspirin demonstrated the greatest stability in decaglycerol octaoleate and the lowest stability in decaglycerol tetraoleate at all temperatures studied. The hydroxyl value and the viscosity of the polyglycerol ester appeared to influence the stability of aspirin.

Keyphrases □ Aspirin—solubility and stability in polyglycerol esters, effect of temperature, hydroxyl value, viscosity □ Polyglycerol esters—as solvents for aspirin, stability, effect of temperature, hydroxyl value, viscosity □ Stability—aspirin in decaglycerol tetraoleate, decaglycerol octaoleate, and decaglycerol decaoleate

In previous reports (1–4), the stability of aspirin in various liquid and semisolid bases was investigated. The decomposition of aspirin in polyethylene glycols was due, at least in part, to a transesterification reaction between aspirin and polyethylene glycols (5). Blocking free hydroxyl groups on the polyethylene glycols retarded the decomposition of aspirin (1).

Polyglycerol esters are synthetic products and may be hydrophilic or lipophilic, depending on the number of hydroxyl groups that are reacted with the fatty acids and/or oils in question (6). The consistency of these esters varies from waxy solids and semisolids to liquids (6). Feeding studies (7) indicated that such esters are completely nontoxic and are degraded fully by the body to yield glycerol and the fatty acid. The Food and Drug Administration approved the use of polyglycerol esters ranging from 2 to 30 moles of glycerin and placed no limits on the amounts for use (6).

Decaglycerol tetraoleate, decaglycerol octaoleate, and decaglycerol decaoleate are liquid at room temperature and possess viscosity values of 6000–8000,

the three currently commercially available capsule dosage forms of doxycycline hyclate and to compare their bioavailability profiles with those obtained from oral administration of an equivalent amount of doxycycline hyclate in solution form or an equivalent dose of doxycycline base in suspension form. Through the use of serial serum determinations and cumulative urinary excretion data collected in a single-dose study of crossover design, *in vivo* parameters were compared.

No statistically significant differences among the three capsule products were found, and the products were judged to be bioequivalent. This finding corroborates one other study (6) which concluded bioequivalency between two of the three brands employed in this study. When these same capsules were compared to the oral solution and suspension, differences were found in one prepeak mean serum level. *In vitro* dissolution tests were conducted on the three capsule products; time for 50% dissolution showed rank-order correlation with corresponding absorption rate constants.

Stability of Aspirin in Liquid and Semisolid Bases V: Polyglycerol Esters

C. W. WHITWORTH [x] and A. F. ASKER

Abstract □ The stability of aspirin in decaglycerol tetraoleate, decaglycerol octaoleate, and decaglycerol decaoleate was studied at 4, 26, and 45°. Degradation of aspirin in these polyglycerol esters was temperature dependent. Aspirin demonstrated the greatest stability in decaglycerol octaoleate and the lowest stability in decaglycerol tetraoleate at all temperatures studied. The hydroxyl value and the viscosity of the polyglycerol ester appeared to influence the stability of aspirin.

Keyphrases □ Aspirin—solubility and stability in polyglycerol esters, effect of temperature, hydroxyl value, viscosity □ Polyglycerol esters—as solvents for aspirin, stability, effect of temperature, hydroxyl value, viscosity □ Stability—aspirin in decaglycerol tetraoleate, decaglycerol octaoleate, and decaglycerol decaoleate

In previous reports (1–4), the stability of aspirin in various liquid and semisolid bases was investigated. The decomposition of aspirin in polyethylene glycols was due, at least in part, to a transesterification reaction between aspirin and polyethylene glycols (5). Blocking free hydroxyl groups on the polyethylene glycols retarded the decomposition of aspirin (1).

Polyglycerol esters are synthetic products and may be hydrophilic or lipophilic, depending on the number of hydroxyl groups that are reacted with the fatty acids and/or oils in question (6). The consistency of these esters varies from waxy solids and semisolids to liquids (6). Feeding studies (7) indicated that such esters are completely nontoxic and are degraded fully by the body to yield glycerol and the fatty acid. The Food and Drug Administration approved the use of polyglycerol esters ranging from 2 to 30 moles of glycerin and placed no limits on the amounts for use (6).

Decaglycerol tetraoleate, decaglycerol octaoleate, and decaglycerol decaoleate are liquid at room temperature and possess viscosity values of 6000–8000,

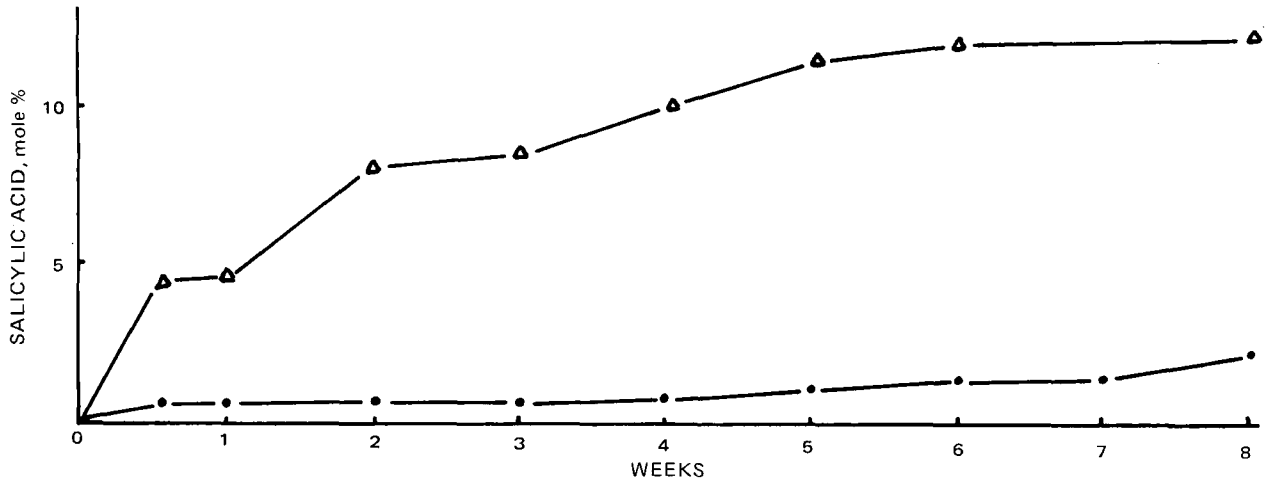

Figure 1—*Appearance of salicylic acid* versus *time for aspirin suspensions in polyglycerol esters at 4°. Key: △, decaglycerol tetraoleate; and ●, decaglycerol decaoleate.*

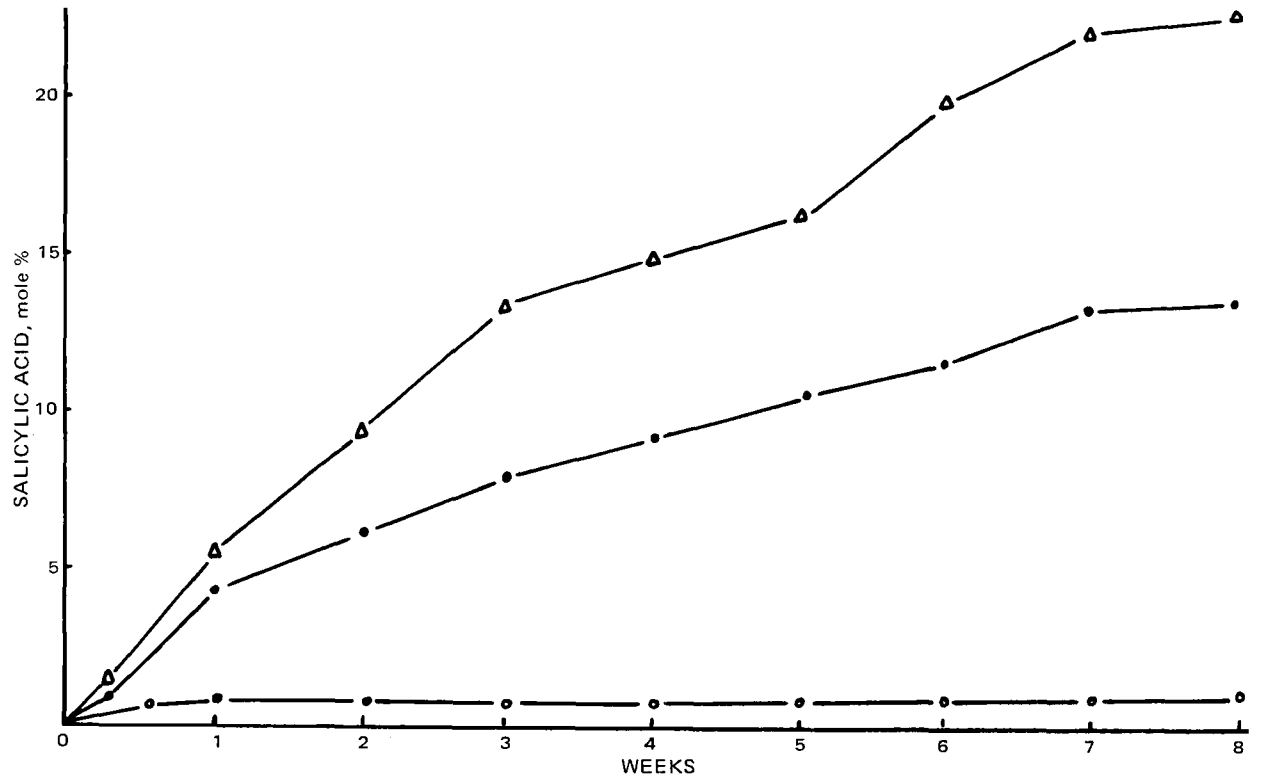

Figure 2—*Appearance of salicylic acid* versus *time for aspirin suspensions in polyglycerol esters at 26°. Key: △, decaglycerol tetraoleate; ●, decaglycerol decaoleate; and ○, decaglycerol octaoleate.*

800, and 400 cps, respectively (8). The hydroxyl values of these esters are 210–250 for the tetraoleate, 70–90 for the octaoleate, and 25–50 for the decaoleate (6, 8). The moisture content of these esters runs about 10%. The solubility of aspirin in the vehicles was determined and found to be 2.76, 2.19, and 2.01 mg/100 mg of vehicle for the tetraoleate, octaoleate, and decaoleate, respectively.

EXPERIMENTAL

Materials—Aspirin[1] USP and salicylic acid[1] were used as received. The polyglycerol esters[2] were supplied by the manufacturer. Chloroform[3] was spectrograde.

Sample Preparation—The samples were prepared by suspending 0.3 g of aspirin in 9.7 g of the polyglycerol ester contained in airtight amber glass vials with screw caps. The suspensions were stored at 4, 26, and 45°.

Analytical Method—UV spectrophotometric analysis, as reported by Tinker and McBay (9), was employed to measure aspirin and salicylic acid. Samples were taken at specific intervals and dissolved in 100 ml of chloroform containing 1% acetic acid. A further appropriate dilution was made, and the absorbance of the dilution was read[4] at 280 nm for aspirin and at 310 nm for salicylic acid.

[2] PVO International Inc., Boonton, N.J.
[3] J. T. Baker Chemical Co., Phillipsburg, N.J.
[4] Cary model 118 spectrophotometer.

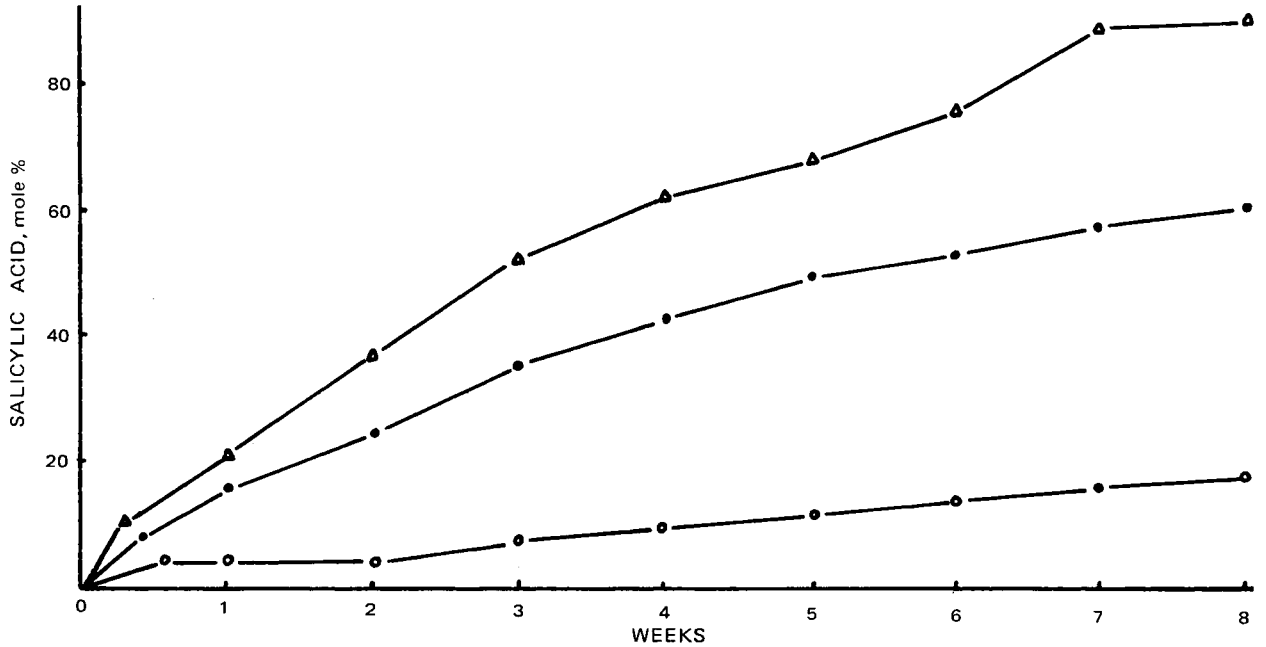

Figure 3—*Appearance of salicylic acid* versus *time for aspirin suspensions in polyglycerol esters at 45°. Key:* △, *decaglycerol tetraoleate;* ●, *decaglycerol decaoleate; and* ○, *decaglycerol octaoleate.*

Standard curves were prepared for aspirin and salicylic acid at these wavelengths. The quantification of aspirin and salicylic acid was based on the standard method of simultaneous spectrophotometric determinations.

Solubility Determination—The solubility of aspirin in each liquid was determined at 26° by adding 1 g of drug to 5 ml of vehicle and mixing with a mechanical stirrer for 24 hr. The mixture was then transferred to a test tube and centrifuged at 5000 rpm for 30 min. Three drops of the supernate were transferred to a 10-ml volumetric flask and accurately weighed.

The sample was dissolved by adding a 1% solution of acetic acid in chloroform, and the absorbance of a diluted sample of this solution was read at 280 and 310 nm. Three samples were used in each determination. The concentration of aspirin was determined by the standard method of simultaneous spectrophotometric determinations.

RESULTS AND DISCUSSION

The overall profiles of aspirin degradation in decaglycerol tetraoleate, decaglycerol octaoleate, and decaglycerol decaoleate at 4, 26, and 45° are shown in Figs. 1–3. Aspirin demonstrated the least stability in decaglycerol tetraoleate at all temperatures studied. Decaglycerol tetraoleate had the highest hydroxyl value (210–250) of the polyglycerol esters studied.

A previous publication (5) reported that the decomposition of aspirin in polyethylene glycols was due, at least in part, to a transesterification reaction and that the blocking of free hydroxyl groups retarded aspirin decomposition (1). Therefore, it appears that the lowest stability of aspirin in decaglycerol tetraoleate could be due to the highest hydroxyl value possessed by this vehicle. Moreover, decaglycerol tetraoleate is dispersible in water, while the octaoleate and the decaoleate are immiscible (6). Therefore, water that might have contaminated the aspirin powder or the decaglycerol tetraoleate during sample preparation would be distributed throughout the vehicle to react with aspirin particles.

Aspirin in decaglycerol octaoleate showed no detectable decomposition at 4°, about 1% at 26°, and 18% at 45° after 8 weeks. Although decaglycerol octaoleate has a higher hydroxyl value than that of decaglycerol decaoleate, aspirin was more stable in the former vehicle. This finding could be explained on the basis that the degradation-enhancing effect due to the higher hydroxyl value would be outweighed by the stabilizing effect due to the higher viscosity possessed by decaglycerol octaoleate. This higher viscosity would hinder diffusion of any moisture that might have contaminated the aspirin powder during sample preparation and, therefore, retard the degradation reaction. The solubility of aspirin in the vehicles was very similar for all three liquids and does not explain the differences in stability.

Microbial Transformation of Aspidospermine

SHEN-KAI LIN *, M. TIN-WA, and E. H. TAYLOR ˣ

Abstract □ Thirty actinomycetes were isolated from soil samples and screened for their ability to modify the structure of aspidospermine. One actinomycete culture converted aspidospermine into *O*-demethylaspidospermine but failed to modify *N*-deacetylaspidospermine, *N*-ethyl-*N*-deacetylaspidospermine, 7-methoxyindole, and 7-methoxytryptophan.

Keyphrases □ Aspidospermine—structural transformation (demethylation) by actinomycetes, UV, IR, and NMR spectral identification of conversion products □ Alkaloids—structural transformation by actinomycetes, UV, IR, and NMR spectral identification of conversion products □ Actinomycetes—structural transformation of aspidospermine, UV, IR, and NMR spectral identification of conversion products

The enzyme systems of microorganisms have been used to transform numerous organic compounds including steroids and other biologically active substances such as alkaloids, flavonoids, terpenoids, and antibiotics. Although interest in the modification of alkaloid structures by microorganisms seems to be increasing, the volume of work in this field is still not large. Typical alkaloids that have been been converted microbiologically include conessine (1), agroclavine (2), 14β-bromocodeinone (3), sparteine (4), nicotine (5), and indoles such as yohimbine (6) and vindoline (7).

These successes in modifying alkaloid structures and the unique advantages of microbial conversions (*e.g.*, reactions at chemically inactive positions, stereospecific substitutions, coupling of several reactions, and mild reaction conditions) led to the investigation of microbial transformations of other alkaloids.

Thirty actinomycete cultures were screened for their ability to modify indole alkaloids. One effectively modified aspidospermine, and the major transformation product was isolated and characterized. This report is the first in the literature concerning the cleavage of a phenyl methyl ether bond of an alkaloid by a microorganism.

EXPERIMENTAL[1]

Materials and Methods—The 30 actinomycetes employed in the screening work were isolated by the usual method (8) from soil samples collected locally. The pure cultures were maintained on sucrose nitrate slants. A crude aspidospermine fraction, previously obtained in this laboratory from the bark of *Aspidosperma quebracho-blanco* Schlecht (Apocynaceae) (9), was purified by recrystallization from ethanol.

N-Deacetylaspidospermine was prepared by acid hydrolysis of aspidospermine (10). *N*-Ethyl-*N*-deacetylaspidospermine was prepared from *N*-deacetylaspidospermine using ethyl iodide (10). 7-Methoxyindole was purchased[2].

Screening Procedures—The microorganisms were grown in 125-ml erlenmeyer flasks in a medium composed of 3% glycerol, 0.35% casamino acid[3], 0.1% K_2HPO_4, 0.05% $MgSO_4 \cdot 7H_2O$, 0.05% KCl, and a trace of ferrous sulfate heptahydrate. The flasks were incubated on a rotary (240 rpm) shaker at 28°. After 2 days, 1 ml of each culture was transferred to new medium and incubated for 2 days.

Aspidospermine (I) was added to each culture (0.2 mg/ml), and the reaction was allowed to proceed for 48 hr. The culture broths were extracted for alkaloids in the usual (acid–base shakeout) manner, and the crude alkaloid mixtures were chromatographed on silica gel GF_{254} TLC plates and developed with benzene–acetone (1:1). After drying, the plates were sprayed with ceric ammonium sulfate reagent (11), followed by Dragendorff's reagent (12).

One isolate, designated as Culture 14823[4], gave a conversion product (different R_f value and chromogenic reaction) and was used for the larger scale production of this conversion product. Control experiments were performed in which no cultures were added. No transformation took place in these control experiments, indicating that the experiment with Culture 14823 was indeed an enzyme-mediated reaction.

Conversion Procedure in Fermentor—Culture 14823 was grown in a 14-liter stirring fermentor. Aspidospermine (200 mg/liter) was added to the culture fluid, and incubation was continued under the cultivating conditions. Samples of 50 ml each were taken at 8-hr intervals, extracted for alkaloids, and analyzed by TLC. The ratio of the amount of the product formed to that of the substrate remaining was determined semiquantitatively by observing the size and color depth of the spots after spraying with Dragendorff's reagent.

When the conversion appeared maximal (48 hr), the alkaloids were extracted and then purified on a silica gel PF_{254}[5] column by eluting with benzene–acetone (1:1). The major conversion product (32% yield) isolated exhibited the same R_f values in three different TLC solvent systems as did the product obtained from the small flask fermentation. Several additional experiments carried out in the fermentor yielded similar results. A few other fermentation products were detected, but the yields were too minute and no further isolation work was performed.

RESULTS AND DISCUSSION

Identification of Conversion Product—The UV spectrum of the major conversion product showed absorptions at λ_{max} (ethanol): 220 (log ϵ 4.39), 258 (3.93), and 293 (3.54) nm (indicative of a dihydroindole moiety) (9). A bathochromic shift to 308 nm (log ϵ 3.90) in 0.1 *N* KOH in ethanol suggested the presence of a phenolic group.

An IR spectrum of this conversion product taken in potassium bromide showed absorptions at ν 2930, 2780, 1635, 1601, 1580, 1475, 1445, 1380, 1360, 1262, 1182, 1132, 1106, 1062, 935, 770, and 740 cm^{-1}. The mass spectrum of the conversion product showed a molecular ion, M^+, at *m/e* 340 (25); other significant ions were observed at *m/e* 339 (20.0), 312 (8.3), 160 (4.1), 152 (5.4), 146 (3.3), and 124 (100.0). Thus, the conversion product showed the same base peak at *m/e* 124 as well as a common peak at *m/e* 152 as the substrate aspidospermine (13), indicating that the nonindole portion of both molecules is the same.

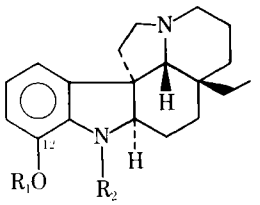
[1] The fermentor used was "Magnaferm" model MA-100 from New Brunswick Scientific Co., New Brunswick, N.J. UV spectra were taken using a Beckman model DB-G grating spectrophotometer, and spectra were examined from 200 to 340 nm. IR spectra were taken using a Beckman IR 18A spectrophotometer, and spectra were recorded from 4000 to 600 cm^{-1}. Mass spectra were determined using a single-focusing Hitachi Perkin-Elmer model RMU-6D mass spectrometer, operating at 70 ev. Proton NMR spectra were taken using a Varian A-60 instrument operating at 60 MHz.

[2] Aldrich Chemical Co. Inc., Milwaukee, Wis.

[3] Difco Laboratories, Detroit, Mich.

[4] Culture 14823 was identified by Dr. T. G. Pridham, Agricultural Research Service, Northern Regional Research Laboratory, U.S. Department of Agriculture, Peoria, Ill., as a strain of subspecies of *Streptomyces griseus* (Krainsky) Waksman and Henrici.

[5] E. Merck, Darmstadt, West Germany.



I: $R_1 = CH_3$, $R_2 = COCH_3$
II: $R_1 = H$, $R_2 = COCH_3$
III: $R_1 = CH_3$, $R_2 = H$
IV: $R_1 = CH_3$, $R_2 = CH_2CH_3$

The molecular ion of the conversion product was at 14 mass units less than that observed for aspidospermine. This finding and the bathochromic shift observed in the UV spectrum suggested that the methoxy at C-12 of aspidospermine was converted to a hydroxyl. If so, the remaining peaks at *m/e* 339, 312, 160, and 146 can be readily identified to be the corresponding peaks of *m/e* 353, 325, 174, and 160, respectively, observed in the spectrum of aspidospermine (13).

An NMR spectrum in deuterochloroform, with tetramethylsilane as an internal standard, confirmed the conversion product to be *O*-demethylaspidospermine (II). An intramolecularly hydrogen-bonded phenolic proton at C-12 appeared as a singlet at δ 10.89, three aromatic protons appeared as a multiplet centered at δ 6.90, the proton at C-2 appeared as a quartet at δ 4.15, the *N*-acetyl group appeared as a three-proton singlet at δ 2.35, and the three protons of the ethyl side chain appeared as a triplet at δ 0.67. The methoxy proton present in the NMR spectrum of aspidospermine at δ 3.89 was absent in the spectrum of the conversion product.

The IR and NMR spectra were superimposable with those of semisynthetic *O*-demethylaspidospermine, prepared according to the method of Witkop and Patrick (10) from aspidospermine.

It appears that the enzyme systems in Culture 14823 cleave the phenyl methyl ether linkage without affecting the neighboring acetyl group. To determine if this type of reaction could be applied to other compounds with the phenyl methyl ether moiety, the substrate specificity of the enzyme system was investigated. Culture 14823 was tested for its ability to transform the following compounds utilizing the same screening procedure: 7-methoxyindole, 7-methoxytryptophan[6], *N*-deacetylaspidospermine, and *N*-ethyl-*N*-deacetylaspidospermine. No significant transformations occurred.

SUMMARY

Aspidospermine was demethylated during the fermentation process by Culture 14823. The phenyl methyl ether bond is stable and requires drastic chemical means for fission, *e.g.*, heating with aluminum chloride at 140° or fusion with sodium hydroxide above 240° (10). However, the cleavage of this bond can be achieved by enzymatic action under very mild conditions.

This culture failed to demethylate *N*-deacetylaspidospermine, *N*-ethyl-*N*-deacetylaspidospermine, 7-methoxyindole, and 7-methoxytryptophan. Since these substances all lack the acetyl group on the indole nitrogen, this group may be essential for this enzymatic reaction to take place.

A literature search revealed that only a few examples of the microbial cleavage of phenyl methyl ether bonds have been reported, *e.g.*, demethylation of griseofulvin by fungi (14), of vanillic acid by bacteria (15), and of 7-methoxyisoflavone by *Penicillium cyclopium* (16).

Antineoplastic and Cytotoxic Components of Desert *Baileya*

Keyphrases □ *Baileya multiradiata*—six antineoplastic and cytotoxic components, isolated and evaluated □ Antineoplastic agents, potential—isolated from *Baileya multiradiata*, biological evaluation □ Cytotoxic agents—isolated from *Baileya multiradiata*, biological evaluation

To the Editor:

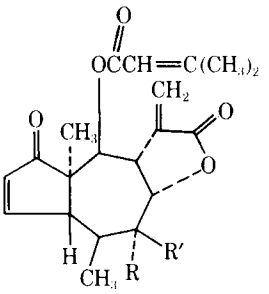
The bright-yellow ray-florets of *Baileya multiradiata* Harv. and Gray (family Compositae)[1] are commonly seen in the southwestern United States from Texas to California. The flowering portion is attractive to sheep, and ingestion has led to the death of many such range animals (1).

In 1966, we collected *B. multiradiata* in Arizona for evaluation in respect to possible antineoplastic components (2). Later, an ethanol extract of the complete plant was found to reach confirmed active status in the National Cancer Institute's murine lymphocytic leukemia P-388 screen. A cell line derived from this PS system suitable for *in vitro* measurements was studied as a bioassay method for isolating the antineoplastic constituents of *B. multiradiata*.

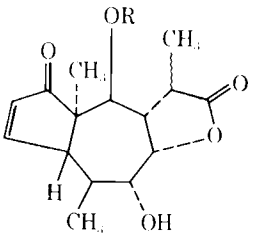
We now wish to report the isolation of six cytotoxic and antineoplastic constituents of *B. multiradiata* and that the new P-388 *in vitro* screening technique[2] proved very efficient for this purpose. The results of this bioassay are expressed as ED_{50}, namely, that concentration of material (in micrograms per milliliter) that produces 50% inhibition of growth in a 48-hr incubation period.

A chloroform-soluble fraction (5.98 g) prepared from *B. multiradiata* Harv. and Gray was partially separated by chromatography on cross-linked dextran gel[3]. The fraction (4.8 g) eluted with methanol–chloroform (6:4) was subjected to careful gradient (benzene to ethyl acetate) elution chromatography on silica gel. The following were obtained (in order of isolation): fastigilin C (I*b*, 0.13 g, ED_{50} 0.004)[4] (4), fastigilin B (II*a*, 0.09 g, ED_{50} 0.078) (4), baileyin (III, 0.05 g, ED_{50} 0.47) (5), and pleniradin (IV*a*, 2.03 g, ED_{50} 5.7), characterized as the monoacetate derivative IV*b* (ED_{50} 2.9) (6).

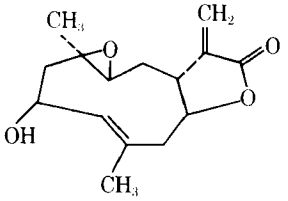
A new pseudoguaianolide, designated multiradiatin (I*a*, ED_{50} 0.02, crystals from acetone–heptane, 0.19 g, mp 226–230°) (4), as well as radiatin (II*b*, 0.67 g, ED_{50} 0.39) (6), was isolated by analogous large-scale chromatography (161 g of chloroform fraction). The structural assignment for multiradiatin was confirmed by the identity of this substance with the ketone obtained by chromic acid (Jones reagent) oxidation of fastigilin C. Both fastigilin C and baileyin (III) were isolated previously from *B. multiradiata* by Waddell and Geissman (5).



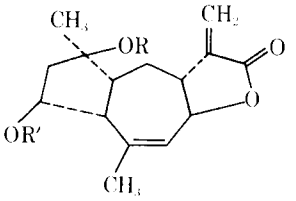
I*a*: R = R′ = O
I*b*: R = OH, R′ = H



II*a*: R = COCH=C(CH$_3$)$_2$
II*b*: R = COC(=CH$_2$)CH$_3$



III



IV*a*: R = R′ = H
IV*b*: R = H, R′ = COCH$_3$

In vivo biological studies against several tumors of the National Cancer Institute's screening systems are now in progress. At present, consistent *in vivo* activity has been obtained, for example, with fastigilin C (I*b*), which in the PS screen leads to a 50% increase in survival time at a dose of 3 mg/kg. Recently, we (7) summarized analogous and encouraging biological activity for the related pseudoguaianolide helenalin. Thus, results of the present study suggest that the pseudoguaianolide lactone of the fastigilin, helenalin, and radiatin type possesses (in addition to the usual cytotoxic properties of such lactones) carrier groups that fall within requirements for *in vivo* antineoplastic activity. Also, the cytotoxicity displayed by the sesquiterpene lactones of *B. multiradiata*, while correlated with the antineoplastic activity, may suggest that these components are responsible for sheep poisonings attributed to this plant.

[1] The plant material was identified by Mrs. E. Lehto, Herbarium curator, Department of Botany, Arizona State University. Voucher specimens are preserved in our Institute and in the University's Herbarium.

[2] For results of a study employing L-1210 cells *in vitro* as a cytotoxicity assay, refer to Ref. 3.

[3] Sephadex LH-20.

[4] Spectral data (mass, IR, and PMR) and elemental analyses were consistent with each structural assignment. Reported yields correspond to the recrystallized (from benzene–ethyl acetate unless otherwise noted) product.

Germination and Morphine Content of *Papaver somniferum* Plants Produced from Commercially Available Poppy Seed

Keyphrases □ *Papaver somniferum*—germination and cultivation from commercial poppy seeds, morphine content, TLC, column chromatography, IR and mass spectra □ Morphine—isolated from *Papaver somniferum* germinated and cultivated from commercial poppy seeds, TLC, column chromatography, IR and mass spectra □ Narcotics—morphine, isolated from *Papaver somniferum* germinated and cultivated from commercial poppy seeds, TLC, column chromatography, IR and mass spectra

To the Editor:

There are no legal constraints to the possession of seeds of *Papaver somniferum*, the opium poppy. However, it is illegal to cultivate this plant in the United States. This paradox is interesting since *Cannabis sativa* (marijuana) seeds must be sterilized prior to sale. The narcotic regulations do not require sterilization of *P. somniferum* seeds.

Because *P. somniferum* could be illicitly cultivated in the United States as a source of codeine and morphine, the present study was carried out to answer the following questions. What is the botanical identification of commercially available poppy seeds? What is the germination rate of such seeds? And will plants produced from commercial poppy seeds grow and produce morphine in a temperate climate such as we have in the United States?

Poppy seeds (100-g samples) were obtained from two commercial bakeries in Chicago as well as from three supermarkets in the area. The seeds were soaked for 2 min in a dilute solution of sodium hypochlorite, washed thoroughly with water, and germinated on wet vermiculite. Approximately 60% of the seeds from each of five lots germinated.

After the seedlings developed well-expanded cotyledons, they were transplanted to potting soil. The plants were grown in a greenhouse in 10.2-cm (4-in.) diameter clay pots. Flowering occurred about 8 weeks after germination. Greenhouse plants were similar in appearance to fieldgrown plants, although they were smaller[1].

Immature capsules of one seed lot (I-9786) were pierced with a suitable needle daily, and the dried latex was scraped from the capsules and accumulated. A total of 24 mg of dried latex was collected in this manner from several capsules.

When the plants were fully mature, the entire plants were dried and then subjected to alkaloid extraction. The latex (24 mg), which had been scraped from the immature capsules, was dissolved in 15 ml of 1% HCl and filtered. After the filtrate was made alkaline with ammonium hydroxide, it was extracted three times with 15-ml volumes of chloroform. The combined chloroform extracts were taken to dryness to yield a 10-mg residue, which was used in the TLC analyses.

TLC of the extract on silica gel G plates, when compared with an authentic morphine sample, indicated morphine to be present in the alkaloid extract in addition to several other alkaloids.

Chromatography of the alkaloid extract over a small column (disposable pipet) containing 1.5 g of silica gel PF_{254}, using chloroform–methanol–ammonium hydroxide (90:10:1) as the eluent, resulted in the isolation of a compound (2 mg) whose R_f on silica gel PF_{254} plates, using the same solvent system, was 0.71.

The mass spectrum of the compound indicated a molecular ion M^+ at *m/e* 285 nm, and the fragmentation pattern was consistent with that reported for morphine (1).

To confirm this identification, additional capsules and foliage (8.38 g) were processed for alkaloids as already described. We wanted to determine if a larger quantity of the compound, tentatively identified as morphine, could be isolated and more definitively identified. TLC analysis of the resulting alkaloid extract indicated the same pattern as was observed for the alkaloid extract prepared from the latex.

Column chromatography of this extract, using 10 g of silica gel PF_{254}, resulted in the isolation of 7.6 mg of the compound. The UV spectrum of the sample (in ethanol) showed a maximum absorption at 284 nm,

[1] The plants were identified as *Papaver somniferum* L. (Papaveraceae) by F. A. Crane, and herbarium specimens (I-9786–I-9790) were deposited at the Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612

The combined chloroform extracts were taken to dryness to yield a 10-mg residue, which was used in the TLC analyses.

TLC of the extract on silica gel G plates, when compared with an authentic morphine sample, indicated morphine to be present in the alkaloid extract in addition to several other alkaloids.

Chromatography of the alkaloid extract over a small column (disposable pipet) containing 1.5 g of silica gel PF_{254}, using chloroform–methanol–ammonium hydroxide (90:10:1) as the eluent, resulted in the isolation of a compound (2 mg) whose R_f on silica gel PF_{254} plates, using the same solvent system, was 0.71.

The mass spectrum of the compound indicated a molecular ion M^+ at *m/e* 285 nm, and the fragmentation pattern was consistent with that reported for morphine (1).

To confirm this identification, additional capsules and foliage (8.38 g) were processed for alkaloids as already described. We wanted to determine if a larger quantity of the compound, tentatively identified as morphine, could be isolated and more definitively identified. TLC analysis of the resulting alkaloid extract indicated the same pattern as was observed for the alkaloid extract prepared from the latex.

Column chromatography of this extract, using 10 g of silica gel PF_{254}, resulted in the isolation of 7.6 mg of the compound. The UV spectrum of the sample (in ethanol) showed a maximum absorption at 284 nm,

[1] The plants were identified as *Papaver somniferum* L. (Papaveraceae) by F. A. Crane, and herbarium specimens (I-9786–I-9790) were deposited at the Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612

which was consistent for the morphine chromophore (2).

The remaining 6.6 mg of the compound was converted to the sulfate salt by dissolving the sample in ether and adding ether saturated with sulfuric acid. A white crystalline material (2.0 mg) was obtained and dried. Its IR spectrum (potassium bromide) was superimposable with that of an authentic morphine sulfate sample.

These data served to confirm the presence of morphine in poppy plants grown from seeds obtained at a local supermarket.

Thermodynamics of Gaseous Anesthesia of Mice

Keyphrases □ Anesthesia—gaseous, thermodynamics of equilibrium process, evaluation of Ferguson principle, mice □ Thermodynamics—gaseous anesthesia, evaluation of Ferguson principle, mice □ Ferguson principle—applicability to thermodynamics of gaseous anesthetics

To the Editor:

Evidence was presented recently indicating that the gaseous anesthesia of mice is largely a gas–biophase equilibrium process (1). This evidence consists principally of the observations that gaseous anesthetic potencies can be correlated against gas–oil distribution coefficients (1) but not against oil–water or 1-octanol–water partition coefficients (2). Since gaseous anesthesia has the characteristics of an equilibrium process, it is appropriate to establish the apparent thermodynamic variables pertaining to the anesthetic process in mice. This report presents such an attempt. The results indicate that the Ferguson principle (3), as presently formulated, is in error. A revised expression of the Ferguson principle is a direct outcome of this study.

The Clausius–Clapeyron equation for the distribution of a gas with a condensed phase is given by:

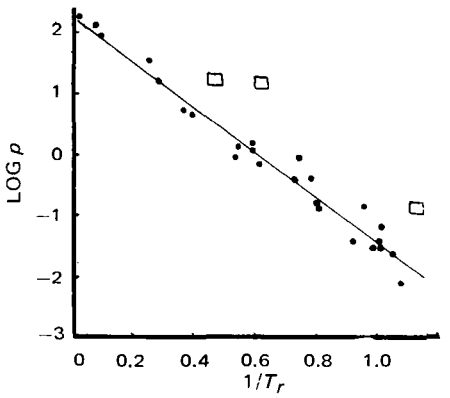

Figure 1—*Graph of anesthetic pressure against the reciprocal of the physiological reduced temperature. Compounds not following the relationship (fluoromethane, perfluoromethane, and perfluoroethane) are identified by the symbol* □.

$$\left(\frac{\partial \ln a_2}{\partial T}\right)_p = \left(\frac{\partial \ln p}{\partial T}\right)_p = \frac{\Delta H_v}{RT^2} = \frac{\Delta S_v}{RT} \qquad \text{(Eq. 1)}$$

where p is the partial pressure of the gas (presumed ideal) at an absolute temperature, T, and pressure, P, and a_2 is the thermodynamic activity of the gas solubilized in the condensed phase.

Equation 1 is appropriate for the determination of the apparent enthalpy and entropy of vaporization, ΔH_v and ΔS_v, at each temperature T from the slopes of graphs of log p against $1/T$ or log T, respectively. However, if the distribution of a number of gases with a condensed phase is of interest, one must either determine the partial pressure variation with temperature for each gas or, following the Principle of Corresponding States, approach the problem in terms of reduced thermodynamic variables so that the same equation of state will apply to each gas.

The reduced thermodynamic variables, P_r, V_r, and T_r, for a substance are obtained by dividing the critical values, P_c, V_c, and T_c, for the substance into the corresponding thermodynamic variables, P, V, and T. Critical values define the point where a gas can no longer be condensed into a liquid phase. When con-

Thermodynamics of Gaseous Anesthesia of Mice

Keyphrases □ Anesthesia—gaseous, thermodynamics of equilibrium process, evaluation of Ferguson principle, mice □ Thermodynamics—gaseous anesthesia, evaluation of Ferguson principle, mice □ Ferguson principle—applicability to thermodynamics of gaseous anesthetics

To the Editor:

Evidence was presented recently indicating that the gaseous anesthesia of mice is largely a gas–biophase equilibrium process (1). This evidence consists principally of the observations that gaseous anesthetic potencies can be correlated against gas–oil distribution coefficients (1) but not against oil–water or 1-octanol–water partition coefficients (2). Since gaseous anesthesia has the characteristics of an equilibrium process, it is appropriate to establish the apparent thermodynamic variables pertaining to the anesthetic process in mice. This report presents such an attempt. The results indicate that the Ferguson principle (3), as presently formulated, is in error. A revised expression of the Ferguson principle is a direct outcome of this study.

The Clausius–Clapeyron equation for the distribution of a gas with a condensed phase is given by:

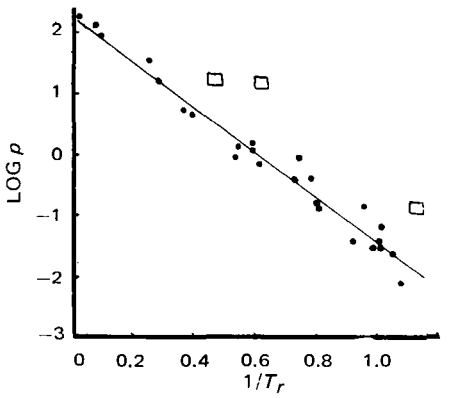

Figure 1—*Graph of anesthetic pressure against the reciprocal of the physiological reduced temperature. Compounds not following the relationship (fluoromethane, perfluoromethane, and perfluoroethane) are identified by the symbol* □.

$$\left(\frac{\partial \ln a_2}{\partial T}\right)_p = \left(\frac{\partial \ln p}{\partial T}\right)_p = \frac{\Delta H_v}{RT^2} = \frac{\Delta S_v}{RT} \qquad \text{(Eq. 1)}$$

where p is the partial pressure of the gas (presumed ideal) at an absolute temperature, T, and pressure, P, and a_2 is the thermodynamic activity of the gas solubilized in the condensed phase.

Equation 1 is appropriate for the determination of the apparent enthalpy and entropy of vaporization, ΔH_v and ΔS_v, at each temperature T from the slopes of graphs of log p against $1/T$ or log T, respectively. However, if the distribution of a number of gases with a condensed phase is of interest, one must either determine the partial pressure variation with temperature for each gas or, following the Principle of Corresponding States, approach the problem in terms of reduced thermodynamic variables so that the same equation of state will apply to each gas.

The reduced thermodynamic variables, P_r, V_r, and T_r, for a substance are obtained by dividing the critical values, P_c, V_c, and T_c, for the substance into the corresponding thermodynamic variables, P, V, and T. Critical values define the point where a gas can no longer be condensed into a liquid phase. When con-

[a] From Refs. 1 and 5. [b] Boiling points at 1 atm. (from "Handbook of Chemistry and Physics," R. C. Weast and S. M. Selby, Eds., Chemical Rubber Co., Cleveland, Ohio, 1967, pp. D113–D137).

sidering gases at 1 atm, the critical temperature, T_c, can be replaced by the boiling point, T_{BP}, in determining reduced temperature, since the temperatures of substances at their boiling points are within 0.66 of their critical temperatures, provided hydrogen bonding or other association effects do not occur in the gaseous or condensed phases (4).

Gases at the physiological temperature of mice, 37° (310°K) (5), differ in relation to their physiological reduced temperature, as obtained from the relation $T_r = 310/T_{BP}$. Table I shows the physiological reduced temperatures for the gaseous anesthetics studied by Miller *et al.* (1, 6). The Clausius–Clapeyron relation (Eq. 1), expressed in terms of physiological reduced temperature, may thus be used to compare the partial pressures of gases for the anesthesia of mice. The criterion of anesthesia is the loss of the righting reflex.

Figures 1 and 2 show the partial anesthetic pressures of gases toward mice plotted according to the two alternative integrated forms of the Clausius–Clapeyron equation. In each graph the fluorinated hydrocarbon, fluoromethane, and the perfluoro compounds, perfluoromethane and perfluoroethane, depart from the general linear trend, perhaps because of the unique solubility properties of fluorinated hydrocarbons. The complimentariness expected on the basis of Eq. 1 between Figs. 1 and 2 is generally real-

Table II—Estimation of the Thermodynamic Activities for Some Gaseous Anesthetics

Gas	Boiling Point, T_{BP}[a]	Enthalpy of Vaporization, ΔH_v[a]	Partial Pressure Pure Liquid, log p^0	Anesthetic Partial Pressure, log p	Thermodynamic Activity, log (p/p^0)

[a] From J. H. Hildebrand and R. L. Scott, "The Solubility of Nonelectrolytes," Dover, New York, N.Y., 1964, pp. 435–439.

ized, except in Fig. 2 where the points for helium, hydrogen, and neon are far from the line. Since these compounds have boiling points close to 0°K, aberrant behavior with respect to other compounds is to be expected in a graph involving log T.

Least-squares regression of the points contained in Figs. 1 (omitting those for the deviant fluorocarbons) and 2 (omitting those for the deviant fluorocarbons, helium, hydrogen, and neon) provides the slopes from which, respectively, apparent enthalpies and entropies of vaporization can be estimated. The derived relationships are expressed by:

$$\Delta H_v = 16.81(\pm 0.32)T_r^2 \quad \text{(Eq. 2)}$$

$$\Delta S_v = 22.31(\pm 1.56)T_r \quad \text{(Eq. 3)}$$

In principle, at a reduced temperature of 1, the constants appearing in Eqs. 2 and 3 should be identical. The fact that they are not, but are nearly so, may be attributed to the use of a biological end-point, the loss of the righting reflex, in making partial pressure assignments for the anesthetic gases. Nevertheless, given the uncertainties in the partial pressure values, the agreement found is remarkable.

Inspection of Table I shows that the reduced temperatures for many important gaseous anesthetics are generally not far from 1, *e.g.*, chloroform, $T_r = 0.93$; ether, $T_r = 1.01$; and cyclopropane, $T_r = 1.29$. The apparent entropy of vaporization of these substances from the biophase responsible for anesthesia in the mouse is thus on the order of 20 cal/mole-°K. This finding may be contrasted with the Trouton's rule value of 21 cal/mole-°K for the entropy of vaporization of nonassociating substances. These anesthetics thus appear to be dissolving in a nonpolar phase; and since the process is universal to the gaseous anesthetics under consideration, the same nonpolar biophase must be involved for them all. No special character to anesthesia is imparted by having electronegative atoms on carbon-bearing hydrogen atoms, as was conjectured recently (2).

A particularly important conclusion can be drawn from the finding of a nonzero slope to the lines shown in Figs. 1 and 2, since this finding designates that the Ferguson principle must be restated. The Ferguson principle as presently accepted states that, under equilibrium or near equilibrium conditions, compounds must accumulate to a certain level in an organism or tissue to elicit an equivalent biological response and that this level of accumulation is directly measured by the thermodynamic activities of the compounds in the phase external to the organism or tissue.

This statement signifies that all gaseous anesthetics would have the same thermodynamic activities at the biological end-point measured as the loss of the righting reflex of mice. If this was indeed true, then the slope of the data presented in Figs. 1 and 2 would have to be zero according to Eq. 1. That is, ΔH_v and ΔS_v would be zero, signifying that gaseous anesthetics behave as if they form an ideal solution with the biophase of mice. The nonzero slope to the line in Figs. 1 and 2 shows that the "solution" formed by gaseous anesthetics in a biophase is not ideal. Hence, *the presently accepted statement of the Ferguson principle applies only if the properties of drugs in a biophase are similar to those of an ideal solution.*

The nonideal behavior of the biosolubilization of gaseous anesthetics provides a basis for understanding the origins of linear free energy relationships in relation to anesthesia. Were the properties of drugs in a biophase to be in accord with the Ferguson principle, no linear free energy relationships could exist, since there would be no variation in enthalpy or entropy. However, the Ferguson principle, as revised to apply to the ideal case, is invalid for gaseous anesthesia. Hence, there are variations in enthalpy and entropy that can be related to corresponding variations in model systems.

In further support of the conclusion that the Ferguson principle is invalid for gaseous anesthesia, the thermodynamic activities for some gaseous anesthetics were determined. The relationship given by Eq. 4 was used, where the vapor pressure of the pure liquid, p^0, was determined using Eq. 5, as suggested by Hildebrand and Scott (7):

$$\log (p/p^0) = \log a_2 \quad \text{(Eq. 4)}$$

$$\log p^0 = \frac{\Delta H_v}{2.3R}\left(\frac{T - T_{BP}}{TT_{BP}}\right) \quad \text{(Eq. 5)}$$

Table II shows the results of these determinations. Log p^0 at the physiological temperature of 37° (310 °K) was relatively constant and of much greater magnitude than the partial pressures of anesthesia given by log p. The calculated thermodynamic activities were found to be roughly constant, due principally to the relatively constant value of log p^0, the anesthetic potencies being small in comparison. There is thus gained the illusion that anesthetics in a biophase behave ideally, since for ideal solutions $a_2 = 1/p_2^0$ when the vapor pressure is measured at 1 atm. Therefore, the Ferguson principle has been founded on an observation that by its very nature excludes the variation in anesthetic partial pressure.

The thermodynamic description of the gaseous anesthesia of mice resulting from this study has led to a restatement of the Ferguson principle. All of the observations made by directly applying thermodynamic principles to the anesthetic potencies are in full accord with the gas–oil distribution studies conducted by Miller *et al.* (1). The distinction here is that thermodynamics have been applied solely to the biological observations rather than in relating the biological observations to the behavior of a model system.

Relationship between Quinidine Plasma and Saliva Levels in Humans

Keyphrases □ Quinidine—plasma and saliva concentrations compared, humans □ Saliva—determination of quinidine levels, correlated with plasma levels

To the Editor:

Increasing applications of the principles of pharmacokinetics to clinical situations (1) have emphasized the need for rapid, noninvasive techniques for monitoring drug concentrations in biological fluids, especially with pediatric patients or whenever a large number of serial samples is indicated. Since several drugs such as salicylate (2), sulfonamides (3), barbiturates (4), tetracyclines (5), phenytoin (6), theophylline (7), and digoxin (8) are secreted in saliva, this measurement appears to have potential use, especially when these levels can be correlated with plasma levels in patients.

There are no previous reports concerning salivary concentrations of quinidine. However, blood level monitoring of quinidine is occasionally useful clinically, since the drug exhibits an extremely narrow range between a usually effective serum level (2 μg/ml) and a usually toxic serum level (8 μg/ml) (9).

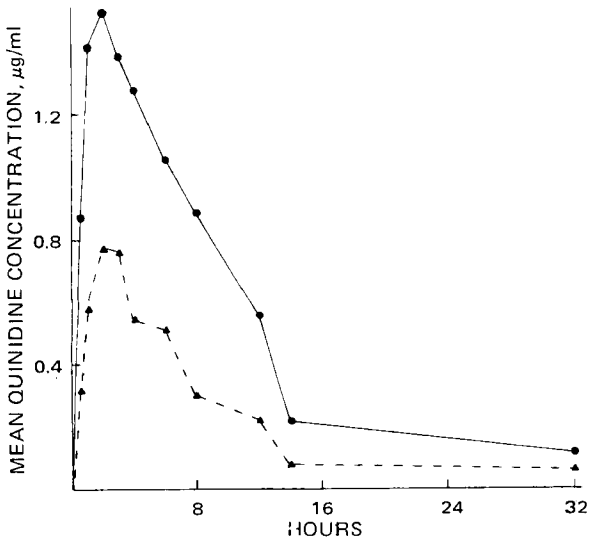

Figure 1—*Mean plasma and saliva concentrations as a function of time for Subject 1. Each concentration is the mean of two determinations. Key: ●, plasma concentrations; and ▲, saliva concentrations.*

Table I—Relationship between Plasma and Saliva Concentrations of Quinidine in Three Subjects

Subject	Mean Plasma–Saliva Ratio (±*SD*)	Correlation Coefficient	Statistical Significance
1	2.29 (±0.89)[a]	0.885	$p < 0.001$
2	1.55 (±0.70)[a]	0.681	$p < 0.01$
3	2.35 (±0.70)[b]	0.825	$p < 0.001$

[a] Eighteen determinations. [b] Nineteen determinations.

Thus, a technique that would obviate the need for collecting serial blood samples would be of value.

The data reported here on saliva levels of quinidine were obtained in conjunction with a larger study on the bioequivalency of various commercially available quinidine sulfate tablets in humans. The specific value of this study relates best to the possible use of saliva in bioavailability studies rather than for clinical monitoring.

Three adult, normal, male subjects involved in the bioequivalence study were selected randomly and, in addition to providing blood samples (by venipuncture), were requested to expectorate into 10-ml test tubes from approximately 5 min before until 5 min after each blood collection or until 3–5 ml of mixed saliva had been obtained. Blood and saliva quinidine levels were determined at 0.5, 1, 2, 3, 4, 6, 8, 12, 24, and 32 hr after administration of two 200-mg tablets of any one of four brands of quinidine sulfate. These same subjects repeated this procedure a second time with at least a 1-week interval between administrations. The values reported in Table I for each subject were pooled from the two different runs and involve 18 or 19 determinations/subject since saliva levels were not always sufficiently high to be determined at the 24- and 32-hr time periods.

Aliquots (0.5 ml) of plasma or saliva (centrifuged to remove sputum) at each time period were assayed by the fluorometric method of Cramer and Isaksson (10) with only slight modifications. Blank specimens of serum and saliva were assayed in the same manner as the samples, and the appropriate blank corrections were applied. Figure 1 shows a plot of plasma and saliva quinidine concentrations as a function of time for one of the three subjects (Subject 1 of Table I).

Although a significant correlation exists between plasma and saliva levels of quinidine, differences in the extent of correlation are evident among the three subjects (Table I). While a number of studies (2, 6) showed an even better correlation between plasma and saliva levels of other drugs, the present study nonetheless suggests that quinidine can be detected in human saliva in measurable concentrations and that these concentrations are related to their corresponding plasma levels. The pH of the saliva samples was not measured, although fluctuations in saliva pH could possibly account for the observed intrasubject variability in plasma saliva ratios for the weak base quinidine (11).

Plasma samples in this study consisted of both bound and unbound drug, and better correlations might have resulted if unbound quinidine in plasma

Relationship between Quinidine Plasma and Saliva Levels in Humans

Keyphrases □ Quinidine—plasma and saliva concentrations compared, humans □ Saliva—determination of quinidine levels, correlated with plasma levels

To the Editor:

Increasing applications of the principles of pharmacokinetics to clinical situations (1) have emphasized the need for rapid, noninvasive techniques for monitoring drug concentrations in biological fluids, especially with pediatric patients or whenever a large number of serial samples is indicated. Since several drugs such as salicylate (2), sulfonamides (3), barbiturates (4), tetracyclines (5), phenytoin (6), theophylline (7), and digoxin (8) are secreted in saliva, this measurement appears to have potential use, especially when these levels can be correlated with plasma levels in patients.

There are no previous reports concerning salivary concentrations of quinidine. However, blood level monitoring of quinidine is occasionally useful clinically, since the drug exhibits an extremely narrow range between a usually effective serum level (2 μg/ml) and a usually toxic serum level (8 μg/ml) (9).

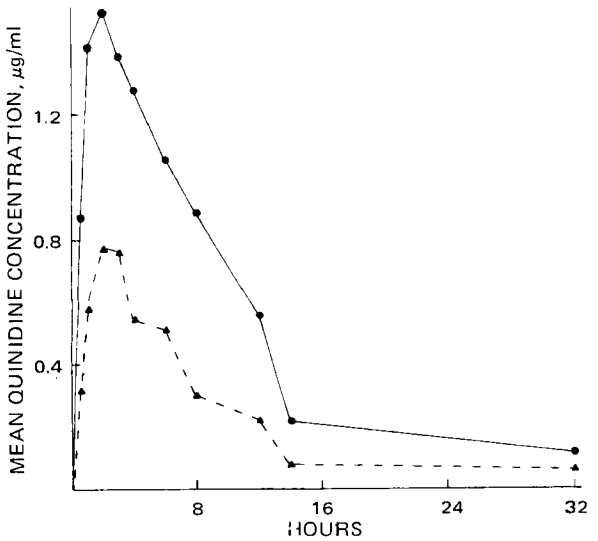

Figure 1—*Mean plasma and saliva concentrations as a function of time for Subject 1. Each concentration is the mean of two determinations. Key: ●, plasma concentrations; and ▲, saliva concentrations.*

Table I—Relationship between Plasma and Saliva Concentrations of Quinidine in Three Subjects

Subject	Mean Plasma–Saliva Ratio (±*SD*)	Correlation Coefficient	Statistical Significance
1	2.29 (±0.89)[a]	0.885	$p < 0.001$
2	1.55 (±0.70)[a]	0.681	$p < 0.01$
3	2.35 (±0.70)[b]	0.825	$p < 0.001$

[a] Eighteen determinations. [b] Nineteen determinations.

Thus, a technique that would obviate the need for collecting serial blood samples would be of value.

The data reported here on saliva levels of quinidine were obtained in conjunction with a larger study on the bioequivalency of various commercially available quinidine sulfate tablets in humans. The specific value of this study relates best to the possible use of saliva in bioavailability studies rather than for clinical monitoring.

Three adult, normal, male subjects involved in the bioequivalence study were selected randomly and, in addition to providing blood samples (by venipuncture), were requested to expectorate into 10-ml test tubes from approximately 5 min before until 5 min after each blood collection or until 3–5 ml of mixed saliva had been obtained. Blood and saliva quinidine levels were determined at 0.5, 1, 2, 3, 4, 6, 8, 12, 24, and 32 hr after administration of two 200-mg tablets of any one of four brands of quinidine sulfate. These same subjects repeated this procedure a second time with at least a 1-week interval between administrations. The values reported in Table I for each subject were pooled from the two different runs and involve 18 or 19 determinations/subject since saliva levels were not always sufficiently high to be determined at the 24- and 32-hr time periods.

Aliquots (0.5 ml) of plasma or saliva (centrifuged to remove sputum) at each time period were assayed by the fluorometric method of Cramer and Isaksson (10) with only slight modifications. Blank specimens of serum and saliva were assayed in the same manner as the samples, and the appropriate blank corrections were applied. Figure 1 shows a plot of plasma and saliva quinidine concentrations as a function of time for one of the three subjects (Subject 1 of Table I).

Although a significant correlation exists between plasma and saliva levels of quinidine, differences in the extent of correlation are evident among the three subjects (Table I). While a number of studies (2, 6) showed an even better correlation between plasma and saliva levels of other drugs, the present study nonetheless suggests that quinidine can be detected in human saliva in measurable concentrations and that these concentrations are related to their corresponding plasma levels. The pH of the saliva samples was not measured, although fluctuations in saliva pH could possibly account for the observed intrasubject variability in plasma saliva ratios for the weak base quinidine (11).

Plasma samples in this study consisted of both bound and unbound drug, and better correlations might have resulted if unbound quinidine in plasma

had been determined since often only the free and nonionized drug establishes an equilibrium between blood and saliva concentrations (3, 4). For example, Killman and Thaysen (3) found that unbound sulfonamides in human saliva were proportional to the concentration of unbound drug in the plasma. Similar findings were reported for phenytoin (6). Thus, we are presently developing methods to study unbound quinidine in plasma so that these values can then be compared to saliva levels to determine if even better plasma–saliva level correlation exists for this drug.

Dissolution of Model Gallstones in Bile Acid Solutions I: Implications for T-Tube Infusion Treatment of Retained Common Duct Stones with the Cholate System

Keyphrases □ Dissolution—gallstones, *in vitro*, T-tube infusion treatment with sodium cholate □ Gallstones—*in vitro* dissolution, T-tube infusion treatment with sodium cholate □ Sodium cholate—infusate for *in vitro* dissolution of gallstones by T-tube infusion

To the Editor:

The problem of retained common bile duct stones affects about 5% of the patients undergoing cholecystectomies (1–3). Considerable effort has been directed by clinicians[1] (2–6) to find a nonsurgical solution to the problem which will save the patient a high risk operation.

One study (2) showed that retained common bile duct stones can be dissolved using a T-tube infusion; sodium cholate solution was used as the infusate. The investigators were able to dissolve retained stones in 12 of 22 patients within 14 days of continuous infusion at a rate of 30 ml/hr. With the same technique and a similar formula, retained stones were dissolved in five of six patients within 5 days (3).

However, recent controlled T-tube infusion studies were less successful[1]. Only two of six patients showed dissolution of the retained stones. This difference in results between the studies was not expected since there was only a 25% difference in the cholate concentration levels between the formulations tested.

This communication presents a probable physical–chemical explanation for the differences observed. This explanation is based upon the surface resistance to the cholesterol dissolution in bile acid media and the influence of electrolytes upon it.

Compressed cholesterol monohydrate pellets were used as model cholesterol stones. Infusion media were prepared according to Way *et al.* (2) and La-Russo *et al.*[1], using a purified grade of cholic acid[2]. The pH of the media was adjusted to pH 7.5 with sodium hydroxide.

Dissolution experiments were conducted using the apparatus and procedures reported previously (7). Equilibrium solubilities were measured after allowing excess amounts of ^{14}C-cholesterol monohydrate to equilibrate with the infusion media with continuous shaking at 37°.

Dissolution rates and solubility values are shown in Table I. The resistance to dissolution, R, was calculated from the equation:

$$\frac{J}{A} = \frac{C_s}{R} \qquad \text{(Eq. 1)}$$

where J/A is the dissolution rate per unit surface area, and C_s is the solubility.

The data show that the rate of cholesterol dissolution in the Way *et al.* (2) and Lansford *et al.* (3) infusion medium is about nine times faster than that in the La Russo *et al.*[1] medium. This large difference in the rate of dissolution cannot be explained on the basis of a diffusion-controlled mass transport mechanism, because the solubility increases by only about a factor of two (Table I) and the diffusivities are not expected to vary significantly.

These results, therefore, point to the likely importance of surface kinetic factors in the dissolution process. A significant interfacial resistance has been shown (7–11) to govern the rate of cholesterol monohydrate and cholesterol gallstone dissolution in bile media generally, and it is proposed that interfacial resistance is the primary factor responsible for the difference in cholesterol dissolution and, hence, the

had been determined since often only the free and nonionized drug establishes an equilibrium between blood and saliva concentrations (3, 4). For example, Killman and Thaysen (3) found that unbound sulfonamides in human saliva were proportional to the concentration of unbound drug in the plasma. Similar findings were reported for phenytoin (6). Thus, we are presently developing methods to study unbound quinidine in plasma so that these values can then be compared to saliva levels to determine if even better plasma–saliva level correlation exists for this drug.

T-tube infusion efficacy between the two solutions.

Previous investigations in our laboratories (11–13) showed that the interfacial barrier to cholesterol transport in bile acid systems may be highly sensitive to electrolytes. It is proposed, therefore, that the difference in the electrolyte levels of the two formulations is primarily responsible for the efficacy difference in retained stones dissolution.

Additional data supporting this interpretation can be seen in Table I. For example, in 75 m*M* sodium cholate, the cholesterol dissolution rate increased fourfold when 77 m*M* sodium chloride was added and an additional threefold when the sodium chloride concentration was doubled.

The results of this study should open the door for a much broader systematic investigation of the formulation–activity relationships of solutions for T-tube infusion in patients with retained common duct stones.

Vehicle for Stabilizing Aluminum Hydroxide Gel

Keyphrases □ Aluminum hydroxide gel—vehicles for stabilization □ Stability—aluminum hydroxide gel, vehicles investigated □ Antacids—vehicles for stabilizing aluminum hydroxide gel

To the Editor:

A recent research article (1) demonstrated that aluminum hydroxide gel loses acid reactivity depending on the vehicle used for dilution and the degree of dilution. A significant loss of acid reactivity occurred when the gel was diluted with double-distilled water. Dilution with dioxane or mother liquor had no effect on reactivity. It was suggested that a carefully designed diluting solution could minimize the loss of acid reactivity normally observed and result in a dosage form with increased efficacy and a longer shelf-life. We now wish to demonstrate the stabilizing effect of a vehicle suitable for use in aluminum hydroxide gel dosage forms.

An aluminum hydroxide gel was prepared as previously described (1) by the reaction of aluminum chloride, sodium bicarbonate, and sodium carbonate at pH 6.5. The gel was divided into four portions and diluted to 3.3% Al_2O_3. One portion was diluted with a saturated aqueous solution of potassium chloride (equivalent to 72 mEq/15 ml). The second portion was diluted with propylene glycol. The third portion was diluted with distilled water saturated with carbon dioxide, and the fourth portion was diluted with double-distilled water to serve as the control.

The acid reactivity was monitored by an automated[1] pH-stat technique similar to the method described by Steinberg *et al.* (2). An appropriate volume of water was added to the reaction vessel and brought to pH 3.0. A volume of sample containing 38 mg of aluminum oxide was then added. The volume of water was adjusted for each sample to produce a reaction volume of 22 ml. The instrument was set to maintain pH 3.0 by adding 1.0 *N* HCl from the autoburet. The instrument was activated simultaneously with the sample injection. The recorder plotted milliliters of 1.0 *N* HCl added *versus* time. The acid reactivity of each sample is expressed as T_{50}: the time re-

Vehicle for Stabilizing Aluminum Hydroxide Gel

Keyphrases □ Aluminum hydroxide gel—vehicles for stabilization □ Stability—aluminum hydroxide gel, vehicles investigated □ Antacids—vehicles for stabilizing aluminum hydroxide gel

To the Editor:

A recent research article (1) demonstrated that aluminum hydroxide gel loses acid reactivity depending on the vehicle used for dilution and the degree of dilution. A significant loss of acid reactivity occurred when the gel was diluted with double-distilled water. Dilution with dioxane or mother liquor had no effect on reactivity. It was suggested that a carefully designed diluting solution could minimize the loss of acid reactivity normally observed and result in a dosage form with increased efficacy and a longer shelf-life. We now wish to demonstrate the stabilizing effect of a vehicle suitable for use in aluminum hydroxide gel dosage forms.

An aluminum hydroxide gel was prepared as previously described (1) by the reaction of aluminum chloride, sodium bicarbonate, and sodium carbonate at pH 6.5. The gel was divided into four portions and diluted to 3.3% Al_2O_3. One portion was diluted with a saturated aqueous solution of potassium chloride (equivalent to 72 mEq/15 ml). The second portion was diluted with propylene glycol. The third portion was diluted with distilled water saturated with carbon dioxide, and the fourth portion was diluted with double-distilled water to serve as the control.

The acid reactivity was monitored by an automated[1] pH-stat technique similar to the method described by Steinberg *et al.* (2). An appropriate volume of water was added to the reaction vessel and brought to pH 3.0. A volume of sample containing 38 mg of aluminum oxide was then added. The volume of water was adjusted for each sample to produce a reaction volume of 22 ml. The instrument was set to maintain pH 3.0 by adding 1.0 *N* HCl from the autoburet. The instrument was activated simultaneously with the sample injection. The recorder plotted milliliters of 1.0 *N* HCl added *versus* time. The acid reactivity of each sample is expressed as T_{50}: the time re-

[1] PHM 26; TTT 11; ABU 12, 2.5 ml; TTA 3; SBR 2; Radiometer, Copenhagen, Denmark.

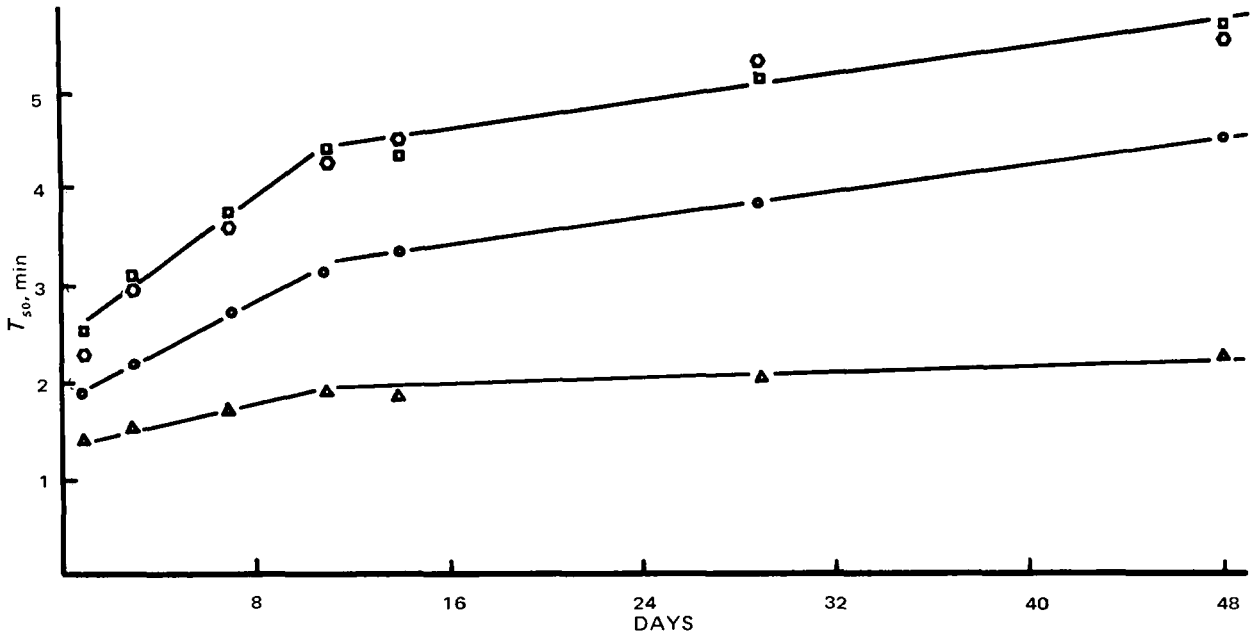

Figure 1—*Effect of diluting vehicle on acid reactivity of aluminum hydroxide gel aged at 25°. Gels were diluted to 3.3% Al_2O_3 with: □, distilled water; ○, carbon dioxide-saturated distilled water; ○, propylene glycol; and △, saturated aqueous solution of potassium chloride.*

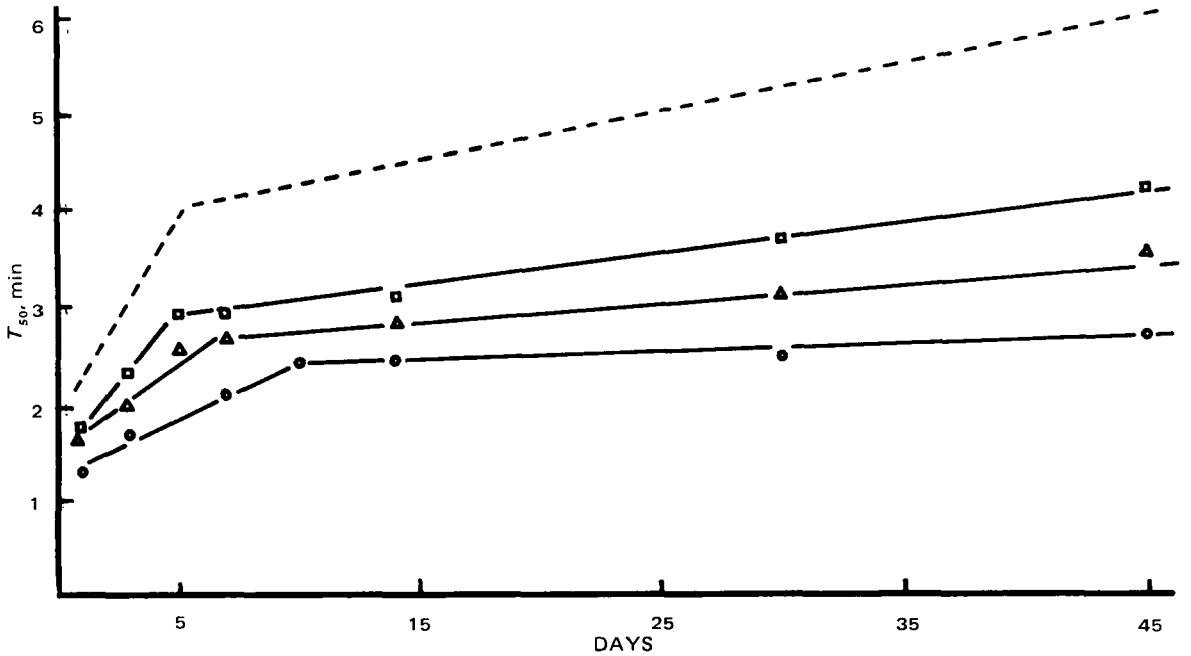

Figure 2—*Stabilization of aluminum hydroxide gel by dilution with potassium chloride solutions. Gels were aged at 25° and diluted to 3.6% Al_2O_3 with: ○, 40 mEq of potassium chloride/15 ml; △, 20 mEq of potassium chloride/15 ml; □, 10 mEq of potassium chloride/15 ml; and - - -, distilled water.*

quired to add 50% of the total 1.0 *N* HCl needed to neutralize the aluminum hydroxide gel at 25°.

As seen in Fig. 1, the acid reactivity of the gel diluted with saturated potassium chloride was virtually unchanged. The sample diluted with propylene glycol was more stable than the portions diluted with distilled water or carbon dioxide-saturated water.

Lower levels of potassium chloride also significantly improve the stability of aluminum hydroxide gel. A second aluminum hydroxide gel was prepared as before, divided into three portions, and diluted to 3.6% Al_2O_3 with solutions equivalent to 40, 20, and 10 mEq of potassium chloride/15 ml. The stabilization by the potassium chloride solution was directly related to the potassium chloride concentration of the diluting solution (Fig. 2).

The samples continue to be monitored, and at 120 days the correlation coefficient for the linear portion commencing at 7 days was 0.999, 0.998, and 0.987 for the gels diluted with 10, 20, and 40 mEq of potassium chloride/15 ml, respectively. The 10-mEq/15-ml dilution resulted in a 30% improvement in T_{50} after 120

days at 25° compared to dilution with distilled water.

The 10 mEq of potassium chloride/15-ml dilution does not have an objectionable taste and could be suitably flavored to produce an acceptable pharmaceutical product. The OTC Antacid Review Panel report (3) stated that potassium presents no problem to normal persons, but that products containing 25 mEq or more of potassium per maximum daily dose must include a warning to patients with kidney disease. Thus, a vehicle designed to maintain the stabilizing ions in the aluminum hydroxide gel appears to be a feasible approach to improving the stability of aluminum hydroxide gel.

BOOKS

REVIEWS

Alicyclic Chemistry, Volume 2—A Review of the Literature Published during 1972. Senior Reporter, W. PARKER. The Chemical Society, Burlington House, London WIV OBN, England, 1974. 470 pp. 14 × 22 cm. Price $35.

This book is part of a series of 32 Specialist Periodical Reports designed, according to the Chemical Society, to give an in-depth coverage of the whole field of chemistry. Ultimately some 40 titles are contemplated. The first volume was published in three reports covering aliphatic, alicyclic, and saturated heterocyclic chemistry from January 1970 to December 1971. Other reports of interest to medicinal chemists are: Aliphatic Chemistry, Saturated Heterocyclic Chemistry, Aromatic and Heteroaromatic Chemistry, Organic Compounds of Sulfur, Selenium and Tellurium (all Volume 2), and Organophosphorous Chemistry, already up to Volume 5.

The present volume consists of four chapters. Chapter 1 covers three- and four-membered rings. The first 10 pages are devoted to theoretical and structural considerations including X-ray studies, MO calculations, and energetics. The remainder of the chapter is divided into syntheses and reactions of three- and four-membered carbocyclic compounds. The coverage is thorough. The reactions considered include those with electrophiles, nucleophiles, thermal reactions, cycloadditions, rearrangements, eliminations, functional group modifications, and radicals. Chapter 2 views five- and six-membered rings in light of structural and conformational considerations, followed by an in-depth overview of their reactivities. A 10-page section also considers fused rings. Thus, the reactions of decalyl tosylates and amines are described in terms of acetolyses, deaminations leading to twist conformers, and ring contractions. Bicyclo[4.3.0]nonane and bicyclo[4.2.0]octane systems are also discussed.

Chapter 3 is devoted to medium and large ring compounds. It has 16 sections. Energies and conformations of seven- to 10-membered rings are covered, followed by synthetic routes to such systems. Intramolecular photochemical electrocyclic and cycloaddition reactions, as well as intermolecular photochemical reactions, are surveyed. Transannular reactions, ring contractions, and ring-opening reactions are briefly covered. Finally there is a section on general reactions, *e.g.*, of cycloalkenes, cyclic ketones, amines, alcohols, and esters. Organometallic derivatives complete the chapter.

The final chapter is titled Bridge Carbocyclics. A lengthy introductory section discusses physical methods and energy calculations. This is followed by a section on bicyclic and polycyclic structures. Of particular interest to medicinal chemists are some references to bornane chemistry and extensive coverage (11 pages) of adamantanes. Extensions of known methods of syntheses for this carbon skeleton are reported. The chapter further details cycloadditions, photo- and organometallic chemistry, and solvolytic reactions. Finally, several miscellaneous reactions, including a new stereospecific reducing agent (lithium tris-s-butyl borohydride) and an enzymatic reduction (horse liver dehydrogenase and NADH), are referred to. An author index is included.

The book is profusely endowed with structural formulas; the reader need not fumble with vast quantitites of IUC nomenclature. Its value to the medicinal chemist would be mainly as an adjunct reference source for new developments in those alicyclic ring systems of potential biological interest either as pharmacophores (adamantanes) or as useful carriers for such groups.

REVIEWS

Alicyclic Chemistry, Volume 2—A Review of the Literature Published during 1972. Senior Reporter, W. PARKER. The Chemical Society, Burlington House, London WIV OBN, England, 1974. 470 pp. 14 × 22 cm. Price $35.

This book is part of a series of 32 Specialist Periodical Reports designed, according to the Chemical Society, to give an in-depth coverage of the whole field of chemistry. Ultimately some 40 titles are contemplated. The first volume was published in three reports covering aliphatic, alicyclic, and saturated heterocyclic chemistry from January 1970 to December 1971. Other reports of interest to medicinal chemists are: Aliphatic Chemistry, Saturated Heterocyclic Chemistry, Aromatic and Heteroaromatic Chemistry, Organic Compounds of Sulfur, Selenium and Tellurium (all Volume 2), and Organophosphorous Chemistry, already up to Volume 5.

The present volume consists of four chapters. Chapter 1 covers three- and four-membered rings. The first 10 pages are devoted to theoretical and structural considerations including X-ray studies, MO calculations, and energetics. The remainder of the chapter is divided into syntheses and reactions of three- and four-membered carbocyclic compounds. The coverage is thorough. The reactions considered include those with electrophiles, nucleophiles, thermal reactions, cycloadditions, rearrangements, eliminations, functional group modifications, and radicals. Chapter 2 views five- and six-membered rings in light of structural and conformational considerations, followed by an in-depth overview of their reactivities. A 10-page section also considers fused rings. Thus, the reactions of decalyl tosylates and amines are described in terms of acetolyses, deaminations leading to twist conformers, and ring contractions. Bicyclo[4.3.0]nonane and bicyclo[4.2.0]octane systems are also discussed.

Chapter 3 is devoted to medium and large ring compounds. It has 16 sections. Energies and conformations of seven- to 10-membered rings are covered, followed by synthetic routes to such systems. Intramolecular photochemical electrocyclic and cycloaddition reactions, as well as intermolecular photochemical reactions, are surveyed. Transannular reactions, ring contractions, and ring-opening reactions are briefly covered. Finally there is a section on general reactions, *e.g.*, of cycloalkenes, cyclic ketones, amines, alcohols, and esters. Organometallic derivatives complete the chapter.

The final chapter is titled Bridge Carbocyclics. A lengthy introductory section discusses physical methods and energy calculations. This is followed by a section on bicyclic and polycyclic structures. Of particular interest to medicinal chemists are some references to bornane chemistry and extensive coverage (11 pages) of adamantanes. Extensions of known methods of syntheses for this carbon skeleton are reported. The chapter further details cycloadditions, photo- and organometallic chemistry, and solvolytic reactions. Finally, several miscellaneous reactions, including a new stereospecific reducing agent (lithium tris-s-butyl borohydride) and an enzymatic reduction (horse liver dehydrogenase and NADH), are referred to. An author index is included.

The book is profusely endowed with structural formulas; the reader need not fumble with vast quantitites of IUC nomenclature. Its value to the medicinal chemist would be mainly as an adjunct reference source for new developments in those alicyclic ring systems of potential biological interest either as pharmacophores (adamantanes) or as useful carriers for such groups.

Inorganic Medicinal and Pharmaceutical Chemistry. By J. H. BLOCK, E. B. ROCHE, T. O. SOINE, and C. O. WILSON. Lea & Febiger, Philadelphia, PA 19106, 1974. 472 pp. 15.5 × 24 cm. Price $18.50.

If there has been a criticism of *Roger's Inorganic Pharmaceutical Chemistry*, perhaps this was due chiefly to the fact that the contents of the work were not organized to stress biological activity or medicinal use. If there has been a criticism of inorganic pharmaceutical chemistry, perhaps it has been that the material the discipline treats is somehow supposed to not be of a great deal of therapeutic or clinical importance.

The present book, the successor to *Roger's Inorganic Pharmaceutical Chemistry*, lays to rest the first criticism and gives the lie to the second. This is not to state that general principles of chemistry are dispensed with. On the contrary, I feel that they are thoroughly and succinctly covered, principally in Chapters 1–4. It is simply that, thereafter, in Chapters 5–12, the emphasis is on the role of inorganic agents in biology and medicine, and the fact that inorganic agents have a great deal of biological and therapeutic significance is most entertainingly and effectively brought home.

To go into greater detail, the first three chapters are summaries of general chemical principles together with appropriate pharmaceutical exemplifications. This statement also applies to Chapter 4 although the proportion of "practical" information in this chapter is greater. Thus in Chapter 1, an account of the electronic structure of atoms and molecules is presented. A somewhat more specialized discussion of coordination chemistry together with descriptions of specific pharmaceutically and therapeutically significant chelating agents follows. Chapter 2 is a survey of group properities of elements. Chapter 3 treats solutions and solubility. The first portion of this chapter treats concentration and solubility expressions and their calculation. Thereafter, material mainly dealing with the physical chemistry of the solution process is presented. Chapter 4 first treats concepts of acidity and basicity, expressions of acidity and basicity in water, and buffer theory, together with appropriate practical pharmaceutical exemplification. The second portion of the chapter deals with antioxidants—first theory, then practical applications. The chapter concludes with a treatment of pharmaceutically significant properties of water and of glass.

There is a greater emphasis on the pharmacological and clinical aspects commencing in Chapter 5, Major Intra- and Extracellular Electrolytes, and continuing in Chapter 6, Essential and Trace Ions. (In these two chapters there are excellent biochemical treatments of the inorganic agents as well.) The other chapters are as follows: Chapter 7, Nonessential Ions; Chapter 8, Gastrointestinal Agents; Chapter 9, Topical Agents; Chapter 10, Dental Products; Chapter 11, Radiopharmaceuticals and Contrast Media; and Chapter 12, Miscellaneous Inorganic Pharmaceutical Agents (Inhalants, Antidotes, Emetics, *etc.*).

Overall, in these chapters, I was impressed with the entertaining and still scholarly style. These chapters also impressed with their conciseness, balance, and logical ordering. Notably, I thought the interplay and balance between the biological and chemical portions was very well struck.

I did detect some minor omissions of biochemical functions of trace ions, some biological actions of nonessential ions, some therapeutic uses of topical agents, and certain agents in the miscellaneous group, but I feel that in most of the cases it would be difficult not to make such omissions in condensing material of such breadth into textbook form.

In summary, I found this book to be a well-balanced blend of the theoretical, the practical, the biological, and the therapeutic aspects of inorganic pharmaceutical chemistry. To return to the comments which opened this review and to place the emphasis a little differently, I sincerely believe that this book *per se* is a clear affirmation of the critical importance of inorganic pharmaceutical chemistry and of courses in which inorganic pharmaceutical chemistry is taught, both to modern pharmaceutical education and to modern pharmaceutical practice. I also believe that this book affords a literate, flexible, compact, and extremely valuable textbook for inorganic pharmaceutical chemistry courses.

The Alkaloids. Volume 4. A Specialist Periodical Report. J. E. SAXTON, Senior Reporter. The Chemical Society, Burlington House, London W1V OBN, England, 1974. xxii + 443 pp. 13.5 × 21.5 cm. Price £14 (about $40.00).

This book is divided into 17 chapters containing up-to-date information on various aspects of alkaloid studies. It is well written and is a very comprehensive review of the literature on alkaloids.

Chapter 1 updates existing information on the biosynthesis of various type of alkaloids as well as specific alkaloids. The contents of the book consist of chapters on the phytochemistry of pyrrolidine, piperidine, and pyridine; tropane; pyrrolizidine; indolizidine; quinolizidine; quinoline, quinazoline, acridone, and related alkaloids; β-phenethylamines and the isoquinoline; aporphine, *Amaryllidaceae*, and related compounds; *Erythrina* and related compounds; indole; *Lycopodium*; diterpenoid; steroidal and miscellaneous alkaloids.

Of particular interest to this reviewer is the fact that pharmacological aspects of certain of the classes of alkaloids are discussed as well as the detailed discussions on spectral interpretations as given by M. Shamma and S. S. Salgar in their chapter on the aporphine alkaloids.

For investigators specialized in alkaloid or students of natural products chemistry, this book is a highly recommended item. One disconcerting aspect of the book is the relatively high cost for a book that is obviously produced by the offset printing process.

Isolation and Identification of Drugs (in Pharmaceuticals, Body Fluids and Post-mortem Material), Vol. 2. Edited by E. G. C. CLARKE. The Pharmaceutical Press, 17 Bloomsbury Square W.C.-1A2NN, London, England (U.S. Distributor: Rittenhouse Book Distributors, 253 South 24th St., Philadelphia, Pa.), 1975. xi + 385 pp. 14.8 × 22.6 cm. Price £13.50 (about $35.00).

Clarke's 1969 presentation by the same title was the first large-scale collation of data of greatest interest to toxicologists, biochemists, pharmacists, pathologists, and forensic and pharmaceutical scientists. He drew into monograph form, in a beautifully produced book, data on drug identification and separation methods, properties, metabolism, and toxicology. It rapidly and most deservedly became a standard text.

This new volume carries forward the same format to a wealth of supplementary material. New monographs for about 250 drugs not covered in the 1969 opus are the heart of the volume, with a cumulative index for both. Most of the notable omissions of drug entries, already evident at the time of publication of the first volume, have been corrected. Not all drug substances, not even all official drugs, are included, but such an enormous task is not called for in a work devoted to the restrictions inherent in the book's title.

Previous chapters on drug metabolism, the three chromatographies (PC, TLC, and GLC) used in the monographs, and spectroscopic and color tests have all been updated by the original authors to maintain the generally high quality established before. The chapter on screening tests for common drugs has been recast entirely and greatly enlarged and is a major plus for the new volume.

Clarke's 1969 presentation by the same title was the first large-scale collation of data of greatest interest to toxicologists, biochemists, pharmacists, pathologists, and forensic and pharmaceutical scientists. He drew into monograph form, in a beautifully produced book, data on drug identification and separation methods, properties, metabolism, and toxicology. It rapidly and most deservedly became a standard text.

This new volume carries forward the same format to a wealth of supplementary material. New monographs for about 250 drugs not covered in the 1969 opus are the heart of the volume, with a cumulative index for both. Most of the notable omissions of drug entries, already evident at the time of publication of the first volume, have been corrected. Not all drug substances, not even all official drugs, are included, but such an enormous task is not called for in a work devoted to the restrictions inherent in the book's title.

Previous chapters on drug metabolism, the three chromatographies (PC, TLC, and GLC) used in the monographs, and spectroscopic and color tests have all been updated by the original authors to maintain the generally high quality established before. The chapter on screening tests for common drugs has been recast entirely and greatly enlarged and is a major plus for the new volume.

The updated chapters are generally adequate for the purpose, but strong exception must be taken to the claim that no significant advances in TLC have taken place since the first volume. In seven years? We need consider only the recent instrumentation introduced for both quantitative and multiple-development applications to turn back such an argument. Has familiarity bred contempt?

Two new chapters deal with radioimmunoassays and mass spectrometry. Both techniques have had an explosive growth in clinical applications and the inclusion of those topics is clearly necessary. Neither, however, appear in the drug monographs. Because of the limited number of drugs for which radioimmunoassay is in general use, treatment within the background chapter is preferred, but the lack of further mass spectral data is puzzling. Both new chapters are strongly practical rather than theoretical in presentation and this is desirable for the intended audience.

One notable development in drug analysis has been ignored and that is high-pressure liquid chromatography. Sufficient data are available, and at least a general chapter could have been expected at this time.

In recommending heartily the supplementing of a copy of Clarke 1 with this new Clarke 2, it is however time to take stock of the broader situation. Drug analysis and identification currently have available several important compilations—Macek on TLC, Sunshine's editing of analytical toxicology data, the recent Zweig and Sherma handbooks of chromatography, Stahl's compilations—all of which compile data in other than monograph style, but nevertheless, the data are readily retrievable. Viewed against these more detailed compilations, Clarke's volumes sometime suffer in the competition. The hardest blow is delivered when these monographs are compared for content with *Analytical Profiles of Drug Substances*, Volumes 1–4, K. Florey, Ed., which is becoming the primary nonofficial work in drug analysis (but as yet covers but a minority of drugs and not all manufacturers). This is not to say that Clarke 1 and 2 do not fulfill an important function, and well, but rather that the working analyst has the joy of being able to resort to more than one leading source for data before plunging into the primary literature for the late news.

Applications of High-Speed Liquid Chromatography. By N. DONE, J. H. KNOW, and J. LOHEAC. Wiley, 605 Third Avenue, New York, NY 10016, 1975. 238 pp. 16 × 24 cm. Price $19.95.

As with any emerging analytical technology, there have been a sizable number of books published in the area of high-speed liquid chromatography (HSLC). All too often these first volumes provide much in the way of theory and generalized approaches to problems but little practical information that can be helpful to the research scientist with a specific problem to solve. Happily these authors have achieved a balance between theory and practice.

In the first part of the book the authors talk of HSLC theory, equipment, and principles. The discussion is neither too simple nor too detailed and serves as a good refresher to the scientist who has had a more intense orientation in the not too distant past. While much could be done to improve the content, such changes would necessitate depth which is beyond the scope of the book.

Part two provides a listing of approximately 150 chromatograms and related chromatographic data compiled from the literature for the period 1969–1973. Although significant numbers of the chromatograms deal with the typical hydrocarbon separations so often presented in the sales literature for commercial instruments, a good percentage of these chromatograms can be useful to an individual interested in pharmaceuticals and related compounds. Each chromatogram is well presented and includes most pertinent data needed to reproduce the chromatogram which is also given. Each also contains the direct literature reference for further detailed information.

Overall, the volume seems to achieve its objectives. There are a few comments that must be mentioned by way of criticism. First is the basic fact that the field of HSLC is moving so very rapidly that, by the time the book was received for review, so much had evolved in the field that the contents of the volume seemed somewhat dated. This is particularly noticeable in the second part of the book when one compares separations reported there with more recent publications using small particle columns. Finally, the value of the book must be weighed against the price charged by the publisher. Although the book is well done, the price of $19.95 seems excessive considering the somewhat dated nature of the contents.

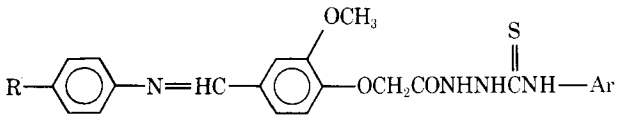
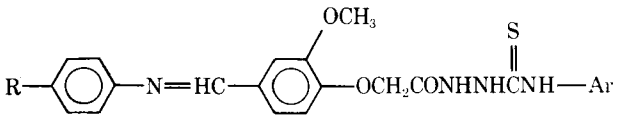
ERRATA

In the article titled "Synthesis of Substituted Anilino-[3-methoxy- 4- (4-arylthiosemicarbazidocarbonylmethyleneoxy)]benzylidenes: Correlation between Anticonvulsant Activity and Monoamine Oxidase Inhibitory and Antihemolytic Properties" (1), the following corrections should be made:

On page 1125, column 1, the structure for IX–XXIV in Scheme I should be:



On page 1126, Table II, the structure should be:



(1) C. Dwivedi, R. D. Harbison, B. Ali, and S. S. Parmar, *J. Pharm. Sci.*, **63,** 1124(1974).

In the article titled "Microbiological Diffusion Assay I: Operations Studied with Cooper Equation" (1), the following correction should be made:

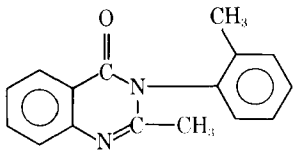
On page 1459, column 2, Eq. 2 should read:

$$X^2 = 4DT_0 \ln (m_0/m') + 4Dh \ln (m_0/m')$$

(1) F. W. Kavanagh, *J. Pharm. Sci.*, **63,** 1459(1974).

In the article titled "Hydrolytic Degradation of Methaqualone" (1), the following correction should be made:

On page 1785, column 1, the structure for methaqualone in Scheme I should be:



(1) J. J. Zalipsky, D. M. Patel, and N. H. Reavey-Cantwell, *J. Pharm. Sci.*, **63,** 1784(1974).

In the article titled "Dose–Response Predictability of Urinary Bladder Hyperplasia by *N*-2-Fluorenylacetamide Feeding in Mice: Its Modification by Sex" (1), the following corrections should be made:

On page 1947, column 1, the material pertaining to Eqs. 2–5 should read:

$$\mathrm{var}(Y) = 1/Snw + x^2/Snwx^2 + 2xz/Snwxz + z^2/Snwz^2 \quad \text{(Eq. 2)}$$

$$x = X - \bar{X} \quad \text{(Eq. 3)}$$

$$z = Z - \bar{Z} \quad \text{(Eq. 4)}$$

By replacing $Y = \bar{Y} + bx + cz$:

$$X = \bar{X} + \frac{-B \pm \mathrm{root}(B^2 - 4AC)}{2A} \quad \text{(Eq. 5)}$$

where:

$$K = \bar{Y} + cz - Y_0$$
$$A = b^2 - t^2/Snwx^2$$
$$B = 2(K - t^2z/Snwxz)$$
$$C = (K^2 - t^2/Snw - t^2z^2/Snwz^2)$$

(1) T. J. Haley, G. Schieferstein, W. E. Jaques, J. Farmer, C. Frith, and R. W. Sprawls, *J. Pharm. Sci.*, **63,** 1946(1974).

In the article titled "Cholelithiasis Chemotherapy: An *In Vitro* Approach" (1), the following corrections should be made:

On page 363, Table I, the last two entries under the first column should read "Benzyldimethyl[(octadecylcarbamoyl)methyl]ammonium chloride[e]" and "Cholesteryl-3-α-amine hydrochloride hydrate[g]."

(1) D. Mufson, K. Triyanond, and L. J. Ravin, *J. Pharm. Sci.*, **64,** 362(1975).

In the article titled "Mathematical Formulation for Nonuniform Multiple Dosing" (1), the following corrections should be made:

On page 464, column 1, Eq. 2 should read:

$$\dot{\mathbf{x}} = K\mathbf{x}$$

On page 464, column 2, Eq. 15*a* should read:

$$\dot{x} = -kx + \delta(t - t_1)$$

On page 465, column 1, Eq. 20 should read:

$$\dot{\mathbf{x}} = K\mathbf{x} + \begin{pmatrix} a_1\delta(t - t_1) + a_2\delta(t - t_2) \\ 0 \\ 0 \end{pmatrix}$$

On page 466, column 1, the first line after Eq. 27 should read "where $\mathbf{b} = P^{-1}\mathbf{x}_0$" instead of "$b = P^{-1}\mathbf{x}_0$."

(1) J. R. Howell, *J. Pharm. Sci.*, **64,** 464(1975).

In the article titled "Drug–Biomolecule Interactions: Interactions of Mononucleotides and Polybasic Amino Acids" (1), the following correction should be made:

On page 476, column 2, the abscissa label in Fig. 3 should read "adenosine 5′-monophosphate concentration" instead of "guanosine 5′-monophosphate concentration."

(1) J. C. Lacey, Jr., and K. M. Pruitt, *J. Pharm. Sci.*, **64,** 473(1975).

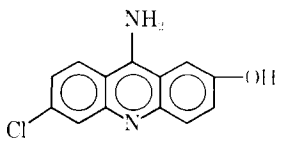
In the article titled "Effect of Surfactants on Absorption through Membranes III: Effects of Dioctyl Sodium Sulfosuccinate and Poloxalene on Absorption of a Poorly Absorbable Drug, Phenolsulfonphthalein, in Rats" (1), the following correction should be made:

Throughout the article, "poloxamer 188" should be substituted for "poloxalene."

(1) S. N. Malik, D. H. Canaham, and M. W. Gouda, *J. Pharm. Sci.*, **64,** 987(1975).

In the article titled "Facile Preparation of 6-Chloro-9-amino-2-hydroxyacridine, a Urinary Metabolite of Quinacrine and Quinacrine Mustard" (1), the following correction should be made:

On page 1418, column 2, Structure II in Scheme I should be:



(1) K. C. Tsou, S. Ledis, E. Steiger, and R. Nietrzeba, *J. Pharm. Sci.*, **64,** 1418(1975).
